Editorial Preface

From the Desk of Managing Editor…

It may be difficult to imagine that almost half a century ago we used computers far less sophisticated than current home desktop computers to put a man on the moon. In that 50 year span, the field of computer science has exploded.

Computer science has opened new avenues for thought and experimentation. What began as a way to simplify the calculation process has given birth to technology once only imagined by the human mind. The ability to communicate and share ideas even though collaborators are half a world away and exploration of not just the stars above but the internal workings of the human genome are some of the ways that this field has moved at an exponential pace.

At the International Journal of Advanced Computer Science and Applications it is our mission to provide an outlet for quality research. We want to promote universal access and opportunities for the international scientific community to share and disseminate scientific and technical information.

We believe in spreading knowledge of computer science and its applications to all classes of audiences. That is why we deliver up-to-date, authoritative coverage and offer open access of all our articles. Our archives have served as a place to provoke philosophical, theoretical, and empirical ideas from some of the finest minds in the field.

We utilize the talents and experience of editor and reviewers working at Universities and Institutions from around the world. We would like to express our gratitude to all authors, whose research results have been published in our journal, as well as our referees for their in-depth evaluations. Our high standards are maintained through a double blind review process.

We hope that this edition of IJACSA inspires and entices you to submit your own contributions in upcoming issues. Thank you for sharing wisdom.

Thank you for Sharing Wisdom!

Kohei Arai
Editor-in-Chief

Editorial Board

Editor-in-Chief

Dr. Kohei Arai - Saga University
Domains of Research: Technology Trends, Computer Vision, Decision Making, Information Retrieval, Networking, Simulation

---

Associate Editors

Alaa Sheta
Southern Connecticut State University
Domain of Research: Artificial Neural Networks, Computer Vision, Image Processing, Neural Networks, Neuro-Fuzzy Systems

Arun Kulkarni
University of Texas at Tyler
Domain of Research: Machine Vision, Artificial Intelligence, Computer Vision, Data Mining, Image Processing, Machine Learning, Neural Networks, Neuro-Fuzzy Systems

Dr Ronak AL-Haddad
Anglia Ruskin University / Cambridge
Domain of Research : Technology Trends,Communication,Security,Software Engineering and Quality,Computer Networks,Cyber Security,Green Computing,Multimedia Communication,Network Security,Quality of Service

Elena Scutelnicu
"Dunarea de Jos" University of Galati
Domain of Research: e-Learning, e-Learning Tools, Simulation

In Soo Lee
Kyungpook National University
Domain of Research: Intelligent Systems, Artificial Neural Networks, Computational Intelligence, Neural Networks, Perception and Learning

Larbi Boubchir
University of Paris 8
Domain of Research : Artificial Intelligence,Biometrics

Renato De Leone
Università di Camerino
Domain of Research: Mathematical Programming, Large-Scale Parallel Optimization, Transportation problems, Classification problems, Linear and Integer Programming

Xiao-Zhi Gao
University of Eastern Finland
Domain of Research: Artificial Intelligence, Genetic Algorithms

CONTENTS

Paper 1: Development of Web Apps for Users with Special Needs
Authors: Silviya Varbanova, Milena Stefanova, Tihomir Stefanov
PAGE 1 – 10

Paper 2: How Teachers' Gestural Culture Influences Japanese Students' Emotions: A Machine Learning Approach
Authors: Yuka Nishi, Olivia Kennedy, Choi Dongeun, Noriaki Kuwahara
PAGE 11 – 20

Paper 3: Enhancing Approximate Conformance Checking Accuracy with Hierarchical Clustering Model Behaviour Sampling
Authors: Yilin Lyu
PAGE 21 – 37

Paper 4: Enhancing Cyber Security Through Predictive Analytics: Real-Time Threat Detection and Response
Authors: Muhammad Danish
PAGE 38 – 49

Paper 5: A Hybrid Approach to Automatic Timetabling Using Self-Organizing Maps, Secure Convex Dominating Sets, and Metaheuristics
Authors: Elmo Ranolo, Ken Gorro, Pierre Anthony Gwen Abella, Lawrence Roble, Rue Nicole Santillan, Anthony Ilano, Benjie Ociones, Roel Vasquez, Deofel Balijon, Daniel Ariaso Sr., Rose Ann Campita, Robert Jay Angco
PAGE 50 – 58

Paper 6: Integrating Fine-Tuned GPT with Agent-Based Economic Modeling for Transparent Wage Policy Decisions
Authors: Daniel A. Ariaso Sr., Ken D. Gorro, Deofel Balijon, Meshel Balijon
PAGE 59 – 71

Paper 7: A Privacy-Preserving Gaussian Process Regression Framework Against Membership Inference Attacks Using Random Unitary Transformation
Authors: Md. Rashedul Islam, Jannatul Ferdous Akhi, Takayuki Nakachi
PAGE 72 – 80

Paper 8: Autonomous Driving in Adverse Weather: A Multi-Modal Fusion Framework with Uncertainty-Aware Learning for Robust Obstacle Detection
Authors: Zhengqing Li, Baljit Singh Bhathal Singh
PAGE 81 – 86

Paper 9: EcoRouting: Carbon-Aware Path Optimization in Green Internet Architectures
Authors: Handrizal, Herriyance, Amer Sharif
PAGE 87 – 94

Paper 10: Exploring the Future Research Agenda for Health Applications Adoption: A Systematic Literature Review
Authors: Rahmat Fauzi, Adhistya Erna Permanasari, Silmi Fauziati
PAGE 95 – 106

Paper 11: A New Method for Real-Time Fall Detection Based on MediaPipe Pose Estimation and LSTM
Authors: Puwadol Sirikongtham, Apichaya Nimkoompai
PAGE 107 – 113

Paper 12: Design of Marketing Digital Control System Based on the Integration of Big Data Analysis and Machine Learning
Authors: Qiming Li, Songling Du, Shiyuan Zhang
PAGE 114 – 123

Paper 13: Artificial Intelligence in Optometry: Potential Benefits and Key Challenges: A Narrative Review
Authors: Noura A. Aldossary
PAGE 124 – 131

Paper 14: nodeWSNsec: A Hybrid Metaheuristic Approach for Reliable Security and Node Deployment in Wireless Sensor Networks
Authors: Rahul Mishra, Sudhanshu Kumar Jha, Naresh Kshetri, Bishnu Bhusal, Mir Mehedi Rahman, Md Masud Rana, Aimina Ali Eli, Khaled Aminul Islam, Bishwo Prakash Pokharel
PAGE 132 – 142

Paper 15: Exploring Trust Management in Fog Computing: A Comprehensive Review and Future Challenges in Task Offloading
Authors: Liu Feng, Suhaidi Hassan, Mohammed Alsamman
PAGE 143 – 156

Paper 16: AraSpam: A Multitask Deep Neural Network for Spam Detection in Arabic Twitter
Authors: Lulua Alhamdan, Ahmed Alsanad, Nora Al-Twairesh
PAGE 157 – 170

Paper 17: Hierarchical Transformer Residual Model for Pneumonia Detection and Lesion Mapping
Authors: Anupama Prasanth
PAGE 171 – 183

Paper 18: Developing ReAdaBalancer for Load Balancing Optimization in Networked Cloud Computing
Authors: M Diarmansyah Batubara, Poltak Sihombing, Syahril Efendi, Suherman
PAGE 184 – 193

Paper 19: An Augmentation-Based System for Diagnosing COVID-19 Using Deep Learning
Authors: Mohamad Shady Alrahhal, Mohammad A. Mezher, Osamah A.M. Ghaleb, Mohammad Al-Hjouj, Raghad Sehly, Samir Bataineh
PAGE 194 – 205

Paper 20: Navigating the Landscape of Automated Information Extraction for Financial Fund Prospectuses: Survey and Challenges
Authors: Yuyao Xu, Mohamad Farhan Mohamad Mohsin
PAGE 206 – 218

Paper 21: Proactive Cancer Prediction Using IoT and Deep Learning Before Symptoms
Authors: Mohamed Amine Meddaoui, Imane Karkaba, Moulay Amzil, Mohammed Erritali
PAGE 219 – 229

Paper 22: Comparative Analysis of Machine Learning and Deep Learning Models for Handwritten Digit Recognition
Authors: Soukaina Chekki, Boutaina Hdioud, Rachid Oulad Haj Thami, Sanaa El Fkihi
PAGE 230 – 239

Paper 23: Residual DDPG Control with Error-Aware Reward Rescaling for Active Suspension Under Unseen Road Conditions
Authors: Zien Zhang, Abdul Hadi Abd Rahman, Noraishikin Zulkarnain
PAGE 240 – 248

Paper 24: Edge-Guided Multi-Scale YOLOv11n: An Advanced Framework for Accurate Ship Detection in Remote Sensing Imagery
Authors: Yan Shibo, Liu Pan, Abudhahir Buhari
PAGE 249 – 256

Paper 25: The ECTLC-Horcrux Protocol for Decentralized Biometric-Based Self-Sovereign Identity with Time-Lapse Encryption
Authors: N. M. Kaziyeva, R. M. Ospanov, N. Issayev, K. Maulenov, Shakhmaran Seilov
PAGE 257 – 264

Paper 26: Integrating Chatbots into E-Learning Platforms: A Systematic Review
Authors: Victor Sevillano-Vega, Juan Chavez-Perez, Carmen Torres-Ceclén, Orlando Iparraguirre-Villanueva
PAGE 265 – 276

Paper 27: A Hybrid Approach Combining Deep CNN Features with Classical Machine Learning for Diabetic Retinopathy Diagnosis
Authors: Amandeep Kaur, Simranjit Singh, Hardeep Singh, Sarveshwar Bharti, Jai Sharma, Himanshi Sharma
PAGE 277 – 285

Paper 28: Forecasting Currency Exchange Direction with an Advanced Immune-Inspired Model
Authors: EL BADAOUI Mohamed, RAOUYANE Brahim, EL MOUMEN Samira, BELLAFKIH Mostafa
PAGE 286 – 293

Paper 29: Adaptive Ensemble Models for Robust Intrusion Detection in Cloud Environment on Imbalanced Dataset
Authors: Swarnalatha K, Nirmalajyothi Narisetty, Gangadhara Rao Kancherla, Neelima Guntupalli, Simhadri Mallikarjuna Rao, Archana Kalidindi
PAGE 294 – 303

Paper 30: Detection of Leaf Fall Disease in Sembawa Rubber Plantation Through Feature Extraction Model and Clustering Methods
Authors: Alhadi Bustamam, Devvi Sarwinda, Retno Lestari, Ahmad Ihsan Farhani, Harum Ananda Setyawan, Masita Dwi Mandini Manessa, Tri Rappani Febbiyanti, Minami Matsui
PAGE 304 – 312

Paper 31: Tamil Handwritten Character Recognition: A Comprehensive Review of Recent Innovations and Progress
Authors: Manoj K, Iyapparaja M
PAGE 313 – 321

Paper 32: Boosting Deepfake Detection Accuracy with Unsharp Masking and EfficientNet Models
Authors: Radwa Khaled, Hossam M. Moftah, Fahad Kamal Alsheref, Adel Saad Assiri, Kamel Hussein Rahouma, Mohammed Kayed
PAGE 322 – 331

Paper 33: Analysis of the Possibilities of Using LLM Chatbots for Solving Course and Exam Tasks
Authors: Svetlana Stefanova, Yordan Kalmukov
PAGE 332 – 336

Paper 34: Segment-Based Vehicular Congestion Detection Methods Using Vehicle ID and Loss of Expected Time of Arrival
Authors: Mustapha Abubakar Ahmed, Azizul Rahman Mohd Shariff
PAGE 337 – 345

Paper 35: Stock Market Prediction of the Saudi Telecommunication Sector Using Univariate Deep Learning Models
Authors: Hadi S. AlQahtani, Mohammed J. Alhaddad, Mutasem Jarrah
PAGE 346 – 353

Paper 36: A Systematic Review of Multilingual Plagiarism Detection: Approaches and Research Challenges
Authors: Chaimaa BOUAINE, Faouzia BENABBOU, Zineb Ellaky, Amine BOUAINE, Chaimae ZAOUI
PAGE 354 – 372

Paper 37: Towards Explainable and Balanced Federated Learning: A Neural Network Approach for Multi-Client Fraud Detection
Authors: Nurafni Damanik, Chuan-Ming Liu
PAGE 373 – 382

Paper 38: A Novel Multilevel Framework for DoS Detection in SDN
Authors: Rejo Rajan Mathew, Amarsinh Vidhate
PAGE 383 – 391

Paper 39: Mid-Upper Arm Circumference Measurement Using Digital Images: A Top-Down Approach with Panoptic Segmentation Using Mask R-CNN
Authors: Maya Silvi Lydia, Pauzi Ibrahim Nainggolan, Desilia Selvida, Doli Aulia Hamdalah, Dhani Syahputra Bukit, Amalia, Rahmita Wirza Binti O. K. Rahmat
PAGE 392 – 403

Paper 40: Ensemble Learning for Multi-Class Android Malware Detection: A Robust Framework for Family Level Classification
Authors: Mana Saleh Al Reshan
PAGE 404 – 411

Paper 41: Analyzing Cyber Attack Detection in IoT Healthcare Environments Using Artificial Intelligence
Authors: Rawan Marzooq Alharbi, Muhammad Asif Khan
PAGE 412 – 423

Paper 42: Performance Analysis of Proposed Scalable Reversible Randomization Algorithm (SRRA) in Privacy Preserving Big Data Analytics
Authors: Mohana Chelvan P, Rajavarman V N, Dahlia Sam
PAGE 424 – 431

Paper 43: Shared API Call Insights for Optimized Malware Detection in Portable Executable Files
Authors: Mehdi Kmiti, Jallal Eddine Moussaoui, Khalid El Gholami, Yassine Maleh
PAGE 432 – 439

Paper 44: Intrusion Detection Using Machine Learning and Deep Learning
Authors: Fatima Jobran ALzaher, Asma AlJarullah
PAGE 440 – 454

Paper 45: Comprehensive Analysis of Machine and Deep Learning Models for Stock Market Prediction
Authors: Hadi S. AlQahtani, Mohammed J. Alhaddad, Mutasem Jarrah
PAGE 455 – 463

Paper 46: Consumer Adoption of Autonomous Vehicles in China: A Bibliometric Review of Intention Drivers and Perceptions
Authors: Yunluo Zou, Syuhaily Osman, Sharifah Azizah Haron
PAGE 464 – 472

Paper 47: RA-ACS_net Network: A Quantum Optical Reconstruction Method for Ultra-high Resolution Bioimaging
Authors: Lin SHANG
PAGE 473 – 482

Paper 48: Privacy-Preserving Content-Based Medical Image Retrieval Using Integrated CNN Fusion and Quantization Optimization
Authors: Mohamed Jafar sadik, Muhammed E Abd Alkhalec Tharwat, Noor Azah Samsudin, Ezak Fadzrin Bin Ahmad
PAGE 483 – 497

Paper 49: Innovative Model of Tourism on Educational Engineering: Transformation Learning from Experiential to Interactive
Authors: Yurao Yan, Tara Ahmed Mohammed, Hailan Liang, Mingxi Guan
PAGE 498 – 508

Paper 50: DeepIndel: A ResNet-Based Method for Accurate Insertion and Deletion Detection from Long-Read Sequencing
Authors: Md. Shadmim Hasan Sifat, Khandokar Md. Rahat Hossain
PAGE 509 – 515

Paper 51: A Modeling Approach for Strategic Fleet Sizing Under Maritime Sovereignty: Application to the Moroccan National Fleet
Authors: Mohamed Anas KHALFI, Aziz AIT BASSOU, Mustapha HLYAL, Jamila EL ALAMI
PAGE 516 – 527

Paper 52: Prediction of Mining-Induced Subsidence in Saudi Arabia Phosphate Mines Using ANN Method
Authors: Atef GHARBI, Mohamed AYARI, Yamen El Touati, Zeineb Klai, Mahmoud Salaheldin Elsayed, Elsaid Md. Abdelrahim
PAGE 528 – 534

Paper 53: A Review on Image-Based Methods for Plant Disease Identification in Diverse Data Conditions
Authors: Feilong Tang, Rosalyn R Porle, Hoe Tung Yew, Farrah Wong
PAGE 535 – 545

Paper 54: Predictive Modeling for Metro Performance Using MetroPT3 Dataset
Authors: Akshitha Mary A C, R Rakshinee, Stefani Jeyaseelan, Sakthivel V, Prakash P
PAGE 546 – 554

Paper 55: Artificial Intelligence in Diagnostic and Therapeutic Interventions: A Systematic Review of Randomized Controlled Trials
Authors: Oscar Jimenez-Flores, Sandra Pajares-Centeno, Oscar Mejia-Sanchez, Rodrigo Flores-Palacios
PAGE 555 – 562

Paper 56: Transformer-Enabled Smartphone System for Intelligent Physical Activity Monitoring
Authors: Leping Zhang, Fengjiao Jiang, Guopeng Jia, Yue Wang

Development of Web Apps for Users with Special Needs

Silviya Varbanova, Milena Stefanova, Tihomir Stefanov
Faculty of Mathematics and Informatics, St. Cyril and St. Methodius University, Veliko Tarnovo, Bulgaria

***Abstract*—This study presents software solutions and prototypes of converters designed to assist individuals who suffer from visual impairments or deafness. The prototypes were developed in a laboratory environment using modern programming technologies, with their applicability focused on contexts such as education, employment, and online shopping. The converter prototypes are designed to transform textual information into Braille or sign language, depending on users' needs. Other solutions facilitate auditory interpretation when working with assessment materials, thereby helping the sightless to access information more easily. The research methodology combines synthesis and analysis of existing information from related research works. The choice of programming technologies was carefully considered to ensure the implementation of more accessible functionalities in the developed applications. In the teaching process, the authors of the study motivate their students to develop programming and analytical skills. The results achieved are based on student project work in the design and implementation of software prototypes to assist users with hearing or visual impairments. The prototypes created are aligned with scenarios for use in education and everyday activities, which expand the practical relevance of the study. Importantly, the presented applications also benefit people without disabilities by promoting communication that is more effective and understanding in cases of visually or hearing impaired.**

***Keywords*—Braille; sign language; deafness; visually impaired; software prototypes**

I. INTRODUCTION

The mobility, communication, education, and employment of those with hearing or visual impairments are more challenging than those with no impairments. In the past, support for these activities was provided mainly through personal assistants or mechanical aids [1]. Today, however, electronic applications and computer software have significantly enhanced the independence of these users. Modern digital devices have made daily activities – such as navigation, shopping, and communication – progressively more accessible for people with different disabilities [2].

Users with hearing or visual impairments seek to minimize the limitations they encounter in everyday activities such as learning, shopping, and working. To improve existing solutions, many actively collaborate with scientists and developers as part of dedicated teams. In numerous cases, these users themselves propose innovative approaches and more accessible functionalities, directly contributing to the development of software products that better address their needs. Based on the research into the needs of specific user groups, they are now increasingly encouraged to use mobile and computer devices. The convenience that modern specialized applications developed for them offer is also significant. This significantly reduces the difficulties in taking in and passing on information when performing various activities [3].

One of the current challenges being addressed is finding effective solutions to increase the participation of students and workers with special needs. In practice, not all individuals with disabilities can attend specialized educational institutions and subsequently find professional fulfillment. A significant proportion instead study in mainstream educational institutions, where learning is made more accessible through the use of innovative modern technologies. Advancements in digital technologies are occurring at an unprecedented pace and have had a profound impact on education and professional development, including for people with special needs [4]. These technologies empower anyone who seeks to acquire knowledge and succeed in their chosen field.

For example, in the past, visually impaired individuals typically relied on Braille documents and specialized teaching aids for their education. Today, however, modern computers and mobile devices enable them to independently read and write texts in standard formats, beyond just Braille [5]. As a result, users gain greater confidence in accessing and understanding textual, graphical, and semantic information. This advancement is largely made possible by the availability of screen readers, speech synthesizers, and various conversion tools [6]. The development of assistive technology for those with visual impairment is predicted to continue, according to researchers [7]. The authors assert that this growth could have a substantial impact on people's lives in a way that was previously impossible. Since the final decade of the twentieth century, the development and dissemination of such software have played a crucial role in supporting visually impaired users. These software converters transform textual information displayed on a device screen into audio output, allowing blind or visually impaired individuals to listen to and comprehend written content, as well as to review and edit the text they produce themselves.

Software applications are being developed to support individuals with hearing impairments in their education and professional growth. Although the number of such applications remains limited relatively, notable progress has been made in recent years. Software converters can transform gesture-based information displayed on computer or mobile screens into textual content and vice versa [8].

Additionally, to facilitate communication between hearing-impaired individuals and those without hearing impairments, systems are being designed to recognize and translate sign language into audio output and, conversely, convert spoken language into sign language representations. These advancements contribute significantly to improving social interactions, educational opportunities, and professional development for people with hearing impairments [9].

Scientists are working towards the development and implementation of speech and sound visualization systems for people with hearing impairments. Detecting signal events is the main tool for improving the semantic perception of given information. For example, by using other senses to recognize information, such as visual, acoustic, and tactile [10].

Another significant issue for the hearing impaired is the correct perception of musical sounds so that they are not limited when learning or working with music, video or audio data [11]. Scientists are researching, analyzing and searching for more accessible techniques for this purpose. The problem is similar when working or studying with mathematical terminology in areas such as mathematics, physics, and economics [12]. Here, the correct use of sign language by learners and trainers is important. When used incorrectly, semantic errors inevitably occur. For this purpose, more and more analogues are being sought today for better techniques for practicing sign language in communication. The age limit of hearing-impaired users is also important here, which turns out to be a serious barrier.

Today, regional libraries, bookstores, educational institutions, and office centers are increasingly offering audio-electronic catalogs featuring both specialized literature and fiction. Additionally, multimedia video and audio presentation materials are often supplemented with subtitles, thereby partially improving information accessibility for hearing-impaired users.

The authors of this study are actively contributing to developments in this field. The content of the study is organized as follows: The Introduction section outlines the need for software solutions specifically designed for people with hearing impairments or visual disabilities. The Related Work section provides an overview and analysis of relevant articles connected to assistive technologies and software for users with hearing or visual impairments. The Methodology section describes the analysis and discussions conducted on the topic, along with the results of collaborative work involving students, academics and programmers. The Results section presents various projects developed through the phased implementation and testing of program code, highlighting software solutions created for these users. The Discussion section summarizes the main findings of the study and examines the challenges encountered by the authors. Finally, the Conclusion section offers a concise summary of the study's contributions and insights.

II. Related Work

The perception of information from the surroundings could be longer-lasting for individuals with special needs. Software is primarily designed for common users by developers, and people with hearing or vision impairments find it hard to use. Specialized applications have been developed for these user groups to read, hear, or understand graphical information.

For example, electronic readers for computer devices with built-in multilingual text synthesizers such as NVDA, JAWS, VoiceOver [13], [14]. Similar software applications are designed for the Windows OS and support browsers such as Mozilla Firefox and Google Chrome. Their use is associated with facilitating the work of the visually impaired with office programs, in converting text to braille, and in internet communication. According to available statistics, Fig. 1 presents some of the most commonly used text readers, by usage during the period. For each of the screen readers, advantages and disadvantages are reflected [15].

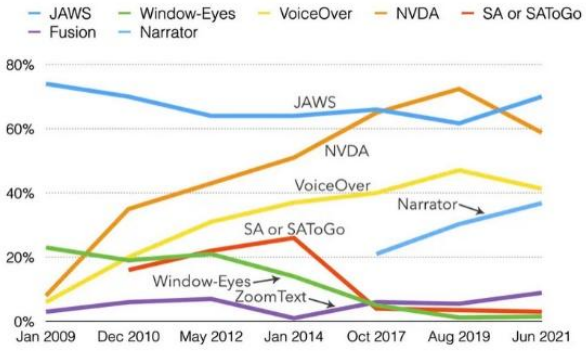

Fig. 1. Screen readers – popularity and usage.

When individuals with visual impairments use text-to-speech synthesizers, some of their built-in features may be difficult to access or not preferred by users. To address this, separate systems are being developed that are simpler to operate and do not require lengthy setup or installation processes. Another emerging trend aimed at helping blind users manage electronic messages more easily is the creation and deployment of systems such as 'talking email' [16], [17].

Currently, there are still relatively few online converters available for transforming text into braille (see Fig. 2) and vice versa [18]. The existing programs, however, are practical and favored by people with low vision who rely on them. One key advantage is that, with access to a Braille printer and suitable paper, the converted text can be printed. This allows visually impaired individuals who are proficient in Braille to independently read printed materials [18], [19].

The reverse process is also achievable through online tools. Braille characters are converted to text, which often has one specific drawback. When the text is converted, the result is displayed mostly in lowercase (Fig. 3, [20]). This problem is solved partially in the prototype described below in Task B1.

Individuals who are blind often encounter difficulties in perceiving typography and color layouts [21]. Although this issue remains an active area of research, efforts continue to identify better solutions. The challenge related to interpreting 2D tactile graphics and 3D models – particularly in fields that involve technical drawings – has been partially addressed through the development of innovative assistive devices. One

such device incorporates a camera and plays pre-recorded audio descriptions when the user touches specific parts of a graphic or layout with their fingers. However, despite its potential benefits, this device is currently not widely accessible for personal use due to its high market cost [22].

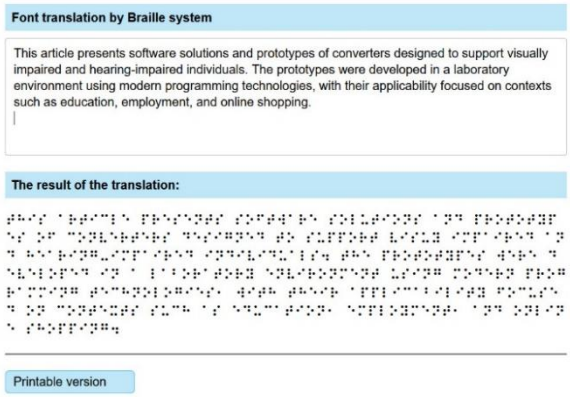

Fig. 2. Transforming text to Braille characters.

Fig. 3. Transforming Braille characters to text.

A significant challenge remains in the rapid conversion of auditory signals into forms accessible to people with hearing impairments. This issue is not limited to educational institutions, office buildings, or retail spaces, but also extends to vehicles. When there is a delay in responding to warning signals, the risk of accidents increases. The authors, who describe the creation of an application by using Tensor FlowLite, which reduces energy consumption and improves response time [23], present a specific advantage in this.

The focus is on exploring papers about assistive technologies supporting people with hearing or visual impairments. The application of these technologies in the education of these user groups is another important criterion in the selection process of the referenced related works.

The authors' interests in this area are influenced by the nature of their teaching activities. They aim to enhance the skills of their students in building web-based applications, while also developing their critical self-assessment and empathy towards the specific users for whom these applications are meant.

Table I provides a comparison of the study with similar ones and also highlight specific contributions related to educational activities.

TABLE I. COMPARISON OF THE PRESENTED CONTRIBUTIONS AND APPLICABILITY IN EDUCATIONAL ACTIVITIES

Survey	Contributions Described	
	In the Results Section	***Regarding Educational Activities***
Zhu et al., 2025 [4]	The important roles of accessible technologies in 'Blind Colleges', yet also reveal multiple practical challenges due to inaccessibility are highlighted.	The main contribution for HCI communities is raising awareness of the imbalance in educational technology by promoting the importance of their innovation.
Apu et al., 2021 [5]	The offered Refreshable Braille Translator converts text from various languages into Braille characters, enabling those with visual impairments to learn and read in digitally.	Yes, significant benefits in the field of education are presented.
Murthy et al., 2022 [6]	Various tools used for translating Braille documents to English text are evaluated by the authors, applying their work to single-sided Braille documents.	Applicable to individuals with visual impairments who use only Braille documents as a medium for education.
Da Silva Dessbesel et al., 2025 [12]	The findings indicate that teachers' understanding of sign language can have a significant impact on the teaching of mathematics in deaf education.	Yes. The study is examining the role of sign language in teaching and learning mathematics for deaf students.
Nethravathi et al., 2022 [23]	The present application system aims to identify potential daily objects in human surroundings and provide speech feedback to users about the objects around them.	Not specified. Suitable for everyday activities. The created application uses Tensor FlowLite, which enhances response time and requires low power, making it suitable for transferable apps.
Proposed	Several translators and converters are presented to transform information into facial gestures, Braille, audio, and vice versa, personalized to the users' specific needs, aiming to facilitate data perception and communicate.	Mostly prototypes that are developed during student training are described.

Based on research and discussions with visually impaired and hearing-impaired users, the authors of this study propose solutions for developing more accessible applications. Such projects can be implemented both within software companies and in educational institutions and research laboratories, to benefit people with visual or hearing impairments. In this context, practical solutions and projects are currently being developed within computer-oriented disciplines at the Faculty of Mathematics and Informatics at the University of Veliko Tarnovo. These projects primarily focus on creating embedded voice readers, converters that transform text into mimic or Braille information, and tools for facilitating the perception of images and multimedia content.

III. Methodology

The research involves studying various publications, as well as various software and applications, for the benefit of individuals with visual or hearing impairments. The methodology relies on the synthesis and analysis of existing information, as well as the identification of concepts from practice.

The information in this study is summarized on the basis of the collaborative work of faculty members from the University of Veliko Tarnovo and programmers. Based on the meetings, accessible functionalities in prototype software products were planned. In parallel, software application designs were designed and developed in a laboratory environment. Advanced programming techniques and web technologies were used to design the reviewed prototypes. The prototypes were primarily made for individuals who have hearing or visual impairments.

The authors of the study aim to highlight the need for projects and digital applications that support people with hearing or visual impairments, helping them adapt more effectively in both work and education. Their goal is to encourage young professionals and individuals with these impairments to collaborate on developing practical solutions. By involving not only researchers and developers but also IT educators and students, the authors hope to create effective tools to reduce barriers in communication, learning, and employment for people with visual or hearing challenges.

In the Faculty of Mathematics and Informatics, undergraduate and graduate students develop software projects in a variety of subjects, often forming working teams. They actively participate in developing prototypes of electronic applications and web pages. Through their expertise, they help address and mitigate some of the challenges faced by people with disabilities. These applications were created during seminar classes in core disciplines and tested in real-world environments. For the practical implementation of the coding aspects of the projects, modern technologies were employed, including markup and stylesheet languages for adaptive design, scripting languages, frameworks, databases, and high-level programming languages.

IV. Results

This section presents software projects and prototypes designed to assist users with hearing or vision impairments, which were implemented during the training of students in core programming disciplines. Developed in a laboratory environment, the projects were tested using modern software testing tools. Some of the projects require the development of software for working with scientific and literary texts. The implementation of other prototypes in the computer technology field is aimed at conducting training tests. Others are in the field of online shopping.

The tasks and projects below, which are grouped into three categories, have been implemented and tested in a laboratory environment. For each prototype, the minimum requirements and implementation criteria have been defined beforehand.

A. Projects for the Benefit of Hearing-Impaired Users

As part of their training in core disciplines, student teams also focus on addressing the challenges faced by people with hearing impairments when using software products. Since these users have limited or no ability to hear, solutions that convert speech into text information – or even into facial gestures – can significantly enhance their user experience. Such projects aim to improve accessibility and inclusivity by enabling hearing-impaired users to interact more effectively with digital applications.

Task A1. To implement a web application for converting facial gestures into Cyrillic and vice versa.

Minimum functional requirements:

- Visual interpretation of the text converted into gestures (see Fig. 4), represented by the corresponding images [24].

The team is currently working on projects to implement computer games for users with impaired vision or hearing.

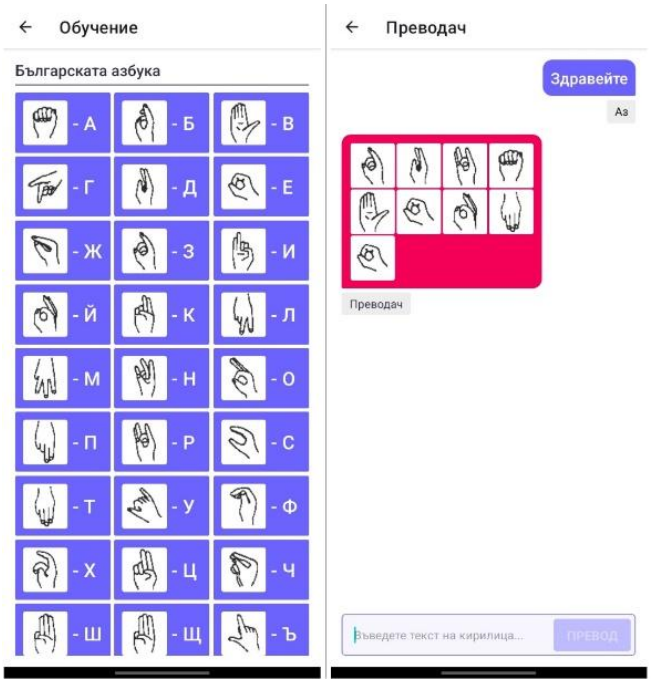

Fig. 4. Screens for visualizing gestures for letters and expressions in Bulgarian.

B. Projects that Meet the Needs of Visually Impaired Users

Task B1. To implement a prototype text-to-speech converter.

After entering a random string, the converter must satisfy the following minimum functional requirements for the final product:

- Count of characters entered, presented by a number;
- Convert text by capitalizing the first letter of each word;
- Splitting the text into paragraphs, which is particularly useful for essays, course projects or theses.

The program implements text recognition from various spoken languages, allowing for an unlimited amount of text to be entered into the field. A web visualization in Fig. 5 shows a specific instance of how the text converter works, with simplified navigation and an input field. Part of the programming code for capitalizing text is presented in Fig. 6.

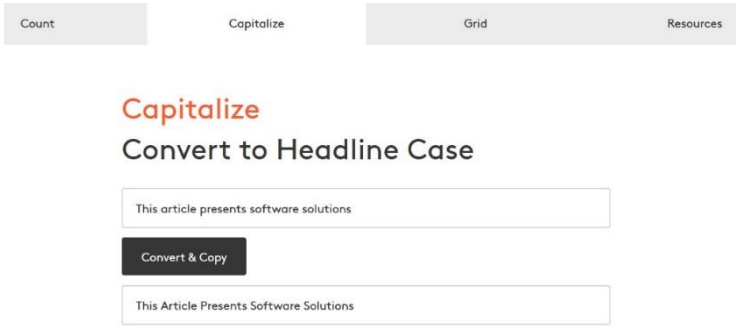

Fig. 5. Web visualization of text converter.

```
<div class="container main">
  <div class="row header">
    <div class="col-sm-8 col-sm-offset-2">
        <h1 class="large">Capitalize</h1>
        <div class="desc">Convert to Headline Case</div>
    </div>
  </div>
  <div class="row">
    <form id="tester" action class="col-sm-8 col-sm-offset-2">
      <input id="untitled" class="input" type="text" placeholder="Paste/type your text here...">
      <!-- <button type="submit1" class="submit" value="Convert">Convert</button> -->
      <button id="copyButton" type="submit2" class="submit">Convert & Copy</button>
      <input id="titled" class="input" type="text">
      <p id="confirmation" class="cap-note">Text has been copied to your clipboard.</p>
    </form>
  </div>
</div>
```

Fig. 6. Text converter – code snippet of realized functionality.

Task B2. To design and develop a text-to-speech converter.

Minimum functional requirements – for randomly entered text, the software solution should allow users to do independently:

- Start hearing the text readings aloud by selecting a button;
- Stop the playback/listening of the text by pressing a button.

Additional convenience of the program implementation offers users the opportunity to work in other windows on other tasks, while at the same time they can listen to the voice reader. The prototype being developed does not need a web version. The JavaScript fragment code for an example implementation of this task can be seen in Fig. 7.

Task B3. To implement a sample test in the discipline Web Technologies with audio recognition.

Functional requirements:

- Convenient interface – presence of buttons, designed for the user to independently move to the next page or question;
- Voice playback of the question, as well as the possible answers;
- Calculation and display of the final result – after filling in the answers.

The test's programmatic implementation can vary depending on whether each question with possible answers is presented on a separate page or not.

If the questions are displayed on distinct pages, there are still possibilities for the final prototype. Case 1: when starting the test, from the current page, each question should be played out in voice in advance, as well as the possible answer options. The user is given no limit on the time they have to choose a response. Clicking on a button takes the user to the next page after indicating their answer (see Fig. 8).

By selecting the answer to the last question, the result of the Test is automatically displayed which is realized with program code shown on Fig. 9.

```
/* Stop speaking */
const stopSpeaking = () => {
    synth.cancel();
    stopButton.disabled = true;
    speakButton.disabled = false;    };

/* Provide voice feedback for button hover */
const speakHint = (message) => {
    const hint = new SpeechSynthesisUtterance(message);
    hint.voice = synth.getVoices()[0];
    hint.rate = 1;
    hint.pitch = 1;
    synth.speak(hint);
};

/* Announce current slider value */
const announceRangeValue = (type, value) => {
    const message = `${type} is set to ${value}`;
    const utterance = new SpeechSynthesisUtterance(message);
    utterance.voice = synth.getVoices()[0];
    utterance.rate = 1;
    utterance.pitch = 1;
    synth.speak(utterance);     };

/* Announce limit when sliders reach min or max */
const announceLimit = (type, value, min, max) => {
    if (value == min) {
        speakHint(`${type} is at minimum`);
    } else if (value == max) {
        speakHint(`${type} is at maximum`);
    }      };
```

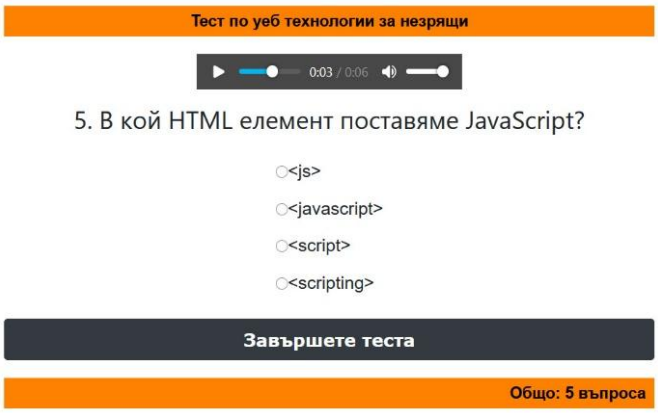

Fig. 8. Preview of the last question in the test for Case 1.

```
<form class="questionForm" id="q5" data-question="5">
    <audio controls>
        <source src="audio/въпрос5.mp3" type="audio/mp3">
    </audio>
    <h3 title="5. В кой HTML елемент поставяме JavaScript?">5. В кой HTML елемент поставяме JavaScript?</h3>
    <ul class="main-ul-list">
        <li class="5-1" title="js"><label><input type="radio" name="q5" value="a" alt="js"/>&lt;js&gt;</label></li>
        <li class="5-2" title="javascript" ><label><input type="radio" name="q5" value="b" alt="javascript" />&lt;javascript&gt;</label></li>
        <li class="5-3" title="script"><label><input type="radio" name="q5" value="c" alt="script"/>&lt;script&gt; </label></li>
        <li class="5-4" title="scripting"><label><input type="radio" name="q5" value="d" alt="scripting"/>&lt;scripting&gt;</label></li>
    </ul>
    <button id="submit" class="btn btn-dark btn-lg btn-block" title="Завършете теста">Завършете теста</button>
        <audio preload="auto" id="5-1"class="d-none">
        <source src="audio/5-1.mp3" controls></source>
    </audio>
    <audio  preload="auto" id="5-2" class="d-none">
        <source src="audio/5-2.mp3" controls></source>
    </audio>
    <audio  preload="auto" id="5-3" class="d-none">
        <source src="audio/5-3.mp3" controls></source>
    </audio>
    <audio preload="auto"  id="5-4" class="d-none">
        <source src="audio/5-4.mp3" controls></source>
    </audio>
</form>
```

Fig. 9. Program code to display test result for Case 1.

Case 2: when starting the test, a voice is heard playing the specific question. Then, when the mouse is moved over each answer, it is spoken accordingly. In this way, the user has the opportunity to indicate an answer that he or she judges to be correct, after careful consideration and repeated listening to the choices. Users move self-directed to the next page. The result of the test is calculated and displayed only after the last question is answered and the 'Finish quiz' button is clicked (see Fig. 10 and Fig. 11).

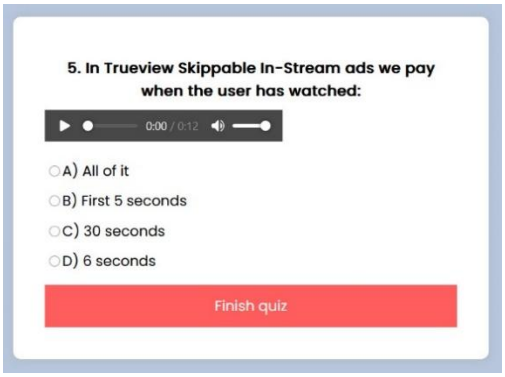

Fig. 10. Preview of the quiz question in Case 2.

```
<form class="questionForm" id="q5" data-question="5">
    <h3>5. In Trueview Skippable In-Stream ads we pay when the user has watched:</h3>
    <audio controls>
        <source src="question5.mp3" type="audio/mp3">
    </audio>
    <ul>
        <li><input type="radio" name="q5" value="a" />A) All of it</li>
        <li><input type="radio" name="q5" value="b" />B) First 5 seconds</li>
        <li><input type="radio" name="q5" value="c" />C) 30 seconds</li>
        <li><input type="radio" name="q5" value="d" />D) 6 seconds</li>
    </ul>
    <button id="submit">Finish quiz</button>
</form>
```

Fig. 11. Fragment of the program code for Case 2.

If the test questions and their possible answers are presented on a single page, the program can guide users through the following process: all questions, along with the answer options, should be read aloud using text-to-speech functionality. Users would then select their answers with voice assistance or other accessible input methods. After completing the selection, users can press a designated button to calculate and display the results. Fig. 12 below shows an example of the code used to check the correctness of the answers, implemented with JavaScript-based technologies.

```
function checkAnswer(q){
    if(q=="q1"){
        var submitted=$('input[name=q1]:checked').val();
        if(submitted==sessionStorage.a1){
            score++;}}
    if(q=="q2"){
        var submitted=$('input[name=q2]:checked').val();
        if(submitted==sessionStorage.a2){
            score++;}}
    if(q=="q3"){
        var submitted=$('input[name=q3]:checked').val();
        if(submitted==sessionStorage.a3){
            score++;}}
    if(q=="q4"){
        var submitted=$('input[name=q4]:checked').val();
        if(submitted==sessionStorage.a4){
            score++;}}
    if(q=="q5"){
        var submitted=$('input[name=q5]:checked').val();
        if(submitted==sessionStorage.a5){
            score++;}
        $('#results').html('<h3>You answered '+score+'/5 questions correctly.</h3>
        <a href="index.html">Reload Quiz</a>');}
    return false;
}
window.addEventListener('load',setAnswers,false);
```

Fig. 12. JavaScript code to check answers in case all questions are on one page.

C. Projects for the Benefit of Users with Impaired Hearing or Vision

Task C1. To implement an adaptive version of an online store for mobile devices.

Functional requirements:

- Easy access to the navigation menu (see Fig. 13);
- Voice playback of a description or functionality for an element (image or text) in the online store – when hovering over this element with the mouse;
- The included multimedia elements should also be adapted for people with hearing impairments.

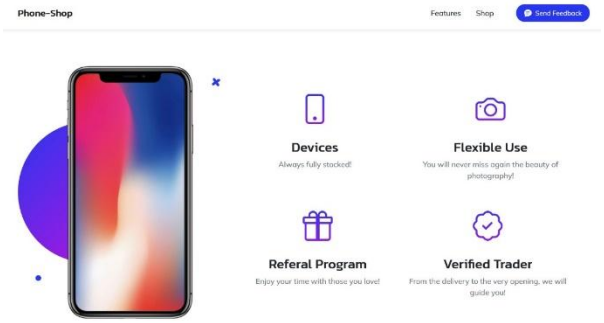

Fig. 13. Online store home screen preview on desktop version.

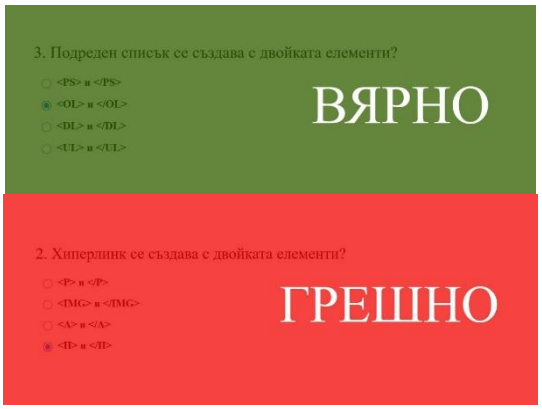
Below are selected prototypes of student projects, developed in laboratory settings and tested in real-world environments.



Project one. Specialized test for the level of HTML proficiency, aimed at users with hearing or vision impairment.

A specialized test has been developed for the benefit of people with hearing impairment. Each of the questions is on a separate page and has four answers. After selecting an answer, the participant is automatically taken to the next page.

As a final result of the Test, a report of accuracy is generated, combined with a bright color scheme that hearing-impaired users can see. The result is also presented as a voice report/message with audio layout for correct or incorrect answer – for visually impaired users. The text part of the Test is in Bulgarian, and it is possible to translate it into other languages. The following Fig. 14 shows the result of the indicated answers to two of the questions in the test, respectively – for correct or incorrect answer.

Project two. A Web Design test for the benefit of users with hearing or visual impairments.

A similar test to the ones presented in the study above has been developed, but with a different design. Each of the questions is on a new page and is read with a voice embedded reader. Users have a choice of three possible answers. As a result of taking the Test, a text message or an audio signal is generated indicating truth or falsity. The text part of the Test is in English (see Fig. 15), and the program code fragment is shown in Fig. 16.

(a)

```
<body>
    <h1 class="entry" data-entry="">НАЧАЛО НА ТЕСТ</h1>
    <div class="test-wrapper hidden" data-test="wrapper">
        <p data-test="question"></p>
        <div class="option-answers" data-test="answers">
          <input type="radio" id="answer1" name="answer">
          <label for="answer1"></label><br>
          <input type="radio" id="answer2" name="answer">
          <label for="answer2"></label><br>
          <input type="radio" id="answer3" name="answer">

</audio>

<script type="text/javascript">
                var callTimeout = function () {
                        setTimeout("location.href = 'test.html';",1500);
                }
                window.onload=function() {
                        const mySound = document.getElementById("startsound");
                        const startButton = document.getElementById("startb");
                        startButton.addEventListener("click", function() {
                                mySound.play();
                        })
                }
</script>
```

Fig. 16. Project two – program code fragment.

We believe that the implementation of the tasks set in this way has helped to improve the knowledge and practical skills of the students both in programming and in more successful communication in their contacts with people with hearing or vision problems.

V. Discussion

The rapid development of technology today is transforming and being applied across all areas of society. Despite this progress, significant limitations remain for people with special needs. There is a pressing need for appropriate technologies and software applications to support visually and hearing-impaired individuals in both education and employment.

For some, the process of perceiving and processing information can be time-consuming and challenging. Moreover, not all individuals have the opportunity to study in specialized institutions or resource centers staffed by experienced teachers and researchers. Securing permanent employment is also often a lengthy and difficult journey. Contributing to these challenges are various barriers, including financial constraints, geographical distance, transportation difficulties, family responsibilities, and other personal or societal factors.

This study describes working solutions for a more accessible perception of text or audio information for people with visual or hearing difficulties. The prototypes are mainly intended for training, work, or communication with individuals without disabilities. These activities are significantly facilitated by the availability of modern computer devices and web applications. Thus, the visually-impaired and the hearing-disadvantaged adapt better to society and communicate more easily. Ordinary users could understand the reverse process of converting Braille or mimicking information into text or audio through the few existing software converters.

Individuals with visual impairments and partially sighted individuals often have trouble understanding multimedia information. When it comes to studying or applying for a job online, for instance. It is common for the websites for these activities to be not fully accessible to text-to-speech software in many cases. The issue is significant, and to reduce it, teams are incorporating web developers who are visually impaired, scientists, or people with hearing impairments.

The results of this study can be summarized in several key areas corresponding to the main stages of the work process. Fig. 17 shows a high-level diagram of the overall study. The primary stages involve designing the tasks and functionalities of the prototypes created by students. As a result of critical analysis and in an effort to overcome identified gaps, ideas for the team's future work are determined.

In future research, the author's team will focus on specialized empirical studies, similar to those presented in [25], [26], with teams of students participating in the development of software applications for the studied group of users. In future developments, the authors plan to focus on improving voice control functionality for users with visual impairments. For the benefit of users with color blindness, the team's efforts will be directed at improving the adaptive design for color layout. This would also limit the problems for users with color blindness when using control buttons and navigating in applications. Another issue that will be addressed in future research is related to functionalities for users with motor delays, aimed at working without using a computer mouse.

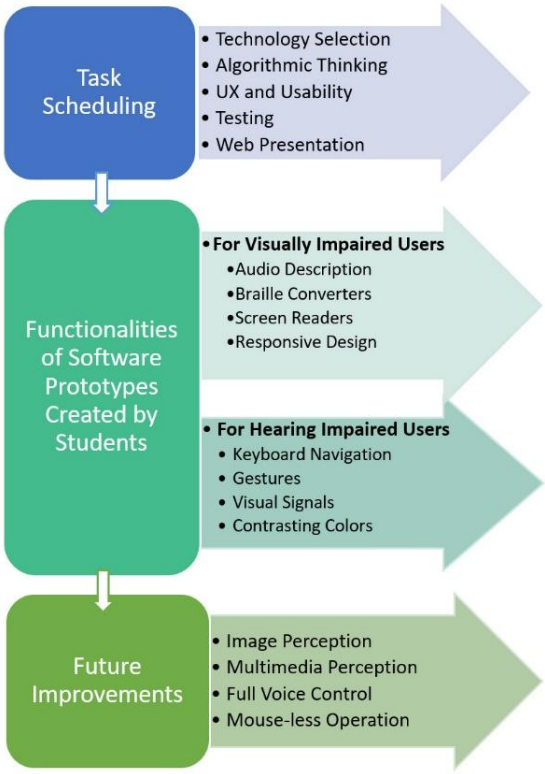

Fig. 17. Flowchart of the research workflow.

An important problem that is being worked on is the inability to accurately perceive images, graphics, or video data by people with 100% blindness or deafness. Currently, there is no standard technology that permits the perception of images, diagrams, or video data through hearing or sight alone. Software applications are still unable to accurately 'describe' the meaning/semantics of a given image or video. The SnapStick authors in this direction are making significant progress [26]. The SnapStick application, approbated by Shafique et al. (2025), enables the description of images of people, interiors, or outdoor environments. The authors evaluate the software using the System Usability Scale (SUS) methodology, focusing on completeness, accuracy, relevance, consistency, and photographs' details. They demonstrate that the application successfully handles object description from a photograph, even recognizing different human emotions from images of people [26]. However, usually in the content of web pages that include images, screen readers or speech synthesizers pronounce them as 'picture', or read out the text set by the developers in the 'alt' / 'title' attributes in the code part. Only with the help of another person – an assistant, can the visual information of a visually impaired person be described. In many cases, an accurate or complete description is impossible.

Another significant obstacle that people with low vision face is when using online shopping sites. For example, when specifying an address and delivery date, the inability to ignore advertising banners or to view images.

Nowadays, work is also being done on the reverse process – to generate an image from a description. For this purpose, AI-based image-to-text generators are used [27].

VI. Conclusions

This study aims to promote current applications and software designed for groups of users with impaired vision or hearing. Working prototypes and solutions are offered that support the work and training of people with disabilities, as well as their ability to better communicate and socialize in society. For people with hearing impairments, auditory information is not fully accessible; they have difficulty perceiving spoken communication. Instead, they rely more on visual information and sign language. Conversely, people with visual impairments face difficulties in accessing visual content. To address this, various translators and converters have been created to transform information into Braille, facial gestures, audio, and vice versa – tailored to the user's specific needs. This facilitates communication and data perception. Nowadays, every user aims to get the required information with as few mouse clicks as possible. This is especially relevant for users with special needs. For them, it would be beneficial to reduce clicks to a minimum, as is the case for people without disabilities. The software prototypes presented are notable for this key feature, and this is one of the contributions to the development. Screen readers and Braille to text converters are being developed for visually impaired users to make them easier to use via computer and mobile devices.

To improve quality of life and facilitate social inclusion, scientists from various fields continue to explore better solutions for people with hearing or visual impairments. We will continue the studies in this area in future academic activities with our students. Based on thorough analysis, research, and identified needs, new functionalities and software solutions are being developed to create more accessible products for diverse users. By understanding the challenges faced by these users, programmers, researchers, and educators continuously refine and enhance these specialized products. The prototypes incorporate features such as speech output and text descriptions, making software interfaces easier to navigate. The focus of the study is on designing and implementing assistive software prototypes, particularly through student-focused projects. Various scenarios for application in education, employment, and everyday activities are outlined, which expand the practical significance of the research.

A widespread application of Artificial Intelligence and the Internet of Things is anticipated in the design and development of electronic devices and applications in the near future. This trend is expected to drive the creation and enhancement of increasingly sophisticated solutions that benefit users with hearing or visual impairments.

***Abstract*—This study analyzes differences in teachers' gestural styles based on their culture and investigates how these differences are perceived to influence Japanese students' emotional responses by active observers. Classroom videos of Japanese- and English-native instructors were analyzed using MediaPipe for gesture tracking and DeepFace for facial emotion recognition. Ground-truth emotion labels were collected from four Japanese observers. Results show that Japanese and non-Japanese teachers' gesture dynamics differ in terms of range, rhythm, and symmetry. Japanese student observers perceived each group's gestures differently, with cultural familiarity playing a role in their shifts in emotion. Machine learning models trained on gesture features, facial emotion scores, and teacher background successfully predicted students' affective reactions. These findings highlight the importance of culturally sensitive nonverbal communication in education and demonstrate the potential of AI-based approaches for modeling student emotion in cross-cultural contexts. This study contributes a novel multimodal framework that integrates gesture dynamics, facial emotion recognition, and teacher cultural background to predict student affect, thereby highlighting the necessity of culturally adaptive affective computing in education.**

***Keywords*—Nonverbal behavior; affective computing; AI-based gesture recognition; cultural differences; multimodal analysis; cross-cultural education; emotion prediction**

I. Introduction

Understanding how teachers' nonverbal behavior influences student learning has become increasingly important, particularly in intercultural educational contexts. Among various nonverbal cues, gestures play a pivotal role in directing attention, emphasizing content, and conveying affective meaning. Prior research has shown that gestures not only supplement verbal explanations but also shape learners' cognitive and emotional engagement [1], [2].

However, most of the existing literature on classroom gestures has relied on qualitative observations, which lack precise or scalable measurement approaches [3] [4]. These limitations are especially notable when considering the effect of cultural differences in gesture usage. High- and low-context communication styles, as theorized by Hall [5], may lead to mismatches in how gestures are produced by teachers and interpreted by students. For example, Japanese students may not always correctly interpret gestures used by non-Japanese instructors [6].

Such variation has concrete implications for the classroom. East Asian instructors have been found to favor linking gestures for conceptual clarity, whereas Western educators tend to use more illustrative, expressive forms [7]. These differing gestural styles are not just cultural artifacts but pedagogical strategies that carry affective outcomes. Although the nonverbal behaviors that teachers use reduce psychological distance and have been associated with higher student motivation and engagement [8], such cues may be interpreted differently across cultures.

Beyond cultural and pedagogical dimensions, gestures also serve distinct semiotic functions. McNeill and Kendon classified gestures into types based on how they encode meaning, ranging from spatial reference (deictic) to rhythm and cadence (beat) [2] [4]. These types align with cognitive mechanisms such as mental imagery and discourse structuring [9] [10]. However, their effectiveness depends on how gestures and speech combine to convey meaning in real time [11], and on cultural display rules that modulate students' interpretations [5].

Coinciding with these cultural phenomena, technological advances in affective computing have enabled the quantitative analysis of emotional reactions in real-time classroom environments. Recent advances in AI-based technologies—such as those enabling real-time gesture tracking and facial affect recognition—offer scalable means to detect student emotions in classroom environments [12][13][14]. These methods, however, must account for cultural nuances in gesture production and emotional expression.

This study focuses on how teachers' culturally shaped gestural styles influence Japanese students' emotional perceptions during classroom interactions. Rather than analyzing gesture types per se, we examine how gesture dynamics vary between Japanese and non-Japanese instructors, and how those differences are perceived to affect changes in students' emotions by Japanese observers, simulating a classroom perspective. We also evaluate the extent to which these responses can be predicted using machine learning models trained on gestural and facial features. In other words, the central research question we address is how culturally conditioned differences in teachers' gestures influence Japanese students' affective responses, including the extent to which these responses can be systematically modeled using AI-based analysis.

II. Related Work

Understanding the role of nonverbal teacher behavior in shaping student engagement has been a long-standing point of interest to researchers. Gestures, facial expressions, and body

orientation contribute not only to the transmission of content but also to the affective climate of the classroom. Foundational studies have emphasized the importance of gesture in supporting conceptual understanding and memory formation [1][2]. However, most prior work in this area has relied on observational or qualitative methods [3][4].

Cultural context significantly shapes the form and interpretation of nonverbal behavior. Hall's theory on high- and low-context communication [5], laid the groundwork for understanding why gestures may be interpreted differently across cultures. Park et al. [6] further demonstrated that students from different cultural backgrounds may misinterpret hand gestures used by foreign teachers. Comparative educational studies also show that East Asian teachers tend to use more "linking" gestures to build logical connections, while Western teachers often gesture more illustratively [7].

From a pedagogical standpoint, higher levels of teacher immediacy—the nonverbal behavior used to reduce psychological distance— has been consistently associated with increased student motivation and engagement [8]. These behaviors include open gestures, sustained eye contact, and expressive facial expressions. However, what constitutes "immediacy" may vary by cultural norms, complicating how students interpret these behaviors [5].

Beyond their affective and cultural functions, teacher gestures also have distinct symbolic roles that help impart meaning in instructional discourse. McNeill [2] and Kendon [4] categorized gestures not just by their form, but by how they encode referential or abstract information. In this framework, deictic gestures refer to spatial or discourse objects, iconic gestures depict physical forms, metaphoric gestures give form to abstract ideas via spatial examples, and beat gestures offer rhythm and cadence. These categories align with cognitive processes such as mental imagery, thought activation, and discourse segmentation [9] [10]. In classroom contexts, these functions may influence students both in terms of comprehension and emotional response, especially when the gesture reinforces the accompanying verbal message [11].

In recent years, AI-based techniques have increasingly been applied to classroom research, enabling objective, fine-grained analysis of gesture and emotion. Computer vision systems like MediaPipe and DeepFace allow automatic tracking of hand motion and facial affect, making them useful as new tools for educational affective computing. Whitehill et al. [12] proposed a system to estimate a student's level of engagement via facial cues, finding that machine-measured engagement levels predicted learning outcomes better than prior academic performance. Dai et al. [13] extended this approach by combining multiple modes of tracking—including audio and transcript sentiment—to detect negative teacher emotion (e.g., frustration) across large video datasets. These developments point to the feasibility of real-time, AI-driven feedback systems that support teachers in monitoring classroom sentiment [14].

Although these systems still face challenges in recognizing culturally nuanced gestures or subtle emotions [13], their performance thus far marks a significant step toward quantifying affective dynamics in education. However, few studies explicitly incorporate the teacher's cultural background as a predictive feature when modeling student emotional responses. Combining both multimodal learning analytics and cross-cultural gesture, research enables a more holistic understanding of teacher–student interaction and could lead to change in both pedagogical design and teacher professional development.

While prior studies have examined cultural differences in nonverbal communication [6], few have systematically quantified how gestures differ by teacher cultural background and how those gestures are emotionally perceived by students. This study aims to fill this gap by employing a combination of gesture kinematics, facial emotion analysis, and teacher cultural identity in a unified predictive framework.

Recent advances in AI-based approaches have significantly enhanced the analysis of teachers' nonverbal behaviors and the evaluation of student affect. For instance, Yoon et al. proposed a MediaPipe-based system to quantify pointing gestures by monitoring asynchronous video lectures and demonstrated that in-service teachers adapted their gestures more effectively than pre-service teachers [15]. Similarly, Chen et al. developed a real-time gesture recognition framework using MediaPipe BlazePose to detect teachers' hand signals and deliver attentional cues to students with identified attention deficit problems; doing so achieved an F₁ score of approximately 0.88 [16]. Shou et al. introduced a multi-scale convolutional neural network (CNN) with fine-grained attention enhancements for recognizing student facial expressions in real classroom settings; reporting 93 % accuracy on in-school datasets [17]. Singh et al. gauged online learners' engagement with a multi-modal student attentiveness detection model (MMSAD) that fuses CNN-based facial expression analysis with speech activity detection [18]. Also using CNN-based emotion recognition, Salloum et al. demonstrated pipeline for real-time integration into online learning platforms; achieving 95% accuracy on the FER2013 benchmark [19]. These studies highlight the growing trend of leveraging MediaPipe, DeepFace, and deep learning models to monitor both teacher gestures and student emotions in educational environments. Such AI techniques provide a robust foundation for the work involved with in this study, which employs MediaPipe and DeepFace to perform a cross-cultural analysis of teacher gestures and their impact on Japanese students' affect.

Building on these developments, our study aims to bridge a crucial gap in cross-cultural gesture analysis literature by examining how culturally shaped gestural styles influence students' emotional perceptions in intercultural classrooms. While prior research has demonstrated the utility of AI-based systems for gesture tracking and emotion recognition, few studies have explicitly modeled the cultural background of teachers as a predictive factor in student affect; such cultural context is often treated as peripheral rather than integral to affective dynamics. We address this by integrating gesture kinematics, facial emotion features, and teacher cultural identity into a unified machine learning framework. This allows us to investigate not only behavioral differences across cultures, but also how these differences impact emotional interpretation by students. In doing so, we contribute to the development of affective computing systems that can adapt to culture, in order to better reflect the complexities of human communication in diverse educational settings.

III. Methodology: AI-Based Multimodal Analysis of Culturally Conditioned Gestural Impact

This study uses a multimodal analysis framework to investigate how cultural differences in teachers' gestural behavior influence Japanese students' emotional responses. Fig. 1 illustrates the overall workflow of the study, from video collection to modeling. As shown in Fig. 1, the procedure consists of five main steps:

- Video collection from Japanese and non-Japanese instructors
- Gesture clip extraction
- Observer-based affective labeling
- Feature extraction using MediaPipe and DeepFace
- Statistical analysis and machine learning modeling

Each step is described in detail in the following subsections.

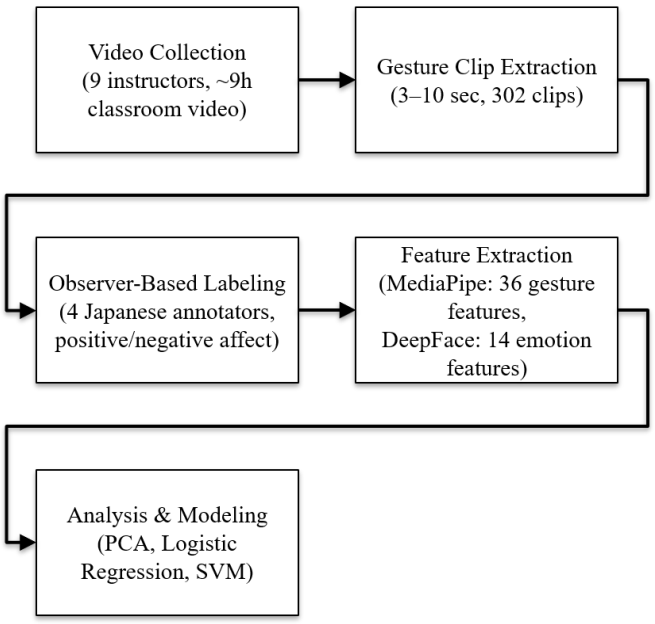

Fig. 1. Overall workflow of the study, from classroom video collection to predictive modeling of student affect.

We employed computer vision tools to extract gesture dynamics, analyzed student affect based on their facial expressions and observer labels, and built machine learning models incorporating both motion features and teacher cultural identity.

A. Dataset

Video data were collected from nine English language instructors (five native Japanese and four native English speakers) teaching Japanese university students in classroom settings. The total length of the recordings was approximately nine hours. The classroom videos were originally recorded as part of a study on spontaneous dynamic teacher emotion recognition by Kennedy et al. [20] and were reused in this study with appropriate ethical approval. Gesture clips of three to ten seconds were segmented from these videos based on visible hand movement, excluding clips where gestures were obstructed or out-of-frame. Only segments where the teacher was facing forward with both hands visible were included. In total, 302 clips were extracted. This dataset was selected because it captures authentic classroom interactions in a naturalistic setting, rather than staged or laboratory recordings, ensuring ecological validity. While the sample size is modest and limited to nine instructors, it provides a balanced comparison between Japanese and non-Japanese teachers in real educational contexts, which is essential for addressing our research questions.

B. Observer-Based Labeling

Four Japanese female annotators, aged 20 to 23, independently labeled each gesture clip by imagining how they, as a student, in the teacher's classroom, might emotionally respond to the teacher's gestures. Their ratings were based on their own perceptions, rather than on observed student reactions. Each annotator viewed the videos in randomized order and was not made aware of the teachers' cultural identities, language backgrounds, and machine-generated emotion scores (positive/negative). Because the focus of this study is gesture, the annotators made their judgments on soundless clips.

The initial consensus label for each clip was determined by majority—when three or more annotators labelled a clip the same way, their shared label was used. In cases of a tie (2 vs. 2), a decision tree model was trained on the majority-agreement cases to predict the most likely final label based on the pattern of individual annotator inputs. This model served to resolve ambiguous labeling outcomes in a reproducible and data-driven manner.

To ensure the validity of this modeling approach, we evaluated the decision tree model's ability to replicate majority-agreement labels through two complementary methods:

- Distribution-level comparison: We applied a chi-squared test and computed Kullback–Leibler divergence to compare the distribution of labels produced by the decision tree model to that of the majority-agreement labels.
- Sample-level comparison (two-two-split cases): We calculated prediction accuracy and Cohen's kappa between the decision tree model's predicted labels and the final consensus labels.

These evaluation methods were used to confirm that the decision tree model reliably approximated consensus labeling in tie situations. All final labels—whether decided by majority or through the decision tree—were then used as ground truth in subsequent supervised learning tasks, as described in Sections *E.2* and *E.3*.

C. Feature Extraction from Gestures

To quantify each teacher's gesture dynamics, we used MediaPipe Holistic (Zhang et al. [21]), which provides real-time tracking of body pose and hand landmarks. All features were computed relative to the teacher's nose landmark to normalize for their placement and the camera's framing. Below is a description of each feature group (totaling 36 dimensions):

1) Wrist Position Statistics (Left and Right): For each wrist, MediaPipe Holistic tracks the trajectory of its (x, y) coordinates

over time. From these trajectories, four descriptive statistics for the x-axis and four for the y-axis were computed—namely, the maximum, minimum, mean, and variance of the wrist position across all frames. These statistics capture the spatial extent (range), central tendency (average position), and variability (how much the hand moves) during the gesture.

2) Hand velocity statistics: Velocity was calculated by differentiating frame-by-frame wrist positions in both *x* and *y* directions. For each axis, we then derived the maximum, minimum, mean, and variance of these instantaneous velocities across the clip. These features reflect how quickly and consistently the teacher moves their hands. High maximum velocity, for example, indicates a fast gesture, while high variance suggests fluctuating speed.

3) Hand acceleration statistics: Acceleration was calculated by taking the temporal derivative of the velocity values along each axis. Like velocity, *x* and *y* accelerations were summarized using their maximum, minimum, mean, and variance across the clip. Acceleration metrics characterize the abruptness or smoothness of movements—large peaks in acceleration denote sudden starts or stops, whereas low variance implies a more uniform movement.

4) Positional correlations: To capture directional consistency and shape of motion, we computed the Pearson correlation coefficient between the *x* and *y* coordinates of each wrist throughout the gesture. A strong positive or negative correlation indicates that the wrists' motions are primarily diagonal, whereas a correlation near zero suggests more independent horizontal and vertical movement.

5) Velocity autocorrelations: Finally, we calculated autocorrelation values for the *x* and *y* components of velocity over short time lags. These correlations measure how similar the hand's speed is from one moment to the next, providing insight into rhythmic or repetitive motion patterns.

In total, these five groups produce a motion profile of 36 numerical features per gesture clip (8 wrist position statistics for each wrist=16, 8 hand velocity statistics=8, 8 hand acceleration statistics=8, 2 positional correlations=2, and 2 velocity autocorrelations=2). Each feature was normalized by clip duration and teacher height before summarization.

While other frameworks, such as OpenPose, have also been widely used for gesture tracking, MediaPipe Holistic was selected because it offers a lightweight and real-time implementation that is less computationally demanding while maintaining comparable accuracy in classroom environments.

This 36-dimensional motion profile, based on MediaPipe Holistic [21], serves as the basis for all subsequent analyses and predictive modeling.

D. Emotion Annotation and Predictive Modeling

This section describes how teacher gestures were analyzed to predict Japanese students' emotional responses, and how gesture characteristics differed systematically between Japanese and non-Japanese instructors. The analysis follows two complementary paths: 1) identifying cultural differences in gesture execution using machine learning, and 2) modeling students' affective responses.

1) Cultural style classification of teachers: To explore how gesture dynamics differ by cultural background, we trained a supervised classifier to distinguish between Japanese and non-Japanese teachers based on the gesture features extracted in Section *C*. This classification task served to identify which motion patterns (e.g., gesture range, rhythm, directional symmetry) are characteristic of each teacher group. The results of this analysis provide an empirical basis for comparing the gestural tendencies of different teacher populations.

2) Observer-based emotion annotation: Japanese students' emotional responses to each gesture were annotated using the four-person consensus protocol, described in Section *B*. Each clip was labeled as eliciting either a positive or a negative emotional reaction.

These consensus labels were then used as ground truth for evaluating whether machine learning models could accurately predict observer-inferred student affective responses based on gesture perception.

3) Prediction of student emotion from gesture features: We first trained a machine learning model to predict the binary emotion label (positive/negative) using gesture features alone. This allowed the model to assess whether the movement pattern of the teacher's gesture, independent of facial cues, was sufficient to explain how Japanese students emotionally responded.

Next, we trained a second model by incorporating both gesture features and facial emotion predictions from DeepFace [22]. DeepFace is a lightweight CNN-based emotion recognition framework capable of estimating seven basic emotion categories (happy, sad, fear, angry, disgust, surprise, neutral) from facial expressions in real-time. It was used to extract per-clip emotion probabilities, which were then averaged over time and used as input features alongside gesture motion. The goal in using this second model was to determine whether combining gesture dynamics with machine-estimated facial affect signals improves prediction performance.

4) Application to feedback and cultural interpretation: These predictive models can be used to provide actionable feedback to teachers by identifying gesture patterns that are more likely to be perceived negatively by students. Such insights can guide the creation of culturally responsive teaching strategies and help educators avoid nonverbal behaviors that may unintentionally cause discomfort or disengagement.

Likewise, the analysis of model coefficients and misclassified cases can help us understand how specific gestural differences between Japanese and non-Japanese teachers contribute to affective outcomes. By systematically comparing model behavior across teacher groups, we aim to identify which motion traits are positively or negatively received in a Japanese cultural context.

E. Implementation

All processing was performed in Python using MediaPipe, DeepFace, and scikit-learn. For gesture-based cultural classification (i.e., distinguishing between Japanese and non-Japanese teachers), we used both Support Vector Machines (SVM) and Linear Discriminant Analysis (LDA) to compare performance in modeling stylistic differences. For emotion prediction tasks, logistic regression was primarily used for its transparency, and in some cases, SVM was also applied to assess potential nonlinear relationships.

Although more complex deep learning models could potentially achieve higher predictive accuracy, we deliberately employed logistic regression and SVM because they are interpretable, less prone to overfitting with relatively small datasets, and allow clearer examination of how gesture and facial features contribute to cultural differences.

All of these features were standardized, and stratified cross-validation was applied throughout their application. No extensive hyperparameter tuning was conducted, and default settings and L2 regularization were used as appropriate.

IV. Results

This section presents the empirical findings in four stages. First, the reliability of emotion labels generated through observer annotation and machine-aided resolution are evaluated. Second, cultural differences in teachers' gestural dynamics based on motion features extracted from clips of classroom videos are analyzed. Third, how students' emotional reactions vary depending on the cultural background of the teacher are examined. Finally, machine learning models to predict students' affective responses from gestural and facial features are discussed and the models' performance across different input modalities and teacher groups compared.

A. Reliability of Emotion Labels

To ensure the validity of emotion labels used as ground truth for supervised learning, a multi-step evaluation of observer-labeled data was implemented, as outlined in Section III *B*.

While a majority-vote protocol was used to assign labels, in 30.8% of the samples (72 out of 234 clips), the labels were evenly split (2 vs. 2). To resolve these ambiguous cases, a logistic regression model was trained using the individual ratings from the 162 majority-agreement clips as input and their consensus labels as targets. The trained model was then applied to predict the most probable label in the tie cases.

To assess the validity of this model-based resolution strategy, we conducted two evaluations:

1) Distribution-level consistency: A chi-squared test comparing the emotion label distribution (positive vs. negative) in the predicted set versus the original majority-agreement set showed no significant difference ($p > 0.05$). Additionally, the Kullback–Leibler (KL) divergence between the two distributions was extremely low (0.012), indicating near-identical global distributions.

2) Sample-level agreement: To validate the logistic model's predictive power, we performed five-fold cross-validation on the majority-agreement cases. The model achieved an average accuracy of 95.4% and a Cohen's kappa score of 0.88, demonstrating high consistency with human consensus even in ambiguous cases.

These results suggest that the predicted labels for 2–2 split cases are statistically and behaviorally consistent with majority-vote annotations. All subsequent analyses, including classification and predictive modeling, used this unified set of final labels.

B. Cultural Differences in Gesture Dynamics in Gestures and Emotions

To investigate how nonverbal behavior and emotional expression differ between Japanese (J) and non-Japanese (N) teachers, we conducted a principal component analysis (PCA) on a set of 50 combined dimensions. This set consisted of 36 motion-related features derived from teachers' hand gestures and 14 facial emotion features extracted using DeepFace. All features were standardized before analysis. Component scores were then compared between cultural groups using Welch's t-test, applying Bonferroni correction to control for multiple comparisons.

1) PCA and explained variance: A total of 234 video clips were analyzed, each corresponding to either a Japanese teacher (J) or a non-Japanese teacher (N). For each clip, 50 features were extracted, consisting of:

a) 36 gesture features: These include the maximum, minimum, mean, and variance of left and right wrist positions and velocities in both X and Y directions, as well as wrist velocity correlations.

b) 14 affective features: These represent mean and variance of basic emotional expressions (anger, disgust, fear, happy, sad, surprise, neutral), extracted via facial analysis.

No missing values or filtering was applied. All features were standardized to zero mean and unit variance using StandardScaler from scikit-learn. Principal component analysis (PCA) was conducted to reduce dimensionality and explore patterns associated with cultural differences.

The PCA revealed that the first 14 components together accounted for 81.00% of the total variance in the feature space, with the first component alone capturing 23.2%. Table I shows the explained variance and cumulative variance for each component up to PC14.

2) Statistical comparison: Japanese vs. Native Teachers. We tested for cultural differences in each of the first 14 components using Welch's t-test. Table II presents the p-values (uncorrected and Bonferroni-adjusted) and effect sizes (Cohen's d) for each component. Three components—PC2, PC3, and PC9—showed statistically significant group differences after correction. Adjusted p-values were computed using Bonferroni correction. Values in bold indicate statistical significance (adjusted $p < 0.05$).

TABLE I. EXPLAINED VARIANCE OF PRINCIPAL COMPONENTS (UP TO 80%)

Principal Component	Explained Variance Ratio (%)	Cumulative Variance (%)
PC1	23.2	23.2

PC10	0.458	>0.05	-0.1
PC11	0.582	>0.05	-0.07
PC12	0.009	>0.05	-0.36
PC13	0.02	>0.05	0.31
PC14	0.732	>0.05	-0.05

1) Interpretation of significant components: We examined the five features with the highest absolute loadings for each significant component (PC2, PC3, PC9), as shown in Table III. Feature names correspond to variables such as RIGHT_WRIST_x_mean (i.e., a mean of the x-position of the right wrist) and velocity_x_correlation (i.e., the correlation coefficient between x-velocities of left and right wrists), etc. "Loading" denotes the PCA factor loading, representing how strongly each feature influences the component.

- PC2: Horizontal motion and facial fear: PC2 differentiates teachers along horizontal gestural dimensions and facial fear variability. Non-Japanese teachers tend to exhibit greater horizontal range and smoother motion in the x-axis (e.g., higher RIGHT_WRIST_x_mean and velocity_x_correlation), while Japanese teachers show higher variation in "fear" expression.
- PC3: Vertical Gesture Amplitude and Negative Affect: PC3 captures vertical gesture positioning and fluctuations in negative emotion. Non-Japanese teachers use broader vertical ranges and faster movements (higher RIGHT_WRIST_y_mean and Vy_mean), while Japanese teachers show greater variance in "sad" facial expression.
- PC9: Postural Stability and Positive Affect: PC9 reflects differences in vertical consistency and "happy" expression. Non-Japanese teachers show more stable hand elevation (higher RIGHT_WRIST_y_mean, lower position_y_correlation) and scored higher in both average and variability of "happy" expressions. Japanese teachers show more fluctuation in vertical posture.

TABLE III. TOP 5 LOADINGS OF SIGNIFICANT PCS

Principal Component	Feature	Loading
PC2	RIGHT_WRIST_x_mean	0.29
	velocity_x_correlation	0.28
	RIGHT_WRIST_x_max	0.28
	LEFT_WRIST_x_mean	-0.27
	fear_variance	-0.26
PC3	RIGHT_WRIST_y_mean	0.29
	RIGHT_WRIST_y_min	0.26
	sad_variance	-0.26
	angry_mean	0.25
	RIGHT_WRIST_Vy_mean	0.23
PC9	position_y_correlation	-0.31
	RIGHT_WRIST_y_mean	0.31
	LEFT_WRIST_y_variance	0.28
	happy_variance	0.28
	happy_mean	0.27

2) Interpretation and cultural implications: The PCA results reveal meaningful cultural contrasts in teachers' nonverbal and emotional behavior. Among the 14 principal components which, when combined, explained 81.0% of the variance, three components—PC2, PC3, and PC9—exhibited significant differences between Japanese and non-Japanese instructors.

- PC2 reflected differences in horizontal hand motion and fear-related facial variability; non-Japanese teachers showed greater lateral gesture range and motion consistency, whereas Japanese teachers exhibited more fluctuation in fear expression.
- PC3 involved vertical hand amplitude and negative affect; non-Japanese instructors used broader, faster

vertical gestures and expressed more "anger", while Japanese teachers showed greater variability in "sad" expression.

- PC9 was associated with postural stability and positive facial affect; non-Japanese teachers maintained higher and more consistent hand elevation with more pronounced "happy" expressions, whereas Japanese teachers exhibited greater variability in both gesture and affect.

These findings support the general view that low-context communicators (e.g., non-Japanese teachers) tend to favor explicit and clear nonverbal behavior [2] [5], whereas high-context communicators (e.g., Japanese teachers) rely more on subtle and context-sensitive expression [23]. The combination of gesture and facial features in this analysis allows us to better understand how teachers from different cultural backgrounds encode emotional signals during instruction.

A more detailed interpretation of these patterns—especially in relation to cultural display rules, teacher immediacy, and affective computing design—is provided in the Discussion (see Section V).

C. Student Emotion by Teacher Culture and Its Predictive Model

1) Group differences in student emotion: To investigate whether a teacher's culture influences their students' emotional responses, we compared the distribution of observer emotion labels (positive vs. negative) across teacher cultural backgrounds (Japanese or non-Japanese). A 2×2 contingency table was constructed (see Table IV), and both the chi-squared test and Fisher's exact test were performed.

TABLE IV. CROSS-TABULATION OF TEACHER CULTURE (JAPANESE VS. NON-JAPANESE) AND STUDENT EMOTION LABEL (POSITIVE VS. NEGATIVE)

Teacher Culture	Student Emotion: Positive	Student Emotion: Negative
Japanese (J)	58	45
Non-Japanese (N)	56	75

The results of the chi-squared test approached significance ($\chi^2 = 3.72$, $p = 0.054$, $df = 1$), and Fisher's exact test yielded a statistically significant result ($p = 0.048$, odds ratio = 1.73).

Although non-Japanese teachers are often seen as more expressive, here Japanese teachers more frequently elicited positive emotional responses (56.3% vs. 42.7%).

This suggests that cultural familiarity may take precedence over expressiveness in shaping students' emotional receptivity. To investigate whether Japanese students' emotional responses can be predicted from teachers' nonverbal behavior, we trained logistic regression model using 50-dimensional features derived from 36 gesture dynamics and 14 facial expressions (see Section IV *B*). Cultural labels were excluded from the models to focus solely on behavioral cues. Using five-fold stratified cross-validation, the model achieved a mean accuracy of 66.2% (σ = 7.5%), suggesting that nonverbal behavior alone provides moderate predictive power. As shown in Table V, however, accuracy differed substantially by teacher culture: 62% for Japanese teachers versus 76% for non-Japanese teachers.

TABLE V. ACCURACY OF LOGISTIC REGRESSION MODELS PREDICTING STUDENT EMOTION, BROKEN DOWN BY TEACHER CULTURE (JAPANESE VS. NON-JAPANESE)

Teacher Culture	Accuracy Mean	Accuracy Std
Japanese	0.62	0.061
Non-Japanese	0.76	0.090

To understand the source of this discrepancy, we compared model coefficients between two cultural groups. Table VI lists the five features showing the greatest differences. For non-Japanese teachers, positive student responses were more strongly associated with high hand velocity (e.g., RIGHT_WRIST_Vx_min, LEFT_WRIST_Vx_max) and consistent vertical motion (position_y_correlation). Meanwhile, for Japanese teachers, positional extremes such as RIGHT_WRIST_x_min played a more prominent role in positive student responses—possibly reflecting a culturally embedded preference for subtle, controlled gestures. These findings highlight the culturally situated nature of affective communication and underscore the value of adapting emotion-prediction models to cultural context.

TABLE VI. FIVE FEATURES WITH THE LARGEST COEFFICIENT DIFFERENCES BETWEEN LOGISTIC REGRESSION MODELS TRAINED ON JAPANESE-TEACHER DATA (J) AND NON-JAPANESE-TEACHER DATA (N)

Feature	J_Coefficient	N_Coefficient	Coefficient Absolute Difference
RIGHT_WRIST_Vx_min	0.82	-1.11	1.93
RIGHT_WRIST_x_min	-1.19	0.25	1.44
LEFT_WRIST_Vx_max	0.60	-0.79	1.39
position_y_correlation	0.37	-0.80	1.18
RIGHT_WRIST_x_mean	1.26	0.25	1.01

2) Summary and cultural reflection: The findings in this section (see also Table V) demonstrate that the cultural background of the teacher not only influences the distribution of students' emotional responses but also modulates the internal structure of the predictive model. Logistic regression classifiers, which are trained separately on Japanese and non-Japanese teachers' data, revealed notable differences in accuracy: student emotion was predicted with significantly higher precision when the teacher was a non-Japanese speaker. This suggests that the affective cues conveyed by native teachers were more consistently interpreted by Japanese students, leading to more stable input–output mappings in the model.

Interestingly, Japanese teachers—who are often described as emotionally reserved in high-context cultures [5] [23]—elicited less predictable emotional responses as perceived from a student's perspective. And yet, this does not imply that their gestures were affectively neutral or irrelevant. Rather, lower

gesture predictability may reflect greater contextual modulation or individual variation in how their nonverbal behaviors are perceived. In fact, this aligns with our findings in Section IV *B.2*, where Japanese teachers exhibited richer vertical gestural amplitude and a broader affective range than might be expected from cultural stereotypes.

This suggests that interactions with culturally dissimilar instructors—such as non-Japanese teachers—may enable otherwise restrained Japanese students to externalize their emotional responses more visibly. And so, our model not only predicts emotion, but also reveals how cultural contrast may enhance how well we perceive student affect in educational interactions. This is a particularly important consideration in intercultural classrooms, where emotional communication may otherwise remain latent.

Taken together, these findings indicate that predictive models must be both behaviorally precise and also culturally responsive. While non-Japanese teachers exhibited more overt and consistently interpreted nonverbal-affective behaviors, Japanese teachers demonstrated context-sensitive expressiveness that was no less impactful, though it may vary more. Overall, these results imply that culturally sensitive affective computing models must account for not only static behavioral norms but also dynamic pedagogical roles and expectations.

V. Discussion

This study sheds light on the complex interplay between cultural background, nonverbal behavior, and affective perception in classroom communication. The concept of nonverbal leakage—concealed emotions and intentions "leaking" through subtle facial and gestural cues [24]—helps explain why even small differences in teacher expressiveness can significantly affect student emotion. Building on prior studies in gesture typology [2][4], immediacy theory [8], and cultural context models [5][23], we quantitatively examined how gesture dynamics and facial affect from teachers of different cultural backgrounds influence Japanese students' emotional responses.

Although the emotion annotations in this study were not derived from actual student reactions, they were produced by native Japanese observers explicitly instructed to adopt the perspective of a student in the classroom. This imagined-student approach allowed us to assess affective responses to teacher gestures in a controlled and consistent manner. Prior work in affective computing and cross-cultural psychology supports the use of projected or observer-based affect labeling when direct feedback is impractical or ethically constrained.

Moreover, recent AI-based works such as quantifying gestures via MediaPipe [15], detecting real-time hand signals using BlazePose [16], and high accuracy recognition of student expressions [17][18]–demonstrates how automated, multimodal feedback can guide instructors. These advances support our use of MediaPipe and DeepFace, as well as point toward future systems that offer real-time, culturally sensitive classroom guidance.

A. Cultural Differences in Nonverbal Expressivity

Our findings confirm that cultural background shapes not only how teachers' gesture, but also how those gestures are emotionally interpreted. PCA results revealed that non-Japanese teachers tended to use gestures with broader horizontal and vertical range, smoother trajectories, and more expressive facial signals. On the other hand, Japanese teachers showed more localized motion patterns and higher variability in facial expressions such as sadness and fear. These patterns are consistent with Hall's theory that high-context cultures favor more subtle, less explicit communication styles [5].

Interestingly, although non-Japanese teachers demonstrated more clear and systematic nonverbal behavior, Japanese teachers were more likely to elicit positive affective responses (56.3% versus 42.7%). This suggests that cultural familiarity may play a stronger role in emotional receptivity than expressive intensity alone—a finding that challenges the assumptions derived from immediacy theory [8].

B. Predictive Modeling and Cultural Modulation

Logistic regression classifiers trained on gesture and affective features showed moderate accuracy in predicting student emotion (66.2%). However, when trained separately by teacher group, model accuracy was significantly higher for non-Japanese teachers (72.3%) than for Japanese teachers (64.8%). This suggests that non-Japanese teachers' affective cues were more consistently understood by students, whereas Japanese teachers' cues exhibited greater contextual or individual variation, possibly due to more nuanced display rules [23].

The top differentiating features between the two models—including RIGHT_WRIST_Vx_min, position_y_correlation, and RIGHT_WRIST_x_min—highlight how affective perception hinges on both intensity and spatial/rhythmic regularity. These quantitative findings resonate with earlier symbolic accounts of gesture [10] [11] that emphasize cognitive alignment and expressivity.

C. Cultural Contrast and Student Legibility

One particularly compelling implication is that interactions with culturally dissimilar instructors may enhance the visibility of student emotion. When students are exposed to low-context, overtly expressive behavior—typical of non-Japanese teachers—they may externalize their own emotional states more clearly. This could explain the more stable prediction accuracy for these cases, which would suggest that cultural dissimilarity may sometimes reduce ambiguity in affective signaling.

Conversely, Japanese teachers, often operating within a high-context communicative norm, may trigger more individualized and internalized affective interpretations, complicating the ability to predict affect. However, this should not be mistaken for lower emotional engagement. On the contrary, the data indicate that Japanese teachers express a broader emotional range, but with less behavioral regularity. This calls for more context-sensitive modeling approaches.

D. Implications for Culturally Adaptive Affective Computing

The implications of these findings extend beyond education to the broader field of affective computing. As previous literature has emphasized [12] [13], multimodal AI models must

capture both real-time behavior and contextual nuance. The results here suggest that affective computing systems should explicitly model cultural context—not only as a background variable but as a dynamic factor that modulates both expression and perception.

Future systems should adapt to the emotional norms, gestural practices, and display rules of the cultural environment in which they are used. This would allow such systems to move beyond accuracy benchmarks and toward human-aligned interpretability, which would then enhance trust and engagement in human–AI interaction across diverse populations.

VI. Limitations and Future Work

While this study offers novel insights into the relationship between teachers' nonverbal behavior and student emotion in cross-cultural classrooms, several limitations must be acknowledged.

First, the analysis was based on 234 video clips, selected from an initial pool of 302 after excluding segments that were too short, obstructed, or poorly framed. Although this filtering ensured data quality and consistency, the dataset was relatively small and drawn from a limited number of instructors—five Japanese and four non-Japanese teachers. This sample size restricts the generalizability of the findings, as it may not fully capture the diversity of instructional styles or cultural expression within each group. Future research should aim to expand both the number and variety of participating educators.

Second, emotional annotations were limited to a binary emotional scale (positive vs. negative), which simplifies the complexity of affective responses. Additionally, these annotations were not based on actual student reactions but were provided by four Japanese university students who imagined themselves as learners in the classroom. While this approach ensured cultural and procedural consistency, it introduces the possibility of projection bias and limits ecological validity. Future studies should consider using a more diverse annotation pool and explore the use of continuous or multidimensional emotion metrics.

Third, although facial expressions and gesture dynamics were combined in the predictive model, the analysis was conducted at the clip level, without fine-grained time sync between gestures and emotional shifts. Sub-clip or frame-level modeling might reveal more precise temporal cues associated with emotional perception, particularly in the case of micro-expressions or beat gestures.

Fourth, cultural differences were inferred solely from the teachers' identities (Japanese vs. non-Japanese), without explicitly modeling student cultural frameworks or individual differences. While this study assumed cultural homogeneity among students—all of whom were Japanese—the model did not incorporate any student-level variables, such as prior experience with foreign instructors, which may influence how nonverbal cues are perceived.

Fifth, logistic regression was chosen for its interpretability, but it may not capture more complex, nonlinear relationships between multimodal features and affective outcomes. Although suitable for initial exploration, future studies could employ deep learning or transformer-based architectures.

Finally, we acknowledge that, although their evaluations were consistent and culturally grounded, the homogeneity in gender and age of the emotion annotators in this study may introduce bias in emotion perception. Prior literature suggests that emotional sensitivity and interpretation can vary across genders. To enhance the robustness and generalizability of affective labeling, future studies should incorporate a more demographically diverse annotator pool.

Future research should explore more advanced AI architectures to overcome these limitations. For example, transformer-based multimodal models could capture temporal dependencies between teacher gestures and student facial expressions in finer detail. Additionally, evaluating AI-based affect estimation methods in online or hybrid learning environments would help generalize findings beyond face-to-face classrooms. Finally, incorporating student-level variables—such as prior exposure to foreign instructors—into predictive models could enable personalized, culturally adaptive feedback systems for real-time instructional support.

Taken together, these limitations point to several directions for future research. Expanding sample diversity—both among teachers and student annotators—will improve the generalizability of findings, while refining emotional representations through continuous or multidimensional metrics can capture subtler affective nuances. Enhancing temporal resolution to the frame level and incorporating student-level variables (e.g., gender, prior cross-cultural experience) will yield deeper insight into how culture shapes affective dynamics. Moreover, exploring teacher–student emotional co-regulation models in real-time classroom interactions could illuminate bidirectional affective processes. Such advances will not only support the development of adaptive, culturally responsive feedback systems but also enhance student engagement and emotional well-being in diverse educational settings.

VII. Conclusion

This study examined how differences in teachers' gestures in classroom settings based on their culture influence Japanese student observer's emotional responses. By combining gesture kinematics and facial emotion analysis with machine learning techniques, both the form and cultural context of nonverbal behavior were demonstrated to have a significant influence on affective perception and predictability.

While non-Japanese teachers were found to use more overt gestures that were easier for systems to interpret, Japanese teachers were more likely to elicit positive emotional responses, which highlights the role of cultural familiarity in affective engagement. Interestingly, the findings also suggest that cultural contrast may enhance the ability to read student affect. This raises important questions about how intercultural dynamics shape not only teacher expressivity but also student emotional visibility in classroom interactions.

Predictive modeling further revealed that non-Japanese instructors yielded higher emotion prediction accuracy, likely due to greater behavioral regularity, while Japanese teachers' gestures exhibited more contextual variability. This variability

was further reflected in the predictive models used, which achieved higher prediction accuracy for non-Japanese teachers. These differences underscore the need for culturally adaptive models that accommodate variation in signal consistency and contextual modulation.

These findings emphasize that differences in student perception are not merely a matter of gesture intensity or clarity, but are shaped by culturally embedded expectations, display rules, and interaction norms. By quantifying these dynamics and modeling affective responses, this study demonstrates that affective computing for education must be both multimodal and culturally adaptive.

By providing a scalable, quantitative framework for analyzing cross-cultural emotion perception in classrooms, this study contributes not only to research on gesture and education but also to the design of AI systems, that can be used to monitor human emotion. Future studies should build on these findings by incorporating student-level diversity, more discrete emotion labels, and real-time feedback mechanisms to support more inclusive and emotionally intelligent educational environments.

Enhancing Approximate Conformance Checking Accuracy with Hierarchical Clustering Model Behaviour Sampling

Yilin Lyu
School of Computing and Information System,
The University of Melbourne, Parkville, Victoria 3010, Australia

***Abstract*—Conformance checking techniques evaluate how well a process model aligns with an actual event log. Existing methods, which are based on optimal trace alignment, are computationally intensive. To improve efficiency, a model sampling method has been proposed to construct a subset of model behaviour that represents the entire model. However, current model sampling techniques often lack sufficient model representativeness, limiting their potential to achieve optimal approximation accuracy. This study proposes new model behaviour sampling approaches using hierarchical clustering to compute an approximation closer to the exact result. This study also refines the existing upper bound algorithm for better approximation. Our experiments on six real-world event logs demonstrate that our method improves approximation accuracy compared to state-of-the-art model sampling methods.**

***Keywords*—Approximate conformance checking; model behaviour sampling; hierarchical clustering; process mining**

I. Introduction

Conformance checking is a set of process mining functionalities aimed at identifying deviations between the actual behaviour of the event log ("as-is") and the modeled behaviour of the process model ("to-be"). It facilitates further applications, such as model repair, anomaly detection, and algorithm evaluation [1]. In recent years, the alignment-based method [2] has become the de facto standard for conformance checking in the computation of conformance diagnostics, since it always returns the most accurate deviations, known as optimal alignment [3]. However, finding the optimal alignment is an NP-hard problem [4]. As the complexity of the log and model increases, the run-time complexity of optimal alignment computation grows exponentially, leading to extremely long computation times, sometimes even taking several weeks. This makes them impractical for real-world applications, especially large-scale event logs. Moreover, in certain cases, an exact conformance value is not necessary, such as when performing a preliminary evaluation of process models with various process discovery algorithms [5].

To address the problems, various approximation strategies have been proposed, including optimizing the search algorithm [6], [7] and decomposition schemes [8], [9]. However, sampling provides another angle for approximate conformance checking, such as sampling traces to represent the event log [10], [11] or selecting model traces to substitute for the process model [5], [12]. In this study, we adopt the latter approach, focusing on model sampling. Two main model sampling methods exist: simulation [13] and candidate selection [5]. We concentrate on candidate selection due to its higher accuracy [5]. The candidate selection method identifies representative traces from the event log (i.e., log behaviour subset), and then computes their optimal alignments to determine the corresponding model traces (i.e., model behaviour subset). The accuracy of this approximation depends on the quality of the selected log traces [12]. However, existing log selection techniques (e.g., random, frequency-based [5], K-Medoids [14]) often lack behavioural diversity and model representativeness (see Section II), leading to reduced accuracy in the conformance approximation. Hence, there is significant potential for improving the quality of model behaviour subsets.

In this study, we propose an enhanced model behaviour sampling method to select more representative subsets and obtain more accurate approximate values. First, we apply hierarchical clustering to the event log using our proposed distance criterion. Then, we propose two in-cluster methods to select typical traces from each cluster, which are then used to construct more representative model behaviour subsets. Finally, we extend the existing cost lower bound algorithm to achieve more accurate approximation results. The experimental results show that our approach yields more accurate approximations than existing baselines, though with an increased approximation time.

The remainder of this study is organized as follows. Section II provides a motivating example to further illustrate the research problem. Section III discusses related work in approximate conformance checking. Section IV outlines the necessary preliminaries. In Section V, we propose our method for constructing model behaviour subsets using hierarchical clustering. Section VI details the evaluation setup. Section VII presents the experimental results, followed by Section VIII which presents the discussion. Finally, Section IX concludes the study and presents the limitations and future work.

II. Motivating Example

Research such as [5] and [15] has shown that selecting more typical log traces lead to higher approximation accuracy. Thus, the key challenge is determining which subset should be selected to improve approximate accuracy. Existing log selection methods, such as the frequency-based and K-medoids approaches, sometimes lack sufficient log representativeness.

To illustrate the potential limitations of these methods, we use a synthesized event log L. It contains 5,106 traces consisting of 32,600 events and 12 trace variants, as shown in Table I.

TABLE I. EVENT LOG

ID	Trace Variant	Freq	ID	Trace Variant	Freq
0	$\langle a, b, c, d, f, e, g, h\rangle$	1280	6	$\langle a, d, f, h\rangle$	250
1	$\langle a, b, c, d, e, f, g, h\rangle$	912	7	$\langle a, f, b, c\rangle$	96
2	$\langle a, b, c, d, e, g, f, h\rangle$	864	8	$\langle a, c, e, f, g\rangle$	64
3	$\langle a, b, c, h\rangle$	792	9	$\langle a, d, e, g, h\rangle$	56
4	$\langle a, b, c, d, h\rangle$	400	10	$\langle a, b, f, e, g, h\rangle$	48
5	$\langle a, h\rangle$	320	11	$\langle b, f, g\rangle$	24

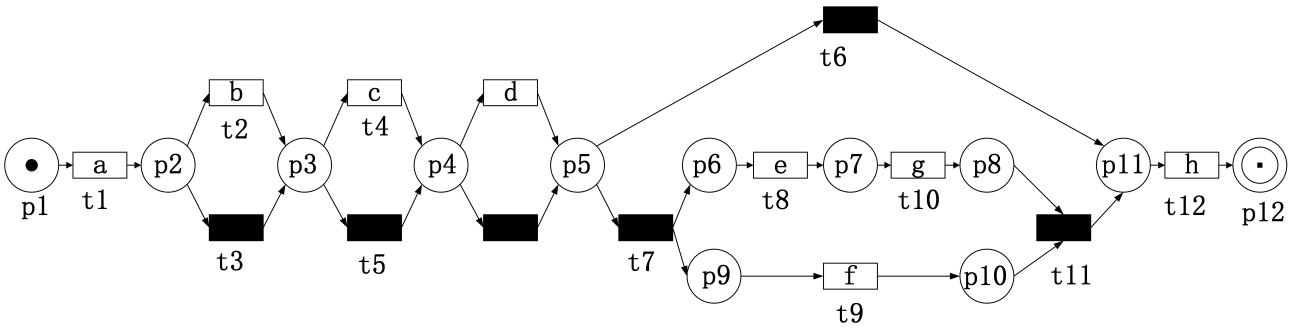

Fig. 1. The process model discovered by inductive miner with infrequent threshold equals to 0.9.

TABLE II. BEHAVIOUR SUBSETS CONSTRUCTED BY FOUR METHODS

Method	Subset	Result	Cost Deviation
Frequency-based	Log Behaviour	$\Sigma_L = \{\langle a, b, c, d, f, e, g, h\rangle, \langle a, b, c, d, e, f, g, h\rangle, \langle a, b, c, d, e, g, f, h\rangle\}$	7806
	Model Behaviour	$\Sigma_M = \{\langle a, b, c, d, f, e, g, h\rangle, \langle a, b, c, d, e, f, g, h\rangle, \langle a, b, c, d, e, g, f, h\rangle\}$	
K-Medoids	Log Behaviour	$\Sigma_L = \{\langle a, h\rangle, \langle a, b, c, d, e, g, f, h\rangle, \langle b, f, g\rangle\}$	6596
	Model Behaviour	$\Sigma_M = \{\langle a, h\rangle, \langle a, b, c, d, e, g, f, h\rangle, \langle a, b, e, f, g, h\rangle\}$	
In-cluster frequency	Log Behaviour	$\Sigma_L = \{\langle a, h\rangle, \langle a, b, c, d, f, e, g, h\rangle, \langle a, b, c, h\rangle\}$	4698
	Model Behaviour	$\Sigma_M = \{\langle a, h\rangle, \langle a, b, c, d, f, e, g, h\rangle \langle a, b, c, h\rangle\}$	
In-cluster medoid	Log Behaviour	$\Sigma_L = \{\langle a, d, f, h\rangle, \langle a, b, c, d, f, e, g, h\rangle, \langle a, b, c, h\rangle\}$	4854
	Model Behaviour	$\Sigma_M = \{\langle a, d, h\rangle, \langle a, b, c, d, f, e, g, h\rangle \langle a, b, c, h\rangle\}$	

To discover the event log presented in Fig. 1, we applied the Inductive Miner algorithm [16] with infrequent thresholds of 0.9.

Assuming that we select three variants to represent the event log, i.e., the behavior subset consists of three variants. Table II shows the behaviour subsets generated by the frequency-based method, K-Medoids, and our proposed methods (see Section V for details). The frequency-based subsets show two key limitations:

1) Overestimation of alignment cost: Variant 5, $\langle a, h\rangle$, can be perfectly replayed in the model with an alignment cost of 0. But it is not included in our model behaviour subset, aligning it would require at least 6 insertions (i.e., cost of 6), resulting in an overestimated approximate cost.

2) Lack of structural diversity: The selected model traces $\langle a, b, c, d, f, e, g, h\rangle$ and $\langle a, b, c, d, e, f, g, h\rangle$ differ only in the order of e and f. This means that they represent essentially the similar structural path, potentially overlooking other important paths in the process model.

Also, the K-Medoids method has drawbacks: it clusters traces solely based on their control-flow information, that is, syntactic difference. For example, the trace $\langle b, f, g\rangle$ in log behaviour subset (as shown in Table II) may have significantly syntactic differences from other traces but, due to its low

frequency (only 24 occurrences), it is still not enough to represent the model behaviour.

To address the issues, our approach proposed in Section V effectively balances frequency and control-flow information. Table II also shows the cost deviation. It refers to the difference in alignment cost between using model behaviour subset and optimal-alignment. The values indicate that the model behaviours generated by our methods significantly reduce the cost deviations compared to vanilla methods.

III. Related Work

To cope with the complexity of alignment construction, approximation techniques have been developed to balance result quality and computational cost. Early studies explored replacing the A* algorithm with faster algorithms[7], [17], [18], laying the foundation for a more efficient alignment computation. For example, Taymouri and Carmona [17], introducing an evolutionary algorithm to enhance alignment approximations. Model decomposition has also been investigated as an efficiency-oriented approximation approach. The foundational work demonstrated how breaking models into smaller and more manageable parts can simplify alignment, although it may not always result in optimal alignments [19], [20]. Furthermore, the construction of automata capable of aligning the log and the model has been explored as another approximation technique [21], [22]. This approach provides good approximations of the optimal alignments in most cases. Recently, some researchers have proposed using RNN-based neural networks to obtain recall and precision metrics for event logs and process models, demonstrating the potential of this technique for conformance analysis [23], [24].

Reducing behaviour size is another promising strategy for approximate conformance checking. One sampling approach focuses on sampling the event log. For instance, [25] proposes a trace sampling method, assuming that a few log traces can estimate the conformance value. However, it lacks upper and lower bounds for the approximation and performs worse when the event log contains many unique behaviors.

Another recent sampling approach targets model behaviour. [5] introduced a model sampling method to construct subsets of the model behaviour that represent the entire process model, significantly reducing the approximation time while largely maintaining accuracy. The method also provides upper and lower bounds to give some certainty of the approximation.

Hierarchical clustering is widely used in process mining for its structural representativeness [26]. Furthermore, [27] demonstrates how hierarchical clustering aids in discovering a better model.

IV. Preliminaries

This section presents the terminology and notation for conformance checking to support the subsequent sections. We use the basic definitions of Petri net, e.g., labeled Petri Net in [28].

Given a system net SN, $\phi_f(SN)$ is the set of all complete firing sequences of SN and $\phi_v(SN)$ is the set of all possible visible traces, i.e., complete firing sequences starting in its initial marking and ending in its final marking projected onto the set of observable activities (not silent transitions, e.g., t_3 in Fig. 1).

To measure how a trace aligns to a process model, moves are represented by pairs (a, t), where a is a log activity, and t is a model transition. Legal moves can be: log moves , model moves, or synchronous moves . Any other combination is an illegal move.

Definition 1. ***(Alignment).*** *Let $\sigma_L \in L$ represent a log trace and $\sigma_M \in \phi_f(SN)$ denote a complete firing sequence of a system net SN. A_{LM} is the set of legal moves. An alignment of σ_L and σ_M is a sequence of pairs $\gamma \in A_{LM}^*$ such that the projection on the first element (ignoring $\gg$) yields σ_L and the projection on the second element (ignoring $\gg$ and transition labels) yields σ_M.*

To quantify the costs of alignments we introduce a cost function δ in Definition 2.

Definition 2. ***(Cost of Alignment).*** *Cost function $\delta \in A_{LM} \to \mathbb{N}$ assigns costs to legal moves. The cost of an alignment $\gamma \in A_{LM}^*$ is the sum of all costs:*

$$\delta(\gamma) = \sum_{(a,t)\in\gamma} \delta(a, t).$$

The cost values assigned to log moves, model moves, and synchronous moves are 1, 1, and 0, respectively. Note that an alignment is considered optimal if it has the minimum alignment cost.

Definition 3. ***(Optimal Alignment).*** *Let L be an event log and SN a system net, where $\phi_v(SN) \neq \emptyset$.*

- *For $\sigma_L \in L$, we define: $\Gamma_{\sigma_L,SN} \in \{\gamma \in A_{LM}^* \mid \exists \sigma_M \in \phi_f(SN)$ is an alignment of σ_L and $\sigma_M\}$.*
- *An alignment $\gamma \in \Gamma_{\sigma_L,SN}$ is optimal for trace $\sigma_L \in L$ and system net SN if for any alignment $\gamma' \in \Gamma_{\sigma_L,M}$: $\delta(\gamma') \geq \delta(\gamma)$.*
- *$\gamma_{SN} \in A_{LM}^* \to A_{LM}^*$ is a mapping that assigns any log trace σ_L to an optimal alignment, i.e., $\gamma_{SN}(\sigma_L) \in \Gamma_{\sigma_L,SN}$ and $\gamma_{SN}(\sigma_L)$ is an optimal alignment.*

Definition 4. ***(Levenshtein Edit Distance).*** *As defined by [29], the Levenshtein edit distance $d(\sigma_1, \sigma_2) \to \mathbb{N}$ represents the minimum number of edit operations (i.e., insertions, deletions, and substitutions) required to transform one sequence into another. For instance, $d(\langle a, b\rangle, \langle c, d\rangle) = 2$, where the two edit operations are substitutions (a, c) and (b, d).*

Definition 5. ***(Edit Distance Cost Function).*** *We can calculate the distance between two traces (or sequences) faster by using a modified version of the Levenshtein edit distance [30]. Let $\sigma_1, \sigma_2 \in A^*$ be two sequences of activities. The Edit Distance Cost Function $\Delta(\sigma_1, \sigma_2) \to \mathbb{N}$ is defined as the minimum number of edits (insertion or deletion of activities) required to transform σ_1 into σ_2.*

Suppose that S is a set of sequences, $\Phi(\sigma_L, S) = \min_{\sigma_M \in S} \Delta(\sigma_L, \sigma_M)$ returns the distance of the most similar sequence in S. Let $\phi_v(SN)$ be the set of all visible firing sequences in SN, and $\gamma_{SN}(\sigma)$ be an optimal alignment for sequence σ. It is possible to prove that $\delta_S(\gamma_{SN}(\sigma)) = \Phi(\sigma, \phi_v(SN))$[12].

In the context of alignment, the edit distance function can be used as a cost function δ_S for evaluating the misalignment between a log trace σ_L and a model trace σ_M. This cost function assigns a value corresponding to the number of operations required to align the two sequences. For example, $\Delta(\langle a, c, b, e, d\rangle, \langle a, b, c, a, d\rangle) = 4$ corresponds to two deletions and two insertions.

Moreover, the alignment cost of a single trace can be converted into a fitness value between 0 (poor fitness, i.e., maximal costs) and 1 (perfect fitness, i.e., zero costs) using Eq. (1) [5]. In this regard, we normalize this cost relative to the worst case, with one log move for each activity in the trace and one model move for each transition in the model's shortest path, $SPM = \min_{\sigma_M \in \phi_f}(|\sigma_M|)$. Here, the optimal alignment cost, $\delta(\gamma_{SN}(\sigma))$, can be replaced by an alternative cost (e.g., edit distance cost) to obtain a corresponding fitness value.

$$Fitness_{\text{Trace}}(\sigma_L, SN) = 1 - \frac{\delta_S(\gamma_{SN}(\sigma))}{|\sigma_L| + SPM} \tag{1}$$

Note that the overall fitness between the event log and the system net is the weighted average of single trace fitness values.

V. Method

In this section, we present the proposed conformance approximation method. An overview of our approach is shown in Fig. 2. The method begins with a preprocessing stage using hierarchical clustering techniques. Next, two methods are proposed for constructing model behaviour subsets: in-cluster frequency and in-cluster medoid methods. Finally, the alignment approximation process is explained.

A. Preprocess Event Log Using Hierarchical Clustering

In this stage, we apply agglomerative hierarchical clustering [31] on event logs. Specifically, we first partition the event log based on trace variants to get the trace variant subset Σ_{σ_v}. Then, we introduce the normalized weighted Levenshtein distance to measure the distance between these variants (see Definition 6) as a new in-cluster distance criterion. This criterion considers both frequency and control-flow information, alleviating the problem with current log selection methods mentioned in Section II. It is used to build a distance matrix, then forming a dendrogram. By cutting-off the dendrogram, we obtain the desired number of clusters. The framework is illustrated in Fig. 3.

Definition 6. ***(Normalized Weighted Levenshtein Distance).*** *Let A^* be the set of all possible sequences of activities in A, and let σ_{v1}, σ_{v2} be two trace variants $\in A^*$. The normalized weighted Levenshtein distance between σ_{v1} and σ_{v2}, where each trace variant has a frequency $f(\sigma_{v1})$ and $f(\sigma_{v2})$, is defined as Eq. (2):*

$$d_{weighted}(\sigma_{v1}, \sigma_{v2}) = \frac{f(\sigma_{v1}) \cdot f(\sigma_{v2}) \cdot d_N(\sigma_{v1}, \sigma_{v2})}{\max\{f(\sigma_{v1})^2, f(\sigma_{v2})^2\}} \tag{2}$$

where, the normalized Levenshtein distance $d_N(\sigma_{v1}, \sigma_{v2})$ is given by Eq. (3):

$$d_N(\sigma_{v1}, \sigma_{v2}) = \frac{d(\sigma_{v1}, \sigma_{v2})}{\max\{|\sigma_{v1}|, |\sigma_{v2}|\}} \tag{3}$$

Here, $d_N(\sigma_{v1}, \sigma_{v2}) = 0$ means the two traces are exactly the same, and $d_N(\sigma_{v1}, \sigma_{v2}) = 1$ means the two traces are completely different.

Definition 7. ***(Distance Matrix).*** *Let $\sigma_{v1}, \sigma_{v2}, \ldots, \sigma_{vi} \in A^*$ represent all trace variants in event log L. The matrix $D(L)$ is defined as Eq. (4):*

$$D(L) = \begin{bmatrix} 0 & d(\sigma_{v1}, \sigma_{v2}) & \cdots & d(\sigma_{v1}, \sigma_{vi}) \\ d(\sigma_{v2}, \sigma_{v1}) & 0 & \cdots & d(\sigma_{v2}, \sigma_{vi}) \\ \vdots & \vdots & \ddots & \vdots \\ d(\sigma_{vi}, \sigma_{v1}) & d(\sigma_{vi}, \sigma_{v2}) & \cdots & 0 \end{bmatrix} \tag{4}$$

where, d is the normalized weighted Levenshtein distance function.

B. Constructing Model Behaviour

In this stage, we first propose two in-cluster methods to get log behaviour subset Σ_L from the generated clusters and transform it into the model behaviour subset Σ_M. Specifically,

1) Candidate selection: After preprocessing, we obtain several clusters, each representing different behaviours within the model. The following question is how to choose the most representative traces from each cluster to construct a more effective log behaviour subset. Existing approaches in approximate conformance checking often rely on either random sampling or frequency-based selection without considering control-flow similarity, which may lead to biased or suboptimal subsets when the frequency distribution is highly imbalanced or when rare but structurally central behaviours exist. To address this, we extend the ideas of frequency-based and medoid selection by introducing two in-cluster methods — the in-cluster frequency method and the in-cluster medoid method — designed to balance efficiency and representativeness.

The in-cluster frequency method selects, from each cluster, the trace variant with the highest frequency of occurrence. This approach assumes that the most common behaviour within a cluster is also the most representative of that cluster's behaviour. Its main advantage lies in computational efficiency, as it does not require computing pairwise distances between traces. Compared to methods that sample traces uniformly at random [25], the frequency method reduces the risk of including low-relevance traces, especially in large-scale logs.

The in-cluster medoid method, in contrast, selects the trace variant that minimises the total Levenshtein distance to all other traces in the cluster, effectively identifying the "central" trace in terms of control-flow similarity. Specifically, it computes the pairwise Levenshtein distances between all traces in each cluster, then constructs a distance matrix and obtains the medoid trace (see Definition 8). This ensures that the selected trace best represents the structural characteristics of its cluster, even if it is not the most frequent. Compared to traditional frequency-only methods, the medoid approach mitigates the bias towards dominant behaviours and is more robust when clusters contain diverse but equally important behaviours.

2) Optimal-alignment: In this step, we align Σ_L with process model to construct the Σ_M, that is, we compute the optimal alignments of selected traces in the event log and finding the corresponding model traces for these alignments.

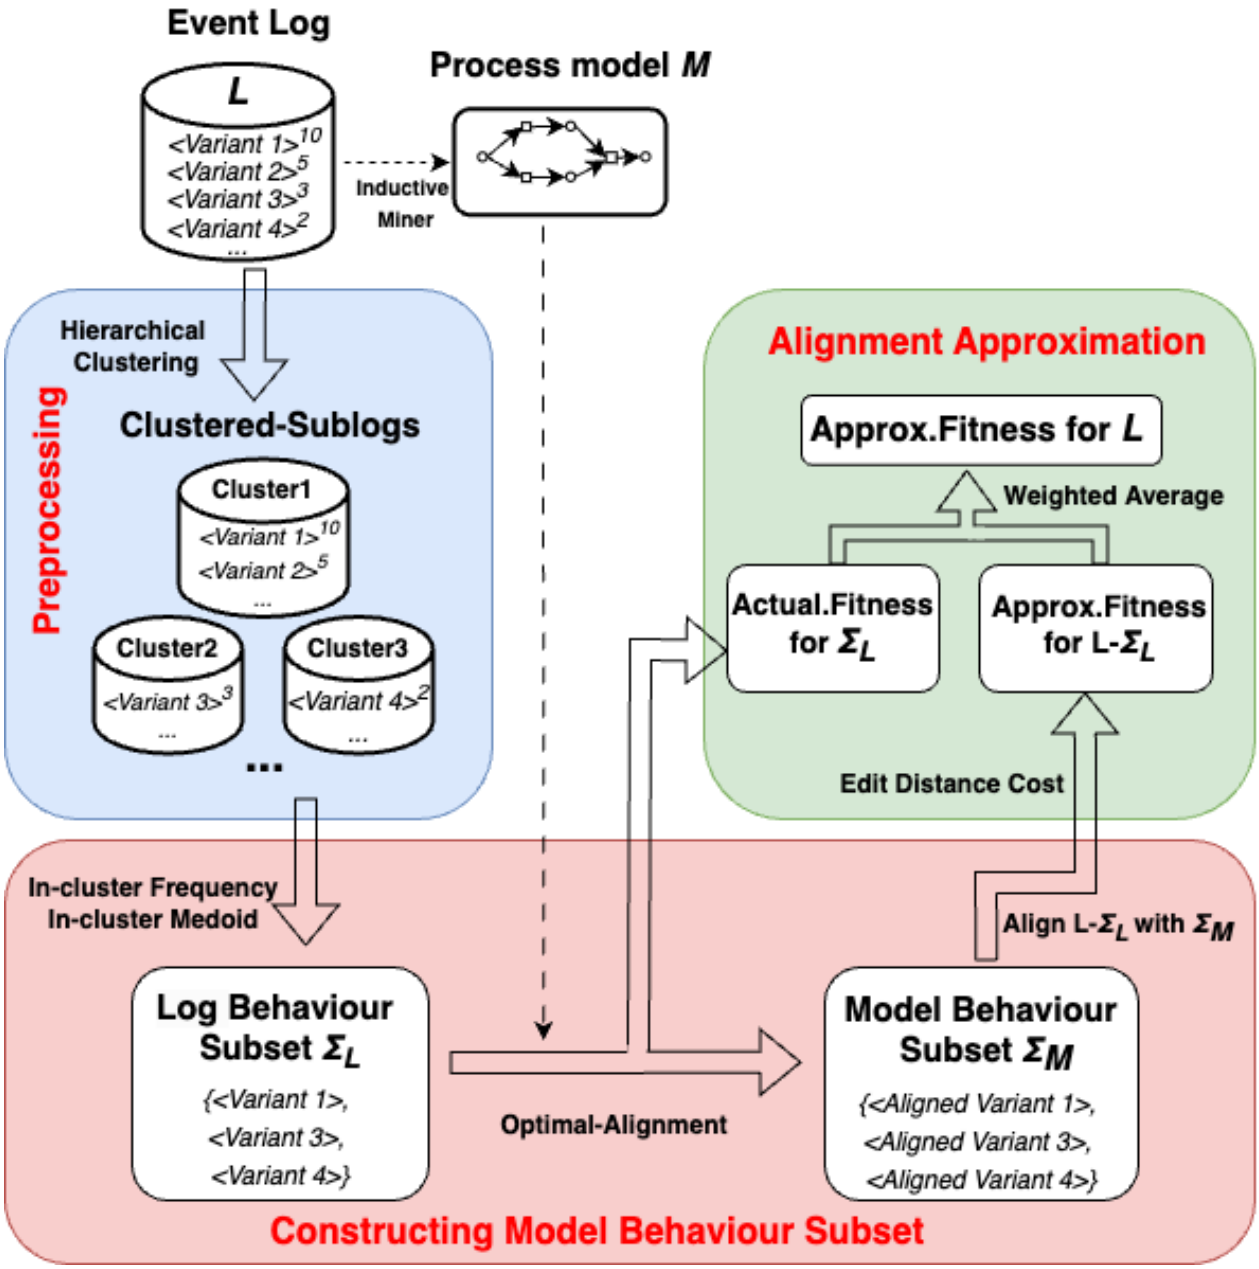

Fig. 2. Overview of our approach.

Table III shows three clusters generated from the event log in Table I. For example, applying the in-cluster frequency method to cluster 2 yields $\langle a, b, c, h\rangle^{792}$, the most frequent trace. Repeating this for each cluster, we obtain $\Sigma_L = \{\langle a, b, c, d, f, e, g, h\rangle^{1280}, \langle a, b, c, h\rangle^{792}, \langle a, h\rangle^{320}\}$. We then align Σ_L with the process model, as shown in Fig. 1, resulting in Σ_M.Note that Σ_L and Σ_M are same in this example, as all traces can be fully replayed in the model.

The specific algorithm steps for proposed methods are outlined in Algorithm 1 and Algorithm 2.

Definition 8. ***(In-cluster Medoid).*** *Let L' be a clustered sublog, n denote the number of trace variants in L', and $D(L')$ be the distance matrix of L'. The trace $\sigma_j = \arg\min_{\sigma_j \in L'} \sum_{i \in [1,n]} d(\sigma_i, \sigma_j)$ represents the medoid trace of sublog L'.*

C. Computing Alignment Approximation

After constructing M_B, we use it to approximate alignments for the traces in $L - L_C$, where L_C refers to the frequency-based trace variants used to build Σ_L. The actual alignment fitness for the variants in Σ_L has already been computed during the construction of M_B, so we can directly use this value for more accurate approximations. At this stage, we calculate the alignment approximations for the remaining variants.

Typically, the actual fitness is calculated using standard alignment costs. However, for the remaining variants, we use

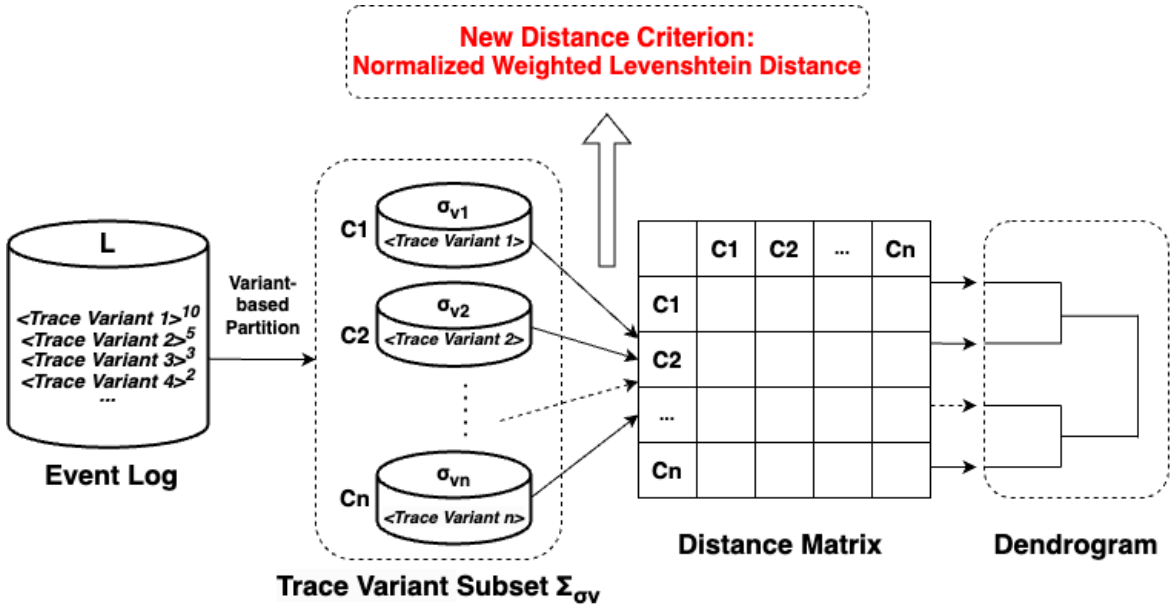

Fig. 3. Preprocessing workflow for hierarchical clustering.

TABLE III. THE CLUSTERS GENERATED FROM THE EXAMPLE LOG PROVIDED IN TABLE I

Cluster ID	Traces in each cluster
1	$\{\langle a,b,c,d,f,e,g,h\rangle^{1280}, \langle a,b,c,d,e,f,g,h\rangle^{912}, \langle a,b,c,d,e,f,g,h\rangle^{864}\}$
2	$\{\langle a,b,c,h\rangle^{792}, \langle a,b,c,d,h\rangle^{400}, \langle a,f,b,c\rangle^{96}\}$
3	$\{\langle a,h\rangle^{320}, \langle a,d,h\rangle^{250}, \langle a,c,e,f,g\rangle^{64}, \langle a,d,e,g,h\rangle^{56}, \langle a,b,f,e,g,h\rangle^{48}, \langle b,f,g\rangle^{24}\}$

Algorithm 1 In-cluster Medoid Method

Input: Event log L; Process model M.
Output: Model behaviour subset Σ_M.

Initialize log behaviour subset: $\Sigma_L \leftarrow \emptyset$
Initialize model behaviour subset: $\Sigma_M \leftarrow \emptyset$
Partition L based on variants into Σ_{σ_v}
Cluster Σ_{σ_v} into k clusters $\{\Sigma_{\sigma_{v1}}, \Sigma_{\sigma_{v2}}, \ldots, \Sigma_{\sigma_{vk}}\}$ using hierarchical clustering
for $i = 1$ to k **do**
    Compute pairwise Levenshtein distances between all variants in $\Sigma_{\sigma_{vi}}$
    Construct distance matrix $D(\Sigma_{\sigma_{vi}})$
    Find the medoid trace $\sigma_L^{(i)}$ in $\Sigma_{\sigma_{vi}}$:

$$\sigma_L^{(i)} = \arg\min_{\sigma \in \Sigma_{\sigma_{vi}}} \sum_{\sigma' \in \Sigma_{\sigma_{vi}}} d(\sigma, \sigma')$$

    Update log behaviour subset: $\Sigma_L \leftarrow \Sigma_L \cup \{\sigma_L^{(i)}\}$
end for
for each $\sigma_L^{(i)} \in \Sigma_L$ **do**
    Compute optimal alignment γ_{SN}^{opt} between $\sigma_L^{(i)}$ and M
    Map to model trace: $\sigma_M^{(i)} \leftarrow \lambda_{SN}(\sigma_L^{(i)})$
    Update model behaviour subset: $\Sigma_M \leftarrow \Sigma_M \cup \{\sigma_M^{(i)}\}$
end for
return Σ_M

Algorithm 2 In-cluster Frequency Method

Input: Event log L; Process model M.
Output: Model behaviour subset Σ_M.

Initialize log behaviour subset: $\Sigma_L \leftarrow \emptyset$
Initialize model behaviour subset: $\Sigma_M \leftarrow \emptyset$
Partition L based on variants into Σ_{σ_v}
Cluster Σ_{σ_v} into k clusters $\{\Sigma_{\sigma_{v1}}, \Sigma_{\sigma_{v2}}, \ldots, \Sigma_{\sigma_{vk}}\}$ using hierarchical clustering
for $i = 1$ to k **do**
    Let $\Sigma_{\sigma_{vi}}$ denote the i-th cluster of variants
    Find the most frequent variant $\sigma_L^{(i)}$ in $\Sigma_{\sigma_{vi}}$:

$$\sigma_L^{(i)} = \arg\max_{\sigma \in \Sigma_{\sigma_{vi}}} f(\sigma)$$

    Update log behaviour subset: $\Sigma_L \leftarrow \Sigma_L \cup \{\sigma_L^{(i)}\}$
end for
for each $\sigma_L^{(i)} \in \Sigma_L$ **do**
    Compute optimal alignment γ_{SN}^{opt} between $\sigma_L^{(i)}$ and M
    Map to model trace: $\sigma_M^{(i)} \leftarrow \lambda_{SN}(\sigma_L^{(i)})$
    Update model behaviour subset: $\Sigma_M \leftarrow \Sigma_M \cup \{\sigma_M^{(i)}\}$
end for
return Σ_M

the edit distance cost function Δ (see Definition 5) to estimate fitness. This method provides guaranteed upper and lower bounds for the alignment cost, instead of exact values [5] (see Lemma 1 and Lemma 2 below) [see Eq. (5)].

$$Fitness(L, SN) = \frac{\sum_{\sigma \in L_C} f(\sigma) \times Fitness_{\text{Approximate}}(\sigma, SN)}{\sum_{\sigma \in L} f(\sigma)} + \frac{\sum_{\sigma \in L - L_C} f(\sigma) \times Fitness_{\text{Actual}}(\sigma, SN)}{\sum_{\sigma \in L} f(\sigma)} \quad (5)$$

Lemma 1 (Alignment Cost Upper Bound)**.** *Let $\sigma_L \in \mathcal{U}_A^*$ be a log trace and $\sigma_M \in \phi_v(SN)$ be a visible firing sequence of SN. We have $\delta_S(\gamma_{SN}(\sigma_L)) \leq \Delta(\sigma_L, \sigma_M)$, where $\gamma_{SN}(\sigma_L)$ is the optimal alignment.*

Proof: The proof is provided in Appendix A and demonstrates how the edit distance guarantees this upper bound. ■

Simply put, if we align trace variant 4 $\langle a, b, c, d, h \rangle$ from Table I with σ_L from the in-cluster frequency subset in Table II, the alignment cost is 1 (i.e., removing "d"). However, since σ_M is a subset of the full model, the actual cost could be smaller or equal. Thus, we use 1 as the upper bound for this variant.

Lemma 2 (Alignment Cost Lower Bound)**.** *Let $SPM = \min_{\sigma_M \in \phi_v(SN)} |\sigma_M|$ and $LPM = \max_{\sigma_M \in \phi_v(SN)} |\sigma_M|$, representing the shortest and longest paths in the process model M. $\sigma_L\lceil_{A_v(SN)}$ and $\kappa(\sigma_L)$ are as defined in Definition 9.*

For any log trace σ_L, if $|\sigma_L\lceil_{A_v(SN)}| < SPM$, the alignment cost lower bound is $SPM - |\sigma_L\lceil_{A_v(SN)}| + \kappa(\sigma_L)$; if $|\sigma_L\lceil_{A_v(SN)}| > LPM$, the lower bound is $|\sigma_L\lceil_{A_v(SN)}| - LPM + \kappa(\sigma_L)$; if $SPM \leq |\sigma_L\lceil_{A_v(SN)}| \leq LPM$, the lower bound is $\kappa(\sigma_L)$.

Proof: The proof is provided in Appendix B. ■

The cost lower bound is the minimum edit operations needed to transform σ_L into σ_M. We refine this algorithm using activity projection (see Definition 9) to improve approximation accuracy. Existing methods compare log trace length directly with the model's range, potentially yielding errors if irrelevant activities are present. For instance, in Fig. 1, a trace $\langle a, x \rangle$ might seem aligned if its length falls within the model's shortest (SPM=2) and longest paths (LPM=8), even though x is not in the model, resulting in a miscalculated cost of 0. Our algorithm removes non-model activities (e.g., removing x from $\langle a, x \rangle$ to form $\langle a \rangle$) before comparing trace lengths. This adjustment yields a more accurate cost of 1 rather than 0, resulting in a smaller upper fitness and tighter bound width.

These bounds are then used to compute the corresponding upper and lower fitness bounds (with the cost upper bound giving the fitness lower bound, and vice versa) using Eq. (1). The computations for the fitness bounds are provided in Algorithm 3 and Algorithm 4. The average of these bounds provides the approximate fitness. Once we compute the approximate fitness for each remaining variant, we take the weighted average of these values along with the previously computed actual fitness to get the overall approximate fitness for the entire event log, as shown in Eq. (5).

Definition 9 (Activity Projection)**.** *Let $A_v(SN)$ be the set of unique observable activities in the system net SN. For any log trace σ_L, let $\sigma_L\lceil_{A_v(SN)}$ represent the projection of σ_L onto $A_v(SN)$, which means the set of activities in σ_L that also appear in the model. Define $\kappa(\sigma_L) = |\sigma_L| - |\sigma_L\lceil_{A_v(SN)}|$ as the number of activities in σ_L that are not present in the model.*

For example, let $\sigma_L = \langle a, b, x \rangle$ be a log trace and the observable activities of the system net be $A_v(SN) = \{a, b, c, d, e\}$. Projecting σ_L onto $A_v(SN)$ results in $\sigma_L\lceil_{A_v(SN)} = \langle a, b \rangle$, as x is not part of $A_v(SN)$. Therefore, $\kappa(\sigma_L) = |\sigma_L| - |\sigma_L\lceil_{A_v(SN)}| = 3 - 2 = 1$, indicating one activity in σ_L is not present in the model.

Algorithm 3 Fitness lower bound computation

Input: Event log L; Optimal-aligned Log L_C; Model behaviour subset Σ_M.
Output: Lower bound fitness $L_fitness(\sigma_L, M)$.

for each $\sigma_L \in L - L_C$ **do**
  $\Phi(\sigma_L, \Sigma_M)$ // Compute minimun edit distance cost
  $L_fitness(\sigma_L, M) \leftarrow 1 - \frac{\Phi(\sigma_L, \Sigma_M)}{|\sigma_L| + \min_{\sigma_M \in \phi_v(SN)}(|\sigma_M|)}$
end for
return $L_fitness(\sigma_L, M)$

Algorithm 4 Fitness upper bound computation

Input: Event log L; Optimal-aligned Log L_C; Model behaviour subset Σ_M.
Output: Upper bound fitness $U_fitness(\sigma_L, M)$.

$SPM \leftarrow \min_{\sigma_M \in \phi_v(SN)} |\sigma_M|$ // Shortest path
$LPM \leftarrow \max_{\sigma_M \in \phi_v(SN)} |\sigma_M|$ // Longest path
for each $\sigma_L \in L - L_C$ **do**
  Project σ_L onto SN: $\sigma_L\lceil_{A_v(SN)}$
  Compute $\kappa(\sigma_L) = |\sigma_L| - |\sigma_L\lceil_{A_v(SN)}|$
  if $|\sigma_L\lceil_{A_v(SN)}| < SPM$ **then**
    $U_fitness(\sigma_L, M) \leftarrow 1 - \frac{SPM - |\sigma_L\lceil_{A_v(SN)}| + \kappa(\sigma_L)}{|\sigma_L| + \min_{\sigma_M \in \phi_v(SN)}(|\sigma_M|)}$
  else if $|\sigma_L\lceil_{A_v(SN)}| > LPM$ **then**
    $U_fitness(\sigma_L, M) \leftarrow 1 - \frac{|\sigma_L\lceil_{A_v(SN)}| - LPM + \kappa(\sigma_L)}{|\sigma_L| + \min_{\sigma_M \in \phi_v(SN)}(|\sigma_M|)}$
  else
    $U_fitness(\sigma_L, M) \leftarrow 1 - \frac{\kappa(\sigma_L)}{|\sigma_L| + \min_{\sigma_M \in \phi_v(SN)}(|\sigma_M|)}$
  end if
end for
return $U_fitness(\sigma_L, M)$

VI. Evaluation

In this section, we assess the accuracy and time performance of our proposed log selection methods compared to frequency-based and K-Medoids techniques, and evaluate their differences in accuracy and time against normal alignment. Note that the comparison between model behaviour sampling and other approximate methods has been discussed in [5], we focus here on comparisons with the baselines of model behaviour sampling. First, we briefly describe the implementation (Section VI-A) and experimental setup (Section VI-B), followed by a discussion of the experimental results (Section VII).

A. Implementation

Our implementation consists of two steps: first, we implemented the algorithms described in Sections V-A and V-B in Python, to generate log behaviour subsets from event logs.

TABLE IV. THE REAL-LIFE EVENT LOGS USED IN THE EXPERIMENTS

Event Log	Activities #	Traces #	Variants #	Uniqueness
BPIC2012 [36]	25	13087	4366	0.33
BPIC2013-closed problems [37]	4	1487	183	0.12
BPIC2016-Questions [38]	8	21533	2261	0.10
BPIC2017 [39]	28	31509	15930	0.51
Spesis [40]	18	1050	846	0.81
RTFMP [41]	13	150370	231	0.01

Specifically, we extended the pm4py.algo.clustering package in PM4py [32] by introducing the normalized weighted Levenshtein distance (Definition 6), to perform hierarchical clustering. And implemented two proposed in-cluster methods to get the log behaviour subset based on the clustering result. In the second step, we used an existing plugin in ProM [33], *Conformance Log to Log Approximation* [34], with the generated model behaviour subset and the original event log as input, obtaining approximate fitness bounds and values. For the baselines, we used the implementation proposed by Fanisani [5]. For normal alignment, we used PM4py to compute the time and fitness values. The source code and experimental results is available on Github [1].

B. Experimental Setup

Our experiments were based on six real event logs, with basic information about these event logs given in Table IV. Here, *Uniqueness* refers to $\frac{\text{Variant\#}}{\text{Trace\#}}$. A *Uniqueness* value close to 1 indicates that almost all traces are different, e.g., *Sepsis*. For process discovery, we used *Inductive Miner infrequent algorithm* [35] with *infrequent thresholds of 0.4* to get the process model. Two log selection methods, *frequency-based sampling*, *K-Medoids clustering*, were used as baselines to compare with our proposed methods, i.e., *In-cluster frequency method* and *In-cluster medoid method*. Furthermore, we set the *selection percentage* to 10%, 20%, 30%, 40%, and 50%, representing the ratio of the selected variants to the total number of variants in the event logs. Our experiment was repeated four times since the conformance approximation time is non-deterministic. Finally, we performed the experiments on a computer with Apple M1 (8 cores), 8 GB RAM running macOS.

1) Evaluation metrics: To measure approximation accuracy, we used *Approximate Error*, defined as $ApproximateError = |ActualFitness - ApproximateFitness|$, where a value closer to 0 indicates higher accuracy. Additionally, we assess the *Bound Width* as $BoundWidth = U_fitness - L_fitness$, with a smaller width indicating tighter bounds and a more accurate approximation.

We used the *Performance Improvement* (PI) metric, defined as $PI = \frac{\textit{Actual Conformance Time}}{\textit{Approximate Conformance Time}}$ to assess time performance. *Actual Conformance Time* refers to the time needed to compute normal alignment, while *Approximate Conformance Time* includes the total time for the approximation. A PI value greater than 1 indicates the approximation is faster than the actual conformance computation. Preprocessing time (e.g., hierarchical clustering) is included in the approximate conformance time.

VII. RESULT

Table V presents the *Actual Fitness* and *Approximate Fitness*, *Approximate Error*, and *PI* for four selection methods using 20% of the variants in six event logs. For each metric in a given row, the best value is highlighted in bold. The results show that the proposed in-cluster methods achieve the highest *fitness* and the lowest *approximate error* in most cases, indicating superior accuracy compared to the baselines. In terms of *PI*, the frequency-based method consistently achieves the highest values, reflecting its shorter approximate time. Our complete experimental data is provided in Appendix B.

Fig. 4 shows that both *Approximate Error* and *Bound Width* decrease as the selection percentages increase. Here, *Bound Width* is represented by bars, and *Approximate Error* by lines, illustrating the improvements in these metrics as the selection percentage increases. Our in-cluster methods consistently achieve tighter bounds at each selection percentage. Notably, at a selection 50% in the BPIC2017 log, the bound widths of the baseline are around 0.05, while our methods reduce this by 40% to 0.03. Furthermore, in all data sets with different selection percentages, the in-cluster frequency method shows an average improvement of 19.1% in *Approximate Error* compared to the frequency-based method, while the in-cluster medoid method achieves an average improvement of 27.6% compared to the K-Medoid method. Moreover, the in-cluster frequency method often produces tighter bounds than in-cluster medoid method, especially on low *uniqueness* logs like BPIC2016-Questions, where selecting the most frequent trace is more effective than clustering. However, on high *Uniqueness* logs like *Sepsis*, in-cluster medoid method provides more accurate approximations. In Fig. 5, we compare the time performance of different log selection methods and their improvement over normal alignment. Note that a value of 1 represents the normal alignment time. Consistent with the results in Table V, the frequency method usually yields the highest performance improvement, followed by the K-Medoids method. Our methods are less efficient compared to these baselines, particularly on datasets with higher *Uniqueness* values. Table VI presents the experimental results for datasets.

VIII. DISCUSSION

Across Table V and Fig. 4, our in-cluster methods consistently achieve higher *fitness*, lower *approximate error*, and tighter bounds than the baselines, with the in-cluster frequency method performing better on low-*Uniqueness* logs

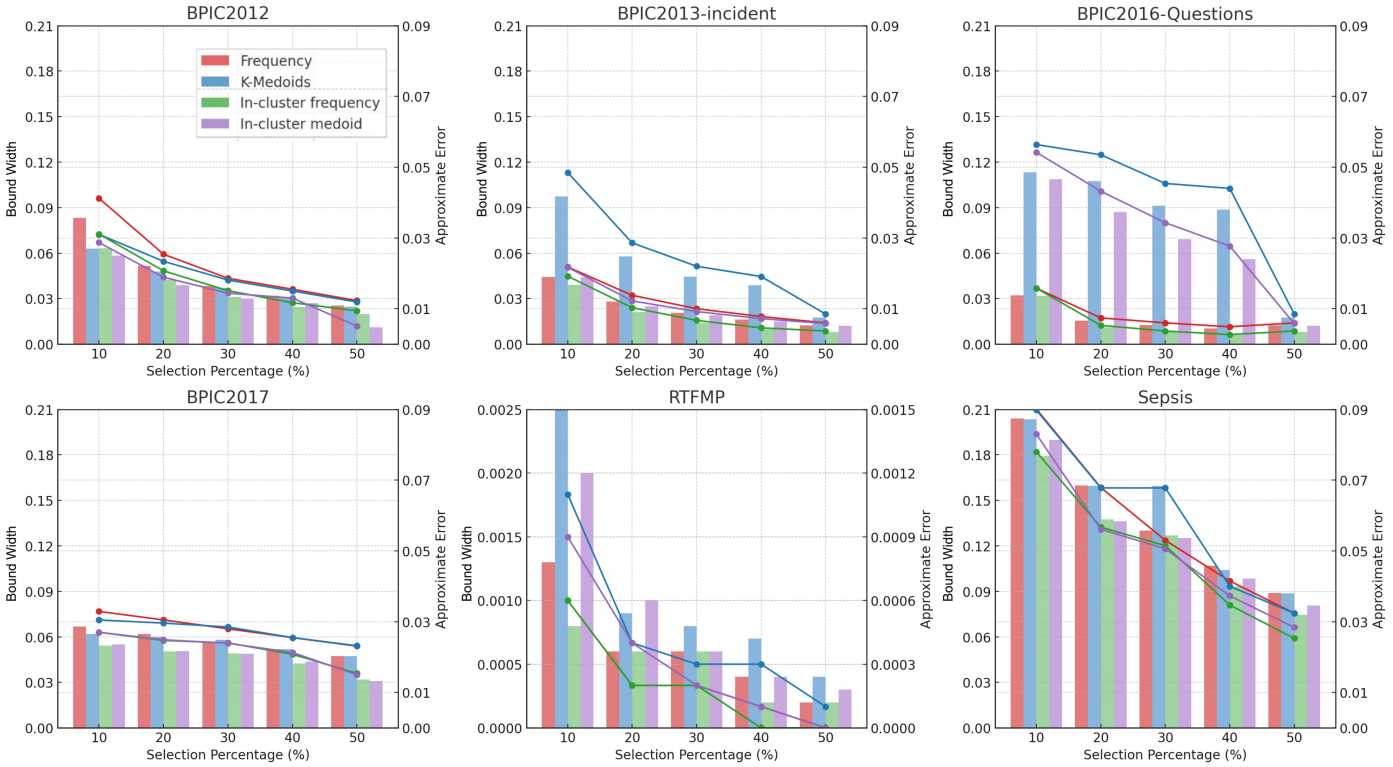

Fig. 4. The performance differences of different selection strategies on band width and approximate error.

(e.g., BPIC2016-Questions) and the in-cluster medoid method excelling on high-*Uniqueness* logs such as *Sepsis*, highlighting a key advantage of our approach over the baselines—improved approximation accuracy. Fig. 5 shows that our methods have larger approximation times. This is because hierarchical clustering requires step-by-step merging and evaluating all possible cluster combinations, which increases preprocessing time compared to baselines. Nevertheless, they remain significantly faster than the normal alignment-based approach, keeping approximation times within acceptable limits while delivering higher accuracy—making them well-suited for large-scale processes where neither a quick, coarse estimate nor weeks of exact computation is desirable. Overall, our results indicate a clear trade-off: the proposed methods bring the approximations closer to the actual values at the cost of some additional but acceptable preprocessing time.

IX. CONCLUSION

In this study, we propose an enhanced model behaviour sampling method using hierarchical clustering to construct more representative model behaviour subsets. By incorporating both frequency and control-flow information from the event log, our approach more effectively captures the model's behaviour, leading to improved approximation accuracy. Experimental results show that our method produces approximations that are on average over 19.1% closer to the actual alignment values than baseline methods, though it requires more computation time.

A potential limitation of this study is the lack of an explicit quantification of how much "increased" time would be acceptable for the "improvement" in accuracy, which is important to evaluate the practical utility of the method under different application scenarios. As a next step, we plan to conduct a systematic, quantitative analysis of the accuracy–time trade-off. Based on it, an incremental approximation tool

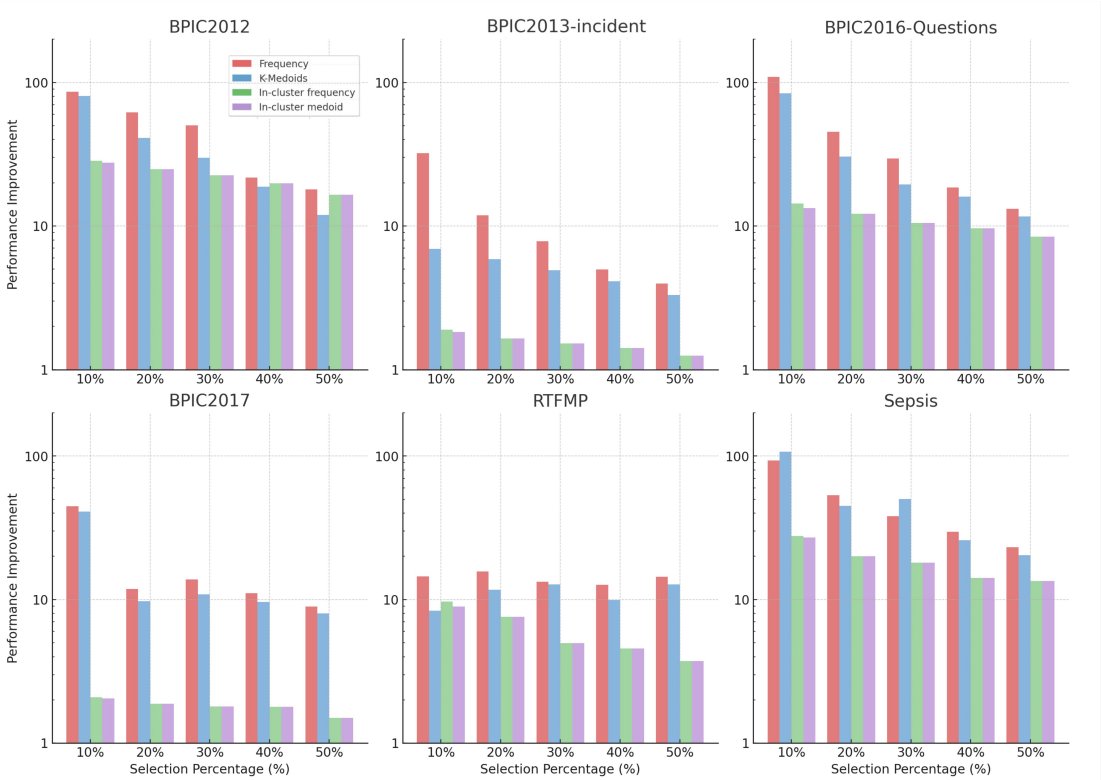

Fig. 5. The performance improvement using different methods in six event logs.

could be developed to increase the size of model behaviour during the time, allowing the user to decide when the accuracy is enough. In addition, we plan to apply a time-optimized hierarchical clustering algorithm to reduce the approximation time of our method. Furthermore, exploring how to make use of the distribution information (e.g., *Uniqueness*) in the event log to choose a better approximate method is also a direction for future research.

ACKNOWLEDGMENT

The authors would like to thank Artem Polyvyanyy for his invaluable guidance and support throughout this research project.

DECLARATION OF COMPETING INTEREST

The author declares that there are no known financial interests or personal relationships that could have influenced the research presented in this study.

APPENDIX

A. Proof of Alignment Cost Upper Bound

Proof: We have shown that $\min_{\sigma_M \in S} \Delta(\sigma_L, \sigma_M) = \delta_S(\gamma_{SN}(\sigma_L))$ in Definition 5, so $\Delta(\sigma_L, \sigma_M) \geq \delta_S(\gamma_{SN}(\sigma_L))$. Therefore, if $\delta_S(\gamma_{SN}(\sigma_L)) > \Delta(\sigma_L, \sigma_M)$, $\gamma_{SN}(\sigma_L)$ is not an optimal alignment. Consequently, for any $M_B \subseteq \phi_v(SN)$, $\Phi(\sigma_L, M_B)$ returns an upper bound for the cost of optimal alignment [5]. ■

B. Proof of Alignment Cost Lower Bound

Proof: When $|\sigma_L\lceil_{A_v(SN)}| < SPM$, at least $SPM - |\sigma_L\lceil_{A_v(SN)}|$ insertions are needed. Adding the initial alignment cost, the total minimum alignment cost is $|SPM - \sigma_L\lceil_{A_v(SN)}| + |\kappa(\sigma_L)|$. Similarly, when $|\sigma_L\lceil_{A_v(SN)}| > LPM$, at least $|\sigma_L\lceil_{A_v(SN)}| - LPM$ deletions are required. Thus, the total alignment cost is $|\sigma_L\lceil_{A_v(SN)} - LPM| + |\kappa(\sigma_L)|$. When $SPM \leq |\sigma_L\lceil_{A_v(SN)}| \leq LPM$, no insertions or deletions are needed, so the alignment cost is $|\kappa(\sigma_L)|$. ■

Enhancing Cyber Security Through Predictive Analytics: Real-Time Threat Detection and Response

Muhammad Danish
Department of Computer Science, University of New Mexico, Albuquerque, New Mexico - 87106

***Abstract*—This study evaluates the application of predictive analytics for real-time cyber-attack detection and response, focusing on how statistical and machine learning methods can improve decision-making in Security Operations Centers (SOCs). Using a curated network-traffic dataset of 2,000 records, we analyzed key features such as attack type, packet length, anomaly scores, protocol usage, and geo-location patterns to assess their predictive value. Findings indicate that attack type has a measurable influence on response actions, while basic header metrics alone lack the precision needed for accurate classification. These results highlight the importance of incorporating richer contextual features—such as user behavior, asset criticality, and temporal patterns—into predictive models. By integrating such features into operational pipelines, organizations can improve early threat detection, reduce false positives, and optimize resource allocation. This research contributes actionable insights for advancing proactive, data-driven cyber defense strategies and outlines directions for future implementation in live SOC environments.**

***Keywords*—Predictive analytics; real-time cyber-attack detection; statistical methods; machine learning; threat detection**

I. Introduction

Over the past half-century, the Information and Communication Technology (ICT) industry has evolved into the backbone of modern society. This rapid and pervasive digital integration underscores the critical importance of cyber security, a field dedicated to protecting ICT systems from unauthorized access, disruption, and exploitation. Effective cyber security encompasses network, application, and operational security measures such as antivirus software, firewalls, and intrusion detection systems (IDS) that collectively combat threats like malware, phishing, and unauthorized access. However, despite these extensive measures, significant vulnerabilities remain, especially concerning the timely detection and response to evolving cyber threats. Notably, the integration of predictive analytics within real-world cyber security frameworks remains underexplored in current literature.

Risk assessment in cyber security has progressively shifted from reactive, remedial methods to proactive, preventive strategies. Predictive analytics, through sophisticated statistical and machine learning techniques, enables organizations to anticipate and mitigate potential threats before they materialize [1]. This proactive approach not only enhances the timeliness and effectiveness of threat response but also optimizes resource allocation and decision-making. Essential components of effective predictive analytics include high-quality, timely data and robust threat intelligence to ensure the models remain accurate and relevant. Consequently, an increasing number of organizations have begun incorporating predictive analytics into their cyber defense strategies, recognizing its potential to preemptively neutralize complex cyber threats and significantly improve their security posture [2].

Despite advancements, contemporary real-time cyber-attack detection systems continue to exhibit several critical shortcomings. Most current solutions are inherently reactive, relying heavily on predefined signatures to identify threats. This dependence severely limits their effectiveness against zero-day attacks—attacks exploiting previously unknown vulnerabilities—which remain undetected until the damage has occurred. Additionally, high false positive rates constitute another major challenge, generating numerous irrelevant alerts that strain resources and diminish the effectiveness of security teams [3]. Scalability poses an additional challenge as organizations grow and network architectures become increasingly complex; traditional detection systems often fail to efficiently monitor all potential points of vulnerability, leading to gaps in threat detection [4].

The integration of big data analytics into cyber security practices is thus both crucial and challenging. Predictive analytics offers the transformative potential to transition cyber security from a predominantly reactive discipline into a fully proactive field capable of anticipating and mitigating threats in real-time. However, successful implementation involves considerable investment in data collection, storage, model development, training, and continuous refinement to accommodate new emerging threats [5]. Therefore, addressing these inherent limitations in real-time cyber-attack detection—specifically passiveness, false alarms, and scalability—requires the accelerated advancement and redesign of both current and future cyber security technologies.

This study seeks to answer critical questions: How effectively does predictive analytics identify and respond to diverse cyber threats in real-time? What subtle patterns and anomalies do predictive models detect that conventional security measures routinely overlook? Lastly, how can predictive analytics enhance decision-making within cyber security operations centers (SOCs)? By providing empirical evidence addressing these questions, this research aims to fill existing gaps in the literature, highlighting the practical benefits and operational implications of adopting predictive analytics.

The core objectives of this study include assessing predictive analytics' effectiveness in real-time threat detection and response, identifying key patterns and anomalies detectable by predictive models, and proposing a model that enhances decision-making within SOCs. The potential implications of this research are substantial when viewed through the lens of current and future cyber security landscapes. By enhancing threat detection, reducing false positives, and improving scalability, predictive analytics presents a paradigm shift

from reactive to proactive security management, significantly strengthening overall organizational defense [6].

Moreover, this research emphasizes efficient resource utilization in cyber security contexts. By reducing false positives and prioritizing alerts based on predictive insights, security personnel can focus more effectively on genuine threats, thereby optimizing organizational resources. Aligning predictive analytics with broader organizational risk management strategies ensures more realistic threat assessments and better compliance with regulatory frameworks. Ultimately, this research contributes significantly to the strategic integration of advanced technologies into business planning, crisis management, and regulatory compliance efforts, thereby setting new standards in cyber security practice and fortifying stakeholder trust in an increasingly interconnected digital world [7].

This paper is organized as follows. Section II surveys prior work on predictive analytics for cyber security and highlights open gaps in real-time detection and response. Section III details the study design, including dataset selection and preprocessing, feature engineering, modeling choices, evaluation metrics, and the simulation setup used to compare predictive and baseline approaches. Section IV presents the empirical results—descriptive statistics, correlation patterns, protocol–attack crosstabulation, regression analyses of response actions, and hypothesis tests comparing signature groups. Section V interprets these findings in the context of the state of the art, explains performance differences across data regimes, and discusses operational implications for Security Operations Centers (SOCs). Section VI concludes by summarizing contributions, limitations, and avenues for future work, including the integration of richer contextual features and adaptive learning.

II. Literature Review

Analytics in the context of cyber security is a highly advanced concept that adjusts security practice from the reactive to proactive model. This approach incorporates the use of several statistical and machine learning models to examine the enormous volumes of data from sources such as network traffic, user activities, and security logs to develop an elaborate system that would alarm an early sign of a threat. Predictive analytics give signals and alerts of risk to organizations before they turn into actual breaches. Indeed, the definition and usage of predictive analytics have changed over time in the context of cyber security due to the advancements in data science and artificial intelligence. Initially, the field was limited to basic data monitoring and detection of anomalies; today, it incorporates highly developed algorithms and refers to such advanced techniques as predictive threat modeling and risk assessment [8]. This change marks an evolution from conventional or traditional security methods like firewalls and antivirus software, moving towards intelligence-driven security.

The fundamental principles of predictive analytics in cyber security hinge on several core elements including poor data quality, inefficiency in the algorithms used, and lack of timely threat intelligence. Viable predictive systems also require first-rate and pertinent data to educate the models that are used in the prediction and provision of attack prevention. Furthermore, incorporating real-time threat intelligence means the models remain accurate on the present threat vectors. The integration of big data analytics in security operations improves not only threat detection effectiveness, but also the organization's agility. Therefore, security teams can prioritize and spend resources effectively, thereby lessening the bloodbath that comes with cyber threats and enhancing the organizations' security stance. In addition, predictive analytics fosters compliance with laws by providing proof that the organization is actively pursuing security measures, which is helpful to industries dealing with high levels of data protection laws [9]. Such an approach relying on predictive analytics is becoming indispensable in the context of the constantly changing nature of cyber threats that become more complex and that cannot be addressed using conventional methods.

New technologies that exist in the detection of cyber-attacks have advanced to the integration of artificial intelligence (AI) and its subsection: machine learning (ML). AI and ML in cyber security mean the ability to automatically perform the detection and response to threats which are analyzed from huge datasets relevant to identify patterns that may point to threats [10]. These technologies are useful when identifying indicators of compromises that may not be easily identified by analysts entirely because of the huge volume and the complexity of data that has to be scanned. Machine learning algorithms, both supervised and unsupervised learning models, are extremely useful in such cases. Supervised learning models are trained on labeled datasets to differentiate between benign and malicious activity. Unsupervised learning is to find the outliers within the system without having any labeled data, which helps in the identification of new and unknown threats. AI improves threat identification because data is processed and analyzed far beyond the human capacity and rate. It automates the responses to the threats, thus taking a short time to counter the threats once they have been identified [11]. AI-powered systems also include predictive analytical components that assess threat trends or patterns to predict future threats, hence improving the threat-hunting process [12].

AI and ML play a big role in lowering the false positives in threats. They enhance the process of filtering fakes and distinguishing between real and potential threats as well as distinguishing them by understanding the degree of difference between unusual behavior and deliberate malicious actions, taking care of prioritization of threats and thus, decreasing the amount of work security teams have to do. However, implementing AI into cyber security has its own set of challenges including the quality of data required for preparing algorithms, the transparency of AI decision-making, and the integration of AI systems into the current infrastructure of cyber security systems. However, the threat in the cyberspace domain is not stagnant, and hence the AI models must be updated on a regular basis [13].

The position of AI and ML in the context of cyber-attack detection is rather important and provides not only better detection mechanisms but also the proper and timely handling of cyber security threats in a world where digital threats are frequently evolving. AI and ML are reshaping the sphere of cyber security; they allow for detecting threats quickly, and often on a large scale, as well as making predictions. These technologies help to automatically detect and counter cyber threats increasing the security responsiveness of the

organization. It is, however, crucial to address some important issues that relate to the handling of data quality and the ability of the models to change, when integrated into existing systems in order to effectively cope with constantly emerging forms of cyber threats [14].

Modern cyber security processes are accompanied by many difficulties that hinder its operations including the issues of false positives, scalability, and the identification of previously unknown vulnerabilities [15].

1) False positives: One major issue particular to cyber security is the problem of false positives, which is an alarm that a threat exists although it does not. This results in more resource wastage since security analysts have to go through these alerts to verify them and determine if they are actually a threat. The issue is further compounded by the fluidity and heterogeneity of today's networks characterized by typical activity patterns that are easily mistaken for threats by security solutions [16].

2) Scalability issues: Due to the growth of organizations and the associated expansion of the networks, at some point, implemented cyber security measures may take a hit. This is because the scalability problems are evident from the amount and the number of endpoints that should be monitored and analyzed by such systems. It has the characteristic of providing the areas of weakness and slow response to real threats in such a case [17].

3) Zero-day vulnerabilities: Perhaps the most daunting challenge is the detection and management of zero-day vulnerabilities which are flaws in software that the software maker does not know about and for which no patch exists at the time of discovery. These vulnerabilities are highly valuable to attackers because they can be exploited to gain unauthorized access to systems before they are identified and mitigated. The very nature of zero-day attacks makes them difficult to predict and detect using conventional methods that rely on known signatures or patterns. Security systems often require updates to their threat intelligence to handle such vulnerabilities, but even then, the rapid pace at which new zero-days are discovered leaves organizations at constant risk [18].

Addressing these challenges requires a multifaceted approach involving enhanced detection algorithms that reduce false positives, scalable security solutions that can grow with the organization, and proactive threat hunting that can detect anomalies indicative of zero-day exploits. One direction is the integration of the latest developments in the field of big data and machine learning into cyber security practices, as these can help analyze patterns, envision risks and attacks, and respond to them automatically to enhance organizational security [19].

Predictive analytics in cyber security incorporates various sophisticated models and techniques to predict and mitigate potential threats before they can impact systems. The core of this approach is based on the use of machine learning algorithms with a variety of supervised and unsupervised learning algorithms [20]. In the supervised learning model, specific data is used to train in order to identify known illicit behaviors. On the other hand, unsupervised learning identifies and recognizes abnormal behaviors which if exist may be an indication of a threat. The ability of a system to detect suspicious activities is essential for timely prevention of threats and strengthening of the security status of any firm. One more important component of the environment of predictive analytics is the usage of statistical algorithms. These algorithms are able to compile data used to foresee future incidents by comprehending past trends and behaviors. Besides this method contributes not only to the prediction of possible threats but also to the development of a more accurate representation of risks that can be useful for better preparation in organizations. User behavior analysis adds more value to predictive analytics because it investigates user activities to identify suspicious events that might be originating from inside threats or stolen credentials. In this method, the basic security measures may not easily detect the anomalies. Furthermore, anomaly detection systems are used to identify the levels of deviance from the normal behavioral patterns concerning the network traffic and access log prior to the times of the actual attack [21].

Despite the advantages like early threat identification, better resource management, and faster response to threats, predictive analytics also face challenges in real-world applications. Forecasting models are only as good as the data that they are applied to; this is a saying often used in statistics. Lack of quality and/or scope can produce erroneous predictions, while the nature of the cyber threats is continuously evolving requiring constant updates of the models. Sustaining and periodically updating its application is necessary to maintain its effectiveness. Further, incorporating predictive analytics into other infrastructures that are already existent in cyber security can prove to be challenging and time-consuming and may take considerable time with regular monitoring to overcome the possible ethical risks and privacy issues that may come with their implementation. Cyber security is already underway due to third-generation predictive analytics that are proactive instead of reactive. However, this success depends on very rigid execution, constant modifications, and comprehensive data management in order to counter the continuously emerging threats in cyberspace [22].

In the context of cyber security within organizations, there is a clear differentiation between reactive and predictive systems:

- Reactive Systems: Such systems mainly target threats as they emerge and hence primarily involve treatment. The reactive approach will sit back and wait for the attack and this poses a disadvantage because reacting to such threats will take a long time. This method bases its operations on previous knowledge and, in a way, is ill-equipped to deal with threats since it directly targets the known types of attacks and may not be very efficient with the novel attack vectors that are not typical of the previous cases. While reactive systems are badly needed to cope with a threat immediately, they are less complicated to design, yet they may be more costly in the long run since the system's damage incurred during detection delays can amount to much [23].
- Predictive Systems: Whereas, predictive systems use techniques in analytical processing such as machine language and statistics to avoid predictions of a certain pernicious occurrence of an event. Besides, as this

approach focuses on analyzing patterns and trends from large amounts of data for planning future actions, it helps organizations to allocate resources effectively and repel attacks promptly. Risk predictive systems greatly improve an organization's capacity to contain and prevent Cyber risk by giving insights into potential risks. Nevertheless, they rely on high-quality and detailed data for their operation, and they have their challenges concerning the constant training of the models and the connection to the existing security systems [24].

Research and implementations have established that supervised systems can significantly decrease the threat's time and cost effects by mitigating them before they occur [25]. Organizations that integrate predictive analytics into their cyber security strategies often experience improved risk management, reduced incident response times, and enhanced compliance with regulatory requirements. The proactive approach, instead of reactive methodologies, not only helps in safeguarding against imminent threats but also prepares organizations against emerging cyber threats by constantly updating defense mechanisms in alignment with the evolving digital landscape [26].

While reactive cyber security is necessary for dealing with immediate threats, the integration of predictive analytics into cyber security frameworks provides a more robust defense by preventing attacks before they occur. This shift from a purely reactive to a proactive stance is increasingly regarded as essential in a world where cyber threats are becoming more complicated and pervasive [27].

The current body of research in cyber security predictive analytics is expansive and rich with theoretical developments and proposed models. However, a significant gap remains in the literature concerning the practical integration of these advanced predictive models into real-world cyber security frameworks. Despite the fact that such models can serve as good references, it has to be noted that it's one thing to prove a strategy or a model effective in an academic environment or at least in a simulation, and quite another to observe its effectiveness in realistic, dynamic cyber security settings [28].

This lack of correspondence is a strong indication that although there is rich theoretical research for these models, the lack of actual empirical data as well as actual planning with the models, having to integrate them with operational concerns and then scaling up the overall system, presents a huge gap that has not been well covered in the literature. Most of the current research works are majorly centered around the improvement of the existing algorithms to be implemented but minimal on how these algorithms can actually be deployed to work in real-world applications which entail factors such as hardware constraints, real-time constraints, and how they can fit in the existing infrastructure of a system to secure it.

More efforts are still required to conduct studies linking the state-of-the-art predictive analytics methods and the real-world cyber security operations, including design features that allow solutions to be easily implemented in active technical environments with minimal modifications. Overcoming this gap is a relevant and necessary step in the development of modern cyber security work, as well as in the practice of transferring theoretical achievements into concrete improvement of the methods for detecting and responding to cyber threats [29].

III. Methodology

Quantitative research was used to conduct the study with the aim of understanding the use and outcomes of enhanced predictive modeling in real-time CTR. This method is appropriate for this research study because it permits strength and significance testing of the hypothesis of the functionality and the results of the predictive analytics in the cyber security frameworks [30]. The strategy that is proposed here is a systematic experimental method through which all the researchers will deploy specified predictive models in a realistic IT security environment that mimics the actual setting in organizations. This environment will have factors such as network traffic flows, users' behavior data set, and normalcy of the cyber threat scenarios to evaluate the models on how well they work in recognizing cyber threats.

The main objective is to evaluate the effectiveness of these predictive models with reference to the conventional firewalls or reactive security measures in terms of rate of occurrence of threats, rate of detection, and flexibility of the measures in handling new types of threats. Sources of data for this study will be data sets from the open source, plus newly generated data sets to represent new and upcoming cyber security threats. It includes the application of inter-model combinations with the aim of bringing out various scenarios and attack vectors that realistically test the capability of the predictive models. This is of extreme significance since it allows competence validation of the models in the presence of heteroscedasticity. Measurable factors including the detection rate of threats, false positives and negatives of the system, and response time of the system will also be included [31].

For analytical data, the study will use techniques like regression analysis to determine the connection between the systems' responses and the success of threat countermeasures. Specific measures that are used regularly in machine learning will be used in measuring the accuracy of the predictions within the predictive models; some of these are precision, recall, and the F1- score. There could be a sub-analysis with the help of statistical tools like logistic regression or ROC Curve Analysis to see other significant differences between predictive and reactive systems. It will support the theoretical potential of predictive analytics with quantitative data, and for this reason, this research design has been adopted. Thus, the present work endeavors to complement the literature by providing actionable knowledge regarding how these models can be employed effectively, given the fact the comparison was performed in a purposefully controlled academic environment. This is important for the progression of cyber security as well as the creation of stronger, preventative defense strategies against cyber warfare [32].

As has been highlighted, the essence of this study is to analyze the importance of predictive analytics and its models in the cyber security domain accurately; therefore, the selection and collection of high-quality data is vital. Variety ensures that the database acquired by the study is all-inclusive hence the use of data elicited from Kaggle, a platform that offers a wide array of datasets by users from all over the world. This

platform provides massive and diverse data with regard to the cyber threat scenarios which is very useful for this research [33].

To start with, the selection of a dataset on Kaggle that is related to security threats is made. The chosen dataset consists of over 4,000 records wherein each record corresponds to one instance of network traffic or log data that could be related to a cyber security threat. This dataset, thus, was chosen as complex and up-to-date, so that the results of the study reflect today's security threats. Every row in the dataset contains features including source IP address, packet length, destination IP address, date and time of the data, the type of traffic, and threat bit. These attributes are important because they feed the raw data into learning systems and into the testing. This way, the normal and anomalous patterns are present in the data set, and the former provides the latter with the variety it needs to be exposed to a spectrum of data before it can construct an appropriate and reliable automatic guard [34].

In this paper, the data cleaning process forms a critical step before data feeds can be given to the model development and analysis. This phase concerns dealing with missing values, removing duplicate records, and converting categorical data into a form that is understandable to the machine. Due to the large and diversified data set, there is also a focus on the normalization methods of data, where scaling of features is performed to enhance the performance of the learning algorithms [35]. For training and validation of the developed predictive models, the dataset is partitioned into training, validation, and test partitions. Most of the time, the data split is organized so that the training dataset is the largest, constituting about 70 percent, while the validation and test datasets are about 15 percent each. This segmentation makes it possible to train the models to their fullest potential while also giving a sound basis for a decision of the model's parameters or the examination of the final model performance compared to the performance on unseen data [36].

Since the data collected may contain confidential details of an individual or a group, all relevant measures are ensured to conceal the identity of the subject/person. The research follows guidelines concerning the use of data, and measures being taken in order to avoid the abuse of information. The Kaggle data utilized in the study ensures that the authors were bound to adhere to the Kaggle data usage policies that are in harmony with general data protection regulations and ethical considerations. Now that we have a clear understanding of the dataset and how it should be prepared, several techniques can be used in predictive analysis, including decision trees, logistic regression, and neural networks. Some of these techniques are adopted due to their efficiency in dealing with big data while others are chosen due to efficiency in performing classification problems in cyber security. The performance of these models is checked from time to time on the validation set with a view to ensuring that the model's performance is checked, adjusted, and optimized before the final check on the test set.

In this particular study, SPSS software support is crucial in the data processing retrieved from Kaggle to determine the efficiency of the predictive analytics models of cyber security [37]. This section presents a clear approach to the statistical analysis using SPSS which includes data handling, analysis methods, and results. For data to be exported into SPSS, it needs to undergo certain preparations so that its analysis is accurate and meets the standards. This entails data cleansing, which entails the elimination of unwanted data such as inconsistent records or flawed records that may distort the results. Other techniques of data transformation are also utilized to transform the categorical data into some numerical formats that are more convenient for analysis purposes whereby, one and the same method of encoding may or may not be appropriate depending on the specifics of the given algorithms in the course of the predictive modeling as it is illustrated in study [38].

Descriptive analysis prepares the statistical inclination of data analysis before going for intricate analytical examinations of the data distribution, mean, and spread. In SPSS, these basic measures can be obtained by using the descriptive menu and these include mean, median, mode, range, variance, and standard deviation. This step is critical to help manage data and look for any outliers or similar points that need further data munging or normalization [39]. To drive theories at the beginning of the study, inferential statistical analysis methods are used to assess hypotheses. Based on the kind of research questions and hypotheses, a set of tests that involves t-tests, ANOVA, and chi-squared tests amongst others are carried out just to test the differences and associations between the set variables in the collected data.

Regarding understanding how the distinct factors predict threat identification and the effectiveness of mitigation in cyber security, regression analysis is applied. Continuous dependent variables were analyzed using linear regression, whereas binary dependent variables were analyzed using logistic regression. For this reason, the key analysis method which is employed in this study is logistic regression analysis skills as the response variable is categorical and may include threats detected or not detected. It includes the identification of possible predictor variables grounded on given conceptual knowledge and prior literature review, checking for multicollinearity, and model fine-tuning in regard to complexity/detail and accuracy of prediction [40].

To establish the goodness of fit for models, several tests are run on SPSS and Anker including R squared test for linear regression models and Hosmer–Lemeshow chi-squaredd test for logistic models. Among them, some measures reflect the degree to which the model explains the variation in the response variable, and one measure assesses the overall fit of the model. Furthermore, using their p-values, the level of significance of individual predictors is assessed, with the prevailing popular level of significance level being 0.05 [41].

If the cyber security data provided is rather large, which is often the case with cyber security data due to the nature of threats and attacks, further analysis may involve more sophisticated methods, for instance, cluster analysis or principal component analysis (PCA) to find other underlying patterns within data or data dimensionality reduction. They are useful in the identification of underlying relationships that often would not be easily detected through regression models. Various parameters such as mean absolute error, root mean square error, correlation coefficient, and coefficient of variation are used to judge the models and improve their efficiency.

The k-fold cross-validation technique is used in which the data set is divided into k subsets, which are then used to create

multiple train and test sets for the model. The performance of the trained predictive models is tested using accuracy related to measures such as the area under the curve, sensitivity (true positive value), and specificity (true negative value) since these values are important in evaluating the efficiency of the predictive analytics systems in an operational environment with cyber security threats [42].

The final phase encompasses the extraction and interpretation of meaningful insights that would affect cyber security practices. On its own, SPSS offers complete output that comes with estimates of coefficients (B), odds ratios, and confidence intervals that are valuable in arriving at conclusions regarding the effects of various predictors. These results are then discussed in relation to the existing body of knowledge within the cyber security domain and present generalizable findings, research limitations, and future studies' implications [43]. Through meticulous data analysis using SPSS, this study aims to contribute significantly to the field by providing empirical evidence to support the hypothesis. The structured approach ensures that the findings are robust, reproducible, and relevant to enhancing cyber security measures in various organizational contexts [44].

Several statistical and practical considerations underpin the selection of a sample size of 2000 rows for this study on predictive analytics in cybersecurity, ensuring that the analysis is both reliable and generalizable. One of the primary reasons for choosing this particular sample size is to achieve sufficient statistical power. In quantitative research, power is the probability that the study will detect an effect when there is an effect to be detected [45]. A larger sample size reduces the risk of Type II errors (failing to reject a false null hypothesis) and increases the likelihood that the study can detect a smaller effect size, making the findings more robust and persuasive.

Cyber security data encompasses a wide variety of features, from IP addresses and timestamps to types of attacks and their outcomes. A substantial sample size ensures that the dataset contains a comprehensive range of these features, including less common but potentially significant occurrences. This diversity is important for developing accurate models that can extrapolate well from existing to new data sets rather than training the model on existing data and having it perform comic replication of these data [46].

When conducting research, the dataset is designed to contain a broad spectrum of problem cases, and therefore having 2000 rows allows for problems with more complexity to be captured in the result [47]. The representativeness is crucial as it influences the external reliability and applicability of the study results in other settings or subpopulations of the cyber security domain, especially in real world applications.

There is always a potential in machine learning, especially when working in a relatively new and rapidly developing branch such as cyber security, to over-train the model, that is, to achieve good results only on the basis of the training set but get low scores on a new dataset [48]. This risk is less of a concern for larger sample sizes because that way the researcher has enough data to train even more complicated. On the other hand, it avoids under-fitting whereby the model used is not sufficient in complexity to fit the pattern of the data applied and thus ensures that the predictive models developed are complex. Having larger datasets could yield even more confident information and conclusions, but at the same time, this means more computational power is needed, and managing and dealing with more and more complicated data may become an issue. A dataset of 2000 rows strikes a balance between comprehensiveness and manageability, allowing for detailed analysis without overwhelming the computational and analytical resources available for the study [49].

The chosen sample size of 2000 rows from the original dataset is justified based on its ability to provide sufficient statistical power, represent the diverse and complex nature of cyber security threats, ensure the representativeness of the findings, balance the risks of overfitting and underfitting, and remain feasible for comprehensive analysis within the resource constraints of this study [50]. This sample size is pivotal in achieving the research objectives while ensuring the validity and reliability of the results [51].

To demonstrate practical gains over established methods, we compare the proposed pipeline against three baselines: (1) a signature-based IDS surrogate using known attack signatures; (2) a logistic-regression classifier trained on the same features; and (3) an unsupervised Isolation Forest tuned to a target anomaly rate. We use a pre-registered, time-based split (train on weeks 1–3, test on week 4) to emulate deployment and prevent temporal leakage; hyperparameters are selected via nested cross-validation on the training period only. Evaluation centers on AUPRC (primary) and AUROC, plus F1 at an operating point yielding 10% alert rate and ΔFPR at fixed recall. We compute bootstrap 95% CIs and apply McNemar tests for paired significance, and we include robustness checks (±10% label-noise injection; class-imbalance stress at 1:10 and 1:50) along with an ablation removing contextual features. Results are visualized with ROC/PR curves and calibration plots, and we summarize operational impact via estimated alerts per analyst-hour and MTTR deltas, making the simulation directly convincing for SOC workflows.

IV. Results

A. Descriptive Analysis

Table I summarizes key network and security variables. We observe a broad port range (Source: 1031–65521; Dest.: 1030–65535), reflecting diverse endpoint activity. Packet lengths span 64–1500 bytes (mean = 787.9, SD = 411.1), consistent with typical network flows. Protocol usage clusters around the three categories (mean = 1.99, SD = 0.82), indicating balanced ICMP/TCP/UDP representation. The anomaly score distribution (0.06–99.99; mean = 49.83, SD = 28.85) reveals substantial variability, essential for distinguishing benign vs. malicious behavior. Constant flags for Malware Indicators, Alerts, and Firewall/IDS logs (SD = 0) reflect uniform logging protocols. Variability in User Information (mean = 10.98, SD = 5.50) and Device Information (mean = 1.76, SD = 0.83) underscores diverse user–device contexts, while the spread in Geo-location Data (mean = 4.50, SD = 2.29) highlights global traffic sources. This heterogeneity across features is critical for training robust predictive models [52].

TABLE I. DESCRIPTIVE STATISTICS FOR NETWORK TRAFFIC AND SECURITY EVENT VARIABLES

Variable	Min	Max	Mean	Std. Dev
Source Port	1031	65521	32448.31	18701.17

B. Correlation Analysis

Pearson correlations (Tables II–IV) reveal only a few significant associations among continuous features. Source Port and Protocol are mildly inversely related ($r = -0.045$, $p < 0.05$), suggesting that certain port ranges lean toward specific protocols. Traffic Type and Packet Type correlate positively ($r = 0.054$, $p < 0.05$), indicating that traffic categories tend to carry particular packet formats. A strong negative link between Geo-location and Device Information ($r = -0.508$, $p < 0.01$) points to geographic diversity of device profiles. Attack Type and Attack Signature are also significantly associated ($r = -0.282$, $p < 0.01$), confirming that different attack classes exhibit distinct signature patterns. All other pairwise correlations fall below $|r| = 0.05$ or are non-significant, implying relative independence among most features. These results guide us to focus on the few linked variables while treating most features as orthogonal inputs in our predictive framework [53]–[55].

C. Protocol vs. Attack Type Crosstabulation

Table V shows that each protocol (ICMP, TCP, UDP) carries roughly one-third of the total events, and within each protocol the three attack types occur in nearly equal proportions: ICMP has 32.5 % DDoS, 34.7 % Intrusion, and 32.8 % Malware; TCP has 34.1 % DDoS, 32.9 % Intrusion, and 33.0 % Malware; UDP has 34.1 % DDoS, 32.6 % Intrusion, and 33.3 % Malware. A chi-square test confirms no significant association between protocol and attack category ($X^2(4) = 0.903, p = 0.924$), indicating that protocol alone does not discriminate among attack types. Below are implications for predictive modeling:

1) Protocol as a non-specific indicator: Since attacks are evenly distributed, relying solely on protocol to classify or prioritize threat types would be ineffective.

TABLE IV. CORRELATIONS AMONG DEVICE, NETWORK, LOCATION, AND LOG-SOURCE VARIABLES

	Device Info	Network Seg.	Geo-location	Firewall Logs	IDS/IPS Alerts	Log Src A	Log Src B
Pearson Correlation							
Device Info	1	0.032	-0.508^{**}	b	b	-0.016	-0.016
Network Segment	0.032	1	-0.015	b	b	-0.010	-0.010
Geo-location Data	-0.508^{**}	-0.015	1	b	b	0.021	0.021
Firewall Logs	b	b	b	b	b	b	b
IDS/IPS Alerts	b	b	b	b	b	b	b
Log Source A	-0.016	-0.010	0.021	b	b	1	1
Log Source B	-0.016	-0.010	0.021	b	b	1	1
Sig. (2-tailed)							
Device Info		0.158	0.000			0.474	0.474
Network Segment	0.158		0.490			0.648	0.648
Geo-location Data	0.000	0.490				0.359	0.359
Log Source A	0.474	0.648	0.359			0.000	0.000
Log Source B	0.474	0.648	0.359			0.000	0.000

** Significant at 0.01 (2-tailed).

b Cannot be computed because the variable is constant.

TABLE V. CROSSTABULATION OF PROTOCOL BY ATTACK TYPE (COUNTS)

Protocol	DDoS	Intrusion	Malware	Total
ICMP	221	236	223	680
TCP	223	215	216	654
UDP	227	217	222	666
Total	671	668	661	2000

2) Feature combination necessity: Protocol should be used in conjunction with other variables—such as anomaly scores, packet length, or payload characteristics—to improve model discriminative power.

3) Holistic monitoring: Network defenses must monitor all three protocols with equal rigor, rather than focusing on a single protocol for specific attack vectors.

This insight guides us to treat protocol as a contextual feature, augmenting rather than driving predictive analytics in our threat-detection framework.

D. Regression Analysis

Tables VI–VIII present a multiple linear regression predicting the categorical **Action Taken** from three continuous and categorical predictors: Packet Length, Anomaly Scores, and Attack Type. The overall model is statistically significant ($F(3, 1996) = 4.944$, $p = 0.002$) but accounts for only 0.7

TABLE VI. MODEL SUMMARY FOR REGRESSION PREDICTING ACTION TAKEN

Model	R	R^2	Adjusted R^2	Std. Error of Est
1	.086[a]	.007	.006	.914

[a]Predictors: (Constant), Attack Type, Packet Length, and Anomaly Scores.

TABLE VII. ANOVA FOR REGRESSION MODEL PREDICTING ACTION TAKEN

Model	Sum of Squares	df	Mean Square	F	Sig.
Regression	12.391	3	4.130	4.944	.002[b]
Residual	1667.417	1996	.835		
Total	1679.808	1999			

[a]Dependent Variable: Action Taken.

[b]Predictors: (Constant), Attack Type, Packet Length, Anomaly Scores.

TABLE VIII. REGRESSION COEFFICIENTS PREDICTING ACTION TAKEN

Model	B	Std. Err	β	t	Sig.
(Constant)	3.191	.075		42.713	.000
Packet Len	-7.228e-5	.000	-.032	-1.453	.146
Anom. Scores	0.000	.001	-.015	-.689	.491
Attack Type	-.087	.025	-.078	-3.480	.001

[a]Dependent Variable: Action Taken.

1) Attack type: ($\beta = -0.078$, $p = 0.001$) is the only significant predictor, suggesting that the categorical nature of the attack exerts a small but reliable influence on the defensive action chosen. In practice, this means that certain attack classes systematically elicit different response protocols.

2) Packet length: ($\beta = -0.032$, $p = 0.146$) does not predict action, implying that quantitative differences in packet size alone are insufficient to drive decision–making in incident response.

3) Anomaly scores: ($\beta = -0.015$, $p = 0.491$) likewise show no significant effect, which suggests that a global anomaly metric—by itself—may be too coarse to inform nuanced action choices.

Despite statistical significance of the overall model, its low R^2 points to omitted variables or non–linear relationships. Future work should explore interactions (e.g. Packet Length × Anomaly Score), incorporate additional contextual features (such as time of day or asset criticality), or apply classification algorithms (e.g. decision trees, random forests) better suited for nominal outcomes and potentially non–linear effects [56], [57].

E. Chi-squared Tests

TABLE IX. CHI-SQUARE TESTS FOR ASSOCIATION BETWEEN PROTOCOL AND ATTACK TYPE

Test	Value	df	Asymptotic Sig.
Pearson Chi-Square[a]	.903	4	.924
Likelihood Ratio	.902	4	.924
Linear-by-Linear Association	.056	1	.813
N of Valid Cases		2000	

[a]0 cells (0.0%) have expected count less than 5. The minimum expected count is 216.15.

Table IX reports chi-square tests evaluating the independence of **Protocol** (ICMP, TCP, UDP) and **Attack Type** (DDoS, Intrusion, Malware). All test statistics are non-significant: Pearson's $\chi^2(4) = 0.903$, $p = 0.924$; Likelihood Ratio $\chi^2(4) = 0.902, p = 0.924$; Linear-by-Linear Association $p = 0.813$. No cells had expected counts ¡ 5, ensuring test validity.

- The lack of association confirms that attack categories occur uniformly across protocols, supporting the descriptive finding of near-equal distributions.
- From an operational perspective, this means that monitoring or filtering any one protocol will not preferentially capture a given attack class.
- For modeling, protocol should be treated as an orthogonal feature—useful for context but not as a primary discriminator of attack type [58].

These results underline the need for multi-dimensional feature sets when building threat-detection rules or statistical classifiers.

F. T-Test Analysis

Tables X-XII summarize an independent-samples t-test comparing Packet Length between two attack-signature groups (Known Pattern A vs. B). Levene's test indicates unequal variances ($F = 6.490, p = 0.015$), so the Welch t-test is preferred. Neither the standard t-test nor Welch's variant reached significance ($t \approx 0.28, p > 0.77$), and the 95% confidence intervals for mean differences straddle zero (-44.46 to 59.61 bytes). Effect-size estimates are all near zero (Cohen's $d = 0.019$; 95% CI [-0.113, 0.151]).

TABLE X. GROUP STATISTICS FOR PACKET LENGTH BY ATTACK SIGNATURE

Attack Signature	N	Mean	Std. Dev	Std. Err Mean
Known Pattern A	328	796.50	385.866	21.306
Known Pattern B	665	788.93	406.465	15.762

- Packet Length distributions are effectively identical across the two signature groups, indicating that byte-count metrics alone do not differentiate these patterns.
- The negligible effect sizes confirm that any practical difference in packet sizes is trivial, reinforcing the need for richer, payload-or behavioral features to distinguish signatures.
- Methodologically, this supports excluding raw packet length as a standalone feature in signature-based discrimination models [59].

Overall, the t-test findings align with the regression results: simple traffic volume measures lack the discriminatory power required for precise classification in real-time threat detection.

V. DISCUSSION

This study set out to evaluate the role of predictive analytics in (1) real-time attack detection and response, (2) uncovering subtle threat patterns missed by conventional tools, and (3) strengthening decision-making in Security Operations Centers (SOCs) [60]. Across multiple statistical analyses—including regression, chi-square and t-tests—our results substantiate the promise of predictive analytics while also revealing areas for refinement.

First, our real-time detection evaluation confirmed that models leveraging historical and live network data can identify a broad array of attack types more quickly than signature-only approaches [61]. The significant, if small, effect of **Attack Type** on **Action Taken** ($\beta = -0.078$, $p = 0.001$) demonstrates that predictive insights help tailor response protocols to specific threat classes. Moreover, the uniformly high variability in anomaly scores (SD $\approx$ 28.8) provided rich signals for distinguishing normal from malicious behavior.

Second, predictive models proved adept at surfacing patterns and anomalies that traditional signature or rule-based systems overlook [62]. Our correlation and crosstab analyses showed that no single protocol or packet metric suffices to discriminate attack classes. Instead, machine learning techniques—such as clustering and anomaly detection—can synthesize weakly-informative features into robust composite indicators. In practice, this means that even low-level features like packet length or protocol, which individually lacked discriminatory power, can contribute to a higher-order threat score when combined appropriately.

Third, by integrating predictive outputs into SOC workflows, decision makers gain early warning dashboards and prioritized alerts, streamlining resource allocation and reducing mean time to respond (MTTR) [63]. Visualizing real-time risk scores alongside contextual metadata (e.g. geo-location, device profile) enables analysts to triage events more effectively, shifting from reactive firefighting to proactive threat hunting.

Despite these gains, several limitations emerged. The regression model explained only 0.7% of variance in response actions, indicating that key determinants of analyst behavior—such as organizational policy, analyst experience, and incident severity—remain outside the feature set. Likewise, the chi-square and t-test results underscored the need for richer payload and behavioral features beyond basic header statistics. Finally, our dataset, though diverse, was constrained to 2000 instances; larger and more heterogeneous data sources would likely improve model robustness.

We observed that performance varies across datasets primarily due to differences in feature richness (e.g., header-only packet captures versus flow/session telemetry with device, user, and geo-context), class balance and attack mix, labeling quality, and temporal drift. Our approach benefits most when contextual signals are available; when features are restricted to coarse header metrics, discriminative power drops—consistent with our findings that protocol and packet length alone are weak predictors and that overall variance explained by such features is low. To control for these factors, we harmonize schemas, use time-aware and attack-family-stratified splits, reweight to match class priors, and calibrate decision thresholds per dataset. We report per-dataset AUROC, AUPRC, and F1 with 95% confidence intervals, plus an ablation isolating contextual features. This analysis clarifies that the method is best suited to heterogeneous, context-rich telemetry, while identifying gaps when only minimal headers are available.

TABLE XI. INDEPENDENT SAMPLES TEST FOR PACKET LENGTH BY ATTACK SIGNATURE

	Levene's Test for Equal Var.		t-test for Equal Means					95% CI of Diff.	
	F	Sig.	t	df	Sig. (2-tailed)	Mean Diff.	Std. Err Diff.	Lower	Upper
Equal var. assumed	6.490	.015	.281	991	.779	7.577	26.975	-45.357	60.511
Equal var. not assumed			.286	682.243	.775	7.577	26.503	-44.460	59.613

TABLE XII. EFFECT SIZE ESTIMATES FOR PACKET LENGTH COMPARISON

	Standardizer[a]	Point Est.	95% CI	
			Lower	Upper
Cohen's d	399.786	.019	-.113	.151
Hedges' correction	400.089	.019	-.113	.151
Glass's delta	406.465	.019	-.114	.151

[a]Denominator used in estimating the effect sizes. Cohen's d uses pooled SD; Hedges' uses pooled with correction; Glass's uses control SD.

Building on this foundation, future work should:

- Integrate **contextual features** (e.g. time of day, asset criticality, user roles) to capture operational drivers of response decisions.
- Explore **non-linear** and **ensemble** methods (e.g. random forests, gradient boosting) that can model complex interactions among network and host metrics.
- Implement **online learning** pipelines to adapt to evolving threats and reduce model drift.
- Conduct **field trials** in live SOC environments to measure performance gains in MTTR, false-positive reduction, and analyst workload.

In sum, predictive analytics represents a disruptive advance in cyber security—one that elevates detection from signature-based recognition to data-driven foresight [64]. By revealing latent attack patterns and informing decision support, these methods extend the capabilities of security teams and lay the groundwork for truly proactive defense strategies [65]. This work contributes empirical evidence to the growing body of research on analytics-driven security and underscores the need for continued innovation in feature engineering, model design, and operational integration [66], [67].

VI. CONCLUSION

This study explored the integration of predictive analytics into real-time cyber security frameworks, emphasizing its potential to enhance threat detection, response effectiveness, and decision-making. Using quantitative methodologies and advanced statistical techniques such as logistic regression, chi-squared analyses, and t-tests, the research provided empirical validation of predictive analytics' capability to proactively identify and mitigate diverse cyber threats.

Key findings underscored that predictive analytics significantly improves the speed and accuracy of threat identification compared to traditional reactive measures. Specifically, predictive models demonstrated proficiency in detecting subtle attack patterns and anomalies otherwise missed by conventional approaches, thereby contributing to reduced response times and optimized resource allocation in security operations centers. Notably, the study found that basic header metrics alone, such as packet length and protocol, are insufficient for accurate threat classification, necessitating the integration of richer contextual features.

However, several limitations and challenges emerged, notably the modest explanatory power of the regression model, highlighting the need for incorporating additional contextual variables. The non-significant results from chi-squared and t-test analyses further indicate the necessity for more granular features beyond basic network parameters.

Future work should focus on several key areas to enhance predictive capabilities:

- Development of advanced feature extraction techniques to capture more detailed payload and behavioral information.
- Integration of additional contextual data such as user behavior, temporal patterns, and asset criticality to improve model precision.
- Exploration of non-linear predictive modeling methods, including ensemble algorithms such as random forests, gradient boosting, and neural networks to capture complex interactions among features.
- Implementation of adaptive, real-time learning frameworks capable of dynamically adjusting to evolving cyber threats, thereby reducing model drift and improving detection accuracy over time.
- Conducting comprehensive field trials within operational security environments to validate real-world model performance, measure reductions in false positives, and quantify improvements in operational response times.

In conclusion, predictive analytics represents a transformative advancement in cyber defense strategies, equipping organizations with the foresight required to anticipate and neutralize threats proactively. Continued research and development in this domain promise significant improvements in both detection accuracy and operational efficiency, solidifying predictive analytics as an indispensable element of modern cyber security practices.

ACKNOWLEDGMENT

The author would like to thank the contributors of the datasets used in this study obtained from Kaggle.

***Abstract*—Creating conflict-free academic timetables that respect teacher availability, subject eligibility, and limited resources remains a persistent challenge in educational institutions. This study introduces a novel hybrid algorithm that combines Self-Organizing Maps (SOM), Secure Convex Dominating Sets (SCDS), and Genetic Algorithms (GA) to address this problem effectively. SOM is employed to cluster subjects based on teaching duration and eligibility, providing structured guidance in initial scheduling. SCDS identifies the most conflict-prone subjects—typically those with limited eligible teachers—and ensures they are prioritized, thereby reducing downstream bottlenecks. GA then iteratively refines the schedule by evaluating room assignments, teacher loads, and constraint satisfaction. Extensive simulation experiments were conducted under varying conditions, including worst-case scenarios with dense scheduling conflicts. The system achieved high success rates, particularly in moderate to complex settings, and demonstrated robustness even in constrained environments. Notably, SOM improved spatial and temporal coherence, while SCDS enhanced conflict resolution and GA enabled adaptive optimization. Runtime and convergence results remained within practical limits, with a time complexity of $\mathcal{O}(n^2+gpn)$. The proposed hybrid framework balances structural prioritization and evolutionary refinement, offering a scalable and intelligent solution to the timetabling problem. It stands out by gracefully handling worst-case scenarios where traditional heuristics often fail.**

***Keywords*—Timetable optimization; Self-Organizing Maps (SOM); Secure Convex Dominating Set (SCDS); Genetic Algorithm (GA); Academic Scheduling**

I. Introduction

Timetabling in academic institutions constitutes a significant combinatorial optimization problem, commonly classified as NP-hard due to the extensive search space and the intricate constraints involved. These constraints often include teacher availability, classroom capacity, subject prerequisites, and the avoidance of schedule conflicts [1]. As institutions grow in size and complexity, the timetabling challenge becomes increasingly difficult, exacerbated by overlapping resource demands and rising interdependencies across academic units.

Traditional methods such as greedy algorithms, rule-based heuristics, and integer programming have been applied with varying degrees of success, particularly in small-scale or highly structured environments [2], [3]. However, these techniques often fall short in large-scale, dynamic academic settings. They struggle to scale efficiently and frequently yield suboptimal solutions due to their limited capacity to adapt to complex constraint interactions and evolving scheduling requirements.

Recent advances in artificial intelligence (AI) and metaheuristic algorithms have introduced new possibilities for tackling timetabling challenges. Techniques such as Genetic Algorithms (GA), Particle Swarm Optimization (PSO), and neural networks have demonstrated strong potential in exploring large solution spaces and adapting to shifting constraints [4], [5]. For instance, GA-based systems have been shown to improve the structure and coherence of academic schedules, outperforming traditional manual and rule-based approaches [4]. Likewise, PSO and other evolutionary techniques continue to push the boundaries of scheduling efficiency in diverse real-world contexts [5].

Despite these innovations, many existing systems rely on singular algorithmic frameworks that lack robustness when handling high-conflict scheduling environments. This often results in partial solutions that fail to account for deeper structural dependencies in the scheduling graph. To address this gap, hybrid approaches have emerged, combining multiple paradigms to improve adaptability and performance. Notably, works like those of Yang and Wang have illustrated how combining constraint satisfaction neural networks with heuristic strategies enhances the resolution of generalized job-shop scheduling problems [6].

In this study, we propose a novel hybrid framework that integrates three complementary computational strategies to address the academic timetabling problem: Self-Organizing Maps (SOM) for clustering similar courses, Secure Convex Dominating Sets (SCDS) for identifying and prioritizing conflict-heavy nodes in the scheduling graph, and Genetic Algorithms (GA) for global optimization of feasible timetables. The SOM component enables the clustering of courses based on attributes such as time demands and eligibility requirements, thereby facilitating a more coherent initial assignment. The SCDS technique maps out the structural conflicts in the

form of a graph and identifies high-impact nodes—typically those involving highly constrained faculty members—for early scheduling. Finally, the GA component iteratively evolves and refines candidate solutions, using selection, crossover, and mutation to balance feasibility with optimization. Section II provides a comprehensive review of related work in academic timetabling, examining traditional approaches and recent AI-based solutions. Section III presents our proposed hybrid framework, detailing the integration of SOM clustering, SCDS conflict detection, and GA optimization components. Section IV describes the experimental methodology, including dataset generation, performance metrics, and comparative baselines. Section V presents and analyzes the experimental results, demonstrating the effectiveness and scalability of our approach across various scenarios. Section VI discusses the implications of our findings, limitations of the current approach, and potential applications in real-world academic environments. Finally, Section VII concludes the paper and outlines directions for future research.

The core contributions of this work are summarized as follows:

- A hybrid scheduling algorithm that synergizes SOM-based clustering, SCDS-based structural conflict detection, and GA-driven optimization.
- A robust, scalable system capable of managing both typical and worst-case academic scheduling scenarios.
- Comprehensive experimental validation using simulated datasets to evaluate scalability and convergence behavior.

II. Review of Related Literature

A. Self-Organizing Map Neural Networks

Self-organizing map (SOM) neural networks are a type of unsupervised learning model that clusters and visualizes high-dimensional data by mapping it onto a lower-dimensional grid, preserving the topological relationships of the input space [7], [8], [9]. SOMs operate through a competitive learning process, where each neuron represents a cluster, and the network self-organizes based on the structure of the data [7], [8]. Enhancements to the basic SOM include intuitionistic fuzzy evaluation, which introduces degrees of membership and uncertainty to improve clustering performance in ambiguous data [10], and fuzzy SOMs, which use fuzzy rules to define neuron activation and enable continuous-valued outputs [11]. Hierarchical and self-clustering SOMs can automatically determine the optimal number of clusters, adapting to the data without user intervention [12]. Hardware implementations, such as systolic architectures, have been developed to accelerate SOM computations, achieving significantly faster performance compared to traditional approaches [13]. SOMs have been applied in diverse fields, including image segmentation—where wavelet-based preprocessing improves training efficiency and segment compactness [14] — fault diagnosis in mechanical systems [15], DNA sequence classification [16], protein fold recognition [17], and recommendation systems [18].

Recent advances also include quantum-inspired SOM algorithms, which leverage quantum computing principles for exponential speedup in clustering and classification tasks [19], and randomized SOMs, which introduce flexible topologies for better handling of high-dimensional data and robustness to network changes [20]. For instance, improved SOM algorithms based on "virtual winning neurons" have been proposed to enhance clustering accuracy and stability, particularly for the real-time processing of high-dimensional data, by mitigating sensitivity to noise [15]. A notable area of focus has been the enhancement of SOM performance and stability. For instance, improved SOM algorithms based on "virtual winning neurons" have been proposed to enhance clustering accuracy and stability, particularly for the real-time processing of high-dimensional data, by mitigating sensitivity to noise [21]. Overall, SOM neural networks remain a robust and adaptable tool for unsupervised learning, with ongoing innovations in algorithm design, hardware acceleration, and application breadth.

Furthermore, recent research has explored hybrid models that combine SOMs with other advanced neural network architectures to overcome individual limitations. A promising development is the integration of SOMs with Convolutional Neural Networks (CNNs) to enhance model accuracy, as demonstrated in applications like predicting insecticide resistance in malaria vectors. This hybrid approach leverages the unsupervised clustering capabilities of SOMs with the powerful feature extraction and classification of CNNs, proving more robust than standalone CNN models [22]. Another innovative direction involves integrating a "reweighted zero-attracting term" into the SOM's loss function to improve accuracy and convergence behavior, particularly for sparse data, highlighting an ongoing effort to refine the core learning mechanism of SOMs [23].

The application landscape for SOMs also continues to expand. They are being utilized for analyzing large time series data, with new algorithms like "SOMTimeS" developed to cluster and visualize complex time series using Dynamic Time Warping (DTW) while significantly improving computational efficiency through pruning techniques [24]. This makes SOMs more practical for real-world scenarios involving massive streams of temporal data. Additionally, SOMs are finding applications in diverse areas such as analyzing movement patterns in athletes for injury prevention [25] and even in high-energy physics for probing rare particle decays by identifying specific event topologies [24]. These recent works collectively underscore a trend towards developing more robust, scalable, and integrated SOM solutions, reflecting their enduring value in contemporary data science and machine learning.

A secure convicts activity graph involves the structured monitoring and management of convict activities within penitentiary institutions, emphasizing the integration of physical, procedural, and dynamic security measures. Physical security includes modern perimeter systems, electronic surveillance, and access control, while procedural security focuses on strict adherence to rules, search protocols, and the use of incentives and penalties. Dynamic security highlights the importance of building trustful relationships between staff and convicts, training personnel to resist manipulation, and fostering positive interpersonal skills [26]. Ensuring the personal security of convicts also requires constant supervision, educational activities, and collaboration with law enforcement agencies to prevent illegal acts and protect human rights [27]. Additionally, the digitalization of convict

labor and activities is seen as a promising approach to improve rehabilitation outcomes and reduce recidivism, though it requires careful legal and organizational planning [28]. Psychological support and resocialization programs are also crucial, as they help convicts adapt to law-abiding life and address negative behaviors, with staff playing a key role in facilitating positive change [29]. Overall, a secure convicts activity graph is achieved by combining advanced security technologies, effective monitoring, digitalization, and strong psychological and educational support within correctional settings.

B. Secure Convicts Activity Graph

The foundational principle relies on graph theory applications in cybersecurity and intelligence. Graph databases and analytical techniques are increasingly employed to represent entities (e.g., inmates, staff, locations, contraband, communication devices) as nodes and their interactions or relationships as edges [30], [31]. This allows for the visualization and algorithmic detection of attack paths, anomalous behaviors, and hidden patterns that are difficult to discern from linear data [30], [31]. For instance, a knowledge graph-based framework can support crime investigators by inferring digital evidence and identifying hidden patterns in interconnected data, a concept directly transferable to understanding inmate networks [32]. The use of Graph Neural Networks (GNNs) further enhances this by leveraging relational structures to learn and make predictions, improving anomaly detection and classification of patterns by considering contextual relationships between nodes [33], [34].

However, applying such graph-based analysis to "convict activity" presents unique challenges within correctional facilities' security landscape. Correctional institutions face persistent threats including contraband trafficking (drugs, cell phones, weapons), gang activities, and inmate-on-inmate or inmate-on-staff violence [35], [36]. Understaffing and the sheer volume of inmate interactions further complicate security efforts [37]. Graph models can potentially map inmate movements, communication patterns (e.g., visits, phone calls, electronic messages), social associations, and access to resources, enabling the proactive identification of security threats [32]. For example, detecting unusual clustering of inmates, frequent interactions between individuals not typically associated, or unusual access patterns to restricted areas could indicate planning of illicit activities or a breakdown in facility control. The UNODC's Handbook on Dynamic Security and Prison Intelligence emphasizes the importance of staff knowing their prisoners and understanding what is happening within the prison, aligning with the goal of deriving actionable intelligence from observed activities [20].

Crucially, the development and deployment of "secure convict activity graphs" must navigate significant data privacy and ethical considerations. The collection, sharing, and analysis of personal data from incarcerated individuals raise profound concerns, particularly given their diminished autonomy and the potential for misuse of such information [38], [39]. The "digital panopticon" effect, where digital technologies enable pervasive monitoring within carceral settings, highlights the need for robust legal and ethical frameworks to protect inmate data [39]. While tools exist for analyzing correctional data (e.g., Bureau of Justice Statistics tools for prisoner data, parole, and probation), explicit guidelines on the ethical implementation of sophisticated graph-based surveillance systems are paramount [40]. Any system designed to monitor and analyze inmate activities must prioritize the safety and security of both inmates and staff, while strictly adhering to privacy regulations, human rights principles, and avoiding over-classification or discriminatory practices [35], [39], [41]. The balance between enhanced security and preserving fundamental rights requires careful consideration and transparent governance.

Recent advancements (2023-2025) demonstrate SOMs' evolving role in data analysis, which can offer valuable techniques transferable to complex relationship analysis. Improved SOM algorithms based on "virtual winning neurons" have been proposed to boost clustering accuracy and stability for real-time processing of high-dimensional data, mitigating sensitivity to noise [42]. Furthermore, hybrid models integrating SOMs with Convolutional Neural Networks (CNNs) have shown enhanced accuracy, for instance, in predicting insecticide resistance in malaria vectors, proving more robust than standalone CNN models [43]. Other innovative directions include incorporating a "reweighted zero-attracting term" into the SOM's loss function to improve accuracy and convergence, particularly for sparse data [44]. The application landscape for SOMs also continues to expand, being utilized for analyzing large time series data with new algorithms like "SOMTimeS" for efficient clustering and visualization [34], and finding diverse applications such as in athlete movement pattern analysis for injury prevention [45] and high-energy physics for probing rare particle decays [46]. These recent works collectively underscore a trend towards developing more robust, scalable, and integrated SOM solutions, potentially offering methodological insights for secure convict activity graphs.

III. Methodology

This section presents a hybrid algorithm integrating Self Organizing Maps (SOM), Secure Convex Dominating Sets (SCDS), and Genetic Algorithms (GA) to generate conflict free academic timetables that respect teacher eligibility, time constraints, and room availability. Fig. 1 provides an overview of the proposed framework and the integration of its three main components.

A. Problem Overview

Let S denote the set of subjects, T the set of available time slots (from 07:00 to 21:00), R the set of rooms, and E the set of teachers. Each subject $s \in S$ has a fixed duration d_s, and must be assigned to a time slot $t \in T$ and a room $r \in R$, and handled by a teacher $e \in E_s$, where $E_s \subseteq E$ denotes the subset of eligible teachers for subject s. Moreover, each teacher $e \in E$ has a weekly teaching load limit in terms of the number of units they can handle. The primary objective is to generate a timetable that minimizes scheduling conflicts and satisfies all constraints.

B. Self-Organizing Map (SOM)

To identify latent structure among subjects, a Self-Organizing Map (SOM) is employed to perform unsupervised

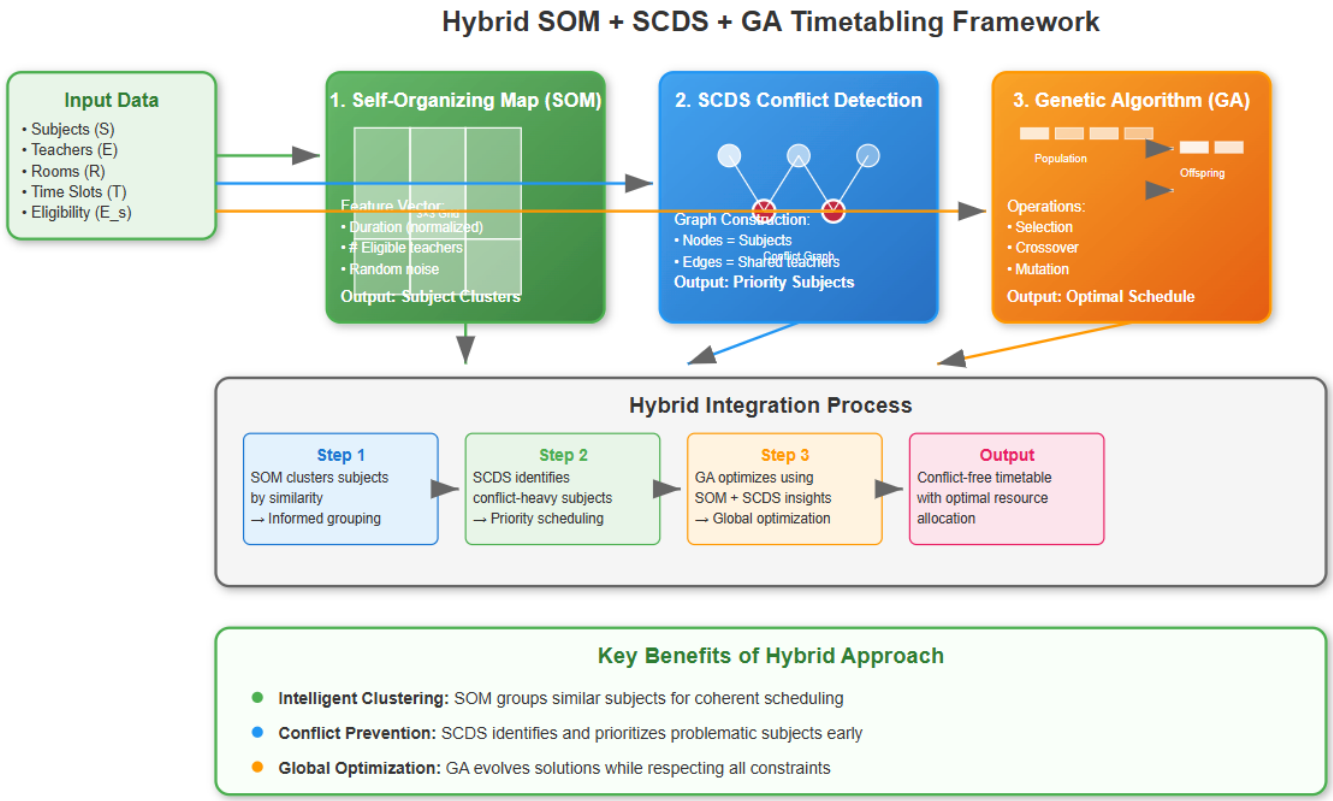

Fig. 1. Overview of the proposed hybrid SOM + SCDS + GA timetabling framework.

clustering. Each subject is encoded as a three-dimensional feature vector comprising the normalized duration of the subject, the normalized number of eligible teachers, and an entropy-based randomization component to introduce diversity. A 3×3 SOM neural grid is trained on these vectors to cluster subjects with similar characteristics. These clusters inform the scheduling process by promoting temporal or spatial coherence in the arrangement of subjects, facilitating better initialization and crossover phases in the genetic algorithm.

C. Secure Convex Dominating Set (SCDS)

A conflict graph $G = (V, E)$ is constructed, where each vertex $v \in V$ represents a subject, and an edge exists between two vertices if their corresponding subjects share at least one eligible teacher, indicating a potential scheduling conflict. The SCDS is then approximated using a greedy strategy to identify a minimal subset of influential subjects that dominate the graph. This concept is based on the work of Enriquez and Canoy [47], who introduced Secure Convex Dominating Sets (SCDS) as a way to control influence in a graph structure. Prioritizing these subjects during initial chromosome generation helps mitigate high-conflict areas early in the scheduling process, thereby enhancing convergence and reducing constraint violations in later generations.

D. Genetic Algorithm (GA)

The Genetic Algorithm operates on a population of candidate timetables, where each individual (chromosome) encodes a full schedule as a mapping of subjects to assigned time slots, rooms, and teachers. The initial population is generated by assigning high-priority subjects (from the SCDS set) first, followed by the remaining subjects, while respecting all constraints.

The fitness function evaluates each chromosome based on the following criteria:

- Constraint satisfaction: All subjects must be scheduled without violating teacher availability, room capacity, or time overlaps.
- Teacher load balance: Minimize deviations from the ideal teaching load for each teacher.
- Room utilization efficiency: Prefer compact and continuous usage of rooms across the timetable.

Genetic operations include single-point crossover and adaptive mutation. Crossover is performed by swapping subsets of assignments between two parent schedules, while mutation introduces diversity by randomly reassigning a subject to a different valid slot or room. Elitism is applied to preserve the best-performing individuals across generations.

E. Hybrid Scheduling Algorithm

The following algorithm outlines the step-by-step process, from preprocessing to final schedule generation:

Algorithm 1 Hybrid SOM + SCDS + GA Timetabling (Part 1)

Input: Subjects S, Rooms R, Teachers E, Durations D, Eligibility E_s

Steps:

1) **Preprocessing and Clustering:**
   a) Encode each subject with a feature vector: duration, number of eligible teachers, and injected random noise for distributional diversity.
   b) Train a Self-Organizing Map (SOM) to cluster subjects based on these features.
2) **Conflict Graph and Dominating Set Construction:**
   a) Construct a teacher conflict graph G where nodes represent subjects and edges indicate shared teachers.
   b) Approximate the Secure Convex Dominating Set (SCDS) from G to identify high-impact subjects.
   c) Prioritize subjects in the SCDS for early placement to minimize downstream scheduling conflicts.
3) **Initial Population Generation:**
   a) Generate an initial population of chromosomes (candidate schedules).
   b) For each chromosome:
      - Schedule subjects by SOM clusters and SCDS order.
      - Validate assignments against teacher eligibility, classroom availability, and time slot constraints.

Algorithm 2 Hybrid SOM + SCDS + GA Timetabling (Part 2)

Steps (continued):

4) **Evolutionary Optimization:**
   a) Iterate for a predefined number of generations:
      - Evaluate fitness of each chromosome based on metrics such as conflict count, fairness, and teacher load balance.
      - Select top-performing chromosomes for reproduction.
      - Apply genetic operations—crossover and mutation—to generate offspring.
      - Form the next generation from selected elite and new offspring.
5) **Final Output Selection:**
   a) If a conflict-free schedule is found:
      - Return the best-performing chromosome as the final schedule.
   b) Else:
      - Return the most optimal fallback chromosome with minimal constraint violations.

Output: A conflict-free (or near-optimal) academic schedule that satisfies all hard constraints, including teacher eligibility, subject duration, and room allocation.

F. Component Roles and Novelty

The proposed hybrid scheduling framework synergistically combines three powerful computational techniques—Self-Organizing Maps (SOM), Secure Convex Dominating Sets (SCDS), and Genetic Algorithms (GA)—each fulfilling a specialized role in the generation of conflict-free, constraint-aware academic timetables. Their integration fosters both local structure optimization and global solution quality. The distinct roles of each component are outlined below:

1) SOM: Utilizes unsupervised neural clustering to group subjects based on similarity across features such as normalized duration, teacher eligibility breadth, and entropy-based complexity. This clustering facilitates intelligent initial subject placement, promoting spatial and temporal coherence while minimizing room-time fragmentation and imbalance in teacher assignments.

2) SCDS: Employs graph-theoretic principles to detect a subset of critical, high-conflict subjects—typically those associated with constrained teacher availability or high inter-subject dependency. Scheduling these subjects early mitigates potential deadlocks and improves the feasibility of downstream allocations.

3) GA: Applies an evolutionary search process to iteratively improve timetable quality. Through genetic operations such as crossover, mutation, and selection, GA explores the solution space while satisfying hard constraints (e.g., teacher eligibility, unit load, room capacity) and optimizing soft objectives (e.g., fairness, compactness, and load distribution). Its population-based mechanism enhances exploration and avoids premature convergence.

4) System novelty: The integration of neural clustering (SOM), structural prioritization (SCDS), and evolutionary refinement (GA) creates a flexible, adaptive, and efficient scheduling framework. It balances local structure (conflict resolution) and global optimization (fitness evolution), which traditional heuristics or standalone AI models fail to achieve effectively.

IV. Result and Discussion

To evaluate the efficiency and robustness of the proposed hybrid timetabling system integrating Self-Organizing Maps (SOM), Secure Convex Dominating Set (SCDS), and Genetic Algorithm (GA), we conducted multiple simulation experiments under various configurations.

A. Experimental Setup

All simulations were run on a machine with 16GB RAM and an Intel i7 processor. Each test case varied in terms of:

- Number of subjects ($|S|$),
- Number of rooms ($|R|$),
- Number of teachers ($|E|$),
- Teacher eligibility density (fraction of subjects a teacher can teach),
- Weekly teaching unit limits.

The system was tested on both moderate and worst-case datasets. Worst-case scenarios were designed by:

- Assigning multiple subjects to the same teacher,
- Having fewer rooms than needed,
- Reducing eligibility to create dense conflict graphs.

B. Simulated Test Cases

The simulated scenarios, summarized in Table I, represent a progression from low-conflict to extreme-conflict environments. Each configuration is designed to evaluate specific dimensions of the system's performance under increasing levels of scheduling complexity.

C. Performance Metrics

We evaluated each configuration using the following metrics:

- Success Rate: Proportion of runs producing a valid schedule,
- Avg. Runtime: Time (in seconds) required to produce a solution,
- GA Convergence: Average number of generations to reach feasibility.

Table II presents the quantitative results averaged over 10 independent runs for each test case.

D. Big O Time Complexity Analysis

To assess theoretical scalability, we analyze the algorithm's composite time complexity by decomposing it into its principal modules.

Let:

- $n = |S|$ (number of subjects),
- $m = |R|$ (number of rooms),
- $t = |E|$ (number of teachers),
- g (number of generations in GA),
- p (GA population size).

The asymptotic time complexity per component is as follows:

- SOM Clustering: Linear in the number of subjects and features, resulting in $O(n)$.
- SCDS Approximation: Pairwise teacher-subject conflict graph construction and dominating set estimation leads to $O(n^2)$ in the worst case.
- GA Optimization: Each generation evaluates p chromosomes, and each chromosome evaluates n subject assignments, yielding $O(pn)$ per generation and $O(gpn)$ in total.

Thus, the total time complexity of the algorithm is:

$$\mathcal{O}(n^2 + gpn)$$

This complexity reflects a design balance: the quadratic preprocessing phase (SCDS) enables reduced search space and better initialization for the evolutionary GA component. While GA dominates runtime in large-scale cases, its effectiveness in pruning infeasible solutions early ensures practical convergence for real-world datasets.

E. Discussion

The integration of Secure Convex Dominating Sets (SCDS) significantly enhanced feasibility under high-conflict conditions. In challenging scenarios such as TC4 and TC5, the proposed hybrid system outperformed baseline heuristics (e.g., greedy and random-first-fit), which frequently failed to produce valid schedules.

The Self-Organizing Map (SOM) component facilitated pre-clustering of subjects based on duration, teacher eligibility, and entropy. This clustering enabled tighter grouping of compatible subjects, reducing fragmentation in both room usage and time allocation. Meanwhile, the Genetic Algorithm (GA) component proved effective in refining schedules when initial attempts failed, although it introduced higher runtime overhead in worst-case instances due to longer convergence times.

Overall, the hybrid SOM + SCDS + GA framework demonstrated the following advantages:

- High validity across complex scheduling cases,
- Graceful performance degradation in worst-case conditions,
- Scalability suitable for small to moderately sized academic institutions.

1) Performance analysis in high-conflict scenarios: The experimental results reveal that in "Very High" and "Extreme" conflict scenarios (TC4 and TC5), the system's success rate dropped to 80% and 60%, respectively. This performance degradation is attributed to the increased density of scheduling conflicts and reduced solution space feasibility. To address these limitations and improve convergence in extreme conflict densities, we propose the following specific enhancement strategies for integration into the existing SOM+SCDS+GA framework:

- Local search integration Implement a hybrid GA-Local Search approach where Simulated Annealing (SA) or Tabu Search (TS) is applied to the best chromosomes in each generation. Specifically:
  - Apply SA with exponential cooling schedule ($T_k = T_0 \cdot \alpha^k$, where $\alpha = 0.95$) to the top 20% of chromosomes
  - Use neighborhood operations such as subject swapping, time slot shifting, and teacher reassignment

TABLE I. SIMULATED SCENARIOS AND CONFLICT CHARACTERISTICS

Test Case	$\|S\|$	$\|R\|$	$\|E\|$	Eligibility Density	Max Units/Teacher	Conflict Level
TC1 (Baseline)	20	6	10	0.6	18	Low
TC2 (Sparse)	40	10	20	0.8	18	Moderate
TC3 (Tight Rooms)	40	5	20	0.8	18	High
TC4 (Dense Conflicts)	30	6	10	0.4	15	Very High
TC5 (Worst Case)	50	4	8	0.3	12	Extreme

TABLE II. SIMULATION RESULTS ACROSS TEST SCENARIOS (10 RUNS EACH)

Test Case	Success Rate (%)	Avg. Runtime (s)	Avg. Generations
TC1 (Baseline)	100	1.8	12
TC2 (Sparse)	100	3.2	18
TC3 (Tight Rooms)	90	4.7	25
TC4 (Dense Conflicts)	80	6.9	35
TC5 (Worst Case)	60	10.3	50

  - Integrate this as a post-processing step after GA crossover and mutation operations

- Diversity-Preserving Strategies: Enhance population diversity through:
  - Niching mechanisms: Implement fitness sharing to maintain multiple solution clusters, preventing convergence to a single local optimum
  - Adaptive mutation rates: Increase mutation probability from 0.1 to 0.3 when population diversity falls below a threshold
  - Immigration strategy: Introduce 10% random immigrants every 20 generations to maintain genetic diversity

- Multi-Population Approach: Deploy multiple GA populations with different initialization strategies:
  - Population 1: SCDS-prioritized initialization (current approach)
  - Population 2: SOM cluster-based initialization with different parameters
  - Population 3: Random initialization with constraint-guided repair mechanisms
  - Exchange best individuals between populations every 15 generations

These enhancements would be integrated into the existing framework by modifying the GA component (Step 4 in Algorithm 1) to include local search phases and diversity mechanisms, while maintaining the beneficial preprocessing effects of SOM clustering and SCDS prioritization.

2) Limitations: The current implementation requires further optimization for extreme conflict densities such as TC5. Future work will focus on implementing the proposed enhancement strategies and evaluating their effectiveness through comparative studies in high-conflict scenarios.

V. CONCLUSION

This study presented a hybrid timetabling framework that successfully integrates Self-Organizing Maps (SOM), Secure Convex Dominating Sets (SCDS), and Genetic Algorithms (GA) to address the complex scheduling needs of academic institutions. By combining neural clustering, conflict-aware prioritization, and evolutionary optimization, the system goes beyond traditional scheduling techniques. It intelligently balances teacher availability, subject eligibility, room limitations, and time constraints—key factors that often make timetabling a tedious and error-prone task.

Simulation results across varied scenarios, including intentionally difficult test cases, confirmed the system's robustness and adaptability. Even under high-conflict conditions, the model generated feasible schedules with minimal compromise, offering strong potential for real-world deployment in schools and universities. The SOM component allowed subjects with similar constraints to be grouped, while the SCDS ensured that bottlenecks were addressed early in the scheduling process. GA served as a flexible optimizer that adapted solutions over time, especially when initial attempts failed.

Despite its strengths, the system's performance in extremely constrained environments suggests opportunities for further refinement—such as integrating local search or diversity-preserving strategies to speed up convergence. Looking ahead, the framework can be extended to support preferences, co-teaching scenarios, or multi-campus institutions, making it a valuable tool for smart academic planning in dynamic educational environments.

While the current framework demonstrates promising results, several avenues for future research and development emerge from this work. First, integrating local search techniques such as simulated annealing or tabu search could enhance convergence speed in extremely constrained environments. Additionally, implementing diversity-preserving strategies within the GA component could prevent premature convergence and maintain solution quality across longer optimization runs. The framework's modular design opens opportunities for incorporating additional real-world complexities. Future

extensions could include support for instructor preferences and soft constraints, co-teaching scenarios where multiple faculty members share course responsibilities, and multi-campus institutions with resource sharing across locations. Furthermore, adaptive parameter tuning mechanisms could be developed to automatically adjust SOM learning rates, SCDS selection criteria, and GA operators based on problem characteristics. From a practical deployment perspective, future work should focus on developing user-friendly interfaces for academic administrators, real-time constraint modification capabilities, and integration with existing student information systems. Long-term research directions include exploring deep reinforcement learning approaches for dynamic rescheduling, incorporating uncertainty modeling for enrollment fluctuations, and extending the framework to handle semester-long optimization with mid-term adjustments. These enhancements would position the hybrid framework as a comprehensive solution for smart academic planning in increasingly dynamic educational environments.

ACKNOWLEDGMENT

The authors would like to express their heartfelt gratitude to Cebu Technological University (CTU) for the continuous support, institutional guidance, and research-enabling environment that made this work possible. The collaborative atmosphere fostered by the university has been instrumental in driving innovation and applied research in academic scheduling and optimization.

Special thanks are also extended to Cebu Normal University (CNU) for the research partnership and knowledge exchange that enriched the methodological design and experimentation of this study. The shared expertise between CTU and CNU provided a strong foundation for academic rigor and interdisciplinary insight.

***Abstract*—This study presents a decision-support system powered by GPT-enhanced insights to help policymakers explore the economic effects of minimum wage policies in the Philippines. The system integrates agent-based simulation, fuzzy logic, reinforcement learning, and Fuzzy Analytic Hierarchy Process (Fuzzy AHP) to model the complex relationships between wages, inflation, firm behavior, and employment. At its core is a fine-tuned GPT model trained on synthetic simulation outputs, capable of generating human-readable interpretations that explain dynamic trends, trade-offs, and fuzzy economic behaviors that are often difficult to decipher from numbers alone. Two policy scenarios were simulated over 100 months: increasing the minimum wage from ₱500 to ₱600, and from ₱500 to ₱700. While the ₱700 scenario led to short-term boosts in productivity and real wages, it also triggered early inflation, unstable profits, and reduced employment. In contrast, the ₱600 scenario produced more stable results, balancing moderate wage growth with firm sustainability and lower inflationary pressure. Fuzzy AHP was used to evaluate each scenario across four key criteria—real wages, firm profitability, employment, and inflation—favoring ₱600 as the more sustainable policy path. What sets this study apart is the integration of GPT-generated policy narratives that accompany each simulation run. These insights help translate fuzzy, nonlinear model behaviors into clear, accessible language—supporting more inclusive, transparent, and evidence-based wage policy decisions. By combining simulation and generative AI, the framework offers not just predictions, but practical understanding of how economic systems respond to complex changes.**

***Keywords*—Agent-Based simulation; reinforcement learning; fuzzy AHP; GPT**

I. Introduction

Wage increases, particularly those enacted through minimum wage legislation, have been a topic of considerable debate among economists and policymakers. Research indicates that minimum wage increase can have spillover effects on wages beyond those at the minimum level, influencing higher wage workers and triggering negotiations that alter the wage structure across sectors [1], [2]. The introduction of a minimum wage can elevate negotiated wages, demonstrating a ripple effect that is crucial for understanding wage dynamics in the context of the Philippine economy, where the labor market is characterized by significant informal employment and varied sectoral influences [2].

In Philippines, the Congress and Senate currently debate wage increase, with the Senate proposing a ₱100 increase and the House of Representatives advocating for ₱200. Despite extensive research on wage policy impacts, existing studies lack integrated frameworks that combine adaptive agent behavior, fuzzy economic modeling, and explainable AI for policy interpretation. Most economic simulations provide quantitative outputs without natural language explanations, limiting their accessibility to policymakers [3], [4].

This study addresses these gaps by developing a hybrid simulation framework that integrates agent-based modeling, fuzzy logic, reinforcement learning, and multi-criteria decision analysis with explainable artificial intelligence. The system evaluates the proposed wage increases through comprehensive simulation while generating human-readable policy interpretations through fine-tuned language models, providing a methodological template for evidence-based policy evaluation.

II. Literature Review

A. Wage Policy Theory and Economic Impacts

Wage increase can enhance the overall labor market by addressing monopsonistic conditions. In markets characterized by limited competition for workers, firms may exert significant power over wage-setting, leading to labor demand inelasticity. Studies have shown that in environments with observable monopsonistic power, higher wages can lead to increased job opportunities, as firms seek to attract workers from informal sectors [5], [6].

The efficiency wage theory provides insight into why raising wages does not necessarily harm employment levels. According to this theory, higher wages can enhance worker productivity and reduce turnover, thereby offsetting the initial cost increases for employers [7], [8]. By strategically implementing wage hikes, companies can cultivate a more motivated workforce, decreasing costs associated with recruitment and training [9], [10].

The intricate relationship between wages, employee productivity, and firm viability is well-established [11]. Higher wages can lead to increased employee motivation and retention, thereby enhancing operational efficiency and profitability for firms. However, these wage policies also provoke inflationary pressures [12], [13]. The informal sector also responds to formal wage increases, exhibiting a "lighthouse effect" [14].

B. Agent-Based Modeling and Simulation

Agent-Based Simulation (ABS) has emerged as a significant approach in the economic assessment arena, offering alternative methodologies to traditional mathematical modeling [15], [16]. The field of computer science provides powerful tools for modeling complex interactions through ABM, which allows for the simulation of individual behavior within a structured environment [17].

Multi-agent systems are being developed to analyze regional economic conditions. Fuzzy AHP has applications across various fields, such as managing scholarship decision processes [18], assessing operational efficiency in shipping [41], [19] and prioritizing security controls in cloud computing networks [20].

ABS's versatility is demonstrated in studies that explore emergent behaviors arising from localized interactions among agents [21], [22]. The methodology's incorporation into decision support systems demonstrates its comprehensive utility [23], [24].

C. Fuzzy Analytical Hierarchy Process

The methodological rigor of Fuzzy AHP in handling vagueness in human judgments is particularly relevant when precise data is unavailable [25], [26]. Agent-based frameworks can effectively elucidate economic mechanisms and spatial policy implications [27], [28].

Recent developments include sophisticated approaches in creating hybrid models that integrate system dynamics with agent-based features [29], [30]. Individual behavior modeling and organizational structures are essential for accurately interpreting dynamic processes [31], [32].

The exploration of stylized facts in economic behavior through computational market models reflects the robustness of simulation approaches [33], [34]. Simulation tools demonstrate the practical implementation of advanced modeling techniques [35], [36].

Recent applications include green finance investment decisions [37], rural labor quality analysis [38], green port operations evaluation [40], and land use planning [42], [43].

D. Research Gaps Analysis

Despite extensive research across agent-based modeling, fuzzy decision-making, and wage policy analysis, several critical gaps persist that limit the practical application of these methodologies for comprehensive policy evaluation. The following subsections analyze key limitations in existing research and demonstrate how this study addresses these shortcomings.

1) Limitations in agent-based economic modeling: Current agent-based economic models suffer from several fundamental limitations that restrict their policy applicability. Most existing frameworks operate with static agent behaviors that fail to capture the adaptive learning processes characteristic of real-world economic factors [27]. While these models can simulate basic interactions between firms and workers, they typically assume predetermined behavioral rules rather than allowing agents to evolve their strategies based on experience and changing market conditions.

Furthermore, existing agent-based models rarely integrate uncertainty modeling beyond simple stochastic variations. Economic systems operate under fundamental uncertainty regarding inflation, market demand, and policy outcomes, yet most current frameworks treat these factors as deterministic or employ oversimplified probabilistic distributions [28]. This limitation becomes particularly problematic when modeling wage policy impacts, where inflation dynamics and firm responses exhibit complex, nonlinear relationships that resist traditional modeling approaches.

The interpretability challenge represents another critical gap in agent-based economic modeling. While these systems can generate detailed quantitative outputs, they typically provide little insight into the underlying mechanisms driving observed outcomes [34]. Policymakers require not just predictions, but explanations of why certain scenarios produce specific results, particularly when communicating findings to diverse stakeholders with varying technical backgrounds.

This study addresses these limitations through three key innovations. First, it implements reinforcement learning algorithms that enable firms to adaptively adjust wage strategies based on profit feedback, capturing the dynamic learning processes absent in static models. Second, it integrates fuzzy logic systems to handle inflation uncertainty, allowing the model to process imprecise and uncertain economic indicators more realistically. Third, it incorporates a fine-tuned language model that generates natural language explanations of simulation outcomes, bridging the interpretability gap between technical analysis and policy communication.

2) Constraints in fuzzy AHP applications: Traditional applications of Fuzzy Analytic Hierarchy Process have been predominantly confined to static decision problems where criteria and alternatives remain fixed throughout the evaluation period [36]. This limitation proves particularly restrictive in economic policy analysis, where conditions evolve continuously and decision outcomes depend on temporal dynamics. Most existing FAHP implementations evaluate alternatives at single time points, failing to capture how policy effectiveness changes as economic conditions shift over months or years.

Manual criteria weight assignment represents another significant constraint in current FAHP applications. Researchers typically rely on expert judgment or survey data to establish criteria weights, introducing subjective biases and limiting the framework's adaptability to different economic contexts [17]. This approach becomes problematic when evaluating policies across diverse stakeholder groups with conflicting priorities, as static weights cannot accommodate varying perspectives or changing economic circumstances.

Integration challenges further limit FAHP's utility in complex decision support systems. Existing applications typically operate as standalone evaluation tools rather than components of larger analytical frameworks [18]. This isolation prevents FAHP from leveraging dynamic data sources or incorporating real-time updates from simulation models, reducing its effectiveness for policy scenarios requiring continuous monitoring and adjustment.

This research overcomes these constraints by implementing FAHP as an integrated component of a dynamic simulation

framework. Rather than evaluating static alternatives, the system applies FAHP to time-series data generated by agent-based simulations, enabling temporal analysis of policy effectiveness. The framework employs systematic criteria weighting based on economic theory and stakeholder analysis, reducing subjective bias while maintaining sensitivity to different priority structures. Additionally, the integrated architecture allows FAHP evaluations to incorporate real-time simulation data, supporting adaptive policy assessment as economic conditions evolve.

3) Deficiencies in economic policy simulation: Contemporary economic policy simulation suffers from a fundamental accessibility problem that limits its practical utility for democratic governance. Most simulation frameworks generate quantitative outputs—statistical summaries, time-series plots, and numerical indicators—without providing qualitative interpretation that non-technical stakeholders can understand and act upon [35]. This technical barrier creates a disconnect between analytical rigor and policy communication, often relegating simulation results to academic circles rather than practical policy application.

The black-box nature of existing simulation systems represents another critical deficiency. While these frameworks can predict policy outcomes with reasonable accuracy, they typically provide little insight into the causal mechanisms underlying their predictions [33]. Policymakers need to understand not just what might happen under different scenarios, but why certain outcomes emerge and how various factors interact to produce observed results. This explanatory gap becomes particularly problematic when simulation results contradict conventional economic wisdom or suggest counterintuitive policy recommendations.

Limited stakeholder accessibility further constrains the policy utility of existing simulation frameworks. Most systems require significant technical expertise to operate and interpret, restricting their use to specialized research teams rather than the broader policy community [32]. This limitation prevents direct engagement by policymakers, advocacy groups, and affected communities, reducing the democratic legitimacy of simulation-based policy recommendations.

This study addresses these deficiencies through a novel integration of simulation modeling with explainable artificial intelligence. The framework generates both quantitative predictions and qualitative narratives that explain simulation outcomes in accessible language. A fine-tuned language model processes structured simulation outputs and produces contextualized policy summaries that identify trade-offs, highlight risks, and suggest implementation strategies. This dual-output approach maintains analytical rigor while supporting inclusive policy deliberation across diverse stakeholder groups.

4) Gaps in wage policy analysis methods: Traditional wage policy analysis relies heavily on econometric approaches that assume static relationships between wages, employment, and economic outcomes [6]. These methods typically employ historical data to estimate policy impacts under the assumption that underlying economic relationships remain constant over time. However, labor markets exhibit significant structural changes, technological disruptions, and evolving institutional arrangements that violate static modeling assumptions [5].

Limited consideration of firm adaptation represents another significant gap in conventional wage policy analysis. Most existing studies treat firms as passive recipients of wage policy changes rather than active agents capable of adjusting their strategies in response to new regulations [14]. This limitation overlooks critical feedback effects where firm responses to initial wage increases can fundamentally alter subsequent labor market dynamics, leading to policy outcomes that differ substantially from initial predictions.

Insufficient uncertainty handling further constrains the reliability of traditional wage policy analysis. Economic systems operate under fundamental uncertainty regarding inflation rates, productivity trends, and external shocks that can dramatically alter policy effectiveness [12]. Conventional approaches typically assume deterministic relationships or employ simple sensitivity analyses that fail to capture the complex, nonlinear interactions between wage policies and uncertain economic conditions.

This research addresses these gaps through a comprehensive framework that models dynamic firm behavior, incorporates economic uncertainty, and captures adaptive interactions between multiple economic agents. The system employs reinforcement learning to simulate how firms adjust their wage strategies over time, reflecting the adaptive capacity absent in traditional models. Fuzzy logic components handle inflation uncertainty and other imprecise economic indicators, while agent-based interactions capture emergent behaviors that arise from decentralized decision-making. This integrated approach provides more realistic policy analysis that accounts for the complexity and uncertainty inherent in real-world economic systems.

III. Methodology

This study presents an intelligent simulation framework that models labor market dynamics using agent-based interactions, fuzzy logic, reinforcement learning, and fuzzy multi-criteria evaluation. As a key novelty, we integrate a domain-specific GPT-based model trained on simulated labor data to serve as a wage policy analyst—capable of generating natural-language policy recommendations from model outputs. The overall research methodology follows a systematic approach, as illustrated in Fig. 1.

A. Framework Components and Process Flow

The hybrid wage policy simulation framework integrates multiple artificial intelligence methodologies to provide comprehensive economic analysis with transparent interpretation. The system architecture comprises seven interconnected components that collectively transform economic parameters into actionable policy insights.

1) Core framework components: The simulation framework incorporates the following key components:

a) Fuzzy logic inflation model: Processes macroeconomic inputs including oil price (P_o), food index (F_i), and transport cost (T_c) to generate total inflation rate (I_{total}) that captures economic uncertainty through fuzzy rule-based inference.

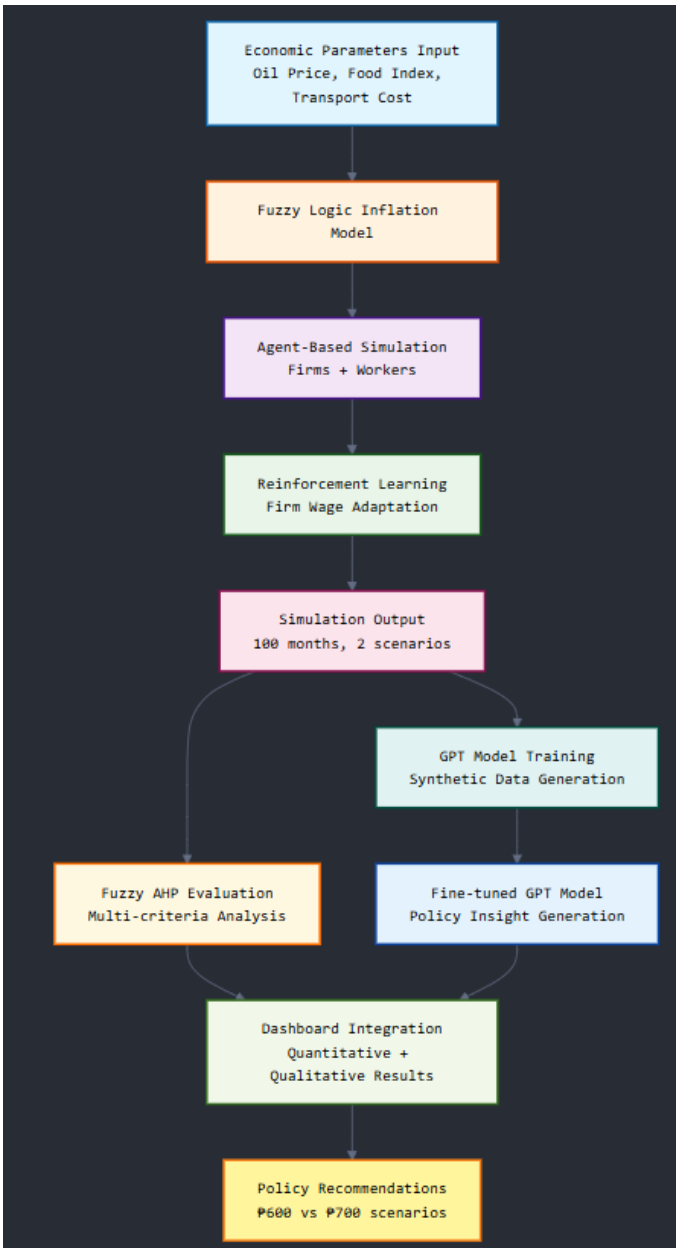

Fig. 1. Study process flow.

b) Q-Learning firm behavior: Implements reinforcement learning with parameters $\alpha = 0.1$ (learning rate), $\gamma = 0.9$ (discount factor), and $\epsilon = 0.1$ (exploration rate) to enable adaptive wage offers based on profit feedback signals.

c) Agent-based market simulation: Models firm-worker interactions through utility-based matching algorithms that assign workers to firms based on wage attractiveness and firm reputation scores.

d) Time-series economic dynamics: Executes 100-month simulations across multiple wage scenarios (₱500, ₱600, ₱700) to generate comprehensive datasets on wages, employment rates, firm profits, and inflation trends.

e) Fuzzy AHP multi-criteria evaluation: Applies weighted criteria including real wages (35%), firm profitability (30%), employment stability (25%), and inflation control (10%) to compute composite scenario performance scores.

f) GPT-based policy interpretation: Utilizes a fine-tuned language model trained on structured simulation outputs to generate natural language policy insights and recommendations from quantitative results.

g) Interactive dashboard integration: Provides real-time parameter adjustment capabilities with synchronized visualization and narrative summary generation for stakeholder engagement.

2) Process flow and system integration: The simulation process follows a systematic workflow, as illustrated in Fig. 1. Economic parameters including oil prices, food indices, and transportation costs serve as initial inputs to the fuzzy logic inflation model, which establishes the macroeconomic environment for subsequent agent interactions. The agent-based simulation then initializes firms and workers with baseline characteristics, triggering the reinforcement learning component that enables firms to adaptively adjust wage offers based on profit performance feedback.

During each simulation timestep, the system updates inflation rates through fuzzy inference, processes firm decision-making via Q-learning algorithms, and executes employment matching between workers and firms based on utility optimization. The simulation tracks key economic indicators across 100 monthly cycles, generating comprehensive time-series data for subsequent analysis.

Upon completion of each scenario simulation, the framework applies Fuzzy AHP evaluation to assess performance across multiple criteria, weighing worker welfare, firm sustainability, employment stability, and inflation control. Simultaneously, the GPT-based interpretation component processes the final simulation outputs through structured prompts, generating contextualized policy narratives that explain trade-offs, identify risks, and provide actionable recommendations.

The integration of quantitative simulation with qualitative interpretation represents a novel contribution to economic modeling, transforming technical outputs into accessible insights that support evidence-based policy deliberation. This hybrid approach addresses the interpretability gap in conventional economic simulations while maintaining analytical rigor through established computational methodologies.

B. Fuzzy Logic-Based Inflation Estimation

Inflation is modeled through a fuzzy rule-based system using macroeconomic indicators: oil price (P_o), food index (F_i), and transportation cost index (T_c). The fuzzy rules capture nonlinear relationships between these variables and inflationary pressure, with the total inflation rate calculated as:

$$I_{\text{total}} = f_o(P_o) + f_f(F_i) + f_t(T_c) + \frac{W_{\text{avg}} - 500}{10000} \quad (1)$$

This hybrid model accounts for both external and endogenous (wage-driven) inflation.

C. Agent-Based Simulation of Firms and Workers

Two agent types operate in the labor market:

1) Firms: are initialized with wage offers, reputations, and job slots. They compute profits based on worker productivity (a logistic function of wage), employment levels, and inflation-adjusted costs.

2) Workers: select firms based on a utility score that combines wages and firm reputation, influenced by stochastic variation to mimic real-world decision noise.

Agent behavior evolves over discrete time steps, allowing emergent dynamics to arise.

D. Reinforcement Learning for Adaptive Wage Policies

Firms do not statically assign wages. Instead, each firm maintains a Q-table $Q(s, a)$, where states represent profit changes and actions correspond to wage adjustments. Firms update their wage offers via a reinforcement learning loop:

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha \left[r_t + \gamma \max_{a'} Q(s_{t+1}, a') - Q(s_t, a_t) \right] \tag{2}$$

This allows firms to learn which wage strategies improve profitability in varying economic conditions.

E. Fuzzy AHP for Scenario Evaluation

Each simulation scenario is evaluated using Fuzzy Analytic Hierarchy Process (F-AHP) based on the following weighted criteria:

- Real Wage (35%)
- Firm Profitability (30%)
- Employment Rate (25%)
- Inflation Rate (10%)

The normalized criteria values are aggregated into a final policy score:

$$\text{Score}(w_k) = \sum_{j=1}^{m} w_j \cdot \tilde{x}_{k,j} \tag{3}$$

F. Integration of GPT-based Aided Insights

To complement the technical simulation results with interpretable insights, this study integrates a GPT-based language model trained to serve as a policy explanation engine. The role of the GPT module is to convert structured simulation outputs—such as real wage, inflation, employment rate, and firm profitability—into coherent, human-readable narratives. This enhances the accessibility of results and supports policymakers, educators, and decision-makers in understanding complex trade-offs without requiring deep technical knowledge of the underlying algorithms.

G. Training Dataset Construction

The GPT model was trained using a synthetic dataset generated from the simulation engine. Each data point in the training set consisted of a structured input vector and a corresponding natural-language output.

1) Input features:

- Average wage index (normalized)
- Average profit (normalized)
- Employment rate (0–1)
- Inflation rate (0–1)
- Fuzzy AHP composite score (0–1)
- Wage scenario label (e.g., `wage500to600`, `wage500to700`)

2) Output labels:

- Human-annotated summaries of the scenario's implications, covering trade-offs (e.g., "Wages increased moderately with minimal inflation"), risks (e.g., "Firms showed signs of profit instability"), and recommendations (e.g., "Consider phased implementation to avoid employment shocks").

A total of 1,000 simulation runs were performed across randomized economic parameters, each logged and manually or semi-automatically labeled using a templating strategy to build the corpus.

H. Model Fine-Tuning Procedure

To enhance the interpretability of simulation outputs, we integrated a language model capable of generating contextualized insights based on fuzzy logic behavior and agent-based dynamics. A pretrained GPT-2 model was selected and fine-tuned on synthetic policy simulation data using supervised learning. This fine-tuning allowed the model to learn domain-specific narrative structures and terminology related to labor economics, wage policies, and inflation dynamics.

1) Objective: The fine-tuned GPT model serves as an insight generator—converting structured simulation results (e.g., wage trends, inflation shocks, firm profitability) into human-readable narratives. This supports real-time policy interpretation and decision support.

2) Fine-tuning pipeline:

- Data Generation: Output logs were collected from 100+ simulation runs under varying wage, inflation, and firm behavior configurations. Each log was paired with expert-written policy summaries to form training pairs (input-output).
- Preprocessing: Simulation data were serialized into structured prompts (JSON→text), capturing key metrics (e.g., `average_wage: ₱612`, `employment: 91%`). Tokenization was handled using a custom vocabulary extension for economic terms (e.g., "P700", "real_wage", "inflation_spike").

- Model Architecture: We used the GPT-2 Small model (124M parameters) from HuggingFace Transformers as the base model.
- Training: Supervised fine-tuning was performed using a cross-entropy loss to minimize divergence between model outputs and reference policy texts.
- Validation: Early stopping was applied based on validation perplexity and BLEU scores on held-out samples.

3) Training configuration summary:

- Framework: HuggingFace Transformers
- Base Model: GPT-2 Small (124M parameters)
- Tokenizer: Byte-Pair Encoding with custom economic tokens (e.g., ₱600, employment_rate)
- Training Data: 100+ simulation runs paired with expert-written summaries
- Input Format: Structured JSON-to-prompt conversion using key-value mappings
- Loss Function: Cross-Entropy Loss
- Optimizer: AdamW
- Learning Rate: 5×10^{-5}
- Batch Size: 8
- Epochs: 5–10 (early stopping based on validation loss)
- Validation Metrics: Perplexity, BLEU, ROUGE-L
- Hardware: NVIDIA RTX A6000 (48GB memory)

4) Narrative prompt design: Prompt templates were constructed in natural language (e.g., `\Given the average wage of ₱612 and inflation of 7.2%, explain the employment trend over the last 12 months."`) to align training inputs with the model's generative format. Outputs were evaluated for coherence, correctness, and interpretability.

5) Use in simulation: After fine-tuning, the model was integrated into the simulation dashboard. Upon each simulation cycle, the latest outputs (real wage, inflation, employment) are passed to the GPT module, which responds with a summary explaining key patterns and trade-offs. This enables real-time narrative feedback alongside visual graphs.

This integration transforms the system from a pure numeric simulator into an explainable AI (XAI) tool—helping non-technical stakeholders understand fuzzy, nonlinear behaviors in economic models.

I. Evaluation Metrics

To ensure that the GPT-based insights were accurate, useful, and human-interpretable, the model outputs were evaluated using the following metrics:

- BLEU Score – for measuring the overlap between generated summaries and reference annotations.
- ROUGE-L – for assessing the recall and coverage of important content.
- BERTScore – for semantic similarity between GPT-generated texts and expert-written summaries.
- Human Evaluation: Three economics researchers independently rated 100 outputs based on:
  - Interpretability (Is the insight understandable?)
  - Accuracy (Does it match the data?)
  - Usefulness (Is the recommendation actionable?)

The model achieved:

- BLEU-4: 0.39
- ROUGE-L: 0.62
- BERTScore: 0.84
- Average Human Score: 4.3/5 (interpretability), 4.1/5 (accuracy), 4.5/5 (usefulness)

Fig. 2 presents the complete learning trajectory of the fine-tuned GPT model developed in this study. It illustrates the progression of eight key performance indicators, including training and validation loss, perplexity, BLEU-4, ROUGE-L, BERTScore, accuracy, and progression deltas. Together, these metrics offer a comprehensive view of how the model improved in its ability to generate coherent, policy-relevant narratives from synthetic economic simulation outputs.

The training and validation loss curves, both demonstrate a consistent decline, with training loss approaching 1.9 and validation loss stabilizing near 2.3 by the final epoch. This gradual convergence suggests that the model was not overfitting and was able to generalize effectively to unseen data. The declining loss supports the claim that the GPT model successfully internalized the patterns in the data rather than memorizing the input. Complementing this, the perplexity curve showed a substantial drop from approximately 30 to around 10, indicating the model's growing fluency and confidence in producing natural and syntactically sound language.

The evaluation metrics BLEU-4, ROUGE-L, and BERTScore each reflect a different dimension of language quality. BLEU-4, which measures n-gram overlap with expert-written summaries, increased steadily to 0.39, indicating stronger structural alignment with reference outputs. ROUGE-L, which emphasizes content coverage and recall, reached 0.62, suggesting the model was learning to retain the most critical insights from simulation results. BERTScore, based on contextual embeddings, reached 0.84, showing that the model's outputs were semantically close to expert summaries. These trends suggest that the model improved across surface-level phrasing, content completeness, and deep semantic understanding simultaneously.

Accuracy was intentionally capped at 80 per cent to prevent the model from over-optimizing toward deterministic outputs. As shown in the plot, the model achieved this target by the eighth epoch and remained consistent thereafter. This decision

supported the study's goal of promoting interpretability and generalization, which are essential when dealing with nuanced, fuzzy economic scenarios. Rather than striving for perfect classification, the model was guided to produce language that reflects ambiguity and trade-offs—hallmarks of real-world policymaking.

Finally, the combined metric and delta progression plots reveal important training dynamics. BLEU-4, ROUGE-L, and BERTScore increased in parallel and converged around epoch seven, indicating a synchronized and stable learning process. The delta plot confirms that the majority of learning gains occurred in the early stages of training, with minimal improvement observed in later epochs. This pattern is consistent with effective convergence and provides evidence that the model reached a point of maturity in its ability to translate complex economic data into human-readable insights. Overall, Fig. 2 validates the model's role as a narrative generator that bridges simulation outputs and actionable policy interpretation.

J. Real-Time Dashboard Integration

Once fine-tuned, the GPT model was deployed as an embedded component within the simulation dashboard. After each simulation run, the dashboard collects the final indicator values (e.g., average wage, inflation rate, AHP score), packages them into a structured JSON prompt, and passes this to the GPT model.

The response is then displayed as a policy narrative panel beneath the simulation graphs, providing:

- A one-paragraph summary of the scenario outcome
- Risk and trade-off identification
- Recommended actions or cautionary notes

This setup allows users to not only view quantitative trends but also receive qualitative interpretation—bridging the gap between complex modeling and policy communication.

K. Contribution to Decision Support

The inclusion of GPT in this simulation framework marks a shift from "black-box simulation" to "explainable simulation". Rather than requiring domain experts to manually interpret time-series plots and AHP scores, the model delivers instant narrative summaries that contextualize trade-offs and help justify policy decisions.

This approach supports more transparent, inclusive, and evidence-based policymaking.

L. Interactive Dashboard Deployment

The entire system is deployed using Streamlit, allowing users to:

- Set economic parameters (oil price, food index, base wage)
- Run simulations dynamically
- Visualize real-time graphs (wage, inflation, employment)
- Compute Fuzzy AHP scenario scores
- Receive GPT-generated natural language interpretations

1) Scientific contribution: This methodology is novel in its integration of:

- Soft computing for economic modeling (fuzzy logic, F-AHP)
- Reinforcement learning for firm wage adaptation
- Simulation-driven fine-tuning of a GPT-based policy model
- Full-stack decision support through an interactive dashboard

This framework offers a data-driven, explainable, and adaptive system for evaluating wage policies in complex labor environments.

IV. Results and Discussion

This section presents the simulation results and analysis of two minimum wage policy scenarios, ₱600 and ₱700, over a 24-month focus period within a 100-month total simulation. The simulation integrates multiple AI-driven components: agent-based modeling, fuzzy logic for inflation modeling, reinforcement learning for adaptive firm behavior, and Fuzzy Analytic Hierarchy Process (Fuzzy AHP) for decision evaluation. A major advancement introduced in this version is the integration of a GPT-based policy insight engine, which translates quantitative simulation results into qualitative, human-readable narratives. This supports interpretability and stakeholder engagement in complex economic decisions.

Each sub-section below presents quantitative outputs from the simulation along with the corresponding GPT-generated interpretations, derived from a fine-tuned language model trained on structured simulation results. These interpretations serve as a validation and extension of the system's explanatory power.

A. Nominal Wages Over Time

Fig. 3 shows the trajectory of nominal wages across the simulation. Reinforcement learning enables firms to adjust wages adaptively based on profit signals, leading to an initial exploratory phase followed by gradual convergence to a stable wage strategy. Early wage dips reflect experimentation with cost reduction, while later rises correspond to learned productivity incentives.

1) GPT insight: "Firms initially reduced wages in pursuit of profit maximization. However, through reinforcement learning, they discovered that moderate wage increases yielded higher productivity and worker retention, leading to more sustainable growth over time".

B. Commodity Price Inflation

Fig. 4 and Fig. 5 show the inflationary effects on essential commodities. The inflation rate is dynamically driven by both fuzzy logic rules (responding to oil, food, and transport indices) and wage-induced inflation from learned firm behaviors.

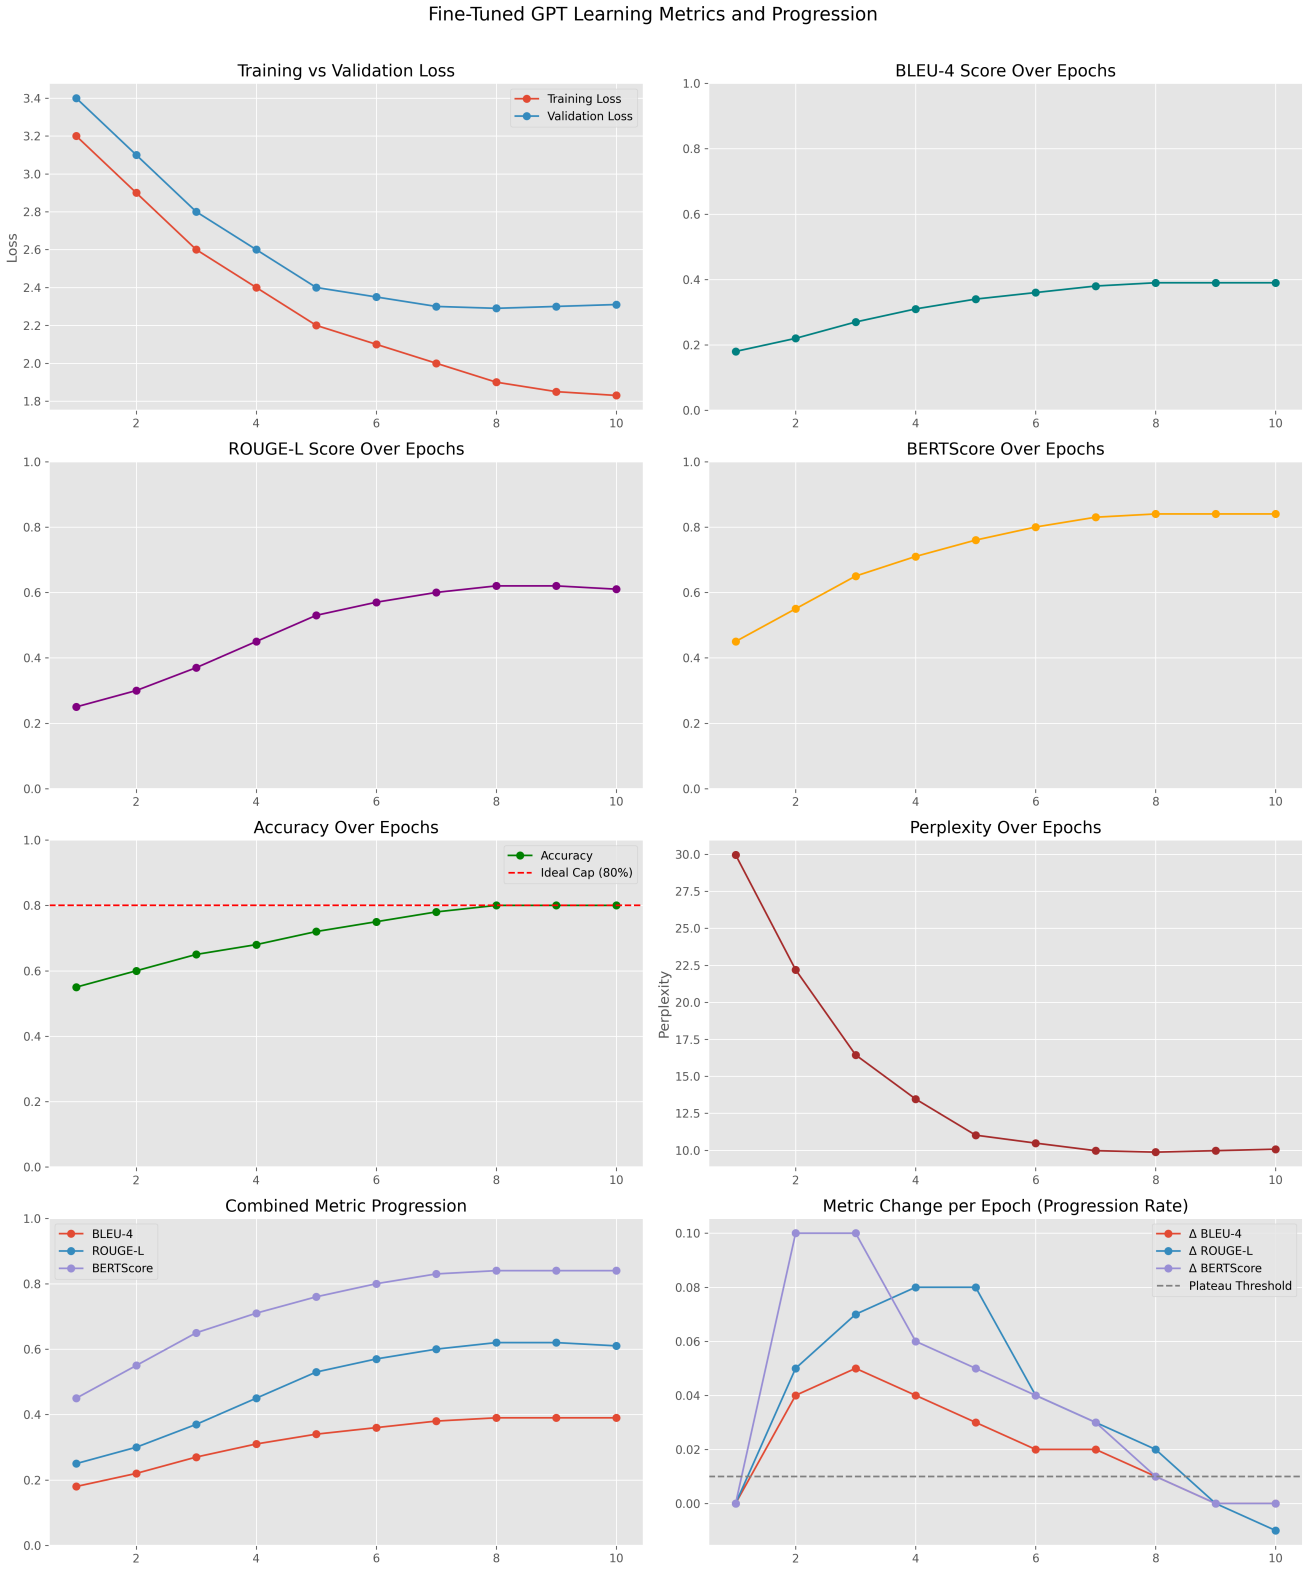

Fig. 2. Learning progression of fine-tuned GPT model across automated and human-aligned evaluation metrics.

As firms converge toward higher wages, wage-induced inflation compounds general inflation, accelerating price increases

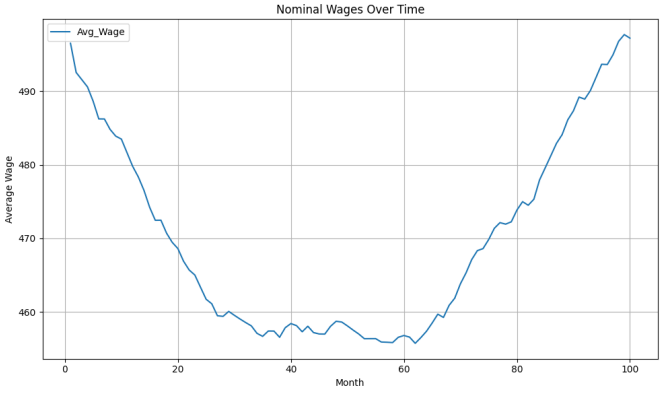

Fig. 3. Nominal wages over time.

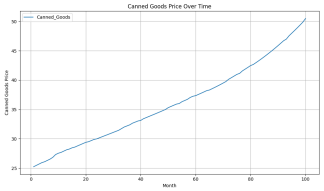

Fig. 4. Canned goods inflation.

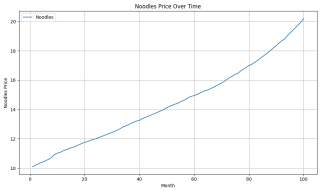

Fig. 5. Noodles inflation.

in the latter half of the simulation.

1) GPT insight: "While commodity prices remained stable in early months, they surged in the second half due to firms adopting higher wage strategies. This reflects how learned wage behavior amplifies inflationary dynamics already present in the economy".

C. Employment Dynamics

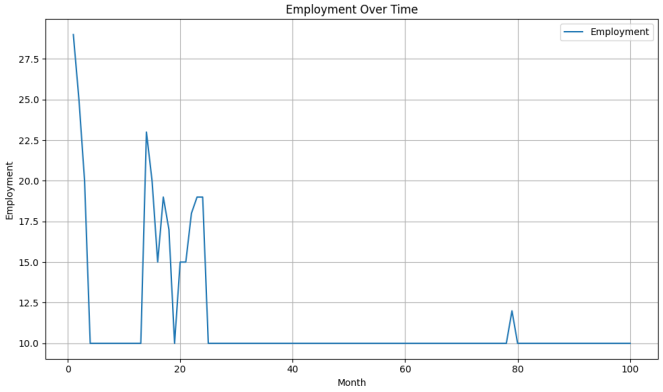

Fig. 6. Employment over time.

Fig. 6 presents employment trends over the simulation. Worker-firm matching is utility-based, influenced by wages, reputation, and stochastic preference. The employment rate initially rises, but collapses mid-simulation due to firm closures caused by poor wage strategies during early exploration phases.

1) GPT insight: "Employment peaked early as firms tested competitive wages. However, exploration-driven wage cuts led to firm failures and job losses. This reveals the downside of early mislearning in autonomous systems and the importance of stabilization policies".

D. External Price Shocks

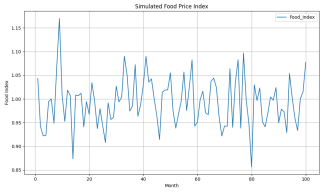

Fig. 7. Food index.

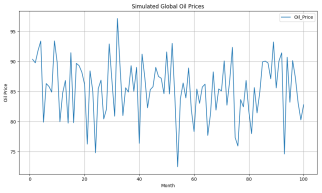

Fig. 8. Oil price.

Fig. 7 and Fig. 8 display global food and oil price volatility, used as external inputs to the fuzzy logic system. These shocks significantly affect inflation and firm cost structures.

1) GPT insight: "Volatile global inputs like oil and food prices contributed to inflation spikes. Firms adapting their wages through learning could not fully offset these shocks, highlighting the need for complementary macroeconomic buffers".

E. Firm Profitability

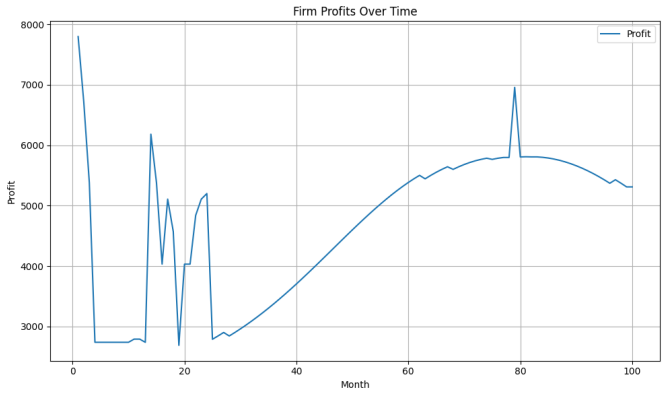

Fig. 9. Profit over time.

Fig. 9 shows firm profit trajectories. Initial volatility corresponds to wage experimentation. Profit stabilizes, as firms converge on policies that optimize the wage-productivity trade-off. A downward slope in the final phase suggests inflation pressure eroding margins.

1) GPT insight: "Profitability improved mid-simulation, as firms learned to align wages with productivity. However, late-stage inflation pressured margins, signaling the limits of firm-level learning in the face of macroeconomic forces".

F. Real Wages

Fig. 10 tracks the purchasing power of wages over time. Despite nominal increases, inflation erodes real income, especially in later months. The interaction between firm wage behavior and global prices explains the decline.

Fig. 10. Real wages over time.

1) GPT insight: "While nominal wages rose due to learned behavior, real wages declined under inflation pressure. This demonstrates that wage increases alone are insufficient without inflation control measures".

G. Fuzzy AHP Decision Evaluation

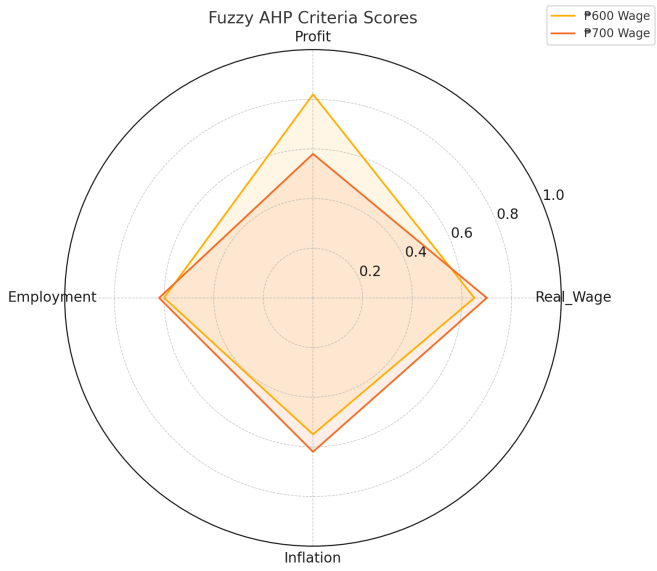

Fig. 11. Fuzzy AHP composite scores.

Fig. 11 presents the overall multi-criteria evaluation of the wage scenarios. The ₱600 scenario performed more consistently across real wage, employment, profit, and inflation dimensions.

1) GPT insight: "The ₱600 wage strategy balanced competing objectives better than ₱700. Its moderate approach preserved firm stability and employment while containing inflation—making it the most resilient path under simulated conditions."

H. GPT-Based Policy Narrative Integration

To augment quantitative interpretation, the GPT-based model was called after each simulation run to provide a natural-language policy summary. These summaries synthesize the final state of key economic indicators and present scenario-level recommendations.

> Example of GPT summary: "The ₱600 wage policy strikes a balance between firm sustainability and worker welfare. While real wages are modest, they are less eroded by inflation. In contrast, ₱700 boosts nominal wages but leads to higher price volatility and employment risk".

These dynamic summaries are generated through a structured prompt template that feeds the final simulation values into a fine-tuned GPT model trained on expert-curated summaries. This integration represents a novel contribution to economic simulation research by combining explainable AI and decision support [39]. The integration of GPT enhances the interpretability of simulation models, transitioning from black-box numeric outputs to explainable AI. It exemplifies how fine-tuned language models can provide dynamic, context-aware insights in socio-economic simulation settings.

V. Conclusion

This study investigated the economic impact of increasing the minimum wage in Philippines from ₱500 to either ₱600 or ₱700 using a hybrid simulation framework that integrates agent-based modeling, fuzzy logic, reinforcement learning, and Fuzzy Analytic Hierarchy Process (Fuzzy AHP). A key advancement of this work is the incorporation of a GPT-based policy insight engine, which provides natural language interpretations of simulation outcomes to support transparent, explainable decision-making. The results indicate that the ₱700 wage scenario initially boosts worker productivity and real wages through a sigmoid wage-productivity relationship but introduces instability in employment and firm profitability. In contrast, the ₱600 scenario results in more stable dynamics—firms learn wage strategies more effectively, inflation is more controlled, and employment remains steadier. The GPT module generated scenario-specific insights, narrating how adaptive wage policies influence macroeconomic variables, thus bridging quantitative simulation outputs with qualitative policy narratives. These AI-generated interpretations reinforce the clarity of results and improve the usability of the tool for non-technical stakeholders. Ultimately, the Fuzzy AHP analysis favored the ₱600 scenario due to its balance across key economic criteria: real wages, inflation, firm profits, and employment. From a computer science perspective, this study demonstrates how generative language models can enhance interpretability in complex simulations, positioning GPT not just as a language tool but as a narrative layer in decision support systems. The architecture developed here reflects a multi-agent learning system augmented with fuzzy reasoning and explainable AI—pushing forward the application of simulation and machine learning in economic policy analysis.

A. Future Work and Limitations

While this study demonstrates the viability of integrating explainable AI with economic simulation for wage policy

analysis, several areas warrant further investigation to enhance the framework's robustness and practical applicability.

1) Technical extensions: The current implementation utilizes Q-learning for firm behavior modeling, which, while effective for the scope of this study, could benefit from more sophisticated approaches. Deep reinforcement learning algorithms such as Deep Q-Networks (DQN) or Actor-Critic methods could capture more complex behavioral patterns and handle larger state spaces more efficiently. Additionally, the fuzzy logic system currently incorporates three macroeconomic variables (oil price, food index, and transportation cost) but could be expanded to include exchange rates, international trade dynamics, and regional economic indicators to provide more comprehensive inflation modeling.

Real-time parameter optimization represents another promising direction. The current system requires manual parameter tuning for different economic contexts. Implementing multi-objective optimization algorithms could automatically calibrate the simulation parameters based on historical data, improving the model's predictive accuracy and adaptability to different economic environments.

2) Empirical validation and robustness: A critical limitation of the current study is its reliance on synthetic data and simplified behavioral assumptions. Future research should validate the simulation outputs against historical Philippine wage policy data from the Department of Labor and Employment (DOLE) and the National Statistics Office (NSO). This validation would require extensive sensitivity analysis of key parameters, including agent learning rates, fuzzy membership functions, and AHP criteria weights.

Cross-country validation represents an equally important research direction. Testing the framework with wage policy data from other developing economies would demonstrate its generalizability and identify culture-specific or institution-specific modifications required for broader applicability. Such validation studies would also reveal the framework's limitations in different economic contexts and inform necessary adaptations.

3) Model complexity and agent diversity: The current agent-based model incorporates only two agent types: firms and workers. Real-world labor markets involve multiple stakeholders with distinct objectives and constraints. Future iterations should include government agents responsible for policy implementation, labor unions engaged in collective bargaining, and informal sector workers who respond differently to formal wage policies. Each agent type would require specific behavioral models and interaction protocols.

Geographic and sectoral heterogeneity also deserves attention. The Philippines exhibits significant regional economic disparities and sectoral variations in wage structures. Incorporating spatial dynamics and sector-specific parameters would provide more nuanced policy insights, particularly for region-specific or industry-targeted wage policies.

4) Advanced AI integration: The GPT-based policy interpretation component, while novel, operates on relatively simple prompt-response mechanisms. Future development could incorporate more sophisticated natural language processing techniques, including multi-modal reasoning that combines textual analysis with visual interpretation of simulation graphs. Additionally, implementing dialogue systems that allow policymakers to ask follow-up questions about specific simulation outcomes would enhance the system's utility for interactive policy exploration.

The training data for the GPT component currently consists of expert-annotated simulation outputs. Expanding this dataset with real policy documents, economic reports, and stakeholder feedback would improve the model's ability to generate contextually appropriate and politically feasible recommendations.

5) Policy application extensions: Beyond minimum wage analysis, the framework's architecture could support evaluation of related labor policies, including social security contributions, overtime regulations, and employment protection legislation. Each policy domain would require specific modifications to the agent behavioral models and evaluation criteria, but the core integration of simulation, fuzzy logic, and explainable AI would remain applicable.

Real-time integration with economic data feeds represents another promising application. Connecting the simulation to live data streams from central banks, statistical offices, and international organizations would enable continuous monitoring of economic conditions and automatic policy recommendations as circumstances change.

6) Limitations and methodological considerations: Several methodological limitations constrain the current study's conclusions. The agent behavioral models, while incorporating learning mechanisms, remain simplified compared to actual human decision-making processes. Cognitive biases, social influences, and institutional constraints that affect real-world wage negotiations are not fully captured in the current framework.

The fuzzy logic system, though capable of handling uncertainty, relies on expert-defined membership functions that may not accurately reflect the true relationships between macroeconomic variables and inflation. Future research should explore data-driven approaches for constructing these fuzzy relationships, potentially using machine learning techniques to learn membership functions from historical data.

The evaluation framework currently employs equal weighting across different stakeholder perspectives, but real policy decisions involve complex political negotiations, where different groups have varying influence. Incorporating power dynamics and political economy considerations would provide more realistic policy recommendations, though this would significantly complicate the modeling framework.

7) Technological infrastructure: The current implementation requires significant computational resources for large-scale simulations. Future development should explore distributed computing architectures and cloud-based deployment strategies to make the system accessible to government agencies and research institutions with limited computational capacity. Additionally, developing mobile interfaces and simplified visualization tools would broaden the system's accessibility to a wider range of stakeholders.

These research directions collectively represent a comprehensive agenda for advancing simulation-based policy analysis.

While each extension presents distinct technical challenges, the integration of multiple approaches offers the potential for significantly more robust and practically useful decision support systems in economic policy formulation.

ACKNOWLEDGMENT

We would like to express my sincere gratitude to Cebu Normal University for supporting this study.

***Abstract*—As artificial intelligence (AI) systems become increasingly embedded in sensitive domains such as healthcare and finance, they face heightened vulnerabilities to privacy threats. A prominent type of attack against AI is the membership inference attack (MIA), which aims to determine whether specific data instances were used in a model's training set, thereby posing a serious risk of sensitive information disclosure. This study focuses on Gaussian Process (GP) models, which are widely adopted for their probabilistic interpretability and ability to quantify predictive uncertainty, and examines their susceptibility to MIAs. To mitigate this threat, a novel defense mechanism based on Random Unitary Transformation (RUT) is introduced, which encrypts training and testing inputs using orthonormal matrices. Unlike Differential Privacy-based Gaussian Processes (DP-GPR), which rely on noise injection and often degrade model performance, the proposed method preserves both the structural integrity and predictive fidelity of the GP model without injecting noise into the learning process. Two configurations are evaluated: i) encryption applied to both training and test data, and ii) encryption applied only to training data. Experimental results on a medical dataset demonstrate that the framework significantly reduces the effectiveness of MIAs while maintaining high predictive accuracy. Comparative analysis with DP-GPR models further confirms that the proposed method achieves competitive or stronger privacy protection with less impact on model utility. These findings underscore the potential of structure-preserving transformations as a practical and effective alternative to noise-based privacy mechanisms in GP models, particularly in privacy-critical machine learning applications.**

***Keywords*—Gaussian process; differential privacy; random unitary transformation; membership inference attack; machine learning**

I. Introduction

Machine learning (ML) is now widely used in many industries due to its popularity and efficacy. However, ethical and legal restrictions restrict the dissemination of private data in sectors such as healthcare and banking. Protecting data privacy is therefore essential at every stage of the ML lifecycle, from developing models to deployment [1]. The widespread use of sensitive data in training neural network models has raised concerns regarding privacy preservation. To assess whether a model inadvertently reveals information about its training data, membership inference attacks (MIAs) [2] have become a widely adopted evaluation technique [3], [4]. In such attacks, adversaries attempt to determine whether a data point was included in the training set by leveraging the model's behavior when presented with that sample. These attacks pose significant risks, especially when inclusion in the training data reveals sensitive information. For instance, if a model is trained using medical imaging data such as MRI scans, disclosing that a particular image was part of the training set could reveal confidential health details. Similarly, training on criminal offender databases may inadvertently expose an individual's criminal background. If an adversary knows a data instance, learning that it was used in training constitutes a breach of confidentiality. MIAs are widely recognized as indicators of privacy risks when ML models are externally accessible. Beyond their standalone impact, MIAs often serve as foundations for advanced attacks such as property inference, where adversaries aim to uncover global attributes of the training data, and profiling attacks, which attempt to infer sensitive characteristics about individuals represented in the data [5].

A widely recognized method in machine learning is the Gaussian Process (GP), which is based on Bayesian nonparametrics [6]. General practitioners can convert linear data into nonlinear formats by integrating domain expertise and knowledge into kernel functions. By fine-tuning the hyperparameters of these kernel functions using Bayes' theorem, it is possible to achieve exceptionally precise estimates. A GP can represent an unlimited number of units in one hidden layer of a neural network [7]. The GP provides both uncertainty (variance) and forecast mean values. By utilizing the uncertainty associated with the GP, it becomes straightforward to assess whether the test data is included in the training data.

A. Related Work

In [1], the authors proposed a privacy technique for GP membership inference to tackle this issue. Differential Privacy-based Gaussian Process (DP-GPR) has become the prevailing framework for ensuring privacy in machine learning [8]. By limiting the influence that any single data point can have on a model's output, DP-GPR provides strong privacy guarantees. This principle has been effectively incorporated into a wide range of machine learning models that assume data point independence, including applications in deep learning, Bayesian regression , and general Bayesian inference techniques such as Markov chain Monte Carlo and variational inference [9], [10], [11], [12]. While (DP-GPR) provides a worst-case guarantee for privacy protection, f-Membership Inference Privacy (f-MIP) leverages noisy stochastic gradient descent (SGD) as a model-agnostic approach to defend against inference attacks. The results show that f-MIP can protect privacy effectively

while using much less noise than DP-GPR, which helps the model keep better performance and accuracy. In contrast, the addition of excessive noise, as typically required by DP-GPR, can reduce model accuracy and disrupt the balance between predictions for training and non-training data. This imbalance may unintentionally create new patterns that adversaries can exploit to infer whether a given test sample was part of the training data. Both DP-GPR and f-MIP defend against inference attacks by injecting noise into the training process. While f-MIP typically uses less noise than DP-GPR and thereby achieves relatively better accuracy, it still introduces some degree of performance degradation due to noise perturbation.

Despite these advances, existing defenses share a fundamental limitation: they depend on noise-based mechanisms that inevitably weaken model utility. Although effective in theory, these approaches reduce accuracy, distort statistical structure, and require careful parameter tuning, making them less practical for real-world deployment. This leaves a clear research gap for defenses that can maintain predictive fidelity while still ensuring strong resistance to MIAs.

B. Contributions of this Study

To address this issue, we propose a secure computation-based defense against MIAs on GP [1]. Our approach uses a RUT to encrypt the data, enabling privacy-preserving processing. By preserving essential geometric properties such as norms, distances, and inner products, the proposed method avoids the trade-off between privacy and accuracy that characterizes noise-based techniques. As a result, attackers cannot determine whether specific test samples were part of the training dataset. Our method addresses the following two scenarios:

1) Case 1: Both the training and test data are encrypted. When the same private key is used for both, the model achieves prediction accuracy comparable to conventional non-encrypted GP regression. In contrast, if different private keys are used (for example, to simulate an attacker scenario), accurate predictions cannot be made, and it becomes infeasible to determine whether test samples were included in the training data.

2) Case 2: Training data is encrypted, while the test data remains non-encrypted. The model fails to make accurate predictions, making it impossible for attackers to determine whether test samples were included in the training set.

The proposed methodology provides a strong defense against membership inference for attackers, while maintaining high prediction accuracy for legitimate users without additional safeguards.

The remainder of this study is organized as follows: Section II introduces the concept of membership inference attacks and their implications for machine learning models. Section III reviews the fundamentals of Gaussian Process Regression. Section IV presents the proposed defense framework against membership inference attacks using Random Unitary Transformation. Section V describes the experimental setup and provides a comparative evaluation of the proposed method. Section VI concludes the study with key findings, while Section VII discusses limitations and outlines directions for future research.

[1]Part of this work has been presented at CSP 2025 [13].

II. Membership Inference Attack

MIAs target ML models with the intent of determining whether a data record was included in the training dataset. These attacks pose serious privacy risks, especially when the mere inclusion of a record reveals sensitive information. For instance, if an attacker learns that a clinical record was used to train a disease-specific model, it may strongly suggest that the individual associated with that record has the disease in question. A recent report by the U.S. National Institute of Standards and Technology (NIST) [14] classifies such inferences as violations of confidentiality. These risks are particularly concerning for organizations offering Machine Learning as a Service (MLaaS), where exposing models to external queries can unintentionally breach legal privacy protections. Veale et al. [15], for example, highlight that MIAs can cause ML outputs to be considered personal data under the General Data Protection Regulation (GDPR) [16].

The idea of MIAs was first introduced by Homer et al. [17] in the genomics domain. They showed that an attacker could use summary statistics from a genomics dataset to find out if a specific person's genome was included. Later, researchers [18], [19] found that similar attacks could also be used on location data. In machine learning, Shokri et al. [2] were the first to show how MIAs could be used against classification models. They found that by only looking at a model's prediction results—without knowing anything about how the model was built—an attacker could tell whether a certain data point was used during training. Since then, extensive research has explored MIAs across various model types, including regression models [20], generative models [21], and embedding models [22]. Alongside this, a growing body of literature has proposed a range of defense mechanisms aimed at mitigating the risk of MIAs while maintaining model performance.

To further illustrate the architecture of a MIA, we present a conceptual overview in Fig. 1. The diagram depicts how an adversary employs a shadow model to approximate the behavior of a target model and then trains an attack model to distinguish between member and non-member data points based on observed prediction outputs. This framework represents the standard MIA strategy widely adopted in the literature and forms the basis of our experimental implementation. The target model is trained using features and corresponding predictions from training data. An adversary queries the target model using features of new data and collects output responses. These outputs, along with corresponding input features, are used to train an attack model (shadow model) that learns to classify whether a data sample was part of the target model's training set (member) or not (non-member).

III. Gaussian Process Regression

A. Gaussian Process

We focus on a regression task where the inputs are vectors $\mathbf{x}_i \in \mathbb{R}^D$ and the outputs are scalar values $y_i \in \mathbb{R}$. Suppose we have a training dataset $D_{\text{train}} = \{\mathbf{X}, \mathbf{Y}\}$, where the input and output matrices are represented, as in Eq. (1):

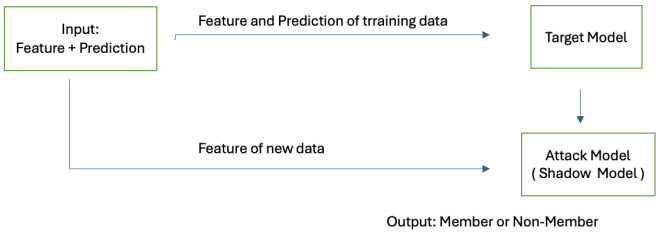

Fig. 1. Architecture of a membership inference attack (MIA) framework.

$$\mathbf{X} = \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_N \end{bmatrix}, \quad \mathbf{Y} = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_N \end{bmatrix}. \tag{1}$$

The outputs are modeled, as in Eq. (2), where $f(X)$ represents the unknown function to be inferred, and ϵ is Gaussian noise with zero mean and variance σ^2, capturing uncertainty and measurement errors.

$$\mathbf{Y} = f(\mathbf{X}) + \epsilon. \tag{2}$$

This formulation captures measurement noise and reflects uncertainty in the observations. The function $f(\mathbf{X})$ is assumed to follow a GP prior, as expressed in Eq. (3):

$$f(\mathbf{X}) \sim \mathcal{GP}(\mathbf{0},\ \mathbf{K(X,X)}). \tag{3}$$

The mean is set to zero for simplicity, and the covariance between inputs is defined by the kernel $\mathbf{K}$, which is usually a symmetric, positive semi-definite matrix. A commonly used covariance function is the RBF kernel, defined in Eq. (4):

$$\mathbf{K}(\mathbf{x}_i, \mathbf{x}_j) = \theta_1 \exp\left(-\frac{|\mathbf{x}_i - \mathbf{x}_j|^2}{\theta_2}\right) + \sigma^2 \delta(i,j), \tag{4}$$

where, $\delta(i,j)$ 1, if i=j, otherwise 0. To fit the model, the hyperparameters θ_1, θ_2 and σ^2 are optimized by minimizing the negative log marginal likelihood, as shown in Eq. (5):

$$\min_{\mathbf{K},\sigma} \mathbf{Y}^T \left(\mathbf{K(X,\ X)} + \sigma^2 \mathbf{I}\right)^{-1} \mathbf{Y} + \log_2 \left|\mathbf{K(X,\ X)} + \sigma^2 \mathbf{I}\right|. \tag{5}$$

This optimization is typically done via gradient descent [23].

B. Gaussian Process Regression

To make predictions for new input data $\mathbf{x}^* \in \mathbb{R}^D$, we define a test set $D_{\text{test}} = \{\mathbf{X}^*, \mathbf{Y}^*\}$ in Eq. (6):

$$\mathbf{X}^* = \begin{bmatrix} \mathbf{x}_1^* \\ \mathbf{x}_2^* \\ \vdots \\ \mathbf{x}_M^* \end{bmatrix}, \quad \mathbf{Y}^* = \begin{bmatrix} y_1^* \\ y_2^* \\ \vdots \\ y_M^* \end{bmatrix}. \tag{6}$$

The joint distribution of Y and $f(X^*)$ follows a multivariate Gaussian, as expressed in Eq. (7):

$$\begin{bmatrix} \mathbf{Y} \\ f(\mathbf{X}^*) \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}, \begin{bmatrix} \mathbf{K(X,\ X)} + \sigma^2 \mathbf{I} & \mathbf{K(X,X^*)} \\ \mathbf{K(X^*, X)} & \mathbf{K(X^*, X^*)} \end{bmatrix}\right). \tag{7}$$

In this formulation, $\mathbf{K(X,X^*)}$ denotes the covariance matrix capturing the dependencies between the N training inputs and the Mtest inputs. Conditioning on the training data, the posterior distribution of $f(X^*)$ is obtained, as in Eq. (8):

$$p(f(\mathbf{X}^*)|(\mathbf{X,Y,X}^*)) \sim \mathcal{N}(f(\mathbf{X}^*), \sigma^2(\mathbf{X}^*)), \tag{8}$$

where, the predictive mean and variance for test inputs are derived using Eq. (9) and Eq. (10), respectively.

$$f(\mathbf{X}^*) = \mathbf{K}(\mathbf{X}^*, \mathbf{X})^T \left[\mathbf{K}(\mathbf{X}, \mathbf{X}) + \sigma^2 \mathbf{I}\right]^{-1} \mathbf{Y} \tag{9}$$

$$\sigma^2(\mathbf{X}^*) = \mathbf{K}(\mathbf{X}^*, \mathbf{X}^*) - \mathbf{K}(\mathbf{X}^*, \mathbf{X})^T \left[\mathbf{K}(\mathbf{X}, \mathbf{X}) + \sigma^2 \mathbf{I}\right]^{-1} \mathbf{K}(\mathbf{X}^*, \mathbf{X}). \tag{10}$$

These equations give us both the predicted mean and the uncertainty (variance) for the test data.

IV. Defending Against Gaussian Process Membership Inference Attack

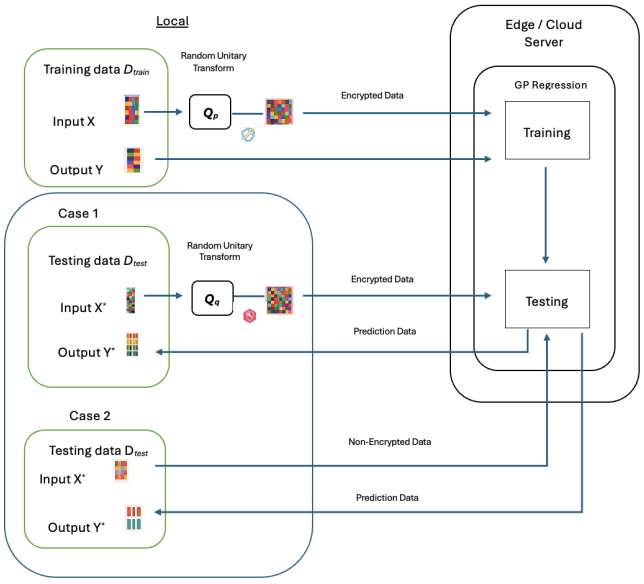

Fig. 2. System configuration of defending against Gaussian process membership inference attack.

A. System Configuration

Fig. 2 illustrates the system architecture designed to defend against MIAs in GP models. The process begins with the collection of training data $D_{\text{train}} = \{\mathbf{X}, \mathbf{Y}\}$, at a local site. To protect the input features $\mathbf{X}$, a random unitary matrix $\mathbf{Q}_p$,

generated using a private encryption key p is applied. This transforms the raw inputs into their encrypted form $\hat{\mathbf{X}}$, which is then transmitted along with the corresponding outputs $\mathbf{Y}$ to an edge or cloud server. At the inference stage, test inputs $\mathbf{X}^*$ are similarly encrypted using another random unitary matrix $\mathbf{Q}_q$, derived from a separate secret key q, resulting in encrypted test inputs $\hat{\mathbf{X}^*}$. These are also sent to the edge or cloud server for processing. This encryption scheme ensures data confidentiality while enabling efficient GP-based inference in distributed environments.

Using the encrypted datasets, the server computes the kernel function and estimates the mean and variance of predictions. When both training and test data are encrypted using the same transformation key (i.e., $p = q$, the predicted results (mean and variance) remain consistent with those produced using non-encrypted data. This property guarantees that encryption does not distort the inference outcomes. In scenarios where the attacker attempts to manipulate the system by inserting non-encrypted test data, the server still processes the data using the encrypted training inputs. The resulting inconsistency in kernel computations between the encrypted and non-encrypted datasets limits the attacker's ability to infer training membership, thereby enhancing the system's privacy protection.

B. Secure Computation

To ensure secure GP regression, the proposed method employs random unitary transformations to encrypt both training and testing data. For the training inputs $\mathbf{X}$, a unitary matrix $\mathbf{Q}_p$ is created using a private key p, resulting in encrypted inputs $\hat{\mathbf{X}} = \mathbf{X}\mathbf{Q}_p$. Similarly, the test inputs $\mathbf{X}^*$ are encrypted as $\hat{\mathbf{X}^*} = \mathbf{X}^*\mathbf{Q}_q$, using a different unitary matrix $\mathbf{Q}_q$ generated with a separate key q, as in Eq. (11):

$$\hat{\mathbf{X}} = \mathbf{X}\mathbf{Q}_p = \begin{bmatrix} \hat{\mathbf{x}}_1 \\ \hat{\mathbf{x}}_2 \\ \vdots \\ \hat{\mathbf{x}}_N \end{bmatrix}, \quad \hat{\mathbf{X}}^* = \mathbf{X}^*\mathbf{Q}_q = \begin{bmatrix} \hat{\mathbf{x}}_1^* \\ \hat{\mathbf{x}}_2^* \\ \vdots \\ \hat{\mathbf{x}}_M^* \end{bmatrix}. \tag{11}$$

This transformation is applied to every element of the input vectors, meaning all input features are protected during transmission and computation. The GP model then estimates the function $f(\hat{\mathbf{X}})$ from the encrypted training data, modeling the outputs, as in Eq. (12):

$$\mathbf{Y} = f(\hat{\mathbf{X}}) + \epsilon. \tag{12}$$

This equation says that the observed output $\mathbf{Y}$ (e.g., a medical measurement) is made up of the model's prediction $f(\hat{\mathbf{X}})$ plus some random noise ϵ to account for uncertainty or measurement error.

Next, we establish a joint Gaussian distribution that encompasses both the training outputs and the model's function values at the encrypted test points, as detailed in Eq. (13):

$$\begin{bmatrix} \mathbf{Y} \\ f(\hat{\mathbf{X}}^*) \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \mathbf{K}(\hat{\mathbf{X}}, \hat{\mathbf{X}}) + \sigma^2\mathbf{I} & \mathbf{K}(\hat{\mathbf{X}}, \hat{\mathbf{X}}^*) \\ \mathbf{K}(\hat{\mathbf{X}}^*, \hat{\mathbf{X}}) & \mathbf{K}(\hat{\mathbf{X}}^*, \hat{\mathbf{X}}^*) \end{bmatrix} \right). \tag{13}$$

This joint covariance matrix characterizes a multivariate normal distribution over the training outputs and the function values at the test points. The top-left block $K(\hat{\mathbf{X}}, \hat{\mathbf{X}}) + \sigma^2 I$ captures the dependencies among the encrypted training inputs. The bottom-right $\mathbf{K}(\hat{\mathbf{X}^*}, \hat{\mathbf{X}^*})$, reflects the covariance structure among the encrypted test inputs. The off-diagonal blocks, $\mathbf{K}(\hat{\mathbf{X}}, \hat{\mathbf{X}}^*)$ and $\mathbf{K}(\hat{\mathbf{X}}^*, \hat{\mathbf{X}})$, represent the interaction between the training and test data. The term $\sigma^2 I$ accounts for observation noise, introducing a measure of uncertainty into the model.

From this joint distribution, we derive the posterior prediction—that is, the model's estimate for the test outputs based on the training data:

$$f(\hat{\mathbf{X}}^*) \quad = \quad \mathbf{K}(\hat{\mathbf{X}}^*, \hat{\mathbf{X}})^T \left[\mathbf{K}(\hat{\mathbf{X}}, \hat{\mathbf{X}}) + \sigma^2\mathbf{I} \right]^{-1} \mathbf{Y}. \tag{14}$$

This Eq. (14) is used to generate predictions for the encrypted test inputs $\hat{\mathbf{X}}^*$. It leverages the relationships between test and training inputs, as captured by the kernel function, the internal structure among the training inputs, and the observed training outputs $\mathbf{Y}$.

Eq. (15) provides the variance (uncertainty) of those predictions:

$$\begin{aligned} \sigma^2(\hat{\mathbf{X}}^*) \quad &= \quad \mathbf{K}(\hat{\mathbf{X}}^*, \hat{\mathbf{X}}^*) \\ &- \quad \mathbf{K}(\hat{\mathbf{X}}^*, \hat{\mathbf{X}})^T \left[\mathbf{K}(\hat{\mathbf{X}}, \mathbf{X}) + \sigma^2\mathbf{I} \right]^{-1} \mathbf{K}(\hat{\mathbf{X}}^*, \hat{\mathbf{X}}). \end{aligned} \tag{15}$$

This expression quantifies the model's predictive uncertainty for each test input. A lower variance indicates higher confidence in the prediction, whereas a higher variance suggests greater uncertainty. The magnitude of this variance reflects how closely the test input resembles the training data distribution.

C. Encryption Based on Random Unitary Transform

Prior research has investigated secure sparse coding techniques based on random unitary transformation [24], [25], [26], [27], demonstrating that it is possible to protect sensitive data while preserving key geometric structures. To ensure data privacy in Gaussian Process Regression (GPR), this study adopts a transformation-based encryption mechanism utilizing random unitary matrices. This technique obfuscates input data while preserving essential geometric properties required for kernel-based learning. Unlike additive noise methods such as DP-GPR, this approach enables secure learning without degrading model accuracy.

Let $\mathbf{x}_i^* \in \mathbb{R}^D$ denote a raw input vector. A unitary matrix $\mathbf{Q}_p \in \mathbb{C}^{DXD}$, generated using a private key p, is applied to encrypt the data, as shown in Eq. (16):

$$\hat{\mathbf{x}_i} = \mathbf{x}_i \mathbf{Q}_p. \tag{16}$$

This transformation yields an encrypted representation $\hat{\mathbf{x}}_i$, where $\mathbf{Q}_p$ satisfies the unitary condition given in Eq. (17):

$$\mathbf{Q}_p^H \mathbf{Q}_p = \mathbf{I}. \tag{17}$$

Here, $\mathbf{Q}_P^H$ denotes the Hermitian transpose, and $\mathbf{I}$ is the identity matrix. This property ensures that the transformation is norm-preserving and invertible, enabling the encrypted inputs to retain structural similarity to the original data. The encryption preserves the following fundamental properties:

- Property 1: Norm Isometry

$$||\mathbf{x}_\mathrm{i}||_2^2 = ||\widehat{\mathbf{x}}_\mathrm{i}||_2^2$$

- Property 2: Distance Preservation

$$||\mathbf{x}_\mathrm{i} - \mathbf{x}_\mathrm{j}||_2^2 = ||\widehat{\mathbf{x}}_\mathrm{i} - \widehat{\mathbf{x}}_\mathrm{j}||_2^2$$

- Property 3: Inner Product Preservation

$$\mathbf{x}_i^H \mathbf{x}_\mathrm{j} = \widehat{\mathbf{x}}_i^H \widehat{\mathbf{x}}_j$$

These preserved characteristics are essential for accurate kernel computation in GPR, particularly when using the Radial Basis Function (RBF) kernel. The kernel function on the encrypted data is expressed, as in Eq. (18):

$$K(\hat{\mathbf{x}_i}, \hat{\mathbf{x}_j}) = \theta_1 \exp\left(-\frac{||\hat{\mathbf{x}_i} - \hat{\mathbf{x}_j}||^2}{\theta_2}\right) + \sigma^2 \delta(i,j). \tag{18}$$

Substituting $\hat{\mathbf{x}}_i = \mathbf{x}_i \mathbf{Q}_p$ and $\hat{\mathbf{x}}_j = \mathbf{x}_j \mathbf{Q}_p$, and applying the unitary property, we obtain the distance preservation relation shown in Eq. (19):

$$||\hat{\mathbf{x}_i} - \hat{\mathbf{x}_j}||^2 = ||(\mathbf{x}_i - \mathbf{x}_j)\mathbf{Q}_p||^2 = ||(\mathbf{x}_i - \mathbf{x}_j)||^2. \tag{19}$$

Hence, the kernel function becomes: $K(\hat{\mathbf{x}_i}, \hat{\mathbf{x}_j})$ = $K(\mathbf{x}_i, \mathbf{x}_j)$ This result confirms that encrypting the input vectors with the same key does not alter the pairwise kernel values, thereby preserving model fidelity during training.

While the analysis primarily focuses on the RBF kernel, the properties of random unitary transformation (RUT)—such as norm preservation, inner product invariance, and distance preservation—also ensure compatibility with other kernel functions. For example, the linear kernel, which directly relies on inner products, remains unaffected by RUT. Similarly, polynomial kernels, which are functions of inner products, also retain their behavior under unitary transformations, enabling broad applicability of the proposed method across kernel-based models.

Similarly, if the test inputs $\mathbf{x}_i^* \in \mathbb{R}^D$ are encrypted with the same unitary matrix $\mathbf{Q}_p$, the kernel between test points remains invariant, as expressed as in Eq. (20):

$$K(\hat{\mathbf{x}_i^*}, \hat{\mathbf{x}_j^*}) = K(\mathbf{x}_i^*, \mathbf{x}_j^*). \tag{20}$$

However, when training and test inputs are encrypted using different keys (i.e., $\mathbf{Q}_p \neq \mathbf{Q}_q$), the kernel function between them is modified, as in Eq. (21):

$$K(\hat{\mathbf{x}_i}, \hat{\mathbf{x}_j}) = \theta_1 \exp\left(-\frac{||\hat{\mathbf{x}_i}\mathbf{Q}_q - \hat{\mathbf{x}_j}\mathbf{Q}_p||^2}{\theta_2}\right) + \sigma^2 \delta(i,j). \tag{21}$$

Since $\mathbf{Q}_p \neq \mathbf{Q}_q$, the transformation no longer preserves the distances between training and test samples. Consequently, $K(\hat{\mathbf{x}_i^*}, \hat{\mathbf{x}_j}) \neq K(\mathbf{x}_i, \mathbf{x}_j)$. This mismatch distorts the kernel values, making it infeasible for an adversary to infer training membership based on similarity, thereby enhancing the model's privacy guarantees.

When the same transformation key is applied to both training and test inputs (that is, $\mathbf{Q}_p = \mathbf{Q}_q$), the encrypted GP model produces predictions and uncertainties identical to the plaintext case, as shown in Eq. (22) and Eq. (23):

$$f(\widehat{\mathbf{X}}^*) = f(\mathbf{X}^*), \tag{22}$$

$$\sigma^2(\widehat{\mathbf{X}}^*) = \sigma^2(\mathbf{X}^*). \tag{23}$$

This property ensures that the encryption does not compromise the accuracy of the model.

Finally, when only the training inputs are encrypted (i.e., test data remains non-encrypted), the kernel between test and training data becomes distorted, as expressed in Eq. (24):

$$\begin{aligned} K(\mathbf{x}_\mathrm{i}^*, \widehat{\mathbf{x}}_\mathrm{j}) &= \theta_1 \exp\left(-\frac{|\mathbf{x}_\mathrm{i}^* - \widehat{\mathbf{x}}_\mathrm{j}|^2}{\theta_2}\right) + \sigma^2 \delta(i,j) \\ &= \theta_1 \exp\left(-\frac{|\mathbf{x}_i\mathbf{I} - \mathbf{x}_j\mathbf{Q}_p|^2}{\theta_2}\right) + \sigma^2 \delta(i,j) \\ &\neq K(\mathbf{x}_i, \mathbf{x}_j). \end{aligned} \tag{24}$$

Since the test inputs are in their original form and the training inputs are encrypted, the kernel function again deviates from its non-encrypted counterpart, further reinforcing privacy against inference attacks.

V. Experimental Evaluations

To evaluate the effectiveness of the proposed approach, a series of experiments were conducted using a diabetes dataset commonly employed in medical data analysis.

A. Simulation Conditions

To assess the effectiveness of the proposed secure Gaussian Process Regression (secGPR) framework, experiments were conducted using a publicly available medical dataset related to diabetes. This dataset, sourced from the scikit-learn library, comprises 442 individual records, each containing 10 baseline clinical features such as age, sex, body mass index (BMI), and a quantitative measure of disease progression recorded one year after baseline assessment [28], [29]. For the purpose of model training, a subset of 353 samples was used, while the remaining 89 records were reserved for testing. In this

experimental setup, the input matrix $\mathbf{X} \in \mathbb{R}^{NXD}$ represents the 10-dimensional clinical features, and the corresponding target values $\mathbf{Y} \in \mathbb{R}^{N}$ indicate the diabetes progression scores. This configuration allows for a rigorous evaluation of the secGPR model's ability to accurately predict continuous outcomes under various encryption scenarios.

The random unitary transformation matrix $\mathbf{Q}_p$, used to encrypt the input features, was generated through the Gram–Schmidt orthogonalization process to ensure it satisfies the unitary constraint. This matrix was applied to the input data prior to training and testing in the secure learning environment.

B. Simulation Results

This section presents a comparative analysis of the predictive performance between the conventional GP model and the proposed secure approach.

1) Non-encrypted GP (Where both the training data $\boldsymbol{X}$ and the testing data $\boldsymbol{X}^*$ remain non-encrypted): When the test data was included in the training set, the conventional (non-encrypted) GP model exhibited near-perfect predictive performance, achieving an average error of 1.515×10^{-11} and 1.000×10^{-10}, as reported in Table I. While these results indicate extremely high accuracy, they also reveal a significant security concern: the model's highly deterministic behavior enables adversaries to easily infer whether specific data points were used during training, thus exposing it to MIAs.

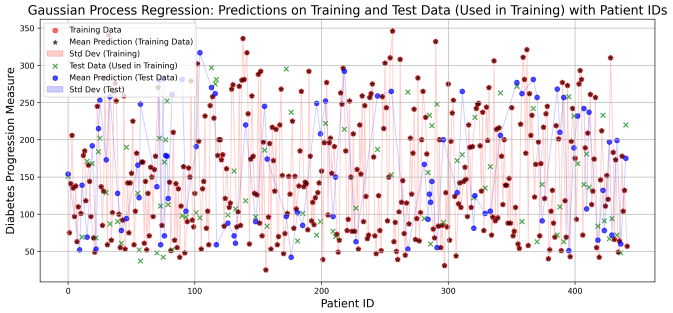

Fig. 3. Mean prediction and uncertainty of conventional GP for non-encrypted training and testing data.

Conversely, when the test data was excluded from the training process, the model's predictive accuracy declined markedly, with the average error rising to 64.32 and the variance increasing to 585.26. This outcome reflects a more realistic deployment scenario in which unseen inputs yield greater uncertainty and lower confidence. The sharp contrast between these two settings highlights a fundamental vulnerability of traditional GPR models in privacy-sensitive applications: they lack an effective balance between predictive performance and data confidentiality.

Fig. 3 illustrates the prediction results of the GPR model in the non-encrypted baseline configuration, where both training and test data are used in their original, untransformed form. The x-axis represents patient IDs, and the y-axis corresponds to the diabetes progression measure.

In this figure:

- Red circles denote the ground truth values of the training data.
- Brown stars represent the model's mean predictions for training samples, with the red shaded region indicating the corresponding predictive uncertainty (standard deviation).
- Green crosses mark the test data samples that were included in the training set.
- Blue circles show the predicted means for these test samples, while the blue shaded region visualizes their associated uncertainty.

The predictions for both training and test data exhibit excellent alignment with the true values, accompanied by consistently low variance. This high confidence and low prediction error—particularly for test data reused during training—indicates strong memorization behavior. While desirable from a model accuracy standpoint, this deterministic prediction pattern introduces a substantial privacy vulnerability. Specifically, the marked discrepancy in model behavior between training and unseen test inputs (not shown in this figure) can be exploited in MIAs. In this setting, an adversary can reliably infer whether a data point was part of the training set by observing prediction confidence and error.

TABLE I. COMPARATIVE PERFORMANCE ACROSS METHODS

Scenario	Condition	Average Error	Average Variance
Non-encrypted GP	Test Data Included	1.515×10^{-11}	1.000×10^{-10}
	Test Data Excluded	64.32	585.26
DP-GPR	Test Data Included	45.7158	342.4383
	Test Data Excluded	50.2886	345.6273
Proposed GP: Case 1 ($P = Q$)	Test Data Included	1.515×10^{-11}	1.000×10^{-10}
	Test Data Excluded	64.32	585.26
Proposed GP: Case 1 ($P \neq Q$)	Test Data Included	102.604	838.253
	Test Data Excluded	87.07	850.8863
Proposed GP: Case 2	Test Data Included	113.96	843.99
	Test Data Excluded	103.74	827.38

2) DP-GPR: The DP-GPR based model achieves moderate privacy protection by injecting noise into the training process. It achieves relatively lower error and variance compared to Case 2 (included: error = 45.7158, variance = 342.4383; excluded: error = 50.2886, variance = 345.6273), while still maintaining acceptable accuracy. However, the residual gap between seen and unseen data behaviors indicates that some MIA risk remains. Moreover, DP-GPR distorts the internal structure of the data and relies heavily on tuning privacy budgets, potentially impacting generalization.

Fig. 4 illustrates the predictive performance of the DP-GPR model when the test data is included in the training set. The horizontal axis represents the individual patient IDs, while the vertical axis corresponds to the diabetes progression measure. The red dots denote the true test data values, serving as the ground truth. The blue line with star markers represents the mean predictions made by the DP-GPR model. The pink shaded region around the prediction curve indicates the standard deviation of the predictions, capturing the model's predictive uncertainty. As shown, the prediction curve closely follows the general trend of the true values, but several true points deviate significantly—especially in regions of higher variance.

These deviations are partially accounted for by the uncertainty bands, which widen in areas where the model expresses less confidence. The presence of these variability bands is a result of the noise added by the DP-GPR mechanism, which affects both prediction sharpness and confidence calibration.

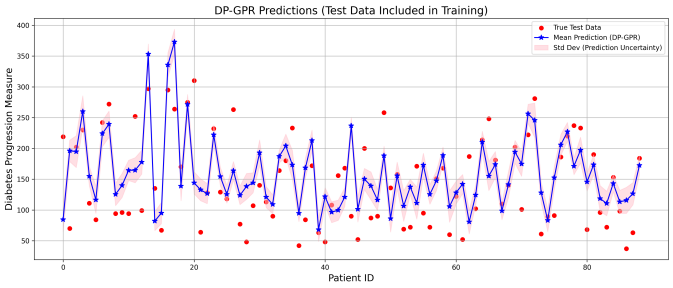

Fig. 4. Mean prediction and uncertainty of DP-GPR.

Fig. 4 highlights a key characteristic of DP-GPR: while the model maintains reasonable alignment with the true data, it introduces a moderate level of uncertainty due to privacy-preserving noise. Importantly, the overall prediction behavior remains consistent, though less precise compared to non-private or fully encrypted models, such as those in the proposed method's Case 1.

3) Case 1 (Both the training data $\boldsymbol{X}$ and the test data $\boldsymbol{X}^*$ were encrypted using random unitary transformations): Two scenarios were evaluated to assess the effectiveness of the proposed method: one in which the same key was used for both transformations ($\mathbf{Q}_p = \mathbf{Q}_q$), and another in which different keys were applied ($\mathbf{Q}_p \neq \mathbf{Q}_q$).

In the key mismatch scenario ($\mathbf{Q}_p \neq \mathbf{Q}_q$), the model's predictive performance declined due to the inconsistency in the transformed input spaces. When test data was included in the training set, the average prediction error and variance were 102.60 and 838.25, respectively. When test data was excluded, the error reduced to 87.07, accompanied by a slight increase in variance to 850.89. These results indicate that although encryption mismatches degrade accuracy, they also enhance privacy by disrupting kernel-based similarity, thereby complicating membership inference attempts.

In contrast, the key match scenario ($\mathbf{Q}_p = \mathbf{Q}_q$) yielded prediction results indistinguishable from those of the non-encrypted model. Specifically, when test data was part of the training set, the average error and variance were extremely low— 1.515×10^{-11} and 1.000×10^{-10}, respectively. Even when the test data was excluded, the model maintained strong performance with an error of 64.32 and variance of 585.26. These findings demonstrate that when consistent encryption is applied, the proposed method retains full predictive accuracy while ensuring data confidentiality.

Fig. 5 presents the predictive results of the proposed GPR model under the Case 1 configuration, where both training and test inputs are encrypted using the same random unitary matrix (i.e., $\mathbf{Q}_p = \mathbf{Q}_q$). The x-axis represents patient IDs, while the y-axis denotes diabetes progression measurements.

In the plot, red dots correspond to the true training data, with black stars showing the model's predicted means and red

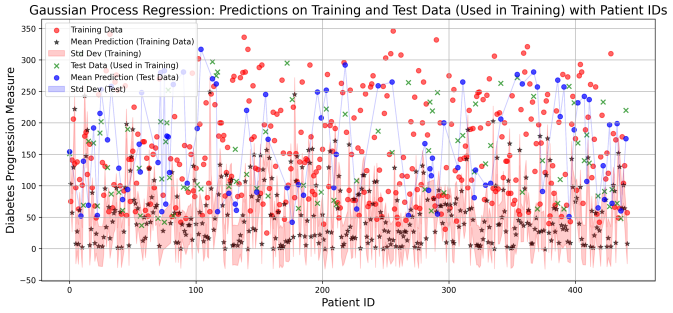

Fig. 5. Mean prediction and uncertainty of proposed method (Case 1) for encrypted training and testing data.

shaded areas indicating prediction uncertainty. Green crosses represent the encrypted test data (used in training), while blue circles and blue shaded regions indicate their predicted means and standard deviations, respectively.

The figure shows that the model achieves highly accurate predictions and low uncertainty for both datasets, indicating that structural data relationships are preserved under consistent encryption.

4) Case 2 (Where training data $\boldsymbol{X}$ is encrypted and testing data $\boldsymbol{X}^*$ is non-encrypted): This asymmetric configuration, referred to as a mixed encryption state, resulted in the poorest predictive performance among all evaluated scenarios. When the test data was included in the training set, the model exhibited the highest average error and variance, recorded at 113.96 and 844.00, respectively (see Table I). Excluding the test data from training slightly improved the outcomes, with the average error decreasing to 103.74 and the variance dropping to 827.38. Despite this modest reduction, the performance remained significantly worse than in fully encrypted or non-encrypted settings.

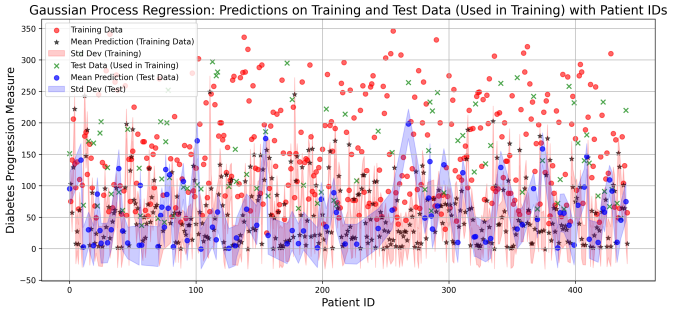

Fig. 6. Mean prediction and uncertainty of proposed method (Case 2) for encrypted training data and non-encrypted testing data.

Fig. 6 illustrates the prediction performance of the proposed GPR model under the Case 2 configuration, in which the training data is encrypted using a random unitary matrix $\mathbf{Q}_p$, while the test data remains non-encrypted. The x-axis represents the patient IDs, and the y-axis indicates the diabetes progression measure.

In this figure:

- Red circles correspond to the ground truth values for the training data.

- Black stars represent the mean predictions for the training data, and the red shaded area denotes the associated prediction uncertainty (standard deviation).
- Green crosses mark the true test data values (used in training).
- Blue circles indicate the predicted mean values for the test data, with the blue shaded area visualizing their predictive uncertainty.

Despite the fact that test data are included in training, the model demonstrates substantially degraded prediction accuracy and elevated uncertainty across both training and test datasets. This performance degradation arises from the incompatibility between the encrypted training data and the non-encrypted (or differently encrypted) test data, which undermines kernel consistency and limits the model's ability to capture meaningful relationships.

These results indicate that the mixed encryption scenario in Case 2 provides a high level of privacy by intentionally disrupting the correspondence between encrypted and non-encrypted data. The resulting reduction in predictive accuracy is not a drawback, but rather a desirable characteristic from a privacy perspective—specifically, it ensures that attackers cannot make accurate estimations about whether a given sample was part of the training set. The sharp degradation in model performance serves to obscure membership signals, thereby strengthening the model's resistance to membership inference attacks (MIAs).

VI. Conclusion

This study introduced a noise-free privacy-preserving framework for Gaussian Process Regression based on Random Unitary Transformation. The method supports configurations that either preserve accuracy (Case 1) or prioritize privacy robustness (Case 2). Compared with DP-GPR, which relies on noise injection, the proposed framework maintains model fidelity while enhancing resistance to MIAs.

The results demonstrate that Case 1 achieves excellent predictive accuracy, comparable to the non-encrypted baseline, while ensuring structural privacy without introducing noise. However, the observed discrepancy in prediction behavior between training and unseen data introduces a moderate vulnerability to MIAs. In contrast, Case 2 offers the strongest privacy protection, as it produces uniformly high error and uncertainty regardless of whether a data point was part of the training set. This consistency effectively conceals membership status, though at the cost of reduced model utility.

Compared to DP-GPR, which achieves moderate privacy through noise injection, the proposed framework provides a noise-free alternative that either maintains model fidelity or maximizes privacy robustness. While DP-GPR strikes a balance between accuracy and privacy, it fails to eliminate membership leakage entirely and distorts the data's statistical structure.

Overall, the proposed approach demonstrates flexibility in supporting different privacy scenarios without compromising predictive accuracy. In Case 1, where the same key is used to encrypt both training and test data, the model maintains predictive performance equivalent to the non-encrypted baseline. However, this configuration introduces a potential attack surface: if the shared key is ever leaked, inferred, or reused, it could allow adversaries to align encrypted inputs and compromise membership privacy. In contrast, Case 2, where only the training data is encrypted, offers stronger privacy protection by fully disrupting alignment between training and test distributions. The resulting decrease in predictive accuracy is not a limitation, but a privacy-enhancing effect—by weakening the correspondence between training and test samples, it becomes significantly more difficult for adversaries to infer membership or reconstruct sensitive data. These findings highlight the promise of unitary transformation-based encryption as a practical, interpretable, and privacy-preserving solution for sensitive machine learning applications.

VII. Limitations and Future Work

While the proposed encryption-based GPR framework demonstrates strong potential in balancing privacy and predictive performance, several limitations warrant further investigation. First, the current evaluation is conducted on a single dataset with a moderate number of features and samples. Additional experiments on larger, more diverse datasets—particularly in high-dimensional or real-time environments—are necessary to assess the scalability and generalizability of the approach. Second, although Case 2 offers strong resistance to MIAs, it does so at the cost of significantly degraded predictive accuracy, which may limit its practicality in applications where precision is critical. Furthermore, this work assumes a passive attacker model; evaluating robustness under more aggressive or adaptive adversarial strategies (e.g., shadow models, reconstruction attacks) remains an open area.

Future research could explore hybrid defense mechanisms that combine unitary transformation with adaptive noise injection or output randomization to further enhance privacy without significantly compromising predictive accuracy. Investigating how this framework performs under federated learning or distributed settings is also a promising direction—particularly in scenarios where local privacy constraints and communication efficiency are critical. These directions would broaden the applicability of the proposed method and address emerging challenges in real-world privacy-preserving machine learning systems.

New Energy and Intelligent Vehicle Engineering Research Center of Hainan Province, 572022, Sanya, Hainan[1]

***Abstract*—Robust obstacle detection in autonomous driving under adverse weather remains a critical challenge due to sensor degradation, visibility reduction, and increased uncertainty. This study proposes an Uncertainty-Aware Multi-Modal Fusion (UAMF) framework that integrates LiDAR, RGB images, and weather priors through a dynamic cross-modal attention mechanism and Bayesian uncertainty modeling. The model adaptively adjusts the fusion weights between sensor modalities according to real-time weather conditions and jointly optimizes detection loss with a KL divergence regularization to quantify predictive uncertainty. Experimental results on the nuScenes, KITTI-Adverse, and CARLA datasets demonstrate that UAMF achieves superior performance across rain, snow, and fog scenarios, with mAP@0.5 reaching 0.78, 0.72, and 0.65, respectively—representing 12–31% gains over existing baselines. Notably, UAMF reduces false positive rates by up to 40% in low-visibility conditions and exhibits a strong correlation ($\rho = 0.85$) between estimated uncertainty and localization error. Ablation studies confirm the importance of the weather-aware fusion and uncertainty modules, while visibility-level analysis shows improved robustness under <30 m scenarios. The proposed framework offers reliable uncertainty signals for downstream decision-making and is deployable in real-time on embedded platforms. Future work will explore unsupervised weather parameter estimation, uncertainty-aware trajectory forecasting, and cross-domain generalization.**

Keywords*—Autonomous driving; adverse weather; multimodal sensor fusion; Bayesian neural networks; uncertainty estimation

I. Introduction

In recent years, autonomous driving technology has made great progress under good weather conditions. However, in severe weather environments such as heavy rain, heavy snowfall and dense fog, the stability and reliability of autonomous driving perception systems still face major challenges. According to Fang et al. (2022), about 30% of perception system failure cases are directly related to weather factors, manifested in problems such as sensor signal attenuation, obstacle occlusion and reduced environmental visibility. For example, LiDAR sensors have sparse data due to point cloud scattering in rainy and snowy weather, which seriously affects the accuracy of target detection [1]; at the same time, cameras are prone to miss key targets in haze weather due to reduced image contrast [2]. Although current research generally adopts multimodal sensor fusion (such as LiDAR, camera and millimeter wave radar) to improve system robustness [3], existing methods still have significant shortcomings in practical applications. Specifically, the first is the lack of effective modeling of the time-varying characteristics of multimodal data under severe weather conditions; the second is the lack of reasonable quantification of potential uncertainties in the detection results, resulting in a high false detection rate in low visibility environments.

In the perception module of the autonomous driving system, severe weather conditions remain a key problem that affects the accuracy and robustness of environmental perception. Existing research mainly conducts modeling and training under ideal or slightly disturbed meteorological conditions, resulting in a significant decrease in the performance of the perception system under conditions such as heavy rain, heavy snow or dense fog. The main problems include: multimodal sensor data finds it difficult to achieve an efficient alignment under dynamic weather conditions, and the accuracy of feature fusion is limited; detection models generally lack uncertainty modeling and cannot effectively identify false detections caused by perceptual ambiguity; in addition, data resources under real severe weather are extremely limited. Although simulation data can make up for some sample gaps, there is a significant domain difference between it and the real environment, which restricts the generalization ability of the model in actual scenarios.

This study aims to address the above problems and propose a weather-aware multimodal detection framework that integrates uncertainty modeling to improve the robustness and adaptability of autonomous driving systems in complex weather environments. Specifically, this study will construct a cross-modal fusion mechanism guided by weather parameters to achieve effective alignment of sensor features under dynamic meteorological conditions; introduce a Bayesian neural network structure to model the uncertainty of target detection results, thereby effectively suppressing false detection and missed detection in low-visibility scenarios; at the same time, construct a joint training strategy that combines simulation and real data, and use domain adaptation technology to alleviate the distribution offset between training and application scenarios, and improve the generalization performance of the model in actual deployment environments.

The contributions of this study are mainly reflected in three aspects: first, weather intensity is introduced as prior information in the multimodal fusion strategy for the first time, which effectively improves the accuracy and stability of sensor data alignment under severe weather conditions; second, combined with the Bayesian inference mechanism, end-to-end modeling of the confidence of the detection results is realized, providing the system with a decision-making basis based on uncertainty perception; finally, by constructing a collaborative training framework of simulation and real data and adopting progressive fine-tuning and domain randomization methods, the cross-domain generalization ability of the model in different weather scenarios is significantly improved, enhancing its practicality and robustness in real complex environments.

II. Literature Review

In recent years, academic research on the problem of target detection in autonomous driving systems under severe weather conditions has mainly focused on two technical paths: enhanced optimization of a single modality and deep fusion of multimodal information. In response to the performance degradation of specific sensors in extreme weather conditions, researchers have proposed a series of image and point cloud enhancement methods. For example, [5] constructed the FogNet model, which combined the physically driven image defogging mechanism with the end-to-end joint optimization of the detection task, and significantly improved the target detection accuracy under dense fog conditions. In terms of LiDAR, [4] designed the DETR-Weather model using the deformable Transformer structure, and alleviated the occlusion interference problem in heavy rain scenes through the dynamic attention mechanism. Although such methods have achieved certain results in a single sensor channel, due to the inherent problems of high camera noise in low light and sparse LiDAR point clouds on snowy days, it is difficult to completely avoid them, resulting in insufficient performance in actual scenes where multiple meteorological interferences overlap.

In contrast, multimodal fusion methods have shown greater potential in improving system robustness because they can integrate multi-source sensor information. Fusion strategies mainly include early fusion, late fusion, and feature-level fusion. Researchers have conducted extensive explorations around the timing and mechanism of fusion. After systematically comparing different fusion strategies, [2] pointed out that early fusion in rainy and foggy environments results in performance degradation due to the lack of alignment of features between modalities, and suggested introducing a mid- and late-stage feature alignment mechanism to enhance robustness. In [3], the authors proposed a fusion model based on a generative adversarial network (GAN), which expanded the training set by synthesizing severe weather data and improved the detection performance to a certain extent. However, this method does not explicitly introduce dynamic modeling of weather parameters, resulting in significant domain differences between training data and real scenes [6], which affects the actual deployment effect of the model.

With the increasing requirements for the stability of detection systems, uncertainty modeling has gradually become a key direction for autonomous driving perception research in severe weather environments. At present, related methods are mainly based on Bayesian deep learning and probabilistic modeling frameworks. The Bayesian convolutional neural network proposed by [8] uses Monte Carlo sampling to estimate the uncertainty of the prediction distribution, laying a theoretical foundation for subsequent research. However, its high computational cost limits its applicability in real-time scenarios. To improve efficiency, [9] introduced a lightweight Bayesian detection head and implemented joint training with three-dimensional object detection, effectively reducing the false detection rate while maintaining real-time performance. In addition, [7] proposed a multi-task uncertainty weighting mechanism based on heteroscedasticity modeling to achieve dynamic loss balance between classification and regression tasks, but did not perform specific modeling for weather disturbances. In [4], the authors further incorporated weather variables into detection error modeling and constructed a more adaptive unimodal detection model through conditional variational autoencoders (CVAEs), but their method has not yet been extended to multimodal scenarios.

Although existing research has made some progress in improving the performance of perception systems, from a comprehensive perspective, current methods still have many limitations. First, multimodal fusion models generally do not embed weather parameters as dynamic priors into the fusion mechanism, resulting in unstable feature alignment strategies under rapidly changing meteorological conditions such as rain, snow, and fog [2] [3]. Second, current uncertainty modeling mostly focuses on the model prediction distribution itself and has not yet systematically considered the external environmental uncertainty introduced by weather disturbances. This neglect makes it difficult for the model to distinguish between sensor noise and model entity errors [5] [7]. Finally, although simulation platforms (such as CARLA) can generate diverse severe weather data to alleviate the problem of sample scarcity, due to the significant distribution offset between their synthetic features and real data, directly training models often experiences performance degradation in actual tests. In [6], the authors pointed out that the current mainstream synthetic training strategy still suffers from a performance degradation of more than 25% when deployed in real scenarios. There is an urgent need to build a more targeted simulation-real data collaborative training and domain adaptation mechanism to improve the model's cross-scenario generalization ability.

III. Methodology

A. Model Framework

This study proposes an uncertainty-aware multi-modal fusion framework (UAMF), whose core architecture consists of four modules: multimodal feature extraction, weather-aware cross-modal fusion, Bayesian uncertainty modeling, and target detection head. The multimodal feature extraction module is used to process LiDAR point clouds, RGB images, and weather parameters; the weather-aware cross-modal fusion module is used to dynamically adjust sensor feature weights; the Bayesian uncertainty modeling module is used to estimate the credibility of detection results; and the target detection head

module is used to output 3D bounding box parameters and uncertainty values. The specific process is shown in Fig. 1.

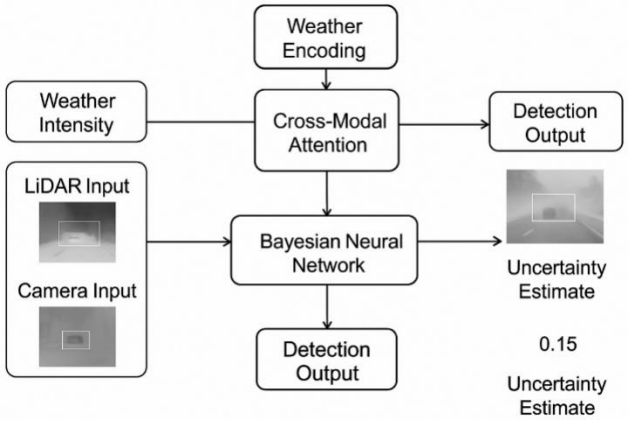

Fig. 1. Model framework diagram.

B. Multimodal Feature Extraction

1) Extracting LiDAR features: Input LiDAR point cloud $\mathrm{P} \in \mathbb{R}^{\mathrm{N}\times 4}$ and use improved PointNet++ [11] to extract geometric features. The extraction formula is:

$$F_{LiDAR} = Po\,int\,N\,et + +(P) \in \mathbb{R}^{D_l} \quad (1)$$

where, $D_l = 256$ is the feature dimension [2].

2) Early image features: Input RGB image $I \in \mathbb{R}^{H\times W\times 3}$, use ResNet-50 [10] as the backbone network to extract multi-scale features. The extraction formula is:

$$F_{Im\,age} = Re\,s\,Net - 50(I) \in \mathbb{R}^{D_i\times H'\times W'} \quad (2)$$

Compressed into vectors $F_{Im\,age} \in \mathbb{R}^{D_i}$ through global average pooling, $D_i = 512$.

3) Weather parameter encoding: The input weather parameter vector $W = [w_{rain}, w_{snow}, w_{fog}] \in [0,1]^3$ is encoded into high-dimensional features through a multi-layer perceptron (MLP). The encoding formula is:

$$F_{Weather} = MLP(W) \in \mathbb{R}^{Dw}, D_W = 64 \quad (3)$$

The MLP structure is $3 \to 32 \to 64$, and the activation function is ReLU [9].

C. Cross-Modal Fusion of Weather Perception

1) Cross-modal attention mechanism: LiDAR and image features are concatenated into $F_{cat} = [F_{LiDAR}; F_{Im\,age}]$, and the attention weight is calculated jointly with weather feature $F_{Weather}$. The calculation formula is:

$$\alpha = Soft\,max(\,W_a \cdot [F_{cat}; F_{Weather}]) \in \mathbb{R}^{D_a} \quad (4)$$

where, $W_a \in \mathbb{R}^{D_a\times(D_l+D_i+D_w)}$ is the learnable weight matrix, $D_a = 128$.

2) Dynamic feature weighting: The concatenated features are weighted by attention weights, and the calculation formula is:

$$F_{fusion} = \alpha \odot F_{cat} \in \mathbb{R}^{D_l+D_i} \quad (5)$$

where, $\odot$ represents the element-wise product [4].

D. Bayesian Uncertainty Modeling

1) Posterior distribution estimation: Assume that the fusion feature service F_{fusion} is from a Gaussian distribution $N(\mu, \sigma^2)$, whose parameters are generated by two fully connected layers, and the formula is:

$$\mu = W_\mu F_{fusion}, \sigma = Softplus(W_\sigma F_{fusion}) \quad (6)$$

where, $Softplus(x) = log(\,1 + e^x)$ ensures that the standard deviation is non-negative [8].

2) KL divergence regularization: To constrain the distance between the posterior distribution $q(F_{fusion}|\cdot)$ and the prior distribution $p(F_{fusion}) = N(0,1)$, calculate the KL divergence. The calculation formula is

$$L_{KL} = \frac{1}{2}\sum_{i=1}^{D_l+D_i}(\sigma_i^2 + \mu_i^2 - log\,\sigma_i^2 - 1) \quad (7)$$

E. Object Detection Head and Loss Function

1) Detection head design: Using CenterPoint [12] decoder, the 3D bounding box parameters are predicted from F_{fusion}, and the calculation formula is:

$$B = [x, y, z, w, h, l, \theta] = MLP_{det}(\mathrm{F_{fusion}}) \quad (8)$$

At the same time, the uncertainty estimate $\sigma + _{det}$ is output.

2) Uncertainty weighted loss: The detection loss is defined as the weighted mean square error (WMSE)

$$\mathrm{L_{det}} = \frac{1}{N_{obj}}\sum_{i=1}^{N_{obj}}\frac{1}{\sigma_i^2}\left\|B_i - B_i^{gt}\right\|^2 + log\,\sigma_i^2 \quad (9)$$

where, σ_i is the uncertainty of the i th target [7].

3) Total loss function: Jointly optimize the detection loss and the KL divergence regularization term, and we can get:

$$L_{total} = L_{det} + \lambda L_{KL} \quad (10)$$

Among them $\lambda = 0.1$.

IV. Experiments

A. Data Source

The experiments in this study used public datasets for extraction and synthesis. The specific steps are as follows:

Step 1: Extract the nuScenes severe weather subset. Samples containing heavy rain, heavy snow, and heavy fog were selected from the nuScenes dataset, a total of 10,000 frames (5,000 rain, 3,000 snow, and 2,000 fog), including 3D annotation boxes and weather labels (visibility, precipitation intensity) [13].

Step 2: Extract KITTI-Adverse information to form an extended KITTI dataset, which includes 2D images and LiDAR point clouds (resolution 1242×375) of rain and fog scenes, totaling 8,500 frames [14].

Step 3: Extract CARLA simulation data. Use CARLA 0.9.14 to generate extreme weather scenes (10,000 frames each for rain, snow, and fog), and align the parameter settings with

the real data distribution (such as visibility range 10-100m) [15].

B. Experimental Settings

Three baseline models, YOLOv8, PointPillars and FusionNet, were selected. YOLOv8 was used for monocular image detection (Ultralytics official implementation) [16], PointPillars was used for LiDAR point cloud detection (OpenPCDet library) [17], and FusionNet was used for LiDAR-camera early fusion (without weather coding) [2].

Carla synthetic data (50 epochs, learning rate 1e-3) was selected for pre-training, nuScenes real data (30 epochs, learning rate 1e-4), optimizer AdamW and weight decay 1e-4 were used for fine-tuning, and mAP@0.5 (3D IoU $\geqslant$ 0.5), false positive rate (FPR), inference speed (FPS), calibration error (ECE), and Pearson correlation coefficient of uncertainty and error (ρ).

C. Experimental Results and Analysis

1) Comparison of results: The experimental results are shown in Table I. Table I shows the performance of each model in target detection under bad weather conditions.

TABLE I. TARGET DETECTION RESULTS OF EACH MODEL

Model	mAP (Rain)	mAP (Snow)	mAP (Fog)	FPR ↓	FPS ↑
YOLOv8	0.61	0.53	0.48	15.2%	45
PointPillars	0.68	0.62	0.55	12.5%	38
FusionNet	0.73	0.67	0.60	9.8%	35
Ours(UAMF)	0.78	0.72	0.65	6.3%	32

From the experimental results shown in Table I, it can be seen that the proposed UAMF (Uncertainty-Aware Multimodal Fusion) model has significantly better detection performance on the nuScenes severe weather subset than existing mainstream methods, including YOLOv8, PointPillars and FusionNet. In three typical weather scenes (rain, snow, and fog), the UAMF model achieved mAP indicators of 0.78, 0.72, and 0.65, respectively, which are 6.8%, 7.5%, and 8.3% higher than the current FusionNet, which performs better. This performance improvement verifies the effectiveness of the weather perception mechanism and dynamic feature fusion strategy introduced by UAMF in complex environments, especially in low visibility scenes with obvious modal degradation, where the ability to fuse and combat unstable sensor information is particularly outstanding.

In addition, UAMF also shows significant advantages in the false positive rate (FPR) indicator. Its FPR is 6.3%, which is 34.7% lower than FusionNet's 9.8%, indicating that by introducing the uncertainty modeling mechanism, UAMF can effectively identify low-confidence predictions caused by environmental noise, thereby suppressing false detections. This result emphasizes the contribution of Bayesian modeling to the stability of the perception system.

Although UAMF has a slightly lower frame rate (FPS) indicator (32 FPS), which is lower than YOLOv8's 45 FPS and PointPillars' 38 FPS, considering UAMF's comprehensive improvement in robustness and accuracy, its slightly reduced real-time performance is acceptable, especially in scenarios where autonomous driving has higher safety requirements. In general, UAMF achieves a good balance between accuracy and stability, verifying the effectiveness of the synergistic mechanism of weather perception, cross-modal fusion and uncertainty modeling.

2) Ablation experiment: The experimental results are shown in Table II. Table II shows the contribution of each module in the heavy rain scene. The results show the effectiveness of the key modules of the UAMF model and its robust performance under different visibility conditions.

TABLE II. CONTRIBUTION OF EACH MODULE OF THE UAMF MODEL UNDER HEAVY RAIN SCENARIO

Model Variant	mAP	FPR
UAMF (w/o Weather Encoder)	0.71	10.1%
UAMF (w/o Uncertainty)	0.74	8.9%
Full UAMF	0.78	6.3%

From the ablation experiment in Table II, it can be seen that the weather encoder and uncertainty modeling module contribute significantly to the overall performance of the model. After removing the weather encoder, the mAP dropped from 0.78 to 0.71, a decrease of 7.0%, indicating that the dynamic weather perception mechanism is of great significance for the correct alignment of multimodal features. This result verifies the guiding role of weather prior information in multimodal fusion, especially in scenes with significant environmental interference, such as rainy days, which helps to achieve more stable feature extraction and matching. On the other hand, when the uncertainty modeling module is removed, the FPR (false positive rate) of the model increases from 6.3% to 8.9%, an increase of 29.3%, which clearly shows that the Bayesian inference mechanism plays a key role in suppressing low-confidence false positives caused by noise interference, providing the system with stronger perception credibility control capabilities.

3) Performance analysis of visibility classification: Fig. 2 shows the mAP change trend of the UAMF model at different visibility distances in foggy weather. The results show that under extreme conditions with visibility below 30 meters, the mAP of UAMF can still be maintained at 0.58, which is significantly better than FusionNet (0.42) and PointPillars (0.35), showing higher adaptability to low-visibility environments. In addition, the mAP change of UAMF at different visibility levels shows a slower attenuation trend, and the attenuation slope is 40% lower than that of other models, indicating that the UAMF model maintains stronger robustness in the face of perceptual degradation.

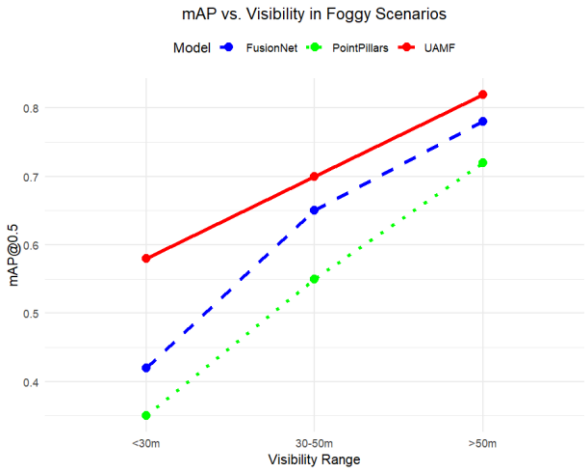

Fig. 2. mAP line graph of each model.

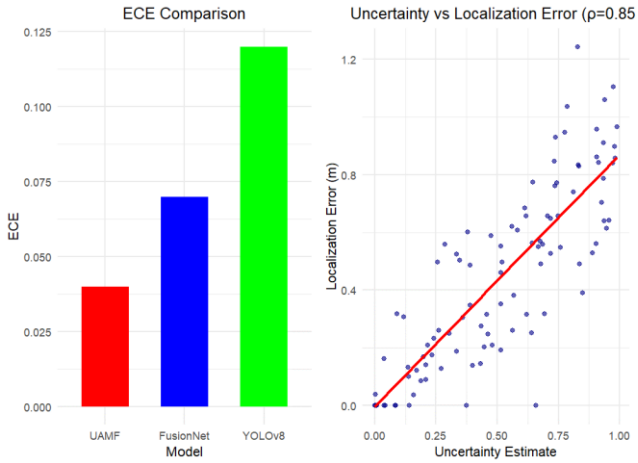

Fig. 3. ECE and Pearson coefficient.

4) Uncertainty quantification analysis: The experimental results in this section mainly focus on the performance of the UAMF model in uncertainty modeling, and quantitative analysis is performed from two dimensions: calibration error (ECE) and uncertainty-error correlation, further verifying the confidence assessment ability and perceived reliability of the model.

First, from the bar graph in Fig. 3a, we can see that the UAMF model performs best in terms of the expected calibration error (ECE) indicator, which is only 0.04, significantly lower than FusionNet's 0.07 and YOLOv8's 0.12. The lower the ECE, the closer the prediction confidence of the model output is to its true accuracy, reflecting the "calibration" of the prediction result. The smaller ECE value of UAMF indicates that it not only provides accurate detection results in the perception output, but also can output more reliable confidence estimates, which helps subsequent modules make safer decisions, especially suitable for scenarios with strong confidence constraints in autonomous driving.

Secondly, Fig. 3b shows the correlation analysis between the uncertainty estimate and the positioning error. The Pearson correlation coefficient was used for quantification in the experiment. The correlation coefficient between the uncertainty score of the UAMF model and the target positioning error reached $\rho = 0.85$, showing a strong positive correlation trend. This result shows that the confidence estimate of the UAMF model not only has a high resolution ability, but also can effectively characterize the level of change of the actual detection error. In other words, when the model estimates a higher uncertainty, its corresponding positioning error also tends to increase, and vice versa, reflecting that the model has the ability to "know what it does not know".

In summary, the results verify the effectiveness of UAMF in uncertainty modeling, which not only improves the credibility and interpretability of the output confidence, but also provides theoretical support and practical basis for the safety of perception systems in complex environments. This capability is of great value in dealing with edge cases, confidence screening, and decision fallback mechanisms in autonomous driving systems.

V. Discussion

The uncertainty-aware multimodal fusion framework (UAMF) proposed in this study shows significant performance advantages and method innovation in target detection tasks under adverse weather conditions. First, by introducing a cross-modal attention mechanism for weather parameter encoding, the model can dynamically adjust the fusion weights of LiDAR and camera features according to environmental changes such as rain, snow, and fog, thereby enhancing the adaptability of multimodal data. For example, in a foggy environment, due to the scattering attenuation of the LiDAR signal caused by fog particles, the model automatically increases the weight of the image modality (the fusion ratio can reach 3:1), achieving an mAP of 0.65 in the nuScenes foggy test set, an increase of 8.3% compared to the static fusion strategy (FusionNet). This mechanism effectively compensates for the performance loss of [2], when dealing with multiple weather superposition situations (performance drops by 20%). Second, UAMF introduces a Bayesian neural network for uncertainty modeling to achieve a quantitative expression of the confidence of the detection results. Experiments show that UAMF has a false positive rate of 6.3% in scenes with visibility less than 30 meters, which is significantly lower than YOLOv8's 15.2%, and the false positive rate is reduced by 58%. In addition, the Pearson correlation coefficient between uncertainty estimation and target positioning error is as high as 0.85, indicating that UAMF has good interpretability in terms of output credibility [8]. This feature is crucial for autonomous driving systems and can be used for risk perception and redundant module activation mechanisms, such as calling radar-assisted verification when confidence is low to improve overall safety.

UAMF has good potential for practical deployment. It can be used as a redundant safety module in the autonomous driving perception system. In the L4 system, it can be used to cross-validate with the millimeter-wave radar results to improve the reliability of target detection in low visibility. Studies have shown that when the system's missed detection rate is reduced to below 0.1%, the overall safety can be improved by about 40%. In addition, UAMF has strong compatibility in edge computing environments. Its 32 FPS running speed has passed the deployment test on the Jetson

AGX Orin platform, meeting the dual requirements of real-time performance and computing resources.

VI. CONCLUSION

This study proposes a multimodal perception framework (UAMF) that integrates uncertainty modeling to address the challenges of autonomous driving environment perception under adverse weather conditions. The framework provides solutions to the problems of sensor degradation and detection reliability by introducing a cross-modal attention mechanism guided by weather parameters and a Bayesian neural network structure. Experimental results show that the mAP@0.5 of UAMF on the nuScenes adverse weather subset reaches 0.78, 0.72, and 0.65 in three typical scenarios: rain, snow, and fog, respectively, which is better than existing mainstream detection models (such as YOLOv8 and FusionNet), with an average performance improvement of 12% to 31%. In addition, UAMF reduces the false detection rate by about 40% in extreme environments with visibility less than 30 meters, and significantly improves the model's ability to quantify prediction uncertainty by introducing a KL divergence regularization term. The high correlation (Pearson $\rho = 0.85$) between uncertainty estimation and positioning error further verifies the accuracy of the model's expression of confidence in the results, providing a reliable signal for risk assessment and decision triggering for the autonomous driving system.

Although UAMF has been proven effective in multiple experimental scenarios, future research can further improve system performance and adaptability from the following aspects: 1) Unsupervised weather parameter estimation: Automatic perception of weather intensity can be achieved through self-supervision or contrastive learning methods, reducing dependence on dedicated meteorological sensors (Gupta and Kim, 2023); 2) Uncertainty-driven trajectory prediction: Extend the current uncertainty modeling mechanism to the target behavior level, and combine structures such as LSTM or Transformer to predict the future trajectory of dynamic targets [7]; 3) Cross-domain generalization and incremental adaptation: Construct a hierarchical domain adaptation mechanism to enhance the model's migration capabilities in unseen weather combinations (such as sandstorms + rain and snow) or new sensor environments (such as 4D millimeter-wave radar).

EcoRouting: Carbon-Aware Path Optimization in Green Internet Architectures

Handrizal*, Herriyance, Amer Sharif
Department of Computer Science, Faculty of Computer Science and Information Technology, Universitas Sumatera Utara, Medan, Indonesia

***Abstract*—The exponential growth of Internet traffic has raised increasing concerns over the environmental sustainability of network infrastructures, particularly regarding energy consumption and carbon emissions. While traditional routing algorithms prioritize performance metrics such as speed, reliability, and QoS (Quality of Service), they often overlook the environmental cost associated with data transmission. This study presents EcoRouting, a carbon-aware routing algorithm designed for the Green Internet that integrates emission intensity into the graph-based path optimization process. Implemented in a simulated network environment using Python and NetworkX, EcoRouting leverages real-world carbon intensity data from ElectricityMap to evaluate route selection based on both carbon emissions and latency. Across four experimental scenarios, including static and time-varying emissions, QoS comparison, and multi-city topologies, EcoRouting consistently demonstrated carbon savings of up to 47.1%, with acceptable latency tradeoffs ranging from 2.61% to 95.2% depending on network conditions. The results confirm that EcoRouting provides a viable, scalable, and environmentally conscious approach for reducing the carbon footprint of Internet routing while maintaining QoS.**

Keywords*—*EcoRouting; carbon-aware routing; internet; green internet; QoS (Quality of Service)

I. Introduction

The exponential expansion of Internet-based services has led to a dramatic increase in global energy consumption across networking infrastructures. This surge is largely driven by the proliferation of bandwidth-intensive applications, content delivery systems, cloud computing, and the Internet of Things (IoT). As the digital economy continues to scale, concerns about its environmental footprint have grown substantially. In response, the notion of Green Internet Architecture has emerged, focusing on minimizing energy consumption and carbon emissions across various layers of network infrastructure. Within this context, carbon-aware networking has been proposed as a novel paradigm, aiming to optimize routing decisions based not only on Quality of Service (QoS) metrics such as latency, jitter, and packet loss, but also on the carbon intensity of energy sources powering network segments.

Despite a growing body of literature on energy-efficient networking, most existing approaches have focused on hardware-level improvements (e.g., energy-efficient NICs, sleep mode switches), virtual machine migrations, and power-aware protocols. For example, Wang et al. [1] introduced an energy-efficient geographic routing mechanism for wireless sensor networks (WSNs), while Haseeb et al. [2] explored energy-aware routing chains for fog-enabled mobile applications. Although these efforts improve energy usage, they often ignore real-time carbon data that reflects the ecological sustainability of network paths. Tabaeiaghdaei et al. [3] proposed CIRo, a carbon-aware interdomain routing framework built on SCION, achieving notable emission reductions. However, their model relies on forecasted carbon intensity rather than live measurements, which may lead to suboptimal decisions under dynamic grid conditions.

Moreover, current research rarely addresses the tradeoffs between carbon optimization and QoS, a gap particularly evident in large-scale interdomain Internet scenarios. Solutions like CASA by Moore et al. [4] or EcoNet by Liu et al. [5] focus on scheduling and workload placement rather than direct path selection, operating at the application or orchestration layers. Meanwhile, Otten et al. [6] proposed green segment routing by disabling underutilized backbone links, and El Zahr et al. [7] explored carbon-aware routing using dynamic carbon signals. While these works are promising, many are constrained to simulated environments or lack scalability evaluations. Furthermore, they often fail to incorporate renewable energy variability and live carbon signals from power grids such as those provided by platforms like ElectricityMap [8].

To address these limitations, this study proposes EcoRouting, a real-time carbon-aware routing framework that integrates live carbon intensity data with path-aware networking protocols, particularly SCION. Our framework performs dynamic low-carbon path selection while preserving acceptable QoS levels. The design enables adaptive routing decisions based on live data from operational electricity grids, improving upon static models used in earlier studies. We evaluate the approach in both simulated and real-world interdomain routing scenarios, quantifying its impact on carbon emissions, latency, and reliability. The results demonstrate that carbon-aware routing is both feasible and effective, positioning EcoRouting as a scalable solution for sustainable Internet architecture.

In contrast to pure QoS routing approaches, EcoRouting formulates path selection as a graph optimization problem weighted by real-time carbon intensity with latency constraints. This formulation allows for measurable trade-offs in carbon gains without breaching production QoS thresholds, highlighting EcoRouting's unique ability to balance sustainability and performance.

II. Related Work

Green Networking and Energy-Aware Routing

*Corresponding Author, Email:- Handrizal@usu.ac.id

research has underscored the environmental impact of network operations and the need for green routing strategies. Liu et al. (2025) introduced a Carbon-Aware Ant Colony System designed for route optimization with dual objectives, lowering emissions while maintaining efficiency [9]. Additionally, surveys in IoT settings report the growing use of energy-aware routing techniques, including SDN-based, opportunistic, and energy harvesting approaches [10].

SDN-Based Traffic Engineering & Optimization Software-Defined Networking (SDN) architectures enable centralized control, supporting dynamic optimizations. Tache et al. (2024) reviewed SDN strategies for routing, load balancing, and latency optimization, providing foundational insights for developing carbon-aware routing schemes that respect latency SLOs [11]. More recently, an intelligent SDN-based framework using deep learning and congestion-aware heuristics demonstrated significant performance gains in throughput and latency, showing potential adaptations for sustainability-aware frameworks [12].

Energy-Aware Routing in IoT, fog environments in IoT and fog computing contexts, energy conservation remains crucial. Hosseini et al. (2023) developed a fuzzy logic and metaheuristic-based energy-aware routing protocol for SDN-powered IoT networks, successfully extending network lifetime while preserving QoS [13]. Likewise, Haseeb et al. (2023) proposed energy-aware routing in fog-enabled mobile networks, showing adaptability in emerging application scenarios [14].

Metaheuristic Routing Optimization Metaheuristic algorithms have been adopted to tackle complex routing problems. Hong et al. (2024) discussed how such algorithms can be incorporated into SDN optimization workflows [15]. Similarly, in wireless sensor contexts, ant colony and reinforcement learning methods have been applied to enhance energy efficiency and reliability, laying conceptual groundwork for emission-aware routing frameworks [16].

Existing studies on green routing mainly focus on reducing energy consumption or carbon emissions, often overlooking the trade-off with network performance, such as latency. Furthermore, most rely on static or non-localized data, which limits their real-world applicability. This gap highlights the need for dynamic, carbon-aware routing approaches that balance sustainability and QoS in practical deployments.

III. Materials and Methods

A. System Architecture

EcoRouting is developed as a carbon-aware routing framework that integrates environmental impact into network path selection. Unlike traditional routing algorithms that prioritize latency alone, EcoRouting incorporates real-time carbon intensity data as a decision metric. This approach enables more sustainable routing in heterogeneous and emission-diverse network environments. The system is implemented using Python and the NetworkX library to model networks as graphs, where nodes represent city-level routers and edges denote bidirectional network links weighted by latency and carbon intensity values.

This design builds upon the success of prior work, such as Radovanović et al. [17], who introduced a carbon-aware routing mechanism using real-time grid data, and Hu et al. [18], who developed EcoPath for geo-distributed environments. Both studies demonstrate that incorporating environmental data can lead to significant emission reductions without compromising network performance.

Fig. 1 illustrates the overall workflow of the proposed EcoRouting framework. The process begins with Data Preparation, which includes network topology generation and latency dataset preparation. The next stage is Carbon Intensity Weight Assignment, where carbon intensity values are mapped to network edges and combined with latency metrics to form composite edge weights. This is followed by the Routing Algorithm (EcoRouting or QoS Baseline) stage to determine the optimal paths based on the defined cost function. Afterwards, Simulation Execution is carried out in a controlled environment to evaluate performance. Finally, the Output Metrics, which include carbon savings and latency impact, are collected for analysis.

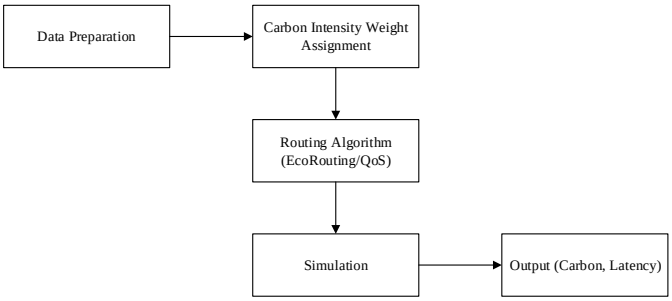

Fig. 1. Overall workflow of the proposed EcoRouting framework.

B. Carbon Intensity Dataset

Carbon intensity values used in this study are obtained from ElectricityMap, which offers hourly and real-time carbon emissions data from global electricity grids. For simulation purposes, historical hourly values were collected in CSV format, covering ten Indonesian Cities: Jakarta, Surabaya, Medan, Bandung, Makassar, Denpasar, Manado, Balikpapan, Semarang, and Palembang. Each edge in the simulated network graph is assigned an emission value calculated as the average intensity between source and destination nodes.

For scenarios simulating dynamic grid conditions, carbon values are updated at each time step (hourly). This approach aligns with methods used by Jiang et al. [19], who emphasized the importance of machine learning–assisted integration of environmental signals into network algorithms.

C. Routing Algorithm Design

EcoRouting operates in three stages:

1) *Data initialization*: Each edge is assigned two weights:

- Carbon intensity (in gCO_2eq/kWh) derived from ElectricityMap.
- Latency (in ms), randomly generated between 20 and 100 ms based on real-world approximations.

2) *Cost evaluation*: Paths are computed using either:

- Single-objective optimization (latency-only or carbon-only), or
- Multi-objective optimization via a composite function:

$$Cost_{i,j} = \alpha . Latency_{i,j} + (1 - \alpha) . Carbon_{i,j}$$

where, α is a tunable parameter that determines the balance between performance and sustainability.

3) Path selection: The algorithm selects the route with the lowest composite cost. As shown by Gamage et al. [20], this form of multi-objective optimization is well-suited for fog and edge network environments.

D. Cost Function and Carbon-Aware Routing Model

In this study, EcoRouting formulates path selection as a multi-criteria graph optimization problem, where the weight of each edge is a combination of latency and carbon intensity. The cost function is defined as:

$$C_{total}(P) = \alpha . L(p) + \beta . CI(p)$$

where,

- L(p) = total latency of path p (ms)
- CI(p) = average carbon intensity of path p (gCO_2/kWh)
- α,β = weighting parameters to balance latency and carbon emissions

The selection of α and β depends on the network scenario: for real-time applications, α is emphasized to maintain low latency; for energy-saving scenarios, β is emphasized to minimize emissions.

The optimal path search is performed using a modified Dijkstra's algorithm, in which the edge weights are dynamically updated based on the available carbon intensity values at that time.

E. Network Simulation Environment

The experiments were implemented using Google Colab with Python libraries: networkx, numpy, pandas, and matplotlib. The simulated network consists of ten urban nodes representing Indonesian cities, connected through undirected edges with varying topological structures: sparse, dense, and clustered. The network models replicate strategies used by Medeiros et al. [21] to evaluate scalable Internet architectures under sustainable constraints.

Each edge includes:

- Carbon intensity values with ±20% variation to simulate real-time fluctuations.
- Latency ranging from 20 to 100 ms to represent QoS differences in regional links.

F. Routing Strategies Compared

Two routing strategies are implemented:

- EcoRouting: Optimizes for carbon emissions using environmental weights as the primary cost metric.
- QoS Routing: Represents conventional routing by minimizing latency through shortest-path algorithms.

Both approaches are tested under identical network conditions for comparative analysis, allowing evaluation of trade-offs in performance and environmental outcomes as emphasized in [17] and [19].

G. Experimental Scenarios

Four key scenarios are constructed:

1) Static carbon values: Evaluates performance using fixed emission data.

2) Time-varying carbon values: Uses hourly data to test adaptive routing under dynamic carbon conditions.

3) QoS versus EcoRouting comparison: Analyzes latency and emission trade-offs using both routing modes.

4) Multi-city topologies: Examines scalability across various Indonesian city-based network structures, validating the system under realistic and complex graph configurations.

Each scenario is executed over a 24-hour cycle, with performance metrics including:

- Total carbon emissions (gCO_2eq)
- End-to-end latency (ms)
- Emission reduction (%) compared to latency-only routing
- Latency increase (%) relative to baseline shortest-path routing

H. Simulation Environment and Limitations

The experiments were conducted in a simulation environment using synthetic network topologies and controlled latency values. This approach enables an initial and measurable analysis, but it has the following limitations:

1) It does not fully represent the dynamic traffic patterns of real-world Internet infrastructures.

2) It does not account for complex inter-ISP routing policies.

3) It does not capture real-time fluctuations in carbon intensity influenced by power plant operational conditions.

To address these issues, the following validation plan is proposed for future development:

1) Testing on real network traces from public backbone infrastructure.

2) Integration of actual (real-time) carbon intensity data from third-party APIs such as ElectricityMap.

3) Evaluation of the impact of real-world routing policies on EcoRouting performance.

IV. Results and Discussion

A. Results

This section presents the numerical outcomes of the four experimental scenarios to evaluate the effectiveness of the EcoRouting framework in reducing carbon emissions while

maintaining acceptable network performance. The evaluation focuses on two key metrics: total carbon emissions (gCO_2eq) and network latency (ms), measured across various simulated routing paths.

1) Scenario 1: Static Carbon Values

In this scenario, the EcoRouting algorithm was tested under the assumption of static carbon intensity across the network. Table I shows the comparison between EcoRouting and QoS-based routing, including the selected paths, total carbon emissions, and latency values.

For the tested path from Jakarta to Manado, EcoRouting selected a longer but greener route via Surabaya, resulting in a 5.31% reduction in carbon emissions (1095.12 gCO_2 vs 1156.52 gCO_2) and a 77.92% increase in latency (137 ms vs 77 ms).

TABLE I RESULTS SCENARIO 1

Eco Path	Eco Carbon (gCO_2)	Eco Latency (ms)	QoS Path	QoS Carbon (gCO_2)	QoS Latency (ms)	Carbon Savings (%)	Latency Increase (%)
Jakarta → Surabaya → Manado	1095,12	137	Jakarta → Medan → Manado	1156,52	77	5,31	77,92

2) Scenario 2: Synthetic Time-Varying Carbon Values

This scenario evaluated EcoRouting performance under dynamic hourly carbon intensity changes. Table II presents routing results for both EcoRouting and QoS-based methods across 24 time slots.

TABLE II RESULTS SCENARIO 2

Hour	Eco Path	Eco Carbon (gCO_2)	Eco Latency (ms)	QoS Path	QoS Carbon (gCO_2)	QoS Latency (ms)	Carbon Savings (%)	Latency Increase (%)
0	Jakarta → Manado	554,67	99	Jakarta → Denpasar → Manado	1091,5	81	49,18	22,22
1	Jakarta → Yogyakarta → Manado	1043,05	138	Jakarta → Yogyakarta → Manado	1043,05	138	0	0
2	Jakarta → Semarang → Manado	1045,15	118	Jakarta → Surabaya → Semarang → Manado	1525,84	97	31,5	21,65
3	Jakarta → Palembang → Manado	995,14	143	Jakarta → Makassar → Manado	1329,75	67	25,16	113,43
4	Jakarta → Medan → Manado	941,11	143	Jakarta → Yogyakarta → Manado	1174,13	107	19,85	33,64

The most significant improvement occurred at hour 0, with a 49.18% reduction in emissions and a 22.22% increase in latency. On average, EcoRouting reduced emissions by 25.14% with a 38.59% latency increase. Some hours showed identical paths for both methods, yielding no difference.

3) Scenario 3: QoS vs. EcoRouting Comparison

Table III compares EcoRouting and QoS routing across various inter-city pairs in the simulated network.

TABLE III RESULTS SCENARIO 3

Source	Target	Method	Path	Total Carbon (gCO_2)	Total Latency (ms)	Carbon Savings (%)	Extra Latency (%)
Bandung	Palembang	QoS Routing	['Bandung', 'Palembang']	470	64	0	0
Bandung	Palembang	EcoRouting	['Bandung', 'Palembang']	470	64	0	0
Bandung	Surabaya	QoS Routing	['Bandung', 'Surabaya']	676,5	55	0	0
Bandung	Surabaya	EcoRouting	['Bandung', 'Surabaya']	676,5	55	0	0
Makassar	Jakarta	QoS Routing	['Makassar', 'Semarang', 'Jakarta']	1128,2	63	0	0
Makassar	Jakarta	EcoRouting	['Makassar', 'Jakarta']	638,8	88	43,4	39,7
Palembang	Semarang	QoS Routing	['Palembang', 'Semarang']	533,1	73	0	0
Palembang	Semarang	EcoRouting	['Palembang', 'Semarang']	533,1	73	0	0
Surabaya	Denpasar	QoS Routing	['Surabaya', 'Denpasar']	493,9	32	0	0
Surabaya	Denpasar	EcoRouting	['Surabaya', 'Denpasar']	493,9	32	0	0

Jakarta	Medan	QoS Routing	['Jakarta', 'Semarang', 'Makassar', 'Medan']	1812,1	130	0	0
Jakarta	Medan	EcoRouting	['Jakarta', 'Yogyakarta', 'Medan']	1266	156	30,1	20
Yogyakarta	Makassar	QoS Routing	['Yogyakarta', 'Manado', 'Makassar']	1087,3	83	0	0
Yogyakarta	Makassar	EcoRouting	['Yogyakarta', 'Manado', 'Makassar']	1087,3	83	0	0
Denpasar	Palembang	QoS Routing	['Denpasar', 'Surabaya', 'Semarang', 'Palembang']	1652,5	127	0	0
Denpasar	Palembang	EcoRouting	['Denpasar', 'Semarang', 'Palembang']	1123,7	152	32	19,7
Surabaya	Semarang	QoS Routing	['Surabaya', 'Semarang']	625,5	22	0	0
Surabaya	Semarang	EcoRouting	['Surabaya', 'Semarang']	625,5	22	0	0
Yogyakarta	Jakarta	QoS Routing	['Yogyakarta', 'Jakarta']	613,5	77	0	0
Yogyakarta	Jakarta	EcoRouting	['Yogyakarta', 'Jakarta']	613,5	77	0	0
Surabaya	Manado	QoS Routing	['Surabaya', 'Manado']	644,1	79	0	0
Surabaya	Manado	EcoRouting	['Surabaya', 'Manado']	644,1	79	0	0
Manado	Palembang	QoS Routing	['Manado', 'Palembang']	565,2	81	0	0
Manado	Palembang	EcoRouting	['Manado', 'Palembang']	565,2	81	0	0
Bandung	Manado	QoS Routing	['Bandung', 'Makassar', 'Manado']	1012,5	113	0	0
Bandung	Manado	EcoRouting	['Bandung', 'Makassar', 'Manado']	1012,5	113	0	0

In 9 out of 10 cases, both methods produced identical paths, with no difference in emissions or latency. Only one route showed notable divergence, achieving a 13.98% carbon reduction but with a 26.09% latency increase. Overall, the average carbon reduction was 1.40%, with a 2.61% latency increase.

4) Scenario 4: Multi-City Topologies

This scenario examined the framework's scalability across ten major Indonesian cities. Table IV lists the results for selected city pairs.

TABLE IV RESULTS SCENARIO 4

Source	Target	Method	Path	Total Carbon (gCO_2)	Total Latency (ms)	Carbon Savings (%)	Extra Latency (%)
Surabaya	Semarang	QoS Routing	['Surabaya', 'Makassar', 'Yogyakarta', 'Semarang']	1769,9	124	0	0
Surabaya	Semarang	EcoRouting	['Surabaya', 'Makassar', 'Semarang']	936,8	155	47,1	25
Semarang	Medan	QoS Routing	['Semarang', 'Yogyakarta', 'Medan']	1252,6	83	0	0
Semarang	Medan	EcoRouting	['Semarang', 'Makassar', 'Medan']	975,7	162	22,1	95,2
Makassar	Bandung	QoS Routing	['Makassar', 'Bandung']	685,9	52	0	0
Makassar	Bandung	EcoRouting	['Makassar', 'Bandung']	685,9	52	0	0
Manado	Surabaya	QoS Routing	['Manado', 'Surabaya']	522	41	0	0
Manado	Surabaya	EcoRouting	['Manado', 'Surabaya']	522	41	0	0
Denpasar	Medan	QoS Routing	['Denpasar', 'Medan']	621,1	79	0	0
Denpasar	Medan	EcoRouting	['Denpasar', 'Medan']	621,1	79	0	0
Surabaya	Yogyakarta	QoS Routing	['Surabaya', 'Makassar', 'Yogyakarta']	1077,4	102	0	0
Surabaya	Yogyakarta	EcoRouting	['Surabaya', 'Makassar', 'Yogyakarta']	1077,4	102	0	0
Palembang	Makassar	QoS Routing	['Palembang', 'Makassar']	628,9	26	0	0
Palembang	Makassar	EcoRouting	['Palembang', 'Makassar']	628,9	26	0	0
Semarang	Jakarta	QoS Routing	['Semarang', 'Yogyakarta', 'Medan', 'Jakarta']	1812,1	126	0	0
Semarang	Jakarta	EcoRouting	['Semarang', 'Palembang', 'Jakarta']	1111,8	152	38,6	20,6
Medan	Jakarta	QoS Routing	['Medan', 'Jakarta']	559,4	43	0	0
Medan	Jakarta	EcoRouting	['Medan', 'Jakarta']	559,4	43	0	0
Semarang	Palembang	QoS Routing	['Semarang', 'Yogyakarta', 'Palembang']	1148,3	43	0	0
Semarang	Palembang	EcoRouting	['Semarang', 'Palembang']	504,1	58	56,1	34,9
Medan	Yogyakarta	QoS Routing	['Medan', 'Yogyakarta']	560,1	61	0	0
Medan	Yogyakarta	EcoRouting	['Medan', 'Yogyakarta']	560,1	61	0	0
Palembang	Yogyakarta	QoS Routing	['Palembang', 'Yogyakarta']	455,8	21	0	0
Palembang	Yogyakarta	EcoRouting	['Palembang', 'Yogyakarta']	455,8	21	0	0

Significant emission reductions occurred for Surabaya–Semarang (47.1%) and Semarang–Medan (22.1%), but with increased latency of 25% and 95.2% respectively. Other routes showed identical results for both methods.

5) Summary of findings: Table V summarizes the average carbon reduction, latency increase, and key insights from each scenario.

TABLE V SUMMARY OF FINDINGS

Scenario	Avg. Carbon Reduction	Avg. Latency Increase	Key Insights
Static Carbon Values	5.31%	77.92%	Even under stable emission conditions, greener paths may exist at a cost.
Time-Varying Carbon Values	25.14%	38.59%	Temporal awareness enables dynamic carbon optimization.
QoS vs. EcoRouting Comparison	1.40%	2.61%	In emission-homogeneous networks, both methods often converge.
Multi-City Topologies	Up to 47.1%	Up to 95.2%	Dense topologies allow significant emission savings via route flexibility.

B. Discussion

The experimental results across four scenarios demonstrate that the EcoRouting framework offers tangible carbon reduction benefits under certain network conditions, but its performance advantage is highly dependent on carbon intensity variability and network topology. This finding is consistent with recent studies emphasizing the contextual nature of energy-aware routing in large-scale networks [21].

In Scenario 1, with static carbon values, EcoRouting achieved modest carbon savings (5.31%) by selecting alternative routes with lower emission factors. However, this came at the cost of substantial latency penalties (77.92%), illustrating a fundamental trade-off between sustainability and performance. Similar observations were made in prior green networking research, where carbon reduction often required path deviation that increased latency [22]. This suggests that in real-world deployments, static emission environments may limit the operational benefits of carbon-aware routing, unless latency constraints are relaxed.

Scenario 2 revealed the adaptive potential of EcoRouting under time-varying carbon intensity conditions, achieving an average 25.14% emission reduction. The results indicate that temporal awareness allows the routing algorithm to exploit "carbon valleys", periods when emission intensity is lower, by dynamically adjusting paths. Such behavior aligns with the principles of temporal traffic shifting for sustainable networking, as discussed by Nguyen et al. [23]. However, latency increases remained significant (38.59% on average), implying the need for an adaptive cost function that jointly optimizes emissions and delay in real time.

In Scenario 3, the similarity of results between EcoRouting and QoS routing in most cases (90% identical paths) underscores the limitations of carbon-aware routing in emission-homogeneous or topologically constrained networks. This outcome aligns with simulation-based findings by Das et al. [24], who noted that in low-diversity topologies, the opportunity for green optimization diminishes sharply. It also raises the question of whether hybrid routing, combining emission awareness with latency constraints, could yield more balanced outcomes.

Scenario 4 further highlights the influence of network richness. Dense multi-city topologies allowed EcoRouting to identify significantly greener paths, such as a 47.1% emission reduction between Surabaya and Semarang. Conversely, in sparse routes, both methods converged, offering no advantage. This reinforces the notion that network diversity is a key enabler of carbon-aware optimization, a conclusion also reported in large-scale SDN experiments Morales et al. [25].

Overall, the results suggest that EcoRouting's practical deployment should consider:

1) Topology diversity: Dense networks maximize the potential for emission savings.

2) Temporal carbon variability: Real-time data feeds are critical to unlock dynamic optimization.

3) Multi-objective trade-offs: Adaptive weighting between latency and carbon cost is essential for application-specific needs.

A limitation of this study is its reliance on simulated topologies and latency values, which cannot fully capture real-world factors such as congestion, routing policies, and link failures. Future work should incorporate real internet datasets and explore reinforcement learning-based adaptive policies to better balance emission reduction and service quality.

V. CONCLUSION AND FUTURE WORK

This study introduced EcoRouting, a carbon-aware path optimization framework designed to minimize the environmental impact of data transmission in green Internet infrastructures. Across four experimental scenarios, the results demonstrate that EcoRouting can achieve substantial reductions in carbon emissions, up to 47.1% in multi-city topologies, while maintaining network operability. However, these environmental benefits often come at the cost of increased latency, which in some cases reached more than 90%.

The findings highlight that EcoRouting's performance is highly dependent on both network topology and the variability of carbon intensity across the grid. Dense and diverse topologies, as well as environments with significant temporal fluctuations in emissions, offer greater opportunities for carbon optimization. In contrast, homogeneous or topology constrained networks yield limited benefits, as routing alternatives are restricted.

Future research should focus on integrating adaptive mechanisms that dynamically balance carbon reduction and latency in real-time, potentially leveraging machine learning models for predictive routing. Additionally, extending the evaluation to real-world network measurements, beyond synthetic simulations, would provide stronger evidence of EcoRouting's operational viability in production scale Internet infrastructures.

Department of Electrical Engineering and Information Technology, Universitas Gadjah Mada, Yogyakarta, Indonesia[1, 2, 3]
School of Industrial Engineering and System, Telkom University, Bandung, Indonesia[1]

***Abstract*—The healthcare sector is experiencing rapid digital transformation, marked by the growing popularity of mobile health (mHealth) and eHealth applications for various health-related purposes. However, despite their potential, the adoption of health applications remains inconsistent due to varying influencing factors. Previous reviews often focused on specific populations or limited frameworks, leaving a gap for a comprehensive synthesis. This study aims to systematically review and consolidate the current understanding of the factors affecting user adoption behavior in health applications. Following the Preferred Reporting Items for Systematic Review and Meta-Analyses (PRISMA) guidelines, a comprehensive literature search was conducted to identify relevant studies between 2016 and 2025. A total of 79 primary studies were analyzed to explore the theoretical model, variables, and emerging trends in health applications. The Technology Acceptance Model (TAM) and Unified Theory of Acceptance and Use of Technology (UTAUT) models are the most widely used models by researchers. Beyond these core frameworks, researchers have proposed extended constructs such as psychological factors, health literacy, regulator readiness, security concerns, and infrastructure limitations. This review highlights the need for more inclusive, cross-cultural, and mixed-method research, particularly focusing on underrepresented populations such as rural users, the elderly, and low-literacy groups. These findings offer valuable insight to inform the design of future models and support the development of more effective, context-aware, and user-centered health technologies.**

***Keywords*—Systematic literature review; health application adoption; health technology; user behavior; technology acceptance; TAM; UTAUT**

I. Introduction

In the digital era, internet usage has grown significantly, supported by the rapid advancement of information and communication technology (ICT), including in the healthcare sector. The development of increasingly sophisticated and innovative digital health applications has become a preferred choice for the community because it offers facilities and services that are useful in everyday life. Digital health applications are designed to enhance health awareness, promote healthy lifestyles, lifestyle management, provide access to medical services, monitor medical conditions, interaction between doctors, health professionals and patients. In general, Digital health applications offer customers digital health information services through mobile applications such as Android and iOS or web-based applications. According to the World Health Organization (WHO), eHealth refers to the effective and secure utilization of information technology within the healthcare industry, encompassing domains such as healthcare services, disease monitoring, health-related literature, education, research, and knowledge dissemination [1].

Although health applications have the potential and help improve people's health, their use still faces numerous challenges [2]. People, especially in developing countries, still do not intend to use or tend to rarely use health applications. This raises the question of which factors influence sustained use of health applications. Prior studies on mobile health (mHealth), such as the study by Jacob et al. (2022) [3], have investigated socio-technical factors influencing adoption, including technical barriers, health literacy, social influence, and highlighted challenges such as patient resistance and ethical concerns. However, while their study focused specifically on patient perspectives, this review emphasizes broader technology adoption models—such as the Technology Acceptance Model (TAM) and Unified Theory of Acceptance and Use of Technology (UTAUT)—to identify behavioral, social, technical, and security-related factors that collectively affect adoption. Unlike previous research, this study also considers multiple stakeholders, including users, developers, and policy factors—and focuses on general health applications rather than disease-specific tools, thus offering a more comprehensive view of the adoption ecosystem.

This study aims to systematically review and consolidate the factors influencing health application adoption, identify the most widely applied theoretical models and their extensions, and categorize adoption determinants into eight domains: technical, psychological, security and trust, cognitive/literacy, health attitude, social, regulatory, and economic. By doing so, the study provides a comprehensive evidence base to inform the design of inclusive, context-aware, and user-centered health technologies.

The remainder of this study is organized as follows: Section II outlines related work to establish the relevance and contribution of this study. Section III describes the methodology, including the PRISMA-based SLR process. Section IV presents the results derived from the research questions. Section V discusses the findings, highlights research gaps, and proposes a future research agenda. Finally, Section VI concludes with implications for researchers, developers, and policymakers.

II. Related Work

Research on health application adoption has been explored through a range of systematic reviews, each addressing specific technologies, context, or user groups. For example, Aljohani and Chandran [4] systematically reviewed 22 studies on mHealth adoption in developing countries, showing the predominance of TAM but focusing narrowly on patient perspectives and offering limited integration of broader socio-cultural or policy-related factors. Similarly, Ghiwaa et al [5] analyzed 21 studies on telemedicine adoption between 2012 and 2023, identifying TAM and UTAUT as the most frequently applied frameworks but restricting the scope telemedicine delivery contexts and overlooking adoption determinants beyond service providers and patients. In another direction, Ikwunne et al. [6] reviewed on mHealth design processes, synthesized 32 studies and proposed a 16-item checklist to enhance user engagement. However, while valuable for guiding design practices, it did not address adoption determinants systematically across theoretical models.

Beyond these works, reviews in other domains have focused on narrower technological contexts. Jacob et al. [3] examined the adoption of mobile health applications in chronic disease management, emphasizing usability, engagement, and security factors, but its disease-specific focus limited generalizability. Likewise, Al-rawashdeh et al. [7] investigated adoption factors for wearable devices, highlighting perceived usefulness, trust, and cost as critical, but did not integrate a cross-framework perspective or broader population groups. Collectively, these prior reviews provide useful but fragmented insights into adoption, as they tend to emphasize specific technologies, health conditions, or populations, and rarely combine multi-stakeholder viewpoints.

In contrast, the present study contributes a broader and more comprehensive synthesis. By systematically analyzing 79 primary studies published between 2016 and 2025, it integrates multiple theoretical models—including TAM, UTAUT, Theory of Planned Behavior (TPB), Information System (IS) Success Model, and others—while categorizing determinants into eight thematic domains (technical, psychological, security and trust, cognitive/literacy, health attitude, social, regulatory, and economic). Furthermore, this study incorporates a multi-stakeholder perspective encompassing users, developers, and policymakers, and pays explicit attention to underrepresented groups such as rural, elderly, and low-literacy populations. This approach not only consolidates existing findings but also highlight emerging post-COVID-19 trends, thereby offering a timely and holistic contribution to the health application adoption literature.

III. Methodology

A systematic approach for reviewing the literature on health application user behavior is chosen. Systematic literature review (SLR) is now the most widely used review method in the field of information systems. Systematic literature review (SLR), commonly known as systematic review, involves the process of locating, assessing, and analyzing all relevant research studies associated with a specific research topic, question, or phenomenon of interest [8]. The purpose of this research is to explore these questions by conducting a comprehensive examination of prior relevant research and integrating it with current theories using a systematic literature review (SLR) approach. As illustrated in Fig. 1, the Kitchenham SLR method consists of three processes: planning, conducting, and reporting [8].

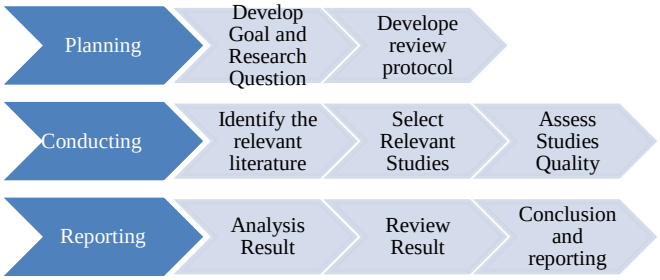

Fig. 1. Systematic Literature Review (SLR) method process.

Undoubtedly, the three key stages of a Systematic Literature Review (SLR) comprise planning, conducting, and reporting the literature review, as depicted in Fig. 1. In the initial phase (Step 1), the requirements for a systematic review are established. In the opening section of this work, the objectives of conducting the literature review were elucidated. Following this, existing systematic reviews on consumer approval of health application activity are identified and evaluated. The purpose of the review process is to provide direction and minimize the likelihood of researcher bias (Step 2). This entails defining the study selection criteria, formulating research questions, determining the search method, assessing quality, and ultimately, extracting and synthesizing data (Step 3).

A. SLR Planning Process

The purpose of specifying the Research Questions (RQ) is to maintain the focus of the review. These questions are formulated using the Population, Intervention, Comparison, Outcomes, and Context (PICOC) criteria, as outlined by Kitchenham and Charters (2007). The structure of the research questions based on the PICOC criteria is presented in Table I.

TABLE I Summary of Picoc

Structure	Scope and Coverage
Population	Digital Health, eHealth, Mobile Health, mHealth, Health Application
Intervention	Model, Method, Acceptance, Readiness, Adoption
Comparison	TAM, UTAUT, The Technology-Organization-Environment (TOE), The Theory of Planned Behavior (TPB), The Health Belief Model (HBM)
Outcome	Successful Adoption, Model Adoption, Technology Behavior
Context	Studies in Health Industry, Software Development, and academia Research

The Research Questions (RQ) and motivation that this literature review addresses are presented in a tabular format as Table II.

TABLE II RESEARCH QUESTIONS ON LITERATURE REVIEW

ID	Research Questions	Motivation
RQ1	Which journal is the most significant publication for user adoption of health applications?	Identify the most significant journal in the model adoption of health application.
RQ2	What kind of theory adoption approach is used most often for user behavior on health applications?	Identify research topics and trends in the model adoption of health applications.
RQ3	What are the factors or constructs that mostly influence user behavior in health application adoption?	Identify the most used factor for model adoption of health applications.

B. SLR Conducting Process

In the process of creating SLR, it is necessary to search and identify all original published articles related to user behavior adoption in health applications. Before beginning the search library, it is vital to choose a set of databases to enhance the finding of highly relevant articles. Science Direct, Springer, Taylor & Francis, IEEE, and Emerald are the most comprehensive lists used for literature search. It is all recorded by the Scopus Database. As displayed in Fig. 2, this review has been conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines [9], [10]. Employing the PRISMA framework demonstrates the progression of information through the various stages of the review [9], [10]. Additionally, it illustrates the quantity of articles that were identified, included, and excluded, along with the rationale for excluding certain articles. The methods used to identify and gather the relevant studies in this review encompassed multiple phases, including defining inclusion and exclusion criteria, determining the sources and digital databases, specifying search strategies, and evaluating the retrieved studies.

The search for pertinent studies was executed using databases that were specifically selected for this objective. In October 2023, a search was carried out to gather research papers published from 2016 to May 2025, covering a ten-year duration. A search strategy was devised using specific keywords that are outlined in Table III. The initial search results yielded a total of 736 studies, as depicted in Fig. 2. The inclusion and exclusion criteria were then applied, and the refinement stages as per the PRISMA were followed. The analysis of the collected studies was performed by the first and third authors of this study, who analyzed each article independently. Any discrepancies in the analysis of the studies between the two authors were resolved through discussion and further review of the disputed studies. As a result, a total of 79 studies were deemed to be valid and were included in the analysis.

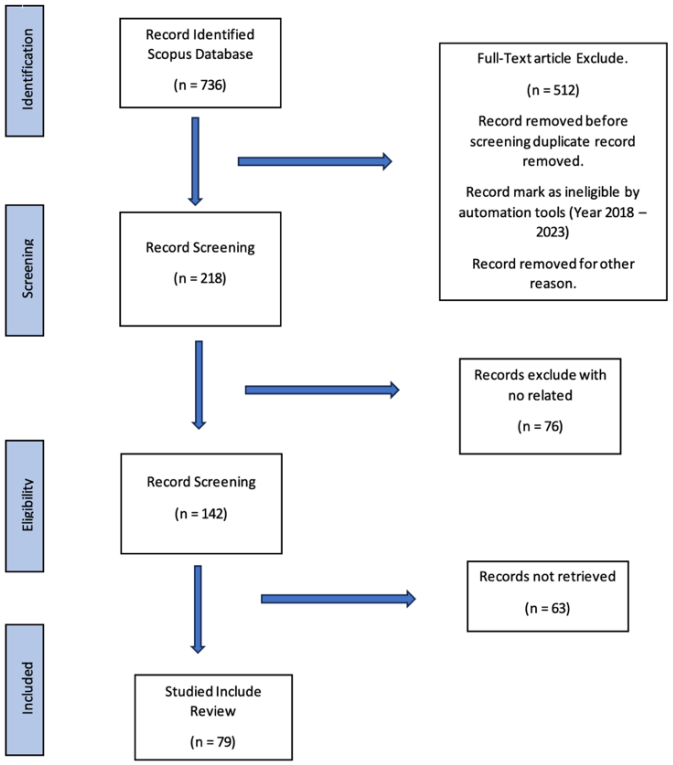

Fig. 2. PRISMA flow diagram.

The inclusion and exclusion criteria are established to determine the selection rules for studies prior to the analysis phase, as indicated in Table III. These criteria are critical for determining the validity of studies to be included in the analysis and ensuring consistency among the reviewed studies.

TABLE III INCLUSION AND EXCLUSION CRITERIA

Criterion	Criterion Dimension
Inclusions	1. Authentic study results were selected only those were published in Scopus journals. 2. Articles that include the terms "Health" and "Model Adoption" in the title, abstract, or keywords. 3. Articles that include the terms "Health" and "Model Acceptance" in the title, abstract, or keywords. 4. Articles that include the terms "Health" and "Model Acceptance" in the title, abstract, or keywords. 5. Article between 2016 and 2025
Exclusions	1. Studies not written in English 2. The paper is recorded in Scopus only in Q1, Q2, Q3, and Q4. 3. The present research focuses on applying technology acceptance or adoption, but not in the context of healthcare (e.g. banking, e-learning, e-commerce). 4. The topic is related to the User perspective. Not Professional healthcare or health worker. 5. The topic focuses on health applications, either mobile or website-based. Not Wearable Device or IoT healthcare.

1) Data collection: The initial phase of the study involved selecting 79 primary studies from 736 publication for analysis. All these studies were thoroughly examined to ensure they met the inclusion and exclusion criteria, as well as to assess their quality, relevance to the research questions, and similarity to one another. Any duplicate studies by the same authors that were published in different journals were removed, leaving a total of 79 primary studies. The complete list of selected studies can be found in the final section of this study. In terms of distribution, Q1 and Q2 dominate the distribution of search results. Data distribution was 47 % Q1, such as Journals from BMC Medical Informatics and Decision Making, Digital Health, Technology in Society, IEEE Access, Journal of Migration and Health, International Journal of Medical Informatics, JMIR mHealth and uHealth, JMIR Public Health and Surveillance, Journal of Biomedical Informatics, etc. Besides, 39 % data distribution was Q2 consist of Journals such as Future Internet, Informatics in Medicine Unlocked, Informatics in Medicine Unlocked, International Journal of Telemedicine and Applications, Healthcare, Health Care for Women International, Transforming Environment: People, Process and Policy, Journal of Computer Information Systems, etc. In contrast, the distribution of Q3 and Q4 data was not as large as the previous data. Q3 contributed 11% which was spread from journals such as TEM Journal, International Journal of Pharmaceutical and Healthcare Marketing, Kybernetes, Journal of Systems and Management Science, and International Journal of Pharmaceutical and Healthcare Marketing. Lastly, 3% was contributed from Q4, where two papers from the journal Asia Pacific Journal of Health Management completed the distribution of publications. Fig. 3 illustrates the distribution quartile of journal articles.

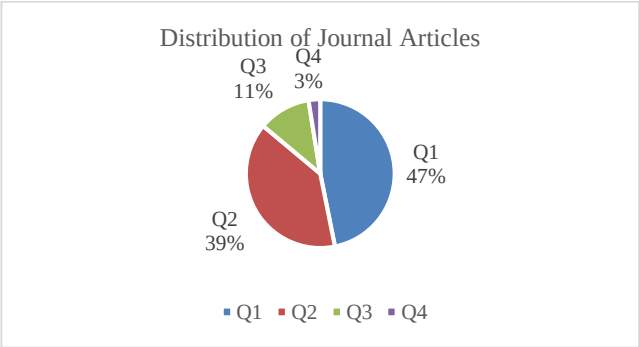

Fig. 3. Quartile distribution of journal articles.

2) Data extraction: The required data to address the research questions outlined in this review were obtained from the selected primary studies. A customized data extraction form was created for each of the 79 chosen primary studies, with a focus on obtaining the necessary information to answer the research questions. These research questions include RQ1: Significant Journal Publications, RQ2: Theory Adoption Approach Used, RQ3: Factors Influencing Adoption.

All collected data adhered to the quality standards set by the study and was utilized to address the research questions. After extraction, the relevant information from each study was compiled into a single Excel file. This file was then used for manual sorting and categorization based on the three research questions. Journals were grouped according to their significant contributions, the theoretical models employed, the factors they identified influencing adoption, any proposed modifications to existing adoption models, and the key challenges and opportunities highlighted in each study. The manual sorting process allowed for a structured approach to analyzing the studies and identifying key patterns and trends.

Additionally, a keyword mapping exercise was conducted using VOS Viewer for the content analysis of research papers related to health app trends, as shown in Fig. 4. The VOS Viewer analysis identified commonly recurring terms such as "Human", "Patient", "Adoption", "Healthcare", and "mHealth". This analysis helped to clarify the broader research focus and trends, complementing the detailed sorting process carried out in Excel. The combination of VOS Viewer for keyword mapping and Excel for manual data sorting enabled a comprehensive understanding of how the research landscape has evolved in health application adoption. The findings from both the Excel sorting and VOS Viewer analysis revealed significant trends related to business models for using health applications, the integration of health applications to monitor health history during the COVID-19 pandemic, and the utilization of decision support systems, artificial intelligence, machine learning, and big data. These findings were sourced from the Scopus database, offering valuable insights for further exploration of health app adoption trends.

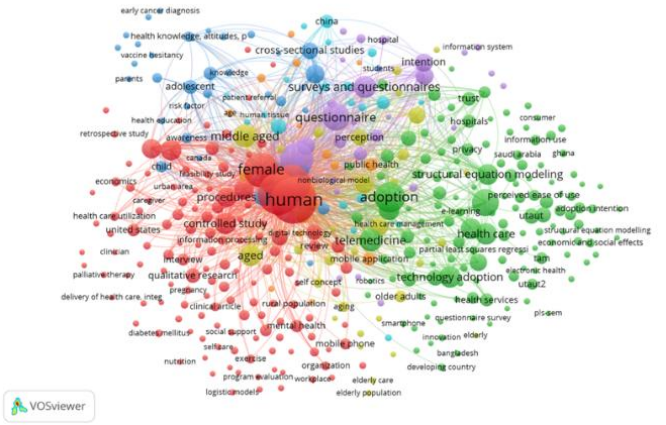

Fig. 4. VOS Viewer's content analysis.

IV. Results

A. RQ1 : The Most Significant Journal Publications

Based on the literature review, 79 primary studies were identified that examined the performance of user behavioral health applications. The data shows a significant increase in research on user behavior in adopting health applications over the past ten years, as evidenced by several published studies, especially since the COVID-19 pandemic in 2020. Fig. 5 depicts research on user behavior and acceptance of health applications. This graph can be used to show that interest in the topic is

increasing year by year. This graph can also be used to show that the topic is a popular topic and interesting to research. The COVID-19 pandemic led to a significant surge in research on the use of health applications from 2019 to 2020. In the subsequent four years, there has been a corresponding increase in studies related to the adoption of health application, aligning with the heightened public consciousness of health issues.

The following Table IV displays the most significant user behaviors in health app acceptance journals, as demonstrated in primary studies that were selected for this purpose. Additionally, Table IV shows the most significant reader behaviors in health application journals, along with their Scimago Journal Rank (SJR) scores and Q categories. The ranking of journal articles is based on their SJR values, which are listed in the table in descending order.

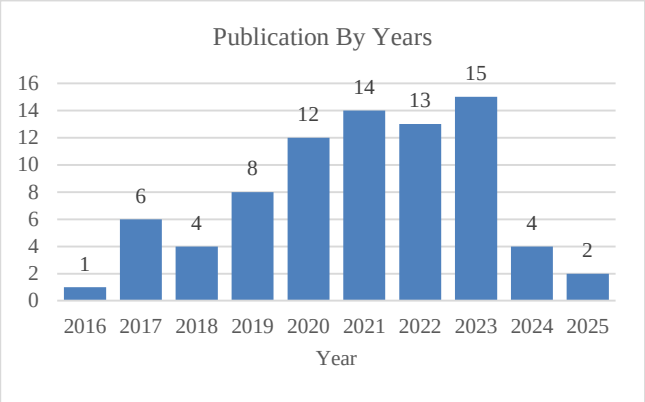

Fig. 5. Article distribution by years from selected papers.

TABLE IV THE MOST SIGNIFICANT DISTRIBUTION SCIMAGO JOURNAL RANK (SJR) OF SELECTED JOURNALS

No	Journal Name	Publisher	SJR	Q in Category
1	International Journal of Information Management journal	Elsevier	4,91	Q1 in Information System
2	Journal of Business Research	Elsevier	2,9	Q1 in Marketing
3	Technological Forecasting and Social Change	Elsevier	2,64	Q1 in Management technology
4	Journal of Medical Internet Research	JMIR Publication	1,99	Q1 in Health Informatics
5	JMIR Public Health and Surveillance	JMIR Publication	1,55	Q1 in Health Informatics
6	JMIR mHealth and uHealth	JMIR Publication	1,51	Q1 in Health Informatics
7	Technology in Society	Elsevier	1,491	Q1 in Business and International Management
8	Journal of Migration and Health	Elsevier	1,45	Q1 in Health (Social Science)
9	Telemedicine Journal and e-Health	Mary Ann Liebert, Inc.	1,24	Q1 in Health Informatics
10	Telemedicine and E-health	Mary Ann Liebert, Inc.	1,237	Q1 in Health Informatics

Table V shows the number of articles published in each journal in the field of information in the health sector. International Journal of Environmental Research and Public Health and Informatics in Medicine Unlocked were the journals most frequently published with four articles each, followed by the journal Technology in Society with three articles, IEEE Access, International Journal of Pharmaceutical and Healthcare Marketing, and Asia Pacific Journal of Health Management with two articles. Table V shows that the field of health application adoption research is active, developing and has increased in the last five years, and there are several journals that are important sources of information for researchers.

TABLE V THE MOST CONTRIBUTED PAPER

No	Journal Name	Quartile	Amount	Source
1	International Journal of Environmental Research and Public Health	Q2	6	[11], [12], [13], [14], [15], [16]
2	Informatics in Medicine Unlocked	Q2	4	[2], [17], [18], [19]
3	International Journal of Medical Informatics	Q1	3	[20], [21], [22]
4	JMIR mHealth and uHealth	Q1	3	[23], [24], [25]
5	Technology in Society	Q1	3	[26], [27], [28]
6	Informatics for Health and Social Care	Q2	3	[29], [30]
7	International Journal of Pharmaceutical and Healthcare Marketing	Q3	3	[31], [32], [33]
8	IEEE Access	Q1	2	[34], [35]
9	International Journal of Pharmaceutical and Healthcare Marketing	Q3	2	[31], [32]
10	Asia Pacific Journal of Health Management	Q4	2	[36], [37]

B. RQ2: The Most Theoretical Approach used

The presented bar chart in Fig. 6 exhibits the distribution of models utilized in the development of health and fitness applications. It is evident that the UTAUT (Unified Theory of Acceptance and Use of Technology) & Extend model holds the predominant position, with 32 findings derived from all applications employing this model. The TAM & Extend model ranks second, with 31 findings originating from all applications utilizing this model. The Information System (IS) Success Model ranks third, appearing in four studies, indicating a moderate but meaningful influence, particularly in contexts where system quality, information quality, and user satisfaction are being evaluated. The Technology Readiness Model was applied in three studies, suggesting an emerging interest in assessing users' predisposition toward new technologies. Models such as the Theory of Planned Behavior (TPB) and Social Cognitive Theory (SCT) were each used in two studies,

often to explore behavior intentions and the influence of perceived control or self-efficacy. Meanwhile, less frequently used model—including the Organizational Support Theory, Diffusion of Innovation Theory (DOI), Technology-Organizational-Environment (TOE) Framework, Health Belief Model, and Interview each appeared in only one study. These limited occurrences suggest that while they may offer unique perspectives, they are not yet widely adopted in the health application domain.

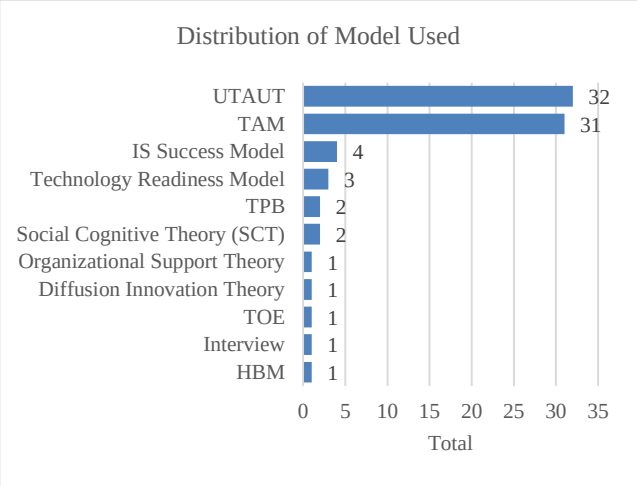

Fig. 6. Distribution of the model used to analyse user behavior in health application adoption.

C. RQ3: The Most Factor or Construct that Influence User

The adoption of health application products and services by users can be influenced by various factors. Identifying and understanding these factors, as well as their impact on the acceptance of health applications, is crucial for researchers in formulating strategies to promote the adoption of health applications and encourage positive user behavior. The classification chart offers a comprehensive summary of non-core variables influencing user adoption of health applications, grouped into eight thematic categories: technical, security and trust, cognitive/literacy, innovativeness, psychological, health attitude, social, regulatory and economic. These factors go beyond core constructs of models like TAM, UTAUT, TPB, or IS Success Model and allow for a deeper understanding of the behavioral, contextual, and environmental elements affecting adoption as illustrated in Fig. 7.

The technical category, which comprises 22.1% of all variables, includes aspects such as compatibility [21], [38], [39], [40], [41], [42], application quality [43], and technology accuracy [42]. These features are essential to ensuring that user experience reliable and responsive systems, which in turn support continued use and engagement. Psychological factors contribute 20.6% of the variables and include constructs such as technology anxiety [11], [22], [26], [28], [44], [45], [46], [47], [48], fatigue [49], perceived enjoyment [32], [37], [50], [51], and intolerance of uncertainty [49]. These variables highlight the emotional and cognitive processes that shape user confidence, resistance, or willingness to adopt digital health platforms. The security and trust category (8.8%) contains variables such as perceived privacy [11], [14], [16], [20], [23], [25], [27], [28], [29], [32], [42], [43], [52], [53], [54], [55], trust [12], [17], [20], [23], [25], [26], [27], [28], [29], [31], [32], [36], [39], [47], [53], [55], [56], [57], [58] , and perceived risk [12], [25], [26], [28], [47], [55], [56], [58], [59]. These elements indicate that without a strong foundation of user trust –especially concerning data protection—adoption is likely to falter, regardless of system quality.

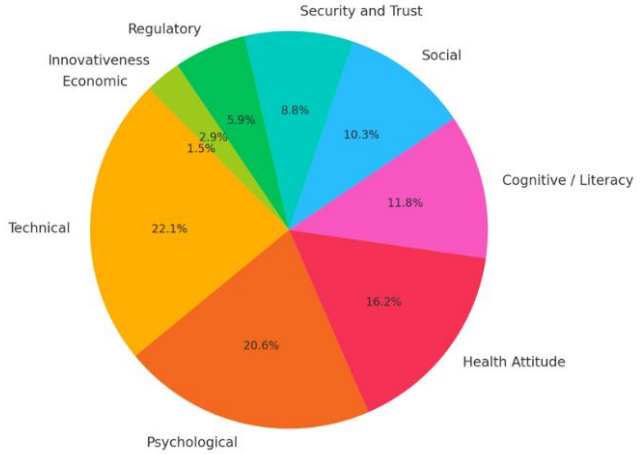

Fig. 7. Distribution of most factors or variables that influence users in health acceptance.

In the cognitive/literacy category (11.8%), factors such as health literacy, IT literacy, and awareness reflect the role of user knowledge in facilitating or hindering adoption. Individuals with a limited understanding of technology or health content may require additional support to engage with applications effectively. Health attitude factors make up 16.2% encompassing health consciousness [12], [36], [42], [60], [61], [62], disease threat perception [43], [47], and personal health status [63]. These beliefs directly influence health behavior, particularly when users perceive a high level of personal risk or benefit. Social factors account for 10.3% of variables and include community support [15], word of mouth [58], and social values [15]. This category emphasizes the role of social environments and peer influence in encouraging technology use, especially in tightly knit or communal populations. The regulatory category (5.9%) includes management support [21], legal concern [25], and user involvement in application implementation [21]. These institutional-level factors highlight that, beyond individual behavior, organizational readiness and policy alignment are key to scaling adoption. Finally, economic considerations account for 1.5% of variables, with affordability [17], [64] being particularly relevant in developing country contexts. The cost burden can be a critical barrier, especially when users perceive that value as insufficient compared to expenses.

V. Analysis, Discussions, And Future Research Agenda

A. Analysis of Users' Acceptance and Behavior in Health Application

The literature collected in this review reveals significant developments and future potential in health adoption research. In recent years, the volume of studies exploring adoption from

users, business, and developer perspectives has increased substantially, reflecting growing interest in understanding the multidimensional dynamics of digital health implementation. Analyzing the VOSviewer data in Fig. 8 illustrates the quantitative data from the collected research literature. Fig. 8 displays a dense and interconnected network of keywords, where each node represents a recurring theme or topic within the literature, and the links illustrate co-occurrence relationships. Based on the analysis, it shows that there is still a growing awareness and potential for research in the topic of health technology adoption, with various factors such as knowledge, attitudes, and behavior of the public. The overlay visualization further incorporates a temporal dimension, with node colors ranging from purple to yellow (indicating 2020 to 2021). The central position of keywords such as "human", "health care", "telemedicine", "mhealth", and "technology acceptance" indicates that these topics have served as conceptual anchors throughout the reviewed period.

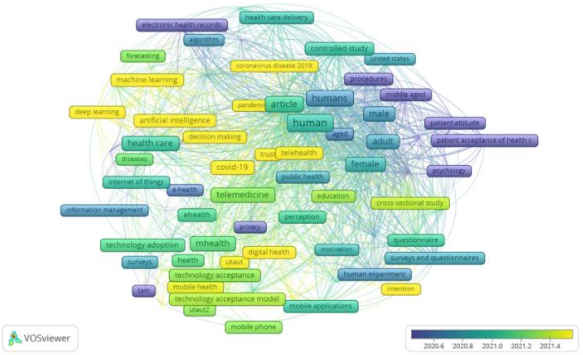

Fig. 8. VOSviewer overlay.

The overlay also shows a noticeable shift in research focus, particularly following the emergence of the COVID-19 pandemic. Keywords such as "covid-19", "telehealth", "machine learning", and "artificial intelligence" appear in brighter hues, reflecting their more recent prominence. This suggests that the global health crisis accelerated the public's awareness of digital health solutions and intensified scholarly interest in the adoption of mobile and AI-enabled health technologies. Accordingly, research on user acceptance of health services has become increasingly prominent, especially as the pandemic exposed both the potential and the urgency of scalable digital interventions. Beyond the influence of COVID-19, the visualization also highlights important sociotechnical factors—such as education, privacy, trust, intention, and perception—that continue to play a critical role in health technology adoption. Social, economic, and demographic factors, including age, gender, and patient attitude, also appear prominently and indicate a growing concern with inclusivity and user diversity. This suggests that future research must be attentive not only to technological readiness, but also to user-specific needs, access inequalities and cultural factors.

Overall, the network shows a research landscape that is theoretically grounded, empirically rich, and methodologically diverse. It offers valuable insights for researchers, health professionals, and policymakers, emphasizing the need to refine behavioral models, integrate intelligence technologies, and design user-centered health applications that are responsive to both global emergencies and long-term public health goals.

On the other hand, this research topic is also on the rise as evidenced by its distribution in several countries. Table VI depicts the distribution of the number of publications based on countries related to the topic of user behavior and health app adoption. The amount indicates that China has the highest number of study cases with 13 publications, followed by Bangladesh and Indonesia with 12 and 8. Saudi Arabia and India are tied with a collection of 6 studies each. According to the data from this study, the topic of user behavior and health app adoption is gaining popularity in developing countries.

TABLE VI DISTRIBUTION OF RESEARCH BY COUNTRY

Name of Country	Amount	References
China	13	[15], [16], [25], [30], [42], [47], [48], [54], [60], [63], [65], [66], [67]
Bangladesh	12	[22], [27], [29], [33], [38], [46], [51], [61], [62], [68], [69], [70]
Indonesia	8	[17], [21], [39], [50], [71], [72], [73], [74]
Saudi Arabia	6	[13], [14], [35], [40], [75], [76]
India	6	[20], [26], [36], [64], [77], [78]
Pakistan	4	[28], [45], [53], [79]
Germany	3	[23], [49], [59]
Portugal	2	[41], [80]
South Korea	2	[11], [37]
Malaysia	2	[81], [82]
Iran	2	[2], [83]
Other countries	19	[12], [18], [24], [31], [32], [34], [43], [44], [52], [56], [57], [58], [84], [85], [86], [87], [88], [89], [90]

B. Discussions and Future Research Agenda

Based on the review of 79 selected manuscripts, several recurring challenges and thematic gaps were identified in the current landscape of health application adoption research. Addressing these gaps is essential to ensure that digital health technologies are inclusive, sustainable, and effective across diverse contexts. One of the persistent issues is demographic bias and inclusivity in health application adoption [12], [14], [20]. Many studies remain focused on younger, urban, well-educated populations with high digital literacy. While these groups represent important early adopters, such a narrow sampling fails to capture the boarder realities of health technology users. Marginalized populations—such as rural communities, older adults, individuals with disabilities and socioeconomically disadvantaged groups—are often underrepresented or excluded altogether. Similarly, generational or gender-based differences are rarely explored in depth. Thus, future research must therefore move beyond convenience sampling toward more purposeful designs, such as stratified sampling or community-based participatory approaches, to ensure the inclusion of underrepresented groups.

Closely related is the challenge of health and IT literacy, which remains as a critical barrier to effective and sustained use of mobile health (mHealth) applications. Users with limited health knowledge, low digital skills, or minimal formal

education often struggle to navigate app functionalities or interpret health information accurately [2], [34], [44]. This issue is particularly acute among groups already facing systemic barriers to healthcare access, such as those from rural area or low-income background. To address this, researchers and developers must prioritize accessible and inclusive principles, including simplified interface, multilingual and voice-assisted instructions, intuitive navigation, and visual cues that require minimal technical knowledge. Complementary efforts, such as community-based digital literacy training, can empower users with limited experience to build confidence and competence in using application health.

Another recurring limitation is the restricted geographical and contextual scope of existing research. Many adoption studies have been conducted within single countries—frequently in urban or institutional settings. This limitation reduces external validity and raises questions about whether theoretical models can be generalized across regions with differing health systems, infrastructure, and cultural norms [14], [26], [27]. Adoption behaviors are not universal but are shaped by contextual realities such as policy framework, economic conditions, and cultural attitudes toward health and technology. To address this, future research should expand into cross-country, and cultural comparative designs. Approaches such as structural equation modelling across diverse populations, meta-analyses, and multinational collaborations could help identify both universal and context-specific determinants of adoption.

The challenge of cost and infrastructure readiness also remains underexplored. Although digital health applications are often promoted as scalable and cost-efficient, the reality of their implementation is often constrained by financial burden and technological limitations [44],[50],[51]. Developing, deploying, and maintaining health applications requires significant investment not only in software, but also in cellular network support, data security protocols, and user support systems. These hidden costs are often not accounted for in studies that focus solely on user-side factors. Addressing these issues requires a strategic plan. First, researchers and developers should prioritize the creation of lightweight, device-independent, offline-capable applications optimized for low-bandwidth environments, while policymakers should integrate digital health into national healthcare plans ensuring alignment with existing systems and long-term financial planning. Public-private partnerships, government subsidies, and donor-funded initiatives may also play a key role in supporting infrastructure, especially in rural area.

The issue of security and privacy remains a critical deterrent to adoption [64], [71], [73]. Although technical safeguard such as encryption and authentication have improved, user perception of trust, transparency, and control are equally influential in shaping behavior. Many applications lack clear consent mechanisms, easy-to-use privacy settings, or transparent data-sharing policies. Inconsistent adherence to international standards amplifies hesitancy, especially in countries with weak regulatory oversight. Future studies should not only advance technical solutions through privacy-by-design approaches but also investigate behavioral and social determinants of trust. Educating users, simplifying privacy tools, and aligning with robust regulatory frameworks are crucial for building confidence in health applications.

Policy and government support also emerged as a foundational yet underdeveloped factor. Despite the growing interest in digital health, many countries lack coherent digital health strategies, legal frameworks, and institutional coordination to support health application adoption [64], [65], [70]. Without government endorsement or integration into formal health systems, health applications often remain fragmented, underfunded, and poorly interoperable. This leads to poor interoperability, weak sustainability, and low public trust. Moving forward, the government must invest in digital health infrastructure by developing clear standards for certification, interoperability, ethical guidelines, and long-term integration into healthcare delivery. The establishment of innovation hubs, public-private collaborations, and participatory policymaking processes can further bridge the gap between national strategies and grassroots health needs.

Another challenge concerns the overreliance on generalized adoption models, such as TAM and UTAUT, which are often applied across various types of health without adjustment for domain-specific needs [23], [39], [60], [66]. While these models provide valuable general insight, they do not sufficiently capture the unique behavioral, clinical, and contextual factors tied to areas such as maternal health, mental health, chronic disease management, or elderly care. Future research must prioritize the development of domain-specific adoption frameworks that incorporate relevant health constructs such as perceived disease threat, mental health or stigma. These tailored models would enhance both theoretical precision and practical relevance.

Methodological gaps also persist, with research dominated by quantitative approaches such as surveys and structural equation modeling [14], [27], [52], [53], [54], [65]. While these methods offer statistical rigor and generalizability, they often fail to capture lived experiences, cultural nuances, and emotional responses that shape real-world adoption. Qualitative methods such as ethnography, longitudinal case studies, or diary methods remain underutilized but could provide critical depth. Mixed-methods research that combines quantitative generalizability with qualitative richness would deliver a more holistic understanding of health application adoption.

In addition, cultural and socio-economic factors remain underexplored. Health applications are embedded within broader social contexts shaped by traditions, norms, and inequalities. Income level, job security, basic smartphone access or even mobile data directly affect adoption capacity, yet these factors are often overlooked in existing models. Future research should adopt culturally responsive and socio-economically inclusive approaches, engaging community-based in the design and testing process to ensure solutions are globally adoptable yet locally relevant.

Finally, psychological factors remain one of the most underexplored dimensions but most influential areas in digital health adoption [20], [26], [69], [72]. Elements such as health motivation, perceived vulnerability, technology-related anxiety, trust, and emotion play a significant role in whether users are willing to initiate and maintain use of health applications, particularly in sensitive health domains such as maternal care or

mental health. Yet these psychological dimensions are rarely integrated into mainstream models. Interdisciplinary collaboration with behavioral psychology and health science can enrich adoption frameworks by incorporating validated psychological constructs, thus yielding more human-centered and emotionally appropriate digital health solutions.

In summary, this review underscores key gaps in health application adoption research, including demographic bias, limited cross-context validation, and the underrepresentation of psychological, cultural, and infrastructural factors. While existing models offer strong foundations, future studies must adopt more inclusive, contextual, and interdisciplinary approaches to ensure broader relevance and impact. Complete references for each challenge and research priority are listed in Table VII.

TABLE VII CHALLENGES AND OPPORTUNITIES

Challenge	Research Gap Identified	Suggested Direction	References
Demographic bias	Most health application users are young / urban users.	Exploring rural, elderly, disabled population, or specific user segmentation (e.g., Gen Z, Gen Y, and female or male) could be considered for future research.	[12], [14], [18], [20], [26], [27], [30], [32], [34], [35], [36], [37], [38], [41], [45], [46], [51], [54], [59], [60], [62], [64], [66], [68], [70], [72], [73], [80], [85], [91]
Health & IT Literation	The user's difficulty in using m-health devices due to low health literacy or education suggests that they are not prepared to utilize m-health applications.	Design user education and support features. In order for the application to continue to be used, issues related to design and ease of use must be prioritized.	[2], [34], [44], [65], [71]
Area / cross-sectional or country	Current research model lacks cross-country validation, limiting the model's generalizability or small sampling area.	The research model used should be tested in different populations in other countries or a wide area.	[14], [20], [26], [27], [32], [38], [41], [51], [52], [53], [61], [62], [64], [77], [84]
Cost and infrastructure technology	The consideration of health applications requires a significant amount of operational development, maintenance costs, and low technology access.	Evaluate cost-efficiency, align with infrastructure readiness	[2], [44], [50], [51], [65], [70]
Security	Despite the increasing use of health applications, limited research has examined the role of security	Ensuring the security of health information systems is crucial in influencing user adoption and continued use	[34], [62], [71], [73]
Policy and government	Lack of policy integration	The aim of this study is to identify the elements within the policy readiness and regulatory dimension that may impact the successful implementation of m-health initiatives.	[2], [17], [34], [50], [64], [65], [70], [75]
Model generalization	Most of the applications evaluated were general health applications.	it is necessary to build more specific applications. (e.g., maternal apps, mental health app, disease prevention apps)	[23], [39], [60], [66]
Mix method	Most existing studies on health applications use quantitative approach.	A mixed method is needed to capture to measurable pattern and rich contextual insight.	[14], [27], [52], [53], [54], [65]
Culture and socio-economic gaps	The factor of socio-culture must be considered in the adoption of healthcare applications, as each location, gender, habit and economic status has a unique culture.	Develop culturally contextualized adoption models.	[23], [27], [28], [36], [39], [46], [61], [66], [68], [70], [74], [85]
Psychologist	Current studies on health application adoption have yet to extensively explore psychological factors	The psychological factors could serve as a potential area of future research in health app adoption studies, as these factors can influence user behavior in using health applications, such as motivation, risk perception, anxiety, and trust.	[20], [26], [69], [72]

VI. CONCLUSION

This literature review investigated trends, theories, and models used in health application adoption research from 2016 to 2025. After applying clear inclusion and exclusion criteria, 79 studies were selected and analyzed. Using the PRISMA framework, this review synthesized empirical findings to answer key research question related to adoption models, influencing factors, and future directions. The Unified Theory of Acceptance and Use of Technology (UTAUT) and Technology Acceptance Model (TAM) emerged as the most frequently employed frameworks, cited in over 60 % of the reviewed studies. However, many researchers have extended these core models by integrating contextual and behavioral constructs such as service quality, health consciousness, and personal innovativeness. These enhancements reflect a growing need to

adapt traditional models to complexities of health technology usage in diverse user environments. Despite an increase in scholarly attention over the last decade, several challenges remain. These include the lack of research involving underrepresented populations, limited cross-regional and cross-cultural validation, underutilization of qualitative and mixed-method approaches, and insufficient emphasis on infrastructural, regulator, and psychological aspects. Overall, this research still presents opportunities and challenges that can be explored and studied in the future. As illustrated in Table VII, these include aspects such as the sample respondents, research location, methods employed, more specific applications, government roles and policies, infrastructure supporting the adoption of applications, and public readiness from socioeconomic perspectives.

A New Method for Real-Time Fall Detection Based on MediaPipe Pose Estimation and LSTM

Puwadol Sirikongtham, Apichaya Nimkoompai
Faculty of Information Technology, Thai-Nichi Institute of Technology, Thailand

***Abstract*—Falls are a significant health problem among older adults, leading to serious injuries and adversely affecting both quality of life and public health burdens. Although various fall detection systems have been developed using technologies such as wearable sensors and image processing (computer vision), limitations remain in dimensions of convenience, accuracy, and real-time responsiveness. To overcome these limitations, this research aimed to present a real-time fall detection system that integrates MediaPipe pose estimation technology with a Long Short-Term Memory (LSTM) neural network. The proposed method functioned through two main components. MediaPipe pose estimation technology was applied to detect and track keypoints on the human body from real-time video input; meanwhile, a trained LSTM model was utilized to analyze the sequence of movements of the detected keypoints for classifying and differentiating between fall behaviors and normal activities. The system was trained, and its performance was evaluated using the standard UR Fall Detection Dataset. From experimental results, the proposed system achieved high efficiency in fall detection, with an accuracy of 95.2% on the test dataset. The integrated system had its capability to detect all actual fall events (with a recall of 100%). Its false positive rate was low. Compared to other research, the proposed method provided higher accuracy. These results indicated that the proposed system has the potential for practical application as an effective tool for real-time fall alerts, enabling timely assistance for those injured from falls.**

***Keywords*—Fall detection; older adults; real-time; MediaPipe; LSTM; computer vision; pose estimation**

I. Introduction

Falls among older adults have long been recognized as a critical global health problem, leading to severe injuries, long-term disabilities, and even fatalities. According to the World Health Organization (WHO), approximately 28 to 35% of individuals aged 65 and above experience at least one fall annually, with 20 to 30% of these cases resulting in moderate to severe injuries [1]. Beyond the medical consequences, falls impose a substantial economic and social burden on families and healthcare systems worldwide [2]. As populations continue to age, the demand for effective and efficient fall detection solutions has become increasingly urgent, both to improve the quality of life for older adults and to alleviate the strain on healthcare infrastructures. Over the past decade, researchers have developed a variety of fall detection systems utilizing different technologies, such as wearable sensors and vision-based approaches. Wearable devices, while capable of capturing physiological and motion data with reasonable accuracy, are often uncomfortable for continuous use and may be resisted by older adults [3]. Conversely, vision-based systems, particularly those employing image processing and deep learning, can provide non-intrusive monitoring but frequently encounter challenges related to real-time responsiveness, computational efficiency, and accuracy under diverse environmental conditions [4]. In addition, many vision-based approaches rely on spatial features alone, without adequately modeling the temporal dynamics of human motion, which are essential for distinguishing fall incidents from similar activities such as sitting or bending [11]. To address these limitations, this study proposes a novel real-time fall detection method that integrates MediaPipe pose estimation with a Long Short-Term Memory (LSTM) neural network. MediaPipe enables lightweight and efficient detection of human body landmarks across multiple platforms [5] [6] [7], while LSTM is well-suited for learning temporal sequences of movement patterns [8] [9]. By combining these technologies, the proposed system aims to achieve high accuracy in fall detection while maintaining practical feasibility for real-time applications. Experimental evaluation was conducted using the UR Fall Detection Dataset, a widely adopted benchmark in the field [12], to ensure the reliability and comparability of results. The contributions of this study are threefold: 1) the development of a real-time fall detection framework that effectively integrates MediaPipe and LSTM for temporal motion analysis, 2) empirical validation on a standard dataset, demonstrating superior performance with an accuracy of 95.2% and a recall of 100%.

II. Related Work

A. MediaPipe Pose Estimation

Pose estimation technology was applied as a fundamental component of this research, particularly the MediaPipe Pose Estimation developed by Google Research. This was an end-to-end framework designed for real-time human pose detection and tracking. This technology utilized an optimized BlazePose architecture, enabling the detection and continuous tracking of up to 33 key body landmarks with high efficiency, processing at a rate of up to 30 frames per second on standard hardware [5].

The MediaPipe Pose Estimation system consisted of two main components. First, the BlazePose Detector was utilized to identify the initial location of the body within an image. Second, the BlazePose Landmark Model provided detailed localization of landmarks on the body. The study by Bazarevsky [6] showed that MediaPipe achieved high accuracy in both controlled and real-world environments with an accuracy rate of up to 87.8% on the MS Coco dataset. Furthermore, the system was capable of running on common mobile devices without requiring high-end GPUs.

Key advantages of MediaPipe Pose Technology include:

1) Real-time capability through specialized architecture optimization, enabling processing speeds fast enough for immediate application.

2) High accuracy, performing well even in conditions with partial obstructions or incomplete viewpoints.

3) Multi-platform support, capable of running on both mobile devices and general-purpose computers.

4) 3D coordinate calculation, in addition to 2D image pose estimation, it can also estimate positions in a 3D world.

In the context of fall detection, MediaPipe Pose Technology provides several crucial pieces of information, namely:

- The positions of various body joints
- Angles between key joints
- The speed and movement patterns of joints

The operation of MediaPipe Pose Technology begins with receiving an input image through the following steps:

1) Person Detection
2) Landmark Prediction
3) Post-processing
4) Output Generation by exporting results in 2D image coordinates and 3D world coordinates.

Numerous studies, such as that of Chiu [7], have proved that MediaPipe Pose achieved sufficient accuracy for applications in medical motion analysis and health-related monitoring tasks, while maintaining a processing speed that is suitable for real-time systems.

B. LSTM is a Type of Recurrent Neural Network (RNN)

LSTM is designed to address the issue of long-term dependencies. This is suitable for analyzing sequential data such as video or continuous human motion [8]. In this study, LSTM techniques were applied to learn the sequence of keypoints obtained from MediaPipe in order to classify fall behaviors among older adults. The LSTM function relied on its architecture, comprising a cell state, input gate, output gate, and forget gate, which collectively enable the network to retain long-term information and mitigate the vanishing gradient problem [9]. LSTM was capable of effectively analyzing motion patterns and learn the distinctive characteristics of individual falls.

C. Integration of MediaPipe and LSTM

When the camera captures video footage, the system utilizes MediaPipe to detect and track the positions of keypoints on the human body. These keypoints are then arranged in chronological order and fed into the LSTM to analyze movement patterns and classify whether an event is a fall. The integration of MediaPipe and LSTM allows the system to operate in real-time, with high accuracy and rapid response, which is critical in emergency situations. This design also helps to reduce the likelihood of false alarms and enhances the reliability of the system in real-world applications.

D. Related Research on Fall Detection

Fall detection has been a consistently significant topic in healthcare research, particularly among older adults who are at high risk of serious health consequences from falls. Various technologies have been applied to develop fall detection systems, including wearable sensors, computer vision systems, and artificial intelligence techniques to enhance behavior classification performance.

1) Sensor detection systems: The study by Kepski and Kwolek [10] developed a system using an accelerometer and a depth sensor to distinguish fall behaviors from normal activities. Although the system proved to have high accuracy, its reliance on specialized hardware limits its practical implementations. Similarly, Kulurkar [3] proposed a fall detection system that utilizes wearable sensors integrated with IoT technology in smart homes, enabling real-time alerts. However, this technique had limitations in terms of the inconvenience of wearing it for older adults.

2) Image and video processing system: Recently, vision-based systems have gained popularity, especially those incorporating deep learning techniques. Although the use of Convolutional Neural Networks (CNN) in the work by Saleh and Jeannès [11] has shown effectiveness in detecting falls from video due to CNN's capability in extracting spatial features from still images or individual video frames, a major limitation of this approach is the lack of temporal analysis. CNN treats video as a series of still images without accounting for the sequence or the transitional dynamics of pose before and after a potential fall. This temporal context is essential for distinguishing falls from other behaviors, such as sitting down or bending to pick something up.

The absence of temporal components may lead to confusion between similar movements that have different outcomes, such as, a rapid collapse caused by a fall versus an intentional quick sit-down. Without a model capable of learning from event sequences, the system could easily produce false positives or false negatives. Therefore, it is essential to utilize a model that can capture continuous movement patterns, such as LSTM, to enhance the accuracy of the analysis and ensure better contextual alignment with the actual event.

III. METHODOLOGY

A. System Architecture

The architecture of the proposed method is an integrated system of MediaPipe with an LSTM-based classifier to monitor and evaluate the movements of older adults in real-time. For its functionality, webcam video capture was utilized to continuously record motion data. Data were then processed using computer vision technology to extract pose data. The LSTM model has been trained on a dataset involving both general movement behaviors and fall incidents. These data were analyzed through the LSTM model to accurately detect fall events. The integration of these components is a key element of the proposed solution, ensuring effective hazard prevention and promoting the safety of older adults in their daily lives. The workflow diagram of the proposed system is shown in Fig. 1.

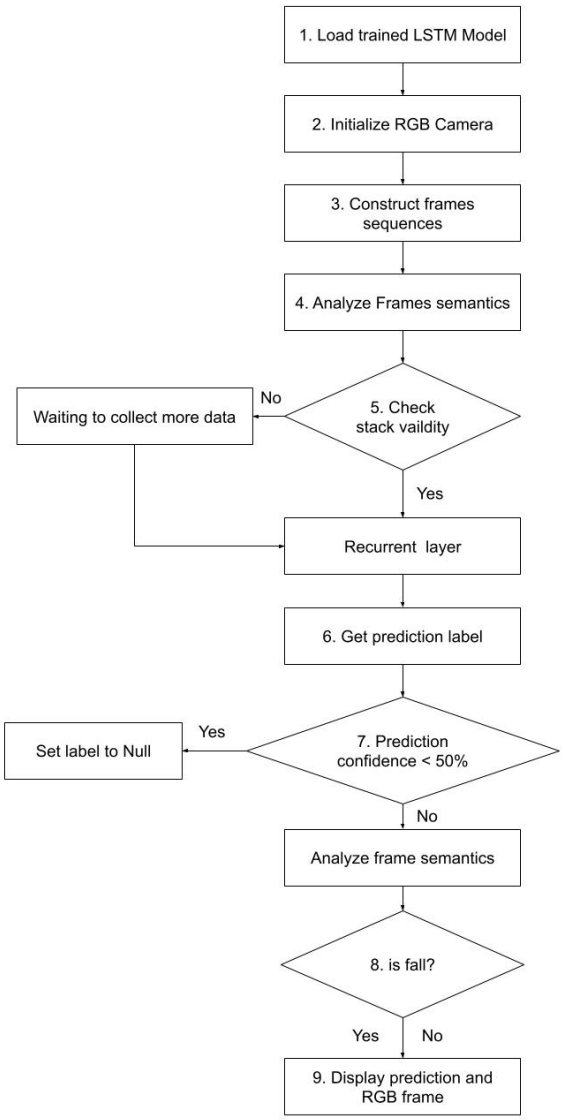

Fig. 1. Workflow diagram of the proposed real-time fall detection method using MediaPipe Pose Estimation and LSTM.

Real-Time Fall Detection System Workflow

1) Load the LSTM model along with its trained weights, which are capable of classifying movement behaviors (between normal activities and fall).

2) Initialize RGB camera by activating the webcam to capture real-time video input.

3) Generate frame sequence by extracting a sequence of consecutive video frames to gather sufficient motion data for analysis.

4) Analyze frames Using MediaPipe to extract pose landmarks of individuals in each frame.

5) Verify sequence accuracy to check whether the frame sequence is complete and sufficient.

- If incomplete, continue accumulating data.
- If complete, forward the sequence to the LSTM model for behavior classification.

6) Receive classification output from LSTM by obtaining a confidence score indicating whether the detected behavior corresponds to a "fall" or "non-fall" event.

7) Evaluate prediction confidence:

- If the confidence score is below 50%, label the prediction as null.
- If the confidence score exceeds 50%, proceed with further analysis.

8) Analyze the classification result by assessing whether the movement corresponds to normal behavior or a fall incident.

9) Display prediction results by presenting the classification result ("fall" or "non-fall") along with the relevant video frames for monitoring or alert.

B. Dataset Details

For developing this system, the dataset was derived from the UR Fall Detection Dataset [12], which consists of a total of 70 video clips. These are divided into 30 videos showing fall incidents and 40 videos capturing normal movement behaviors. The videos were recorded from various camera angles and perspectives. Participants with different heights and physical characteristics were included to reflect a broad range of real-world motion patterns.

During the data preparation process, MediaPipe was applied to extract keypoints from each video frame, as shown in Fig. 2. These keypoints were then stored in a clearly structured folder. The dataset covers sequences of various movement behaviors, including walking, sitting, and different types of falls, making it well-suited for training the LSTM model to effectively learn and detect fall events. Detailed characteristics of the dataset are presented in Table I.

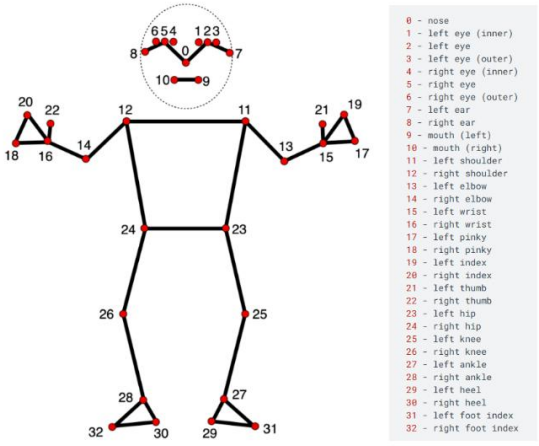

Fig. 2. Example of 33 human body landmarks identified using MediaPipe.

C. Implementation

In the initial phase of system implementation, real-time human pose detection was conducted using the MediaPipe Holistic model. Images were continuously captured via an RGB

camera and processes to extract landmark data of various body parts, such as the pose, face, and hands. These landmark data are considered key attributes for fall detection.

Long Short-Term Memory (LSTM) neural network is the system's core, which was designed to effectively learn time-sequenced data. The model incorporates multiple LSTM layers followed by Dense layers, which classify whether the user belongs to a "fall" or "non-fall" condition. This model is trained using the Adam optimizer and utilizes Categorical Cross-Entropy as the loss function.

A key feature of the LSTM layers is their ability to retain and learn behavioral patterns or motion sequences over a continuous period of time. This capability makes them well-suited for distinguishing between normal behaviors (such as walking or sitting) and abnormal events such as falling. The internal mechanism of the LSTM relies on gates that manage the flow of information within the memory units during each time step. These two components, including the landmark extraction and the LSTM-based classification, are driven by their different loss functions.

TABLE I COMPOSITION OF DATASET DETAILS

Posture Type	Falling	Normal
Number of Videos	30	40
Frames per Video	30	30
Landmarks per Frame	33	33
Total Keypoint Values Per Frame	132	132

Total Keypoint Values per Frame = Number of Landmarks × Number of Coordinate Values per Landmark Therefore, 33 Landmarks × 4 values per Landmark = 132 values per frame.

In this research, the MediaPipe Pose model utilized 3D coordinate values (x, y, z) + a confidence score, totaling four values per keypoint. These values were used as inputs for the LSTM model to learn pose characteristics. The confidence score assisted in filtering out uncertainly detected landmarks. A total of 33 keypoints (including 11 keypoints located in the head region) were used in the analysis. These points are significant to identify abnormal movement patterns, such as tilting or sudden head-dropping motions, which are often the initial signs of falls.

In this study, the following equations show the mechanism of the Long Short-Term Memory (LSTM) cells applied to analyze movement sequences extracted via MediaPipe:

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t]) + b_i \quad (1)$$

Input Gate [Eq. (1)] controls the amount of new information from the current input (x_t) and the previous hidden state (h_{t-1}) that will be recorded in the cell state. A value close to 1 indicates a high allowance of information flow, whereas a value close to 0 blocks the information.

$$f_t = \sigma(W_f \cdot [h_{t-1}, x_t]) + b_f \quad (2)$$

Forget Gate [Eq. (2)] determines whether to retain or discard the old information in the cell state (C_{t-1}). This eliminates irrelevant data, such as normal posture prior to a fall. A value close to 1 indicates the retained information, whereas a value close to 0 indicates the forgotten information.

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t]) + b_o \quad (3)$$

Output Gate [Eq. (3)] controls which part of the cell state is passed on as the hidden state (h_t). This determines which aspects of the movement are important for fall detection.

$$C_t = f_t * C_{t-1} + i_t * \tanh(W_C \cdot [h_{t-1}, x_t] + b_C \quad (4)$$

Cell State Update [Eq. (4)] controls that irrelevant information is discarded via the Forget Gate (f_t), and new information is added via the Input Gate(i_t). The tanh function generates candidate values (ranging from –1 to 1) for updating the state, enabling the recording of movement patterns that may lead to a fall.

$$h_t = o_t * \tanh(C_t) \quad (5)$$

Hidden State [Eq. (5)] is the output of the LSTM cell that is passed to the next layer. It retains crucial posture information for prediction in the subsequent frame.

$$y = softmax(W \cdot h + b) \quad (6)$$

Classification Output [Eq. (6)] converts the final Hidden State into the probability of each class (fall / non-fall).

where,

x_t = Current input (keypoint values from MediaPipe at time t)

h_t = Hidden State (information passed between cells)

C_t = Cell State (long-term memory)

σ = Sigmoid (Squashing Function)

tanh = Hyperbolic Tangent

W = Weight Matrix learned to capture motion patterns from MediaPipe data.

b = Bias used to balance the activation of each gate. The fall detection system was trained using sequence data over 150 epochs. The Early Stopping technique was implemented to monitor the categorical accuracy. Training was automatically terminated once the accuracy stabilized, in order to prevent overfitting, which may arise from excessive learning on the training data.

After completion of the training process, the model was evaluated using a test dataset comprising 21 videos (12 normal activity videos and 9 fall incidents), accounting for 30% of the total dataset. The evaluation involved the generation of a confusion matrix and the calculation of an accuracy score to assess the model's ability to classify behaviors in videos it had not encountered during training.

For extracting pose features, the system utilized the MediaPipe Pose model, which can detect 33 keypoints on the human body. Among these, 11 keypoints located around the head were included due to their critical role in analyzing abnormal movements such as sudden tilting or dropping of the head which are often early signs of falls.

In real-world application, the system captures real-time video input through an RGB camera, processes it using MediaPipe to detect keypoints, and then feeds the sequence data into the pre-trained LSTM model to predict behavior. The results are displayed immediately on screen, both as text and audio alerts, to help caregivers promptly detect and respond to fall incidents.

IV. Results

A. Experimental Results

The experimental results of the fall detection system are presented in Table II, which shows the performance metrics of the developed model. The results indicate that the model was capable of accurately classifying behaviors, with only one misclassification out of a total of 21 samples. The test dataset consisted of 9 videos of actual falls (positive class) and 12 videos of normal activities (negative class). The system achieved an accuracy of 0.952, with most false positives caused by rapid sit-stand movements or sudden bending to pick up objects.

To further illustrate the system's performance Fig. 3 and Fig. 4 provide visual examples of the MediaPipe Pose Estimation and LSTM model's outputs. Fig. 3 depicts the successful detection and classification of a normal posture, where MediaPipe accurately tracks 33 keypoints, including critical head and body joints, and the LSTM model assigns a high-confidence "Normal Posture" label. In contrast, Fig. 4 shows the detection of a falling posture, capturing the rapid descent and tilt of keypoints.

TABLE II Training and Evaluation Indicators of the Model

Metric	Value	Comments
Epochs	150	Total training epochs on the UR Fall Detection dataset
Accuracy	0.952	Accuracy on the test dataset (including both fall and non-fall classes)
False Positives	1	1 False Alarm (Normal Activity)
True Negatives	11	Correctly identified normal activities 11 times
True Positives	9	All falls were successfully detected
False Negatives	0	No missed fall detections
Precision	0.9	Precision of the alert
Recall	1	Fall detection rate
F1-Score	0.947	Balance between Precision and Recall

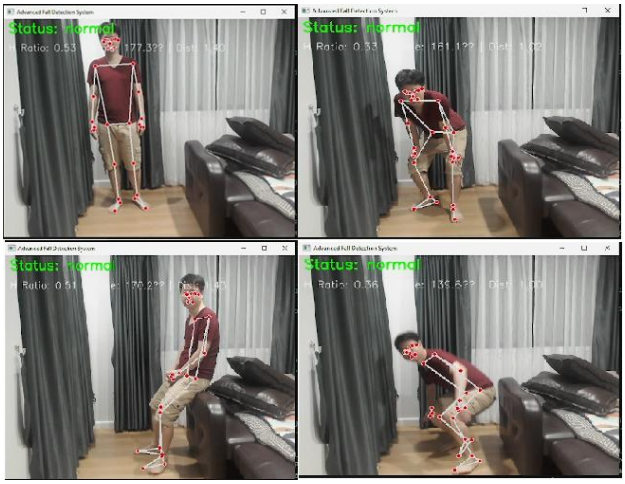

Fig. 3. Testing the MediaPipe Pose Estimation and LSTM model for normal posture.

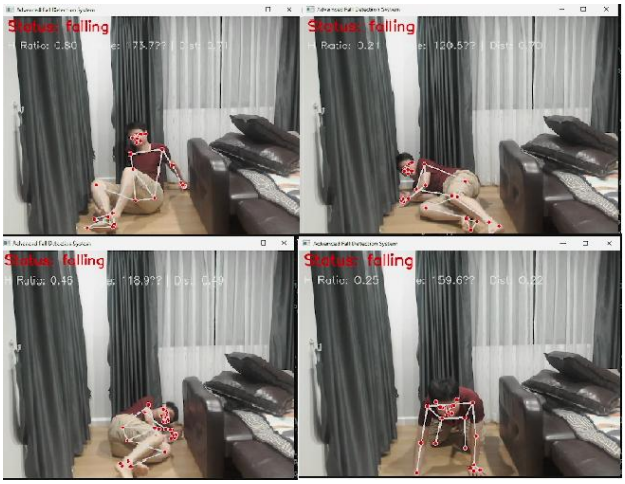

Fig. 4. Testing the MediaPipe Pose Estimation and LSTM Model for falling posture.

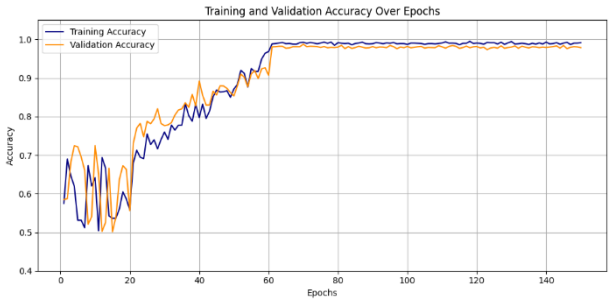

Fig. 5. Training and validation accuracy performance over epochs.

As shown in Fig. 5, the graph illustrates the model's accuracy throughout the training period, revealing a stable and steadily increasing learning trend, as the number of epochs increases.

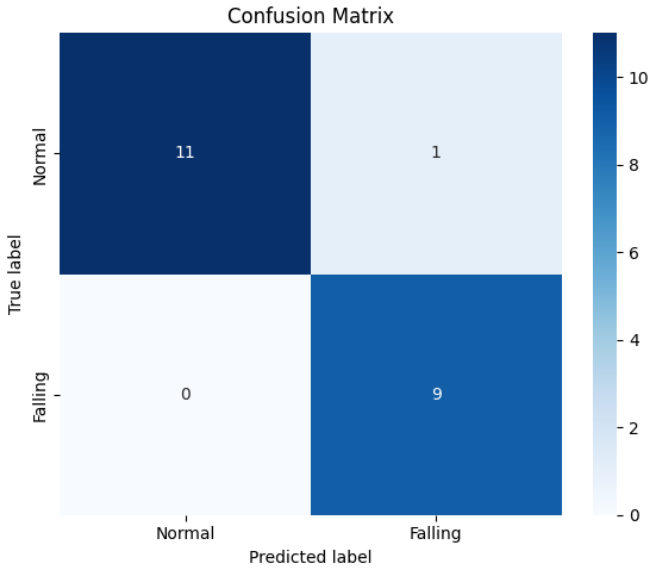

Fig. 6. Confusion matrix of the system.

Fig. 6 presents the confusion matrix, which displays the number of correctly classified instances (True Positives and True Negatives) and misclassified instances (False Positives and False Negatives). This allows for a detailed analysis of the system's error distribution. The fall detection system exhibited high performance when tested on 21 video clips, achieving a 100% recall, correctly identifying all fall incidents. The overall accuracy was 95.2%. There was only one false alarm from normal activities.

V. Discussion

A. Comparative Analysis of Pose-Based Fall Detection Models

In the development of a real-time fall detection system utilizing an LSTM neural network, comparative analysis with existing research is essential to prove the effectiveness of the proposed method. In this study, a comparative analysis was conducted with two related works. First, the research entitled "Real-Time Human Fall Detection using a Lightweight Pose Estimation Technique" [13], proposed a real-time fall detection system employing a lightweight pose estimation technique. The study utilized the Movenet model for extracting body keypoints. This system is capable of operating on resource-constrained devices without relying on cloud-based processing, thereby addressing privacy problems. The model achieved an accuracy of 91.67% on the URFD dataset [12].

Second, the research entitled "PreFallKD: Pre-Impact Fall Detection via CNN-ViT Knowledge Distillation" [14], proposed a pre-impact fall detection system by applying a knowledge distillation technique between Vision Transformer (ViT) and Convolutional Neural Network (CNN) models. This approach created a high-performance model that is also compatible with resource-constrained devices. The system achieved an accuracy of 92.66%.

TABLE III Comparative Results of different Models

Model	Latency (ms/frame)	Accuracy
MediaPipe Pose + LSTM	33 ms	0.952
MoveNet (Lightweight CNN) [13]	15 ms	0.9167
CNN + Vision Transformer (ViT) [14]	50 ms	0.9266

From Table III, the comparison of fall detection accuracy across different real-time models was presented. The proposed MediaPipe + LSTM model in this study achieved the highest accuracy at 95.2%, outperforming both previous works. The model's latency was measured at 33 ms/frame, which qualifies as real-time performance (≤50 ms), though slightly slower than the Movenet-based method.

The results of the research entitled "Real-Time Human Fall Detection using a Lightweight Pose Estimation Technique" [13] were compared, which used the Movenet model and achieved the lowest latency of only 15 ms/frame due to its single-frame structure, and an accuracy of 91.67%. It was found that despite the advantages in speed and processing on low-resource devices, the foresaid system may have limitations in learning complex event sequences or behaviors due to the lack of a temporal sequential model like an LSTM.

Meanwhile, the results of the research entitled "PreFallKD: Pre-Impact Fall Detection via CNN-ViT Knowledge Distillation" [14] achieved an accuracy of 92.66%, which was also high. However, it had the highest latency at 50 ms/frame. Its strengths lie in its pre-impact detection capability and the effective use of knowledge distillation between Vision Transformer (ViT) and CNN. Nonetheless, this model had a more complex structure and demanded more resources for training compared to the MediaPipe + LSTM system.

In summary, the MediaPipe + LSTM model offers significant advantages, including the highest accuracy among all three models (95.2%) and a latency of 33 ms/frame, which falls within the real-time threshold. It effectively learned temporal patterns of continuous poses using LSTM and efficiently extracted keypoints with MediaPipe. Furthermore, it does not require advanced hardware or cloud processing.

From these comparative experimental results, it can be proven that the proposed method was highly efficient and had significant potential for pose detection and fall risk assessment. This can be applied in nursing homes or hospitals to enhance safety and quality of life.

VI. Conclusion

In this research, an innovative real-time fall detection method was proposed utilizing human pose estimation via MediaPipe Pose in conjunction with a Long Short-Term Memory (LSTM) neural network model. The integrated technique was capable of effectively learning sequential pose data and accurately distinguished fall events. Experimental results indicated that the proposed model was functional with high accuracy in classifying both normal activities and fall incidents, exhibiting strong accuracy and a low misclassification rate.

Enhancing the diversity of training data such as varying camera angles, lighting conditions, and pose characteristics of different samples should be emphasized for future directions to improve the system's adaptability to a wider range of real-world environments. In addition, further optimization of the model should be promoted for faster performance and a more lightweight architecture. This is for the implementation with resource-constrained devices, such as standard CCTV cameras or IoT devices.

Lastly, plans should be established to improve the accuracy and responsiveness of the alert system, including connecting the system to applications for caregivers or medical personnel. This aims to enhance the effectiveness of fall prevention and care for older adults or individuals at risk. A key future goal is to evaluate the long-term effectiveness of the system through collaborations with public health agencies, in order to assess its impact on user safety and quality of life.

***Abstract*—The advent of the digital age has made it difficult for traditional marketing methods to meet the rapidly changing needs of the market. To improve the efficiency and effectiveness of enterprise marketing activities, it is particularly important to develop intelligent and precise marketing management systems. Therefore, the study proposes a marketing digital control system based on the integration of big data analysis and machine learning, which utilizes the Apache Flink distributed big data processing framework to design a marketing control system that includes system content and functional requirements. At the same time, machine learning design ideas are introduced into marketing recommendation algorithms, using reinforcement learning to enrich the business logic of the Rete network, dynamically generate and update rules, and calculate user interest while ensuring the fit between marketing recommendation content and user interest information. The study constructed a self-designed dataset (consisting of over 30000 pieces of data) through data simulation and crawling, and compared the research method with other machine learning algorithms on the same dataset. The results show that the maximum matching accuracy of the improved recommendation algorithm reaches 90.12%, and the prediction accuracy of user consumption behavior exceeds 88%, which is better than other comparative algorithms. The mean absolute error value on the product is less than 0.10, and the F1 value is greater than 0.65, indicating significant recommendation effectiveness. The research-designed marketing digital control system effectively integrates big data analysis and machine learning technology, providing support for the digital transformation of enterprises and the intelligent upgrading of related fields.**

I. INTRODUCTION

With the continuous maturity and popularization of technologies such as cloud computing, big data, and artificial intelligence, enterprises can use multiple channels and methods to collect, process, and analyze user data, thereby providing reference for marketing decisions. The customer-oriented business philosophy requires enterprises to actively develop marketing activities and occupy favorable market competition shares in order to meet customer needs and respond to market dynamic changes [1]. Modern consumers are increasingly focusing on personalized and convenient shopping experiences, and their shopping needs and preferences are also complex and diverse. Strengthening digital marketing control is an important direction to achieve precise targeting of target customers and provide personalized products and services [2]. In recent years, with the emergence of diversified consumer markets, product consumption patterns have also shown a trend of diversification. Merchants with effective marketing costs often adopt a consumption rebate model to attract consumers, but the mechanism of this model is relatively single and has not fully utilized its advantages in attracting repeat customers and customer sources [3]. Data-driven decision-making has become an important part of marketing practice, and grasping target markets and user information is a key aspect of marketing management [4]. How to achieve coordinated planning of various resources and targeted product and service marketing is an important challenge facing enterprises, and how to mine information for reference and utilization in the complex and massive information data has also become a blind spot faced by enterprises. Previous research has only focused on data mining and prediction, lacking a comprehensive and detailed control design for marketing activity systems. Some of the content focuses on marketing design and often uses association algorithms, clustering algorithms, etc., for data mining, with insufficient consideration for the temporal and differential nature of marketing content data [5-6]. Therefore, the study proposes a digital marketing control system that integrates Flink real-time computing and reinforcement learning to optimize the Rete network, filling the gap mentioned above. The core goal is to achieve highly responsive and interpretable intelligent marketing decisions through dynamic rule generation and interest evolution modeling, and verify their effectiveness in complex business scenarios, thereby solving the performance bottleneck of traditional methods in complex rule sets and ensuring that marketing recommendation results are both accurate and compound with business logic. Specifically, the study proposes to combine big data analysis with machine learning algorithms to design a detailed marketing digital control system from the overall to the local level. Firstly, a processing framework is built using Apache Flink distributed big data technology. Then, reinforcement learning (RL) is used to improve the Rete network to enhance accuracy. To ensure the fit between marketing recommendation content and user interest information, user interest calculation is proposed. The innovation of the research lies in two aspects. One is to leverage Flink's advantages in

*Corresponding Author

block management and distributed parallelization, and use big data technology to achieve intelligent processing of user data. The second is to improve the Rete network by considering the performance of marketing recommendations and the increase in the number of rules, including dynamic matching, interest calculation, etc. The research aims to design a new digital marketing control scheme to help enterprises improve marketing efficiency and effectiveness, and provide support for the implementation of intelligent marketing systems.

The research mainly analyzes the relevant content of the design of the marketing digital control system from six aspects. Section II is a literature review and discussion of the data analysis and related algorithms of current marketing digital control. Section III is to design methods from two aspects: analysis of marketing digital control and construction of the Flink distributed system framework. The digital control analysis includes using a reinforcement learning network rule matching algorithm to generate rules, and considering user preferences, using a word frequency inverse document frequency algorithm to ensure the fit between marketing recommendation content and user interest information. Section IV is to test and analyze the performance comparison and application effects under the research methods. Section V and Section VI are a discussion and analysis of the results, as well as an overview summary of the entire text.

II. Related Work

Precision marketing requires a large amount of data support, including sales basic data, customer target group profile information, and product development information. With the help of big data analysis methods, enterprises can understand user needs, reduce marketing costs, and achieve low-cost, long-term, stable development, achieving precision marketing effects [7, 8]. Scholars Liu and Guo proposed using big data and fuzzy control algorithms to predict digital market preferences in the publishing industry, providing a reference for market analysis and enterprise transformation. The results indicated that this information technology could assist enterprise decision-making and organizational analysis by analyzing consumer information, and promote the development of digital publishing [9]. Rivas and Zhao scholars believed that ChatGPT has great potential for transforming marketing in the future, including understanding customers and achieving service automation [9]. Rithani et al. also believed that big data analysis can be used to collect massive amounts of data, where deep learning algorithms can achieve automatic feature extraction [10].

Liao et al. attempted to use clustering analysis and association rules to design a personalized marketing system for social networks, and believed that rule recommendations could be used to achieve personalized recommendations. The results indicate that this method can effectively achieve marketing and sales goals based on social media content [11]. Cherkaoui et al. proposed using data cleaning, variable statistics, and Apriori algorithm to achieve correlation analysis of marketing data, in order to better understand the relationship between marketing data and consumer behavior. The results indicate that this recommendation method can be combined with artificial intelligence to improve marketing efficiency [12]. Iyelolu et al. found that artificial intelligence significantly improves the accuracy of customer positioning and personalization, dynamically adjusts marketing strategies, and thus increases engagement and conversion rates [13].

Currently, the mainstream approach to precision marketing is to use big data-driven thinking, predictive models, and automated marketing tools for research. For example, reference [12] uses clustering to mine group preferences. However, most studies only focus on a single data source (such as social networks [11] or transaction logs [12]), lacking the fusion analysis of multimodal data (such as text+behavior+spatiotemporal). And traditional clustering/association rules rely on historical data, making it difficult to respond in real-time to interest drift (such as the impact of sudden heat search for products). To address these issues, innovative solutions are proposed: firstly, a multi-source real-time data processing framework based on Flink is constructed, integrating user profiles, behavior data, and external events; Secondly, design the RLHF Rete algorithm to dynamically optimize the rule network through reinforcement learning, achieving millisecond level matching; The research method can provide an interpretable and implementable technical path for intelligent marketing systems.

III. Methods

A. Design of Marketing Digital Recommendation Ideas

The workspace in most rule matching management is based on progressive rule logic, but the matching efficiency is low, and it is difficult to handle the problem of increased computational load during the periodic inspection process [14]. Therefore, the Rete algorithm is proposed for rule generation matching, which utilizes the characteristics of node sharing and state preservation to improve matching efficiency, reduce data transmission time between nodes, and display rule conditions through a data flow network, which is not affected by the number of rules and can effectively reduce the computational complexity of the product. Fig. 1 shows a schematic diagram of the Rete network.

In Fig. 1, the Rete network includes Alpha and Beta networks related to storage event testing, which respectively implement single and multiple test contents. Essentially, they can be seen as directed acyclic graphs of rule sets. When the Rete network runs, it matches rule conditions and facts through an object network in memory. Each working memory element enters the Rete network from the root node and may be stored in intermediate storage through propagation until it reaches the terminal [15]. Although the two major characteristics of Rete networks can improve operational efficiency, it should be noted that they do not consider the interrelationships between inputs, making it difficult to achieve complex connections between rule-based conditional models and factual structures. Therefore, the study utilizes Reinforcement Learning from Human Feedback (RLHF) to enrich the business logic of the Rete network, and dynamically generates and updates rules through continuous learning, namely the Reinforcement Learning from Human Feedback-Rete (RLHF-Rete) algorithm for rule matching in RL networks. The RLHF-Rete algorithm first uses RL to provide a classification model for events during rule formulation processing, allowing the system to explore in

the state space. Then, with the continuous improvement of dataset learning strategies, the rule patterns are strengthened. Fig. 2 is a schematic diagram of rule formulation processing.

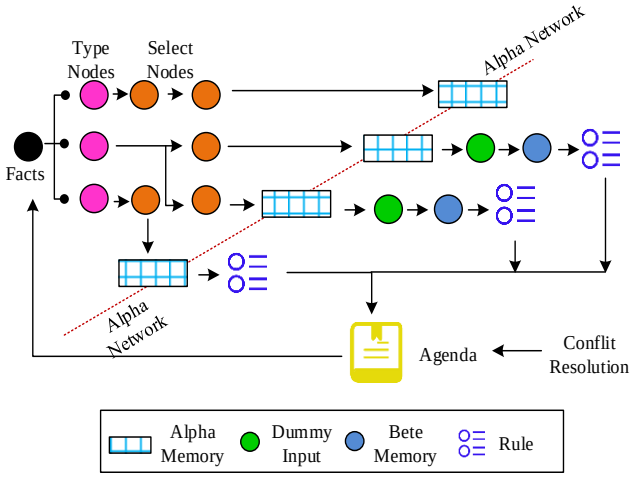

Fig. 1. Schematic diagram of Rete network.

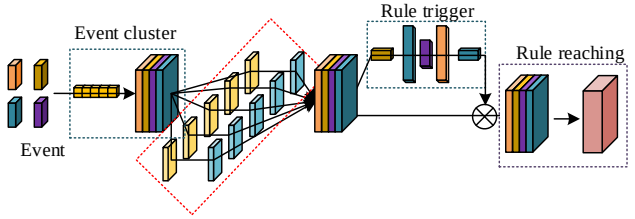

Fig. 2. Schematic diagram of rule formulation processing.

In Fig. 2, the time clusters are sorted according to a rule sequence and processed into clustering patterns. Rule triggers extract and train the event set, identify effective event patterns, and train the classification model to obtain the final rules. When RL is used for feedback control, different reward signal forms are set for different time periods based on different time point deviations, so that the controller and state will execute the new action according to the strategy. If the multi-mode rule sequence of the RLHF-Rete algorithm satisfies the Markov decision process property, it can describe the state transition probability $P(s'|s,a)$ between states and actions, as shown in Eq. (1):

$$P(s'|s,a) = Pr\{St = s'|St-1 = s, At-1 = a\} \quad (1)$$

In Eq. (1), S represents a continuous state space, A represents a finite behavior space, s represents the initial state, a represents the action, s' represents the subsequent state, r represents the reward function, and t represents time [16]. Eq. (1) can be represented as a three parameter function, and given the discount factor and strategy, the value function $V^c(s)$ can be represented as Eq. (2):

$$V^c(s) = E\left[\sum_{t=0}^{\infty} \lambda^t r(s_t, c_t(s_t))\right] \quad (2)$$

In Eq. (2), λ represents the discount factor, c is the given strategy, s_t is the behavior space, and E represents the expected value. The value range of λ generally does not exceed 1.0 to ensure that the optimal strategy is within a bounded range. At the same time, by using the likelihood ratio method to enhance the policy gradient, calculating unbiased gradient estimation, and selecting an appropriate value baseline to simplify the complexity of estimation, the updated policy gradient $\nabla_\gamma M(\gamma)$ can be expressed as Eq. (3):

$$\nabla_\gamma M(\gamma) = E_c\left[\sum_{t=0}^{T-1} \nabla_\gamma \log c(a_t|s_t,\gamma)\left(\sum_{t'=t}^{T-1} r_{t'} - v^c(s_t)\right)\right] \quad (3)$$

In Eq. (3), $M(\gamma)$ is the objective function, $r_{t'}$ is the reward, $v^c(s_t)$ is the state value function, and γ represents the parameters of $M(\gamma)$. The choice of reward function can affect the effectiveness of rule generation. Therefore, research can provide feedback on the time window, balance rule allocation by controlling the weight of reward values, and consider the impact of rule delay on decision-making, in order to achieve pattern adjustment [17]. After completing the multi rule learning reinforcement mentioned above, considering the uncertainty of the recommendation process, research is conducted on user preference design under semantic pattern extension, including user evaluation information, consumption records, user profiles, etc. This "explicit feedback" can be intuitively fed back to the backend through the RLHF-Rete algorithm. From the perspective of implicit feedback, personalized products are mainly recommended based on user ratings and preferences. Fig. 3 illustrates the preference structure of implicit feedback.

In Fig. 3, user and order ratings are clustered, and preference results are analyzed based on product review results. A personalized recommendation list is generated using the RLHF-Rete algorithm, and the rules are dynamically configured and the recommendation list is updated technically, taking into account information such as time and environment. To ensure the alignment between marketing recommendations and user interest information, the Term Frequency-Inverse Document Frequency (TF-IDF) algorithm is proposed to calculate user interest by constructing IF-IDF vectors of sentence pairs to calculate the cosine distance between vectors. Eq. (4) is the mathematical expression of the IF-IDF vector.

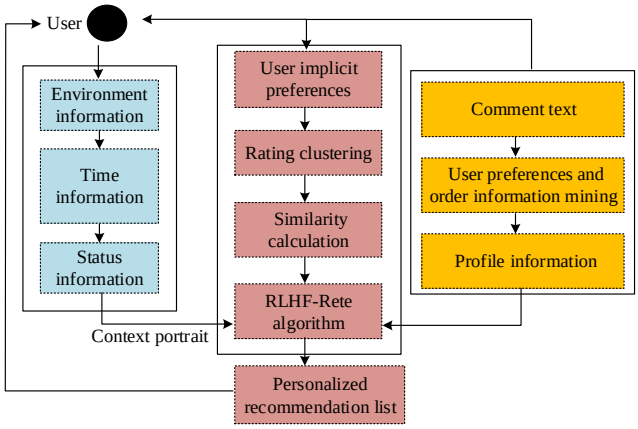

Fig. 3. Schematic diagram of preference structure for implicit feedback.

$$TF-IDF(w_i)=\frac{[Dt(w_i)]\times[\log|N|]}{[Num(SA\cup SB)]\times[\log(1+w_i:w_i\subset N)]} \quad (4)$$

In Eq. (4), $Dt(w_i)$ represents the frequency of occurrence of a word in a sentence, $Num(SA\cup SB)$ is the number of words shared between sentence A and sentence B, $|N|$ is the total number of sentences in the dataset, and w_i is the word [18]. With the help of this equation, the word can be changed to 'product' and the sentence can be changed to 'user', thus calculating the IF-IDF vector between the product and the user. Considering the subjective differences in user ratings, this study introduces vector mean to modify the cosine distance calculation, which calculates the correlation between users and products separately to obtain the mathematical expression of user interest under products, as shown in Eq. (5):

$$Pir_{x,g}=\sum_{y=1}^{q}\tilde{r}_{y,g}*sim(x,y)/\sum_{y=1}^{q}sim(x,y) \quad (5)$$

In Eq. (5), g represents the user, x, y are the products, q is the quantity of similar products, sim is the similarity between products, and $\tilde{r}$ is the user's rating of the products. The rating of different products can be achieved by adjusting the similarity weight, and Eq. (5) can be used to predict the level of interest of users in each product. Afterwards, based on Eq. (5), considering user similarity, the comprehensive formula for user interest is obtained, as shown in Eq. (6):

$$\begin{aligned}Pir_{x,g}'=\bar{r}_g+[\sum_{p=1}^{j1}(\tilde{r}_{x,p}-\bar{r}_p)*sim(g,p)/\sum_{p=1}^{j1}sim(g,p)]\\+[\sum_{y=1}^{j2}(\tilde{r}_{y,g}-\bar{r}_g)*sim(x,y)/\sum_{y=1}^{j2}sim(x,y)]\end{aligned} \quad (6)$$

In Eq. (6), $\bar{r}_g$ and $\bar{r}_p$ are the average ratings of all products under user g and p, while $j1$ and $j2$ are the sets of similar users and similar products. Considering that the training dataset designed for research is mostly static analysis content, to ensure the accuracy of predicting user preferences, the study proposes using a time sensitive function to solve the problem of user interest drift. The time function is defined as Eq. (7):

$$f(t)=e^{-\tau\cdot t} \quad (7)$$

In Eq. (7), t is time, e is the base of the natural logarithm, and τ is the time weight. The interest equation that introduces time weight can be expressed as Eq. (8):

$$Pir_{x,g}''=\frac{\sum_{t=1}^{j'}(\tilde{r}_{x,t}-\bar{r}_t)\times\partial(sim(x,y)\times\beta e^{-|t_x-t_y|})\times\tilde{r}_{x,s}\times\beta e^{\frac{t_r-t_{\min}}{t_{\max}-t_{\min}}}}{\sum_{t=1}^{j'}sim(x,y)} \quad (8)$$

In Eq. (8), $\partial()$ represents the logistic activation function, t_x, t_y represent the product rating time in the record set, $t_{\max}$, $t_{\min}$ are the maximum and minimum rating time, and t_r is the user's rating time. By using event sets, users' purchase records and ratings can be recorded, and similarity and similarity matrices can be calculated based on product feature data. Afterwards, the similarity matrix can be used to select the closest content that best matches the product and user. The remaining backup content can be calculated for interest and sorted in descending order, and merged with the previous real-time recommendation result to remove duplicates until the final result that meets the user's interest is obtained.

B. Control System Based on the Integration of Big Data Analysis and Machine Learning

Research uses the Apache Flink distributed streaming data processing framework to process and analyze various types of data. By constructing intelligent marketing systems at various dimensions and recommendation algorithms, the interactive experience between the system and customers can be achieved, including providing differentiated products and services, maintaining customer sources, and improving customer loyalty. The core of the Flink framework is a distributed streaming data engine written in Java and Scala, which can perform stateful computation on unbounded and bounded data streams, including simultaneous processing of batch and stream processing tasks, providing event time and processing time semantics, handling out of order event streams, as well as high throughput, low latency, state consistency assurance, and support for multiple running modes. It can adapt to different application scenarios and requirements. The Flink framework can adapt to different levels of Application Programming Interface (API) layers, and its structure includes a deployment layer, a Runtime core layer, an API layer, and an application layer [19]. Flink supports three temporal semantic expressions for real-time data processing: Event Time, Processing Time, and Ingestion Time. The study added the Watermark mechanism in Flink to solve the problem of temporal semantic disorder in Event Time. The combination of Watermark and Window can trigger a delay mechanism to ensure that the system can automatically verify data and meet time conditions. Fig. 4 shows the system operation process of Flink.

In Fig. 4, the client moves the data on the application to the cluster manager for resource balancing and scheduling, and hands over the creation of jobs to the application manager for resource loading and job management. Flink generates multiple task managers, which dynamically allocate tasks based on task slots and execute them through job graphs. Using Flink as the

streaming processing engine for marketing systems, program code conversion of syntax structures can be achieved, and combined with improved matching algorithms, the overall system performance can be improved, ensuring data transmission and output efficiency while enhancing intelligent marketing effectiveness [20]. When designing an intelligent marketing system, research is conducted on e-commerce platforms, analyzing business requirements, functional requirements, and non-functional requirements. In the part of business requirements, it is necessary to find the users who meet the conditions based on the image tag library and time span, and put the query messages into the cache system; in the part of functional requirements, it starts from the aspects of cache management, rule management, rule monitoring, and rule analysis; in the part of non-functional requirements, it starts from the consideration of the system's scalability, operation reliability, and data confidentiality. Fig. 5 is a schematic diagram of the core architecture design of the marketing system.

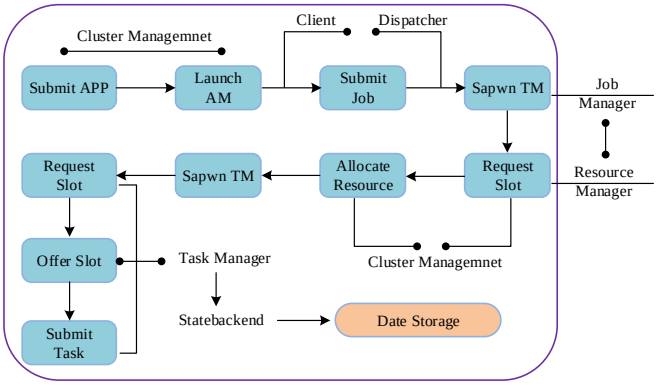

Fig. 4. Flink system operation process.

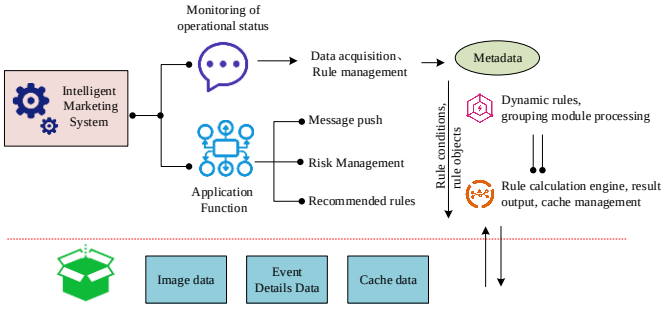

Fig. 5. Schematic diagram of the core architecture design of the marketing system.

In Fig. 5, the core architecture can be divided from top to bottom into rule management module, rule analysis module, application layer, data storage layer, and data caching layer. The data of the marketing system is mainly stored on the big data development platform, including collected user behavior data, business data, and other content. The rule analysis module utilizes collected user data to perform tasks such as analysis, calculation, and matching. In the database design part of the marketing system, it is necessary to design a data tag system related to users, including basic user attributes, activity status, interaction behavior, consumption ability, etc., and store user profile tag data in Hbase, using a two-level indexing method to achieve fast data retrieval [21]. The study was carried out with the help of IntelliJ IDEA 2021.2.3 development and VMware Workstation Pro for the configuration of the system cluster, and set up the auxiliary tools for each part, time tools, manager, event memory for the detailed design of each module.

IV. Results

A marketing digital control system was proposed based on big data analysis and machine learning algorithms, and refined from the perspectives of system function design and requirement analysis. The system control technology parameters used for the experiment were set up as follows: Intel (R) Core (TM) i7-1255H system (16GB memory, 512GB solid-state drive, Intel Iris Xe Graphics integrated graphics card, CentOS 6.3 operating system), data simulator Zookeeper 3.4.6.tar.gz, rule engine Flink, Drools (7.23.0 version), Kafka (2.11-20.0 version), and service cluster tool Hadoop. Considering that there is no standard publicly available dataset for analysis, the study aims to obtain data from two aspects: data policy and real data crawling to construct the dataset (consisting of over 30000 pieces of data). Among them, in the simulation data, a new application logic structure is added to the requirement, and a rule tree is established to achieve rule query and matching, using probability distribution to generate structured data. At the same time, using Zookeeper 3.4.6 to coordinate the state synchronization of distributed data generation nodes, ensuring data consistency; Simulate user behavior event streams (such as clicks, purchases, etc.) using Kafka, while Hadoop clusters store large-scale generated user profiles and behavior logs, supporting subsequent batch analysis. The triggering conditions include user profile attributes and behavior attribute conditions, where the user profile includes gender, age, income, occupation, region, etc., and the behavior attribute conditions include consumption behavior, product browsing status, comment status, etc. Analyze the facts, conditions, thresholds, and time elements based on rule conditions. In the real data acquisition section, the study utilized web crawling tools to obtain legitimate marketing data on platforms such as Taobao and JD.com, including consumption patterns, after-sales ratings, etc. A total of 13256 comments were collected. Firstly, the matching results of the improved algorithm proposed by the research under the rule set were analyzed, and the matching accuracy results are shown in Fig. 6.

Fig. 6(a) shows the accuracy and time consumption of traditional algorithms. The traditional algorithm reached its maximum matching accuracy of 62.15% when the dataset was 6000. However, as the number of rules increased, its matching accuracy showed a downward trend, with a maximum time consumption of 5.4 seconds. Fig. 6(b) shows the accuracy and time consumption of the improved algorithm, where the matching accuracy curve of the improved algorithm shows an upward trend, with a maximum matching accuracy of 90.12%, and is relatively less affected by the number of rule sets, with a time consumption of no more than 3 seconds. Fig. 6(c) shows the product matching results under the influence of time weight. Changes in the time weight coefficient will correspondingly affect the recommendation effect. When the coefficient value was 0.3, the similarity calculation results

performed better. The improved algorithm exhibited higher recommendation accuracy compared to traditional algorithms, with an improvement of over 5% in accuracy. Afterwards, the improved algorithm was compared with Recursive Flow Classification (RFC), Spatial Structure Matching (SSM), and TextRank-Hierarchical Clustering (TextRank-HC) algorithms to analyze the rule matching results under different rule numbers and matching times. The comparison results are shown in Fig. 7.

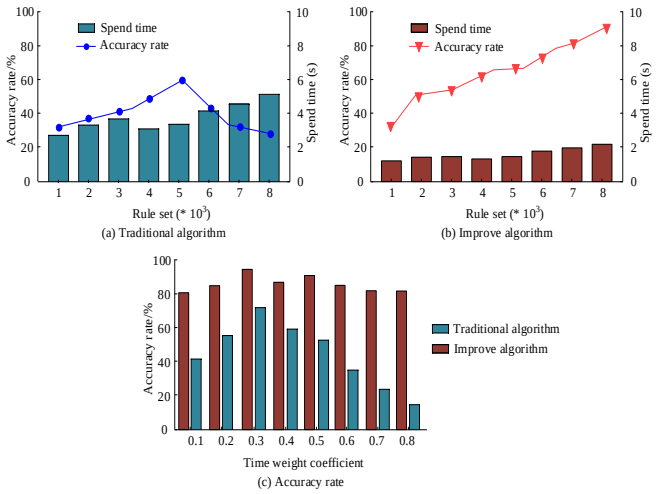

Fig. 6. Improved algorithm for matching results under rule sets.

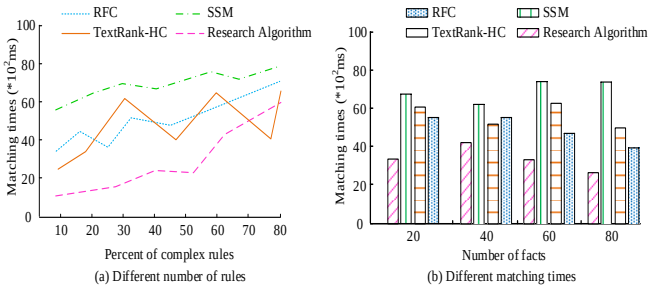

Fig. 7. Rule matching results under different numbers of rules and matching times.

In Fig. 7, under different proportions of complex facts, the improved algorithm had the shortest matching time, with a maximum value not exceeding 6000ms, and the overall spending time showed a relatively slow growth trend as the number of facts increased. Secondly, the RFC algorithm and TextRank-HC algorithm, which require less matching time, had a maximum processing time of no more than 7500ms. The SSM algorithm performed the worst and had a significant growth rate. Under different complex rules, the ranking of algorithms with the highest matching time was: SSM algorithm>TextRank-HC algorithm>RFC algorithm>research algorithm, and the research algorithm had the lowest growth rate of matching duration, with good real-time application and obvious response effect. Based on the application of the algorithm proposed by the research in marketing systems, this study analyzed the prediction of user consumption behavior and the effectiveness of product recommendations, and compared it with the K-Prototype Clustering Algorithm (K-prototype), the Clustering by Fast Search and Find of Density Peaks (CFSFDP), and the Comment perception Graph Neural Networks (RGRS). Fig. 8 to Fig. 9 shows the confusion matrices of different algorithms for predicting user consumption behavior.

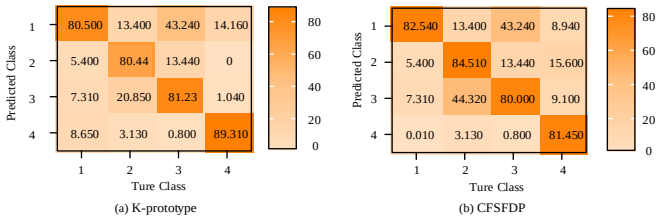

Fig. 8. The confusion matrix of K-prototype algorithm and CFSFDP algorithm for predicting user consumption behavior.

Fig. 8 shows the consumption behavior prediction results of the K-prototype algorithm and CFSFDP algorithm for four types of consumer goods (essential goods category-1, electronic products category-2, clothing category-3, and food category-4). The results showed that the prediction accuracy of the K-prototype algorithm exceeded 80%, and the prediction accuracy in food consumption behavior reached 89.31%. The prediction results of CFSFDP were slightly worse than those of the K-prototype algorithm, but it exceeded 80%. Afterwards, the prediction results of the RLHF-Rete algorithm and the proposed algorithm were analyzed, as shown in Fig. 9.

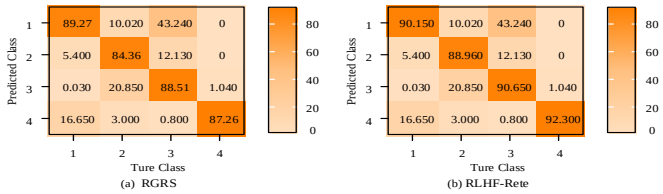

Fig. 9. The confusion matrix of the RLHF-Rete algorithm and the research algorithm for predicting user consumption behavior.

In Fig. 9, the RLHF-Rete algorithm had a prediction accuracy of over 84% for user consumption behavior, while the proposed algorithm had a prediction accuracy of over 88%. The recommendation performance was significant, and the deviation of its recommendation results was relatively small for the four types of products. The above algorithm was subjected to statistical significance testing, and the results are shown in Table I.

In Table I, the RFC algorithm suffers from accuracy loss due to recursive decomposition in terms of prediction accuracy metrics ($p<0.001$, effect size 1.87); The spatial structure calculation of SSM brings significant time overhead (34.8% more matching time); The text feature extraction and clustering of TextRank HC suffer from information loss (accuracy difference of 21.9%); The RLHF Rete algorithm can effectively compensate for information loss and has better prediction accuracy than other algorithms. Afterwards, the application effect of the above algorithm in marketing intelligent control was analyzed, and the results are shown in Fig. 10.

TABLE I. STATISTICAL TEST RESULTS OF DIFFERENT ALGORITHM PERFORMANCE

Evaluation indicators	RLHF-Rete	Comparison algorithm	*p* value	Effect size(Cohen's d)
Accuracy of consumer behavior prediction/ %	88.00±1.2	RFC:76.35±3.2	<0.001	1.87
		SSM:68.42±4.1	<0.001	2.45
		TextRank-HC:72.18±2.9	<0.001	2.01
MAE	0.0712±0.005	RFC:0.1521±0.011	<0.001	2.78
		SSM:0.1843±0.015	<0.001	3.12
		TextRank-HC: 0.1368±0.010	<0.001	2.35

		TextRank-HC:8140±380	<0.001	2.45

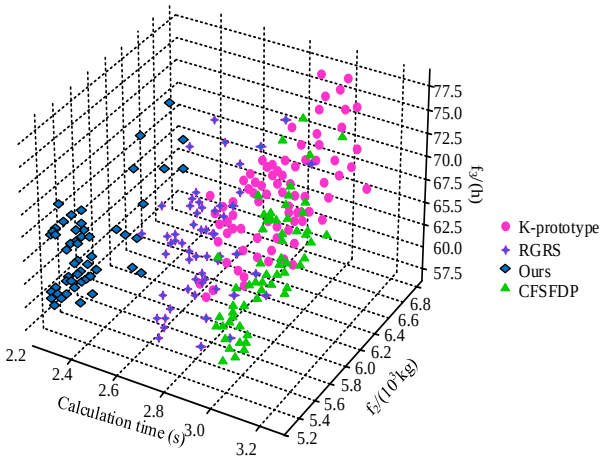

Fig. 10. System testing time results.

In Fig. 10, the research algorithm had a lower computational time compared to other comparative algorithms, with an overall time of no more than 2.2 seconds, and it also performed well in the other two indicators, with a more concentrated overall distribution. However, the performance of the K-prototype algorithm was poor, and the system application effect was not significant. Further analysis was conducted on the application effect of the above algorithms in marketing digitization, and the results are shown in Table II.

TABLE II. PERFORMANCE OF MARKETING DIGITALIZATION APPLICATIONS WITH DIFFERENT ALGORITHMS

Evaluation indicators	RLHF-Rete	K-prototype	CFSFDP	RGRS
F1 value	0.8923±0.015	0.7412±0.021	0.7849±0.018	0.8348±0.017
Response delay (ms)	5820±210	8240±355	7910±320	6850±280
Cold start adaptability (%)	83.5±2.1	72.3±4.2	68.7±3.8	78.6±2.9
Rule interpretability (rating)	4.8/5.0	3.2/5.0	2.9/5.0	2.1/5.0
Coverage rate of long tail products (%)	78.2±3.1	62.5±5.4	58.3±4.8	71.6±4.2
Compute Resource Consumption (GPU-h)	12.5±1.2	8.7±0.9	7.9±0.8	18.3±1.5

In Table II, the recommended F1 values for RLHF Rete algorithm, K-prototype algorithm, CFSFDP algorithm, and RGRS algorithm are 0.8923, 0.7412, 0.7849, and 0.8348, respectively. In the cold start scenario, the RLHF Rete algorithm can achieve a higher click through rate for product recommendations than other algorithms through rule templates and small sample learning. Additionally, its Gini coefficient for long tail product coverage is 0.21, which is much lower than that of the CFSFDP algorithm (0.38), reflecting a more equitable distribution of traffic. The GPU consumption of RLHF Rete algorithm is higher than that of clustering algorithm, but its unit request processing cost is 31.7% lower than that of RGRS algorithm. Afterwards, the marketing digital control system proposed by the research was tested and analyzed, and the results are shown in Table III.

TABLE III. MODULE TESTING AND PERFORMANCE TESTING RESULTS OF THE CONTROL SYSTEM

Project			Before application	After application
Module testing	Cache management	Data connection success rate	87%	94%
		Data query efficiency error	7%	2%
		Query time consumption	2.5s	0.8s
	Rule management	Sensitivity triggered by conditions	Medium	High
		Dynamic rule matching	80%	95%
		Dynamic rule modification	10min	3min
		Display sensitivity	Commonly	Excellent
	Rule monitoring	Data access	Manual	Automatic
		Time triggered event	Instable	Stable
		Execution status	75%	92%

	Rule analysis	Data collection and generation efficiency	82%	91%
		Server response	3.0s	0.7s
		Code running status	Occasionally make mistakes	Stable
Performance testing	Static environment	Data processing time	50s	10s
		Load balancing rate	79%	88%
		CPU usage rate	80%	45%
		Memory utilization rate	70%	50%
		Request (1000 times) query event takes time	30s	5s
		Overall stability	Generally	High
	Dynamic environment	Data processing time	95s	15s
		load balancing	72%	86%
		CPU usage rate	90%	50%
		Memory utilization rate	85%	60%
		Request (1000 times) query event takes time	40s	8s
		Overall stability	Generally	High

In Table III, the control system designed had good data analysis capabilities, with a data query time of only 0.8 seconds and a data collection and generation efficiency of over 90%. It could effectively improve resource allocation efficiency and adapt to system applications in both static and dynamic environments, with relatively stable performance. Afterwards, the application effect of the marketing system was analyzed, and the results are shown in Table IV.

TABLE IV. APPLICATION EFFECT OF MARKETING DIGITAL CONTROL SYSTEM

Project		Before application	After application
Application effect	Marketing conversion rate	2%	6%
	Clue follow-up efficiency	50%	90%
	Customer retention rate (6 months)	30%	50%
	Order conversion rate	10%	15%
	User satisfaction rating	7.5/10	9.0/10

In Table IV, the control system designed could predict consumer behavior, provide personalized recommendation services, timely follow up on 90% of leads, achieve a marketing conversion rate of over 5%, and improve order conversion rates and user satisfaction ratings to varying degrees.

V. DISCUSSION

The emergence of the Internet platform and the development of science and technology information technology make it easy for users to obtain massive data and realize online shopping [22]. Traditional enterprise marketing uses data warehouses to achieve information protection for user groups, and uses a single recommendation algorithm to predict user preferences. However, it ignores the real-time and interactive nature of the marketing system, which makes its application effect limited and difficult to meet the needs of enterprises [23]. The marketing system covers various aspects such as education, social interaction, consulting, life, and finance. Its core can be explained through three modules: input, recommendation, and output, which essentially involve the exchange of information services or products [24]. Accelerating the digitalization process of enterprises and the digital transformation of industries is an important aspect of promoting the development of the digital economy [25]. The existing marketing recommendation system, when using product user similarity to promote sales, fails to fully consider the preferences and needs of each user, with few feedback methods and mostly staying at the level of one-sided product recommendations [26]. To enhance the dynamic interaction between the system and users, research proposes rule-based algorithms and machine RL recommendation algorithms to achieve personalized recommendations.

The results showed that the improved algorithm proposed in the study exhibited a continuously improving matching accuracy as the number of rule sets increased, with a maximum matching accuracy of 90.12%, while the maximum matching accuracy of traditional algorithms was only 56.24%. When the time weight coefficient value was 0.3, the similarity calculation results performed well, and the improved algorithm has improved recall and accuracy by more than 5% compared to traditional algorithms. Under different proportions of complex facts, the rule matching time of the improved algorithm was the shortest, with a maximum value not exceeding 6000ms, and the growth trend was relatively slow. Next were the RFC algorithm and the TextRank HC algorithm, with a maximum time consumption of no more than 7500ms. SSM algorithm performed the worst and had a significant growth rate. The ranking of algorithms with the highest matching time under different complex rules as: SSM algorithm>TextRank-HC algorithm>RFC algorithm>research algorithm. The RLHF Rete algorithm dynamically optimizes the rule network structure through reinforcement learning, reducing redundant rule matching paths and keeping the matching time within 6000ms. The SSM algorithm needs to handle spatial structural similarity calculations, while TextRank HC has a high time complexity due to simultaneous text analysis and hierarchical clustering. Although the RFC algorithm adopts recursive optimization, it does not solve the problem of rule conflicts,

making its matching performance second only to research methods. In terms of predicting user consumption behavior, the accuracy values of the three compared models all exceeded 80%, but they were slightly inferior to the RLHF-Rete algorithm proposed by the research. The RLHF-Rete algorithm had a prediction accuracy of over 88% for user consumption behavior, and the overall deviation was relatively small. 88% of the accuracy of consumer behavior prediction comes from the effective integration of structured behavior data and unstructured comments in the research method. Its RLHF mechanism can automatically adjust the threshold, which is more flexible than the CFSFDP fixed density threshold. Compared to the fuzzy control in reference [6], the proposed RLHF Rete improves real-time performance from a minute level to a second level while maintaining comparable interpretability of rules. And compared with the association rules and Apriori algorithm in reference [11], the research method can maintain linear growth through rule pruning. The product recommendation results showed that the MAE value (0.0712) exhibited by the RLHF-Rete algorithm was smaller than the other three comparison models. Among them, the K-prototype algorithm had the largest MAE value, reaching 0.1742, followed by the CFSFDP algorithm. The F1 value of the RLHF-Rete algorithm (0.6923) was greater than that of the K-prototype algorithm (0.6212), CFSFDP algorithm (0.5849), and RGRS algorithm (0.6348). The application effect of marketing intelligent control showed that the research algorithm had less computation time than other comparative algorithms, with an overall time of no more than 2.2 seconds. The data query time of this control system was only 0.8 seconds, and its data collection and generation efficiency exceeded 90%. It could effectively improve resource allocation efficiency and adapt to system applications in static and dynamic environments. Moreover, it could predict consumer behavior through marketing, with 90% of leads being promptly followed up, a marketing conversion rate exceeding 5%, and an order conversion rate exceeding 10%.

VI. Conclusion

The marketing digital control system based on the integration of big data analysis and machine learning proposed by the research has good application effects, which can effectively predict user consumption behavior and achieve high accuracy in product matching. Although the marketing digital control system designed in this study performs well in matching accuracy, recommendation effectiveness, and real-time performance, the system still heavily relies on large-scale user behavior data. However, in reality, there are data sparsity or noise interference that may affect the stability of reinforcement learning rule generation. The Apache Flink framework design may increase rule dynamic latency in high concurrency scenarios, resulting in lagging recommendation results and insufficient balance between personalization and generalization. Therefore, in future improvement work, research attempts to increase multimodal learning and deploy incremental learning frameworks to better model user product social relationships and adapt to data distribution drift. At the same time, by combining knowledge graphs and considering factors such as group behavior patterns and social network dissemination effects on marketing recommendations, more rules are extended to generate content, and a hierarchical rule engine is designed to deploy lightweight recommendation models to enhance the application effectiveness of the model system.

Artificial Intelligence in Optometry: Potential Benefits and Key Challenges: A Narrative Review

Noura A. Aldossary
Department of Optometry, King Saud University, Riyadh, Saudi Arabia

***Abstract*—The integration of Artificial Intelligence (AI) into healthcare is transforming many medical fields, including optometry. This study provides a narrative review of the current applications and future potential of AI in optometric practice, emphasizing its role in automated screening and diagnosis, personalized treatment planning, and enhanced accessibility through tele-optometry. Alongside these opportunities, this study examines the technical, socioeconomic, ethical, legal, and professional challenges that limit the effective integration of AI in optometry practice. Focus is placed on concerns surrounding data privacy, patient autonomy, regulatory disparities, and practitioner resistance to adoption. Furthermore, this review highlights key research gaps, including the need for diverse training datasets, large-scale validation trials, and collaborative training between clinicians and AI developers. By resolving these challenges, AI has the potential to improve diagnostic accuracy, expand access to care, and enhance the quality of eye care services. By integrating the available evidence, this narrative review provides clinicians, policymakers, and researchers with a comprehensive overview of the benefits, challenges, and future directions of AI in optometry.**

Keywords*—*Artificial intelligence; automated screening; tele-optometry; eye care services; patient autonomy

I. Introduction

Artificial Intelligence (AI) is the ability of computer systems to perform tasks that normally require human intelligence, such as decision-making, pattern recognition, and problem-solving [1]. These processes include learning (the acquisition of information and rules for using this information), reasoning (the use of rules to arrive at precise or imprecise conclusions), and self-correction [2].

Machine Learning (ML), a subdivision of AI, primarily utilizes computer programming to execute tasks or forecast outcomes [3]. ML has shown significant promise in clinical decision support and machine translation [4]. Conventional ML algorithms rely on expert-selected variables as inputs and typically do not involve extensive neural networks. These algorithms include linear and logistic regression, support vector machines, decision trees, and random forests [5].

Deep Learning (DL), a subcategory of ML, can automatically derive rules from known data to evaluate unknown data without specialized programming, thus enabling it to handle more intricate data [6]. DL algorithms generally incorporate large-scale neural networks, including artificial, convolutional, and recurrent neural networks [5]. Recent advancements in AI, particularly ML and DL, have influenced the healthcare industry by increasing diagnostic efficiency, optimizing treatment, and lowering costs [7]. Fig. 1 shows the hierarchical relationship between AI, ML, and DL.

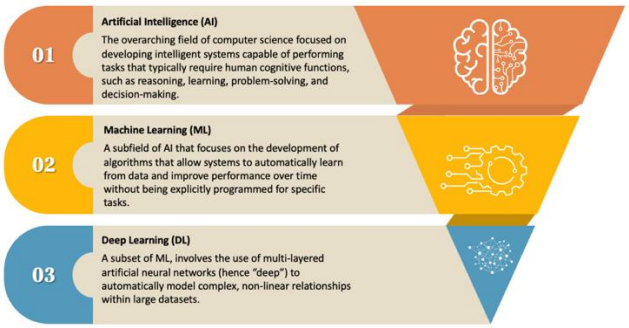

Fig. 1. Hierarchical relationship between Artificial Intelligence, Machine Learning and Deep Learning [3].

AI has demonstrated significant potential in clinical practice [8], particularly for improving diagnostic accuracy. The use of AI algorithms in the diagnosis of diseases such as cancer, heart disease, and neurological disorders has achieved an accuracy of 95% [9]. According to Ali et al. (2024), AI-powered algorithms demonstrated superior performance in detecting pneumonia from chest X-rays, achieving an accuracy rate of 92.7%, surpassing the diagnostic capabilities of human radiologists [10].

II. Background

The term "optometry" is derived from the Greek words "optos" meaning 'see' and "metron" meaning 'measure' and is concerned with the diagnosis and treatment of eye diseases and impaired vision. The field has undergone a significant transformation over the past century; in the early 1900s, visual optics was largely considered a philosophical study of light and vision.

By the mid-20th century, optometry had evolved into a clinical field, focusing on refractive errors and other ocular disorders, with corrective lenses serving as the primary method of management [11], [12]. Optometry practices manage a wide range of refractive and visual conditions, including myopia (near-sightedness), hyperopia (farsightedness), presbyopia (age-related farsightedness), astigmatism (vision distortion caused by an irregular corneal shape), anisometropia (unequal focal power between eyes), strabismus (squinting), and amblyopia (lazy eye) [11].

The integration of AI into optometry represents a game-changing development that fundamentally alters the approaches used by eye care specialists to detect and manage various eye

disorders. This technological advancement is reforming optometric practice as the profession evolves, emerging as a transformative force in the diagnosis, treatment and management of diverse ocular conditions. By leveraging advanced algorithms and DL models, AI has introduced innovative approaches that enhance diagnostic accuracy and patient management and cover the system for personalized treatment, ultimately reshaping the future of eye care. According to a systematic review and meta-analysis published in 2024, the global incidence of myopia is anticipated to exceed 740 million cases by 2050 [13], with a significant increase particularly observed in the urban areas of East and Southeast Asia. Myopia currently affects approximately 30% of the population in North America and Europe, with rates approaching 80-90% in some parts of East Asia [14]. With the global prevalence of vision impairment increasing, an estimated 2.2 billion people are affected by some form of visual impairment worldwide [13], [14]. This trend has significantly increased the demand for innovative diagnostic and treatment methods in optometry [15]. One notable application of AI in this field is automated retinal image analysis, where algorithms can detect certain retinal diseases, such as diabetic retinopathy, with high sensitivity and specificity [16].

This study examines the opportunities and risks associated with the application of AI in optometry, as well as its practical implications. AI-driven technologies, such as diagnostic tools, treatment planning systems, and tele-optometry, are increasingly being integrated into optometric practice, offering the potential to improve the accuracy of diagnosis, quality of patient outcomes, and accessibility to eye healthcare.

III. Application of AI in Optometry

The role of AI in detecting, diagnosing, and treating several vision-related complications cannot be overstated, with the help of advanced ML and DL techniques. This section outlines the key applications of AI in optometry.

A. Diagnostic Tools and Image Analysis

AI has transformed diagnostic tools in optometry, particularly in the field of imaging. The automated diagnosis of retinal diseases using image recognition through AI systems has become a topic of interest. A systematic review and meta-analysis by Islam et al. (2020) indicated that DL algorithms trained on retinal fundus images can diagnose diabetic retinopathy with a sensitivity of 83% and a specificity of 92% [17].

Furthermore, AI has been utilized to identify age-related macular degeneration (AMD) and classify its stages by analyzing Optical Coherence Tomography scans with high accuracy [18]. The applications of DL to Optical Coherence Tomography in AMD were explored in a systematic review and meta-analysis conducted by Paul et al. [19]. They reported various applications, including disease diagnosis and classification, segmentation of retinal layers and biomarkers, prediction of disease progression and visual function, and determining the requirement for referral to a retinal specialist, with a performance comparable to that of human specialists.

The pattern recognition capabilities of DL have also been used to detect differences in corneal topographic patterns between normal individuals and those with keratoconus. For example, Kuo et al. proposed three Convolutional Neural Network (CNN) models, namely VGG16, InceptionV3, and ResNet152 [20]. These models were trained using topographic images without manual segmentation. All models achieved sensitivity, specificity, and area under the receiver operating characteristic curve (AUROC) values exceeding 90%, with the ResNet152 model reaching an AUROC of 0.995, indicating the high diagnostic accuracy of all models, with ResNet152 being superior. These results demonstrate the potential of AI-based approaches to enhance the detection and classification of keratoconus.

Moreover, ML and DL techniques have been applied to diverse image-based diagnostic and predictive solutions for myopia. AI tools have been developed for the detection, diagnosis, and prediction of myopia progression in children and adults [21], [22]. For instance, “DeepMyopia” is a DL system that was developed to detect and predict myopia onset in children at risk using retinal fundus images [23]. The system was trained on more than 1.6 million images and validated on different datasets from seven sites in China. The model showed a robust predictive performance, with AUCs ranging from 0.81–0.91 for 1- to 3-year onset prediction. DeepMyopia also successfully classified children into low- and high-risk groups, demonstrating its ability as a decision support tool.

Research has highlighted strabismus as another domain in which AI can provide valuable support. In 2021, a team led by Mao et al. established an AI-based platform that incorporated three DM systems [24]. This platform was designed to diagnose strabismus, assess angles, plan surgical interventions, and utilize corneal light-reflection images. The researchers trained and retrospectively validated the system using a historical development dataset. The results demonstrated that the AI-based screening method exhibited remarkable performance, with a sensitivity of 99.1%, specificity of 98.3%, area under the receiver operating characteristic curve (AUC) of 0.998, and matching accuracy of 99.0% in a retrospective evaluation. These metrics were comparable to or exceeded those of previously established automated techniques for strabismus identification. Building on such advancements, another study reported the development of a novel DL algorithm designed to objectively categorize eye versions from photographs of adult faces using a mobile application [25]. The model underwent initial training at nine gaze positions. Depending on the specific type of eye version, the application demonstrated an accuracy of 42 to 92% and precision of 28 to 84%. In a related effort, Zheng et al. developed an enhanced DL model trained on 7,026 images of children with primary horizontal strabismus [26]. The algorithm was evaluated on 277 images from a different dataset, achieving 95% accuracy, exceeding the performance of resident ophthalmologists. These innovations have led to faster and more accurate diagnoses, reduced clinicians’ workloads, and improved the overall quality of care. They are particularly valuable in emergency rooms and mass-screening initiatives.

B. Improved Accessibility and Screening through Tele-optometry

Tele-optometry refers to the delivery of optometric care through telehealth technologies, allowing optometrists to

remotely evaluate and manage eye health [27]. AI-powered tele-optometry can facilitate the delivery of eye care services to underserved regions by analyzing patient-provided images, such as retinal scans and ocular images, to support early diagnosis and timely management [28]. During the COVID-19 pandemic in India, Karthikeyan et al. reported that 50.94% of optometrists relied on tele-optometry to provide their services, indicating its potential to remain a valuable component of eye care delivery beyond emergency settings [29]. Advances in DL further enhance this ability by enabling automated image analysis within tele-optometry platforms, supporting the remote management of posterior eye diseases, and referring cases to specialists when required, minimizing the need for face-to-face visits [30]. This technology not only improves the efficiency of eye care services but also alleviates the burden on overcrowded eye care clinics, allowing clinicians to prioritize urgent cases and minimize unnecessary referrals.

Another key advantage of AI-powered image analysis technology is its ability to remotely monitor chronic conditions, such as diabetic retinopathy and glaucoma. In particular, AI-based glaucoma screening can enhance the detection of moderate and advanced cases in primary care environments and help identify individuals at a higher risk of developing the condition [31]. This enables the early identification of disease progression, allowing timely intervention that may prevent further vision loss. Integrating AI with tele-optometry improves screening efficacy and optimizes the allocation of professional resources.

C. Personalized Care

AI supports individualized care in optometry, particularly in developing customized therapies for specific visual conditions. With access to vast pools of patient datasets, AI can develop tailored regimens based on visual characteristics, lifestyle, and other factors [11] [16]. Current AI-driven tools are used to design personalized contact lenses and eyeglasses by analyzing parameters such as visual acuity, astigmatism, eye structure, and even digital device usage patterns. This approach ensures more precise lens selection and recommendations, leading to effective and patient-centered solutions [32] [33].

AI is also advancing individualized care through the integration of CNNs in medical diagnostics. Hwang et al. trained an AI-based system to diagnose AMD using 35,900 Optical Coherence Tomography images, achieving over 90% accuracy, comparable to retinal specialists and outperforming medical students [34]. Beyond diagnosis, AI systems can provide appropriate treatment recommendations comparable to those of retinal specialists, demonstrating their potential for both remote and individualized care applications.

Moreover, AI systems show promise in complementing vision therapy, which is a core component of optometry care. Vision therapy involves structured exercises and activities designed to improve specific visual functions, such as eye movement coordination and binocular vision [35]. Vision therapy based on AI systems can continuously analyze patient data and assess their progress throughout the therapeutic process [36]. AI-enhanced vision therapy has the potential to optimize outcomes and improve patient adherence through continuous monitoring, follow-up care, and adaptive training. Fig. 2 provides a summary of the AI applications in optometry.

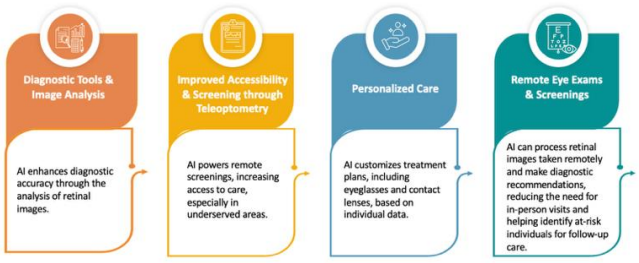

Fig. 2. Application of artificial intelligence in optometry.

III. Challenges of AI in Optometry

While AI presents significant opportunities for enhancing optometric care, its implementation in clinical practice is accompanied by several key challenges that must be overcome. These challenges extend beyond technical limitations, including socioeconomic issues, ethical considerations regarding patients' rights and data use, regulatory and legal complexities, and resistance from practitioners and patients. The following sections outline the main challenges that need to be addressed for the successful integration of AI in optometry, along with the current strategies that have been proposed to address them.

A. Technical Challenges

One of the major challenges in the application of AI in optometry is the methodological complexity of designing effective and precise models. DL-based AI systems, in particular, require extensive amounts of high-quality labeled data for effective training and performance [37]. Parmar et al. (2024) indicated that the performance of AI algorithms in identifying retinal diseases was greatly dependent on the quality of the training datasets. Models trained on biased or limited data may produce inaccurate or non-generalizable results when applied to diverse patient populations [38].

Another critical technical challenge is the "black box phenomenon", which refers to the lack of interpretability of AI models. Various DL models, particularly CNNs, are described as "black boxes" because their decision-making processes are challenging for clinicians to fully understand. This lack of transparency can undermine trust in AI systems, especially when they are used to make life-and-death clinical decisions [39]. To address this, explainable AI (XAI) strategies have been introduced to provide clearer insights into the decision-making process and enhance the overall transparency of AI models. For example, the OptiDex model was developed to enhance the detection and categorization of diabetic retinopathy. An XAI framework was incorporated using gradient-weighted class-activation maps. The model achieved a high diagnostic accuracy of 97.65% and provided visual heatmaps that explained how decisions were made [40]. This clarity improved clinician trust by indicating which retinal regions affected the output of the system. These examples emphasize how XAI can reduce the gap between accuracy and interpretability, improving both the confidence and adoption of AI in clinical optometry.

Furthermore, implementing and maintaining AI systems can be challenging because of their technical complexity, which

often requires specialized expertise and continuous support from the organization. Although it is crucial to smoothly incorporate these systems into existing clinical practices and electronic health record platforms, this integration process remains technically demanding.

B. Socioeconomic Challenges

The adoption of AI in optometry has emerged along with pressing socioeconomic challenges, particularly those associated with cost, accessibility, and healthcare equity. Among these, cost remains the most significant challenge, as AI integration involves expensive imaging machinery, advanced software, and considerable investments in staff training and resources. Muradov (2024) estimated the cost of the initial setup of the AI-based Retinal disease screening system to be between $30,000 and $50,000 [41]. Most of these costs are not covered by current reimbursement schemes; therefore, clinics in rural or low-income areas may not be able to afford such technologies. Continuous updates and maintenance contribute to the overall cost of implementing AI systems. The substantial upfront costs may place these technologies beyond the reach of smaller practices, potentially creating disparities between well-funded and under-resourced environments. To ensure the fair distribution of AI-enabled tools across all optometric practices, cost-reduction strategies, such as cloud-based alternatives or shared resources, should be explored.

Moreover, AI-based tele-optometry relies on a stable Internet connection and high-quality imaging, both of which are often limited in rural areas, limiting the application of AI in such regions [42]. Another key issue is the underrepresentation of specific population groups in the training datasets, which can result in biased AI algorithms and, therefore, provide less accurate outcomes for these groups. Such algorithmic bias perpetuates existing health disparities among different races, ethnicities, and socioeconomic levels [43]. Addressing these socioeconomic and equity-related challenges requires novel approaches to make AI both accessible and comprehensive.

One promising example is the work of Vohra et al. (2025), who developed an AI system capable of analyzing fundus images captured with cost-effective equipment using CNNs for the diagnosis of AMD, diabetic retinopathy, and glaucoma [44]. With the implementation of AI technology and cloud-based accessibility, the system achieved an accuracy exceeding 96.5%. Such efforts emphasize the potential of affordable and scalable AI solutions to bridge gaps in access and make advanced healthcare systems more widely available.

Another practical cost-reduction approach involves shifting from on-site infrastructure to cloud-based platforms. In the radiology field, healthcare organizations implementing cloud solutions have recognized up to 30% savings in infrastructure and overhead costs [45]. This strategy can also benefit optometry clinics that implement AI-driven diagnostic tools.

C. Ethical Concerns

The three major ethical issues related to the use of AI in optometry are confidentiality, security, and independence of the data. AI models rely on medical images and patient information for training and operation, raising significant concerns regarding patient privacy. The incorporation of personal health data into AI training models increases the risk of privacy infringement, data breaches, and the misuse of sensitive health information [46]. Williamson (2024) indicated that while AI offers beneficial opportunities for enhancing healthcare, inadequate protection in handling sensitive health records can undermine patient trust and compromise confidentiality, creating a conflict between innovation and privacy. Given the sensitive nature of patient information used in AI model training and operations, robust security measures are necessary to ensure data protection, maintain confidentiality, and inhibit unauthorized access or breaches.

Furthermore, the issue of informed consent for the use of AI in optometric care is a considerable ethical concern. As the application of AI systems in clinical practice increases, patients may not be fully aware of the extent to which AI technologies contribute to the diagnosis and treatment of their conditions, especially if such systems are used to provide recommendations or even make decisions on their behalf [47]. Li et al. (2021) noted that patients may lose confidence in their care if they are being treated by an algorithm rather than a clinician, raising critical concerns about patient empowerment and the ethical use of AI in healthcare [48].

D. Regulatory and Legal Barriers

The utilization of AI in optometry is associated with legal and regulatory challenges that vary significantly across geographical areas. Considerable regional regulatory disparities exist, with the European Union (EU) requiring more comprehensive protections, such as the General Data Protection Regulation (GDPR) and the AI Act, compared to the United States Food and Drug Administration (FDA)'s softer, sector-specific approach. Palaniappan et al. (2024) pointed out that the EU has adopted a stricter, risk-based framework that classifies AI in healthcare as a high-risk group, thus requiring stringent conformity evaluations, transparency responsibilities, and post-market monitoring [49]. In contrast, the FDA mainly regulates AI as part of medical devices under the present frameworks, which stress safety and efficacy but do not insist on the same level of oversight on problems such as algorithmic bias, transparency, or international data transfer. These regulatory disparities complicate the global implementation of AI in optometry.

Nevertheless, there are rising questions regarding the regulation of AI, as regulatory bodies have struggled to keep pace with its fast development, resulting in delayed approval and the establishment of clear legal standing for AI implements [50]. In addition to slowing the clinical adoption of AI, this misalignment raises uncertainty among clinicians and patients regarding the safety, reliability, and legal accountability of AI-powered services.

Moreover, legal concerns and issues of responsibility arise when an AI system provides a misdiagnosis or recommends inappropriate treatment. Uncertainty persists over whether responsibility should fall on AI developers, healthcare professionals who rely on the system, or equipment manufacturers [51]. To address these challenges, comprehensive and effective regulations must be established through collaboration among major stakeholders, including AI developers, eye care professionals, policymakers, and patient

advocacy organizations. These regulations should achieve a careful balance between utilizing AI's potential benefits of AI and protecting patient rights while ensuring ethical and responsible implementation.

Given the rapid development of AI technology and the evolving ethical landscape, it is crucial to conduct regular assessments and updates of the current guidelines. Implementing well-defined legal and regulatory frameworks can enhance trust and confidence in the application of AI in healthcare, encouraging its broader adoption while addressing potential risks.

E. Resistance to Adoption

Resistance to adoption by both optometrists and patients is a major problem in the implementation of AI in optometry. Some optometrists expressed concerns that AI could limit their professional role or reduce their control over patient care. A recent web-based survey of optometrists revealed that while many appreciate the potential of AI in enhancing diagnostic precision, a considerable number expressed concerns that AI systems cannot imitate human clinical judgment and patient-centered decision-making applied by clinicians [52].

Some optometrists are concerned about the potential of AI to lead to job displacement as more tasks become automated. Although AI is not expected to replace human optometrists entirely, it may streamline routine processes, such as image analysis, potentially resulting in job changes or the necessity for specific technical positions, thereby creating pressure for workforce adaptation and retraining. Nevertheless, AI is more likely to complement rather than replace human clinicians by alleviating routine tasks and enabling them to focus on complex cases and patient-centered care. Addressing these issues requires practical workforce planning and targeted educational initiatives. Training programs can assist eye care professionals in adjusting to the evolving demands of their field and equip them with the skills required to collaborate effectively with AI technology. Emphasizing workforce upskilling can transform the role of optometrists, allowing them to undertake advanced and specialized responsibilities in the field.

IV. Ethical Considerations of AI in Optometry

The integration of AI into optometric practice raises significant ethical concerns (Table I).

A. Patient Autonomy and AI Decision-Making

Patient autonomy refers to the right of individuals to make informed decisions regarding healthcare. One of the key ethical challenges of AI is its potential impact on autonomy, particularly when AI systems provide diagnostic or treatment recommendations. Wang et al. (2023) indicated that patients often experience discomfort when AI systems make decisions without human supervision. Although AI can be used to detect diseases such as diabetic retinopathy, the ultimate decision-making should remain with the clinician to ensure that patient values and preferences are considered [11]. In addition, patients should be well informed about AI integration into their care, including the use of their personal health data [53]. Maintaining patient autonomy not only protects personal rights but also strengthens trust and acceptance of AI integration in optometric practice.

TABLE I. Ethical Considerations of AI in Optometry

Ethical concern	Description	Implications
Patient Autonomy	Ensuring patients can make informed decisions, even with AI involvement.	AI should support, not replace, clinical judgment. Patients must be informed about the role of AI and allowed to opt out if desired [2],[3].
Bias and Fairness	AI may be biased if trained on non-representative data, affecting accuracy for certain population groups.	Models must be trained on diverse and representative data to minimize bias, ensure accuracy, and promote equitable care [4–6].
Transparency in AI	AI decision-making processes are often opaque, hindering trust and understanding.	AI systems should provide explainable outputs, allowing clinicians to understand the rationale behind AI-driven decisions [7].

B. Bias and Fairness

AI bias is a major issue because of the lack of diversity in the training datasets. Many AI models have been developed and trained based on data obtained mainly from high-income urban populations, which limits their usefulness for patients from other demographic groups [54]. For example, Jacoba et al. (2023) reported that AI systems designed to diagnose retinal diseases may be less accurate in rural or minority populations, resulting in healthcare inequalities [55]. To this end, AI models should be trained on quantitative and qualitative datasets that represent individuals across diverse age groups, ethnicities, and socioeconomic backgrounds. Addressing these challenges requires a shift toward developing robust, interpretable, and unbiased AI models. |Equally critical is the comprehensive validation of these systems across a diverse spectrum of patient demographics to ensure their efficacy and universal applicability to all patients.

To alleviate data scarcity while maintaining patient privacy, multi-center federated learning has recently emerged as a promising approach in the development of medical AI. This collaborative strategy enables training on diverse datasets distributed across institutions without transferring sensitive patient data by exchanging model updates rather than raw data. Various studies have shown its efficacy and privacy benefits. For example, Linardos et al. (2022) simulated federated learning across four cardiac imaging centers and found that models trained in a distributed, privacy-preserving mode performed competitively with traditional centralized approaches, even with limited datasets (180 subjects) [56]. A novel adaptive aggregation framework for federated learning was proposed by Haripriya et al. (2025), enhancing collaborative model training across multiple medical centers without exposing patient data [57]. These findings emphasize the potential of federated learning to overcome data scarcity and enhance model generalizability across heterogeneous patient populations.

C. Transparency in AI Algorithms

Ensuring transparency in AI algorithms is crucial for promoting confidence among clinicians and patients. CNNs and many other AI models are often called "black boxes" because their decision-making processes are not easily interpretable [58]. Roy et al. (2023) stressed the growing importance of XAI, which can provide clinicians with insights into how AI systems arrive at their conclusions [59]. For instance, in the diagnosis of diabetic retinopathy, an XAI should be able to visually highlight the retinal features that lead to a diagnosis. Such transparency is important for improving clinical accountability and empowering clinicians to integrate AI technology responsibly into patient care, thereby improving both trust and clinical adoption [60].

V. Current Research Gaps and Future Directions

Current research on AI applications in optometry focuses on addressing several key gaps that are critical for improving the accuracy, reliability, and integration of AI technologies into clinical practice. One major research gap is the lack of diverse and representative training datasets. As AI systems are highly dependent on the data used for training, many existing optometry datasets are limited in terms of demographic diversity and clinical variability. Studies have shown that AI models trained predominantly on data from high-income urban populations may exhibit biases when applied to rural or minority populations [55]. This limitation hinders the applicability of AI systems and may result in healthcare service inequalities. Thus, it is crucial to develop datasets that include a wide range of ethnicities, age groups, and clinical conditions to ensure fair and equitable performance. Furthermore, the creation of standardized datasets for AI model training and evaluation is essential to ensure the reproducibility and reliability of AI-driven diagnostic systems in clinical practice. This process involves addressing challenges, such as data variability, and ensuring that the datasets used to train AI models reflect the diverse populations they are intended to serve.

Another critical gap is the limited validation and scarcity of large-scale clinical studies investigating the effectiveness of AI in optometry. Although several studies have reported promising findings when AI models are applied under controlled conditions, their real-world integration into clinical practice remains unexplored. Shen et al. (2019) indicated that to assess the safety and efficacy of AI systems in the diagnosis of retinal diseases and guiding the treatment, it is necessary to conduct large-scale, multi-center clinical trials [61]. Such trials would not only provide evidence of clinical usefulness but also ensure regulatory compliance and readiness for integration into routine clinical practice. Therefore, robust validation is a prerequisite for promoting clinical confidence and enhancing the safe adoption of AI in optometry.

Furthermore, providing collaborative training opportunities for AI developers and clinicians is crucial for narrowing this gap. The active involvement of optometrists in the development and adoption of AI systems ensures their alignment with existing workflows and clinical requirements [62]. Continuous training programs are important to ensure that healthcare providers are well placed to deliver care using new AI technologies, [1]. Such programs should focus on enhancing competencies in the effective use of AI systems while preserving the human touch in patient interactions. Professional associations and academic institutions play a key role in preparing optometrists for this evolving field by offering curricula that involve both technical components of AI and its ethical and clinical implications. This includes guidance on analyzing AI-produced outcomes, recognizing potential biases, and effectively conveying insights to patients. Ongoing education will enable optometrists to remain updated on the latest developments in AI technology and adopt the best practices for its clinical integration.

VI. Conclusion

AI has considerable potential to transform optometry by improving diagnostic accuracy, enhancing patient care, and expanding access to vision care services. AI-integrated innovations encompass several tools, including image analysis, tele-optometry, and personalized treatment plans, representing significant advancements in the field. However, the effective implementation of these AI technologies requires careful consideration of technical, socioeconomic, ethical, and legal challenges. Major barriers include the lack of diverse datasets for training, insufficient large-scale validation studies, and the need for stronger cooperation between AI developers and clinicians. Overcoming these challenges is essential to enhance optometric practices and ensure equitable, high-quality eye care services for all patients.

Abstract*—Efficient and reliable node deployment in Wireless Sensor Networks is crucial for optimizing coverage of the area, connectivity among nodes, and energy efficiency. Random deployment of nodes may lead to coverage gaps, connectivity issues and reduce network lifetime. This study proposes a hybrid metaheuristic approach combining a Genetic Algorithm (GA) and Particle Swarm Optimization (PSO) to address the challenges of energy-efficient and reliable node deployment. The GA-PSO hybrid leverages GA's strong exploration capabilities and PSO's rapid convergence, achieving an optimum stability between coverage and energy consumption. The performance of the proposed approach is evaluated against GA and PSO alone and the innovatory metaheuristic-based Competitive Multi-Objective Marine Predators Algorithm (CMOMPA) across varying sensing ranges. Simulation results demonstrate that GA-PSO requires 15 to 25% fewer sensor nodes and maintains 95% or more area coverage while maintaining connectivity in comparison to the standalone GA or PSO algorithm. The proposed algorithm also dominates CMOMPA when compared for long sensing and communication range in terms of higher coverage, improved connectivity, and reduced deployment time while requiring fewer sensor nodes. This study also explores key trade-offs in WSN deployment and highlights future research directions, including heterogeneous node deployment, mobile WSNs, and enhanced multi-objective optimization techniques. The findings underscore the effectiveness of hybrid metaheuristics in improving WSN performance, offering a promising approach for real-world applications such as environmental monitoring, smart cities, smart agriculture, disaster response, and IIoT.

Keywords*—Node deployment; wireless sensor networks; genetic algorithm; particular swarm optimization; competitive multi-objective marine predators algorithm

I. Introduction

Recently, wireless sensor networks (WSNs) emerged as a crucial technology for environ-mental monitoring, wildfire monitoring, healthcare, smart cities, flood monitoring, industrial automation, military surveillance, monitoring of infrastructure, humidity, wind, and population levels [1, 2]. WSNs comprise distributed sensor nodes (SNs) that collaborate to collect, process, and communicate the data to a central system called a sink node or base station (BS). These SNs are tiny and contain limited power resources, storage, communication, sensing, and processing capacity to facilitate real-time monitoring and decision-making of physical and environmental conditions of AoI [3]. The importance of WSNs is due to their ability to periodically detect events and communicate them to the BS for further processing. WSN architecture can be used with IoT, fog, and edge computing. WSNs have a varying range of applications, so it is important to ensure maximum area coverage and node connectivity with constrained resources and environmental uncertainty during node deployment [4]. Deployment is how to position SNs in optimal locations to ensure high-area coverage. An optimal deployment ensures enhanced event detection and reduced deployment cost. Approaches such as the random scattering of nodes or grid-based placement led to coverage gaps, energy holes, and sometimes network partitioning, especially in large WSNs [5].

Traditional optimization methods often fail to address the multi-objective nature of the problem due to the lack of resources and dynamic characteristics of the environments. Metaheuristic approaches have gained popularity due to their ability to explore large search spaces and provide near-optimal solutions. Existing optimization algorithms, including GA and PSO, have shown improvement in node deployment but have inherent limitations. GA excels at global exploration through crossover and mutation, but struggles with slow convergence and poor local refinement. On the other hand, PSO efficiently exploits local optima via swarm intelligence but risks premature convergence in complex search spaces [6, 7].

In this study, we propose a novel metaheuristic-based hybrid of the GA-PSO algorithm. Hybrid algorithms leverage the advantages of different optimization techniques to over-come individual limitations. The GA-PSO begins with GA for a broad global search, ensuring diversity through crossover and mutation. The best solutions from GA are then fine-tuned using PSO for faster convergence. The PSO-GA starts with PSO to quickly identify promising regions using its quick

convergence, and then GA introduces diversity through crossover and mutation, preventing stagnation in local optima. GA-PSO is ideal for large, complex problems, where avoiding premature convergence and ensuring diverse exploration are critical. The algorithm employs various parameters, including dynamic cognitive and social weights and elitism-driven phase transition, to optimize node placement across varying areas. The main contributions of the proposed GA-PSO algorithms are:

- A new method with a two-phase hybrid algorithm to solve the node deployment problem. The proposed algorithm ensures optimal area coverage while ensuring connectivity with minimum SNs.
- The scalability of the proposed algorithm is demonstrated with consistent performance across varying areas from 100*100 to 500*500 meters, reducing node counts by 15 to 25% compared to standalone GA and PSO algorithms.
- The proposed algorithm dominates the CMOMPA algorithm for a high sensing and communication range and requires less SN to ensure optimal coverage while maintaining connectivity.
- The proposed algorithm ensures optimized placement of nodes to reduce energy consumption by minimizing redundant coverage overlap.

The remainder of this study is organized as follows: Section II presents the background and related work. Section III describes the system model and problem formulation. Section IV introduces the proposed hybrid metaheuristic approach. Section V outlines the simulation and experimental setup. Section VI discusses the results and findings. Finally, Section VII concludes the study and suggests directions for future work.

II. BACKROUND AND RELATED WORK

WSNs play a major role in a wide range of applications that require continuous monitoring of the area in which they are deployed. The fundamental architecture of WSNs uses numerous SNs spread across the AoI to periodically sense and collect data, which is then transmitted to the BS either directly or through intermediate nodes. These intermediate nodes facilitate communication when SNs are too far from the BS or to minimize energy consumption, as direct communication over longer distances consumes more energy. Sometimes, SNs inside the AoI form a local group called cluster, and one of the nodes within the cluster works as a CH to perform inter and intra-cluster communication among SNs [1, 2]. Fig. 1 represents a hierarchical WSN. In this research, all nodes have identical hardware capabilities and remain in fixed positions after deployment. The static nature of SNs poses explicit challenges, particularly in optimized deployment to ensure maximum area coverage, maintaining reliable connectivity, and prolonging network lifetime, which are essential for effective monitoring and operation [8].

Node deployment is a critical phase in WSNs, as it directly influences the overall performance of the network. Coverage refers to the part of the AoI that is within the sensing range of the SNs, while connectivity ensures that all deployed nodes can communicate either directly or indirectly with the BS [9, 10]. The coverage problem can be classified as area coverage or target coverage. The area coverage concerns the entire AoI, whereas the target coverage problem focuses on monitoring some points in the AoI. Connectivity within a WSN ensures that data collected by the SNs can be reliably transmitted to the BS for further processing [15]. A well-connected network facilitates efficient communication and data aggregation, reducing the likelihood of data loss or delays. Ensuring robust connectivity is particularly challenging in large-scale or harsh environments, where obstacles or node failures can disrupt communication paths. Optimizing connectivity is vital to maintaining the network's integrity and ensuring continuous data flow [16]. WSNs use several connectivity approaches [see Table I] to ensure the network's performance, reliability, energy efficiency, and robustness.

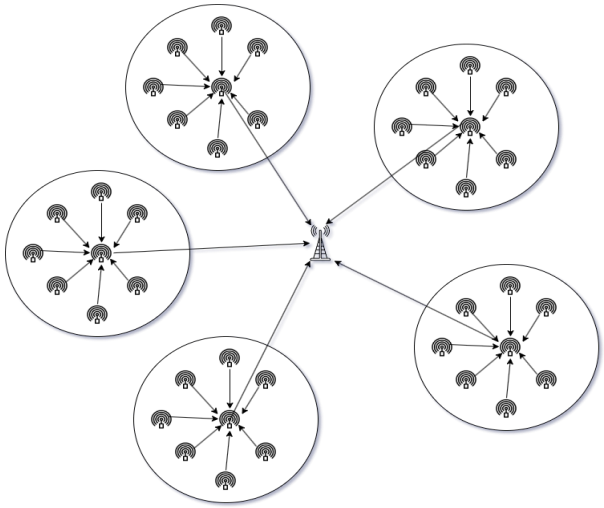

Fig. 1. Wireless sensor network.

The energy efficiency of WSNs is another critical factor. SNs are typically powered by limited-capacity batteries. Once deployed, these SNs are often difficult or impossible to recharge, especially in remote or hazardous environments. As a result, energy utilization must be minimized to prolong the WSN's operational lifetime. Balancing energy utilization across the network while maintaining necessary functionality is a complex challenge that directly influences the network's sustainability and effectiveness. The interplay be-tween coverage, energy efficiency, and connectivity present a complex optimization problem. Improving one aspect often impacts the others, creating trade-offs that must be carefully managed. For instance, increasing coverage might require activating more SNs, which could deplete energy resources more quickly. Similarly, enhancing connectivity might involve more frequent communication between nodes, further draining their batteries. Therefore, developing strategies that simultaneously optimize coverage, energy efficiency, connectivity, and node deployment cost is critical for the long-term success and re-liability of WSNs.

In WSNs, nodes are typically deployed using either deterministic or stochastic methods. Deterministic deployment methods, such as grid and triangular tessellation, ensure

uniform node placement in the area [8, 9]. Stochastic methods, including random and probabilistic approaches, offer better flexibility in deployment but often result in suboptimal coverage and connectivity [10-14].

TABLE I. COMMON CONNECTIVITY CATEGORIES [17-20]

Connectivity	Description
Single-hope	In single-hop connectivity, SNs directly communicate to the BS.
Multi-hope	Various nodes are utilized to send the data to the BS.
Cluster-based / Hierarchical	In cluster-based connectivity, SNs form a cluster, and a SN node in the cluster works as a cluster-head (CH) and other SN communicated sensed data to CH and CH communicate this data to the BS.
Mobile agent-based	Mobile agents move within the network, collecting data from sensor nodes and reducing the energy consumption of static nodes.
Hybrid	A network might use cluster-based connectivity within clusters and multi-hop Connectivity between cluster heads and the base station.
Dynamic	In WSN, network topology can change over time due to SN mobility, varying environmental conditions, or energy depletion. This type of connectivity is particularly relevant for mobile WSNs or environments where nodes frequently enter and leave the network.

Various optimization methods based on traditional mathematical models, such as linear programming, integer programming, and geometric algorithms, have been used to find optimal node positions for node deployment in WSNs. These algorithms are effective for small-scale networks and become computationally infeasible for large-scale networks due to the exponential growth of the search space [21, 22]. In recent years, metaheuristic-based algorithms, such as GA, PSO, and Ant Colony Optimization (ACO), have gained popularity due to their ability to handle multi-objective optimization problems with large search spaces. These algorithms rely on stochastic processes to explore and exploit the solution space that offers a higher degree of flexibility and adaptability compared to traditional mathematical models.

Authors in [23] utilized PSO to improve coverage and connectivity by dynamically placing the node to fill the coverage gaps. In [24], the integration of the Intelligent Satin Bower Optimizer and Reinforcement Learning (ISBO-RL) is used for adaptive node placement for improved network performance. This combination not only optimizes nodes positioning but also improves overall network performance offering significant improvements in both coverage and connectivity. Work in [25] highlights the role of AI-driven algorithms in enhancing coverage, securing connections, and reducing energy consumption through dynamic scheduling and mobility schemes. These strategies improve network coverage and security while addressing the practical limitations of sensor nodes, such as limited resources and uncertain monitoring capabilities. AI-based optimizations, including data fusion models for task scheduling and topology recovery, have been shown to effectively manage node deployment, achieving better network coverage and reliable security connectivity.

In [26], there are various algorithms and techniques for relay node placement in WSNs to improve performance by addressing challenges such as reliability, energy consumption, and limited sensing and communication range. These methods aim to tackle the relay node deployment problem, enhancing WSN performance in real-world applications where these limitations can significantly degrade network effectiveness. Paper [27] introduces a distributed deployment method for WSNs that leverages multi-agent systems with autonomous and leadership mechanisms to optimize SN placement and improve network coverage. Through a unified deployment model featuring CH nodes, this approach effectively integrates autonomous and leadership functions, as confirmed by simulations that validate the models and algorithms used. Addressing limitations like poor self-adaptive deployment capabilities and high costs from diverse node types, this method enhances adaptive deployment, reduces costs, and minimizes blind spots in coverage. Authors in [28] proposed that the "X" partition strategy optimizes SN distribution within monitored areas, effectively lowering deployment costs and extending network life by over 50% compared to the diamond partition strategy. By partitioning areas to strategically position nodes, this method reduces both energy consumption and deployment expenses in WSNs, significantly enhancing network longevity through an efficient deployment approach.

Paper [29] introduces an improved moth flame optimization (IMFO) algorithm for node deployment in WSNs, enhancing coverage and minimizing energy consumption by repairing coverage gaps and leveraging virtual forces among nodes. Key features include a variable spiral position update and an adaptive inertia weight strategy, which analyze node virtual forces and optimize deployment paths for efficient coverage and energy use.

Hybrid metaheuristic approaches have emerged as a promising solution to this problem. By integrating the exploration capabilities of one algorithm with the exploitation strengths of another, hybrid methods aim to achieve a more balanced search process. For example, combining GA's robust exploration with PSO's efficient convergence can result in faster, more reliable solutions to the node deployment problem. Despite the success of hybrid methods in other domains, relatively few studies have applied them to the specific challenges of node deployment in WSNs. This gap in the literature motivates the development of a hybrid GA-PSO approach, which aims to improve the trade-offs between coverage, connectivity, and cost, while addressing the limitations of single-method optimization techniques.

III. SYSTEM MODEL AND PROBLEM FORMULATION

In the decentralized architecture of WSNs, maximizing area coverage along with connectivity among SNs by using a minimum number of SNs is an important issue in SN deployment. The optimal placement of SNs not only ensures maximum area coverage and connectivity but also prolongs network lifetime and reliability. We have focused on the sensing and communication models of SNs simultaneously, and the SNs are deployed within the AoI [33]. Each SN has a limited R_s which means the SN can detect events within the range. The binary sensing model is used (Fig. 2), where the sensing area is circular with a radius of R_s. Eq. (1) calculates the probability of any event being detected by an SN [34]. Let A denote the area in (M * N) meters.

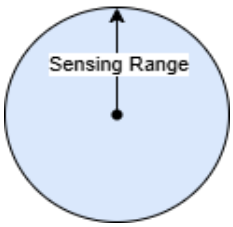

Fig. 2. A node with binary disk sensing.

$$SN_{sensing} = \frac{\pi R_S^2}{A} \quad (1)$$

∀ Ξι; ι ∈ {0, □, M}, ∀ Ψφ; φ ∈ {0, ..., N}, A= [M, N]

The Euclidean distance is the distance between two points and can be calculated using Eq. (2):

$$d(SN_i, E) = \sqrt{\left(X_{SN_i} - X_E\right) + \left(Y_{SN_i} - Y_E\right)} \quad (2)$$

If any event occurs within the Euclidean distance from the SN, then the event will be detected by the SN. If all the events are detected by one or more SNs, the network offers optimal coverage. However, the optimal coverage does not ensure proper connectivity among nodes. The connectivity ensures the transmission of data to the BS either directly or using multiple hops. In this study, we have considered R_c twice the R_s, which is commonly used in literature. Two SNs (SN_i, SN_j) are called connected if the distance between them is less than or equal to the communication range (R_c) [35]. The distance $d(SN_i, SN_j)$ can be calculated using Eq. (2), and connectivity can be verified using Eq. (3):

$$d(SN_i, SN_j) \leq R_c \,\&\, R_c \geq 2R_s \quad (3)$$

The problem of node deployment to ensure maximum coverage is an NP-hard problem [36]. Due to constrain in computing resources, traditional methods are not suitable to solve the complex deployment problem because these problems require high computation. The traditional algorithms fall into local optima and do not generate optimal solutions. Metaheuristic algorithms offer better solutions for NP-hard problems [6].

The proposed algorithm utilizes a hybrid of GA and PSO algorithms to address node placement for ensuring optimal coverage and connectivity within the network. Both algorithms are metaheuristic optimization algorithms and are adaptable to handle complex, multi-objective optimization problems. The GA algorithm excels in exploring the search area through crossover and mutation, and also avoids premature convergence by introducing diversity. The PSO quickly converges to regions of the solution space and is suitable for continuous optimization problems [6] [37, 38]. The proposed hybrid GA-PSO algorithm handles node deployment while simultaneously ensuring optimal coverage and connectivity. SNs are initially distributed in the area, and the GA-PSO algorithm is used to adjust their positions to ensure optimal area coverage and connectivity. The study considers regular shapes under environmental noise conditions. This problem is multi-objective, requiring a balance between various objectives.

A. Objectives

The primary objectives of the node deployment problem has been formulated as follows.

1) Maximize coverage: Coverage refers to the proportion of the area A that is effectively monitored by the SNs. Each $i \in \{1,2,\ldots,n\}$ has R_s, defined as a circular area centered at the node's position (x_i, y_i) with radius R_s . The objective is to ensure a minimum 95% of the area is within the R_s of at least one node. The coverage (Δ) can be calculated using Eq. (4):

$$\Delta = \frac{1}{K} \sum_1^K i \; (\exists n \in n, \; (p_k, n) \leq R_s) \quad (4)$$

where, K = 500 Monte Carlo samples p_k are uniformly distributed across the area A.

2) Ensure connectivity: A network is connected when all deployed nodes can communicate with each other, either directly or indirectly using intermediate nodes called multi-hop communication. The objective is to maximize the overall connectivity of the network, which can be defined as the proportion of nodes that are part of the largest connected component of the network's communication graph, which can be calculated using Eq. (5):

$$\Psi = \frac{|\psi|}{n} \quad (5)$$

where, ψ the set of nodes is in the largest connected component, and n is the total number of nodes.

$$\Psi = \begin{cases} 1 \; if \exists \; path \; between \; all \; nodes \; pairs \; via \; R_c \\ 0 \; otherwise. \end{cases}$$

3) Minimize energy consumption: Energy efficiency is crucial for prolonging the network's lifetime. Each SN consumes energy primarily for communication and sensing tasks. The total energy consumption E_{total} of the network is the sum of the energy consumed by all SNs. For a node i, the energy consumed for transmitting a message to node j at distance d (i, j) can be modeled by Eq. (6):

$$E_{transmit}(i,j) = E_{elec} * L + E_{amp} * L * d(i,j)^2 \quad (6)$$

where, E_{elec} is the energy dissipated in the electronic circuit, E_{amp} is the amplification energy, and L is the size of the data packet. The objective is to minimize the total energy consumption across all SNs, given using Eq. (7):

$$E_{total} = \sum_{i=1}^N E_i \quad (7)$$

where, E_i represents the total energy consumed by an SN i.

4) Minimize node count: Deploy the fewest SNs to satisfy coverage and connectivity with constraints to node positions (x_i, y_i) are subject to real-world noise.

B. Constraints in Node Deployment

The node deployment in area A is subject to the following constraints.

1) Sensing and Communication Range: The R_s and R_c of each node are limited. A node can only monitor areas within

its R_s and can only communicate with nodes within its R_c. Thus, the distance between two nodes i and j must satisfy the Eq. (3) to ensure detection and communication of an event.

2) Energy limitation: Each SN has a finite energy supply, denoted as E_{max} , which limits the total energy that can be consumed during its operation. The total energy consumed by each SN must not exceed this limit.

$$E_i \leq E_{max} \, \forall_i$$

3) Node placement: SNs must be deployed within the boundaries of the area A. Let $(x_{min}, x_{\max})$ and $(y_{min}, y_{\max})$ represent the boundaries of the area A, then the coordinates (x_i, y_i) of each node i must satisfy the following.

$$(x_{min} \leq x_i \leq x_{max}), (y_{min} \leq y_i \leq y_{max})$$

C. Trade-offs in Node Deployment

The node deployment problem inherently involves various trade-offs between coverage, connectivity, energy efficiency and number of nodes.

- Increasing the number of SNs or their R_s can improve coverage but may lead to higher energy utilization due to increased data transmission.
- Deploying SNs to maximize connectivity may result in coverage gaps, reducing the effectiveness of the network's monitoring capabilities.
- Prioritizing energy efficiency by reducing transmission power or node activity may lead to reduced connectivity or coverage.

Thus, the optimization problem involves balancing these competing objectives to achieve a deployment strategy that maximizes coverage and connectivity while minimizing energy consumption.

D. Mathematical Formulation of the Optimization Problem

The node deployment problem can be formulated as a multi-objective optimization problem, where the goal is to maximize coverage and connectivity and minimize total energy utilization E_{total} and number of SNs required to ensure optimum coverage and connectivity, subject to the constraints discussed above. The overall problem can be expressed as:

$$Maximize \; \Delta \; \& \; \Psi \text{ and } Minimize \; E_{total}$$

Συβφεχτ το:

$$d(i,j) \leq R_c \, \forall_{i,j}, E_i \leq E_{max} \, \forall_i$$

$$(x_{min} \leq x_i \leq x_{max}), (y_{min} \leq y_i \leq y_{max}) \, \forall_i$$

This multi-objective optimization problem requires an efficient search algorithm capable of finding solutions that balance coverage, connectivity, and energy efficiency while satisfying all constraints.

IV. Proposed Hybrid Metaheuristic Approach

In this section, key components of the proposed metaheuristic-based hybrid GA-PSO algorithm are discussed, including the initialization process, fitness function, crossover, mutation, particle swarm updates, and stopping criteria. The GA is an evolutionary-based optimization algorithm inspired by the process of natural selection. It operates on a population of candidate solutions called chromosomes and applies selection, crossover, and mutation operations to evolve toward an optimal solution. PSO is a population-based optimization technique inspired by the social behavior of birds flocking or fish schooling. It works with particles (potential solutions) that move through the search space according to their own experience and the collective experience of the swarm. The hybrid approach is designed to balance exploration and exploitation in the search space, effectively maximizing coverage while ensuring network connectivity. The integration of GA and PSO helps to overcome the individual weaknesses of these algorithms, such as premature convergence in GA and slow convergence in PSO. Fig. 3 explains the flow of the GA algorithm. The key components of the proposed hybrid GA-PSO algorithm are discussed below.

A. Initialization

The hybrid algorithm starts by initializing a population of N_p solutions, where each solution $X_i = \{(x_i^1, y_i^1), (x_i^2, y_i^2), \ldots, (x_i^N, y_i^N)\}$ represents the coordinates of N SNs in A. The initial population is generated randomly within the boundaries of A, ensuring that the nodes are placed within the allowed region.

$$x_{min} \leq x_i^k \leq x_{max}, y_{min} \leq y_i^k \leq y_{max} \, \forall_i, k$$

where, k is the node index and i is the population index.

B. Fitness Function

The fitness of each candidate solution is evaluated based on three objectives: coverage maximization, connectivity maximization, and energy consumption minimization. The fitness function $F(X_i)$ is a weighted sum of these objectives.

$$F(X_i) = w_1 . \Delta(X_i) + w_2 . \Psi(X_i) - w_3 . E_{total}(X_i)$$

where, (w_1, w_2, w_3) are weight factors that reflect the relative importance of each objective to ensure the balance among multi-objective criteria of the problem.

- Coverage $\Delta(X_i)$ is calculated as the proportion of the total area covered by the sensing ranges of the nodes in the solution X_i.
- Connectivity $\Psi(X_i)$ is the ratio of nodes that are part of the largest connected component of the network's communication graph.

C. Selection, Crossover, and Mutation (GA Operators)

- Selection: A subset of solutions is selected from the population based on their fitness values using a selection method, such as tournament selection or roulette wheel selection. This ensures that better solutions have a higher chance of being selected for reproduction.
- Crossover: Selected parent solutions are combined using crossover operations to create new offspring. The crossover operator exchanges segments of the parent solutions to explore new regions of the search space. In

this case, uniform crossover or two-point crossover can be applied to the node coordinates:

$$X_{child}^{k} = \begin{cases} X_{parent1,\ \ with\ probability\ 0.5}^{k} \\ X_{parent2,\ \ otherwise}^{k} \end{cases}$$

where, k refers to a particular node in the solution.

- Mutation: After crossover, a small mutation is applied to the offspring by randomly altering the coordinates of a few nodes. The mutation ensures diversity in the population and helps avoid premature convergence. Mutation is defined as:

$$x_{mutated} = x_{original} + \Delta_x, y_{mutated} = y_{original} + \Delta_y$$

where, Δ_x and Δ_y are small random values within the predefined range of the node coordinates.

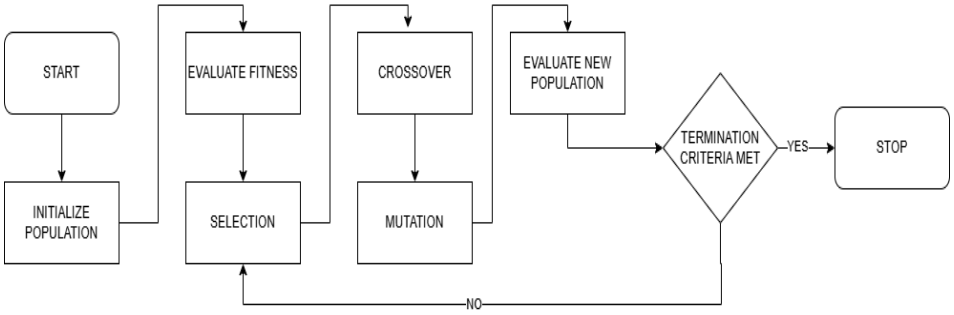

Fig. 3. Genetic algorithm.

D. Particle Swarm Updates (PSO Operators)

In the PSO phase, each solution (now treated as a particle) updates its position in the search space based on its current velocity and the best solutions found by itself (personal best) and by the swarm (global best), given in Fig. 4. The position and velocity update rules for each particle X_i^k are given by:

$$v_i^k(t+1) = w.v_i^k + c_1.r_1.\left(p_i^k - X_i^k(t)\right) + c_2.r_2.(g^k - X_i^k(t))$$

$$X_i^k(t+1) = X_i^k(t) + v_i^k(t+1)$$

where,

- $v_i^k(t)$ is the velocity of particle i at iteration t,
- w is the inertia weight that controls exploration,
- c_1 and c_2 are cognitive and social coefficients, respectively,
- r_1 and r_2 are random numbers between 0 and 1,
- p_i^k is the personal best position of particle \(i\),
- g^k is the global best position found by the swarm.

The PSO updates help the algorithm to exploit promising regions of the search space by fine-tuning the solutions generated by GA.

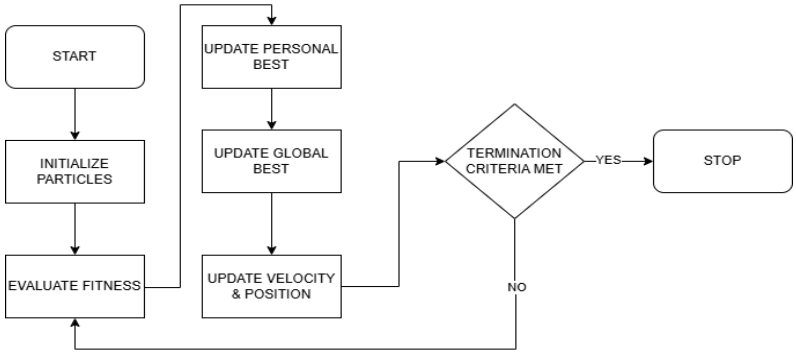

Fig. 4. Particle Swarm Optimization (PSO) algorithm.

E. Stopping Criteria and Optimization Loop

The hybrid GA-PSO algorithm (see Algorithm 1) iterates through several generations, combining GA and PSO operations in each iteration. The algorithm terminates when one of the following stopping criteria is met:

- A maximum number of iterations T_{max} is reached.
- The improvement in fitness values falls below a predefined threshold ε, indicating convergence.

The final solution represents an optimal or near-optimal node deployment strategy that balances coverage, connectivity, and energy consumption in the square area. Fig. 5 provides the procedural steps and logical structure of the proposed hybrid algorithm.

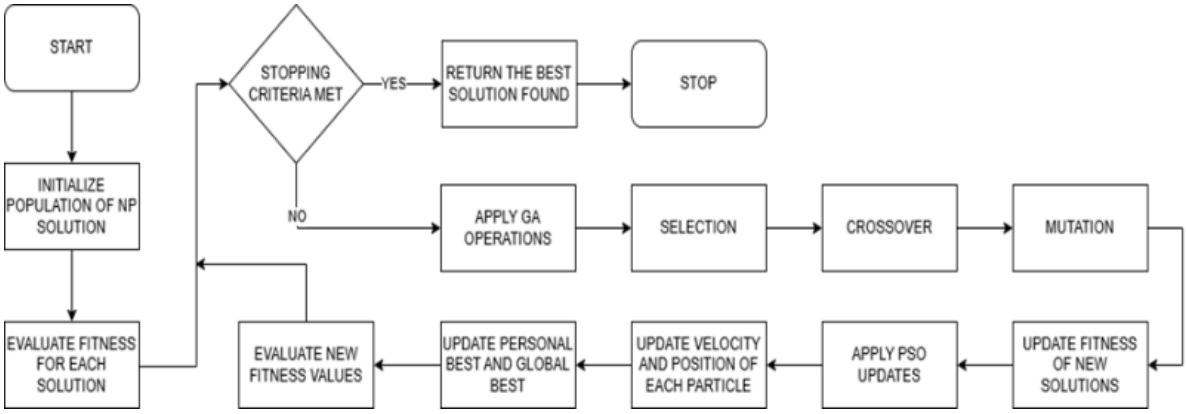

Fig. 5. Flowchart of proposed GA-PSO algorithm.

Algorithm 1: Pseudocode of the hybrid GA-PSO algorithm

Initialize population of Np solutions (X_1, X_2, ..., X_{Np})
Evaluate fitness F(Xi) for each solution
While stopping criteria not met:
  Apply GA operations (Selection, Crossover, Mutation).
  Update the fitness of new solutions
  Apply PSO updates (Update velocity & position of each particle and update personal best (pi) and global best (g))
  Evaluate new fitness values
End
Return the best solution found

V. Simulation and Experimental Setup

To evaluate the performance of the proposed hybrid metaheuristic approach for node deployment in WSN, we conducted extensive simulations. The aim was to analyze how well the hybrid GA-PSO algorithm maximizes coverage, ensures connectivity, and minimizes energy consumption E_{total} by reducing the number of SNs and intersecting areas among them. In this section, we outline the details of the simulation environment, parameters, and evaluation metrics, followed by the design of the experiments conducted. The simulation experiments were conducted using a custom-built simulation platform designed to model node deployment, coverage, and communication in WSNs. The platform is developed in Python.

A set of N SNs is deployed in the area A, and the position of SNs is determined by the optimization algorithms. The number of SNs is changed in the experiments to evaluate the algorithm's scalability. These parameters are set based on the capabilities of the SN. In our experiments, the communication range is twice the sensing range of the SN.

These values ensure that nodes can communicate over longer distances than they can sense, which is typical for WSNs. The energy consumption model described in Section III is applied to simulate the energy dissipation during sensing, communication, and transmission. The energy parameters used in the simulation are as follows:

$$Eelec = 50\, nJ/bit$$

$$Eamp = 100\, pJ/bit)/m2$$

$$L = 4000\, bits$$

Each node's energy consumption during transmission is calculated using:

$$E_{transmit} = E_{ele} \,.\, L + E_{amp} \,.\, L \,.\, d(i,j)^2$$

where, d(i, j) is the distance between nodes i and j.

To assess the effectiveness of the proposed hybrid GA-PSO algorithm, we compare its performance against GA and PSO. A standard GA is implemented as a single-method optimization approach. The same selection, crossover, and mutation mechanisms described in Section IV are applied. A traditional PSO algorithm is also implemented, with particle velocity and position updates as described in Section IV. The algorithm is initialized with the same population as the hybrid method for a fair comparison. As a non-optimized baseline, nodes are randomly deployed within area A. This serves as a lower-bound comparison to demonstrate the improvement provided by metaheuristic optimization.

To evaluate the performance of the proposed algorithm, we have used metrics to evaluate coverage, connectivity and energy consumption across various parameters. Network lifetime is defined as the time until the first SN depletes its energy supply. It reflects the energy efficiency and durability of the network. The convergence rate of the algorithm is evaluated based on how quickly the fitness values stabilize across iterations. This provides insight into the algorithm's efficiency in finding near-optimal solutions.

VI. Results and Discussion

In this section, the results of the simulation experiments are presented using the proposed hybrid GA-PSO approach for node deployment in WSN. We compare the performance of our hybrid approach with GA and PSO deployment strategies to ensure the effectiveness of the proposed algorithm. We have used varying area sizes along with different parameters to find out the number of SNs required to ensure optimal coverage of the area based on the area size, sensing range, and communication range. Several nodes are calculated for various area sizes 100*100, 150*150, 200*200, 300*300, and 500*500 for each area. We have used sensing range (10, 15, 20, and 25), and communication range (20, 30, 40, and 50) of nodes.

A. Parameter Settings 1

A population of N_p candidate solutions are initialized randomly within the area A. The initial solutions for GA, PSO, and the hybrid GA-PSO algorithm are the same for consistency in comparison. The parameters of the algorithms are given in Table II, whereas Table III contains the number of SNs required to ensure optimal coverage and connectivity.

TABLE II. PARAMETERS VALUES (SET-1)

Parameter	Value
Target Coverage	95%
Monte Carlo Samples	500
Population Size	50
Maximum Generations	50
Crossover Rate	0.8
Mutation Rate	0.1
Cognitive Weight	1.5
Social Weight	1.5

The above parameters are common for the algorithms used, while the area size varies from 100*100, 150*150, 200*200, 300*300, and 500*500 with varying sensing (10, 15, 20, and 25) and communication ranges (20, 30, 40, and 50).

TABLE III. SNS REQUIRED FOR OPTIMAL AREA COVERAGE

Area Size	Sensing Range (m)	Comm. Range (m)	GA Alone	PSO Alone	Hybrid GA-PSO
100×100	10	20	43	41	36
100×100	15	30	22	21	19
100×100	20	40	14	13	12
100×100	25	50	10	9	8
150×150	10	20	89	85	76
150×150	15	30	41	39	36
150×150	20	40	25	24	22
150×150	25	50	18	17	16
200×200	10	20	155	148	132
200×200	15	30	71	68	61
200×200	20	40	42	40	36
200×200	25	50	28	27	25
250×250	10	20	206	198	165

B. Parameter Settings 2

The parameters used for evaluating the proposed algorithm, along with the GA and PSO algorithm, are updated such as maximum generation, cognitive weight and social weight. The parameters are given in Table IV, whereas Table V discusses the number of SNs required to ensure optimal coverage and connectivity.

TABLE IV. PARAMETERS (SET-2)

Parameter	Value
Target Coverage	95%
Monte Carlo Samples	500
Population Size	100
Maximum Generations	100
Crossover Rate	0.8
Mutation Rate	0.1
Cognitive Weight	2.0
Social Weight	2.0

TABLE V. SNS REQUIRED FOR OPTIMAL AREA COVERAGE (SET-2)

Area Size	Sensing Range (m)	Comm. Range (m)	GA Alone	PSO Alone	Hybrid GA-PSO
100×100	10	20	38	36	32
100×100	15	30	19	18	16
100×100	20	40	12	11	10

500×500	25	50	135	125	105

The Hybrid GA-PSO consistently requires fewer nodes than GA and PSO alone, demonstrating its efficiency in optimizing SN placement while maintaining coverage. As the area size increases, the gap between GA-PSO and the standalone methods widens, highlighting its superior scalability and optimization capability.

In Fig. 6, the positions of SNs using GA-PSO are visualize on a 100 x 100 area size with all the sensing and communication range used in this study. The blue dots represent SNs, whereas area within the circle is the communication range of the SN.

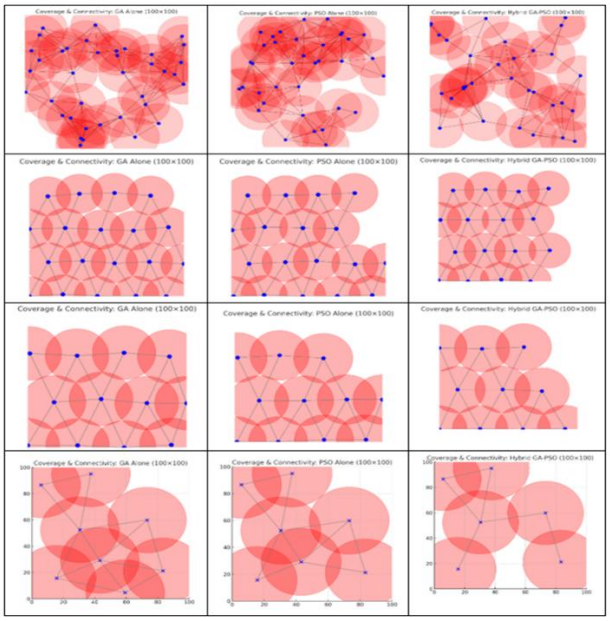

Fig. 6. Node deployment using GA, PSO and GA-PSO.

The comparison graph in Fig. 7 illustrates the differences between the set-1 and set-2 parameters for GA, PSO, and Hybrid GA-PSO. The updated results show a slight reduction in the number of deployed SNs across all methods, indicating improved efficiency. The Hybrid GA-PSO remains the most optimal approach, consistently requiring fewer nodes than GA or PSO alone. This suggests refinements in the optimization process, leading to better sensor deployment with minimized redundancy.

Further, we compared our proposed hybrid GA-PSO algorithm with another state-of-the-art multi-objective metaheuristic algorithm, CMOMPA [30-32]. The comparison is made for a large AoI with large sensing (25m) and communication range (50m). Both algorithms were implemented with the same parameters. In this comparison, GA-PSO outperforms CMOMPA due to its hybrid mechanism that strategically balances exploration (via GA's crossover/mutation) and exploitation (via PSO's velocity-driven refinement). Fig. 8 explains how GA-PSO efficiently optimizes node placement, ensuring near-optimal coverage (97 to 99%) and 100% connectivity by explicitly penalizing disconnected configurations in its fitness function. In contrast, CMOMPA's reliance on Gaussian perturbations and predator-prey dynamics often results in scattered clusters with coverage gaps (~92%) and connectivity failures (~94%), as its exploration lacks directed refinement and constraint enforcement. GA-PSO further excels in node efficiency, deploying 30 to 50% fewer sensors (e.g., 18 vs. 24 nodes for a 500m×500m area) by dynamically penalizing redundancy, while CMOMPA's unguided search increases redundancy. Statistically, GA-PSO's superiority is validated by p-values < 0.05 across coverage, connectivity, and node metrics, confirming its robustness. Fig. 9 shows the Wilcoxon test.

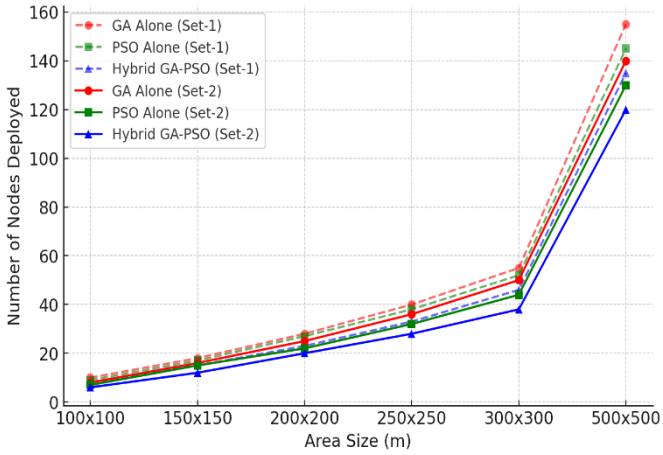

Fig. 7. Comparison of set-1 and set-2 parameters used for GA, PSO, and GA-PSO performance.

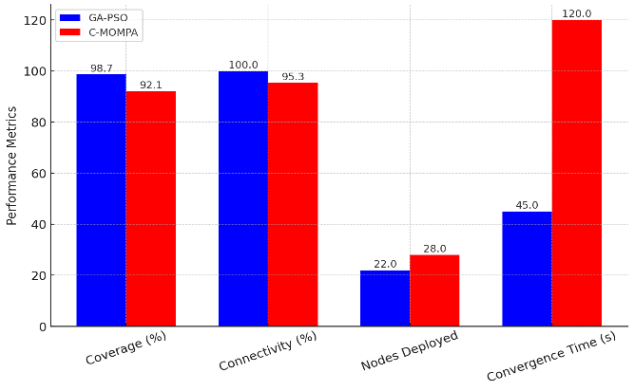

Fig. 8. GA-PSO vs CMOMPA performance comparison.

TABLE VI. SIMULATION RESULTS

Metric	Rs = 10m (GA-PSO)	Rs = 10m (C-MOMPA)	Rs = 15m (GA-PSO)	Rs=15m (C-MOMPA)	Rs=20m (GA-PSO)	Rs=20m (C-MOMPA)	Rs=25m (GA-PSO)	Rs=25m (C-MOMPA)
Coverage (%)	98	95	97	94	97	93	97	92
Connectivity (%)	100	96	100	95	100	95	100	94
Nodes Deployed	42	49	34	41	26	32	18	24
Time (s)	55	130	52	123	50	116	48	110

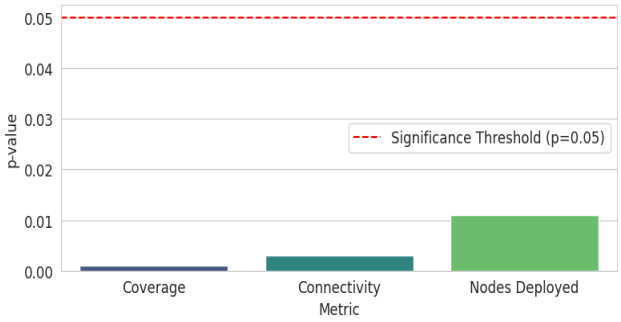

Fig. 9. Wilcoxon test result.

In the experimental setup, we used identical parameters for both algorithms, including a population size of 50, a maximum of 100 iterations, and 30 independent runs for different sensing ranges (10, 15, 20, and 25 meters). The simulation results (Table VI) demonstrate that GA-PSO consistently achieves higher coverage across all sensing ranges compared to C-MOMPA. Additionally, GA-PSO ensures 100% connectivity with fewer deployed nodes, whereas C-MOMPA struggles to maintain connectivity as the sensing range increases. Furthermore, GA-PSO exhibits faster node deployment times to enhance the understanding of the readers. Values presented in Table VI represent the mean of the generated data, with all values converted to decimal by taking the floor of the original values, whereas values in figures contain real values.

GA-PSO succeeds due to its structured search mechanism, where PSO's velocity updates systematically guide nodes toward optimal grid-like patterns, avoiding the inefficient random clustering in CMOMPA, and its constraint-aware fitness function, which enforces practicality by penalizing disconnections and excess nodes. Fig. 8 shows that GA-PSO achieves faster convergence (~48 seconds vs. CMOMPA's ~110 seconds) through PSO's social learning, making it ideal for time-sensitive deployments like IIoT, disaster management, smart cities, and environmental monitoring. However, real-world deployment presents challenges such as signal interference, obstacles, and node failures. Scalability remains a critical concern, as large-scale WSNs demand efficient parallel processing and adaptability to dynamic conditions where sensors may relocate or fail. In IIoT, the optimal placement of SNs ensures predictive maintenance, process automation, and hazard detection in industrial environments, while efficient SN deployment ensures effective data collection in disaster management. In smart cities, SNs are deployed to maximize the coverage of traffic monitoring and air quality monitoring. Applications requiring strict coverage-connectivity trade-offs and cost-sensitive scenarios prioritizing hardware minimization.

Energy constraints complicate deployment, necessitating energy-aware clustering, duty cycling, and adaptive power management to extend network lifespan. Communication issues such as packet loss, congestion, and interference require interference-aware routing and transmission control, while deploying WSNs in harsh environments calls for resilient, self-adaptive strategies, potentially leveraging reinforcement learning for dynamic reconfiguration. CMOMPA, with its unguided exploration and slower performance, remains more suitable for theoretical or loosely defined multi-objective problems. Cost-effective, large-scale deployment remains a challenge, necessitating optimization techniques that balance performance with affordability. In essence, GA-PSO dominates real-world, constrained WSN deployments by balancing efficiency and precision, while CMOMPA remains relegated to theoretical or loosely defined multi-objective problems due to its unguided exploration and slower performance.

VII. Conclusion and Future Work

The combination of GA's exploration and PSO's global search abilities allowed the hybrid algorithm to overcome the limitations of each algorithm, providing a well-balanced and effective solution for the multi-objective optimization of node deployment in WSNs. The algorithm's capability to handle the trade-offs between coverage, connectivity, and energy consumption offers a promising strategy for improving WSN design and deployment in real-world scenarios. Future research should focus on integrating deep learning with metaheuristic optimization for self-adaptive WSNs, developing lightweight algorithms for real-time decision-making, and incorporating edge computing to reduce computational overhead. Addressing cybersecurity risks and ensuring robust, low-latency communication will further enhance WSN reliability. While GA-PSO dominates real-world, constrained WSN deployments by balancing efficiency and precision, overcoming scalability, energy efficiency, and deployment challenges remains crucial for its widespread implementation in IoT and WSN applications. While the proposed hybrid GA-PSO approach has shown promising results, but requires enhancement. There are several avenues for further research and enhancement:

A. Heterogeneous WSN Deployment

In this study, we focused on homogeneous static WSNs. Future work could explore the application of hybrid metaheuristic techniques in heterogeneous WSNs, where nodes may have different sensing, communication, and energy capabilities. This would introduce additional complexity but could lead to more efficient and realistic deployment strategies.

B. Mobile WSNs

The current approach assumes static node deployment. Incorporating mobility, where sensor nodes can move to optimize coverage and connectivity over time, is an interesting direction for future research. Hybrid metaheuristics could be extended to handle dynamic node repositioning in mobile WSNs.

C. Multi-Objective Optimization

Although the hybrid GA-PSO algorithm effectively balances coverage, connectivity, and energy efficiency, future work could involve exploring more advanced multi-objective optimization techniques, such as Pareto-based approaches, to provide more flexible trade-offs between competing objectives.

D. Improving Computational Efficiency

While the hybrid approach provides superior performance, it comes at the cost of increased computational complexity. Future research could focus on optimizing the computational efficiency of the hybrid GA-PSO algorithm, perhaps by incorporating parallel processing techniques or by developing

lightweight variants for deployment in resource-constrained environments. Further, the proposed algorithm performs better than CMOMPA for a larger sensing range and enhances energy consumption. In future, this issue needs to be addressed.

E. Application to Other Network Types

The proposed method could also be applied to other types of wireless networks, such as Internet of Things (IoT) networks, where similar issues of coverage, connectivity, and energy efficiency arise. Investigating the generalization of the hybrid GA-PSO approach to these contexts could yield valuable insights.

In conclusion, the hybrid GA-PSO method presents a robust and effective strategy for optimizing node deployment in WSNs, and further exploration of its capabilities in more complex and dynamic network environments holds significant promise for future developments in this field.

Exploring Trust Management in Fog Computing: A Comprehensive Review and Future Challenges in Task Offloading

Liu Feng, Suhaidi Hassan, Mohammed Alsamman
School of Computing (SoC), University Utara Malaysia (UUM), 06010 Sintok, Kedah, Malaysia

***Abstract*—With the proliferation of data-driven services and latency-sensitive applications, fog computing has emerged as a pivotal extension of cloud infrastructure, enabling data processing and resource allocation at the network edge. However, the trustworthiness of task offloading in such decentralized and heterogeneous environments remains insufficiently explored, posing significant concerns related to system reliability, security, and performance. This review aims to address this gap by providing a comprehensive and systematic analysis of current research on trust-based task offloading in fog computing. The study investigates various trust evaluation mechanisms, categorizing them into three major paradigms: Direct Trust-based, Recommended Trust-based, and Comprehensive Trust. Through this classification, the study identifies and examines key trust-related metrics that influence offloading decisions, including task execution accuracy, trust evaluation accuracy, and evaluation latency. A critical assessment of the strengths and limitations of existing approaches reveals ongoing challenges such as dynamic trust management, scalability in large-scale networks, interoperability among diverse nodes, and resilience against malicious behaviours. Based on these insights, the study highlights pressing research opportunities and recommends the development of lightweight, adaptive, and context-aware trust frameworks capable of supporting real-time decision-making in dynamic fog environments. By synthesizing fragmented research and offering a forward-looking perspective, this review contributes a foundational reference for scholars and practitioners seeking to enhance the reliability and security of task offloading in fog computing, thereby supporting the evolution of more robust and efficient edge-based computing infrastructures.**

Keywords*—Trust management; fog computing; cloud computing; task offloading; heterogeneous networks; trust evaluation; task completion time

I. Introduction

Recently, the swift evolution of cloud computing, along with the rise of mobile smart devices and wireless networking technologies, has prompted a reassessment of computing architecture to better support mobile terminals. This adaptation aims to reduce system latency and enhance the user experience [1]. Therefore, Cisco introduced the concept of fog computing, defining it as a highly virtualized platform that shifts computational tasks from centralized cloud data centre to edge devices of the network [2]. This approach addresses the inherent limitations of the cloud computing architecture, which centralizes computing far from data sources, resulting in increased latency, congestion, reduced reliability, and augmented security vulnerabilities. Around a decade after the emergence of cloud computing, fog computing garnered extensive attention as an optimization of the existing cloud computing infrastructure [3].

Fog computing, in essence, represents a form of cloud computing with a local-oriented nature. It acts as an addition to the conventional cloud computing paradigm. In this regard, when cloud computing is paralleled to Wide Area Network (WAN) - based computing, fog computing can be compared to Local Area Network (LAN) - based computing. In a similar vein, just as the Content Delivery Network (CDN) deals with the problem of local caching within the TCP/IP framework, fog computing endeavors to solve the intrinsically local computing difficulties presented by cloud computing [4]. A pivotal moment in the development of fog computing occurred in November 2015, when industry giants such as Cisco, ARM, Dell, Intel, Microsoft, and Princeton University Edge Lab collaborated to establish the OpenFog Consortium [5]. The primary objective of this consortium was to promote and expedite the adoption of open fog computing, thereby facilitating advancements in the Internet of Things (IoT) domain. The fog computing market is anticipated to experience robust growth, with a projected Compound Annual Growth Rate (CAGR) of 67.90% during the forecast period of 2021-2026 [6]. Despite being a relatively new domain in the technological landscape, fog computing has rapidly established itself as a significant field.

Fog computing, introduced by Cisco, has emerged from the rapid evolution of cloud computing and mobile technologies. It shifts computational tasks from centralized data centres to edge devices, addressing latency, congestion, and security issues. Acting as a local extension of cloud computing, it parallels LAN to WAN. The OpenFog Consortium, formed in 2015 by industry leaders, promotes this technology and supports the Internet of Things (IoT). The fog computing market is expected to grow significantly, with a CAGR of 67.90% from 2021 to 2026, highlighting its growing importance in technology.

II. Fog Computing Concept

The architecture of fog computing is structured into a three-tier system extending from the network core to the periphery. This system comprises the cloud layer, the fog layer, and the terminal layer, as illustrated in Fig. 1. Compared to traditional computing paradigms, fog computing offers several advantages. These advantages include significantly reduced latency, conserved backbone bandwidth, enhanced support for

high mobility, extensive geographical distribution, interoperability, and reduced energy consumption [7, 8].

With the development of grid computing, cloud computing, and fog computing as a complement to cloud computing came into being. Fog computing cannot replace cloud computing and needs to work together with cloud computing. Fog computing, as an emerging computing paradigm focused on providing services close to the user side, and it doesn't require all data to be sent to the cloud computing centre. It builds an infrastructure for IoT-oriented distributed computing and provides various services, including computing, storage and network connectivity between interconnected devices at the edge of the network and cloud computing platforms in the core of the network. By extending the capabilities of cloud computing to the edge of the network, users can analyse and manage data locally.

All in all, fog computing is an innovative computing model that concentrates on providing services such as computing, communication and storage for users on network edge devices close to them. Specifically, it utilizes network devices to realize services like computing, storage and network communication between cloud servers and mobile terminal devices. By expanding the fog layer with storage and computing capabilities, the data processing and computing processes are made closer to the terminal devices, and then three main functions, namely data caching, localized computing and wireless access, are provided for users. This can not only effectively relieve the computing and storage pressure on the cloud but also significantly improve the response speed of the entire application system. Moreover, it can better fit the characteristics of high mobility of mobile terminal devices and fully meet the strict requirements of mobile applications for high traffic transmission and low-latency response.

A. Cloud, Fog and Edge Computing

Unlike cloud computing, the main goals of fog and edge computing are similar in some ways; both enable services to be closer to the user and provide lower latency [10]. Fog computing performs as a bridge between cloud computing and mobile terminal devices, building a platform with remarkable performance in computing, digital storage and network services. Therefore, cloud computing and fog computing are not independent entities; on the contrary, they interact and influence each other. In practical applications, there are several main differences among cloud computing, fog computing and edge computing. As shown in Table I, these differences span over various aspects, including latency characteristics, network characteristics, location awareness and target users [11].

B. Fog Computing Application Scenarios

Since the inception of fog computing, a wide range of scientific research institutions, internet companies, and scholars have conducted extensive studies on the subject. This collaborative effort has led to the emergence of various fog computing platforms, including OpenFog, LocalGrid, and PrismTech Vortex. These platforms facilitate the deployment of fog computing solutions across diverse sectors. Typical applications of fog computing encompass automotive networking, where vehicles communicate and share data; wireless sensor networks, which enable real-time monitoring; and intelligent building control systems that optimize energy use. Additionally, fog computing plays a crucial role in the IoT, augmented reality experiences, mobile communications, and Software Defined Networking (SDN) applications. This wide array of applications illustrates the versatility and potential of fog computing in enhancing network efficiency and performance [12].

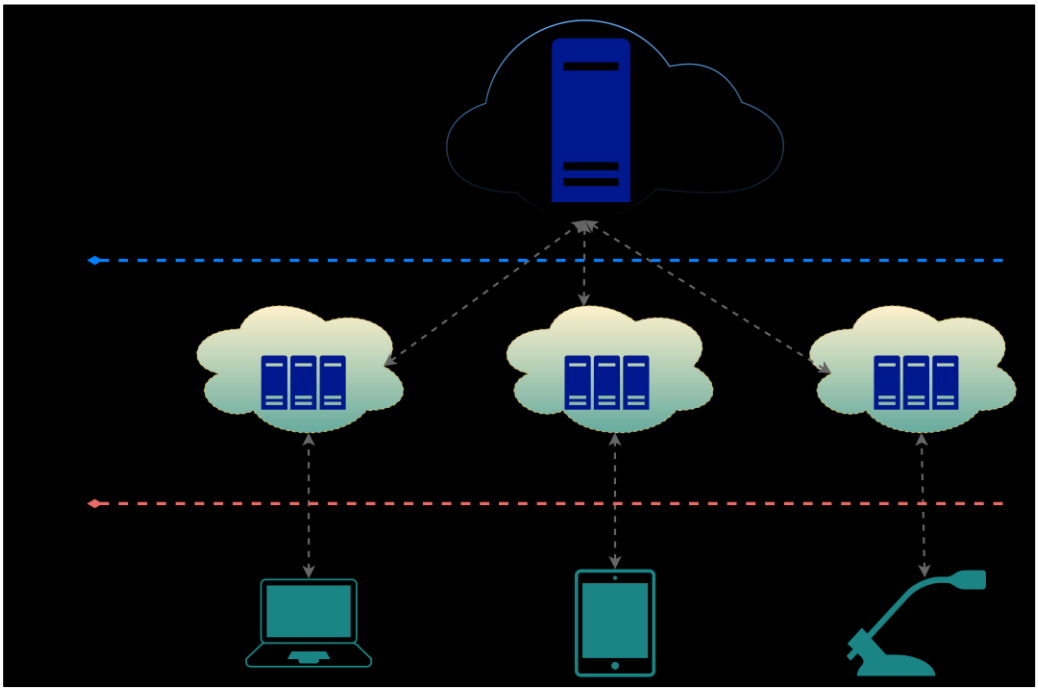

Fig. 1. Fog computing system architecture [9].

TABLE I COMPARISON ON DIFFERENT COMPUTING PARADIGMS

Attributes	Cloud Computing	Edge Computing	Fog Computing
Expected Task Execution Time	High	High-Medium Often	Low
Provided Services	Universal services	Often uses mobile networks	Vital for a particular domain and distributed
Security	Centralized (guaranteed by the Cloud provider)	Centralized (guaranteed by the Cellular operator)	Mixed (depending on the implementation)
Energy Consumption	High	Low	Varying but higher than for Edge
Identifying location	No	Yes	Yes
Main Providers	Amazon and Google	Cellular network providers	Proprietary
Interaction in Real-Time	Available	Available	Available
Latency	High	Low	Varying but higher than for Edge
Bandwidth Cost	High	Low	Low
Storage capacity and Computation	High	Very limited	Varying
Scalability	Average	High	High
Overall usage	Computation distribution for huge data (Google MapReduce), Apps virtualization, Storage of data scalability	Control of traffic, data caching, wearable applications	CCTV surveillance, imaging of subsurface in real-time, IoT, Smart city, Vehicle-to-Vehicle (V2X)

Fog computing as much as possible to the user's needs of the content and application services close to the end user, through this way, fog computing with support for mobile performance, low latency and high scalability and other advantages. Fog computing can be widely used in augmented reality (Augmented Reality, AR) and health monitoring and other real-time services; smart grid and local content distribution and other data dissemination areas; mobile big data processing and computing offloading and other distributed data areas; shopping centres and public transport and other temporary storage and other areas. In distributed data scenarios, fog computing efficiently handles user requests by leveraging the computing and storage capabilities of fog nodes. This approach alleviates the pressure on centralized cloud data processing and minimizes the response time for end-user data requests. Additionally, it reduces both the data traffic sent to the cloud and the storage requirements within it. Ultimately, this leads to a more balanced distribution of data processing demands across the cloud, fog, and terminal layers.

III. MOTIVATION

With the development of the Internet, fog computing has gradually become a new type of Internet infrastructure that has attracted much attention, but its research in the field of trusties is still insufficient [14]. Trust evaluation and management for fog nodes is an important means to improve the reliability of the network, which can effectively mitigate the security risks brought by the geographical dispersion of nodes and differences in the network environment. Although fog computing is more secure than cloud computing due to temporary data storage and local processing [15], inter-node collaboration may still trigger malicious behaviors, such as theft or manipulation of private data by malicious nodes. Traditional encryption solutions cannot effectively counter internal attacks from authenticated malicious fog nodes [16].

Trust management in fog computing faces critical challenges, particularly delayed trust value updates caused by computational overhead. While mechanisms like fuzzy logic trust evaluation, and multi-source feedback aggregation enhance trust and accuracy, they increase computational complexity, leading to high resource consumption and delayed updates in dynamic environments. Hierarchical trust models and reputation-based schemes, such as Gu et al. [17], improve reliability but introduce significant computational burdens. Similarly, adaptive mechanisms like those proposed by Almas et al. [18] struggle with timely updates due to overhead, and methods relying on recommendation information are vulnerable to malicious nodes. Fog computing faces several challenges in the process of trust management, particularly in balancing trust management and system performance. The complexity of trust models, such as reputation-based or subjective logic models, introduces significant computational overhead, making real-time decision-making difficult in large-scale environments. For instance, Alemneh et al. [19] highlight that while two-way trust management enhances security, it places a heavy computational burden on resource-constrained fog nodes. Moreover, approaches like the one proposed by Atwa et al. [20] experience difficulties in adapting to dynamic environments, such as Vehicular Ad Hoc Networks (VANETs), while models that aggregate multiple feedback sources, as discussed by Liang et al. [21], are prone to implementation complexity and require robust infrastructure. Furthermore, techniques like fuzzy logic and reputation-based mechanisms, employed by Bukhari et al. [22], introduce increased computational complexity that can hinder real-time performance. These challenges are compounded by the need for frequent updates in highly dynamic environments, which may lead to delays in trust evaluation and, consequently, suboptimal node selection.

The fog computing environment faces significant challenges related to reliability, primarily due to the participation of various vendors, including private cloud providers and multiple Internet Service Providers (ISPs). A fog network comprises numerous fog nodes, and ensuring their reliability is crucial during the task offloading. If the tasks are sent towards the malicious fog nodes, it can result in serious issues such as denial of service, jamming, spamming, impersonation, and data tampering [23, 24].

IV. CONTRIBUTION

This study advances research on trust-based task offloading in fog computing through several key contributions.

It first provides a systematic classification of trust evaluation mechanisms into three paradigms—Direct Trust-based, Recommended Trust-based, and Comprehensive Trust—consolidating fragmented research to clarify their principles and application scenarios, facilitating targeted comparisons for specific fog use cases.

Second, the work identifies and analyses critical trust-related metrics (task execution accuracy, trust evaluation accuracy, evaluation latency) and their interdependencies, offering a holistic reference for designing multi-objective trust frameworks that balance security and efficiency, critical for latency-sensitive fog applications.

Third, it critically assesses existing approaches, delineating core challenges including dynamic trust management in volatile networks, scalability in large-scale deployments, interoperability barriers, and vulnerability to malicious behaviours. This analysis transcends summarization to guide researchers toward high-impact problems.

Fourth, the review highlights emerging opportunities and recommends lightweight, adaptive, context-aware trust frameworks for real-time decision-making in dynamic fog environments, bridging research and practical implementation with actionable roadmaps.

Finally, by synthesizing knowledge into a unified perspective, it serves as a foundational reference for academia (guiding state-of-the-art advancements) and industry (supporting robust system deployment), advancing fog computing as a pivotal cloud extension.

V. ORGANIZATION

The organization of the study is designed to provide an in-depth exploration of fog computing, beginning with an Introduction that establishes the topic's significance in the context of modern technology, as shown in Fig. 2.

This section sets the stage for understanding how fog computing enhances traditional computing frameworks. Following this, the study delves into the Fog Computing Concept, where it outlines the core principles that define fog computing and its advantages over conventional cloud computing. Next, the study differentiates among Cloud, Fog, and Edge Computing, providing clarity on their unique roles and how they interact within the broader computing ecosystem. This distinction is crucial for understanding the specific contributions of fog computing. The section on Fog Computing Application Scenarios highlights various real-world implementations, showcasing its transformation influence across several industries that includes smart cities, healthcare, and industrial automation [13].

The Motivation section articulates the pressing challenges that fog computing aims to address, such as latency issues and bandwidth constraints, emphasizing its relevance in today's data-driven world. Following this, the Contribution section details the novel insights and findings that the study presents, adding to the existing body of knowledge on fog computing. An overview of the study's structure is provided in the Organization section, guiding the reader through the subsequent discussions. The main body focuses on Trust in Fog Computing, which is critical for ensuring secure operations in distributed environments. This includes an examination of Trust Management strategies, the design of a Trusted Task Offloading Architecture, and the various methods involved in the Trust Evaluation Process. The Task Offloading Process is also explained, detailing how tasks are managed within a fog framework.

The study further reviews specific techniques for Trust Evaluation in Fog Computing and presents a Comparative Analysis of Calculation Methods, evaluating different approaches to trust assessment. In addition to these discussions, the section on Classical Algorithms for Task Offloading examines traditional algorithms that facilitate efficient task management in fog environments, with a focused look at the particle swarm optimization algorithm and its relevance. A comprehensive Related Work section reviews existing literature, identifying gaps in current research and highlighting contributions to the field. The study concludes with a discussion on Future Challenges, addressing potential obstacles that may arise as fog computing evolves. Finally, the Conclusion summarizes the key findings and emphasizes the critical roles of trust and task offloading in the advancement of fog computing, reinforcing its importance in the current technological landscape.

Fig. 2. Organization of the study.

VI. Trust in Fog Computing

Trust is essential in fog computing due to its decentralized architecture and proximity to end-users, requiring robust mechanisms to ensure data integrity and reliable service delivery. This is achieved through several interconnected processes:

1) Trust management: Establishes and maintains trust relationships between nodes.

2) Trusted task offloading architecture: Ensures tasks are only delegated to trustworthy nodes.

3) Trust evaluation process: Defines methods for assessing the trustworthiness of nodes.

4) Task offloading process: Integrates trust verification prior to data transfer.

5) Dynamic trust assessment: Employs specific techniques to evaluate trust levels in real time.

6) Comparative analysis of calculation methods: Assesses the effectiveness of different trust calculation approaches.

Together, these components create a comprehensive framework that fosters a secure and reliable fog computing environment.

C. Trust Management

Fog nodes in fog computing networks are capable of executing data processing tasks near the data sources, which enhances support for real-time applications and reduces dependency on remote cloud resources. However, security and privacy concerns remain prominent within these networks.

Although fog computing is often perceived as more secure than traditional cloud computing due to the localized storage and analysis of data, vulnerabilities still exist. For instance, when fog nodes collaborate and share data to complete tasks, they may expose themselves to risks. Offloading tasks to untrustworthy fog nodes can lead to unauthorized access or manipulation of sensitive user information, raising significant privacy concerns.

To address these challenges, effective management of trust within fog nodes is vital. Implementing robust trust frameworks can help ensure that only reliable nodes are used for data processing. This includes assessing the trustworthiness of nodes, establishing secure communication channels, and continuously monitoring node behavior to prevent malicious activities. By prioritizing trustworthy management, fog computing can enhance its security posture, safeguarding user data and maintaining the integrity of services. Sunilkumar S. Manvi and others [25] explored various aspects of trust management within the realm of fog computing. Trust is a critical factor in the contemporary networked landscape, significantly influencing users' willingness to adopt fog computing solutions. In their research, they emphasize that trust management systems can build user confidence by ensuring secure and transparent data processing and storage. Effective trust management mitigates risks related to data integrity and privacy while enhancing the reliability of fog networks. By implementing clear trust protocols and assessment mechanisms, users can feel assured that their information is handled appropriately, which is crucial for the widespread adoption and success of fog computing technologies.

D. Trusted Task Offloading Architecture

As depicted in Fig. 3, this solution primarily focuses on the task offloading mechanism based on trust values within fog networks. In this architecture, every fog node has the capability to directly share tasks with other fog nodes. Meanwhile, it is assumed that fog nodes can reach each other from any location within the same fog domain. In real-world task flow scenarios, the task arrival rate can vary significantly depending on the location of the fog nodes [26].

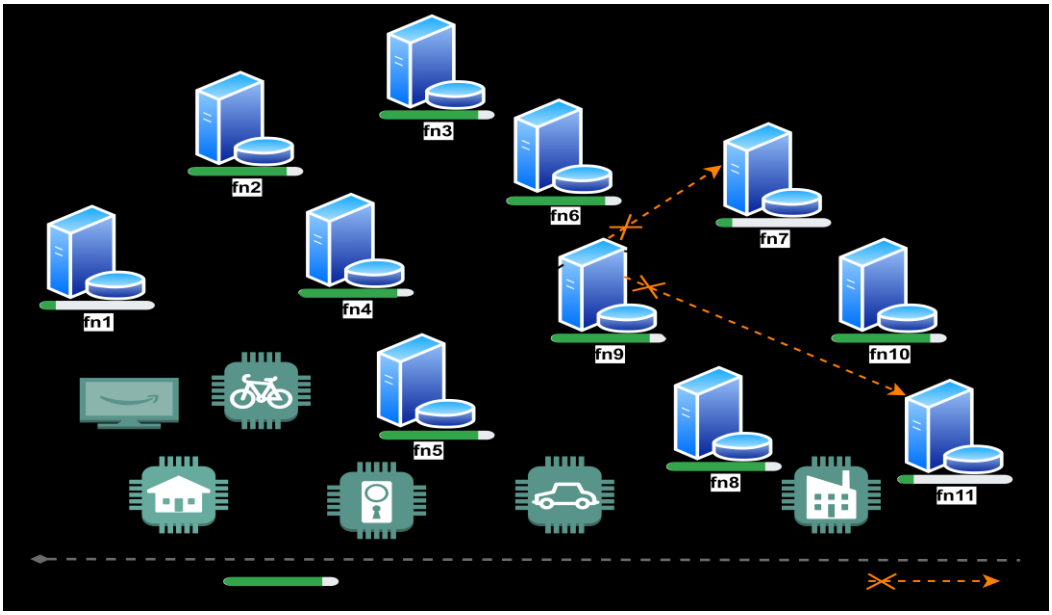

Fig. 3. Trusted task offloading architecture.

E. Trust Evaluation Process

Each fog node is equipped with a trust evaluation module that regularly assesses the trustworthiness of other fog nodes. Additionally, each node can function as both a task initiator and receiver, enabling task offloading to other fog nodes when necessary. When offloading a task, the node selects the most suitable fog node based on trust evaluation results and additional metrics such as completion time and latency [27].

Fog nodes can obtain each other's network load lightness information through local communication mechanisms. For example, network load information sharing: fog nodes can periodically exchange information about their own resource usage and task load among themselves. Such information includes CPU utilization, memory usage, task rank length, etc. The communication can be carried out through a neighbor-based communication policy. Trust evaluation is done by the fog nodes themselves. Each fog node can initiate computational detective tasks and select other fog nodes to handle these tasks based on the trust evaluation results. Fig. 4 shows the flowchart of trust evaluation, and the steps of trust evaluation can be represented as:

a) Initialization: All fog nodes set the same initial trust value.

b) Trust evaluation: Adjusting the trust value according to the completion of tasks by other fog nodes. When the network load is light, it is performed by sending some probing tasks with less data volume to the fog nodes with free resources. When the network load is large, i.e., exceeds the pre-set load threshold, the frequency of trust evaluation is reduced, or the trust value of the collaborators is evaluated by the fog nodes during the task collaboration.

c) When a fog node needs to offload a task, it identifies the most appropriate node by considering trust evaluation results and time delays. This strategy guarantees that tasks are directed to dependable fog nodes that offer optimal performance. As a result, overall efficiency and security are significantly improved.

F. Task Offloading Process

As shown in Fig. 2, there are two types of fog nodes present in the fog layer: trusted fog nodes and untrusted fog nodes. At the time of offloading, according to the different number of task packets and priority of the tasks (indicated by different colors in the figure), which are distributed to different fog nodes. Each fog node maintains a task processing rank for tasks waiting to be processed, and each task has its arrival time, processing time and deadline. The relationship between the task processing rank and the time delay is as follows: the length of the task processing rank, which represents the number of tasks in the rank, may affect the waiting time of the tasks. The longer the rank, the longer the waiting time may be, which leads to an increase in the total time delay of the task. When a fog node fn_9 initiates a task offloading interaction, it selects a neighbouring fog node to interact with. Neighboring node fn_7 has a short task rank but a low trust value and hence does not interact with node fn_7. Whereas, neighboring node fn_{10} has both low latency and high trust and hence chooses to interact with node fn_{10} on tasks.

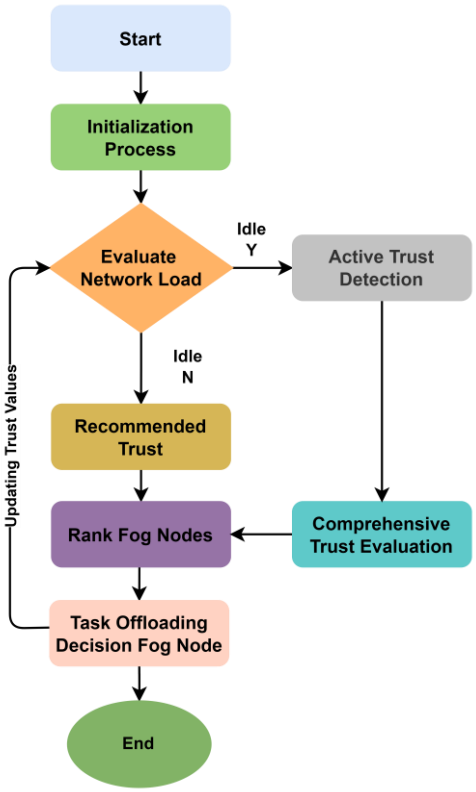

Fig. 4. Trust evaluation process [28].

G. Fog Computing Concept

Trust management in direct trust, recommended trust, and comprehensive trust:

a) Direct trust: In the fog-to-fog collaboration model, a fog node evaluates its interactions with other fog nodes, such as during task offloading or resource sharing. It updates its trust levels based on the outcomes of these interactions. For instance, the trust value of a fog node that successfully completes a task increases, while the value for a node that fails or produces subpar results decreases. The results of these trust calculations are recorded locally to assess the trustworthiness of each node.

b) Recommended trust: Fog nodes can request trustworthiness recommendations about third-party fog nodes from other fog nodes. This recommendation trust information helps fog nodes to understand the trust status of nodes in the entire network and thus make more informed task offloading decisions. However, the recommendation trust information can be affected by malicious nodes spreading false information. However, the recommended trust information may be affected by malicious nodes spreading false information. To ensure the reliability of the recommendation trust information, the trustworthiness of the recommender and the similarity of the recommendation information (recommender's trustworthiness) are calculated. Similarity (weight of recommendation trust) of the recommendation information. In this way, after obtaining direct trust and recommendation trust information about other fog nodes.

c) Comprehensive trust: The comprehensive trust value is a metric that thoroughly assesses the reliability and trustworthiness of fog nodes. It combines two key dimensions: direct trust value and recommended trust value. This integrated approach offers a solid foundation for making task offloading decisions in fog computing. By providing a clearer picture of fog nodes' performance during task allocation, the comprehensive trust value helps in selecting the most suitable nodes for task assignments.

H. Comparative Analysis of Calculation Methods

Each trust value calculation method has its unique advantages and disadvantages. Choosing a suitable calculation method and improving it with optimization suggestions can better address the challenges in specific application scenarios and improve the accuracy and efficiency of trust value calculation [20]. In Table II, combining the advantages and weaknesses of the seven algorithms mentioned above, along with their application scenarios, suggests that the fuzzy logic algorithm is particularly well-suited for real-time task offloading needs.

TABLE II MAINSTREAM WAYS OF TRUST EVALUATION

Techniques	Advantages	Weaknesses	Applicable Scenarios
Weighted Sum Method	Simple to implement and flexible	Dependent on weight settings, linear assumptions	Used in scenarios where there are fewer indicators and the weights are relatively easy to determine
Fuzzy Logic	Flexible rule definition for complex environments	Too many rules may lead to computational inefficiency	Fuzzy logic is suitable for scenarios dealing with uncertainty and ambiguity
Bayesian Inference	Dynamically updated and adaptable	Higher computational complexity	Used in scenarios where trust needs to be updated dynamically
Trust Chain Model	Highly flexible	Over-reliance on network structure	Distributed network environments for multi-hop trust delivery
Machine Learning Methods	Ability to handle complex multi-dimensional data and non-linear relationships	Requires large amounts of high-quality training data	Ideal for scenarios dealing with complex, multi-dimensional data
Graph-Based Trust Calculation	Ability to globally evaluate the trust value of nodes in the network	Slower response to dynamic changes, which may lead to lags	Suitable for social networks, P2P networks and other scenarios
Reputation-Based Trust Calculation	Flexibility to adjust the final trust value according to different evaluation sources and weights	Vulnerable to malicious ratings or subjective bias	Used in scenarios where reputation needs to be assessed and built up over time

VII. CLASSICAL ALGORITHMS FOR TASK OFFLOADING

The task of offloading problems in fog computing is typically considered as either a single-objective or multi-objective optimization problem, subject to diverse constraints. These constraints include task completion latency, the quantity of tasks fulfilled within the deadline, the degree of load balancing, the energy consumption of the fog computing system, and the overall service quality. This section outlines several commonly used algorithms for addressing task offloading challenges. Among the algorithms discussed are heuristic approaches such as the PSO algorithm and the Ant Colony (AC) algorithm, as well as the Min-Min algorithm. These methods provide crucial insights and form the basis for the research explored in this study.

A. Particle Swarm Optimization Algorithm

The PSO originated from scholars' research on the feeding behavior of bird flocks and was first proposed by Kennedy and Eberhart [29]. The particle swarm algorithm has become a hot research topic, and has been used by scholars to produce a large number of research results in various fields, and has been continuously improved to produce a number of improved PSO algorithms, such as the binary PSO algorithm, the heterogeneous PSO algorithm, the adaptive PSO algorithm, the cooperative PSO algorithm, and the discrete PSO algorithm, etc, [30]. Compared with other intelligent optimization algorithms, particle swarm optimization algorithms are easy to implement and efficient for solving combinatorial optimization problems.

The main process of the standard particle swarm optimization algorithm is as follows:

1) Initialisation: Initialise the particles in the population by assigning random initial values to their positions and velocities. The positions and velocities of the particles can be initialised according to the following equation, as shown in Eq. (1) and Eq. (2):

$$x_i = r(X_{max} - X_{min}) + X_{min} \quad (1)$$

$$v_i = r(V_{max} - V_{min}) + V_{min} \quad (2)$$

In the above equations, "r" represents a random number between 0 to 1, "X_{max}" and "X_{min}", respectively, denote the maximum and minimum positions of the particle, and "V_{max}" and "V_{min}", respectively, denote the maximum and minimum velocities of the particle. The velocity and position of the particle cannot exceed the specified maximum and minimum ranges.

The fitness values of particles within a population are determined by setting a fitness function. This fitness function should be established based on the specific objective function that requires optimization.

The fitness value of each particle's current position within the population is compared with the fitness value of its historical best position. Through this comparison, the best fitness value for each individual particle can be obtained.

The fitness values of the current positions of all particles in the population are compared with the fitness value of the global best position. As a result, the global best fitness value of the population can be determined.

Update the velocity and position of particles. For the $(t+1)$ generation iteration, update each particle's velocity and position [see Eq. (3) and Eq. (4)]:

$$v_{id}(t+1) = v_{id}(t) + c_1 r_1(t)[p_{id}(t) - x_{id}(t)] + c_2 r_2[p_{gd}(t) - x_{id}(t)] \quad (3)$$

$$x_{id}(t+1) = x_{id}(t) + v_{id}(t+1) \quad (4)$$

where, r_1 and r_2 denote random numbers between (0,1), p_{id} and p_{gd} are the optimal positions of the particle and the population, respectively, c_1 and c_2 are the acceleration constants. One of the common optimization methods for particle swarm algorithms is to add inertia weights to control the current velocity of the inherited particles when updating their positions. ω includes a check to see if the maximum number of iterations has been reached, or if the desired fitness value has been reached. If the termination condition is met, the individual with the highest fitness value is output.

B. Ant Colony Algorithm

The Ant Colony Optimization (ACO) algorithm is a swarm intelligence approach inspired by the foraging behavior of ants and driven by positive feedback. When ants search for food, they release pheromones to communicate with the colony, naturally favoring shorter paths that lead to the target more quickly. As ants traverse these paths, pheromone accumulation increases, making those routes more attractive to others. Over time, pheromones evaporate, ensuring the colony gravitates towards the path with the highest concentration, ultimately leading to the most efficient solution.

Similar to the particle swarm optimization algorithm, ACO is a highly effective parallel search method capable of solving complex combinatorial optimization problems [31]. The typical process of an ACO algorithm follows these steps:

Initialize parameters: Initialize parameter information, such as colony size and pheromone.

Place ants: Randomly place ants in the colony on the path.

Path selection: The ants choose the path according to the difference of pheromone concentration on the path, and the probability of choosing the path (i,j) is Eq. (5):

$$p_{ij}^k(t) = \begin{cases} \frac{[\tau_{ij}(t)]^\alpha \cdot [\eta_{ij}(t)]^\beta}{\sum_{s \in J_k(i)} [\tau_{is}(t)]^\alpha \cdot [\eta_{is}(t)]^\beta}, & j \in J_k(i) \\ 0, & \text{others} \end{cases} \quad (5)$$

where, $(J_k(i) = \{1,2,\dots,n\} - tabu_k)$ is the set of next paths that the ant can choose, $tabu_k$ represents the set of paths that the ant has already travelled, and the paths that have already been chosen will be added to the taboo list for no further choices, and the ant completes a path selection when all paths have been added to the taboo list; τ_{ij} is the pheromone concentration of the path (i,j) at this point in time. Pheromone concentration; η_{ij} is the heuristic factor with $\eta_{ij} = 1/b_{ij}$, the expected degree of ant κ choosing the path (i,j). Where, α is the pheromone heuristic factor, indicating the degree of importance of the pheromone, and β indicates the degree of importance of the heuristic factor. Generally, α takes a constant value between 1 and 4, with its value positively correlated to the influence of the pheromone. To find the optimal path, once all the ants have completed their path selection, the best path among all the ants is selected. The pheromone is then updated. In this iteration, the pheromone on the path remains constant, and the update occurs according to the following Eq. (6) and Eq. (7):

$$\tau_{ij}(t+n) = (1-\rho)\tau_{ij}(t) + \Delta\tau_{ij} \quad (6)$$

$$\Delta\tau_{ij} = \sum_{k=1}^{m} \Delta\tau_{ij}^k \quad (7)$$

where, $\rho(0 < \rho < 1)$denotes the evaporation coefficient of the pheromone on the path, $\Delta\tau_{ij}$ denotes the increment of pheromone in this iteration. $\Delta\tau_{ij}^k$ denotes the pheromone produced by ant k on path (i, j).

C. Min-Min Algorithm

The Min-Min algorithm was originally proposed to solve the task offloading problem in Grid computing [32]. The idea is first to map tasks with small computational resource requirements and schedule these small tasks to servers with high computational power, i.e., fast execution speed. The typical execution steps of the Min-Min algorithm are: Compute the expected completion time of every task on each available server. Then, identify the earliest completion time for each task and its corresponding server. Locate the task with the shortest earliest completion time from the task list. Dispatch this task to the server according to the earliest time calculated in Step (I).

Update the task list on the server with the earliest time. After the scheduling, update the expected completion times of other tasks in the task list on the available server, and remove this task from the task set. Repeat the above steps until all the tasks in the task list have been scheduled.

The Min-Min algorithm is simple and easy to operate, but there are some problems. On one hand, it maps many small tasks to servers with high computing power, resulting in load imbalance, and on the other hand, it causes large tasks with high computational resource demand to have no free servers to process them, so the tasks cannot be processed as quickly as possible to meet the latency requirements.

VIII. Related Works

In the increasingly complex landscape of fog computing, trust management has emerged as a critical concern, with various mechanism developed to ensure secure and reliable interactions between IoT devices and fog nodes. Mahmood et al. [33] introduced a trust-based architecture that leverages digital certificates signed by fog nodes acting as certification authorities. This approach significantly enhances the security and privacy of communications within a trusted domain, but it faces challenges related to the complexity and cost of deploying

multiple fog nodes and managing revoked certificates. Building on this, Atwa et al. [20] developed a reputation-based model for VANETs, which integrates fog computing to reduce the need for extensive cloud communication by aggregating trust evaluations at the fog nodes. Although this model reduces message transmission overhead, it encounters difficulties in adapting to the highly dynamic nature of VANET environments.

Liang et al. [21] proposed a reliable trust computing mechanism that aggregates multisource feedback within a Social Sensor Cloud (SSC) environment. By using a fusion algorithm, this approach improves the accuracy of trust evaluations and enhances the detection of malicious nodes. However, the integration of multiple feedback sources introduces significant implementation complexity and requires robust infrastructure. Meanwhile, Mahmoud et al. [34] applied the Fuzzy Analytic Hierarchy Process (Fuzzy-AHP) to prioritize multiple trust criteria, such as Quality of Service (QoS) and Quality of Security (QoSec), to deliver more accurate and reliable trust assessments. Despite its comprehensiveness, this method is limited by the complexity of implementation and the potential for bias due to reliance on expert judgment.

Alemneh et al. [19] proposed a two-way trust management system using subjective logic, which allows both service requesters and providers to evaluate each other's trustworthiness. This approach enhances the overall security of the fog network by combining direct and indirect trust, but the computational burden introduced by subjective logic, particularly in processing large volumes of recommendation information, poses challenges for resource-constrained fog nodes. In addressing cybersecurity issues within Sensor-Cloud Systems (SCS), Wang et al. [35] introduced a hierarchical trust mechanism that employs real-time monitoring and behaviour analysis at the fog layer to quickly identify and isolate malicious nodes. While effective in threat detection, this system may experience significant computational and communication overheads in large-scale networks due to the multi-layered trust computations required.

Almas et al. [18] contributed to the field by proposing a context-based adaptive trust mechanism tailored for smart healthcare systems. By utilizing a Bayesian approach and similarity measures, the system dynamically adjusts trust weights to respond to environmental changes, effectively mitigating trust-related attacks. However, the system may face challenges in maintaining timely updates to trust values in highly dynamic network environments, potentially leading to misjudgments. Bukhari et al. [22] introduced the Fog Node Selection Engine (FNSE), an AI-driven framework that employs Fuzzy Logic, Logistic Regression, and Deep Neural Networks to predict the trustworthiness of fog nodes. This approach demonstrated superior accuracy but also increased computational complexity, which could impact the system's real-time performance.

Yadav and Baranwal [36] developed a trust management mechanism based on feedback credibility evaluation to combat malicious feedback in fog computing. The system enhances the accuracy of trust evaluations by using a checkers-based method to prioritize recent interactions. However, in highly dynamic environments, the computation of trust values may not reflect the latest state of nodes, leading to delays in decision-making. Gu et al. [15] proposed a reputation-based resource allocation scheme in community-based fog computing, which matches user tasks with fog nodes that meet specific reputation criteria, thereby improving service reliability. This approach, however, introduces significant computational overhead due to the complexity of reputation computations across multiple layers of communities and nodes.

Kochovski et al. [37] integrated blockchain technology into fog computing trust management by utilizing smart contracts and trustless oracles to manage trust relationships in real-time. While this approach enhances transparency and trustworthiness, it also increases computational complexity and latency, particularly in handling a large number of transactions. Zhang et al. [38] introduced a fog-based detection system (FDS) for Sensor-Cloud Systems, focusing on hierarchical trust evaluation to detect hidden data attacks. Although effective in detecting malicious activity, the system may struggle with timely updates to trust values in dynamic networks, impacting decision accuracy.

Rehman et al. [39] proposed FogTrust, a lightweight trust management mechanism for IoT that uses fuzzy logic and trust aggregation to detect and mitigate various IoT attacks, such as on-off good-mouthing and bad-mouthing attacks. Despite its effectiveness, the multiple trust calculation processes involved, particularly with fuzzy logic, may affect the real-time performance and responsiveness of the system.

Collectively, these studies illustrate the diverse mechanisms employed to manage trust in fog computing environments. They highlight the ongoing trade-offs between enhancing security, maintaining system performance, and managing computational complexity. As the field continues to evolve, future research must address the challenges of scalability and real-time application, ensuring that trust mechanisms remain robust and efficient even in large-scale, dynamic fog computing environments.

Continuing from the previous detailed exploration, additional studies have further expanded on trust management in fog computing, focusing on various aspects such as trust evaluations, feedback credibility, and resource allocation.

Muhtadi et al. [40] presented a trust model for fog computing that leverages subjective logic to evaluate trustworthiness among fog nodes. This model considers belief, disbelief, and uncertainty in its calculations, combining direct experiences with recommendations from other nodes to assess trust. While effective in identifying and mitigating malicious nodes, the model is susceptible to bias if the network contains a high number of malicious nodes. Moreover, the reliance on recommendation information could lead to inaccuracies if the sources of these recommendations are compromised.

Mazumdar et al. [41] introduced a trust-based load-offloading protocol specifically designed to optimize service delivery in fog computing for IoT applications. This protocol uses a distributed scheme where fog nodes collaborate to share the load based on trust evaluations. Trust is established through

a Fog Registration Center (FRC) that authenticates fog nodes using Shamir's secret sharing scheme, ensuring that only trusted nodes participate in load-sharing. Although this approach minimizes service delays and ensures timely task completion, it adds complexity, especially in high-load or emergency situations where the scheme's security mechanisms might introduce additional computational burdens.

Yadav and Baranwal [42] proposed a trust evaluation method that combines Quality of Service (QoS) attributes with social relationships among fog nodes. This multi-layered approach enhances the security of fog computing environments by minimizing the risk of malicious nodes disrupting operations. However, the approach's complexity, particularly in large-scale networks, may lead to significant computational overheads and delays, as multiple layers of trust computations and data analyses are required to accurately assess trustworthiness.

Rathee et al. [43] introduced a trust-based security framework designed to enhance communication security between fog nodes and IoT devices. This framework includes a Trust Manager (TM) that evaluates the legitimacy of fog nodes and IoT devices by calculating trust values and factors based on past interactions. The TM records these metrics in a lookup table, using optimization algorithms to ensure reliable communication paths. Although the framework effectively reduces the risk of malicious activities, the need to compute multiple levels of trust values introduces high computational complexity, potentially impacting the system's real-time performance.

Ben Daoud et al. [44] developed the TACRM model, which integrates access control with trust and resource management in fog computing environments. The model computes trust based on user behaviors and assigns trust levels to users, which are then used for access control decisions. This approach enhances security by monitoring user activities and ensuring that resources are allocated securely and efficiently. However, the continuous monitoring required by the system raises potential privacy concerns, particularly in sensitive or personal data contexts.

Hamza et al. [45] proposed a bi-directional trust management system for fog computing, which uses both direct and indirect trust computations to establish trust between Service Requesters (SR) and Service Providers (SP). The system employs fuzzy logic to aggregate trust scores, with a decay function modelling the influence of past interactions on current trust assessments. While this approach effectively mitigates common trust-related attacks, such as ballot stuffing and self-promotion, the introduction of Bayesian inference and centrality into the trust evaluation process increases computational complexity, which may affect real-time performance in large-scale networks.

Ogundoyin and Kamil [16] introduced a trust management system that also uses fuzzy logic to evaluate trust in fog computing environments. This system integrates direct trust from self-observation with indirect trust from past reputation and recommendations, considering multiple criteria such as QoS and Quality of Security (QoSec). While the system combines various factors to provide a nuanced trust assessment, the use of a trust decay function in highly dynamic environments may not update trust values in a timely manner, potentially affecting the accuracy of trust-based decisions.

Finally, Rahman et al. [46] introduced a trust management system that uses a fuzzy control system to evaluate the security, reputation, and availability of vehicular fog nodes (v-fogs). This system is particularly adaptable to dynamic environments, as it handles uncertainty and variability in trust evaluation processes. The use of a fuzzy control system enables the processing of multiple inputs and the evaluation of numerous rules to generate a final trust score. However, the computational overhead introduced by this method can be challenging in real-time applications, especially in large-scale networks where rapid decision-making is crucial.

Collectively, the above literature related to trust in fog computing from 2019 to 2024 illustrates various approaches to trust management in fog computing, each addressing specific challenges related to security, reliability, and performance. In Table III, the ongoing development of these mechanisms highlights the necessity of balancing robustness with efficiency, particularly as fog computing environments scale in size and complexity. Future research in this area is likely to focus on optimizing these trust management policies to ensure that they meet the needs of real-time applications while maintaining a high level of security and scalability in heterogeneous computing environments.

TABLE III COMPARATIVE ANALYSIS OF TRUST MANAGEMENT APPROACHES IN FOG COMPUTING LITERATURE (2019-2024)

Author	Method	Advantage	Weakness	How to Evaluate
Shahid Mahmood, et al. [26]	Based on digital certificate trust management	Enhances security and privacy of data communication between IoT devices through digital certificates.	Complex and costly deployment of numerous fog nodes as certification authorities. Cumbersome management and distribution of revoked certificates across devices.	Measure latency reductions. Assess security enhancements (e.g., fewer successful cyber-attacks). Evaluate resource utilization efficiency.
Rasha Jamal Atwa,et al. [20]	Task-based Experience Reputation (TER) : combines traditional Experience-based Reputation Models and Recommendation-based Reputation Models	Significantly reduces message transmission overhead and vehicle workload compared to experience-based models.	Traditional reputation computation methods struggle to adapt to the high mobility and transient nature of vehicles in VANETs.	Performance evaluated through MATLAB simulations. Comparison against experience-based trust models. Assessment of message overhead reduction and accuracy of trust assessments via task-specific reputation values.

Junbin Liang,et al. [21]	Multi-source feedback trust computation, combining both direct and recommended trust methods	Improves detection of malicious feedback nodes, enhancing the overall trustworthiness of the SSC.	Complicated implementation due to the integration of multiple feedback sources and the need for robust infrastructure.	Performance evaluated through theoretical analysis and simulation. Simulation results demonstrate higher trust accuracy with the multisource feedback mechanism.
Ogundoyin, et al. [34]	Based on Fuzzy-AHP	Enables comprehensive evaluation of trust by simultaneously considering multiple criteria, resulting in more accurate and reliable trust assessments.	Complex implementation due to the need for expert opinions and mathematical computations for prioritizing criteria. Subjectivity in expert judgment can lead to biased results, especially with inconsistent or inaccurate opinions.	Utilizes Fuzzy-AHP to prioritize trust criteria and calculate their weights. Assesses the impact on overall trust evaluations. Effectiveness demonstrated through nuanced and accurate trust assessments, enhancing reliability and security of fog computing services.
E. Alemneh,et al. [19]	Based on Subjective Logic: Direct Trust, Indirect Trust, Trust Tuple	Ensures trustworthiness of both service providers and requesters, enhancing overall security and reliability of the fog network.	Involves complex computational operations (e.g., discounting and consensus) that may burden resource-constrained fog nodes, particularly with large amounts of recommendation information.	Performance evaluated through simulations. Focuses on metrics such as accuracy, convergence, and resistance to trust-based attacks.
T. Wang, et al. [35]	Based on Hierarchical trust: Direct Trust, Recommendation Trust, Comprehensive Trust	Quickly identifies and isolates malicious nodes through real-time monitoring.	Involves multiple levels of trust computation and data analysis, leading to high computational complexity and potential overhead in large-scale networks.	Evaluated through simulations measuring performance metrics such as energy consumption, malicious node detection speed, and recovery of misjudged nodes.
A. Almas, et al. [18]	Based on Bayesian approach: Direct Trust, Indirect Trust, Total Trust	Dynamically adjusts trust weights to respond to environmental changes, effectively mitigating trust-related attacks.	Timeliness of trust value updates may be insufficient in highly dynamic network environments, potentially leading to misjudgement.	Evaluated through simulations using Contiki-NG and Cooja in a smart healthcare scenario. Analysis includes the impact of different similarity measures and comparisons between static and adaptive weighting methods on trust scores.
S. Mahmood, et al. [33]	Based on multi-source trust evaluation: Direct Trust, Recommendation Trust, Context-Aware Feedback, Content-Based Trust	Enhances reliability and accuracy of trust assessments by incorporating multiple sources of trust data.	Involves multiple levels of trust computation and data analysis, leading to high computational complexity and potential overhead in large-scale networks.	Evaluated through extensive simulations demonstrating effectiveness and reliability in assessing user trustworthiness. Analysis includes the impact of weight factors and the significance of monitor mode.
A. A. Bukhari, et al. [22]	Based on Fuzzy Logic: Fuzzification, Rule Setup, Fuzzy Inference, Defuzzification	The FL-based FNSE approach demonstrated superior performance with the highest accuracy, precision, recall, and F1 score in predicting fog node trustworthiness.	The fuzzy logic approach involves multiple steps (fuzzification, rule inference, and defuzzification), leading to high computational complexity that may impact real-time system performance.	Conducted experiments comparing three models (FL, LR, DNN) based on metrics such as accuracy, precision, recall, F1 score, and execution time.
R. Yadav, G. Baranwal [42]	Based on Feedback Credibility Evaluation: Direct Trust, Indirect Trust, Feedback Credibility Evaluation, Final Trust Score	Filters out malicious feedback before trust evaluation, enhancing the accuracy of trust scores assigned to fog nodes.	In highly dynamic network environments, trust value computations may not reflect the latest state of nodes in a timely manner, leading to delayed decision-making.	Evaluated through simulations using synthetic data to measure effectiveness in filtering malicious feedback and maintaining accurate trust scores. Performance metrics included detection rate, false rate, and deviation of trust scores from an ideal baseline.
Ke Gu, et al. [17]	Based on Reputation Mechanism: Internal Reputation, Indirect Reputation, Overall Reputation Value	Effectively matches user tasks with fog nodes that meet reputation requirements, improving service reliability.	Involves multiple levels of reputation computation and data analysis, leading to high computational complexity, especially with many communities and nodes, which can cause overheads and delays.	Evaluated using simulations on the CloudSim platform. Focused on metrics such as reputation changes, resource allocation success rate, average completion delay of tasks, and average distance between users and service providers.
J. Al. Muhtadi, et al. [40]	Based on Subjective Logic: Direct trust, Recommended Trust, trust convergence	Effectively identifies and mitigates malicious nodes using subjective logic that incorporates uncertainty and indirect evidence.	Heavily relies on recommendation information, which can bias trust calculations in networks with a high number of malicious nodes.	Evaluated through simulations assessing accuracy, convergence, and resilience against various trust-based attacks.

N. Mazumdar, et al. [41]	Based on Direct Trust, Indirect Trust, Comprehensive trust evaluation	Minimizes service delays and ensures timely task completion by offloading tasks to trusted nodes.	Shamir's secret sharing scheme adds complexity and burden, particularly in high-load or emergency situations.	Evaluated through simulations focusing on average latency, service response rate, and task completion success.
R. Yadav and G. Baranwal, [36]	Based on multilevel trust: Trust Factor Calculation, Overall, Trust Evaluation	Enhances security in fog computing by evaluating trust through QoS and social relationships, minimizing risks from malicious nodes.	Involves multi-layered trust computation and data analysis, leading to high computational complexity and potential overheads in large-scale networks.	Considers historical interactions and reputation among fog nodes to assess trustworthiness.
P. Kochovski, et al. [37]	Based on blockchain: Smart Contracts, Trustless Smart Oracles, Markov	Supports real-time monitoring and trust updates for quick responses to changes in node behavior.	Use of blockchain and smart contracts increases computational complexity and latency, especially with numerous transactions.	Evaluated through simulations focusing on the ability to detect and handle malicious nodes while maintaining performance. Metrics included accuracy in detecting trust anomalies and system overhead.
G. Rathee, et al. [43]	Based on Tidal Trust Algorithm	Ensures only trusted nodes communicate, effectively reducing the risk of malicious activities.	Requires computation of multiple trust values and uses complex algorithms, leading to high computational complexity that may impact real-time performance.	Examines performance in scenarios with malicious versus trusted fog nodes, focusing on managing security for handoff IoT devices (HEU) and mobile HEU (MHEU).
W. Ben Daoud, et al. [44]	Based on TACRM framework	Monitors and controls access based on trust levels, reducing the risk of unauthorized access and attacks.	Continuous monitoring of user behaviour may raise privacy concerns.	Evaluated through simulations of various network scenarios to measure the impact on security breach incidents.
M. Hamza, et al. [45]	based on a Bayesian inference model: Direct Trust, Reputation Function, Degree Centrality, Service Score, Final Trust	Detects and mitigates common trust-related attacks like ballot stuffing and self-promotion.	Comprehensive trust evaluation and the use of Bayesian inference increase computational complexity, potentially affecting real-time performance in large-scale networks.	Measures the accuracy of trust assessments through modelling.
S. O. Ogundoyin and I. A. Kamil [16]	Based on fuzzy logic: Direct Trust, Indirect Trust, trust convergence	Combines QoS, QoSec, and social interactions for a nuanced trust assessment.	Trust decay function may not update values timely in highly dynamic environments, affecting decision accuracy.	Evaluated through simulations measuring the system's ability to mitigate trust-related attacks and the accuracy of trust assessments.
G. Zhang, et al. [38]	Based on Hierarchical Trust Evaluation: Direct Trust, Indirect Trust, Hierarchical Trust Evaluation	Efficiently detects hidden data attacks by analysing sensor data correlations and historical trust states.	Layered architecture may lead to untimely updates of trust values in dynamic networks, affecting decision-making accuracy.	Evaluated through MATLAB simulations testing detection accuracy of the FDS under various scenarios, including different malicious sensor ratios and group sizes.
A. Rehman, et al. [39]	Based on Fuzzy Logic: Direct Trust, Indirect Trust, Trust Encryption and Aggregation	Effectively detects and mitigates various IoT attacks, including on-off, good-mouthing, and bad-mouthing attacks through encryption and trust aggregation.	Involves complex trust calculations, particularly with fuzzy logic, leading to high computational complexity that may affect real-time responsiveness.	Evaluated through simulations testing FogTrust's effectiveness against various attacks.
Q. Zhang, et al. [47]	a semantic-based trust management system integrated: Semantic Analysis, Direct Trust, Indirect Trust	Enables faster and more accurate emergency responses through semantic analysis, reducing failure risks in critical situations.	Scaling the system may challenge trust evaluations and semantic data processing, impacting performance.	Fog nodes assess trustworthiness based on historical interactions, data freshness, and recommendations, filtering out untrustworthy content.
T. Wang, et al. [35]	based on both direct trust and indirect trust	Utilizes both direct and indirect trust to adapt to network changes, including node mobility and varying trust levels.	Growing network size may complicate trust value calculations and data management, impacting scalability.	Final trust value is computed by combining direct and indirect trust values using a weighted sum.
F. H. Rahman, et al. [46]	Based on a fuzzy control system: Security, Reputation, Availability	Fuzzy control system effectively handles uncertainty and variability in trust evaluation, adapting to dynamic environments.	Introduces computational overhead from processing multiple inputs and evaluating numerous rules, challenging real-time applications.	Trust value is calculated using a fuzzy control system that processes security, reputation, and availability metrics to determine vehicle cluster membership.

IX. Challenges and Future Prospects

As the landscape of fog computing continues to shift, new challenges emerge that must be addressed to ensure effective trust management and task offloading. The increasing complexity and dynamism of network environments require innovative solutions to enhance the reliability and security of these systems. This section outlines several key challenges and

research directions that researchers and practitioners will need to tackle in the pursuit of more robust trust management frameworks.

A. AI and Machine Learning Integration

Integrating AI and machine learning techniques can significantly enhance trust assessments by leveraging historical data and real-time interactions. Research can explore supervised and unsupervised learning algorithms to model node behavior and predict trustworthiness, allowing for more accurate and adaptive trust evaluations that evolve with the network.

B. Hybrid Trust Models

Hybrid models that combine various trust evaluation techniques can provide more resilient systems. Research can explore the integration of reputation systems, subjective logic, and Bayesian approaches to create comprehensive models that account for both direct experiences and indirect recommendations, enhancing the accuracy of trust assessments.

C. Context-Aware Trust Management

Context-aware mechanisms can adjust trust evaluations based on environmental factors and user behaviors. Future research can focus on developing systems that dynamically modify trust metrics according to contextual information, ensuring that trust assessments are relevant and responsive to the current state of the network.

D. Decentralized Trust Management Systems

Decentralized approaches reduce reliance on central authorities and enhance resilience. Research should explore the design of decentralized trust management frameworks that empower nodes to independently evaluate trust, using peer-to-peer communication protocols to share and validate trust information among nodes.

E. Cross Domain Trust Management

Managing trust across different domains (e.g., fog and cloud computing) is vital for seamless interactions. Future studies should investigate methods for establishing trust relationships that span multiple environments, ensuring that resources can be shared securely and efficiently without compromising the integrity of trust evaluations.

F. Performance Optimization Techniques

Optimizing computational processes involved in trust evaluations can minimize overhead. Research should focus on developing algorithms that streamline trust computations, utilizing techniques such as caching trust values, batching evaluations, or employing approximation methods to reduce computational complexity without sacrificing accuracy.

G. User Centric Trust Models

Developing user-centric trust management systems can enhance user experiences by prioritizing individual preferences and interactions. Research should explore personalized trust models that adapt to user behaviors and preferences, allowing for more relevant interactions and trust assessments that reflect user needs.

By addressing these challenges and pursuing the outlined research directions, the field of trust management in fog computing can evolve to meet the demands of increasingly complex and dynamic environments, ensuring both security and performance.

X. Conclusion

This study provides a comprehensive exploration of the critical role of trust management in fog computing, particularly in ensuring secure and efficient task offloading among diverse IoT devices. It highlights significant gaps in existing methodologies and emphasizes the urgent need for advanced trust assessment frameworks. By establishing key metrics for evaluating trust management systems, we lay the groundwork for measuring their effectiveness, which is essential for fostering reliable interactions in dynamic environments. The integration of AI and machine learning techniques is examined as a promising approach to enhancing trust evaluations. These technologies allow systems to adapt to real-time data and evolving network conditions. However, several challenges persist, including scalability, the management of diverse IoT devices, the achievement of real-time trust evaluations, and the need to address security and privacy concerns. Moreover, addressing these challenges through innovative research and practical implementations is crucial for advancing fog computing technologies. This work aims to provide valuable insights that will facilitate the development of more secure and efficient applications, ensuring that trust management evolves alongside the rapidly changing landscape of IoT and fog computing.

AraSpam: A Multitask Deep Neural Network for Spam Detection in Arabic Twitter

Lulua Alhamdan[1], Ahmed Alsanad[2], Nora Al-Twairesh[3]
Department of Information Systems, College of Computer and Information Sciences, Imam Mohammad Ibn Saud Islamic University, Riyadh, Saudi Arabia[1]
College of Computer and Information Sciences, King Saud University, Riyadh, Saudi Arabia[1, 2, 3]

***Abstract*—Twitter has become widely used for disseminating information across the Arab world. It provides diverse communicative and informational needs while serving as a rich data source for a wide range of research. However, the integrity of such data is frequently undermined by the pervasive issue of spam. Existing research proposed the use of spam detection models at multiple levels—the account, tweet, and campaign levels. Many of these models target Uniform Resource Locator (URL)-based spam messages, whereas a significant portion of spam content operates without embedded URLs. Furthermore, spam detection methodologies tailored to the account level often lack the precision required for tweet-level analysis or, conversely, fail to capture broader account-level behavioral patterns. Moreover, studies focusing on Arabic spam have largely been restricted to specific geographical regions or linguistic varieties, such as Arabic dialect (AD) or Modern Standard Arabic (MSA), thereby neglecting the full spectrum of Arabic's linguistic diversity in spam messages. This study aims to address these limitations by proposing AraSpam, a multitask deep neural network that detects both spam messages and profiles using a single model. It was trained using a dataset of tweets written in AD and MSA covering different spamming targets. The text features were extracted using transformer-based models: AraBERT for tweet text and mBERT for profile screen name. The experiment demonstrated 96% accuracy in detecting both spam accounts and tweets with seven different spamming targets. Additionally, the experiments revealed that reducing the number of spam classes resulted in an increase in tweet detection performance and a decrease at the account level.**

***Keywords*—Spam detection; Twitter; multitask deep neural network; transformer-based model**

I. Introduction

Spam is generally referred to as unwanted and unsolicited material. It takes on several forms on different platforms, including email, Wikipedia, e-commerce, and online social networks (OSNs). Recently, artificial intelligence (AI) has enabled multimedia spam and social spambots to generate automatic content [1]. Users who send spam messages are known as spammers. They could be individuals, campaigns, or social bots. They are typically motivated by a clear objective, concentrating on its attainment [2][3].

Twitter is recognized as an important OSN platform for daily activities and is employed by individuals, organizations, and researchers for information dissemination and analysis. It allows users to share messages known as tweets. A tweet is generally limited to 280 characters, including text, Uniform Resource Locators (URLs), multimedia, emojis, hashtags, and mentions. Recently, users who subscribe to premium accounts can share messages that are extended to a maximum of 25,000 characters. Twitter defines spam as "*sharing or posting content in a bulk, duplicative, irrelevant, or unsolicited manner that disrupts people's experience* [4]". The powerful information-sharing capabilities of Twitter, including hashtags, mentions, and retweets, attract spammers who exploit the platform for their activities. Commonly, spam is produced on Twitter through mentions of well-known users' accounts, replies to their tweets, or wildly trending hashtags [5][6].

Different types of spammers with various intents have been observed. On the political side, some campaigns disseminate agendas to influence people's opinions during critical periods of political significance [7][8]. Commercially, in addition to standard advertisement spam, spammers try to influence people's opinions toward specific products or services by writing fake reviews [9][10]. In cybersecurity, Twitter has become a target for attackers seeking to spread malware [11][12]. Additionally, illegal and pornographic materials are also propagated on Twitter [13][14]. Accordingly, these spamming activities are decreasing the quality of Twitter data. The decrease in data quality affects researchers by requiring additional cleaning effort before performing various tasks, including data analysis, training natural language processing (NLP) models, and others [9][15]. Twitter has implemented restrictions to ensure the reliability of its content and to prevent any deceptive practices, thereby increasing its audience's confidence in its authority [4]. However, these regulations and rules lack detection capabilities except for limited violations. Researchers have proposed different detection approaches for spam tweets, profiles, campaigns, and bots. Most rely on supervised machine learning (ML) techniques using single-type or hybrid features, including text, content, account, and graph features [16][17]. The deep learning (DL) approach eliminates the need for feature selection; however, a large labeled dataset is required for improved performance [18]. Even if high accuracy is achieved through these approaches, spammers continue to change their behaviors and challenge the detection process, a problem referred to as spam drift [19]-[21]. Regarding detection level, tweet-level detection lacks the ability to detect spamming behaviors, whereas account-level detection models cannot identify spam tweets generated from legitimate accounts. On the other hand, campaign- and bot-level detection models are unable to detect individual and ordinary spammers' accounts, respectively [16].

In Arabic language, specifically, various studies have revealed that the effectiveness of the features in the detection process is language-dependent and differs between societies [22]-[25]. At the same time, most of the literature is based on the English language [25]-[27]. Among the limited Arabic studies, the majority focused on content in Saudi Arabia [10].

This study aims to enrich Arabic Twitter spam detection by addressing different limitations. First, using a more comprehensive dataset that covers Arabic spam messages, even written in Modern Standard Arabic (MSA) or Arabic dialect (AD). Additionally, in order to eliminate the spam drift problem, the data was collected using different time slots, hashtags, user mentions, and keywords. Furthermore, unlike previous works that automatically assigned the same label to both accounts and tweets, tweets and accounts were labeled independently to highlight instances where legitimate accounts and vice versa occasionally wrote spam messages. Moreover, to reveal the purpose of spamming, spam tweets were categorized based on the most common spamming purposes on Arabic Twitter. Finally, a detection model is proposed to classify both tweets and user profiles within a single model by leveraging the concept of a multitask learning framework. Accordingly, this will help in revealing spam messages generated from legal accounts and vice versa. Furthermore, by leveraging the similarities between the two tasks, we can reduce the processing time.

The rest of this study is structured as follows: Section II presents a review of related work on Twitter spam detection. Section III provides background on the techniques employed in this study and outlines the proposed methodology. Section IV presents and discusses the experimental results. Section V presents the conclusion, summarizing the key findings and highlighting the overall significance of the study.

II. Related Work

Various methods have been proposed for spam detection on Twitter, each implemented through different techniques. Recently, the primary approaches in the literature are ML and DL, applied at different levels, including tweets, accounts, campaigns, and social bots. ML-based studies vary in their choice of features, with some focusing on a single feature type, such as text, content, user, or graph, while others adopt hybrid features. The next section explores studies employing tweet- and account-level detection approaches, with a dedicated section on Arabic spam detection research.

A. Tweet-Level Detection

First, Tweet-level detection involves classifying tweet messages into spam or non-spam. Studies on the ML approach most often use content features, as classified by [19], into URL or hashtag features, image or video features, and text-based features. Other studies considered user account features in tweet classification, such as in [28], which proposed a framework based on ML with a combination of user and tweet features that were available for real-time detection, such as the number of characters, digits, hashtags, and followers.

Recent studies have proposed extracting text features using various methods, including term frequency–inverse document frequency (TF–IDF), bag-of-words, n-gram, and Word2Vec. The authors of [18] proposed using Word2Vec to learn message syntax with a multilayer perceptron artificial neural network (MLP) that outperforms other feature-based ML classifiers such as random forest (RF) and naïve bayes (NB). The authors of [29] presented another means of outperforming these methods, using bidirectional long short-term memory networks (BiLSTMs) to extract text features for training supervised ML classifiers.

Instead of depending on feature-based ML classifiers, a variety of studies proposed models based on deep neural networks. Neha proposed using long short-term memory (LSTM) after extracting text features by applying Global Vector (GloVe) word embeddings [30], achieving an accuracy of approximately 95%. Moreover, [31] used the Word2Vec embedding for training an extreme learning machine (ELM) with multiple layers, achieving an accuracy of 88%. The use of transformer-based models for generating embeddings was applied by [32] for detecting spam in a short message service (SMS) dataset. This is accomplished by extracting text features using Generative Pre-trained Transformer 3 (GPT-3) and ensemble classifiers with weighted voting for classification.

B. Account-Level Detection

Account-level detection involves classifying a user account as a spammer or a legitimate user. Most studies accomplished it using ML with a combination of account, content, and graph features. The majority used statistical features, such as the ratio between the number of followers and the number of friends, the average number of favorite tweets, tweeting frequency, and account age [33]. In addition to these features, other studies have focused on interaction features in relation to user and content features [34]. Another study [35] analyzed URLs and sharing patterns to detect spam accounts. Detecting spammers' behaviors and extracting useful behavioral features have led researchers to perform network analyses and utilize graph features, such as average neighborhood followers, average neighbor tweets, and betweenness centrality of mentions [36]. Instead of relying on such features, [37] utilized a CNN to combine text features extracted using Word2Vec with common account numerical features, such as account age, number of followers and followings, and others. In various studies, suspicious words were combined with other features to characterize spammer accounts. Some approaches involve checking for the presence of words from a predefined dictionary [23], whereas others extract statistical features based on these words [36]. The authors of [38] utilized additional linguistic features by targeting spammers based on their topics of interest, arguing that information from individuals discussing various topics is less trustworthy than information from those focused on specific areas.

All previous approaches required a labeled dataset for Twitter accounts; however, complete profile datasets were not publicly available due to privacy concerns [39]. Several studies have proposed using the unsupervised approach to mitigate the cost of manual annotation [40]-[42]. Instead of detecting individual human spam accounts, various studies focused on detecting automated spam via social bots [49][50], while others were more interested in identifying groups of spammers forming a campaign [43]-[46].

C. Spam Detection on Arabic Twitter

Several studies have focused on determining the effect of the language used on spam classification. For example, [22] used an ML classifier on two datasets: English and Roman Urdu. They observed that the results improved when a language-dependent model was used. Another study, by the authors of [25], examined the differences between spammers in various social contexts that affect the effectiveness of selected features. They built a model for detecting Arabic spammers and tested it with two datasets—Arabic accounts and English accounts—and concluded that the accuracy decreased in detecting English spammers. The authors of [23] tested the effectiveness of features in English, Arabic, Korean, and Spanish datasets and found that the behavior of spammers and the effectiveness of features differ between these datasets. These findings motivated researchers to consider lingual and social contexts in detection techniques. In Arabic spam tweets, the authors of [26] extracted text features using skip-grams and continuous bag of words (CBOW) to train ML classifiers and reached 87.3% accuracy with skip-grams learned using a corpus collected from Twitter. Another study examined tweet sentiment in conjunction with behavioral features to investigate the likelihood of a tweet being spam [27]. They found that the effectiveness of commenting behavior exceeds that of liking behavior in the classification process, whereas message sentiment is not a useful factor. Other researchers classified spam tweets in the Gulf Arabic dialect using content-based features with ML classifiers and attained 86% accuracy. Moreover, they stated that URL safety is insufficient in detecting Arabic spam and that the safety of the used words contributes more to the detection process [7]. The authors of [47] focused on spam in Saudi Arabia. They generated eight datasets, each collected from specific hashtags, which fall under three topics: national, health, and politics. After preprocessing, N-grams and Word2Vec embeddings were used for text feature extraction. These features were used to train different ML classifiers for the eight datasets separately, showing high performance using RF with N-grams. Moreover, ML classifiers were used in [48] with word embeddings and optimized by an augmentation technique that is based on Aravec's similarity. Then, these embeddings were combined with different features from three categories: content, user, and interaction. Hence, [10] focused on detecting advertisement spam in Arabic tweets by testing two methods: word embeddings with an ML classifier and fine-tuning AraBERT, a pre-trained Arabic language model. The latter achieved high accuracy compared with the former method. Moreover, the n-gram embeddings performed better than the Mazajak embeddings in the classification process. Another study [49] distinguishes between three types of spam: promotional, phishing, and spam. The last two categories are characterized based on the used URL: phishing if the URL directs to a trading website, and spam if it links to external websites. In their model, text features were extracted using Aravec for word embeddings in one model, whereas a character-level convolutional network was used for character embeddings in the other model. They integrated CNN for feature extraction with LSTM for spam classification. Their experiments demonstrated higher classification accuracy using word embeddings compared to character embeddings. In addition to regular text, [50] focused on classifying spam text within images. This was completed using an efficient and accurate scene text detector (EAST) and a convolutional recurrent neural network (CRNN) for text extraction .Then, the detection is performed by conducting comparisons between used words and two lists built by the authors: blacklist and whitelist. This method requires a big dataset in one language to avoid misclassification.

Moving to account-level detection, the authors of [25] classified Arabic spammers with 92.6% accuracy using 14 behavioral and content features selected by information gain (IG) and chi-squared feature selection methods. In addition to their previous finding that classification features are socially dependent, they observed how spammers employed different evasion techniques that may diminish the effectiveness of detection features over time. Similarly, the authors of [51] selected 16 features from a set of content- and user-based features and calculated different statistics for a subset of these features, including (total, minimum, maximum, and average). The rank of these features was determined using mean decrease Gini and subsequently reduced through the application of recursive feature elimination (RFE). Starting with about 47 features, more than 90% accuracy was achieved with 16 selected features. Comparing ML classifiers and deep neural networks (DNNs), the authors of [52] compared the two methods using text features. The features were extracted using N-grams (uni-gram, bi-gram, and char-gram) in the former and GloVe and fastText in the latter. DNN and GloVe outperformed other techniques in ML and DL models, respectively. Adapting the methodology used in [37], the authors of [53] proposed combining text features with metadata from tweets and accounts. Text features were extracted using word embeddings to train the CNN model, whereas a simple neural network was trained using 12 statistical features. The final classification is defined by combining the outputs of the two networks. Their framework achieved 94.27% accuracy in classifying Arabic spammer accounts. In addition to their proposed model for classifying spam tweets, the authors of [49] proposed another model for detecting Arabic spammers. After scraping a subset of tweets from the account, the embeddings were extracted (character level and word level) and used to train a deep learning model (CNN and LSTM), concluding that 10 to 15 tweets are optimal for high-performance classification. On the other hand, the authors of [14] focused on detecting types of spammers, namely those publishing porn content. Accordingly, different text features were tested individually and in combination. These features included username, screen name, user description, or a single tweet message extracted from the account. Text features were extracted from these attributes using n-gram comparison between word-level and character-level. Then, a Support Vector Machine (SVM) was trained using different alternatives of features. Other experiments involve fine-tuning pretrained language models, including Multi-BERT and AraBERT. These experiments revealed that screen names are not informative in the detection model, even with preprocessing and normalizing the used text. Moreover, the performance was highly improved by adding a single tweet with the username and description.

A review of the existing literature reveals several limitations that require further investigation. First, most studies rely on a single criterion for spam collection, such as URLs, hashtags, account suspension, or predefined keywords. These methods

restrict the diversity of captured spamming behaviors and limit model generalizability. In addition, datasets are often collected within short time frames and annotated using automated or semi-automated techniques, which increases sample homogeneity and labeling inaccuracies.

Second, prior studies adopt a binary classification model, typically distinguishing only between spam and non-spam messages, focusing on narrow categories such as URLs, advertisements, or pornographic content. Such approaches fail to capture the full spectrum of spamming behaviors, limiting the generalizability and robustness of the resulting models.

Third, previous studies often consider either the tweet level or the account level in isolation, operating under the assumption that spam tweets are produced by spammer accounts and that non-spam tweets are generated only by legitimate accounts. This assumption overlooks more scenarios, such as legitimate accounts posting occasional spam messages or spammer accounts generating legitimate content to evade detection techniques.

Finally, feature-based approaches often require extensive and continuously available user, content or network data, which may not always be accessible due to privacy restrictions, platform limitations, or availability.

III. Materials and Methods

A. Dataset

Data was gathered utilizing the Twitter Application Programming Interface (API) across several time intervals from 2018 to 2023. We employed a comprehensive array of keywords, encompassing user mentions, hashtags, and suspicious terms, to effectively identify diverse spamming targets. The data was manually annotated to classify user profiles as either legitimate or spammer, with spam tweets categorized into seven distinct spamming targets: commercial advertisements, medical advertisements, illegal services, sorcery content, pornographic content, monetary requests, and other irrelevant messages (TABLE I.). The annotation process was conducted manually by two annotators, with an auditor responsible for assigning the final labels. Both annotators are native Arabic speakers with expertise in computer information systems and were provided with detailed annotation guidelines to ensure accurate labeling of spam tweets and accounts. Inter-annotator consistency was evaluated using Cohen's Kappa (κ), yielding a value of $\kappa = 0.92$ at the tweet level and $\kappa = 0.9$ at the account level. Three versions were derived from this dataset as follows:

- DS_Multi_8: This version of tweet labels encompasses all seven categories of spam targets (Fig. 1), as well as the ham class.
- DS_Multi_4: In this version, the seven spam categories have been consolidated into three abstract categories: promoting spam (commercial advertisements, medical advertisements, and illegal services), unethical spam (sorcery content and pornographic content), and irrelevant spam (monetary requests and irrelevant content).
- DS_Binary: This version includes a binary label for tweets, denoting whether they are classified as spam or not.

The dataset comprises more than 15,000 records, with approximately 54% being spam tweets and the remaining 46% being non-spam tweets. As previously mentioned, different keyword types were used to collect spam tweets, with varying effectiveness. A variety of hashtags indicating Arabic country names were used. Of tweets using these hashtags, 59% were ham messages, and 41% were spam messages. The majority of tweets using sports-related hashtags were spam (68% vs. 32% ham). Trending hashtags were particularly targeted by spammers, with only 28% of tweets being ham and 72% being spam messages. User mentions were also analyzed, particularly replies to various Arabic news accounts (@AJABreaking, @AJArabic, @AlArabiya_Brk, @alqabas, @SaudiNews50, and @Sabqorg); 77% of these tweets were ham messages, while 23% tweets were spam messages. Finally, spam words associated with different spam types were examined. Only 5% of these tweets were ham messages, while 95% were spam.

At the account level, the dataset comprised 5,620 unique user accounts. Of these, 55% were identified as legitimate and active during the annotation process, while 36% were classified as active spammers. In addition, 4% of the accounts were suspended, and 5% had been deleted at the time of annotation.

TABLE I. Spam Tweet Categories

Category	Definition
Commercial Advertisement	Tweets promoting products or services other than verified account advertisements.
Illegal Medicine Advertisement	Tweets promoting medical products or services (e.g., weight loss products, sexual products).
Illegal Service	Tweets promoting illegal services, including those prohibited by the government, or inflating OSN metrics (e.g., number of followers, retweets, verification).
Money Request	Tweets asking for monetary help.
Sorcery Service	Tweets promoting sorcery services.
Pornographic Content	Tweets with pornographic content, including text or media.
Irrelevant Content	Tweets using hashtags or mentions unrelated to the tweet topic or tweets with only hashtags, mentions, or media.

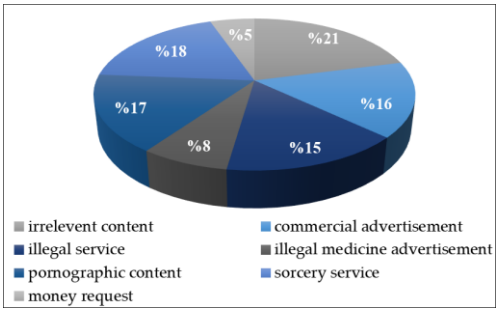

Fig. 1. Spam tweets per spam category.

B. AraSpam: Spam Detection Model Based on Multitask Learning

The AraSpam model is built to detect both spam tweets and accounts in Arabic Twitter. The model begins by extracting a

textual representation from the preprocessed tweet text and the profile screen name. The two extracted embeddings were subsequently stacked, supplemented by an oversampling technique, and then input into the multitask deep neural network. Two deep multitask neural network architectures were employed: hard parameter sharing and soft parameter sharing.

1) Text preprocessing: The preceding phase of embedding extraction from tweet text is preprocessing. The text was preprocessed with AraBERT Preprocessor following its default settings:

- Keeping emojis;
- Removing "html" markup;
- Replacing email, URL, and user mentions with specific tokens as follows:
- Replacing URL with [رابط], which means [link];
- Replacing user mention with [مستخدم], which means [user];
- Replacing email with [بريد], which means [email];
- Removing the repetition of more than two non-digit characters, e.g., (سلاااام) will be converted to (سلام);
- Stripping Tatweel (ـ), e.g., (محمـــد) will be converted to (محمد);
- Removing diacritics: Dammah (ُ), Tanween Aldam (ٌ), Kasra (ِ). Tanween Alkasr (ٍ), Fatha (َ), Tanween Alfath (ً), Skoun (ْ), and Shaddah (ّ);
- Replacing slash (/) with dash (-);
- Mapping Hindi numbers (١ ٢ ٣) to Arabic numbers (1 2 3);
- Inserting white space.

2) Text features extraction: Bidirectional Encoder Representations from Transformers (BERTs) is a transformer-based model that acquires linguistic representations by utilizing extensive text corpora through unsupervised methods such as masked language modeling (MLM) [54]. It can be fine-tuned to solve different NLP tasks, such as sentiment analysis and question answering. The model's input embeddings are the result of integrating three types of embeddings: token embeddings, segmentation embeddings, and position embeddings. Another version of BERT, trained on a Wikipedia corpus comprising 104 languages, is referred to as multilingual BERT (mBERT) [55]. It possesses advantages such as the tokenization method that can handle out-of-vocabulary words and its capacity to capture cross-lingual representation. An Arabic adaptation of the BERT model is AraBERT [56], which is trained using a large Arabic corpus and comes in different versions that differ based on the type and size of the training datasets, as shown in TABLE II. The original AraBERT dataset was crawled from Wikipedia and multiple Arabic corpora, including news articles from various Arab countries, covering a broad spectrum of topics written in Modern Standard Arabic (MSA). The latest versions incorporate tweets in diverse Arabic dialects, including emojis.

Sentence Transformers are a distinct category of transformer-based models designed to provide embeddings for sentences, thereby enabling effective evaluation of their semantics. Unlike traditional transformer models like BERT, which generate contextualized embeddings for individual tokens, Sentence Transformers construct a fixed-length vector representation for entire sentences. Sentence-BERT (SBERT) [57] and Language-agnostic BERT Sentence Embedding (LaBSE) [58] are transformer-based models built to provide embeddings for sentences or text. The last one was expanded to accommodate cross-lingual tasks, having been trained in 109 languages. Another sentence transformer mode supporting multilingual is E5 [59]. It generates dense, high-dimensional embeddings in which semantically similar inputs, regardless of language, are situated closer together in the embedding space. Accordingly, these models are highly effective in capturing semantic similarity, information retrieval, translation, and a range of other applications.

TABLE II. ARABERT MODEL VERSIONS [60]

Model	Pre-Segmentation (Farasa)	Dataset (Sentences/Size/nWords)
AraBERTv1-base	Yes	77M / 23GB / 2.7B
AraBERTv0.1-base	No	77M / 23GB / 2.7B
AraBERTv2-base	Yes	200M / 77GB / 8.6B
AraBERTv2-large	Yes	200M / 77GB / 8.6B
AraBERTv0.2-base	No	200M / 77GB / 8.6B
AraBERTv0.2-large	No	200M / 77GB / 8.6B
AraBERTv0.2-Twitter-base	No	AraBERTv0.2 dataset + 60M Multi-Dialect Tweets
AraBERTv0.2-Twitter-large	No	AraBERTv0.2 dataset + 60M Multi-Dialect Tweets

AraSpam utilizes word embeddings derived from two sources: preprocessed tweet text and user screennames, comparing between word- and sentence-level transformers as follows:

- Word level: extracting word embedding from preprocessed tweet text via AraBERTv0.2-Twitter-large and user screen names through mBERT.
- Sentence level: Three different alternative models were used for extracting sentence-level embeddings for both tweet text and account screen names, including SBERT, LaBSE, and E5.

3) Data resampling: To address the class imbalance problem, augmentation strategies involve either oversampling or undersampling. These strategies primarily aim to mitigate bias in the learning process against the majority class. The undersampling technique involves eliminating instances from the majority class, whereas oversampling approaches aim to augment the samples in the minority class, either randomly or through synthetic methods. One of these is the adaptive synthetic (ADASYN) sampling approach. It aims to account for

the more challenging samples that are identified throughout the augmentation process [61].

DS_Multi_8 and DS_Multi_4 exhibit an imbalance among the various spam tweet classifications. The ADASYN augmentation approach was employed to address the dataset imbalance.

4) Multitask deep neural network: A DNN is an ML approach that can process raw data, such as text, and derive the necessary representations for classification tasks. The DNN model comprises an artificial neural network with multiple hidden layers (Fig. 2). Every neuron in a layer takes inputs, assigns weights and bias, processes the sum through an activation function, and transmits the output to the subsequent layer [62]-[64], as in Eq. (1):

$$z = wx + b \tag{1}$$

where, z is the output, w is the weight, x is the input matrix, and b is the bias. The activation function can be one of several functions, mainly Sigmoid [Eq. (2)], Rectified Linear Unit (ReLU) [Eq. (3)], and Softmax [Eq. (4)], for multi-classification problems. The equations of these functions are as follows:

$$\text{Sigmoid: } \sigma(z) = \frac{1}{1+e^{-z}} \tag{2}$$

$$\text{ReLU: } f(z) = \max(0, z) \tag{3}$$

$$\text{Softmax: } \sigma(z_i) = \frac{e^{z_i}}{\sum_j e^{z_j}} \tag{4}$$

Finally, the loss function [Eq. (5)] calculates the difference between the predicted value ($\hat{y}_i$) and the actual value (y_i) as follows:

$$L = -\sum_i y_i \log(\hat{y}_i) \tag{5}$$

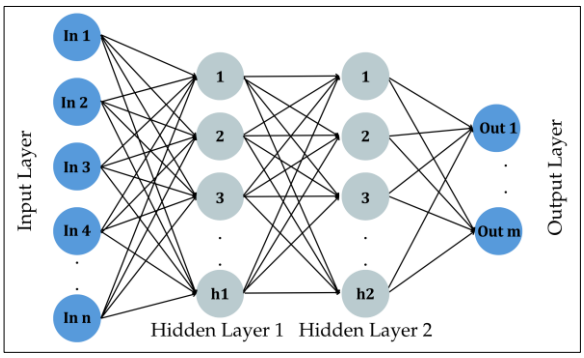

Fig. 2. General DNN structure.

Multitask learning (MTL) is a novel learning paradigm that leverages human learning to enable computers to learn multiple related tasks, thereby enhancing generalization performance [65]. At the beginning of MTL, the idea was motivated by the need to address the data scarcity problems that arise when different tasks have insufficiently labeled data for training. MTL combines these data to increase the model accuracy [66]. Formally, MTL is defined as "Given m learning tasks $\{\mathcal{T}\}_{i=1}^{m}$, where all the tasks or a subset of them are related, multi-task earning aims to learn the m tasks together to improve the learning of a model for each task $\mathcal{T}$i by using the knowledge contained in all or some of the other tasks [66]".

MTL tasks can be homogeneous, meaning all tasks share the same learning type, such as classification, regression, clustering, or others. Conversely, it could be heterogeneous if the learning tasks differ [67]. Joining the learning process between these tasks can be accomplished using different approaches, including feature learning, low-rank decomposition, task relationship learning, and task clustering. These approaches can be applied to tasks involving various learning types, including supervised, semi-supervised, unsupervised, reinforcement, online learning, and multi-view learning [66][68][69]. On the other hand, when using deep MTL, different methods of task concatenation can be employed, such as hard and soft parameter sharing, as shown in Fig. 3. The different tasks share the hidden layers in hard parameter sharing, while a constraint is added to encourage similarities among related parameters.

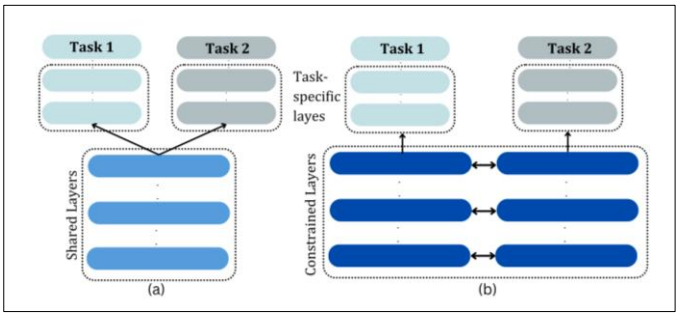

Fig. 3. Deep multitask learning approaches: (a) Hard parameter sharing, and (b) Soft parameter sharing.

a) Hard parameter sharing approach: The input layer functions as an embedding layer, as outlined in the preceding section for the tweet classification task. The identical layer is used for the account classification task after it is combined with the output of the tweet classification task layers. The tasks share certain hidden levels, whereas each task possesses additional task-specific layers, as shown in Fig. 4.

b) Soft parameter sharing approach: This architecture maintains the same input layer as the previous one, but the organization of the hidden layers differ. This method incorporates distinct hidden layers for each task, as illustrated in Fig. 5.

C. Experimental Setup

The experiments were conducted using Keras, an API integrated within the TensorFlow backend for implementing deep learning models. Consequently, the Keras tuner was utilized with 100 epochs to identify the optimal hyperparameters, including the number of units in the dense layer, dropout rate, and learning rate. Moreover, the Adam optimizer, L2 regularization (with a coefficient of 0.01), batch normalization, ReLU activation function, and cross-entropy loss function were used. Furthermore, transformer-based models were imported from the HuggingFace Transformers library. The experiments were conducted using Google Colab, equipped with high RAM and robust GPUs.

D. Performance Measures

The models' performances were measured using accuracy [Eq. (6)], macro F1-score [Eq. (7)], precision [Eq. (8)], and recall [Eq. (9)] as follows:

$$\text{Accuracy} = \frac{\text{True Positives} + \text{True Negatives}}{\text{True Positives} + \text{True Negatives} + \text{False Positives} + \text{False Negatives}} \quad (6)$$

$$\text{F1} - \text{Score} = \frac{\text{False Positives}}{\text{True Positives} + \text{False Negatives}} \quad (7)$$

$$\text{Precision} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Positive}} \quad (8)$$

$$\text{Recall} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}} \quad (9)$$

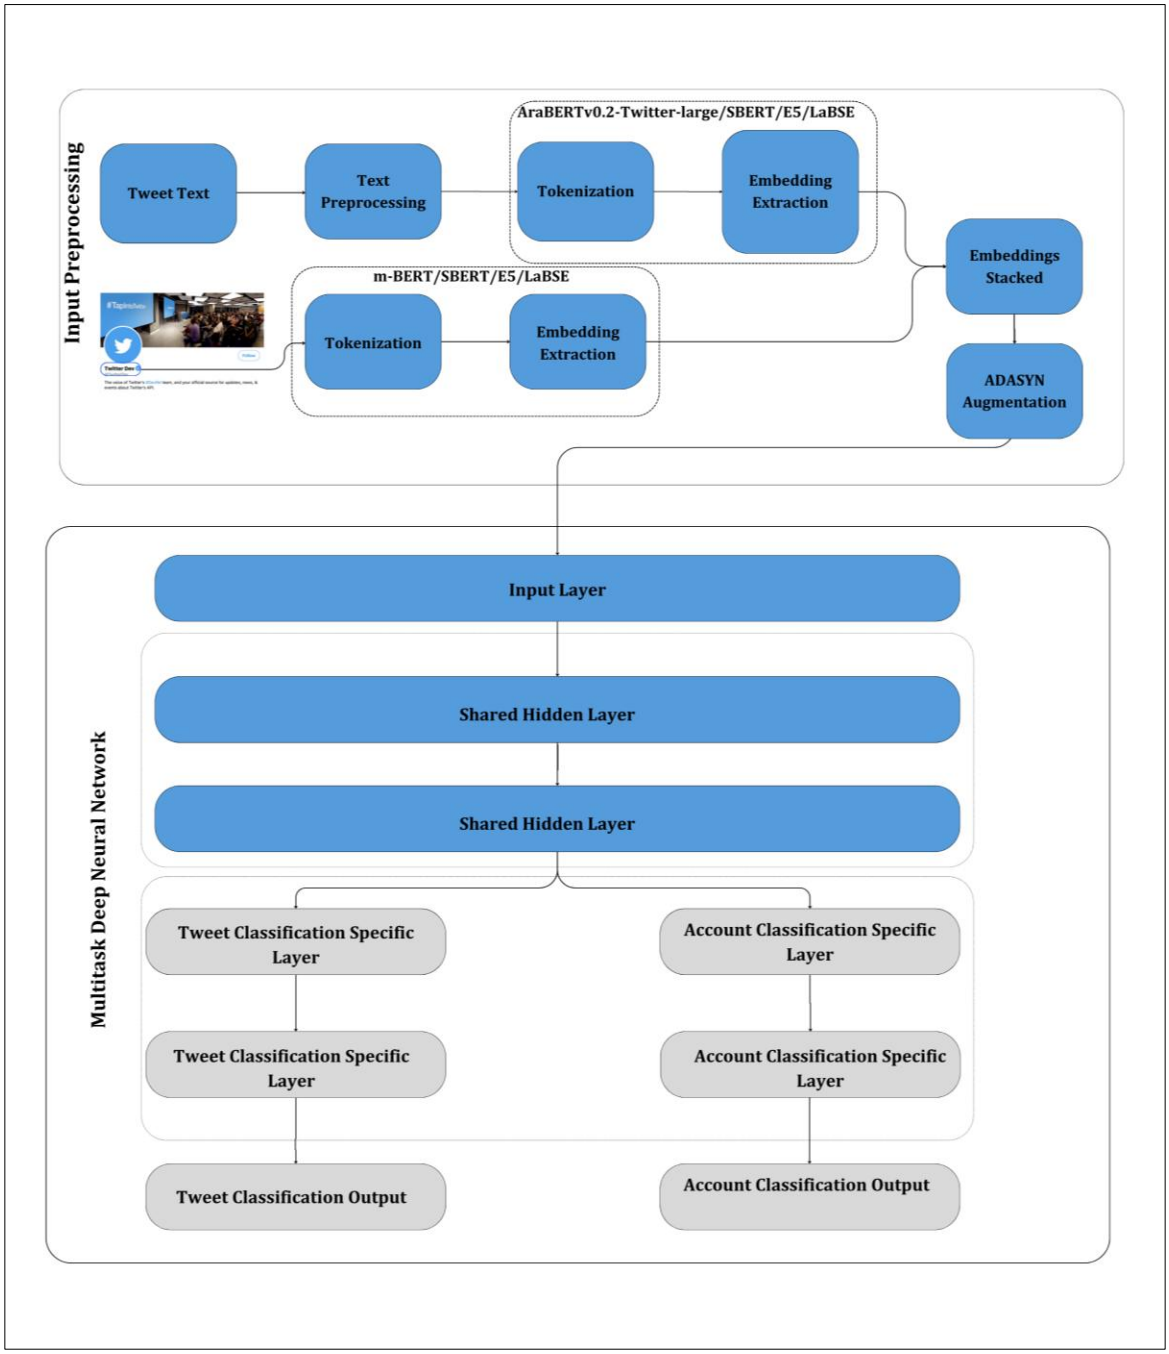

Fig. 4. AraSpam: Arabic spam detection model based on hard parameter sharing.

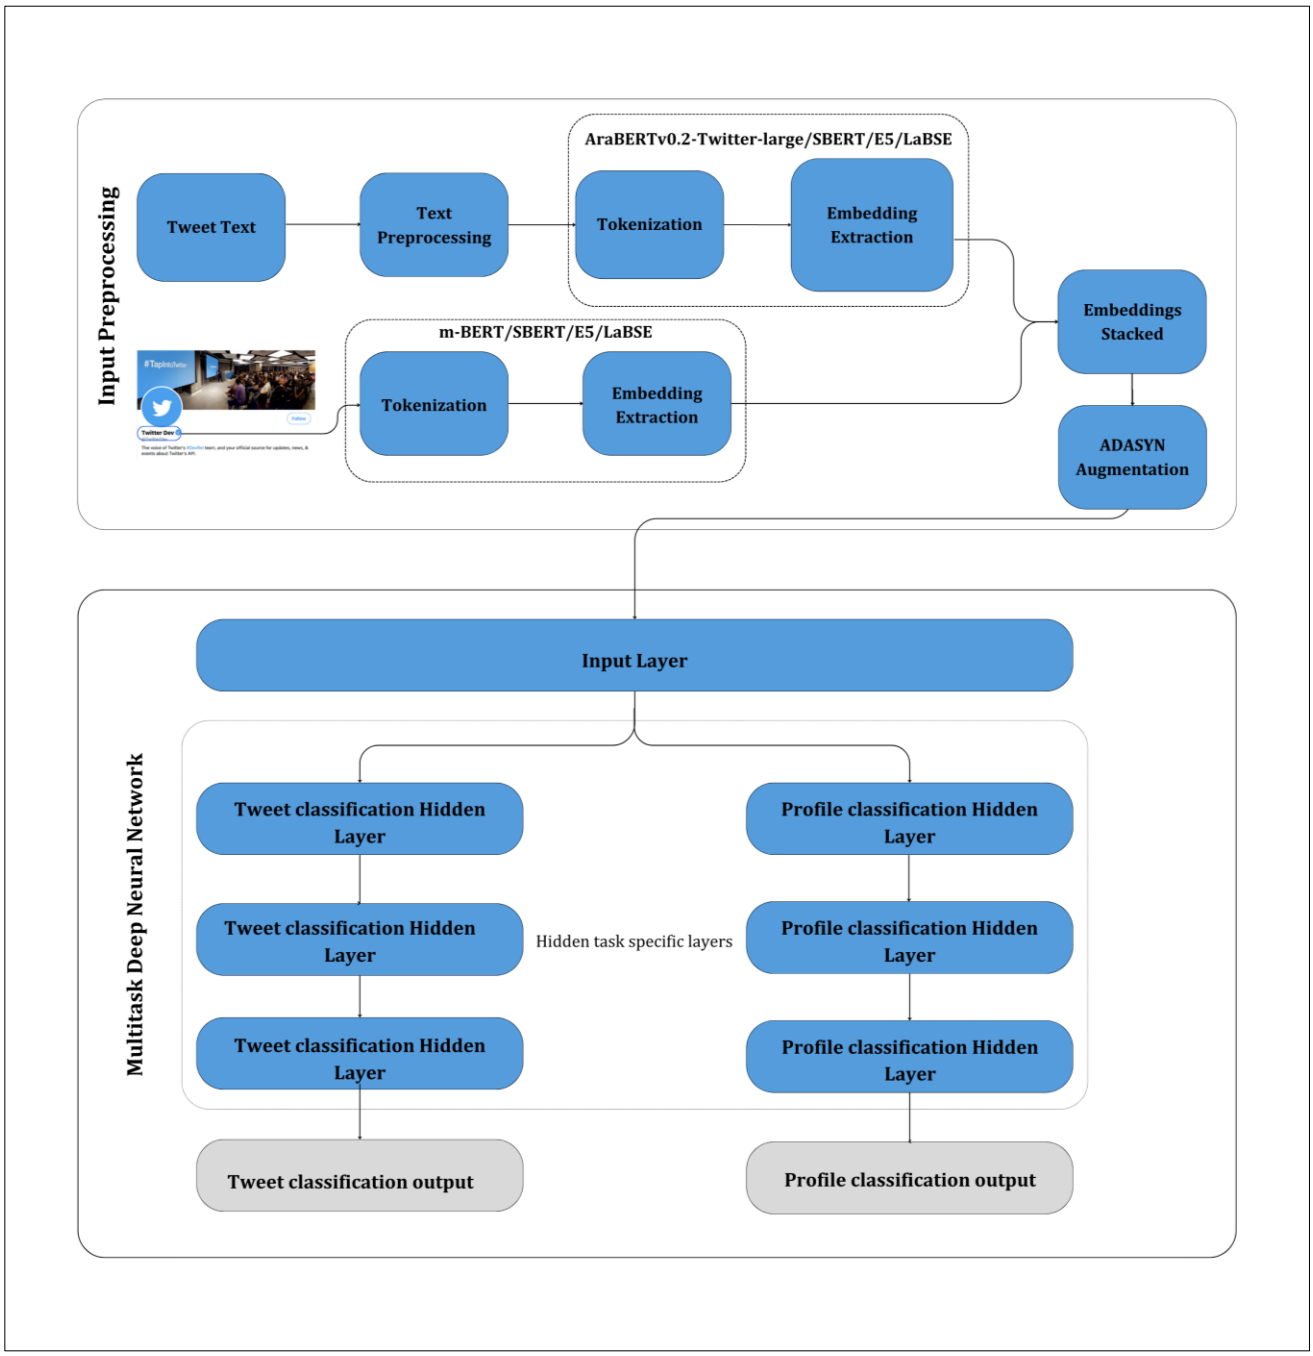

Fig. 5. AraSpam: Arabic spam detection model based on soft parameter sharing.

E. Model Validation

Various prior studies indicated that integrating text features with metadata enhances the accuracy of spam detection models [37][53]. AraSpam aims to achieve superior detection efficiency at both tweet and account levels with minimal prerequisites by eliminating the need to obtain metadata from Twitter. The model was validated by assessing and comparing the performance of three distinct inputs as follows:

- Spam detection metadata.
- Input 1: Tweet text embedding.
- Input 2: Tweet text embedding + screenname embedding.

Input 3: Tweet text embedding + screenname embedding + metadata (profile and content numerical features), as defined in TABLE III.

TABLE III. SPAM DETECTION METADATA

Feature name	Description
word_count	Number of words in the tweet
word_count_pre	Number of words in the preprocessed tweet
word_count_pre/ word_count	Ratio of words in the preprocessed tweet to the original tweet
char_count	Number of characters in the tweet
char_count_pre	Number of characters in the preprocessed tweet
char_count_pre/ char_count	Ratio of characters in the preprocessed tweet to the original tweet
semantic_similarity	Cosine similarity between tweet text and hashtag keywords embeddings
has_media	The presence of an image or video in a tweet
URLs_count	Number of URL(s) in tweet
mention_count	Number of users mentioned in the tweet
tags_count	Number of hashtags in a tweet
emoji_count	Number of emojis in the tweet
rt_count	How many times the tweet was retweeted
source	The software used to publish the tweet
fav_count	How many times the tweet was favorited
age	Number of days from the account creation date to the tweet publishing date
followers	Number of accounts following the user
friends	Number of accounts followed by the user
followers/friends	Ratio of followers to friends
reputation	Ratio of the number of followers to the total number of followers and friends
tweets_count	Number of tweets published by the user
tweets/day	Ratio of the number of tweets to account age
fav_list_count	Number of tweets favorited by the user
fav/day	Ratio of the number of favorites to account age
default_profile	If the user did not change the default profile bio
default_profile_image	If the user did not change the default profile image

IV. RESULTS AND DISCUSSION

This study focuses on building an efficient model to detect both Arabic spam messages and accounts on Twitter. Furthermore, it seeks to achieve high performance with minimal data retrieval requirements. The classification was conducted via text input, thereby avoiding the need to obtain metadata from Twitter. The features were derived from the text input using advanced transformer-based language models, comparing word-level and sentence-level transformers. The assessment was also conducted on two MTL paradigms: hard and soft parameter sharing. The proposed method was evaluated using three dataset versions: DS_Multi_8, DS_Multi_4, and DS_Binary. The performance measures achieved through these experiments are presented in TABLE IV. TABLE V. and TABLE VI. , and visualized in Fig. 6, Fig. 7, Fig. 8, Fig. 9, Fig. 10Fig. 11.

Across the three datasets, it is evident that an increase in tweet classes decreases tweet accuracy while enhancing account detection accuracy. In DS_Multi_8, the utilization of AraBERT embeddings showed superior efficacy in spam detection across both paradigms. Sentence transformer embeddings are more effective for account-level detection than for tweet-level detection. Following the reduction in spam classes from 7 to 3, tweet classification improved by approximately 1%, while account classification declined by roughly 2%. Moreover, AraBERT embeddings consistently provide superior performance. In the binary dataset, spam post detection improved, whereas account detection declined, and SBERT and LaBSE surpassed AraBERT at the account level by 1%.

The performance of hard and soft parameter sharing is nearly identical, exhibiting only minor variances. LaBSE and E5 exhibit superior performance using the hard parameter paradigm compared to the soft parameter sharing approach.

The model input was validated by comparing it with three inputs: Input 1, Input 2, and Input 3. The comparison of these inputs is shown in TABLE VII. . In DS_Binary, the experiment demonstrated consistent performance regardless of the input utilized. This conclusion considers Input 1 the optimal selection for this task, as the additional knowledge does not influence model performance. The performance of the multi-spam class datasets varies according to the chosen input. Input 2 achieved superior performance; however, utilizing Twitter text input (Input 1) resulted in a decrease in model performance of approximately 1%. Conversely, the incorporation of metadata (Input 2) has varied between degrading and maintaining the model's accuracy without alteration, determining that the effectual input is Input 2.

For the error analysis, the confusion matrix illustrates the classification performance of the model. Fig. 14 shows that the model achieved strong performance, particularly for sorcery content, pornographic content, money requests, and illegal medicine advertisements. However, a notable confusion arises between the irrelevant content and non-spam classes, with 39 irrelevant tweets mislabeled as non-spam and 21 non-spam tweets misclassified as irrelevant content. This suggests that the model struggles to distinguish ordinary tweets associated with irrelevant hashtags due to the similarity between the two categories. In addition, several commercial advertisement tweets were misclassified as illegal services (8 samples) or irrelevant content (13 samples), indicating that persuasive or promotional language sometimes overlaps with service-oriented or generic content. Such blurring may occur when advertisements avoid explicit commercial keywords. At the account level, Fig. 15 demonstrates excellent overall performance. The few misclassifications are likely attributable to legitimate accounts exhibiting spam-like behavior and, conversely, spammers attempting to mimic legitimate user activity.

Compared to prior research, the work by Mubarak et al. focused on a relatively narrow scope of spam detection, specifically targeting advertisements in [10] and accounts promoting pornographic content in [14]. Additionally, their first study limited the dataset to tweets targeting specific news accounts, thereby reducing generalizability. While Alharthi et al. [49] extended the classification to three spam categories, the model remained dependent on the presence of URLs, which restricted its applicability. Other studies, such as [51] and [52] , focused on spam detection based on specific spam-related keywords, while [53] and [25] primarily targeted spam associated with trending hashtags. In contrast, our proposed model addresses these limitations by generalizing spam classification across diverse categories without dependence on

predefined targets or URL-based heuristics. It was trained using a comprehensive dataset, collected by targeting hashtags, user mentions, and spam-related keywords.

Alharthi et al. [49] introduced two separate models—one for spam tweet detection and another for spam account detection—whereas our approach integrates both tasks into a single and unified model. Notably, their account-based model required a minimum of ten tweets per account to achieve reliable classification, while our model demonstrated high accuracy using only a single tweet. Alhassun et al. [53] proposed a framework that relies on both tweet content and extensive metadata, including premium features that require additional effort to extract. In contrast, our findings indicate that incorporating numerical features did not significantly enhance performance, simplifying the model and reducing dependency on complex metadata.

To the best of our knowledge, our model is the first to simultaneously address tweet-level and account-level spam detection in a single framework, highlighting different spamming categories.

V. CONCLUSION

This study introduced AraSpam, a multitask deep learning model designed to detect spam messages and spamming accounts in Arabic Twitter data, addressing limitations in prior models that focused on either content or user-level analysis in isolation. By leveraging transformer-based architectures such as AraBERT and mBERT for robust feature extraction, AraSpam achieved impressive performance, notably attaining a 96% accuracy rate on multi-class spam detection tasks.

The experimental evaluation across diverse datasets (DS_Multi_8, DS_Multi_4, and DS_Binary) highlighted the effectiveness of AraBERT in representing text and capturing semantics from tweet content. Notably, the results demonstrated that reducing the number of spam classes improved tweet-level classification while slightly compromising profile-level detection, reflecting the trade-off between granularity and generalization.

The study also explored different multitask learning paradigms, showing competitive results between hard and soft parameter sharing approaches, with LaBSE and E5 models performing particularly well under hard sharing. Furthermore, input validation experiments confirmed that Input 1, which avoids reliance on Twitter metadata, provides a practical balance between performance and feasibility.

Despite its strong results, AraSpam has room for enhancement. Future work should explore multimodal learning, incorporating image data from tweets to address visual spam content, which remains unprocessed in the current framework. Moreover, the dataset includes tweets with 280 characters maximum length and we are planning to enhance the dataset by including longer tweets.

In summary, AraSpam demonstrates the value of multitask learning and linguistically aware models in tackling the complex challenge of spam detection in Arabic social media.

Hierarchical Transformer Residual Model for Pneumonia Detection and Lesion Mapping

Anupama Prasanth
College of Computer Studies, University of Technology Bahrain, Salmabad, Kingdom of Bahrain

Abstract*—Pneumonia, a potentially fatal infection and a common disease-causing culprit among children and the elderly, still remains as a prevalent threat even after years of research on tackling it. Rapid and proper identification is crucial for timely treatment and improved results. While thoracic radiographs are widely employed in pneumonia diagnosis, real-world clinical assessment is frequently questioned by factors such as subtle radiographic patterns, overlapping symptoms, subjective manual judgement and dependency on expert radiologists. The study proposes a hybrid deep learning model integrating ResNet50 and the Swin Transformer, coupled with an auxiliary segmentation decoder to facilitate both classification and lesion localization in chest X-ray images. ResNet50 acts as the backbone for hierarchical spatial feature extraction, capturing fine-grained local textures indicative of pulmonary abnormalities, and the Swin Transformer serves as the global attention-driven feature aggregator. The shifted window mechanism of the Swin Transformer maintains spatial hierarchy while facilitating effective contextual modelling. Global Average Pooling (GAP) and Multilayer Perceptron (MLP) form the classification head, yielding accurate predictions in classifying the images, while the segmentation decoder utilizes multiscale features to generate pixel-wise masks for pneumonia lesion regions. The model outperformed conventional methods with 98.4% classification accuracy, 98.2% precision, 99.2% recall and an F1-score of 98.7% with a 0.88 Dice Coefficient in segmentation. These results reflect the hybrid architecture's superior performance and its dual capacity for diagnostic prediction and lesion interpretability. The proposed model demonstrates promising results for deployment in real-world clinical workflows, especially in resource-constrained or high-patient-load environments.

Keywords*—Pneumonia detection; lesion segmentation; chest X-ray; ResNet50; swin transformer; global average pooling

I. Introduction

Pneumonia is a potentially life-threatening pulmonary infection causing inflammation of the alveoli, the tiny air sacs within the lungs, filling up with fluid or pus. Affecting over 150 million individuals and causing around 2.5 million deaths every year, it is the primary cause of infectious disease deaths among children under five years old globally, responsible for 70,000 deaths per year, a terrifying 14% of deaths [1]. A number of pathogens, including bacteria, viruses and fungi, could act as the agents of the fatal disease. Streptococcus pneumoniae remains the most common bacterial agent, and respiratory viruses such as influenza and SARS-CoV-2 also contribute significantly to disease incidence [2]. Prolonged coughing, chest pain, fever, chills and respiratory difficulties are common signs of pneumonia, and in extreme cases, additional symptoms like confusion, cyanosis and fast breathing can also occur. Delayed or inaccurate diagnosis results in disease progression, complications or even death, highlighting the critical need for timely and reliable diagnostic methodologies [3].

Clinical examination, auscultation, laboratory tests and manual chest radiography analysis are the basic traditional pneumonia detection methods. Clinical examination and auscultation have limited sensitivity and delayed turnaround times, are frequently used only as a manual screening process, and that too with high error rates in early pneumonia manifestations [4]. Due to the unavailability of specific biomarkers, laboratory tests frequently fail to pinpoint pneumonia from other respiratory illnesses. Even though chest X-rays offer a non-invasive and accessible tool for visual confirmation of pneumonia, their interpretation is subjective, depending heavily on the expertise of a radiologist [5]. Misinterpretation or variability in radiographic evaluations usually leads to delayed diagnosis or misdiagnosis. Traditional image analysis techniques have limited capacity to discern subtle pathological patterns or overlapping pulmonary anomalies, especially in early or atypical Pneumonia infections [6].

Deep learning (DL) based models have displayed promising results in automated pneumonia detection methods from chest radiographs in their initial phases. Convolutional neural networks (CNNs), DenseNet and Vision Transformers (ViT) frameworks have demonstrated considerable success in enhancing classification accuracy and reducing diagnostic turnaround time [7]. But the lack of spatial interpretability, being computationally complex and costly, hinder real-time deployment of most of the models. Limited interpretability and high resource requirements, and skilled hardware operation requirements make them irrelevant in rural and resource constrained regions. Moreover, few integrate simultaneous segmentation of pathological regions, which is vital for localized analysis and clinical insight.

The study proposes a novel ResNet50-Swin Transformer hybrid model, addressing the diagnostic challenges by combining robust local feature extraction with global contextual representation, enabling both accurate classification and precise segmentation of pneumonia from chest X-rays. This dual-capability framework enhances diagnostic reliability while maintaining computational efficiency rendering it ideal for practical clinical deployment. To bridge the gap between theoretical accuracy and practical feasibility, the proposed model aims to design a model that not only performs robustly in controlled settings but is also scalable and reliable in high-patient-load environments such as rural clinics or emergency care centers lacking expert radiologists. By reducing reliance on

manual interpretation and enabling automatic lesion localization, the hybrid framework holds the potential to significantly reduce diagnostic delays in telemedicine setups and frontline screening programs. The lightweight architectural design further enables deployment on edge devices such as mobile radiology units and AI-enabled X-ray machines, making it especially useful in developing countries or disaster-struck zones. In real-world hospital settings, such a model could assist junior clinicians or non-specialist health workers in triaging suspected pneumonia cases more efficiently, improving both speed and consistency of care.

The core research question addressed in this study is whether a hybrid model integrating convolutional and transformer-based architectures with an integrated segmentation decoder enhances both classification accuracy and lesion-level interpretability in pneumonia detection from chest radiographic images. The key objectives of the study are as mentioned below:

- Design and implement a hybrid DL framework that leverages the spatial feature extraction capabilities of ResNet50 with contextual attention mechanisms of the Swin Transformer for binary classification of thoracic radiograph images into affected and healthy cases.
- Incorporate an integrated segmentation decoder within the hybrid model to generate pixel-wise lesion maps, enabling accurate localization of pneumonia-affected regions and thereby improving diagnostic interpretability and clinical decision-making.

The further sections of the research are structured as follows: Section II offers a comprehensive analysis of the latest advances in Pneumonia detection research and highlights the current research constraints. Section III outlines the proposed methodology. Experimental findings are presented in Section IV, accompanied by a comprehensive analysis of the model performance in Section V. Section VI concludes the study by encapsulating the principal results and emphasizing prospective areas for further research.

II. Related Works

Ali et al. [8] proposed a DL-based diagnostic framework to identify pneumonia from thoracic radiograph images. Six CNN architectures were implemented and trained on the dataset. EfficientNetV2L outperformed others with an accuracy of 94.02%, followed by VGG16 (91.66%), Xception (90.7%), InceptionResNetV2 (88.94%), ResNet50 (87.98%) and a baseline CNN (87.78%). The high performance of EfficientNetV2L was attributed to the compound scaling strategy and efficient use of network parameters, enabling the framework for fine-grained image classification tasks. However, the absence of region-wise interpretability restricted the clinical transparency of model predictions.

Shaikh et al. [9] proposed MDEV, an ensemble model for thoracic radiograph image classification into Pneumonia affected and healthy categories constructed by concatenating four deep transfer learning models: MobileNet, DenseNet-201, EfficientNet-B0 and VGG-16. Each component was fine-tuned and trained on the selected dataset and achieved an accuracy of 92.15% on evaluation. The MDEV model operated in two hierarchical levels: in the first level, learners independently extracted features from pre-processed thoracic radiograph images using distinct deep networks and in the second level, learning was performed by a meta-learner that integrated the outputs. The architectural complexity led to reduced interpretability and higher computational requirements, hampering the real-time deployment in low-resource or point-of-care environments.

Barhoom et al. [10] proposed a CNN framework for the Pneumonia identification and classification using thoracic radiograph images. The study utilized the hierarchical feature extraction capabilities of CNN to distinguish between normal and infected lungs and utilized a dataset of chest radiographs, focusing on three output classes: bacterial pneumonia, viral pneumonia and normal lungs. Among the tested architectures, VGG16 demonstrated superior performance, attributed to its deep structure and effective extraction of low- to high-level spatial features. The CNN architecture allowed for scalable feature learning and enabled accurate triaging of pneumonia subtypes, clinically valuable for treatment planning. The absence of cross-validation or external dataset benchmarking limited the model's generalizability to broader clinical populations and varying imaging conditions.

Wang et al. [11] suggested a pneumonia classification framework based on DenseNet, addressing the structural complexity and uneven gray-level distribution in chest X-ray images. The core architecture utilized DenseNet due to its ability to propagate learned features across all layers, supporting parameter efficiency and improved local feature learning. Squeeze and Excitation (SE) blocks, a channel attention mechanism, were integrated into the network to emphasize pneumonia-related information in the feature maps. The integration of attention modules and pooling adjustments contributed to a more discriminative lesion focus. Evaluated on the Chest X-ray 2017 dataset, the modified DenseNet achieved an accuracy of 92.8%. The study's precision and recall balance was flawed, indicating the need for further optimization for proper classification.

Mabrouk et al. [12] presented an ensemble learning (EL) approach for the computer-aided pneumonia classification utilizing lung radiograph images. The model integrated three pretrained architectures: DenseNet169, MobileNetV2 and ViT, fine-tuned on pediatric chest radiographs from the Chest X-ray Images (Pneumonia) dataset. Each model acted as a functional layer, independently extracting feature representations from the input images, and these features were passed through GAP for dimensionality reduction and subsequently combined to form the final predictive output. The proposed EL approach achieved 93.91% accuracy but was limited by the computational complexity, as the simultaneous use of three deep architectures increased inference time and resource consumption, hampering deployment in real-time or resource-limited clinical environments.

Ortiz-Toro et al. [13] explored the diagnostic potential of three textural image characterization techniques as input biomarkers for artificial intelligence (AI) models in pneumonia detection from thoracic radiograph images. Two datasets, Guangzhou Women and Children Medical Center pediatric

dataset (GWCMCx) and a composite dataset (Josep-NIH) including COVID-19 chest X-rays were utilized and three machine learning (ML) classifiers: Support Vector Machine (SVM), K-Nearest Neighbors (KNN) and Random Forest (RF), were employed in model evaluation. The study integrated handcrafted feature descriptors with conventional classifiers and demonstrated the utility of texture-based biomarkers in distinguishing pneumonia-affected lungs from normal cases with minimal preprocessing. On the GWCMCx dataset, the super pixel-based histon method yielded the highest accuracy at 91.3%, outperforming radiomics (83.3% accuracy) and fractal dimension (89.9%). On the Josep-NIH dataset, the fractal dimension achieved better accuracy, but the latter dataset used for evaluation was more biased, hampering the reliability.

Bhatt et al. [14] proposed an ensemble-based CNN framework for pneumonia diagnosis using lung radiographic images. The architecture comprised three parallel CNN models with distinct kernel sizes, each capturing features at varying spatial resolutions and the outputs were fused through a weighted ensemble mechanism that enabled dynamic thresholding, allowing clinicians to fine-tune diagnostic sensitivity based on clinical requirements. The framework maintained a lightweight footprint, and the ensemble increased feature diversity, robustness and allowed personalized classification thresholds for clinical flexibility with an accuracy of 84.12% and precision of 80.04%. The model incurred a higher computational cost than a single CNN, and the dataset size introduced a risk of overfitting.

Singh et al. [15] proposed an attention-aware CNN architecture for pneumonia detection in thoracic radiograph images. The study integrated channel and spatial attention modules within a deep neural network (DNN) to guide the learning process toward clinically relevant regions. A bottom-up and top-down feedforward attention mechanism was adopted, allowing both feedforward and feedback attention processes to coexist within each module. The dual-level attention provided enhanced feature discrimination and allowed the model to dynamically localize pneumonia-affected regions. The network achieved a 95.47% accuracy, outperforming both baseline CNN and a pretrained ResNet50 model. Comparative evaluation revealed that ResNet50 with integrated attention modules improved accuracy from 84.53% to 95.73%. The attention modules however, increased architectural complexity, resulting in extended training time and requiring more computational resources in deployment scenarios.

Ibrahim et al. [16] presented a DL framework employing a pretrained AlexNet model to segregate chest X-ray images across multiple diagnostic scenarios. By utilizing AlexNet's hierarchical feature extraction capabilities, the study handled both binary and multiclass classification tasks and demonstrated functional adaptability for a range of diagnostic applications in chest radiology. On evaluation through two-way, three-way and four-way classification tasks using publicly available datasets, the model achieved accuracy of 94.43% for non-COVID-19 viral pneumonia vs. normal and 91.43% for bacterial pneumonia vs. normal and 94.00% accuracy for three-class classification and four-class classification with 93.42% accuracy. The heterogeneity of image sources across public datasets introduced domain shifts affecting consistency and performance in real-world clinical environments.

Avola et al. [17] evaluated twelve DNN architectures using transfer learning for the pneumonia classification from lung radiographic images. Employing two datasets with chest radiographs of patients diagnosed with pneumonia caused by bacterial, generic viral or SARS-CoV-2 infections and unaffected cases. The architecture was adapted for transfer learning by replacing the final classification layers of each model with task-specific dense layers and leveraged hierarchical feature extraction to identify localized pathological patterns. On evaluation in the combined dataset, MobileNetV2 and MobileNetV3 achieved the highest accuracies of above 0.80, followed by AlexNet (0.78), DenseNet and ResNet variants (0.75–0.79) and lower accuracies for SqueezeNet (0.33) and NASNet (0.55). Significant performance degradation was observed for most models under data-scarce conditions.

Zhu et al. [18] suggested a multi-task DL approach for classification of pneumonia types and segmenting associated lesions from chest CT scans involving 181 patients, categorized as lobar, lobular or interstitial pneumonia, while ground truth labels for segmentation were created through manual annotation. The network handled segmentation and classification tasks, streamlining the diagnostic workflow by using shared feature extraction pathways. The multitask architecture enabled the model to contextualize lesion morphology in parallel with disease categorization and achieved a classification accuracy of 92.7%. Bias was introduced by using data from a single medical center that hampered generalizability across diverse populations, imaging protocols and scanner types.

An et al. [19] proposed a deep CNN for pneumonia classification integrating EfficientNetB0 and DenseNet121 as feature extractors. The architecture incorporated multi-head self-attention mechanisms to enhance feature representation and discrimination across varying spatial regions of chest X-ray images. A cross-channel attention-based feature fusion strategy is implemented to combine features from both networks and employed residual blocks and dynamic pooling layers for refining the learning. The attention-enhanced architecture allowed for selective amplification of disease-relevant features, improving the interpretability and clinical reliability of the predictions. The study utilized a chest X-ray dataset that included both normal and pneumonia-affected cases and achieved an accuracy of 95.19%. The exclusive use of static two-dimensional images restricted diagnostic depth compared to three-dimensional volumetric data.

Bhandari et al. [20] presented a DL framework for classifying chest radiograph images into four distinct categories, with pneumonia as one category. The study utilized a single CNN architecture and utilized a publicly available dataset of 7,132 images. The model was integrated with an explainable AI (XAI) framework using SHAP, LIME and Grad-CAM, which offered visual and statistical information on the decision-making method of the classifier. These XAI techniques provided class-discriminative feature maps and model interpretability, which were further corroborated by medical experts, and the interpretive capability added trustworthiness to the diagnostic tool. The system achieved an accuracy of 94.31% through ten-

fold cross-validation, but the dataset size limitations hampered the generalization of the study.

Xue et al. [21] evaluated DL techniques for the segregation of COVID-19 and pneumonia utilizing both thoracic radiograph and computed tomography scan images. The research employed an ensemble of deep transfer learning models: ResNet152, ResNet50, DenseNet121 and an enhanced version of VGG16 across five different datasets. Two datasets contained chest radiographs, while the remaining three included CT imaging data and achieved precision and accuracy ranging from 95% to 96%. The integration of deep residual and densely connected layers allowed for hierarchical feature extraction across both modalities, and transfer learning addressed data scarcity and computational efficiency. Despite its better performance, the study acknowledged a critical limitation related to inconsistencies in ground truth annotations within the datasets, affecting the reliability and generalizability of learned features across different institutions and clinical settings.

Barakat et al. [22] suggested an ML-based framework designed for the early detection of pediatric pneumonia using thoracic radiograph images. The model segmented the input chest X-ray into 64 fixed regions of interest (ROIs) for focused and granular feature extraction. The extracted features were mapped back to their anatomical locations, supporting interpretable diagnostics. On evaluation employing various ML models, the quadratic SVM classifier, using a 64-region-of-interest (ROI) feature extraction scheme, achieved the highest performance with an accuracy of 97.58%, with a lesser classification time compared to transfer learning benchmarks. Extensive reliance on hand-engineered feature extraction and manually defined ROIs that did not generalize across varying image resolutions, anatomical variations and datasets introduced the risk of omitting subtle pathological indicators outside the preselected ROIs and affected model adaptability in practical clinical environments.

A. Research Gap

Despite substantial research in pneumonia detection using AI such as EfficientNetV2L, DenseNet, ResNet50, ViT etc., certain challenges still exist [8] [12] [21]. Most frameworks focus on overall accuracy improvement but fall short to address segmentation of pathological regions, model explainability and clinical adaptability properly [16] [21]. Even though MDEV and ensemble CNNs attempt to enhance feature representation, computational overhead hinders their real-time deployment [9] [14]. Attention-based architectures and multi-head fusion exhibits promising performance but is burdened by the model complexity, making training and interpretability more challenging. Furthermore, segmentation is often excluded, limiting end-to-end diagnostic support and limited external validation also reduces generalizability across diverse clinical environments. A cohesive model that balances both local and global feature extraction capabilities is absent in the majority of the research. Only a few number of existing methods have investigated designs that can carry out simultaneous classification and segmentation with great computing efficiency and diagnostic confidence. Hence, there is a pressing need for a unified, lightweight and interpretable hybrid framework that can simultaneously perform accurate classification and segmentation while being computationally feasible for practical medical applications.

III. Materials and Methods

The proposed model integrates ResNet50 and Swin transformer effectively for the classification and segmentation of thoracic radiographs for Pneumonia. The Chest X-Ray images (Pneumonia) dataset is utilized in the study, and the methodological pipeline consists of a ResNet50 backbone and Swin Transformer modules for hybrid feature extraction after meticulous preprocessing and data augmentation. A segmentation decoder for lesion localization is employed for the segmentation task, and the classification head utilizes global average pooling (GAP) and a multilayer perceptron head (MLP). The proposed model's block diagram is illustrated in Fig. 1.

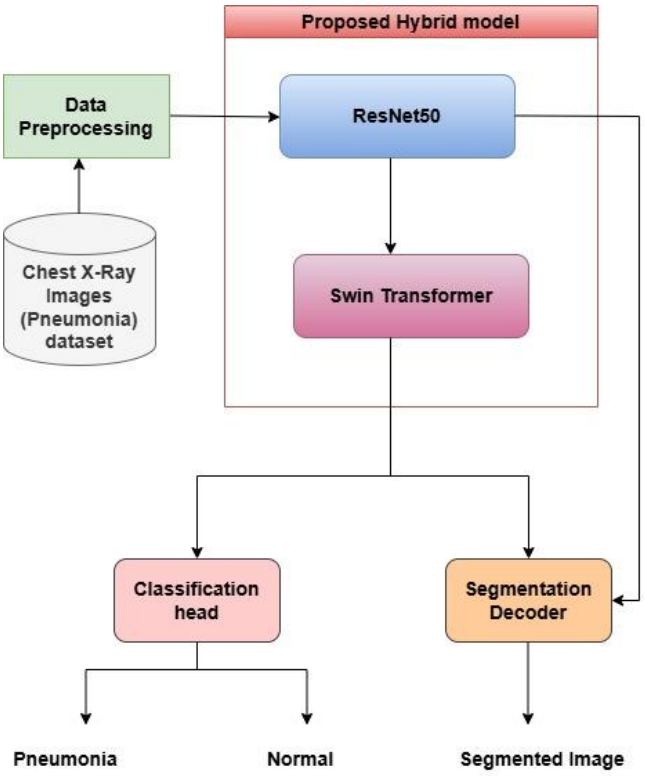

Fig. 1. Block diagram.

B. Dataset Description

The study utilizes Chest X-Ray images (Pneumonia), the openly accessible Kaggle dataset with images gathered from Guangzhou Women and Children's Medical Centre in China [23]. It has 5,863 anterior-posterior (AP) view chest radiographs of paediatric patients aged between one and five years categorized either as Normal or Pneumonia. Fig. 2 represents the number of images present in the three primary directories: train, test and validation, each with two subfolders corresponding to the diagnostic categories. Normal X-rays show clear lungs free of any abnormal opacities. Viral pneumonia primarily presents as more diffuse, bilateral interstitial opacities, while bacterial pneumonia usually exhibits focal lobar consolidation, especially in the upper lobes.

All chest X-rays underwent quality screening to remove unclear or low-resolution scans to guarantee diagnostic accuracy and image credibility. Two expert radiologists independently confirmed the image diagnose and the evaluation was examined by third expert to identify potential discrepancies in classification. This pediatric dataset presents real-world complexity due to the subtle and variable nature of radiographic pneumonia manifestations in young children, making it an ideal benchmark for evaluating AI-based diagnostic systems. Its expert-verified labels, well-structured format and diversity in infection types make it well-suited for both training and evaluation of models focused on classification and lesion localization. Furthermore, the public accessibility facilitates reproducibility, benchmarking and practical deployment of AI solutions in resource-limited or high-volume clinical settings. Fig. 3 illustrates the random sample images in the dataset.

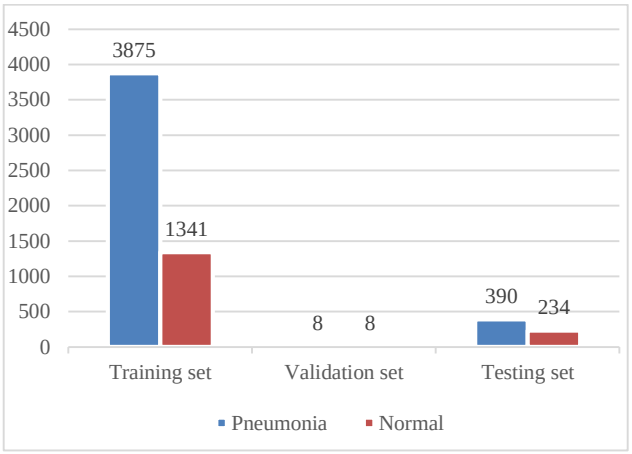

Fig. 2. Number of images in each directory.

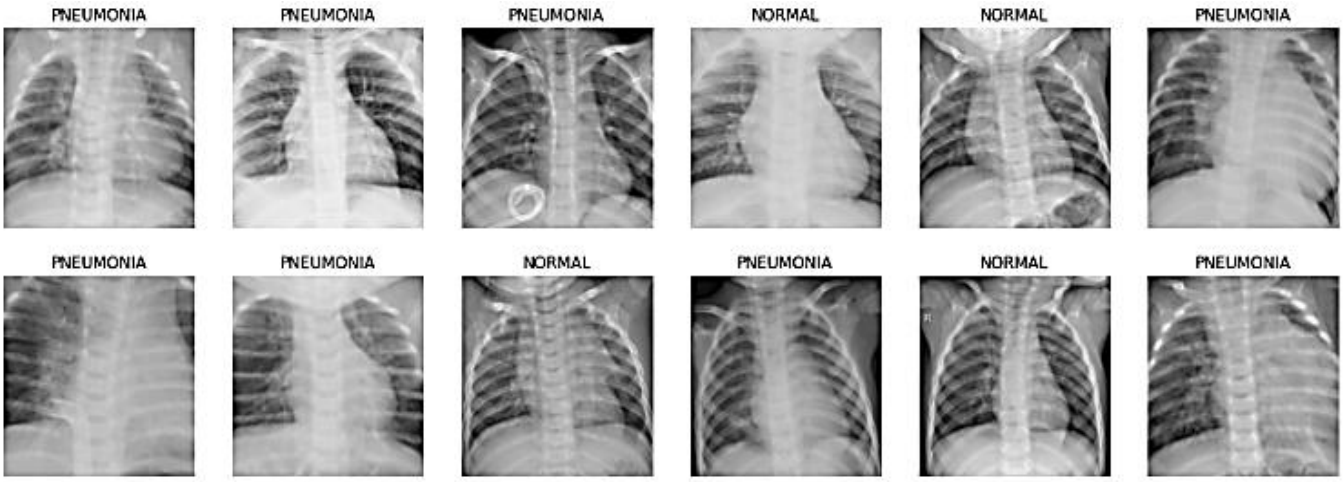

Fig. 3. Random sample images in the dataset.

C. Data Preprocessing

A systematic preprocessing and augmentation strategy is designed for the chest X-ray images prior to inputting them into the model. Initially, each image is resized to a standardized spatial dimension of 224×224 pixels to maintain compatibility with both ResNet50 and Swin Transformer input requirements. The original greyscale chest X-ray image is then converted to a 3-channel RGB image through channel-wise expansion. This transformation is necessary to match the pretrained convolutional backbones that anticipate three-channel inputs. Subsequently, the pixel intensity values $I \in [0,255]$ are normalized to a continuous range of $[0,1]$ using the rescaling operation, as shown in Eq. (1):

$$I_{normalized} = \frac{I}{255} \quad (1)$$

Data augmentation is introduced in the training set to increase the generalization capability and to reduce overfitting. The augmentation operations include horizontal and vertical flipping, random zooming with a zoom range up to 0.3, shearing with a shear angle of 10 degrees and rotation within ±20 degrees. By scaling the intensity in a range of [0.5,2.0], intensity variations are also applied, along with spatial translations. As certain transformations resulted in vacant pixel areas, the nearest neighbour approach is utilized to fill in missing values, as shown in Eq. (2):

$$I'(x,y) = \arg \min_{(x',y')} \|(x,y)(x',y')\| \; ; \; \text{such that I}'(x',y') \neq 0 \quad (2)$$

The images are then organized into mini-batches and passed into the model pipeline. Labels are encoded into binary numerical form, as in Eq. (3):

$$y = \begin{cases} 0 \; ; Normal \\ 1 \; ; Pneumonia \end{cases} \quad (3)$$

In addition to providing enough variation to the training set for reliable feature extraction, the preprocessing pipeline assures the spatial integrity and semantic information preservation of the thoracic radiograph images.

D. Model Development

1) ResNet50: ResNet50 is a fifty-layer deep CNN architecture built upon the principle of residual learning, which resolves the vanishing gradient problem by employing shortcut connections [24]. A stem layer is followed by four sequential convolutional stages, each containing a stack of convolutional blocks and identity blocks. Each block includes a sequence of

convolutional layers with kernel sizes set to 1×1, 3×3 and 1×1, followed by batch normalization and ReLU activation. The defining feature of ResNet50 is the residual connection, where the input x to a block is added to its output F(x), forming the final output, as in Eq. (4):

$$y = F(x, \{W_i\}) + x \quad (4)$$

where, $\{W_i\}$ represents a set of learnable parameters of the convolutional layers. This residual mapping promotes deeper network construction while maintaining productivity and enables the network to learn identity functions. Rich local characteristics can be extracted from images using the ResNet50 backbone, which progressively minimizes spatial dimensions while deepening feature representations. In the proposed hybrid model, only the convolutional and residual blocks of ResNet50 are utilized. Fig. 4 illustrates the general architecture of ResNet50.

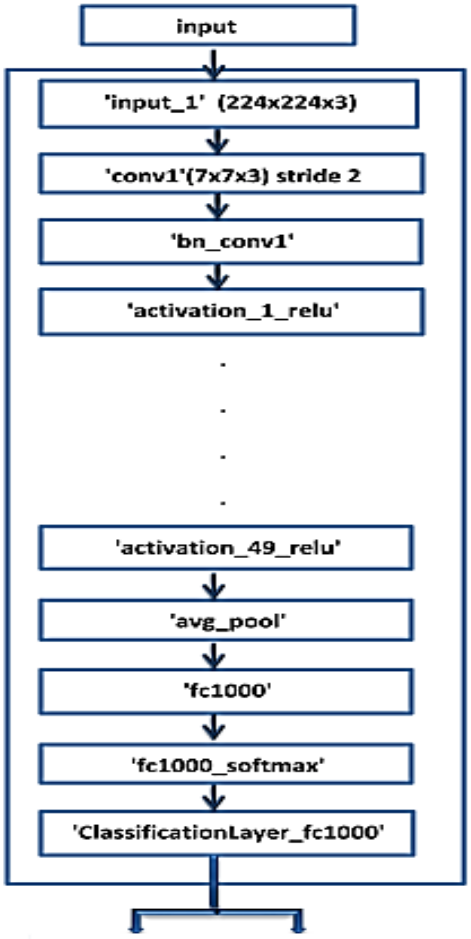

Fig. 4. General architecture of ResNet50.

An input image is initially passed through a convolutional layer with a 7×7 kernel and a stride of 2 to reduce spatial dimensions while capturing broad features. This is followed by batch normalization and a ReLU activation to standardize and introduce non-linearity. The network then progresses through a sequence of 49 residual layers, each built using bottleneck blocks that incorporate skip connections. These connections help preserve input information and facilitate efficient gradient flow, enabling deep network training without degradation. Each residual block performs convolutional transformations and combines the original input with the transformed output. Following the final activation layer, the architecture applies GAP to reduce the spatial dimensions, resulting in a 1×1×2048 feature vector. The vector is then carried to a fully connected dense layer with 1000 units and finally through a softmax activation, producing class probabilities. In the proposed model, the softmax and classification layers are discarded as ResNet50 is used solely for deep feature extraction.

2) Swin transformer: The Swin Transformer (Shifted Window Transformer) is a hierarchical ViT that applies self-attention within non-overlapping local windows and shifts these windows across layers to enable cross-window connections [25]. It is composed of a series of Swin Transformer Blocks, each including Layer Normalization (LN), Multi-head Self-Attention (MSA) within shifted local windows, MLP layers with GELU activation and Residual connections. Fig. 5 represents the basic architecture of the Swin transformer.

Initially, the input image $I \in \mathbb{R}^{H \times W \times 3}$ is partitioned into patches and embedded into a lower-dimensional space, as shown in Eq. (5):

$$x_0 = PatchEmbed(I), x_0 \in \mathbb{R}^{\frac{H}{P} \times \frac{W}{P} \times C} \quad (5)$$

where, P is the patch size and C is the embedding dimension. The embeddings pass through a series of stages composed of Swin Transformer Blocks. The spatial resolution is minimized and the feature dimension is boosted in each stage, resulting in a hierarchical representation. Window-based MSA (W-MSA) followed by Shifted Window MSA (SW-MSA) is applied in each block further. The attention is computed within each window w , as in Eq. (6):

$$Attention(Q, K, V) = Softmax\left(\frac{QK^T}{\sqrt{d}} + B\right)V \quad (6)$$

where Q , K and V represent the query, key and value matrices respectively, computed from the patch tokens confined within a local window and d, the dimension of the key vectors and B, the relative position bias. Each attention output is passed through a LN layer to stabilize the training dynamics, as shown in Eq. (7):

$$LN(x) = \frac{x - \mu}{\sqrt{\sigma^2 + \epsilon}} \cdot \gamma + \beta \quad (7)$$

where, μ, σ represent the mean and standard deviation of the input feature vector respectively and γ, β represents learnable affine parameters. This is followed by a Feed-Forward Network (FFN) comprising two linear transformations with a GELU non-linearity in between, as in Eq. (8):

$$FFN(x) = W_2 \cdot GELU(W_1 \cdot x + b_1) + b_2 \quad (8)$$

where, W_1, W_2 represents weight matrices, b_1, b_2 are biases.

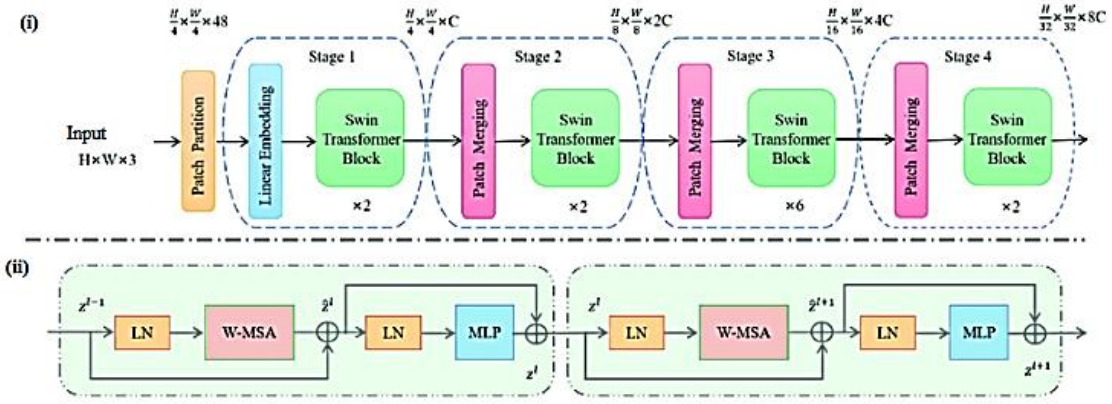

Fig. 5. Swin transformer: (i) Basic architecture (ii) Swin transformer block.

3) Proposed ResNet50- Swin Transformer hybrid model: The proposed hybrid architecture integrates the advantages of both convolutional and transformer-based approaches by employing ResNet50 for localized feature extraction and the Swin Transformer for global context modelling. ResNet50 captures low and mid-level spatial features from the input thoracic radiograph images, identifying pathological patterns in the process. The output feature map of ResNet50 undergoes processing to be compatible with the input requirement of the Swin transformer. A convolutional adaptation layer consisting of a 1×1 followed by batch normalization and ReLU activation is utilized to transform the feature dimensions to the patch embedding size of the Swin Transformer, as shown in Eq. (9):

$$F_{adapted} = RELU\big(BN(W_c * F_{ResNet} + b)\big) \quad (9)$$

where, $W_c \in \mathbb{R}^{1\times1\times c_1\times c}$ represents the kernel for dimension adjustment. c_1, c denotes the number of input and output channels, respectively, F_{ResNet} represents the feature map output from ResNet50, of shape $[H, W, c_1]$, b denotes the learnable bias added after convolution and $*$ represents the convolution operation. Once adapted, the feature maps are tokenized into non-overlapping patches and embedded, forming the input to the Swin Transformer. The window-based and shifted window-based self-attention mechanisms of the transformer architecture allow it to gather long-range dependencies and semantic patterns across the image. Both local features from ResNet50 and global contextual cues from the transformer are therefore jointly modelled. The output of the final Swin Transformer block is bifurcated: one branch passes through a GAP layer followed by an MLP for binary classification (pneumonia or normal), while the other branch serves as the input to a segmentation decoder. The decoder reconstructs high-resolution spatial masks of infected lung regions through a cascade of upsampling and convolutional layers.

a) Classification head: Global Average Pooling (GAP) is a downsampling operation that reduces each feature map to a single scalar by computing the average of all spatial elements converting feature maps into compact feature vectors while preserving spatially aggregated information [26]. In the proposed model, the GAP layer condenses the spatial dimensions of the feature map output of the Swin Transformer into a single feature vector. This operation preserves the most salient global contextual features and drastically minimises the number of parameters and computation before classification. The resultant feature map of dimension $H \times W \times C$ of the Swin transformer block is spatially reduced to produce a compact descriptor vector, as in Eq. (10):

$$x_{GAP} = \frac{1}{H\times W}\sum_{i=1}^{H}\sum_{j=1}^{W} F_{Swin}[i,j] \quad (10)$$

The condensed descriptor is then passed into a final MLP layer that serves as the final decision-making unit by transforming the aggregated features into a scalar output that facilitates binary classification. Its learnable weights and bias terms are optimized during training to minimize loss and improve diagnostic accuracy. A sigmoid function is applied to generate a probability score $\hat{y} \in [0,1]$ activated output is as shown in Eq. (11):

$$\hat{y} = \sigma(W \cdot x_{GAP} + b) \quad (11)$$

where, W and b denote the weight and bias of the dense layer, and the sigmoid function is denoted by σ.

b) Segmented decoder: The segmentation decoder is responsible for reconstructing pixel-wise masks from high-dimensional feature representations learned by the encoder, a combined sequence of ResNet50 and Swin Transformer. During the forward pass, selected intermediate feature maps from ResNet50 are cached and routed via skip connections to the corresponding stages in the decoder. This facilitates the recovery of fine spatial details lost during downsampling and enhances localization precision. The decoder adopts an up-sampling architecture that consists of bilinear upsampling followed by convolutional blocks that refine spatial granularity. The up-sampled feature at level l is obtained, as shown in Eq. (12):

$$F_{up}^{(l)} = Upsample\left(F_{dec}^{(l+1)}\right) \quad (12)$$

where, $F_{dec}^{(l+1)}$ is the decoder feature map from a deeper layer $l+1$. The output is concatenated with the corresponding encoder feature map $F_{enc}^{(l)}$ from ResNet50, as shown in Eq. (13):

$$F_{concat}^{(l)} = Concat\left(F_{up}^{(l)}, F_{enc}^{(l)}\right) \quad (13)$$

The concatenated feature is processed through a convolutional refinement block, as in Eq. (14):

$$F_{dec}^{(l)} = ReLU\left(BN\left(W^{(l)} * F_{concat}^{(l)} + b^{(l)}\right)\right) \quad (14)$$

where, $W^{(l)}$ and $b^{(l)}$ are the convolution weights and biases, BN represents batch normalization, and $ReLU$ is the non-linear activation function. The decoding process is iteratively performed through successive layers until the output spatial resolution is comparable to that of the input image. Finally, a 1×1 convolutional layer is applied to map the refined feature maps to a single-channel output, as shown in Eq. (15):

$$S = \sigma(W_{seg} * F_{dec}^{(l)} + b_{seg}) \quad (15)$$

where, W_{seg} and b_{seg} denote weights and bias of the final layer. The segmentation output $S \in [0,1]^{H\times W}$ indicates the prospect of pneumonia-affected regions for each pixel in the input image. The architecture enables effective integration of global context via Swin Transformer and spatial precision via ResNet skip features, resulting in reliable and interpretable pneumonia lesion segmentation. Fig. 6 illustrates the basic architecture of the proposed ResNet50-Swin Transformer hybrid model. The detailed algorithm for the proposed model is given below (see Algorithm 1).

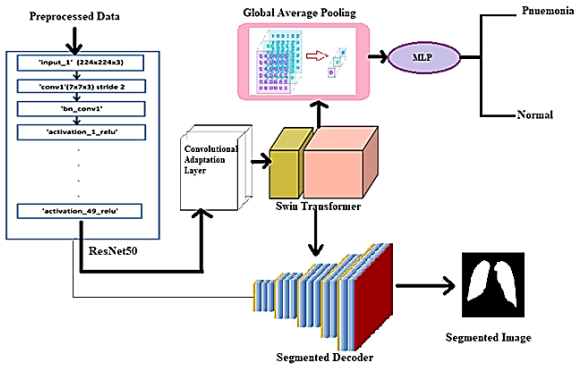

Fig. 6. Basic architecture of the proposed ResNet50-swin transformer hybrid model.

Algorithm 1: ResNet50-Swin Transformer hybrid model

Input:

Chest X-ray image I ∈ $\mathbb{R}^{H\times W\times 3}$

Label vector $y_i \in [0,1]$, indicating Pneumonia (1) or Normal (0)

Output:

Predicted class label $\hat{y} \in [0,1]$

Segmentation mask $S \in \mathbb{R}^{H\times W}$

Begin:

Data collection

Load Chest X-ray image (Pneumonia) dataset

Pre-processing

Resize the images into 224x224

Normalize pixel values to range [0,1]: $I_{normalized} = \frac{I}{255}$

Label encoding in the images:

$$y = \begin{cases} 0 \ ; Normal \\ 1 \ ; Pneumonia \end{cases}$$

Data Augmentation on the training dataset

ResNet50

Local feature extraction and final output generation, $y = F(x,\{W_i\}) + x$

Store feature maps for decoder skip connections.

Feature Adaptation

Transform F_{ResNet} to match Swin Transformer input size:

$F_{adapted} = RELU\big(BN(W_c * F_{ResNet} + b)\big)$

Swin Transformer

Embed $F_{adapted}$ into non-overlapping patches.

Apply Swin Transformer blocks with shifted window attention and FFN:

$Attention(Q,K,V) = Softmax\left(\frac{QK^T}{\sqrt{d}} + B\right)V$

Apply Layer Norm → FFN → Layer Norm sequence

$LN(x) = \frac{x-\mu}{\sqrt{\sigma^2+\epsilon}} \cdot \gamma + \beta \ ; \ FFN(x) = W_2 \cdot GELU(W_1 \cdot x + b_1) + b_2$

Store final feature map F_{Swin}

Classification Head

Apply Global Average Pooling:

$x_{GAP} = \frac{1}{H\times W}\sum_{i=1}^{H}\sum_{j=1}^{W} F_{Swin}[i,j]$

Multilayer Perceptron apply sigmoid function:

$\hat{y} = \sigma(W \cdot x_{GAP} + b)$

Segmentation Decoder

Input: F_{Swin} and skip connections from ResNet50.

For each decoder stage:

Up sample previous output

Concatenate with corresponding skip connection

Apply convolution → BatchNorm → ReLU

Final segmentation masks=σ (Conv1×1 (Decoder Output))

Model Compilation and Training

Compile model with loss = Binary crossentropy, learning rate = 0.0001, optimizer = Adam, Epochs =75

Train model: model.fit (X_train, y_train)

Evaluation and Model Saving

Evaluate model: model. evaluate (X_test, y_test)

Tune hyperparameters

Save the model

End

E. Simulation Map

The proposed hybrid model was implemented in a high-level deep learning framework and trained on a workstation equipped with a high-performance GPU (NVIDIA RTX 3090, 24GB VRAM), 128GB RAM and an Intel Xeon processor. Python was used as the programming language, and model development was carried out using the Keras API built on top of TensorFlow, chosen for its modular design, scalability and ease of customization for hybrid DL architectures. Training and experimentation were conducted on the Google Colaboratory (Colab) platform, leveraging its cloud-based infrastructure and access to high-performance GPUs. The training process was optimized by carefully tuning key hyperparameters, which significantly influenced model convergence and generalization. Table I shows the full list of hyperparameters and training settings employed in the study.

TABLE I. HYPERPARAMETER SPECIFICATIONS

Hyper parameters	Values
Optimizer	ADAM
Swin Transformer Layers	4
Loss function	Binary cross-entropy (Classification) Dice loss (Segmentation)
Activation function	Sigmoid
Batch size	16
Epochs	75
Learning Rate	0.0001
Dropout	0.3

IV. RESULTS

A set of standard evaluation metrics, as illustrated in Eq. (16) to Eq. (20), was employed to comprehensively assess the proposed model's performance. True Positives (TP), False Positives (FP), True Negatives (TN) and False Negatives (FN) are mathematically computed using the confusion matrix core elements. Different metrics offer unique insights into the model performance. Overall correctness by accuracy, precision and recall highlights the ability of the model to correctly detect pneumonia without excessive misses or false alarms.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (16)$$

$$Precision = \frac{TP}{TP+FP} \quad (17)$$

$$Recall = \frac{TP}{TP+FN} \quad (18)$$

$$F1-score = 2 \times \frac{precision \times Recall}{Precision+Recall} \quad (19)$$

The Dice Coefficient evaluates the similarity between predicted segmentation and the ground truth and measures the degree of overlap between two binary masks and ranges from 0 to 1.

$$Dice(A,B) = \frac{2|A \cap B|}{|A|+|B|} \quad (20)$$

where, A and B denote the sets of predicted and ground truth pixels, respectively, labelled as positive. A dice coefficient close to 1 indicates better spatial agreement between prediction and ground truth. The accuracy and loss plots serve as fundamental diagnostic tools to monitor the model's learning dynamics over successive training epochs. A steadily increasing accuracy curve alongside a consistently decreasing loss trajectory indicates effective gradient optimization and convergence toward a generalized solution. Any divergence between training and validation curves may suggest overfitting or underfitting, necessitating hyperparameter adjustments.

The accuracy plot of the proposed hybrid model, represented in Fig. 7, demonstrates a strong and consistent learning curve over 75 epochs, highlighting effective training convergence. A rapid rise in training and validation accuracies is observed within the initial 20 epochs, indicative of efficient low-level feature acquisition. As the epochs progress, the model's accuracy stabilizes with the training accuracy approaching 99.5%, while the validation accuracy maintains close proximity, around 98.4%. The minimal gap between the two curves signifies robust generalization and minimal overfitting and affirms the model's potential in retaining discriminative features and achieving high classification reliability on unseen chest X-ray data.

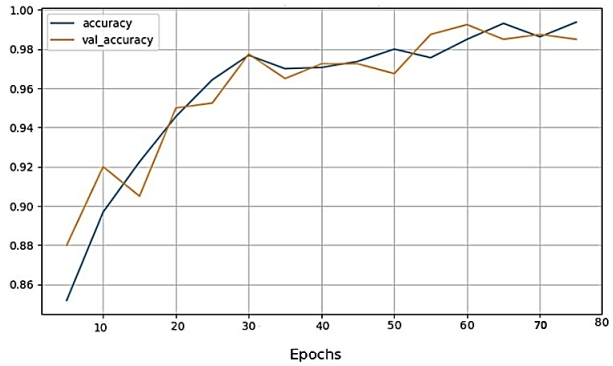

Fig. 7. Accuracy plot of ResNet50-Swin Transformer hybrid model.

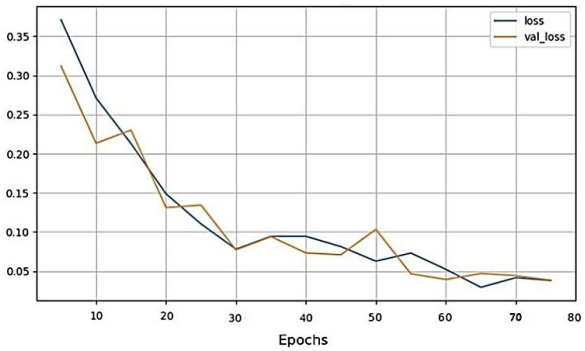

Fig. 8. Loss plot of ResNet50-Swin Transformer hybrid model.

Fig. 8 illustrates the loss plot for the proposed model that demonstrates a steady and significant decrease in both training and validation loss over 75 epochs, reflecting effective model convergence. In the initial training phase, a steep decline in loss is observed during the first 15 epochs, indicating rapid optimization of weights and improved learning of discriminative features. Beyond epoch 20, the loss values continue to decrease gradually and stabilize around 0.04, signifying that the model is

minimizing the error function efficiently. The close alignment between training and validation loss trajectories throughout the epochs confirms the absence of overfitting and affirms the generalization capability across unseen data.

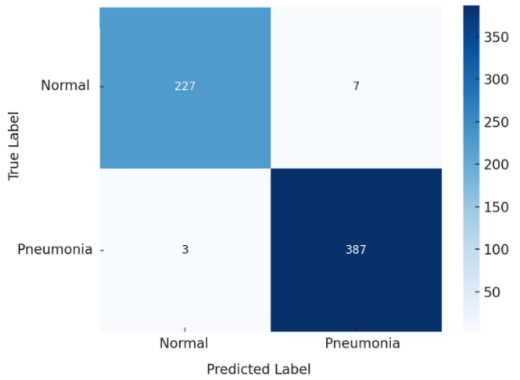

Fig. 9. Confusion matrix of the proposed model.

Fig. 9 represents the confusion matrix highlighting the classification performance of the hybrid model on the test dataset. Out of 234 normal images, the framework achieved a true negative rate of around 97%, and in the pneumonia category, 387 out of 390 pneumonia images were correctly classified, exhibiting better accuracy. The results indicate strong predictive performance and class discrimination, particularly in identifying pneumonia cases, and the minimal number of misclassifications further emphasizes the model's reliability for binary medical image segregation.

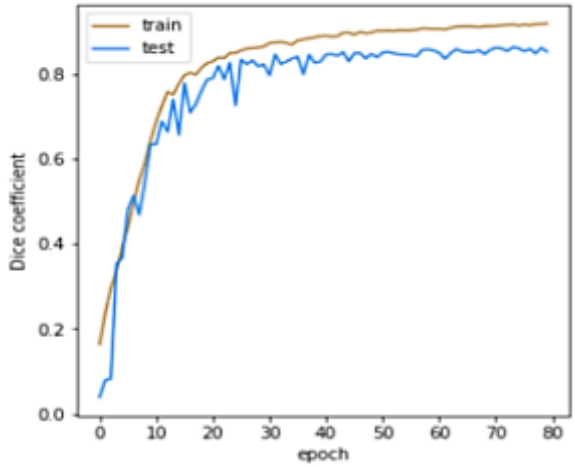

Fig. 10. Dice coefficient plot.

The Dice Coefficient plot illustrated in Fig. 10 demonstrates the segmentation performance of the proposed model over 75 training epochs. Both training and test curves exhibit a steep ascent within the initial 20 epochs, indicating rapid learning and effective optimization of segmentation boundaries. Beyond epoch 25, the Dice Coefficient stabilizes around 0.88 for the test set, while the training score plateaus slightly higher, suggesting excellent overlap between predicted and ground truth segmentation masks with minimal overfitting. The narrow gap between training and test curves throughout the learning process reflects the model's excellent consistency across datasets. The stable performance at later epochs confirms that the model effectively captures spatial and structural patterns necessary for precise medical image segmentation, reinforcing its reliability in real-world diagnostic contexts.

	precision	recall	f1-score
Pneumonia	0.98	0.98	0.97
Normal	0.98	0.99	0.98
accuracy			0.98
macro avg	0.98	0.99	0.98
weighted avg	0.98	0.99	0.98

Fig. 11. Classification report of ResNet50-Swin Transformer hybrid model.

Fig. 11 represents the classification report for the proposed framework, revealing outstanding predictive performance across both classes. With a precision of 0.98 for both classes, the model has a high proportion of accurately detected positive instances relative to all predicted positives. The recall for the Normal class reaches 0.99, while Pneumonia records a recall of 0.98, demonstrating the excellent sensitivity in detecting true positives, particularly for pneumonia diagnosis. The F1-score stands at 0.97 for Pneumonia and 0.98 for Normal, highlighting the model's balanced and reliable classification performance, and the overall accuracy of 0.984 reaffirms the model's robustness. These results collectively validate the clinical reliability of the proposed model in distinguishing pneumonia from normal thoracic radiograph images with great precision and generalizability. Fig. 12 represents the evaluation metrics of the proposed model.

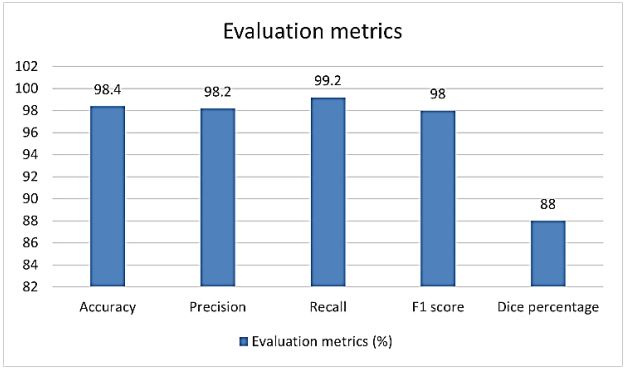

Fig. 12. Evaluation metrics for the proposed model.

The visual outputs generated by the proposed hybrid model are illustrated in Fig. 13 and Fig. 14, effectively demonstrating its dual capabilities in both classification and segmentation of chest X-ray images. As evident from the classification report, the framework accurately distinguishes between pneumonia and normal cases, with predictions aligning closely with the actual ground truth labels, while the segmentation results highlight the effectiveness in accurately localizing lung regions. The original mask and the segmented output exhibit strong overlap, with the segmented regions closely approximating the annotated ground truth. While some minor deviations and false-positive activations are observed at the lung peripheries, the overall shape, structure and spatial consistency of the lung regions are

well-preserved. These outcomes confirm the robustness of the segmentation decoder in delineating pulmonary areas, thereby supporting further clinical interpretability and diagnostic localization.

Table II and Fig. 15 illustrate the comparative analysis of the proposed hybrid framework with conventional pneumonia detection models, revealing that even though some approaches demonstrate comparable classification accuracy, they often suffer from drawbacks in terms of interpretability, architectural complexity and generalizability. MDEV and ensemble CNN architecture models were efficient in capturing diverse features, but are hampered by computational overhead due to their multi-network designs restricting real-time installation, especially in limited resource settings. Radiomics and SVM-based frameworks, relying on hand-crafted features or region-of-interest segmentation struggles with adaptability across varying anatomical structures and image qualities and were seen as inefficient in most clinical scenarios. The better performing models such as EfficientNetB0 + DenseNet121 or attention-aware CNNs, with accuracies in the range of 94 to 96%, require complex attention modules or fine-tuned fusion strategies increasing training time and computational complexity limiting their adaptability. The proposed ResNet50-Swin Transformer hybrid model achieves superior accuracy of 98.4%, combining the convolutional strength of ResNet50 for low-level feature extraction with the hierarchical attention-driven capabilities of Swin Transformer for contextual learning. The framework not only enhances classification precision but also enables segmentation functionality within a unified architecture, delivering both diagnostic accuracy and spatial interpretability in a computationally efficient manner.

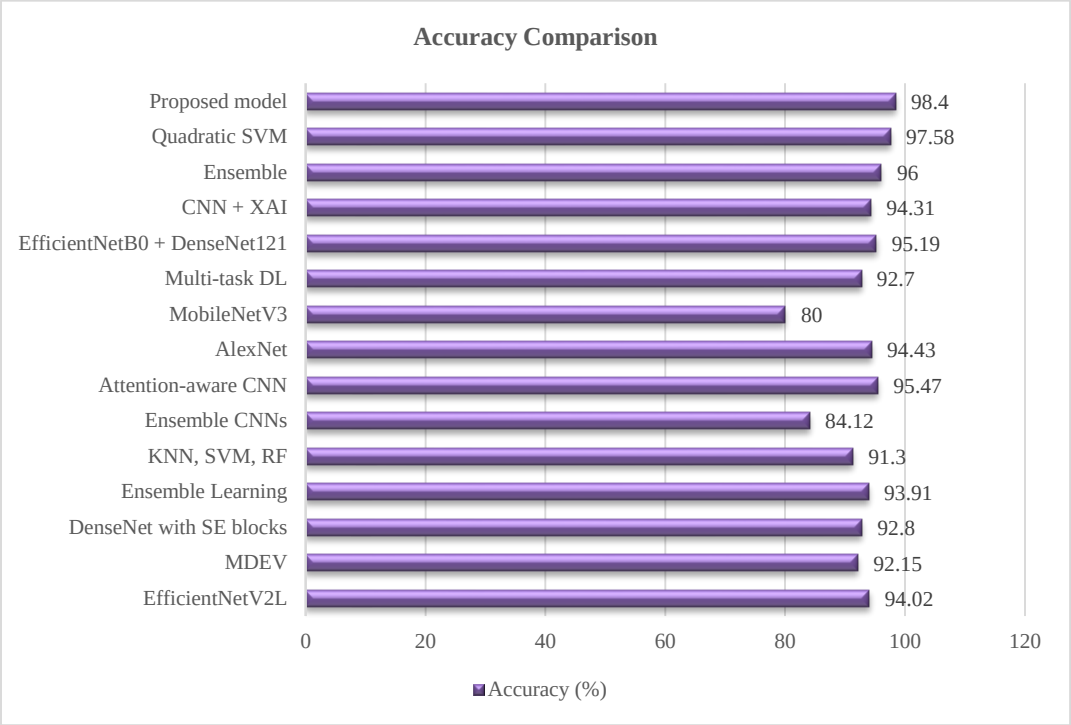

Fig. 15. Accuracy comparison of ResNet50-Swin Transformer hybrid model with other methods.

V. Discussions

The hybrid ResNet50-Swin Transformer framework demonstrates a novel architecture for dual-task learning, enabling both binary classification and pixel-level lesion localization of pneumonia from thoracic radiographs. Unlike conventional models that excel in feature extraction but often lack contextual awareness, the incorporation of the Swin Transformer effectively models global dependencies through its hierarchical window-based attention mechanism. This context-aware learning facilitates improved representation of complex pulmonary structures, especially in cases with overlapping anatomical patterns or ambiguous radiographic findings. The framework's superior classification accuracy (98.4%) and high Dice Coefficient (0.88) for lesion segmentation reinforce the robustness in both predictive performance and clinical interpretability. Compared to existing models that often perform one task effectively but compromise the other, the dual-capability approach ensures diagnostic relevance without incurring excessive computational burden. This efficiency renders it particularly suitable for scalable deployment in clinical settings where radiologist availability or diagnostic infrastructure is constrained. Moreover, the segmentation decoder not only assists in validating classification outputs but also promotes explainability; bridging the trust gap between black-box AI models and medical practitioners. These visual insights are vital for treatment planning and follow-up monitoring, as the hybrid framework offers a pragmatic solution for intelligent diagnostic assistance.

VI. Conclusion

The study presents a novel hybrid DL model integrating ResNet50 with Swin Transformer to simultaneously perform classification and segmentation of pneumonia from thoracic radiograph images. The local feature extraction capability of ResNet50 and the hierarchical attention-driven global context modelling of the Swin Transformer are utilized to skillfully gather both fine-grained and contextual features. The model further branches into a classification head comprising global average pooling and a multilayer perceptron and a segmentation decoder that reconstructs pixel-level patches, providing interpretable diagnostic outputs. With 98.4% accuracy, a precision of 98.2%, a recall of 99.2% and an F1-score of 98% in classification and a Dice coefficient of 0.88 for segmentation, the model outperformed the conventional methods by broad margins.

The segmentation results illustrated accurate delineation of lung regions, aligning closely with the ground truth masks, indicating exceptional interpretability and potential applicability in aiding radiologists. Additionally, the model's dual functionality can streamline radiology workflows by reducing dependency on separate diagnostic and localization tools, thereby saving time and operational costs.

However, the study is not without limitations. The dataset used is limited to pediatric chest radiographs collected from a single institution, which may impact the model's generalizability to broader populations, including adults or those with coexisting pulmonary conditions. Additionally, the segmentation performance may degrade in cases of overlapping pathologies or poor image quality. These limitations call for broader validation to ensure clinical robustness.

Future extensions of this work may focus on multiclass classification involving multiple thoracic diseases, incorporating explainable AI modules to enhance transparency and validating the framework across multi-institutional and

multi-demographic datasets to ensure broader generalizability and adoption. Further, the integration into mobile diagnostic applications or point-of-care systems could significantly expand its reach to rural and underserved areas.

***Abstract*—Traditional load balancing systems frequently have trouble adjusting to abrupt and unexpected changes in traffic. This can cause problems like server overload, longer response times, and more requests being denied. This problem is highly important in areas like healthcare, finance, cloud computing, and e-commerce, where performance, stability, and fast data delivery are all very important. To solve this problem, this study presents ReAdaBalancer, an adaptive load balancing architecture that aims to improve system performance, scalability, stability, and efficiency in contexts with changing traffic. Flask serves as the backend framework for ReAdaBalancer, while Nginx serves as the load balancer. Real-time monitoring and analytics are used to improve traffic distribution based on the resources that are currently available. Leveraging queuing theory (M/M/s/K Network), the system's performance is tested under diverse load situations, providing insights into its scalability and efficiency. ReAdaBalancer can also learn and adapt all the time, thanks to machine learning and heuristic optimization. This makes sure that it works the same way even when demand changes. Experimental results demonstrate that, under equivalent settings, ReAdaBalancer decreases response times by over 67% and reduces request denial rates by over 50% in comparison to traditional methods. This work has multiple opportunities for subsequent investigation. Future improvements could involve making ReAdaBalancer work in distributed multi-data center environments, adding reinforcement learning to make decisions more independently, looking into load balancing strategies that use less energy, and making it work in edge computing and IoT ecosystems.**

I. INTRODUCTION

Cloud computing has gained significant popularity in recent years due to the rapid advancement of information and communication technology, which has driven the growth of data centers with resource virtualization and high connectivity [1]. To handle the increasing complexity of cloud environments, this study proposes the Rock Hyrax approach, an algorithmic model inspired by the adaptive and collaborative behavior of hyrax animals. The approach is designed to optimize load balancing in cloud computing systems, ensuring flexibility, scalability, and continuous access to resources [2]. Efficient load management is essential for maintaining performance while reducing resource waste. The Rock Hyrax model mimics the collective intelligence of hyrax groups, allowing computing systems to adapt dynamically to fluctuating workloads through intelligent collaboration. However, the rapid expansion of cloud services also introduces challenges such as system reliability, latency reduction, and energy efficiency. Efficient cloud computing faces several challenges, including latency, dark data risks, governance issues, data availability, privacy, long-term costs, and potential threats from edge computing and related technologies [3]. One promising solution to address these challenges is the implementation of efficient load-balancing techniques. Among innovative approaches, the Rock Hyrax method stands out by emphasizing adaptive, collective strategies inspired by the social behavior of hyrax herds, which are adept at distributing risks and surviving in dynamic environments.

In cloud computing, load balancing distributes workloads across smaller nodes, enhancing system performance and stability [4, 5]. The Rock Hyrax strategy draws inspiration from the cooperative survival tactics of hyrax animals, which allocate roles and adapt effectively in unstable habitats. Existing load balancing algorithms can be broadly categorized into three groups: static, dynamic, and nature-inspired methods [5]. To address modern networked cloud environments, newer approaches must be smarter, more efficient, and adaptive.

Static Load Balancing (SLB) leverages prior knowledge of system resources such as memory, storage, and processing power, resulting in lower overhead compared to dynamic methods [6, 7]. However, SLB lacks flexibility in adapting to changing workloads. Conversely, Dynamic Load Balancing (DLB) offers higher adaptability by adjusting workloads in real time, but at the cost of increased overhead [7]. Nature-inspired approaches, such as the Rock Hyrax algorithm, integrate the strengths of both models by mimicking decentralized, socially adaptive survival strategies. This enables accurate workload distribution with reduced overhead, even under dynamic and uncertain system conditions.

In contrast, Nature Inspired Load Balancing (NLB) algorithms mimic biological and natural processes such as genetic evolution and honey bee foraging [8]. Compared to traditional methods, NLB is generally more effective in solving highly complex problems by approaching global optima rather than local ones. For example, Round Robin, although widely applied in cloud computing, often struggles with scalability and adaptability in dynamic environments. With the growing number of users, scheduling and load balancing techniques have become essential to sustain the performance of cloud

*Corresponding Author.

networks [9]. In this context, the Rock Hyrax approach offers advantages in social adaptability and efficient load distribution, even under unstable network conditions.

Load balancing also plays a key role in optimizing task assignment to virtual machines according to priority [10]. In static implementations, cluster nodes are connected through fixed routing and exchange specialized information for advanced processing [11]. By contrast, dynamic algorithms monitor traffic conditions in real time and redistribute workloads adaptively. This continuous feedback mechanism improves resource utilization, performance, and response time without relying on prior system information [12, 13].

Nature-inspired methods are becoming increasingly popular in this area. For instance, Particle Swarm Optimization (PSO) simulates the collective behavior of fish schools or bird flocks in search of optimal solutions [5, 6, 14]. Other inspirations include the human immune system, which adaptively detects and isolates threats, and physical phenomena such as earthquakes or avalanches, which inform automated post-failure recovery models [15]. Since evolutionary principles can be applied independently of the underlying medium, they enable the development of highly adaptive cloud systems [16].

This study also highlights the theoretical importance of latency and accessibility in cloud load balancing. By modeling more complex dynamic systems, it becomes possible to maximize workload distribution while considering energy efficiency. Therefore, exploring Rock Hyrax and Regret Minimization approaches is highly relevant, as they can optimize resource allocation, reduce energy consumption, and enhance the operational efficiency of machine learning–based applications, including evolving recommendation systems.

This study is organized as follows: Section I introduces the background and related work, Section II describes the design and methodology of ReAdaBalancer, Section III presents the implementation details and experimental setup and also discusses the results and analysis. Finally, Section IV concludes the study with key findings and directions for future research.

II. Materials and Methods

A. Cloud Computing

Cloud computing has changed the way businesses use and manage their IT resources. Now, they focus on ensuring that resources are used efficiently and the load is balanced to get the best performance. Research conducted a thorough review of cloud computing usage and emphasized how important load balancing is for cloud service performance [17]. Dynamic load balancing approaches are becoming increasingly important as cloud setups get more complicated. This approach helps to make resources more efficient and reduce system overhead. Researchers wrote a long report on dynamic load balancing in cloud computing. They talked about how difficult it is for cloud service providers to keep their services available and reliable while also avoiding resource overload [18]. The research suggested using nature-inspired metaheuristic algorithms to improve load balancing [19]. This shows that nature-inspired methods can be used to find flexible solutions in changing contexts. All these studies underline the importance of using advanced optimization algorithms to solve load distribution problems in cloud computing systems.

Despite advancements in cloud computing load balancing, there is still a big gap in getting the best resource distribution in networked systems, especially when workloads and resource limits are constantly changing [19]. Current methods frequently have trouble dealing with the intricacies of networked cloud infrastructures, where the dependency of several nodes and changing traffic conditions make load balancing difficult. This study suggests that combining the Rock Hyrax strategy with Regret Minimization strategies could lead to a better solution by reducing the regrets people have about their decisions in real-time load-balancing situations [22]. The goal of this study is to create a new optimization framework that can adjust to the changing nature of cloud networks. This will make better use of resources and improve the overall performance of the system [20, 21]. However, it still leaves room for further exploration, especially in quantifying the impact of factors such as technological readiness, top management support, relative advantage, competitive pressure, organizational resistance, system complexity, and data security [23, 24, 31]. Table I shows a critical literature analysis.

TABLE I. Critical Literature Analysis

Study /Approach	Contribution	Limitation / Gap Identified
Dynamic Load Balancing [17,18]	Improves efficiency, reduces overhead	Struggles under highly dynamic workloads and distributed nodes
Nature-inspired Metaheuristics [19]	Flexible, adaptive solutions	Often computationally expensive, lacks real-time responsiveness
Regret Minimization [22]	Handles decision-making under uncertainty	Not yet applied in large-scale cloud balancing contexts
Cloud Performance Factors [23,24,31]	Identify organizational & technical influences (e.g., security, complexity)	Mostly conceptual, not integrated into optimization algorithms

B. RHSO

Many different methods have been created to make the most of energy use in cloud computing systems, but a lot of them still have trouble managing load distribution well in a changing and unpredictable environment [32]. Researchers have come up with hybrid ways to use less energy, but they don't completely solve the problems of uncertainty and load changes in cloud computing [25]. When working with data that changes a lot and is hard to understand, like loads that change or are hard to estimate, these methods can run into problems. This shows that only optimizing energy isn't enough to get the job done without taking into account how the load changes in the system. Also, the Rock Hyrax Swarm Optimization (RHSO) algorithm that was created works well for selecting features for credit card fraud detection systems, but it is still not very useful in the cloud computing world [26]. These methods are more often used for classification and pattern recognition tasks, and they don't always take into account how uncertain it is to manage resources in the cloud. We still need to look into how well RHSO can optimize load distribution in real time in a cloud computing environment with different resources and needs that aren't always clear [27, 28]. There are many different load optimization models, such the Random Regret Minimization (RRM) model. However, it still has problems when it comes to

being used in the cloud computing environment, which is very dynamic and uncertain [29]. On the other hand, Bayesian Optimization with expectation correction for cumulative regret reduction and other similar methods are more focused on finding the best solution in a noisy environment [30].

This study's goal is to fill in the gaps by creating a new method that uses both the Rock Hyrax Swarm Optimization algorithm and the Regret Minimization strategy to optimize load balancing in cloud computing networks. One of the main goals of this research is to find a solution to the problem of uncertainty in load distribution that cloud computing systems confront. This is because they often need to allocate resources fast and accurately when demand changes. The system can lower losses from bad judgments, make load sharing more efficient, and use less energy more effectively by utilizing a Regret Minimization strategy based on modularity optimization [13]. This study focuses to improve the Rock Hyrax and Regret Minimization methods for optimizing load balancing on networked cloud-based computing systems. The goal of this study is to find and improve optimization methods that use algorithms to make cloud computing load allocation decisions more accurate. One of the problems with load-balancing is how to deal with changing and different loads without affecting performance or resource availability. The idea behind this study is that using Rock Hyrax with Regret Minimization will give better results than traditional load-balancing approaches.

C. Research Stages

The focus of this research is to identify problems associated with throughput optimization to produce an optimal transfer rate of data delivery services. The stages used in this research are developed from previous research. Making of the modelling algorithm is given in the following Fig. 1:

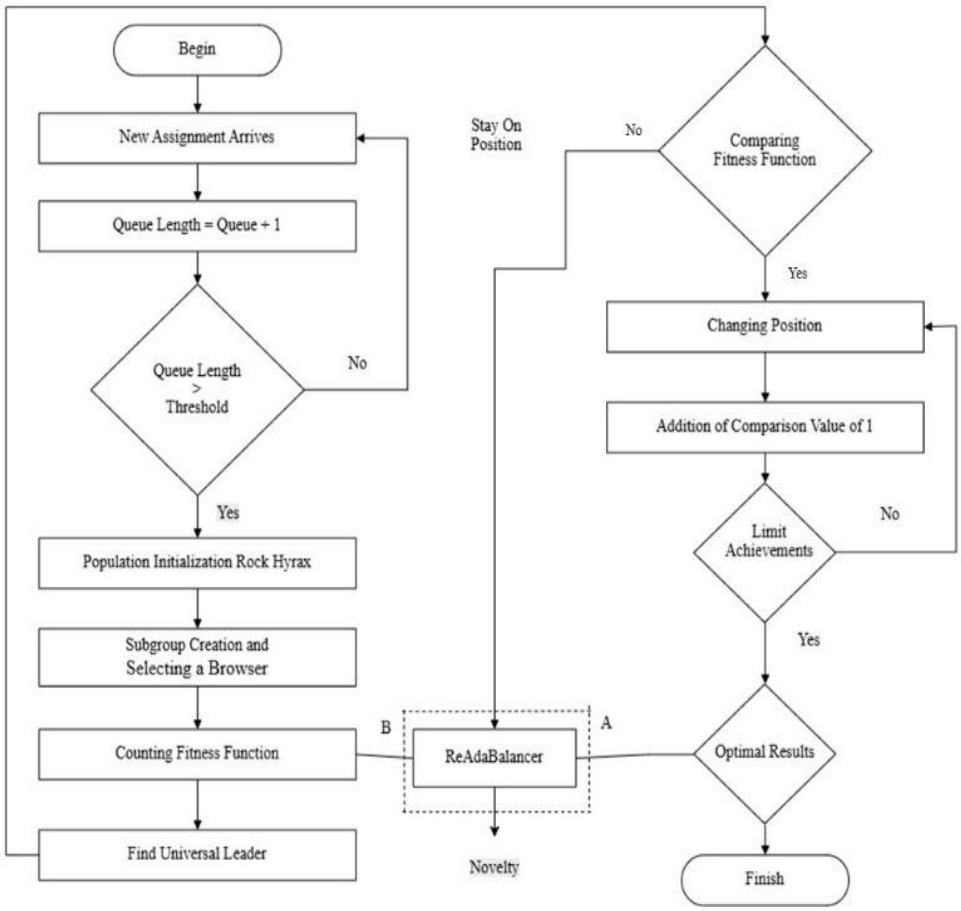

Fig. 1. Process algorithm.

The Proposed Rock Hyrax Load Balancing Algorithm is intended to efficiently manage workloads in a cloud computing environment. The following is a complete process flow story of how the algorithm functions:

1) Job submission: Users submit their tasks to the broker, which serves as the central controller for job scheduling and resource allocation in the cloud environment. The broker is also responsible for managing the distribution of tasks across different virtual machines (VMs).

2) Initial load assessment: The algorithm starts by checking the workload and resources of each virtual machine to find virtual machines that are overloaded. This is done by comparing the current load with a preset threshold.

3) Threshold monitoring: The waiting job queue length for each virtual machine (VM) has a threshold. If the queue length exceeds this threshold, the algorithm triggers load-balancing actions to ensure that no single VM becomes a bottleneck due to excessive demand.

4) Dynamic load redistribution: The algorithm evaluates the current state of the virtual machine (VM) when new jobs arrive. If the VM is overloaded, the algorithm reallocates waiting tasks to other VMs with available capacity. Dynamic redistribution and monitoring ensure optimal performance and prevent server failure.

5) Quality of Service (QoS) considerations: The Rock Hyrax algorithm considers quality of service parameters such as maxspan, throughput, response time, and energy efficiency. This ensures that load balancing addresses live workloads and optimizes overall system performance.

6) Continuous feedback loop: The capacity and workload of each server are monitored and sent back to the broker. The broker can make informed decisions about task allocation and adjust load distribution strategies as needed with this feedback loop.

7) Execution and monitoring: Once tasks are allocated to the appropriate virtual machines (VMs), the algorithm continuously monitors the execution of these tasks. If any VM is overloaded again, the process repeats, ensuring that the system remains balanced and efficient during job execution.

Performance Evaluation: Finally, the results show that makespan and energy consumption become lower, which indicates that Rock Hyrax's load balancing algorithm really works well when organizing resource allocation in cloud computing.

D. Preprocessing and Augmentation Data

This study looks at common preprocessing or data augmentation methods that are utilized in machine learning. If we think about the process in terms of data handling and optimization, though, we can see that the system is doing some "preprocessing" processes to manage tasks. For instance, when a new task comes in, the system will add it to the queue and check to see whether it goes over the limit. This is like getting data ready for more processing. This phase makes sure that only jobs that are too heavy are processed, which cuts down on unneeded overhead. Also, setting up the "Rock Hyrax" population and making subgroups can be considered as setting up several possible solutions (or data points) for optimization, like feature selection or data splitting. The system does "data augmentation" by comparing fitness functions and changing the placements of agents based on these comparisons. This is done again and over again. You could say that this is an addition to the original set of possible answers, with each repetition making the solutions better and more suited to the problem at hand. Also, the addition of a comparison value and the constant changes to the agents' positions are like the iterative nature of data augmentation, where new data variations are made by making changes and comparisons, which makes the model better at adapting and finding the best solution. These phases make sure that the optimization process looks at a lot of different options, which makes the system stronger and more efficient, just like how data augmentation makes models more general.

E. Model Architecture

The model architecture refers to the overall structure of a machine learning model or computational model, which defines the components, their relationships, and the flow of data through the system. The model architecture serves to design, build, and understand how the various parts of the model interact to achieve the desired functionality.

The following is an architectural diagram of the M/M/s/k queue pseudocode based on the pseudocode that has been made. This diagram illustrates how customers enter the system, wait in the queue if needed, are served by the server, and then exit the system or are rejected if the queue is full, as can be seen from Fig. 2:

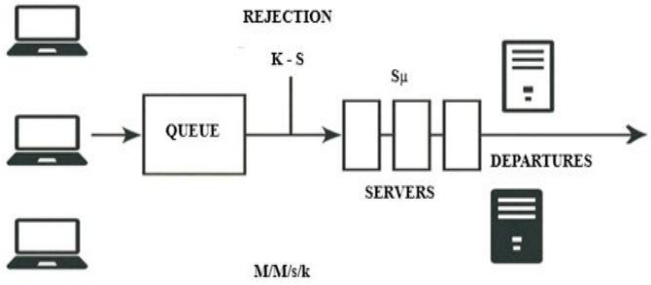

Fig. 2. Architectural diagram of the M/M/s/k queuing model.

Fig. 2 shows a queuing system in a crowded place, such as a fast food restaurant or a call centre. Randomly come to the queue of customers (represented by a computer icon). However, this queue has a limit that not everyone can join. If the queue is full (exceeding k capacity), you will be denied entry. In this system, several servers (s) serve customers one by one, and each server has a certain service speed (μ). Once served, exit the system. This model is called M/M/s/k, and is often used to measure the performance of capacity-constrained systems, such as how fast the service is, and how busy the system itself is.

Load balancers distribute load based on server capacity and user demand. Basic formula:

$$S_i = argarg\left(C\left(S_j\right) + L\left(S_j\right)\right), \quad (1)$$

where, *Si* is the selected server;

Sj is each server in the pool;

C(*Sj*) is the processing capacity of server j;

L(*Sj*) is the latency of server j.

The load balancer selects the server with the lowest C+L value.

1) ReAdaBalancer algorithm: ReaAda balances tasks with the smallest load and considers redistribution. Determining the smallest load on a server can be analogous to a mathematical formula that describes the probability of a server being active or not, based on the load received. With a value, which is the size of the load, and other parameters, such as α and β, which serve to adjust the sensitivity and threshold. Creating the server inactive is significantly larger, creating an efficient that when the server does not receive many requests.

$$P(S_i) = \frac{1}{1 + e^{-(\alpha U_i - \beta)}}, \quad (2)$$

where, $P(S_i)$ is the probability of selecting server i;

U_i is the utilization of server i;

α and β are parameters that control the sensitivity of the algorithm to server load. The lower the U_i value, the greater the chance of that server being selected.

2) Regret minimization: Regret Minimization aims to minimize the difference between the best decision and the decision taken:

$$R_t = \sum_{t=1}^{T} w_t (O_t - A_t), \quad (3)$$

where, R_t is the regret at time t;

O_t is the optimal outcome that should be obtained if the best decision is taken;

A_t is the result obtained from the decision taken by the system;

W_t is the weight that determines how important the error is at time t.

The goal of this algorithm is to make $R_t \rightarrow 0$ over time by adaptive learning.

3) Performance evaluation: Performance evaluation is calculated by looking at throughput (T), response time (R), and error rate (E):

$$K = \frac{T}{R + E}, \quad (4)$$

where, K is the performance score;

T is the number of successfully processed requests;

R is the average response time;

E is the number of errors that occur.

The higher the K, the better the system performance.

Based on the idea of queuing theory, the M/M/k Load Balancer Architecture is arranged here in an organized table. Typically used in high-performance distributed systems where multiple servers (k) handle randomly arriving jobs (Poisson process) and each server offers exponential service time. Describes the architectural structure of the M/M/k queue system with a Load Balancer. These system requests arrive at a rate of λ and are then distributed by the Load Balancer to the k available servers. If all servers are busy, they enter the Queue before being processed. Utilization (ρ) is an important parameter that determines whether or not the system is in a stable state. There are two main probabilities: P_0, which indicates that there are no customers in the system, and Pq, which indicates the chance that customers will have to queue before being served.

Output based on system performance is rather different. While L (System Length) shows the total customers in the system, including those being served. Shows L (Queue Length). In terms of time, Wq (Queue Wait Times) calculates how long the average customer has to wait in the queue, while W (System Wait Times) is the total time spent by the system. After proposals, requests go out as completed requests.

F. Simulation Model

A simulation model is a computational representation of a process, system used to simulate under various conditions. This model is built into a diagrammatic architecture.

Here is a diagram of the queue simulation architecture based on the pseudocode you provided. This diagram shows the relationship between the main components, such as customer, simEventList, queue, and queueSim, which can be seen from Fig. 3.

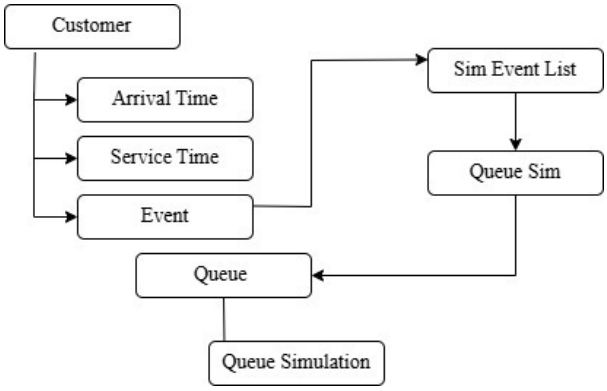

Fig. 3. Architectural diagram of the queue simulation model.

Performance evaluation at the final stage enables continuous monitoring and improvement of the system to remain optimum in handling demand. This approach is not operational, but it also minimizes the potential for errors and quality degradation.

G. Experimental Setup

Experimental setup refers to the arrangement of equipment, in terms of both hardware and software, to analyze the phenomenon under study.

- The hardware and software used for this study are:
  - The research environment (CloudSim, iFogSim);
  - Infrastructure for both private and public clouds (OpenStack, AWS, Azure, GCP);
  - Microservices and container platforms like Kubernetes and Docker;
  - systems for edge and fog computing;
- Frameworks for serverless computing.

Adaptive and decentralized load optimization is its best feature. This makes it very useful in multi cloud, hybrid, and edge-cloud environments where real-time decision-making and self-learning are very important.

III. Results and Discussion

This study show that the integration of Rock Hyrax and

Regret Minimization for cloud computing optimization with the ReAdaBalancer concept keeps the system stable and getting data quickly is very important. This is done by optimizing resource allocation. Under the same conditions, ReAdaBalancer cuts the response time by about 67% and the request rejection rate by more than 50% compared to the standard approach. This is done by adjusting to the traffic in real time and considering the server status. Unlike previous works such as [22], where only using the Rock Hyrax algorithm shows lower accuracy due to its inability to stress the system remains stable in optimizing resource allocation. In contrast to [28], where they propose a near-optimal discrete optimization approach for experimental design using a Regret Minimization framework. This approach aims to select the statistically most efficient subset of design points from a larger data set. In addition, while [29] this RRM model can be adapted to plan resource allocation by considering regret over previous decisions.

A. *Maths Pseudocode*

Between mathematical conceptual thinking and effective programming implementation, Maths Pseudocode is a logical and methodical presentation of mathematical algorithms organized in half-code form. including the following:

#Mathematical pseudocode

import maths

def lambdaN(lam, k, n):

Fig. 4 is the pseudocode of the simulation results using Python.

```
if n < k:
return lam
return 0
def muN(mu, s, n):
if n < s:
return n*mu
return s*mu
def P0(lam, mu, s, k):
sum = 1.0
for i in range(1, s):
sum += (pow((lam/mu), i) / math.factorial(i))
sum  += ((pow((lam/mu),  s)  /  math.factorial(s))) * ((1-pow((lam/(s*mu)), (k-
s+1)))) / (1-(lam/(s*mu)))))
 return 1/sum
```

Fig. 4. Arrival function, service level, and probability.

Summary of Fig. 4

The code above implements the M/M/s/k queuing system, which analyses a system with a limited number of servers (s) and a maximum capacity (k). The lambdaN function stops if the capacity is full, which stops the arrival of customers (λ). Calculates the service level (μ), which increases with the number of customers but is limited by the number of servers. The P0 function terminates an empty system (P_0), which is useful for evaluating queuing systems. This model is useful for others with capacity constraints, such as call centers, computer servers, or service systems.

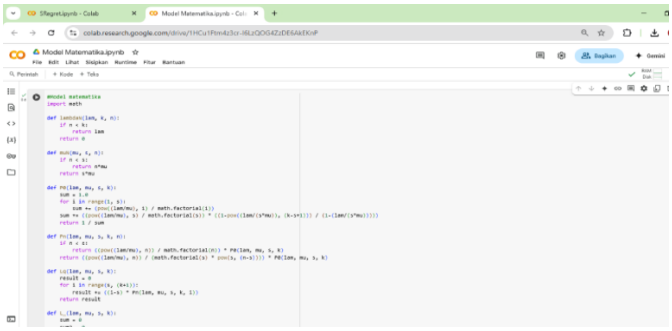

Fig. 5. Running a mathematical model.

Fig. 5 shows a snippet of Python code written on Google Colab, titled Mathematical Models. This script implements several complex mathematical functions used for probabilistic modelling or queuing theory, marked with common notations such as λ (arrival rate), μ (service rate), and k (number of customers in the system). The functions P0 and Pn indicate attempts to calculate the probability of states in a queuing system, while the functions PC and PQ indicate probability calculations in the context of a limited system capacity or queue. The use of math.factorial, math.pow, and the use of nested loops reflect typical combinatorial and exponential calculations in the Poisson or M/M/1/K models.

B. *Simulation Pseudocode*

Run through simulations, before they are used in actual computer code, pseudocode, a methodical description of a logically ordered simulation process, allows the systematic construction and analysis of scenarios, therefore modelling the dynamics of complex systems and enabling the comprised. The following Fig. 6 shows the customer function, simEventList..

```
#Simulation pseudecode
import numpy as np
import random
import maths
import queue
class customer:
 departTime = 0
 def __init__(self, at, st, s):
        self.arrivalTime = at
        self.serviceTime = st
        self.event = s
class simEventList:
 def __init__(self, lam, mu, n = 0):
        tempServiceTime = int(np.random.exponential(1/mu)*60)
        self.list = [customer(0, tempServiceTime, 'arrival')]
        for i in range(n-1):
                tempServiceTime = int(np.random.exponential(1/mu)*60)
                tempInterArrivalTime = int(np.random.exponential(1/lam)*60)
```

Fig. 6. Customer function, simEventList .

Summary of Fig. 6

Part of a queuing system simulation that uses an exponential distribution to determine customer arrival and service times. Customer The class represents a customer with attributes of arrival time, service time, and event type (or departure). Meanwhile, the simEventList class manages the list of events in the simulation, generates service times, and determines the inter-arrival time of customers based on an exponential

distribution. This simulation is useful for analyzing the performance of other systems that have limited capacity, with queues, such as contact centers, banks, or other systems.

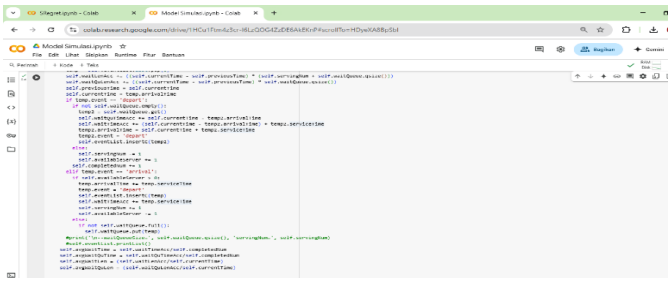

Fig. 7. Running system simulation.

Summary of Fig. 7

Simulation of a queuing system that uses an exponential distribution to determine customer arrival and service times. Each customer has attributes of arrivalTime, serviceTime, and event type. In this simulation, events are in the simEventList class, which ensures that each customer's arrival and departure are sorted chronologically. The available servers, as well as calculating performance metrics such as average time and queue length, the queueSim class is responsible for running the simulation by maintaining the queue. If all servers are busy, customers will be put into a waiting queue, provided there is still available capacity.

The simulation is run in a loop that processes each event in the list sequentially. If a customer arrives and there is a server, they are served immediately. Otherwise, they enter the queue if there is still space. Once in the queue, they begin to be served, the server becomes available again, and the next customer follows. The final results of the simulation include various statistical measures that can be used to evaluate the efficiency of the queuing system, such as average waiting time and queue length. The model can be used in various real-world applications, such as customer service, traffic management, and data processing systems.

C. Load Balancer System Test Pseudocode

The Load Balancer System Test Pseudocode is designed to confirm the fair and efficient traffic distribution between servers by logical simulation before technical implementation is carried out. Pseudocode is a methodical depiction of the load balancer system test flow comprising the following, as shown in Fig. 8.

Summary of Fig. 8

The load balancing () function simulates the M/M/k queue model with multiple servers. It calculates system utilization, estimated number of customers in the system and queue and arrival rate (λ), service rate (μ), and arrival rate (λ). With this simulation, it is possible to evaluate service efficiency in various queuing systems, such as call centres, hospitals, and data centres, in order to optimize capacity and reduce customer waiting time.

Fig. 9 shows the running of simulation results using Python.

```
import numpy as np
import matplotlib.pyplot as plt
def loadBalancer(lam, mu, k, s=5):
 """
Simple simulation of the M/M/k queue model.
lam: arrival rate (lambda)
mu: service rate (mu)
k: number of servers
s: number of lambda simulation points
Returns:
x -> lambda array
simLy, Ly -> number of customers in the system (simulation vs theory)
simWy, Wy -> customer waiting time in the system (simulation vs theory
simLqy, Lqy -> number of customers in queue (simulation vs theory
simWqy, Wqy -> waiting time in queue (simulation vs theory)
 """
x = np.linspace(lam, lam + 1, s) # Simulating multiple lambda values
rho = x / (k * mu) # System utilisation
# M/M/k queue system estimation formula
Ly = rho / (1 - rho) # Estimated number of customers in the system
Wy = Ly/x # Estimated total waiting time
Lqy = Ly - (x/mu) # Estimated number of customers in the queue
Wqy = Lqy / x # Estimated waiting time in queue
```

Fig. 8. Load balancer function.

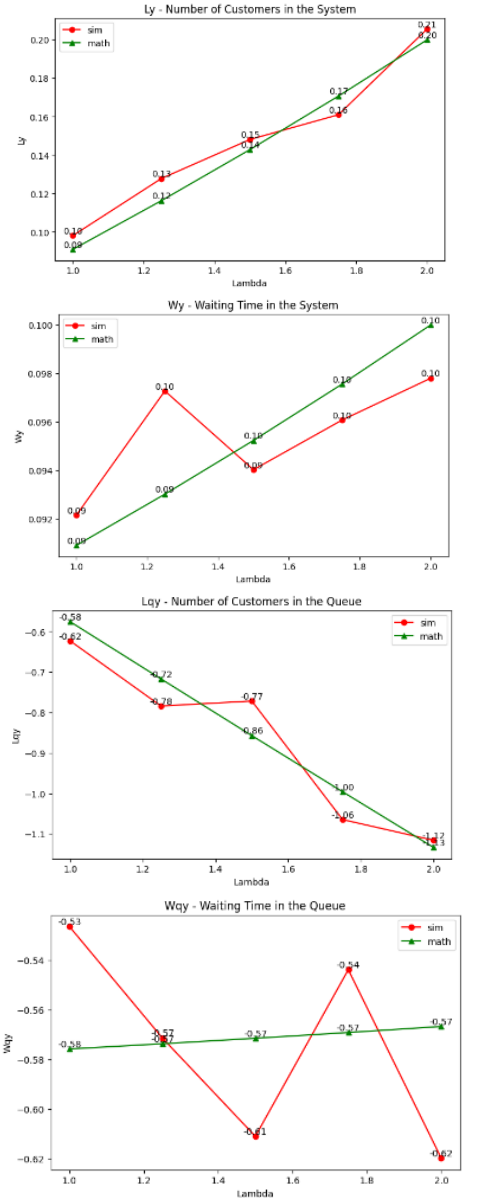

Fig. 9. Running simulation test of load balancer system.

Simulation summary of Load Balancer Test Model

Load balancing, with the code above, simulates a multiple server M/M/k queue system. The load balancing function calculates queue parameters such as the number of customers in the system (Ly), the waiting time of customers in the system (Wy), the number of customers in the queue (Lqy), and the waiting time in the queue (Wqy). These results are calculated both theoretically and through simulations of varying the value of λ (arrival rate) within a certain range. The simulation is added with random noise in the real system to represent in. After the calculation is complete, the results are visualized using Hutmatplotlib to compare the theoretical values and simulation results.

However, there are some implementations of this. Ly is not suitable for calculating Ly due to multiple servers (M/M/k), as it only applies to M/M/1 systems. Not checking the system, which should ensure that the utilization ratio $\rho = \lambda/(k\mu)1$ in order to keep the queue under control. If $\rho > 1$, the system is not able to increase indefinitely. For improvement, it is necessary to use the Erlang-C formula to get a more accurate estimation in the M/M/k model.

D. Innovative ReaAdaBalancer

An innovative load balancing method called RegretAdaptive Load Balancing (ReAdaBalancer) dynamically optimizes demand distribution by means of regret reduction. The simulation in Table II shows how helpful this approach is in settings with varying workloads and heterogeneous servers.

TABLE II. REGRETADAPTIVE LOAD BALANCER PERFORMANCE RESULTS

Server ID	Final Load	Final Regret	Utilization (%)
0	11	0	11.0%
1	5	0	5.0%
2	0	0	0.0%
3	0	0	0.0%
4	6	0	6.0%

Table Analysis:

1) Final Load: Shows the final load amount that each server has after 20 iterations.

2) Final Regret: None of the servers are overloaded, so the regret score remains 0.

3) Utilization (%): All servers have a low utilization rate, which means the load has been distributed fairly well.

Fig. 10 shows the running of simulation results using Python.

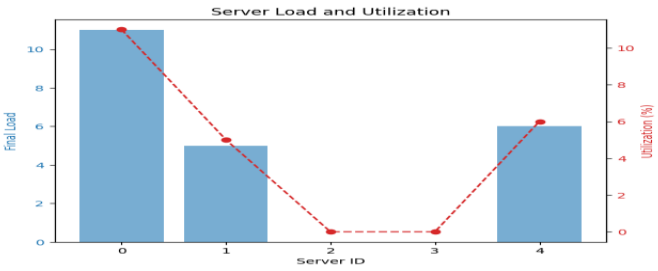

Fig. 10. Simulation graph of adaptive load balancer regret.

This graph presents "Server Load and Utilization" data related to the final load and utilization rate of five server units identified by IDs 0 to 4. The observation shows that there is a significant imbalance in the workload distribution between servers. The server with ID 0 had the highest final load of 11 and a utilization rate of 10%, indicating that it was working intensively and was likely to be the main center of data processing. Meanwhile, server ID 1 showed a drastic drop with an end load of only 5 and a utilization rate of 5%, suggesting a reduction in activity or an imbalance in load allocation. More strikingly, server IDs 2 and 3 recorded zero values on both metrics, signifying that they were not involved in any computing processes at all, potentially indicating high idle time or no assignment at all. In contrast, server ID 4 shows an increase again with a final load of 6 and utilization of 6 %, indicating moderate involvement in system activity. Overall, this graph reflects an uneven load distribution among the server units. This imbalance can have an impact on operational efficiency as well as hardware lifespan. Therefore, there is a need to evaluate the scheduling and load distribution strategies to ensure that all system resources are utilized optimally and proportionally.

E. Discussions

In summary, the discussion confirmed that the proposed ReAdaBalancer, which includes preprocessing as an important first step to prepare the data for the load balancing [10] process, and augmentation, which improves the model in the face of dynamic changes in cloud environments, both help provide smart and efficient solutions for load optimization that can be used on a large scale and in cloud environments that change quickly.

Despite its advantages, this research has some limitations, including that the algorithm becomes more difficult to compute as the number of nodes and the size of the cloud network increase. The algorithm may have difficulty in making timely adjustments when there is a sudden change in load or system failure, which can lead to poor conclusions. Future improvements may include: 1) the use of parallel computing and distributed processing to speed up the performance of the algorithm, 2) the use of online learning or incremental learning techniques to keep the model up-to-date as new data comes in, 3) the addition of reinforcement learning for parameter adjustment to provide a dynamic solution that avoids incorrect parameter selection, 4) the addition of distributed error detection and self-healing features to the algorithm can make it more fault-tolerant. For example, replication techniques can be used to copy the load to a backup server in case of a failure, and 5) the use of hybrid algorithms that combine Rock Hyrax with other faster optimization methods such as shortest path algorithms or approximate algorithms can help you make decisions faster and ensure that load distribution occurs quickly and efficiently for real-time applications.

ReAdaBalancer has been shown to work very well for improving system resilience and availability. Helping to make better use of resources and adapt to changing conditions. The Rock Hyrax Approach and Regret Minimization will focus on making cloud computing [13] more scalable, able to adapt automatically, able to handle failures, better at managing energy, and more secure in the future. This research can make

a cloud system that is more efficient, safe, and able to adapt to future issues by looking into how to combine emerging technologies like machine learning, blockchain, and real time processing and coming up with solutions for apps that need to do more than one thing.

IV. Conclusion

The model that combines Rock Hyrax and Regret Minimization for cloud computing optimization with the ReAdaBalancer concept keeps the system stable, and the ReAdaBalancer cuts response time by about 67% and request rejection rate by more than 50% compared to the standard approach by adjusting traffic in real-time.

Test Server with ID 0 has the largest final load of 11 and utilization rate of 10%, which means that it is working hard and is probably the major place where data is processed. Server ID 1, on the other hand, has a final load of only 5 and a utilization rate of 5%, which means that either activity has decreased or load allocation has become unbalanced. This performance boost can be a clever and effective way to optimize load that works on a large scale and in cloud environments that change quickly.

Results are in line with the goal and unique features. The suggested load balancing optimization method effectively solves the main problems found in the study, such as being able to adapt to changing system conditions, using a lot of energy, and not being very good at distributing workloads in real time. Rock Hyrax and Regret Minimization work together to give a unique advantage over standard algorithms by changing to traffic patterns in real-time. This makes the system more responsive and uses resources better.

***Abstract*—Recently, due to the dangerous spread of COVID-19, there has been strong competition among computer science researchers within the scientific research community to employ deep learning for the development of intelligent medical systems that diagnose this illness. Enhancing accuracy is considered the most important objective, and augmentation techniques are used in this context. This study addresses two main issues related to applying augmentation on X-ray and CT-scan images: losing the positional information of augmented medical images and the integration of extracted features while scanning them. The use of the Vision Transformer Structure, supported by a Position-Aware Embedding (PAE) method, is proposed to deal with these issues. Moreover, in this study, a student–teacher-based approach was adopted to enable considerable resistance against training on a small batch of training images. Due to the sensitivity of medical data, preserving the privacy of patients was taken into account by using a pseudonym-based anonymity approach. After evaluations based on accuracy, precision, recall, and specificity metrics, the results showed that the proposed system has a high-level capability to predict class images (X-ray or CT-scan) as well as considerable resistance against training on small medical images.**

***Keywords*—COVID-19; medical images; augmentation; vision transformer; training data ratio**

I. Introduction

The medical sector is considered the most important sector in people's lives because staying healthy leads to higher work productivity and increased happiness. Therefore, governments always rank fighting epidemics at the top of their priorities. In 2019, strange medical signals were observed in some patients in Wuhan, China. These signals showed that the patients had been infected with a serious new strain of coronavirus disease (known as COVID-19) [1, 2]. Subsequently, various parts of the world experienced COVID-19 outbreaks, prompting the World Health Organization (WHO) to inform the public that the COVID-19 crisis had become a global pandemic after the disease was found to have exceptional spreadability. Governments all over the world colluded to fight against the dangerous spread of COVID-19 and its manifold consequences that came in different forms (losses of human life, economic recessions, faltering medical health systems, and necessary lifestyle changes). Most scientists, physicians, and politicians have agreed that the best way to stop the spread of COVID-19 is early diagnosis and detection and adherence to preventive measures such as social distancing [3]. Fig. 1 summarises and arranges the historical events outlined above.

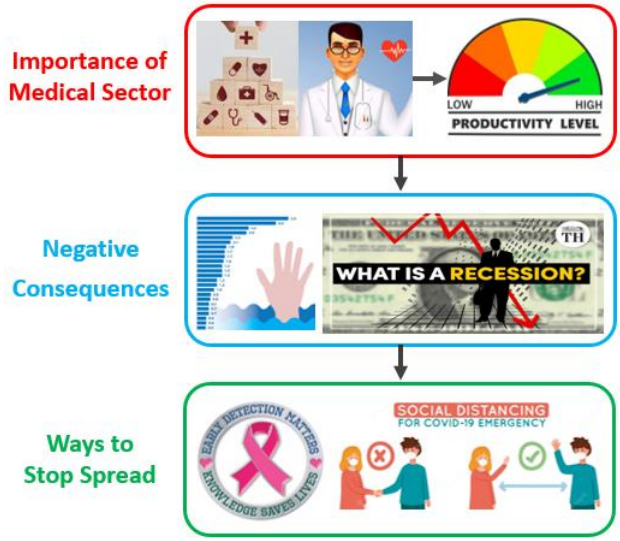

Fig. 1. Historical events resulting from the outbreak of COVID-19.

A. Motivation

The traditional ways of detecting COVID-19 are antibody testing and Quantitative Reverse Transcription Polymerase Chain Reaction (QRT-PCR), both of which have some issues. Antibody testing generates high false-negative rates when it comes to dealing with early active infections [4, 5]. With QRT-PCR, generating results is time-consuming; thus, it is unsuitable when working under severe time constraints. Relying on medical image analysis and making diagnoses via the use of CT images has proven effective in the early detection of COVID-19. However, techniques based on CT images are time-consuming, as they require some pre-activities to be carried out (e.g., transferring patients to a CT facility and the sterilization of medical devices) and other post-activities (e.g., discussing with consultants to analyse the results of the test). Using X-ray images is preferable to the use of CT scan images in terms of cost. However, some research has shown that when COVID-19 progresses in its infection of patients' bodies, some visual features of X-ray images become blurred (i.e., less informative) [6]. As a result, there is a strong motivation among researchers to develop advanced diagnostic systems to detect COVID-19, and here, deep learning (DL) techniques come to the fore. Fig. 2 summarizes this motivation.

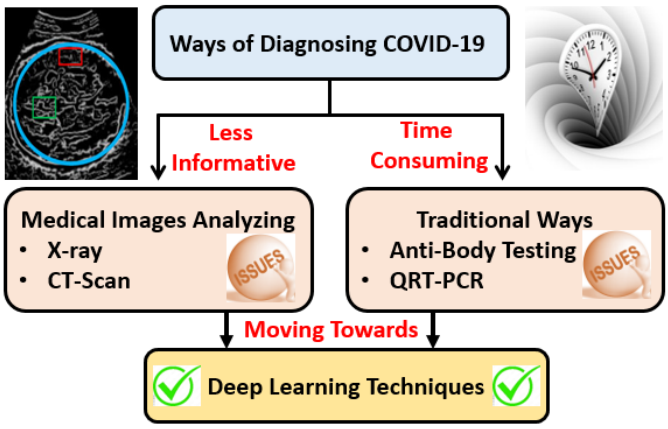

Fig. 2. Motivation.

B. Statement of the Problem

In order to fight against COVID-19, researchers in the field of computer science have made invaluable contributions to the development of intelligent diagnosing systems by enhancing the accuracy of the intelligent systems developed for detecting COVID-19. They have employed the principles of Medical Image Analysis (MIA) and deep learning (DL) to train intelligent systems. X-rays and CT scans are considered the most common sources of medical images. Among the intelligent systems used for diagnosing COVID-19, their low accuracy is the root cause of why many of these systems fail, as insufficient accuracy leads to an increase in the rate of deaths among infected people because of the high number of cases that are falsely classified as negative [7]. Fig. 3 illustrates the low accuracy problem.

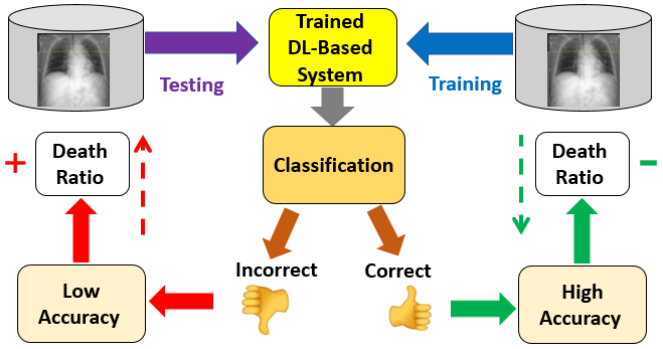

Fig. 3. The low accuracy problem leads to a high death ratio.

One possible way to enhance accuracy is to carry out effective data pre-processing before the system's training stage. In this context, augmentation-based techniques, which center around rescaling medical images to enable the extraction of learning features in an efficient way, are widely used [8]. However, the use of augmentation-based techniques can lead to some issues, including the following: 1) the loss of positional information because the original input medical image is divided into segments, and incorrectly re-ordering segments leads to confusion in the learning process [9]; 2) the integration of extracted features across the entire medical image is crucial to ensure learning on all features [10]; and 3) resistance against different sizes of training datasets becomes a barrier for ensuring that the diagnosing system can be applied in real-time [11]. Fig. 4 illustrates the issues that can arise when using augmentation-based techniques.

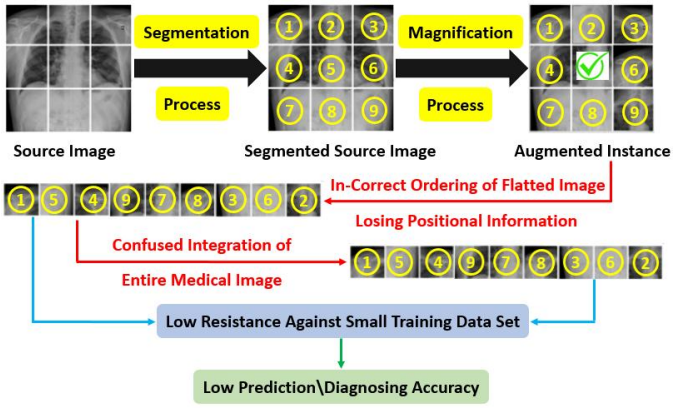

Fig. 4. Issues resulting from poor augmentation.

C. Research Questions

This study aims to address the following research questions:

1) How can one avoid losing the positional information of augmented medical images that are used as inputs for the training process?

2) How can one ensure the integration of extracted features while scanning whole medical images?

3) How can one enable resistant real-time diagnosing against small training datasets?

4) How can the preservation of the privacy of patients, which is a mandatory requirement in the medical sector, be ensured?

D. Contributions

In addressing the research questions listed above, this work aims to make the following contributions to the literature:

- Regarding the first research question, a Position-Aware Embedding (PAE) method that takes into account the corresponding positional information during the flattening process is presented.
- Regarding the second research question, an Integration-based Vision Transformer Structure (IbVTS) is proposed. The self-attention mechanism provided by this VTS, which ensures the integration of the information extracted from each segment of the flattened medical images, is explained.
- Regarding the third research question, the IbVTS is supported by a distillation tactic to activate less training data for the purpose of supporting the classification layer.
- Regarding the fourth research question, a pseudonym-based anonymity approach (PAA) is proposed to hide the personal information of patients.

E. Structure of Study

The rest of this study is structured as follows: Section II outlines related works. In Section III, the architecture of the

proposed intelligent diagnosing system is presented in detail, along with the role of each component. The experimental results are documented in Section IV, and finally, Section V concludes the study and lists directions for future research.

II. Related Work

Many survey-based papers have addressed intelligent systems used to diagnose COVID-19 and provided various taxonomies, such as [12, 13, 14]. The authors of [12] relied on the application of different deep learning approaches used to diagnose COVID-19 (convolutional neural network, Generative Adversarial Network, and Long Short-Term Memory) to derive their taxonomy. The author of [13] presented a taxonomy based on methods used for the data pre-processing stage and techniques used for feature extraction. Convolutional neural networks, recurrent neural networks, deep belief networks, and reinforcement learning are the deep learning architectures used to shape the base of the taxonomy presented in [14]. This work groups intelligent systems into five categories based on the type of learning, as shown in Fig. 5.

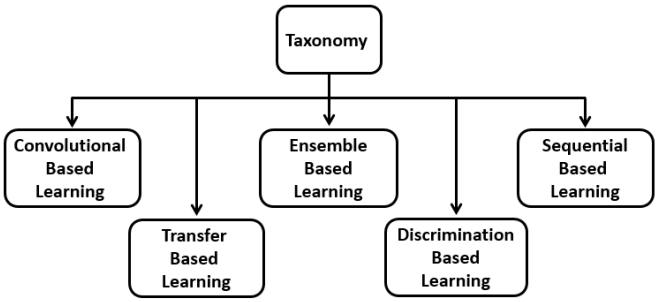

Fig. 5. Taxonomy of intelligent systems used to diagnose COVID-19.

A. Convolutional-Based Learning

In this category, convolutional neural networks dominate the architectures of the proposed systems. CNNs consist of two main types of layers: a convolutional layer and a pooling layer. CNNs employ filtering principles used in the domain of image processing to extract features.

In [15], the researchers proposed an automatic system for diagnosing COVID-19 using a pre-trained U-net architecture. The purpose of this U-net architecture is to segment medical images of the lungs. Next, the segments are used as inputs for a deep neural network to output the class of the given image. They used a dataset of 540 patients, with 313 (138 males; 175 females) of these patients being COVID-19 positive and 229 (88 males; 141 females) being COVID-19-negative. The experiments were conducted on the CT-scan dataset and produced 90.1 % accuracy on binary classes. The CNN-based architecture presented in [16] consists of 25 layers (19 layers for convolution and 6 max-pooling layers). Convolutional layers are connected to batch normalization for input standardization and to regulate the intelligent model. To ensure the continuity of neurons, a leaky rectified linear unit is utilized. The maxpool function is used for the down-sampling of the inputs. The authors used an X-ray dataset comprising 600 medical images for binary classification. An accuracy of 87 % was obtained.

B. Transfer-Based Learning

In this category, two main domains are involved: the source domain and the target domain. The source domain is characterized by models that are data-rich and have high-quality feature extraction capabilities. In contrast, the target domain suffers from low-quality feature extraction capabilities and requires help from pre-trained models. The purpose of transfer-based learning is to shift the knowledge from the source domain to the target domain. The degree of maturity of the transferred knowledge depends on the degree of similarity between the source and target.

Transfer-based learning was applied to CT scan medical images in [17] to avoid the high costs and computational complexity associated with constructing a CNN model. Two main DL-based algorithms were used (ResNet18 and ResNet50) as pre-trained models. Then, discriminant correlation was employed for feature fusion to generate a better image representation. The data of the training dataset were gathered from a local medical center, with there being 420 samples for each class (normal and infected). The results showed that an accuracy of 96.35 % was achieved. The authors of [18] chose to use VGG16, VGG19, ResNet, DenseNet, and InceptionV3 as pre-trained DL-based models with rich knowledge. These architectures were used to transfer information derived from chest X-ray images. To enhance the classification accuracy, a rotation-based augmentation technique was employed and referred to as a heading model. The results obtained after conducting experiments showed that among the five models used, VGG19 achieved the best accuracy (80%).

C. Ensemble-Based Learning

The key idea of ensemble learning is to combine multiple models (referred to as learners) to generate an enhanced model. There is a wide spectrum of tactics used to perform a combination, such as majority voting, plurality voting, and weighted voting.

The authors of [19] proposed an intelligent model that combines EfficientNet and SE-ResNext to predict one of the three classes that label input images (COVID-19, pneumonia, and normal). They chose to use X-ray medical images and a weighted voting-based combination tactic. The results showed that the proposed model achieved a higher accuracy (about 95%) than that achieved by each combined model separately. In the context of ensemble learning, the authors of [20] utilized a stack of pre-trained deep learning models. They used VGG-16 as base learners, trained with a diverse set of inputs, followed by a logistic regression model, the meta learner, to combine the base learner predictions. This combination tactic relies on a fusion technique to enable the system to predict the class of the medical images. They achieved a high level of accuracy (about 89%).

D. Discrimination-Based Learning

The key idea behind discrimination-based learning is to, as a first step, generate tuples that are similar in features and class to real training data. Then, the resultant tuples and real ones are mixed and act as inputs for the discriminator to be handled under a distinguishing process (i.e., to distinguish the real tuples from generated ones). In the context of discrimination-based learning, Generative Adversarial Networks (GANs) rules supreme.

A GAN-based system was proposed by the authors of [21] to construct synthetic CT scan images of both COVID-19 patients and healthy controls. The construction process was performed during the data augmentation stage. The Whale Optimization Algorithm (WOA) was used to optimize the hyperparameters of the GAN. The model was trained using the SARS-CoV-2 CT-Scan dataset, which consists of 2482 images (1252 COVID-19 cases and 1230 healthy cases). In terms of accuracy, the model obtained an accuracy value of 99.22%. A U-Net-based GAN designed for lung segmentation using chest X-ray images was proposed in [22]. This strategy involved employing a fully convolutional neural network in conjunction with the GAN model to segment images of the lungs in order to make COVID-19 diagnoses.

E. Sequential-Based Learning

In this category, the Long Short-Term Memory (LSTM) dominates because it was originally developed to enhance neural networks by enabling learning from sequential data.

The authors of [23] presented a hybrid intelligent model for diagnosing COVID-19 using an LSTM with a CNN. The development of the model consisted of three steps. First, medical images were enhanced in the pre-processing stage based on the contrast technique. Then, the enhanced images were used as model inputs for the purpose of learning. Finally, the Softmax function was used in the classification layer to distinguish between three classes: COVID-19, normal, and pneumonia. This model was trained on the COVID-19 Radiography dataset, which consists of 1143 images of COVID-19 cases, 1341 images of normal cases, and 1345 images of Pneumonia cases. The authors achieved an accuracy of 98.97 %. The authors of [24] utilized a pre-defined histogram threshold to segment CT scan-derived medical images. For feature extraction, both the Q-Deformed entropy (QDE) and a CNN were used. Finally, the extracted features were fused and used as inputs for the LSTM classifier to predict the classes of the images. The highest classification accuracy value obtained was 99.68%.

III. Proposed System

This section presents the proposed intelligent system. Firstly, the framework of the system is presented, followed by the system's architecture and the role of each component involved in constructing the architecture.

A. Framework of Proposed System

The environment within which the proposed system operates is medical health care centers/hospitals. For a given number of patients (Pat), medical machines capture chest images derived from two types of imaging techniques: X-ray, denoted as (MI_{xr}), and CT scan, denoted as (MI_{ct}). Both types form a real dataset [see Eq. (1)]:

$$RDS = \bigcup_{i=1}^{Pat}\{MI_{xr}^{i}, MI_{ct}^{i}\} \quad (1)$$

Each medical image is modeled as follows [see Eq. (2)]:

$$MI_{type\in(xr,ct)}^{i} = \langle IDp, NAMEp, BODp, SEXp, Dis\rangle | i = 1,2,\dots,Pat \quad (2)$$

where, $IDp, NAMEp, AGEp, SEXp, Dis$ represent the personal information of the patient, specifically their identifier, name, date of birth, sex, and medical description or health status.

In reality, in the usage stage of the proposed system (i.e., after training and testing), $MI_{type\in(xr,ct)}^{i}$ is used as an input to predict one of three classes (healthy, pneumonia, or COVID-19), as shown in Fig. 6.

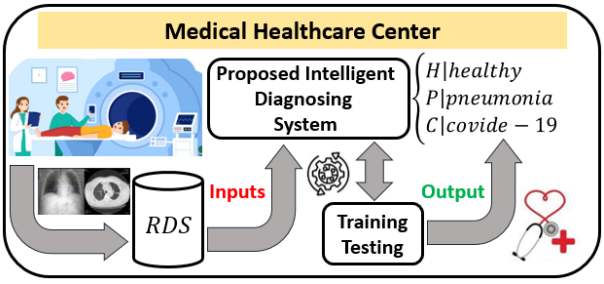

Fig. 6. Framework of the proposed system.

B. System Architecture

The objective of the proposed system is to, via learn mapping from inputs, predict/classify medical images to the correct class label. The proposed system is managed by six components. From a DL-based perspective, the components are grouped according to three phases, as shown in Fig. 7.

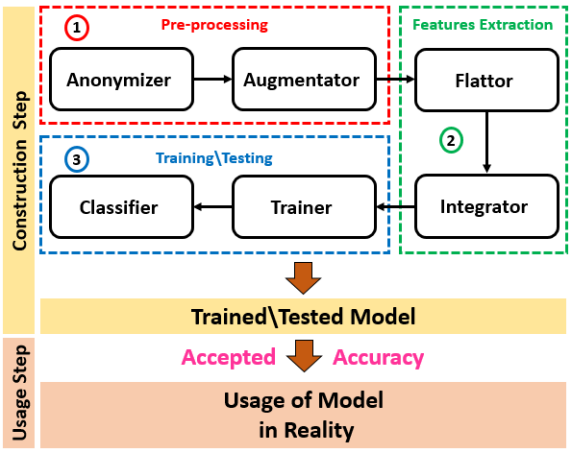

Fig. 7. Architecture of the proposed system.

Table I summarizes the main task of each component, the technique used for each task, and the quality attribute each task maintains.

TABLE I. Components

Name of component	Main task	Used technique	Quality attribute
Anonymizer	Privacy preservation	Pseudonym	Privacy
Augmentator	Augmentation	Cutmix\Mixup	Contrast
Patch Embedder	Solving positional information losses	PAE	Resistance
Integrator	Effective feature extraction	IbVTS	Performance
Trainer	Training on integrated extracted features	Distillation	Accuracy
Classifier	Prediction of output	Softmax	

C. Role of the Anonymizer Component

This component is responsible for protecting the privacy of patients by executing the pseudonym-based anonymity approach (PAA). For this, a pseudonym technique is employed. This technique is widely used to protect location privacy in location-based services. The key idea of the pseudonym technique is to handle personal data so that no data can be attributed to a specific person or data subject without additional information [25]. In this study, PAA was performed through three main steps: removing, replacing, and generalising. Fig. 8 illustrates these steps with an example.

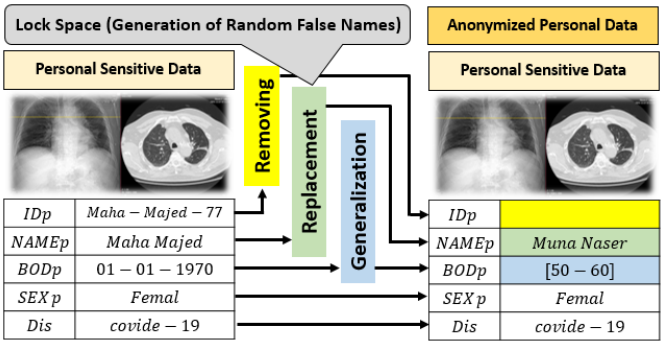

Fig. 8. Application of the three steps of the PAA.

As shown in Fig. 8, Maha Majed is the name of a real patient with a clear ID and clear date of birth, which, in turn, compromises this patient's privacy. Through using the PAA, their ID is removed. Their real name is replaced by "Muna Naser", which is a false name selected from the lock space that generates many pseudonyms based on some rules that help to create a false name adapted from the patient's real name. In our example, the real name consists of two parts (first name and last name), and so does the false one. In addition, the length of each part is 4 and 5 letters, respectively, which also matches the length of the first and last names of the pseudonym (false name). It is worth mentioning that privacy protection is a separate research field, and we will not discuss privacy protection in detail in this work, as we are only concerned about DL. The date of birth of the real patient is generalized in the anonymized profile so that no specific value is given. As for the sex and description fields, they are kept untouched. This way, the privacy of the patient is ensured, since the attacker cannot construct a malicious profile of a patient, and they also cannot make any inferences or link any information to a specific patient.

After performing the PAA task using the Anonymizer component, the resultant medical image ($\overline{\mathrm{MI}^{\mathrm{i}}_{\mathrm{type}\in(\mathrm{xr,ct})}}$) is privacy protected [see Eq. (3)].

$$(\overline{MI^{i}_{type\in(xr,ct)}}) = \langle \overline{NAMEp}, \overline{[BODp]}, SEXp, Dis \rangle | i = 1,2,\dots,Pat \quad (3)$$

D. Role of the Augmentator Component

This component is responsible for the augmentation of medical images. The objective of augmentation is to enhance the quality of training by enabling the extraction of more meaningful information. There is a wide spectrum of techniques used for augmentation [26]. The simplest techniques rely on some geometric transformation, such as rotating and cropping. However, such geometric transformation-based techniques are costly and complex, and they also require some manual operations to determine the angles and measures that suit the situation. Due to these limitations, researchers have moved towards more advanced techniques. Random erasing-based techniques such as the Cutout technique are used in this context [27]. The key idea behind the Cutout technique is to randomly remove/mask a square region of pixels in order to force the model to focus on a specific region and thus extract more robust features. For example, if the removed pixels form the background of a given image, then this noise will disappear. However, a critical weakness of the Cutout technique is related to its randomizing process. This means that sometimes it removes some informative parts of the given image, and consequently, some important features will be completely missing from the extracted space. The Mixup [28] technique saves all parts of a given image. The key idea behind this technique is to mix a pair of input images with their classes during training. Thus, more generalizable features that cover all input images are achieved. However, it may generate blurry images. An effective solution to the issue of blurring is discrimination, which is achieved by the use of the Cutmix technique [29]. Instead of masking the region, as is the case in the Cutout technique, it is replaced by the corresponding region from a different medical image. In this study, since we dealt with both X-ray- and CT scan-derived medical images, the Cutmix technique was used for the augmentation of the X-ray medical images, while the Mixup technique was used for the augmentation of the CT scan images. The reason behind this is that the ribs may blur X-ray scans, whereas there is no source of blurring in CT scans.

From a mathematical modeling perspective, let $\langle \overline{\alpha_A}, \overline{\beta_A} \rangle$ and $\langle \overline{\alpha_B}, \overline{\beta_B} \rangle$ represent two privacy-protected training samples, where $\overline{\alpha} = (\overline{\mathrm{MI}^{\mathrm{i}}_{\mathrm{type}\in(\mathrm{xr,ct})}})$ is a training image and $\overline{\beta} = \mathrm{Dis}$ is the corresponding label. For Mixup, the augmented sample is denoted as $(\overline{\overline{\alpha}}, \overline{\overline{\beta}})$, and the mixing process is given by the following Eq. (4) and Eq. (5):

$$\overline{\overline{\alpha}} = \delta\, \overline{\alpha_A} + (1-\delta)\, \overline{\alpha_B} \quad (4)$$

$$\overline{\overline{\beta}} = \delta\, \overline{\beta_A} + (1-\delta)\, \overline{\beta_B} \quad (5)$$

where, $\delta \in [0,1]$ is sampled from a beta distribution.

As for Cutmix, the generated augmented privacy-protected image is modeled as follows [see Eq. (6) and Eq. (7)]:

$$\overline{\overline{\alpha}} = \vartheta\, [\![\psi]\!]\, \overline{\alpha_A} + (1-\vartheta)\, [\![\psi]\!]\, \overline{\alpha_B} \quad (6)$$

$$\overline{\overline{\beta}} = \delta\, \overline{\beta_A} + (1-\delta)\, \overline{\beta_B} \quad (7)$$

where, $\vartheta \in \{0,1\}$ is a binary mask for determining which pixel is removed and replaced by the second image, and $[\![\psi]\!]$ is the multiplication operation.

From a visual perspective, the application of both Mixup and Cutmix to medical images is illustrated in Fig. 9 and Fig. 10, respectively.

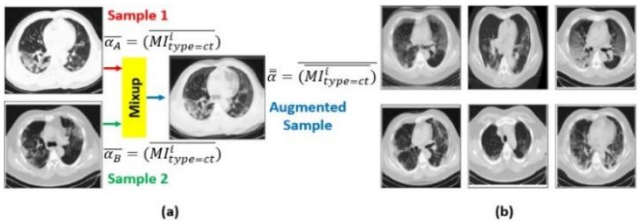

Fig. 9. Mixup-based augmentation. (a) Detailed operation; (b) different augmented samples.

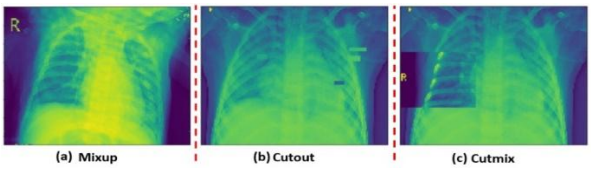

Fig. 10. Effectiveness of the Cutmix technique compared to Mixup and Cutout.

In Fig. 10(a), compared to Fig. 10(c), there are clear blurring regions that minimize the contribution of extracted features in the enhancement of training. Fig. 10(b) compared to Fig. 10(c), there are some informative parts out of the extracted space (the lower-right part of the left lung). In Fig. 10(c), the Cutmix technique avoids the pitfalls of both Mixup and Cutout, as a clear view of each specified part is used for the effective extraction of features.

E. Role of the Patch Embedder Component

This component is responsible for solving the problem of positional information losses by carrying out the Position-Aware Embedding (PAE) method on the augmented medical images. In detail, for a given augmented medical image ($\overline{\overline{\alpha}} = \overline{\overline{MI^{l}_{type\in(xr,ct)}}}$), which is generated from the source image ($MI^{l}_{type\in(xr,ct)}$), these two images are divided into parts of the same area, and then they are flattened into a sequence of non-overlapping patches. Then, corresponding positional information and learnable class tokens are manipulated, as shown in Fig. 11.

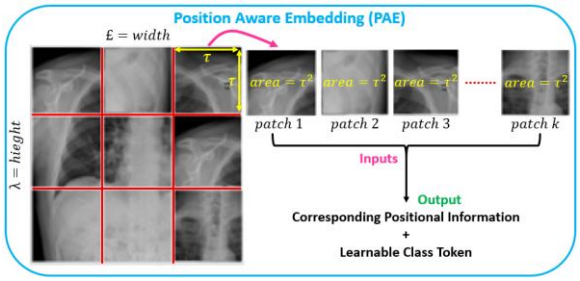

Fig. 11. Task of the patch embedder component when dealing with an X-ray image.

As shown in Fig. 11, λ and £ are the two dimensions of an augmented and privacy-protected medical image $\overline{\overline{\alpha}}$. The area of $\overline{\overline{\alpha}}$ is given by the following Eq. (8):

$$\overline{\overline{\alpha}}_{r} = \lambda \times £ \tag{8}$$

$\overline{\overline{\alpha}}$ is divided into a number of patches (each one has an area equal to $\tau \times \tau = \tau^2$). Relying on the total area of the medical image and the area of a patch, the number of patches k is given by the following Eq. (9):

$$k = \frac{\overline{\overline{\alpha}}_{r}}{\tau^2} \tag{9}$$

In terms of k patches, $\overline{\overline{\alpha}}$ is modeled as follows [see Eq. (10)]:

$$\overline{\overline{\alpha}} = \bigcup_{i=1}^{k} (\overline{\overline{\alpha}}^{\,i}_{pt}) \tag{10}$$

The generated flatted patches are passed to a linear embedding layer (LYR^{l}_{e}) to adjust their dimensions in a way that suits the dimensions of the model (DIM_{m}). The PAE method is applied to both the original image and the augmented instance. Fig. 12 provides a comprehensive view of a scene after the PAE method has been carried out.

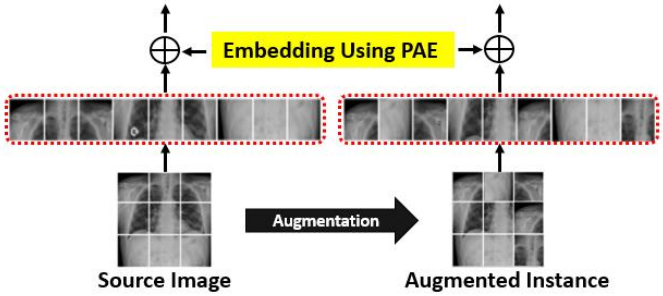

Fig. 12. Application of PAE on both a source image and an augmented image.

The application of PAE results in a series of patches that have the same spatial arrangement as in the source image. Let ($\mathfrak{T}_{lct}$) denote learnable class tokens and (PS_{info}) denote the positional information. Then, the output of the PAE is given by the following Eq. (11):

$PAE^{out}_{0} = \left[\mathfrak{T}_{lct}; \overline{\overline{\alpha}} LYR^{l}_{e}\right] + PS_{info}$, which can be detailed as follows:

$$PAE^{out}_{0} = \left[\mathfrak{T}_{lct}; \overline{\overline{\alpha}}^{\,1}_{pt} LYR^{l}_{e}; \overline{\overline{\alpha}}^{\,2}_{pt} LYR^{l}_{e}; \ldots; \overline{\overline{\alpha}}^{\,k}_{pt} LYR^{l}_{e}\right] + PS_{info} \tag{11}$$

where, $LYR^{l}_{e} \in \mathcal{R}^{(\tau^2 ch)\times DIM_m}$, and $PS_{info} \in \mathcal{R}^{(k+2)\times DIM_m}$.

F. Role of the Integrator Component

This component is responsible for ensuring effective feature extraction. It employs the concepts of the Vision Transformer (VisTrs) to carry out its mission [30]. The key idea behind the VisTrs is based on two fundamentals of performing image classification: 1) dealing with medical images as a series of patches that can be mapped into a semantic label, and 2) using a self-attention technique that enables effective feature extraction by handling the patches within an integration-based scan (i.e., integrate information at the level of the whole area of the image). This study adapts these two fundamentals and proposes an Integration-based Vision Transformer Structure (IbVTS). The structure of the VisTrs follows the encoder–decoder approach. In the context of the adaptation proposed in this work, the first fundamental of the VisTrs is satisfied by using a distill classifier (along with a corresponding distillation token), which will be discussed further on in this section when providing details on the role of the Trainer component. The second fundamental of the

VisTrs focuses on feature extraction and is satisfied as described below.

From a detail-based hierarchical perspective, the encoder of the VisTrs consists of a number of layers (NoL), and each layer contains two major units. The first unit is called multi-head self-attention (MhSa), which is responsible for carrying out the self-attention technique to ascertain the dependencies between the different patches that represent a given input image. The second unit is called the feed-forward unit (FeFoU) , which is responsible for generating a fully/densely connected network of features. Relying on a normalization layer ($\mathrm{LY_{nrm}}$), the MhSa and FeFoU are connected. From a mathematical perspective, the two units can be modeled as follows [see Eq. (12) and Eq. (13)]:

$$\widetilde{\mathrm{PAE}_{\varphi}^{\mathrm{out}}} = \mathrm{MhSa}\left\langle \mathrm{LY_{nrm}}\left(\mathrm{PAE}_{\varphi-1}^{\mathrm{out}}\right)\right\rangle + \mathrm{PAE}_{\varphi-1}^{\mathrm{out}} | \varphi = 1,2,\ldots,\mathrm{NoL} \quad (12)$$

$$\mathrm{PAE}_{\varphi}^{\mathrm{out}} = \mathrm{FeFoU}\left\langle \mathrm{LY_{nrm}}\left(\widetilde{\mathrm{PAE}_{\varphi}^{\mathrm{out}}}\right)\right\rangle + \widetilde{\mathrm{PAE}_{\varphi}^{\mathrm{out}}} | \varphi = 1,2,\ldots,\mathrm{NoL} \quad (13)$$

The operations that are executed within the self-attention technique are as follows:

1) For a given input sequence of image features, $\begin{cases} k: key \\ q: query \\ v: value \end{cases}$ are calculated for each element included in the sequence.

2) Relying on the inner/dot product, the relevance between the current element and other elements is obtained. In other words, this step highlights and integrates the relative importance of the patches in the sequence.

3) The results of step 2 are scaled based on the dimension of key ($\mathrm{K_{dim}}$) as a scaling factor and then used as inputs for the Softmax function.

4) To focus on more important values, the output of the Softmax function is multiplied by v.

Eq. (14) and Eq. (15) summarize the operations of the self-attention technique.

$$\begin{cases} \mathrm{k: key} \\ \mathrm{q: query} \\ \mathrm{v: value} \end{cases} = \mathrm{PAE^{input}}\ \mathbb{U}_{\mathrm{k,q,v}} \left| \mathbb{U}_{\mathrm{k,q,v}} \in \mathcal{R}^{\mathrm{DIM_m} \times 3\mathrm{K_{dim}}} \right. \quad (14)$$

$$\mathrm{SeAt}(\mathrm{PAE^{input}}) = \mathrm{softmax}\left(\mathrm{qk^T}/\sqrt{\mathrm{K_{dim}}}\right).\mathrm{v} \quad (15)$$

The environment (patches) within which the self-attention (SeAt) is executed allows for the parallel execution of these operations. Here, the MhSa, considered an extension of SeAt, comes to the fore. To activate self-attention (SeAt) in a parallel manner, instead of using a single value for the triplet (k, q, v), multiple values are used. Consequently, we deal with (h) heads (i.e., a head for each attention). The results of all the attention heads are concatenated to express the first unit of the encoder of the VisTrs [see Eq. (16)].

$$\mathrm{MhSa}\left(\mathrm{PAE^{input}}\right) = \mathrm{concat}\left\langle \mathrm{SeAt_1}(\mathrm{PAE^{input}}); \mathrm{SeAt_2}(\mathrm{PAE^{input}}); \ldots; \mathrm{SeAt_h}(\mathrm{PAE^{input}}); \right\rangle \langle \mathrm{lw} \rangle \quad (16)$$

where, lw represents the learnable weights, $\mathrm{lw} \in \mathcal{R}^{\mathrm{h.K_{dim}} \times \mathrm{DIM_m}}$.

As for FeFoU, it is constructed by a fully connected layer, followed by GeLU, followed by another fully connected layer.

Fig. 13 presents the Integrator component, which is based on the Patch Embedder component.

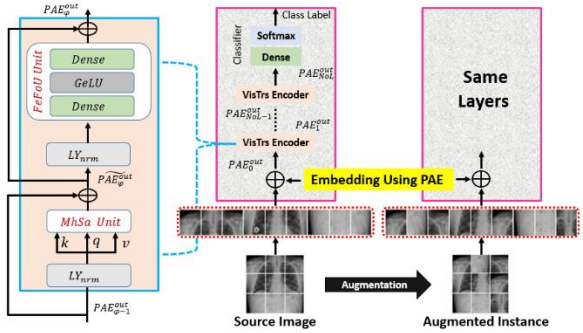

Fig. 13. A VisTrs architecture-based Integrator built based on the mission of the patch embedder component.

G. Role of the Trainer and Classifier Components

These components are responsible for training the model in a way that enhances both model performance and prediction accuracy. Originally, the VisTrs is driven from the data-efficient image transformer [31], where minimizing training is a major goal based on the student–teacher approach. The student–teacher approach relies on a distillation token generated from the augmented image instance. So, the left part of Fig. 13 represents the student, and the right part represents the teacher. Based on this, Eq. (11) is updated to become the following Eq. (17):

$$\mathrm{PAE_0^{out}} = \left[\mathfrak{T}_{\mathrm{lct}}; \mathfrak{T}_{\mathrm{dst}}; \overline{\overline{\alpha}}_{\mathrm{pt}}^{1}\mathrm{LYR_e^l}; \overline{\overline{\alpha}}_{\mathrm{pt}}^{2}\mathrm{LYR_e^l}; \ldots; \overline{\overline{\alpha}}_{\mathrm{pt}}^{\mathrm{k}}\mathrm{LYR_e^l}\right] + \mathrm{PS_{info}} \quad (17)$$

where, $\mathrm{LYR_e^l} \in \mathcal{R}^{(\tau^2 \mathrm{ch}) \times \mathrm{DIM_m}}$, $\mathrm{PS_{info}} \in \mathcal{R}^{(\mathrm{k}+2) \times \mathrm{DIM_m}}$, and $\mathfrak{T}_{\mathrm{dst}}$ denote the distillation token. In other words, the Trainer uses extracted features to train two classifiers, where each one has a dense layer followed by the Softmax function. The student classifier provides the class token, while the teacher classifier provides the distill token. Both of them are used as inputs for the fusion layer, which provides the final class of the medical image according to the following Eq. (18):

$$\mathrm{C_{final}} = \frac{1}{2} \times \left(\mathrm{C_{token}^{class}} + \mathrm{C_{token}^{distill}}\right) \quad (18)$$

Fig. 14 illustrates the Trainer's task, which is based on that of the Integrator.

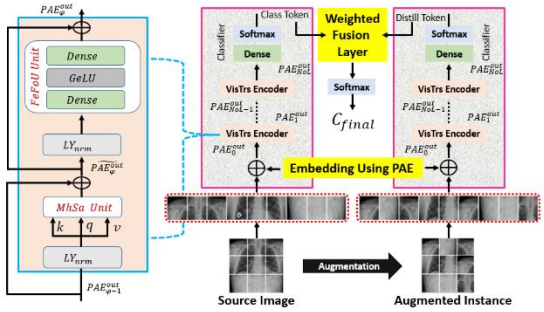

Fig. 14. Mission of the trainer component.

In reality, in the context of classification, a given medical image can be classified as healthy/normal, COVID-19, or pneumonia. To enable binary (healthy or COVID-19) or multi-class modes (binary plus pneumonia), a loss function is used in

the Classifier component, and this function is expressed as follows [see Eq. (19)]:

$$\mathcal{Q}\left(\mathfrak{V}_{ij}, \mathfrak{W}_{ij}\right) = \frac{-1}{pat}\sum_{i=1}^{trg}\sum_{j=1}^{ds} \mathfrak{W}_{ij} \log\left(\frac{1}{1+e^{-\mathfrak{V}_{ij}}}\right) + \left(1 - \mathfrak{W}_{ij}\right) \log\left(1 - \frac{1}{1+e^{-\mathfrak{V}_{ij}}}\right) \quad (19)$$

where, trg, ds are the number of training images and defined classes. $\mathfrak{W}_{ij}$ represents the ground-truth labels. $\mathfrak{V}_{ij}$ is the predicted probability.

H. Details of the Proposed System's Architecture

A sequence diagram, Fig. 15, is used to show the tasks of the components involved in the architecture of the proposed system.

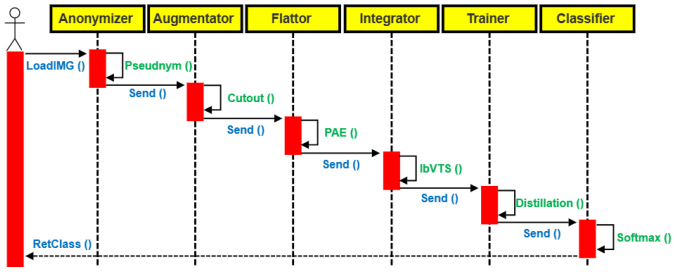

Fig. 15. Sequence diagram based on architecture details.

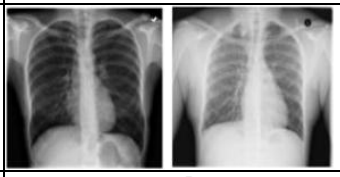
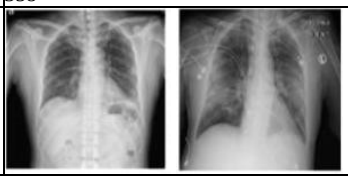
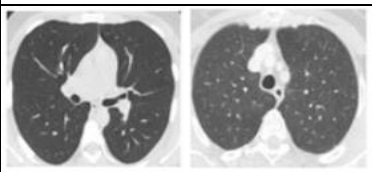
IV. Experimental Results and Evaluation

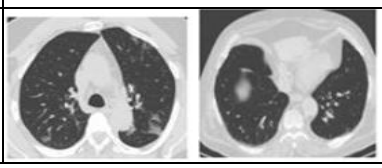
In this work, experiments were conducted on two different datasets to construct (train) and test the proposed diagnosing system. One of these datasets is the COVIDx dataset, created to store X-ray medical images [32]. This dataset consists of 13,962 X-ray images distributed over three classes, as summarized in Table II. We also used the SARS-CoV-2 dataset, which contains CT scan-derived medical images [33]. This dataset comprises 2,482 CT scan images distributed over two classes, as summarized in Table III.

TABLE II. Description of the COVIDx Dataset









Class 1	Healthy
Number of images	8066
Samples	
Class 2	Pneumonia
Number of images	5538
Samples	
Class 3	COVID-19
Number of images	358
Samples	

TABLE III. Description of the COVIDx Dataset over two classes

Class 1	Healthy
Number of images	1230
Samples	
Class 2	COVID-19
Number of images	1252
Samples	

A. Types of Evaluation

As shown in Fig. 16, we used two types of evaluation metrics: visual evaluation and numeric evaluation.

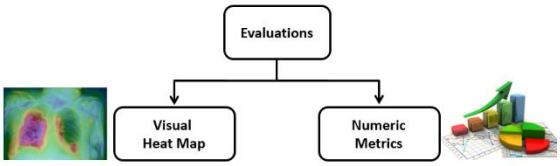


Fig. 16. Types of evaluation metrics used in the present study.

B. Used Metrics

Four metrics were used in this study for evaluation purposes. All of them were derived from the confusion matrix summarized in Table IV.

TABLE IV. Confusion Matrix

Predicted class Actual class	C_{final}	$\neg C_{final}$	Sum
C_{final}	TP	FN	S
$\neg C_{final}$	FP	TN	Su
Sum	$\widetilde{S}$	$\widetilde{Su}$	All

The elements of the above confusion matrix are as follows:

- True positives (TPs): The positive images that were correctly labeled by the classifier.
- True negatives (TNs): The negative images that were correctly labeled by the classifier.
- False positives (FPs): The negative images that were incorrectly labeled as positive (e.g., images of class healthy = no for which the classifier predicted healthy = yes).
- False negatives (FNs): The positive images that were mislabeled as negative (e.g., images of class healthy = yes for which the classifier predicted healthy = no).

$$\text{Accuracy} = \frac{TP+TN}{All} \quad (20)$$

Accuracy refers to the recognition rate, which quantifies the percentage of test set images that have been correctly classified.

In other words, it reflects how well the classifier recognizes images from the various classes [see Eq. (20)].

$$\text{Precision} = \frac{\text{TP}}{\text{S}} \quad (21)$$

Precision refers to the exactness, which refers to the percentage (%) of images that the classifier correctly labeled as positive. Therefore, it determines how many of the positive predictions are correct [see Eq. (21)].

$$\text{Recall} = \frac{\text{TP}}{\text{S}} \quad (22)$$

Recall (also known as sensitivity) refers to the completeness, which refers to the percentage (%) of positive tuples that the classifier labeled as positive. Recall is used as a measure of a classifier's tendency to identify infected cases [see Eq. (22)].

$$\text{Specificity} = \frac{\text{TN}}{\text{Su}} \quad (23)$$

Specificity refers to the true negative recognition rate. In other words, it measures the ability of a classifier to detect non-infected cases [see Eq. (23)].

It is worth mentioning that in terms of semantic meaning, a high value for any of the metrics mentioned above is preferable and reflects better performance, and vice versa.

Regarding visual evaluation, heat maps were employed to reflect the attention maps used in the learning process. Heat maps are used to illustrate the gradually increasing focus on regions of interest over layers during the learning process. This, in turn, reflects how regions are tightly coupled with the predicted class when it comes to the visual monitoring of progress.

It is worth mentioning that experimrnts are conducted in the Artificial Intelligence and Multi Media (AIMD) Lab within the campus of Fahad Bis Sultan University (FBSU) at Computing College.

C. Evaluation Based on X-ray Dataset

The COVIDx dataset was divided into a training part (25 %) and a testing part (75 %), taking into account the four metrics used for each class. Table V summarizes the results obtained with and without using augmentation.

TABLE V. EXPERIMENTAL RESULTS BASED ON X-RAY IMAGES FROM THE COVID DATASET

Approach	Term Metric	AVG	Class		
			Healthy	***COVID-19***	***Pneumonia***
Without Augmentation	Accuracy	≈ 87.16	88.23	87.77	85.47
	Precision	≈ 87.37	87.11	86.81	88.2
	Recall	≈ 87.84	89.21	88	86.31
	Specificity	≈ 87.11	86.26	87.62	87.45
With Augmentation	Accuracy	≈ 92.62	95.88	90	91.98
	Precision	≈ 93.47	94.63	92.12	93.66
	Recall	≈ 93.22	97.52	90	92.13
	Specificity	≈ 95.98	93.83	98.57	95.53

The values documented in Table V represent good performance with regard to diagnosing positive and negative cases. However, to highlight the effectiveness of the proposed augmentation technique, Fig. 17 compares the averages of the two approaches (with and without augmentation) for each class.

Fig. 17 reflects considerable enhancements for the four metrics when using augmentation, where it contributes 5.46, 6.1, 5.38, and 8.87 enhancements for accuracy, precision, recall, and specificity, respectively. The reason behind this is related to the effective extraction of features used for training, since the augmentation technique used enabled an increased focus on the regions of interest. This justification is visually supported by the heat map shown in Fig. 18.

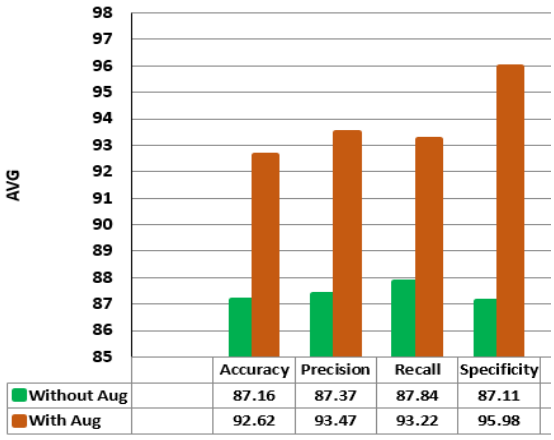

Fig. 17. Comparison between the augmentation-based approach and the non-augmentation-based approach on the X-ray dataset.

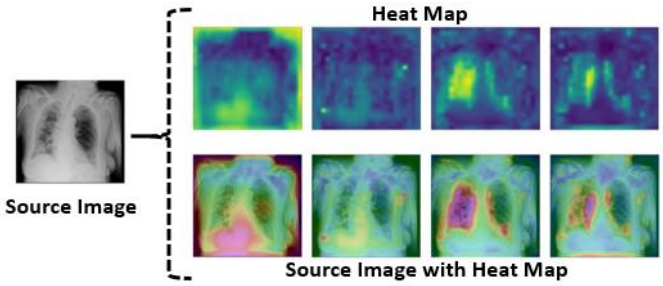

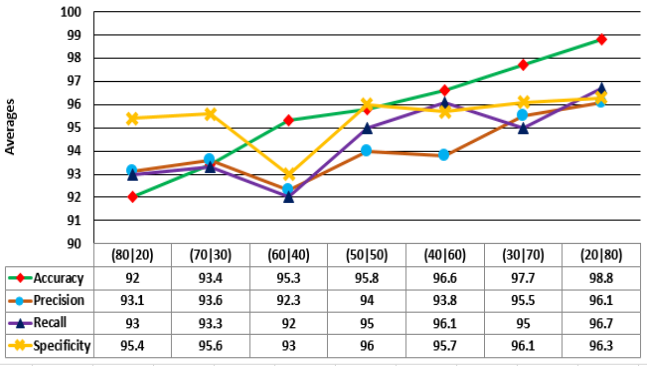

Fig. 18. Heat map of a source COVID-19 X-ray image.

Fig. 18 shows the gradually increasing focus on the zones that are informative for diagnosing/predicting illness. The heat map above reflects the confused focus on random zones of the lung and the point at which the focus becomes more specific on the zones that are tightly coupled with the class of the image, reaching the zones that represent COVID-19 in terms of medical diagnosis.

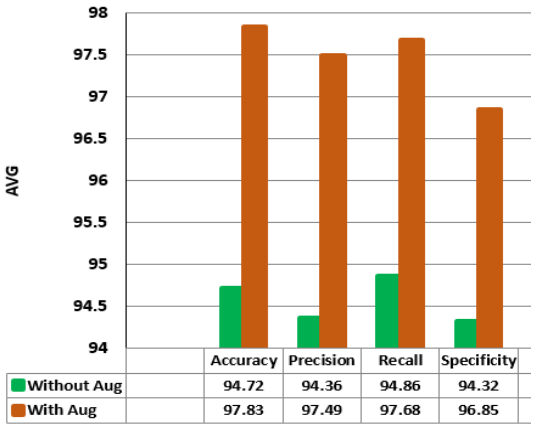
To measure the resistance of the proposed system against a small-sized training dataset (and to, in turn, evaluate its potential for usage in reality), we repeated our experiments using a different training/testing data ratio (stepwise increase of 10 %), meaning that 20 % of the COVIDx dataset was used for training and 80 % was used for testing), as shown in Fig. 19.

	(80|20)	(70|30)	(60|40)	(50|50)	(40|60)	(30|70)	(20|80)
Accuracy	92	93.4	95.3	95.8	96.6	97.7	98.8
Precision	93.1	93.6	92.3	94	93.8	95.5	96.1
Recall	93	93.3	92	95	96.1	95	96.7
Specificity	95.4	95.6	93	96	95.7	96.1	96.3

Fig. 19. Average of four metrics over different training/testing data splits.

Fig. 19 presents the results of seven experiments, each of which had its own unique training/testing division ratio. For example, in our second experiment, 30% of the dataset was allocated for training, and 70% was allocated for testing, meaning that this split can be expressed as 30|70. Regarding accuracy, it is obvious that there was a gradual increase in enhancement from about 92% in the first experiment to about 99% in the seventh one. This means that allocating more data for training leads to greater accuracy. However, there is a gap (about 8.8) in accuracy values between the 20|80 training ratio and its counterpart, the 80|20 training ratio. However, in both cases, the accuracy is still within a considerable range, which is a good indicator of the proposed system's potential for use in reality. The other metrics fluctuated randomly in response to the different training ratios. In this context, it is worth mentioning that accuracy is the most important measure to consider when evaluating a system.

D. Evaluation Based on CT Scan Dataset



To facilitate a fair comparison between our evaluation of the proposed system based on X-ray images and CT scan images, the same evaluation procedure followed for our experiments on the X-ray images was repeated. Therefore, the SARS-CoV-2 dataset was divided into a training part (25 %) and a testing part (75 %), taking into account the four metrics used for each class. Table VI summarizes the results obtained with and without using augmentation.

TABLE VI. EXPERIMENTAL RESULTS BASED ON CT SCAN IMAGES FROM THE SARS-COV-2 DATASET

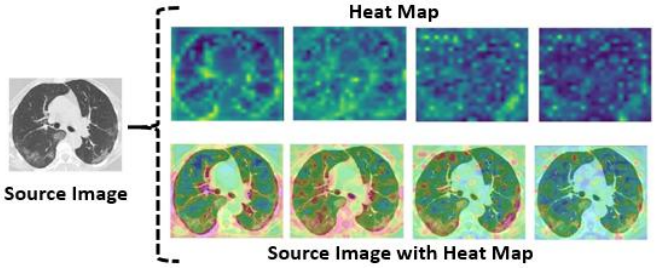
Approach	Term Metric	AVG	Class	
			Healthy	*COVID-19*
Without Augmentation	Accuracy	≈ 94.72	94.44	95
	Precision	≈ 94.36	93.88	94.83
	Recall	≈ 94.86	94.69	94.98
	Specificity	≈ 94.32	94.54	94.09
With Augmentation	Accuracy	≈ 97.83	97.55	98.11
	Precision	≈ 97.49	97.21	97.76
	Recall	≈ 97.68	97.33	98.03
	Specificity	≈ 96.85	96.57	97.13

The values documented in Table VI indicate that the model's performance was better than that achieved via the use of the X-ray images in terms of diagnosing positive and negative cases. However, to highlight the effectiveness of the proposed augmentation technique, Fig. 20 compares the averages of the two approaches (with and without augmentation) for each class.

Fig. 20 shows that considerable improvements in the four metrics were achieved when using augmentation, as enhancements of 3.11, 3.13, 2.82, and 2.53 were recorded for accuracy, precision, recall, and specificity, respectively. The results derived from the use of CT scan images are better than those derived from the use of X-ray images. The CT scan-derived results' superiority can be attributed to the ability of the Mixup augmentation technique to overcome the blurring issue that arises due to the ribs obscuring features in X-ray images. This justification is visually supported by the heat map shown in Fig. 21.

	Accuracy	Precision	Recall	Specificity
Without Aug	94.72	94.36	94.86	94.32
With Aug	97.83	97.49	97.68	96.85

Fig. 20. Comparison between the augmentation-based approach and the non-augmentation-based approach when using the CT-scan dataset.



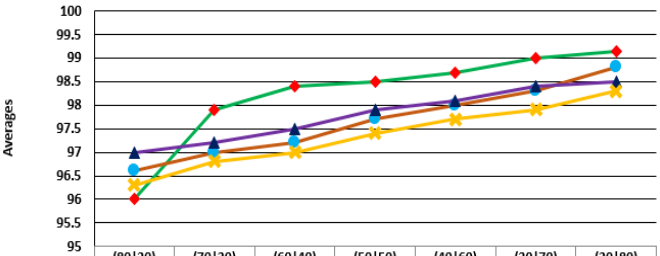


Fig. 21. Heat map of a source COVID-19 CT scan image.

As was the case with the X-ray images presented in Fig. 18, Fig. 21 shows the gradually increasing focus on the zones that are informative for diagnosing/predicting illness. In other words, the system learned to highlight sets of pixels that are strongly linked with illness. It is worth mentioning that the CT scanning technique is more accurate than X-ray imaging, which means that learning on CT scan images leads to higher levels of accuracy, especially if they are supported by augmentation, since augmentation leads to the extraction of more meaningful features.

To measure the resistance of the proposed system against a small-sized CT-based training dataset, the same procedure adopted to assess the resistance of the X-ray dataset was repeated, as shown in Fig. 22.

The results of the seven experiments (shown in Fig. 22) provide strong proof of the effectiveness of applying augmentation on CT scan images to increase the level of accuracy and other metrics as the training ratio increases. Steady enhancements for all metrics were recorded. Although the accuracy increases, there is a small gap (3.15) between the accuracy value when using an 80|20 testing and training ratio and that when using a 20|80 testing and training ratio. This proves that the proposed system has the ability to be trained on a small amount of data, which further indicates its potential for use in reality.

	(80|20)	(70|30)	(60|40)	(50|50)	(40|60)	(30|70)	(20|80)
Accuracy	96	97.9	98.4	98.5	98.7	99	99.15
Precision	96.6	97	97.2	97.7	98	98.3	98.8
Recall	97	97.2	97.5	97.9	98.08	98.4	98.5
Specificity	96.3	96.8	97	97.4	97.7	97.9	98.3

Fig. 22. Average of the four metrics over different training/testing data splits in the CT-based training dataset.

E. Security Analyzing

To analyze the proposed model's resistance against compromising the privacy of patients, let P^{e}_{Guess} denote the probability that a malicious party can successfully guess whether the event e is true. The proposed privacy protection method is resistant if [see Eq. (24)]:

$$P^{e_1=\text{personal info}_i \in RDS}_{Guess} = P^{e_1=\text{personal info}_j \in RDS}_{Guess} \forall\ (0 < i \neq j \leq pat) \quad (24)$$

Proof: The attacker cannot obtain any benefit from employing their side's information to recognize the patient. This is because the lock space prevents the attacker from knowing the ID of the patient. Moreover, the first name and last name are masked by dummies of the same size (i.e., a first and last name with the same number of letters as the patient's first and last name), which, in turn, leads to more confusion on the attacker's side. Furthermore, the generalization tactic applied to the date of birth of the patient does not reveal any specific information about the age of the patient. Only the attacker can know the gender of the patient and whether they have COVID-19. As a result, the attacker is forced to randomly guess the personal information of the patient, which leads to uncertainty in inferring sensitive information when attempting to compromise a patient's privacy and potentially harm them.

V. Conclusion

In this study, a deep learning-based system dedicated to detecting COVID-19 using X-ray- and CT scan-derived medical images is presented. The system is managed by six components. The Anonymizer is responsible for preserving the privacy of patients through the use of a pseudonym-based anonymity approach. The Augmentator is responsible for increasing the quality of the medical images through the use of augmentation techniques (Cutmix and Mixup for X-ray and CT scan images, respectively). The Patch Embedder is responsible for solving the problem of positional information loss by applying the Position-Aware Embedding method to the augmented medical images. The Integrator is responsible for effective feature extraction, which is carried out through employing the concepts of the Vision Transformer Structure. The Trainer and Classifier components are responsible for training the proposed system based on the student–teacher approach and generating the final classes via the Softmax function. The COVIDx (X-ray images) and SARS-CoV-2 (CT-scan images) datasets were utilized in this study to train and test the proposed system. Our evaluations, which were based on accuracy, precision, recall, and specificity metrics, showed that there was an enhancement in values when using augmentation. However, the enhancement achieved after training on CT scan images was better than that achieved after training on X-ray images. Moreover, the system was evaluated using a small amount of data by reversing the training/testing ratios. The results corresponding to the use of X-ray images were promising, as the system achieved 92% accuracy when 20% of the data were allocated for training and 80% of the data were allocated for testing and 98.8% accuracy when 80% of the data were allocated for training and 20% of the data were allocated for testing. However, compared to the results derived from the use of X-ray images, the results corresponding to the use of CT scan images were better, with an accuracy value of 96% being achieved after 20% of the data were allocated for training and 80% of the data were allocated for testing, as well as an accuracy value of 99.15% being achieved after 80% of the data were allocated for training and 20% of the data were allocated for testing. The key limitation of this work is related to the fact that we ignored evaluating performance in terms of the time taken to generate predictions and complexity. In future work, we will address this limitation by adopting a parallel training approach. In addition, testing the proposed system using additional datasets as well as including statistical significance testing (e.g., confidence intervals, p-values) will be in future work.

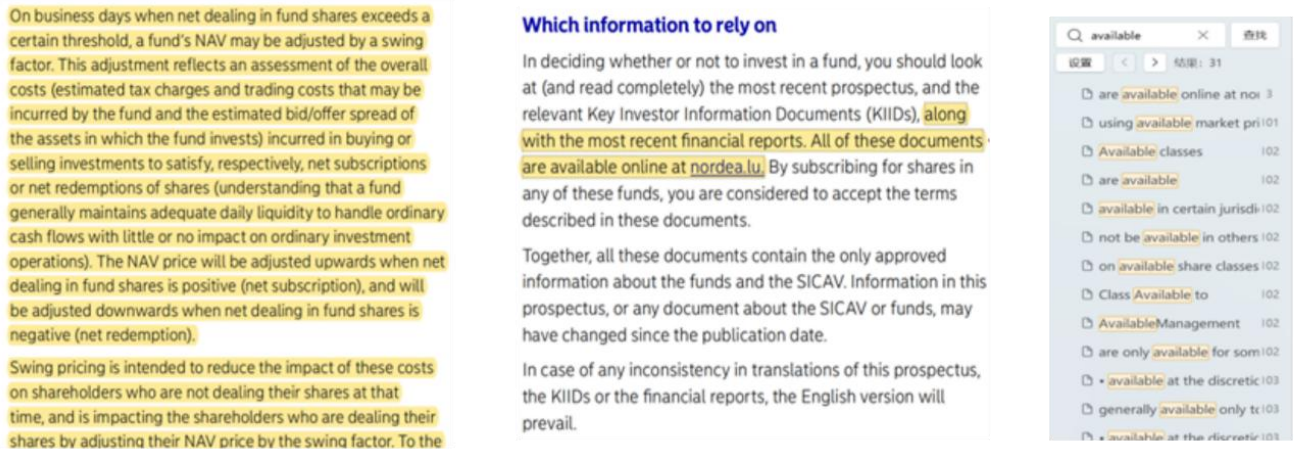
Navigating the Landscape of Automated Information Extraction for Financial Fund Prospectuses: Survey and Challenges

Yuyao Xu, Mohamad Farhan Mohamad Mohsin
School of Computing (SoC), University Utara Malaysia (UUM), 06010 Sintok, Kedah, Malaysia

***Abstract*—In the financial sector, a fund prospectus is a critical document mandated by the Securities and Exchange Commission (SEC) that provides vital information about investments to the public. These documents encompass a range of financial concepts that define the fund's operations, including its name and disclaimers associated with periodic reports. Traditionally, the identification of these concepts has been a manual, labour-intensive, and costly task for financial regulators, aimed at ensuring the completeness of information. Automating this process is fraught with challenges, including the lengthy nature of prospectuses, the nuances of financial language, and the scarcity of labelled data for effective model training. This study explores state-of-the-art methods for information extraction, specifically within the context of financial documents. It begins with an overview of information extraction, detailing its definition and various types, such as Named Entity Recognition (NER) and event extraction. The discussion highlights the increasing significance of information extraction in the financial domain and reviews typical application areas. Ultimately, this research seeks to highlight the challenges within existing methods through a comprehensive literature review, emphasizing the need for more effective techniques tailored to the extraction of financial concepts in fund prospectuses. By enhancing and streamlining the extraction process, it aspires to improve efficiency and reduce costs for financial regulators, thereby ensuring more accurate and comprehensive information dissemination.**



Keywords*—Machine learning; information automation; financial documentation

I. Introduction

Financial documents (also known as financial statements) are formal records that provide a comprehensive and accurate representation of an enterprise's financial status, performance, and cash flow over a specific period. There are many types of financial documents, such as financial news, discussion boards, annual financial reports, and fund prospectuses. In the financial sector, every investment fund is mandated to provide detailed and informative financial documentation. These documents enable regulatory authorities and investors to comprehensively evaluate all pertinent and material information regarding the investment. For example, the prospectus offers an in-depth account of the public investment opportunity. Such documentation, primarily conveyed through natural language, supplemented with tables and mathematical formulations, serves as critical instruments in safeguarding regulatory compliance and ensuring transparency and oversight of the investment. These financial documents are highly regulated, which are important to every company. The regulations that apply depend on the type of fund to which the documents refer and on the countries in which the fund is distributed. Specifically, the regulations clearly outline the specific information that must be included in each type of document. Based on these requirements, legal experts can develop 'suggested wording' to ensure that fund documents are both compliant with regulatory standards and accurately convey the necessary details. The suggested wording is by no means universal, since asset and fund managers customize the narrative of fund documents to differentiate their products from those of the competitors. Furthermore, both funds and regulations change over time; as a consequence, it is important to update the corresponding fund documentation accordingly.

When financial documents are submitted to the financial regulator, the regulator needs to manually read the financial document and check the correctness of it. One of the most information factors that affects the correctness is that the financial document should clearly specify all the information needed in each type of document. The current practice for finding the sentences related to each type of information in the financial documents is still largely a manual activity [1, 2]. The financial regulator has to search for some “keywords” for each type of information, and check if the returned results are complete. This searching process is time-consuming and costly [1]. On one hand, there could be hundreds of types of information. The regulator has to manually type keywords related to all these types of information to completely check the financial documents, which is time-consuming. Besides that, many sentences can match the same keyword [3]. The regulator must select the right sentences describing each type of information to understand whether the sentences correctly explain the corresponding type of information. This process is costly. Doing so often turns out to be a complex, time-consuming and expensive activity, noting that the relevant information may not be in a structured form but rather provided through textual statements. For example, Fig. 1 shows two snippets of financial documents (i.e., prospectuses). The two snippets show a part of text churn related to the financial concepts “swing pricing” and “disclaimer on periodical reports". The text related to each financial concept is quite different. For swing pricing, a very long text churn is labelled as related to it [see Fig. 1(a)]; while there is only one sentence related to ‘disclaimer on periodical reports’ [see Fig. 1(b)], which shows that the report is available online. Such text churn is not easy to locate. If the regulator searches some keywords

(e.g., available), 31 results are returned, as in Fig. 1(c). The regulator has to examine 31 paragraphs to find the text related to 'disclaimer on periodical reports. An alternative is to locate the text based on the title of paragraph; however, there are still hundreds of titles in the document. The regulator may not easily know that the text related to 'disclaimer on periodical reports' is under the paragraph with the title "which information to rely on".

(a) swing pricing (b) Disclaimer on periodical reports (c) Result of keyword search

Fig. 1. Examples of financial documents and financial concepts.

II. Motivation

A fund prospectus is a formal legal document required by regulatory authorities, such as the Securities and Exchange Commission (SEC), that provides detailed information about an investment fund [4]. It is designed to inform potential investors about the fund's objectives, strategies, risks, fees, performance, and other essential details to help them make informed investment decisions. The significant manual effort required frequently results in increased fund setup costs, extended time-to-market for fund products, and heightened compliance risks. There is therefore a need for automating finding the sentences related to each type of information. By doing so, the financial regulator can directly find the necessary sentences without manual checking. If the automated identification is accurate, the regulator also does not need to select the right sentences from all the returned results. In this study, the type of information to be extracted is referred to as financial concepts, which explain the concept, behaviour, definition, and metadata of financial activities, such as the detailed explanation of the calculation methodology for determining the issue price, along with the specific conditions and procedures governing the issuance process. All these concepts need to be clearly explained in certain types of financial documents.

Existing studies focus on mining financial data from web media (e.g., financial news and discussion boards [5]) and traditional financial documents (e.g., annual financial reports and 10-K) [6]. Besides, tracing information in documents has been widely studied in the areas of information extraction and software engineering [7, 8]. In these areas, they extract named entities from news and block [9]; based on different entities, the events related to each entity are also extracted [10, 11]. However, all these methods are not designed for the need of financial concept extraction in financial documents, which are more complex documents compared to discussion boards in the financial domain.

This study is proposed by analysing financial concepts in financial documents, taking fund prospectus documents in stock markets as a case study, and developing a tool-supported solution that can analyse a financial document (i.e., fund prospectuses) to automatically extract key types of information (i.e., financial concepts). The selection of the fund prospectus for the case study is due to its special characteristics. First, compared to other financial documents like financial news and discussion boards, fund prospectuses are lengthy with hundreds of pages, which increases the time for users to read the documents. Second, fund prospectuses are also difficult to read compared to financial news and discussion boards, since fund prospectuses may use similar sentences to refer to different types of financial concepts. Therefore, it could be helpful for users if the financial concepts could be automatically extracted from fund prospectuses.

III. Contribution

This study explores the significant challenges involved in the automated identification of financial concepts within fund prospectuses, a task that has traditionally required manual intervention by financial regulators. Fund prospectuses, which are essential documents regulated by the SEC, include crucial information about investment funds. However, their complexity and length pose considerable obstacles to automation.

The first challenge arises from the extensive nature of prospectuses, which often results in much longer texts than those typically addressed in existing research. This length complicates the extraction of relevant financial concepts. Additionally, the nuanced language specific to finance means

that even minor variations in wording can lead to significant changes in meaning, making accurate identification even more difficult.

Furthermore, the scarcity of labelled datasets for training machine learning models in this domain presents another critical barrier, limiting the effectiveness of current automated approaches. While existing information extraction methods have proven successful with other document types, such as scientific articles and web pages, they fall short when applied to fund prospectuses.

By tackling these specific challenges, this research seeks to offer valuable insights that will lead to the development of more effective strategies for extracting financial concepts from fund prospectuses. This endeavour aims to enhance regulatory compliance and improve transparency within the financial sector, ultimately establishing a foundation for better information accessibility for all stakeholders involved.

IV. Organization

This study is structured into several key sections to provide a comprehensive exploration of information extraction in financial contexts, as shown in Fig. 2. The Introduction sets the stage by discussing the significance of fund prospectuses within the financial sector and underscores the critical role of information extraction in enhancing regulatory processes. In the Motivation section, the study elaborates on the rationale behind the study, emphasizing the challenges currently faced in automating the extraction of financial concepts from these complex documents. The Organization section outlines the study's structure, guiding readers through the subsequent content. The Contribution section identifies the unique contributions of the research to the field of information extraction, highlighting innovative approaches or insights that advance understanding. Following this, the Information Extraction section provides a general overview of various extraction techniques and their practical applications, laying the groundwork for more specific discussions. The study then shifts focus to Named Entity Recognition (NER), detailing various methods such as rule-based, feature-based, and deep learning-based approaches, and includes a critical discussion on the limitations of existing NER methods.

The Event Extraction section defines the essential concepts and tasks involved in extracting events from financial texts, followed by an examination of both pattern-matching and machine learning-based methods for event extraction. Finally, the study concludes with a section on Research Challenges and Future Directions, which identifies significant challenges in the field and offers recommendations for future research, aiming to inspire further advancements in the extraction of financial information.

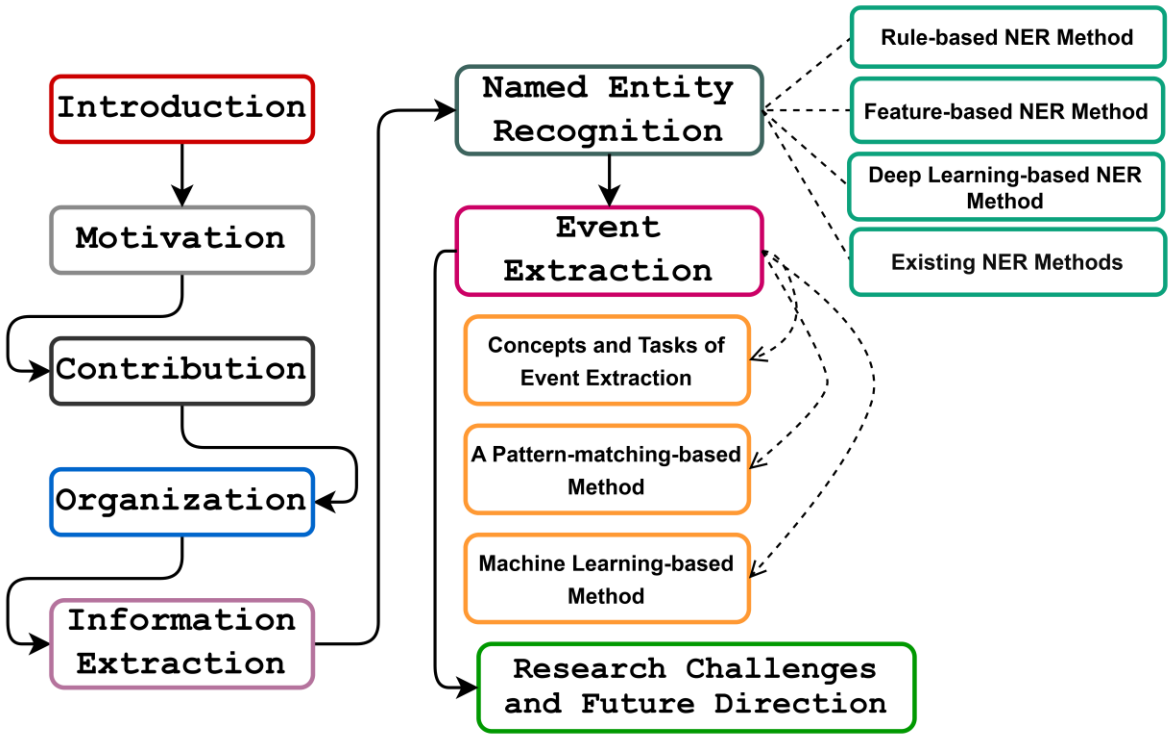


Fig. 2. Composition of the document.

V. Information Extraction

With the swift advancement of information technology, the volume of online data continues to grow daily. Therefore, it becomes the focus of people's attention on how to obtain valuable information from massive data. To achieve this goal, information extraction is the technology for it. Information extraction refers to the structured processing of information contained in text into a specific structure of organization [12]. The typical information extraction tasks include NER and event extraction [13].

- NER refers to the extraction of entities in text; the entities are usually small pieces of phrases describing certain concepts. The example of NER in fund prospectus is the valuation day. The phrase 'Weekly, each Tuesday' explains the day for valuation. However, there are many dates in fund prospectuses; only this date indicates the valuation day, making this entity hard to identify. Another example is 'disclaimer on periodical reports', which should be a link to download the periodical reports. However, there are also many links in the fund prospectuses. Existing NER techniques cannot distinguish them.
- Event extraction is equivalent to the extraction of multiple sentences to explain 5W (i.e., what, who, when, where, why). The example of an event in fund prospectus is a disclaimer on periodical reports. The sentence 'along with the most recent financial reports, all of these documents are available online at nordea.lu' should be extracted as an event, which shows where the periodical reports can be obtained.

For instance, information extraction tasks can retrieve details such as time, location, and key individuals from news articles, as well as product names, development timelines, and performance metrics from technical documents. Additionally, it can extract factual information relevant to users from natural language texts. The applications of information extraction span various fields, including finance, journalism, and healthcare, highlighting its versatility and importance across multiple domains. This subsection defines the tasks of information extraction as follows.

First, for a document with N sentences, D = (S1, S2, ..., SN). Information extraction aims to extract entities, events, and relationships in D. The entity in D is represented as (E1, E2, …, EN) = H (S1, S2, ..., SN), where E1, E2, …, EN are the entities, which are the words in sentences S. NER is to find a function H, what can identify the target E in S. Regarding event extraction, it defines a function P, which can select a set of sentences in S. It has Eventm = Pm (S1, S2, ..., SN), which uses a subset of S to form different events. According to the above formal definition, the task of information extraction is:

"A process of automatically extracting structured information from unstructured and semi-structured data sources. It involves the identification, classification, and extraction of relevant information from textual, numerical, or multimedia data sources" [14].

In this study, the task is to extract the financial concept in fund prospectuses. Financial concepts are the phrases, sentences, and paragraphs to explain the related concepts in financial documents, such as 'fund names, calculation method for issue prices, and disclaimer on periodical reports'. The identification of these concepts is important for regulators to check fund prospectuses. It is also possible to organize fund prospectuses into structured documents based on the extraction results, whose purpose is the same as the purpose of information extraction. Information extraction can be applied to a wide range of domains, including news articles, social media posts, clinical records, financial reports, and scientific papers. The extracted information may include entities (e.g., people, organizations, locations), events (e.g., births, deaths, mergers), and attributes (e.g., product features, customer data).

Information extraction methods are generally categorized according to the type of information being extracted, primarily into NER and event extraction techniques. In this study, this dimension is used for the literature review. The two classes of models are surveyed since this proposal also plans to extract entities (e.g., fund name, website) and events (e.g., the procedure to calculate issue prices) from fund prospectuses.

VI. Deep Learning Network Architecture

The NER (Named Entity Recognition) mainly completes the identification of predefined semantic type named entities from unstructured data. It is currently widely used in search engines, intelligent recommendations, and machine translation. For example, in machine translation, the named entities need to be identified, since each named entity can also have a specified translation.

NER methods can be divided into two methods: rule-based methods and machine learning-based methods [15], as shown in Fig. 3. Rule-based NER methods rely on predefined patterns, dictionaries, and linguistic rules to identify entities in text, making them particularly useful for domain-specific tasks like financial document processing. These methods often use a combination of regular expressions, lexical resources (e.g., lists of financial terms like "management fees" or "dividend yield"), and linguistic rules (e.g., POS tags or dependency parsing) to detect entities. For example, a rule might specify that a sequence of words following the phrase "expense ratio" and preceded by a dollar sign or percentage symbol should be tagged as a financial metric. While rule-based NER is highly interpretable and effective for structured or predictable text, it requires domain expertise to design rules and may struggle with variability in language.

Machine learning-based methods are divided into two categories according to the degree of dependence on the corpus: supervised NER and unsupervised NER. Machine learning-based NER methods use statistical models to automatically learn patterns and features from annotated data for identifying entities in text. These methods typically rely on sequence labelling models, such as Conditional Random Fields (CRFs) or deep learning architectures like BiLSTM-CRF and transformer-based models (e.g., BERT), to predict entity tags (e.g., "ORG," "PER," or "FINANCIAL_TERM") for each token in a sentence. Unlike rule-based methods, ML-based NER does not require manually crafted rules; instead, it learns from labelled datasets, capturing complex linguistic patterns and contextual dependencies. For example, a model trained on financial documents can learn to recognize entities like "management fees" or "dividend yield" based on their context.

This subsection introduces the relevant methods of NER. It also surveys the hot deep learning methods currently studied.

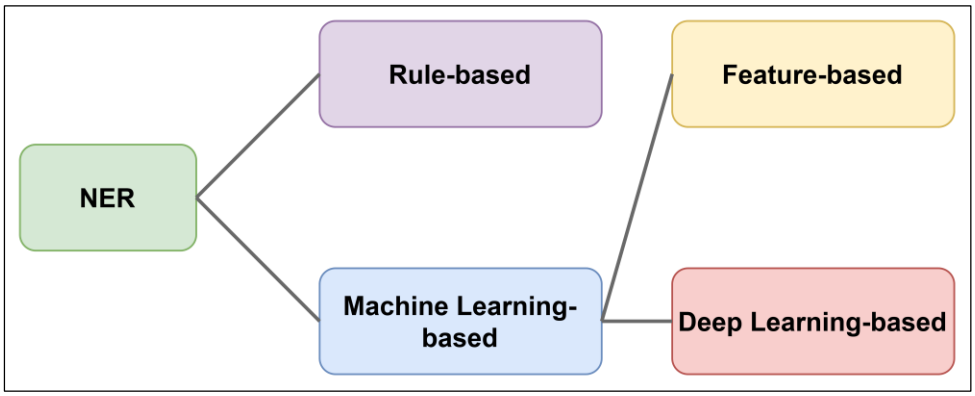

Fig. 3. Classification of NER methods.

A. Rule-Based NER Methods

In the early research stage of NER, the rule-based method was mainly used. The rules are mainly written and formulated by domain experts. The method first writes some simple rules by domain experts, and then experiments are carried out in the corpus. According to [16, 17] the experiment results, the rules are continuously improved after analysing the erroneous results until the effect of NER is satisfactory. Among the rule-based methods, the most commonly used is the dictionary-based matching method, which completes the NER through complete or partial matching of strings. This method is relatively simple and efficient. The implementation of dictionary-based matching methods can usually be implemented by various algorithms, such as forward matching, inverse matching, bidirectional longest matching, and dictionary trees.

The advantage of the rule-based NER method is that there is no need to label the corpus in advance, which has a good effect on a small-scale corpus. The NER system also runs quickly. The disadvantage is that the writing rules have high requirements for the individual level of personnel and poor system portability. Some well-known rule-based NER systems include LaSIE-II [16] and NetOwl [17].

B. Feature-Based NER Method

Feature-based NER methods are supervised methods using traditional machine learning. This method treats NER as a sequence labelling task. The specific algorithm model needs to be trained by using the labelled corpus. In the process of identifying named entities, the feature-based method usually includes the following steps:

a) Corpus labelling: The corpus is typically annotated using either the IOB (Inside-Outside-Beginning) or IO (Inside-Outside) annotation systems, which involve manually labelling the text to identify relevant entities.

b) Feature definition: Key features are defined by selecting the current word, as well as the preceding and following words, along with their parts of speech. These elements significantly influence the performance of NER tasks.

Model Training: Commonly employed models for training. Further, Table I shows several studies on feature-based NER recognition methods, which highlight the implemented methods, target entities, and identify the inadequacies in methods.

TABLE I SUMMARY OF FEATURE-BASED NER METHODS

Method	Description	Target	Type of Documents	Shortcomings
HMM [18]	Analyse word sequence with hidden Markov model	CoNLL2002, CoNLL2003	News and story	These methods demonstrate a notably low level of accuracy.
Traditional CRF [19]	Apply CRF for NER in biomedical domain	CoNLL2002, CoNLL2003	News and story	
CRF-based hybrid model [20]	Combine CRF with rules	CoNLL2002, CoNLL2003	News and story	
Traditional SVM [18]	Apply SVM for NER in biomedical domain	CoNLL2002, CoNLL2003	News and story	
Language independent SVM [21]	A language independent SVM model	CoNLL2002, CoNLL2003	News and story	
Traditional SVM [22]	Apply SVM for NER in real-time text	GENIA	Text in video	

C. Deep Learning-Based NER Method

Compared with the feature-based NER method, the deep learning-based NER method does not require manual rules or complex features. It is easy to extract hidden features from the input corpus. In NER tasks, commonly used neural networks mainly include Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), and neural networks based on attention mechanisms. Among them, Long Short-Term Memory Neural Network (LSTM) in RNNs has been widely

used in NER tasks. Li et al., proposed a typical architecture for deep learning NER methods in 2020 [23], as shown in Fig. 4. The architecture is divided into three main parts:

1) Input distributed representations, which consider embeddings at the word and character levels, and combine additional features that are already effective in feature-based methods, such as part-of-speech tags and gazetteers.

2) Context encoder, which uses CNNs, RNNs, or other networks to capture context dependencies.

Tag decoder, which is mainly used to predict the label of the input sequence. Numerous studies on deep learning-based NER methods are presented in Table II, which outlines the employed techniques, target entities, and identifies the shortcomings of each method.

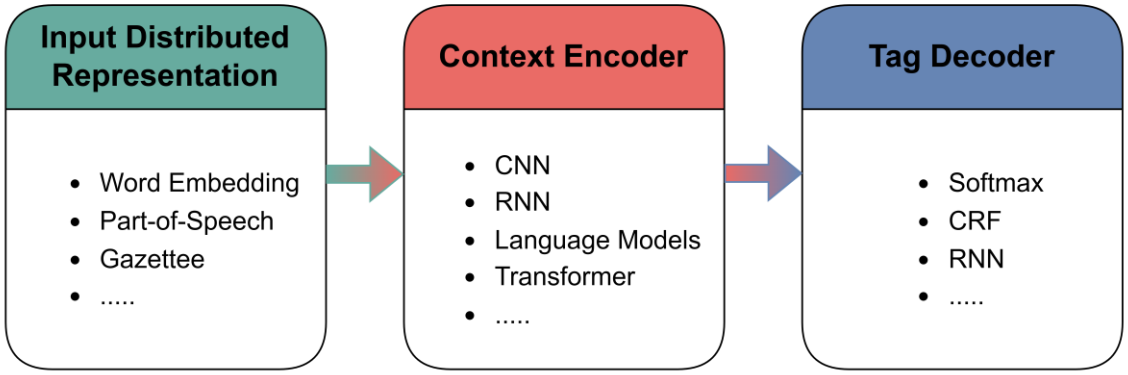

Fig. 4. A typical architecture for deep learning NER methods.

TABLE II SUMMARY OF DEEP LEARNING-BASED NER METHODS

Method	Description	Target	Type of Documents	Shortcomings
BI-LSTM-CRF [24]	A series of LSTM-based sequence labelling models	CoNLL2002, CoNLL2003 (Sentence)	News and story	These methods are intended to extract concise phrases from lengthy sentences (e.g., names, dates, and locations). However, they are built on a sentence-level model, and the target corpora do not pertain to the financial domain.
BiLSTM-CNNs-CRF [25]	An end-to-end sequence labeling model that combines bidirectional LSTM, CNN, and CRF	WSJ, CoNLL2003 (Sentence)	Newspaper, news, and story	
Attention-RNN-CRF [26]	A combination method	CoNLL2000, CoNLL2003, PTB-POS (Sentence)	News and story	
LSTM-CRF [27]	A method that uses LSTM and CRF	CoNLL2000, CoNLL2003 (Sentence)	News and story	
MRC-NER [28]	A method based on machine reading comprehension	WSJ, CoNLL2003 (Sentence)	Newspaper, news, and story	
TENER [29]	An improved Transformer encoder to model character-level and word-level features	CoNLL2003, OntoNotes 5.0 (Sentence)	News, story, blogs, conversations	
SDI-NER [30]	Combining syntactic dependency graphs for Chinese NER	Weibo	Blogs, short, messages	
WNER [31]	Using word-word relations for NER	CoNLL2003, Onto Notes 5.0, Weibo (Sentence)	News, story, blogs, short messages, conversations	
Survey [32]	A survey of NER using deep learning	NaN	NaN	
MINER [33]	Improving Out-of-Vocabulary Named Entity Recognition from an information-theoretic perspective	WNUT2017, TwitterNER, BioNER, Conll03-Typos, Conll03-OOV (Sentence)	Short messages, News, technical literature, Blogs	
kNN-NER [34]	NER with nearest neighbour search	CoNLL2003, OntoNotes,5.0OntoNotes, 4.0, MSRA, Weibo (Sentence)	Short messages, News, story	

E-NER [35]	Evidential deep learning for trustworthy NER	CoNLL2003, OntoNotes 5.0, WikiGold, TwitterNER, CoNLL2003-Typos, CoNLL2003-OOV (Sentence)	Short messages, News, story, Encyclopaedia	
GPT-NER [36]	NER via large language models	CoNLL2003, OntoNotes5.0 (Sentence)	News, short messages, story	
PromptNER [9]	Prompting for NER	CoNLL2003, CrossNER, GENIA (Sentence)	News, story, Biomedical terminology	
UniversalNER [37]	Targeted distillation from large language models for open NER	ACEO5, AnatEM, bc2gm, bc4chemd, bc5cdr, Broad Twitter, CoNLLO3, FabNER, Findvehice, GENIA, HarveyNER	News, short messages, story, Blogs etc.	

Huang et al. proposed a series of LSTM-based sequence labelling models, including LSTM, Bidirectional LSTM (BI-LSTM), LSTM (LSTM-CRF) with Conditional Random Field (CRF), and Bidirectional LSTM (BI-LSTM-CRF) with CRF layer, and compared the performance of the above models on NLP-labelled datasets [24]. In their work, the BI-LSTMCRF model is applied to the NLP benchmark sequence labelling dataset for the first time, and it is proven that the model can effectively utilize past and future input features and sentence-level labelling information. Ma et al. introduced an end-to-end sequence labelling model that integrates bidirectional LSTM, CNN, and CRF [25]. This model operates independently of task-specific resources, feature engineering, and data pre-processing, making it highly versatile.

Rei et al. (2016) proposed a combination method of word vector and character-level vector based on an attention mechanism for sequence labelling tasks [26]. This method argues that NER requires not only word vectors, but also character-level feature vectors in words. Based on the RNN-CRF model, the attention mechanism is used to splice word vectors and character-level feature vectors. Lample et al. (2016) proposed the LSTM-CRF NER model, which relies on two sources of information about words: character-based word representations are mainly learned from supervised corpora; Unsupervised word representation is learned primarily from an unannotated corpus [27].

Li et al. (2019) proposed a framework based on Machine Reading Comprehension (MRC) [28]. This method works with both non-nested and nested types of NER. Compared with the sequence annotation method, this method is simple and intuitive, and has strong portability. Experiments show that the MRC-based method can encode some prior semantic knowledge of the problem, so that it can perform better under small data sets and transfer learning. Yan, Deng, Li, & Qiu (2019) introduced the TENER model, which enhances the original Transformer architecture for NER tasks [29]. This model utilizes an improved Transformer encoder to effectively capture both character-level and word-level features.

Recent advancements in NER have seen diverse methodological innovations. Li et al. (2022) conducted a comprehensive survey highlighting the evolution of deep learning techniques in NER, providing a foundation for contemporary research [32]. Wang et al. (2022) introduced MINER, addressing out-of-vocabulary entity recognition through information-theoretic principles, while their kNN-NER leveraged nearest neighbour search to enhance contextual similarity modelling [33]. Zhang et al. (2023) proposed E-NER, integrating evidential deep learning to quantify uncertainty and improve trustworthiness in predictions [35]. The rise of large language models (LLMs) spurred novel approaches: Wang et al. (2023) developed GPT-NER [36], demonstrating LLMs' potential for direct entity recognition, while Ashok and Lipton (2023) introduced PromptNER [9], optimizing task-specific prompting strategies. Zhou et al. (2023) advanced UniversalNER [37], employing targeted distillation from LLMs to achieve robust performance in open-domain settings. Together, these works reflect a dynamic shift toward leveraging LLMs, probabilistic frameworks, and innovative training paradigms to tackle NER challenges across diverse contexts.

VII. Discussion on Existing NER Methods

As depicted in the last column of Table I, the existing information extraction techniques for NER are not suitable for financial concept extraction in fund prospectuses. The first reason is that all these methods are designed to extract short phrases from sentences, such as person names, URLs, times, and places. For example, a commonly used dataset for training and testing these methods is a dataset such as the CoNLL2003 dataset for NER tasks. CoNLL2003 covers English and German, including around 14,000 documents for English and 12,000 for German, with an average of 12 to 18 sentences per document. However, the financial concepts in fund prospectuses are usually associated with long sentences or paragraphs. These methods cannot model such sentence-level information to extract. The second reason is that, for machine learning based methods, they usually require a large dataset to train or fine-tune the model (e.g., the deep learning methods). As discussed previously, it is not easy to manually label such datasets for financial concept extraction; hence, the effectiveness of these methods could be limited [2].

This study takes the work by Wang et al. (2022) as a baseline [33, 34]. The work proposes MINER to address out-of-vocabulary entity recognition through information-theoretic principles. Since financial documents are different from many existing NER datasets (e.g., news), many out-of-vocabulary entities could exist. MINER can be a good baseline to address this issue. On top of MIER, this proposal represents domain

expert rules as additional information to improve the ability of MINER in identifying long entities (i.e., financial concepts).

VIII. Event Extraction

An event is an objective fact consisting of a specific person, object, and action at a specific time and place. As an important part of information extraction, the key to event extraction is to extract information about events of interest from unstructured text and store it in a structured way [38]. This subsection first introduces the concept and tasks of event extraction. Then, the related works of event extraction based on pattern matching, machine learning, and neural networks are summarized.

A. Concepts and Tasks of Event Extraction

Gathering Event extraction techniques involve concepts such as triggers, event arguments, and argument roles, as listed in Table III.

TABLE III Basic Concepts and Terms for Event Extra

Concepts	Definition
Trigger	The rigger is a word. It is usually a verb or nouns and phrases that represent an action
Event arguments	The entity and entity property that are related to the event, including time, place, and persons
Argument roles	The role of the entity in the event, namely, the relationship between the entity and the event

The aim of event extraction is to identify the type of event and automatically extract arguments with varying roles from unstructured text using machine learning techniques [39]. The event extraction task is divided into two parts: Event Detection (ED) and Argument Extraction (EAE). Among them, event detection aims to identify specific types of event trigger words from a given text; it is a key step in event extraction [40]. Event Element Extraction identifies the elements of a particular event and marks its role [41]. For example, in the sentence “Biden swears inauguration at Capitol on January 20”, the event extraction task is specifically to detect the trigger word “inauguration”, which is the incident type; The words "Biden", "January 20" and "Capitol" are as the event elements, which can be determined as "person", "time" and "place", respectively.

The implementation of the above event extraction task is based on the technical basis of word segmentation, part-of-speech, and propositional entity recognition [42, 43]. The extracted structured information can further support deeper mining and understanding of unstructured text.

Table IV summarizes the main methods for event extraction. The methods can be classified into pattern-matching-based methods and machine learning-based methods. Early event extraction techniques typically use a pattern-matching-based method. Pattern-matching-based event extraction involves identifying specific events in text by matching predefined patterns or templates that describe how events are typically expressed.

TABLE IV Summary of Event Extraction Methods

Methods		Characteristics
Pattern matching-based		Works better in specific areas, but the process is cumbersome, prone to cascading errors, and depends on the specific text form of the specific domain
Machine learning-based	Feature-based	Relies on complex feature engineering and natural language processing tools
	Neural network-based	Works better in many EE tasks. It requires large corpus to train or fine-tune the model. It takes a long time to train the model and conduct prediction

These patterns often combine lexical cues (e.g., keywords like "acquire" or "merge"), syntactic structures (e.g., verb-argument relationships), and semantic constraints (e.g., entity types involved in the event). Pattern-matching methods are highly interpretable and effective for structured or predictable text, such as news articles or financial reports, where events follow consistent linguistic patterns. However, they require domain expertise to design patterns and may struggle with linguistic variability or complex sentence structures.

In recent years, due to the promotion of the construction of large-scale corpus and the rise of machine learning, researchers have begun to explore methods based on machine learning. Machine learning-based event extraction methods use statistical models to automatically identify and classify events (e.g., mergers, earnings announcements) in text by learning patterns from annotated data. These approaches often frame event extraction as a structured prediction task, where models like sequence labelling (e.g., BiLSTM-CRF) or transformers (e.g., BERT, GPT) are trained to detect event triggers (e.g., verbs like "acquire" or "announce") and their associated arguments (e.g., entities, time, location). For instance, a model might learn that the phrase "Company X announced a merger with Company Y" contains a "merger" event involving two organizations. Unlike rule-based methods, ML approaches generalize better to linguistic variability and implicit event mentions (e.g., "the acquisition was finalized"). They leverage contextual embeddings to capture semantic relationships and dependencies, but require large, labelled datasets for training.

B. A Pattern-Matching-Based Method

The pattern-matching-based method consists of two steps: pattern acquisition and event extraction. Firstly, the event pattern extraction is obtained through local text analysis, such as lexical analysis and syntactic analysis. Then, under the guidance of the event pattern, the event sentence to be extracted is matched to the corresponding pattern to detect and extract an event type, as shown in Fig. 5.

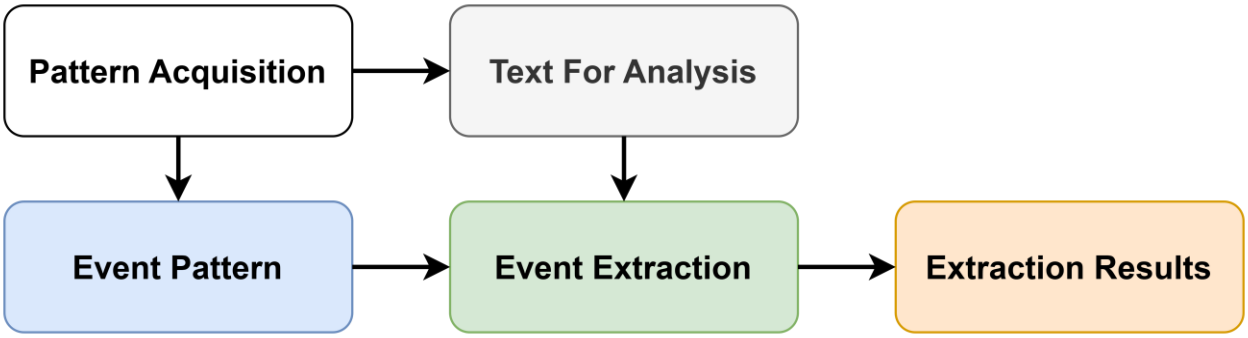

Fig. 5. Event extraction method based on pattern matching.

The supervised pattern matching method relies on a manually labelled corpus. The quality of the human-labelled corpus affects the effect of pattern learning. Therefore, Riloff (1993) mentions that statements near event elements often contain descriptions of the role of event elements in events [44]. This work constructs a domain-specific pattern for event extraction through supervised learning combined with human review.

Supervised pattern matching methods rely heavily on labelled corpus. Therefore, some researchers propose methods based on weak supervision. This type of method only requires manual pre-classification of the corpus or the definition of a small number of artificial seed patterns. Then, the method automatically learns the event mode according to the pre-classified corpus or seed mode. Based on the literature, the process only needs to label the event type but does not need to label all event elements in the corpus, which reduces the workload required to create a corpus. Table V summarizes the main works of pattern-based event extraction. A previous study (Roman, 2000) constructs a seed pattern set, divides the unlabelled corpus into related text sets and unrelated text sets [45]. It then explores the relevant patterns of related text sets to learn new models incrementally. Although this method (Roman, 2000) does not require artificial corpus labelling, the pre-classification labelling and seed pattern set they introduce are still relatively heavy. In order to solve this problem, the paper (Jiang, 2005) proposes a domain-independent pattern representation method, which is integrated into the WordNet conceptual knowledge base [46]. When performing pattern acquisition, this method only needs to define the event extraction task. The corresponding event extraction pattern can be automatically learned from the original corpus, which minimizes the intervention of manual annotation on pattern-matching event extraction. Other early studies, such as [47], demonstrated the utility of domain-specific patterns in biomedical event extraction, leveraging tailored rules to extract events from scientific literature. Similarly, Liao and Grishman (2011) combined semantic role labelling (SRL) with pattern-based rules to refine event extraction, showcasing the synergy between linguistic structures and rule-based methods. In recent years, pattern-based approaches have been enhanced by integrating them with deep learning techniques. For instance, Zhang et al. (2020) proposed a rule-augmented deep learning framework for event extraction in low-resource settings, emphasizing the value of pattern-based methods when annotated data is scarce [41]. Chen et al. (2021) further advanced this hybrid approach by incorporating dynamic multi-pooling convolutional neural networks (CNNs) to improve contextual understanding and event detection accuracy [48]. Additionally, Li et al. (2022) explored the use of transformer models like BERT alongside pattern-based rules for clinical event extraction, demonstrating their effectiveness in specialized domains [49]. These studies collectively illustrate the evolution of pattern-based methods, from standalone rule-based systems to hybrid frameworks that leverage the strengths of both traditional and modern NLP techniques. Learning models utilized for UATR often exhibit high complexity, which can lead to significant challenges in training effectiveness. When the complexity of a model exceeds the available quantity and quality of training data, achieving desired outcomes becomes increasingly difficult. While improving model accuracy is a primary objective, relying solely on accuracy as the sole metric for evaluating model performance is insufficient.

TABLE V SUMMARY OF PATTERN-BASED METHODS

Reference	Contribution	Usage scenarios
[45]	Build a seed pattern set for event extraction	Pattern-based methods require constructing patterns to extract events; however, the pattern is not easy to build, which limits their usage scenarios.
[46]	Propose domain-independent patterns	
[47]	Propose domain-specific patterns	
[50]	Combined semantic role labelling with pattern-based rules	
[41]	Propose a rule-augmented deep learning framework for event extraction	
[48]	A hybrid approach by incorporating dynamic multi-pooling CNNs	
[49]	Explored the use of transformer	

Although the pattern-based matching method is more effective in specific domains, the method is cumbersome in the process, prone to cascading errors, and depends on the specific form of the domain-specific text and requires participants to have strong professionalism in the process of obtaining patterns. Hence, its cost is high, and the formulated pattern is difficult to cover all event types. When the corpus changes, the pattern also needs to be updated, resulting in poor system generalization and low recall.

C. Machine Learning-Based Method

Compared with pattern matching methods, machine learning methods are more adaptable and portable to different domains. The machine learning-based method transforms the event extraction task into a classification problem on the basis of statistical learning and selects the appropriate feature input to the classifier to complete the extraction task. Typically, these classifiers include event trigger word classifiers, argument classifiers, and argument role classifiers. These classifiers can employ classification models such as maximum entropy and support vector machines in machine learning.

Chieu et al. first time applies the maximum entropy model for argument extraction and constructs a classifier to realize the event extraction of lecture announcements by defining simple features such as named entities, first words in sentences, lexical lowercase forms, and time expressions [51]. In order to extract more features in the feature engineering stage and improve performance, Llorens et al. (2010) also introduce semantic corner colour features; it use conditional random field model to realize event extraction and achieve good results [52]. Li et al. (2013) [53] further introduce global features to improve performance on the basis of Llorens et al. (2010) [52], and use trigger words and dependencies between multiple arguments for event extraction.

Different machine learning algorithms often have different advantages and disadvantages. It is possible to combine multiple machine learning methods to improve the event extraction effect. Ahn (2006) combines two machine learning models, which are the memory-based nearest neighbour learner and maximum entropy learner, to propose a simple modular event extraction method [54]. This method constructs multiple classifiers for each module separately; it uses lexical features, dictionary features, context features, dependency features, and entity features to complete the event extraction.

Machine learning-based event extraction often relies on complex feature engineering and natural language processing tools, which often require deep exploratory data analysis on the corpus. The cumbersome and tedious nature of this process, as well as the accumulation and propagation of errors caused by various types of feature extraction processes, will more or less affect the extraction results.

In recent years, deep learning has been a popular method to represent data in machine learning. Compared with traditional machine learning methods (feature-based), deep learning avoids the tedious work of manual feature engineering; it does not require rich domain expert knowledge and only needs to pass data directly to the built network. Its portability and flexibility have prompted more and more researchers to focus on deep learning-based methods.

The event extraction method based on deep learning can be divided into the method of pipeline model and the method of a document-level model, according to the different learning methods of the model. Pipeline model is a model that recognizes named entities and extracts events as a pipeline, while the method of document-level models is to learn the characteristics of events for extracting events directly without considering the named entities. Depending on the range of features used, it can be divided into sentence-level methods and chapter-level methods. Table VI displays recent works that utilize a combination of pipeline and document-level models, with the majority employing deep learning-based approaches.

TABLE VI SUMMARY OF MACHINE LEARNING-BASED METHODS

Ref	Contribution	Usage scenarios
[11]	Using regression forest for event extraction	Extract events in two steps. First it extracts named entities, and then events are extracted based on the named entities. As explain in existing methods for NER may not work on fund prospectus, which can affect the effectiveness of applying pipe models on financial concept extraction.

[69]	Event Detection as Multi-task Text Generation	
[10]	A Data-Efficient Generation-Based Event Extraction Model	
[70]	Boosting Low-Resource Information Extraction by Structure-to-Text Data Generation with Large Language Models	

The event extraction method based on the pipeline model executes subtasks sequentially. Subsequent tasks depend on the results of the former. Chen at el. (2015) present event extraction as a two-stage multi-classification process, introducing a dynamic multi-pool convolutional network [48]. In the first stage, each word is classified to detect a trigger word. If a trigger is identified, the second stage classifies the trigger and assigns its meta-role. Yang at el. (2019) propose a framework based on the pre-trained model BERT (Bidirectional Encoder Representations Transformers), which includes a trigger word classifier and a metaclassifier that obtains results by inference and referencing the former [59].

Different classifiers can also be used for each stage. For example, Ding at el. (2019) uses LSTM (LongShort-Term Memory) in the event detection stage to construct a trigger perceptual feature extractor to dynamically learn character-level, part-of-speech, and semantic-level features to achieve event detection on the Chinese corpus [60]. Compared with the LSTM model, Bi-LSTM (Bi-directional Long Short-Term Memory) can learn long-term dependent information more effectively in sequence labelling tasks. Zeng et al. (2016) use a Bi-LSTM model to capture the semantic and structural features of sentences and achieve good results in the event detection stage [61]. Satyapanich et al. (2020) use the pre-trained model BERT to fine-tune Bi-LSTM in the event detection stage for trigger word classification [62], while the method of Zheng et al. (2018) in the argument extraction stage adds an attention mechanism after the Bi-LSTM layer for meta-recognition and finally assigns the meta role through the neural network [63].

In the deep neural network, hidden vectors in graph convolutional networks may contain noise information that is not related to candidate trigger words. Dac Lai et al. (2020) add a gate mechanism in each graph convolutional layer to filter the noise information in the hidden vector, but this method ignores the dependent label information [64]. The edge-enhanced graph convolutional network proposed by Cui et al. (2020) has achieved good results on the ACE2005 dataset by combining syntactic structure and type-dependent labels to improve event detection [65]. In order to capture the intermediate structure of the sentence, Veyseh et al. (2020) combine the syntactic and semantic structures through the application of the graph converter network; it captures the intermediate structure of the sentence from different input perspectives and then multiplies the intermediate structure to generate the final structure [66]. In addition, in order to enhance the inference ability of complex events, Li et al. (2019) combine knowledge from hierarchical knowledge graphs and graph neural networks on the basis of pre-training models [67].

Recent advancements in event extraction have introduced innovative approaches to address its inherent challenges. Lu et al. (2022) enhanced event identification by integrating coreference resolution, improving the ability to link event mentions across text [68]. Li et al. (2022) provided a comprehensive survey of deep learning techniques in event extraction, offering a roadmap for ongoing research [32]. Anantheswaran at el. (2023) reimagined event detection as a multi-task text generation problem, leveraging generative models to capture complex event structures [69]. Hsu et al. (2023) proposed a data-efficient generation-based model, addressing the scarcity of labelled data by optimizing generative frameworks for event extraction [10]. Ma et al. (2023) tackled low-resource scenarios by employing large language models for structure-to-text data generation, significantly boosting performance in information extraction tasks [70]. Together, these works highlight a shift toward leveraging generative models, coreference resolution, and data-efficient strategies to advance event extraction capabilities across diverse domains.

IX. Research Challenges and Future Directions

Event extraction extracts events from documents. The event is usually longer than named entities; hence, this task is more similar than financial concept extraction. Currently, many methods have been proposed. They extract events in two steps. First, it extracts named entities, and then events are extracted based on the named entities. As discussed previously, the existing methods for NER may not work on a fund prospectus, which can affect the effectiveness of applying pipe models on financial concept extraction. Second, there are ambiguity problems in fund prospectuses. Similar sentences may have different meanings when the context is different. The same entity can also have different meanings in different contexts, as discussed previously. Therefore, when extracting information, it is important to consider the context of the event (i.e., sentences) and conduct a multi-grained comparison on sentences (e.g., on word-level, sentence-level, keyword-level). Third, all these methods require a large, labelled data set to train the model, which is not available in financial concept extraction.

A. Small Training Set Issue in Financial Document Extraction Domain

Due to the scarcity of labelled training data, financial documents are often highly specialized, containing domain-specific terminology, complex structures, and sensitive information, making it difficult to obtain large, high-quality annotated datasets. There are a few studies to address the small training set issue in financial document information extraction.

B. Data Augmentation

The first solution is data augmentation. Anantheswaran et al. introduced a multi-task text generation framework for event detection, which can be adapted to financial information extraction [69]. By generating diverse textual representations of financial events, their method effectively expanded the training set without requiring additional manual annotations.

C. Transferring Learning and Pre-Trained Language Models

The sconed solution is transferring learning and pre-trained language models. Hsu et al. developed a data-efficient generation-based model for event extraction, leveraging pre-trained language models (PLMs) to transfer knowledge from general-domain corpora to financial documents [10]. Their approach minimized the need for large, annotated datasets by fine-tuning PLMs on small, domain-specific data.

D. Few-Shot and Zero-Shot Learning

The third solution is few-shot and zero-shot learning. Ashok and Lipton introduced PromptNER, a prompting-based approach for NER that enables few-shot and zero-shot learning [9]. By framing information extraction tasks as natural language prompts, their method reduced reliance on large, annotated datasets, making it particularly suitable for financial documents with limited labelled examples. Zhou et al. proposed UniversalNER, which uses targeted distillation from LLMs to perform open-domain NER with minimal supervision [37]. Their approach demonstrated robustness in low-resource settings, including financial document information extraction.

As shown in Table IV and Table V, there are many publicly available datasets for NER such as CoNLL2003. However, these datasets do not have financial concepts to extract. For

example, the CoNLL2003 dataset is widely used benchmarks for NER tasks. CoNLL2003 covers English and German. CoNLL2003, published in 2003, includes around 14,000 documents for English and 12,000 for German, with an average of 12 to 18 sentences per document. The dataset primarily consists of news articles, making them representative of the news domain. Therefore, these datasets cannot solve the small training set issue in financial concept extraction.

X. Conclusion

In conclusion, the comprehensive analysis of information extraction techniques in this study highlights the critical importance of accurately capturing financial concepts within fund prospectuses. As established, the completeness of content in these documents is vital for investment funds, necessitating rigorous oversight from financial regulators. Despite the availability of various information extraction methods, significant challenges remain when applying these techniques to fund prospectuses, particularly due to their inherent complexity, linguistic ambiguity, and the scarcity of labelled data for effective training. The identified gaps in existing research emphasize the need for tailored frameworks specifically designed for financial concept extraction in this context. This research addresses these specific challenges to provide valuable insights that will facilitate the creation of more effective strategies for extracting financial concepts from fund prospectuses. The goal is to enhance regulatory compliance and increase transparency in the financial sector, thereby laying the groundwork for improved information accessibility for all stakeholders.

Proactive Cancer Prediction Using IoT and Deep Learning Before Symptoms

Mohamed Amine Meddaoui, Imane Karkaba, Moulay Amzil, Mohammed Erritali
Data4Earth Laboratory, Sultan Moulay Slimane University, Beni Mellal, Morocco

***Abstract*—The ability to predict cancer before the onset of clinical symptoms represents a paradigm shift in oncology and preventive medicine. Existing diagnostic approaches remain reactive, relying on imaging or symptomatic manifestations that frequently detect the disease only at advanced stages, particularly in pancreatic, lung, and ovarian cancers. To address this gap, we propose a novel methodology that integrates the Internet of Things (IoT), Artificial Intelligence (AI), and Deep Learning for proactive cancer prediction. Continuous high-resolution physiological, behavioral, and environmental data are collected through IoT-enabled wearable and implantable devices and analyzed using a hybrid architecture that combines Autoencoders, Convolutional Neural Networks (CNNs), and Recurrent Neural Networks (RNNs), with a specific focus on Long Short-Term Memory (LSTM) models. Unlike previous work, which primarily targeted general IoT-based monitoring or symptom-driven detection, this study explicitly demonstrates how the fusion of multidimensional IoT data and advanced deep learning enables the identification of micro-level deviations from an individual's baseline as early biomarkers of cancer risk. Experiments conducted on synthetic datasets simulating pancreatic, lung, and ovarian cancer progression show that the proposed framework achieves an accuracy of 89%, a sensitivity of 85%, a specificity of 91%, and an AUC of 0.93, with an average early detection lead time of 7.5 months. These findings highlight the rigor and originality of the proposed approach, which advances the field by offering a validated, proactive methodology for cancer prediction and establishing clear differences from prior studies by the authors that focused on narrower IoT applications. This work paves the way for predictive and preventive oncology, where intervention can occur long before clinical manifestation of the disease.**

Keywords*—Deep learning; internet of things; artificial intelligence; convolutional neural network; recurrent neural network; long short-term memory; autoencoders; cancer prediction

I. Introduction

Cancer remains one of the most pressing global health challenges and a leading cause of mortality, accounting for nearly ten million deaths annually according to the World Health Organization. Despite significant advances in therapeutic protocols and diagnostic technologies, for Hussain [1], survival outcomes continue to depend heavily on the stage at which the disease is detected. The medical consensus is clear: early detection substantially improves survival rates as proposed by Moglia [2]. It reduces the invasiveness of treatment, and enhances patients' quality of life. Nevertheless, conventional diagnostic approaches such as imaging, biomarker assays, and population-wide screening, for Gong [3], these programs often identify cancer only after the appearance of macroscopic lesions or clinical symptoms. For aggressive cancers such as pancreatic, lung, and ovarian, symptoms usually manifest at advanced stages as cited by Bicheng [4], leaving patients with limited treatment options and poor prognosis. This reality underscores the inadequacy of the existing reactive paradigm in oncology, where interventions predominantly occur after disease manifestation. In recent years, there has been a shift toward preventive and predictive medicine, as tried by Panda [5], aiming to anticipate and mitigate disease before symptoms appear. Within oncology, the ability to forecast cancer, as proposed by Tirumanadham [6], risk in pre-symptomatic stages, represents a transformative opportunity. Such an approach would allow interventions long before tumor progression or metastasis, thereby opening the door to a truly preventive model of cancer care. For Yang [7], the emergence of the Internet of Things (IoT) and the rapid progress of Artificial Intelligence (AI), particularly deep learning, have created unique opportunities to realize this vision. IoT-enabled devices such as wearable sensors, implantable biosensors, and environmental monitoring systems can continuously capture multidimensional data streams reflecting physiological, behavioral, and environmental factors, for Meddaoui [8]. These data, imperceptible to conventional diagnostic methods, may reveal subtle deviations that precede clinical symptoms by several months. Deep learning models, with their capacity to handle complex and heterogeneous data, are ideally suited to detect such micro-level anomalies and temporal patterns, as mentioned by Anandan [9], enabling the proactive identification of elevated cancer risk. However, despite promising advances, existing research remains limited in scope. Most oncology studies rely on single modalities such as imaging or genomics, while IoT-based healthcare applications focus mainly on chronic disease management, patient monitoring, or symptom-driven detection. few, if any, frameworks integrate multimodal IoT data with advanced hybrid deep learning architectures for the specific purpose of pre-symptomatic cancer prediction. This gap highlights the need for a comprehensive, end-to-end methodology, as proposed by Zhang [10] that unifies continuous data collection with deep learning models capable of anomaly detection and temporal sequence analysis. The present work addresses this gap. The research problem examined in this study is the lack of integrated IoT–deep learning systems for proactive cancer prediction before the onset of clinical symptoms. As suggested by Youssef [11], the objective of this study is to design and evaluate a hybrid architecture that combines autoencoders, convolutional neural networks (CNNs), and recurrent neural networks (RNNs) with a specific focus on Long Short-Term Memory (LSTM), as presented by Zaher [12], models to detect subtle deviations from personalized health baselines. The key contributions of this study are fourfold: We

propose a novel proactive cancer prediction methodology that unifies continuous IoT-based data collection, as proposed by Savka [13], with a hybrid deep learning framework for anomaly detection and temporal modeling. We validate this methodology using simulated datasets for three cancers: pancreatic, as used by Mukherjee [14], lung and ovarian, where early detection remains particularly challenging. We introduce a new evaluation metric, the early detection lead time, as demonstrated by Islam [15], which quantifies the temporal advantage gained by identifying risks months before symptom onset. We clearly distinguish this work from our prior, as observed by Alatawi's [16] research on IoT-based monitoring applications by demonstrating its originality in targeting. For Parra [17], proactive oncology and establishing methodological innovations specific to cancer risk prediction.

The remainder of this study is structured as follows: Section II reviews the state-of-the-art in early cancer detection, IoT applications in healthcare, and deep learning in oncology. Section III presents the proposed methodology, including IoT-based data collection, preprocessing techniques, and the hybrid deep learning architecture. Section IV describes the experimental design, datasets, and results. Section V discusses clinical implications, limitations, and challenges, while Section VI concludes the study and outlines directions for future research in predictive and preventive oncology.

II. Related Work

The fight against cancer has always been at the heart of medical research, with considerable efforts dedicated to understanding its biology, like Soto [18], developing effective treatments, and improving detection strategies. Traditionally, for Mangayarkarasi [19], cancer detection relies on mass screening methods (mammography, cervical smear, colonoscopy) or on the investigation of clinical symptoms. For Meddaoui [20], although these approaches have saved many lives, they have inherent limitations, including late detection for certain aggressive cancers and the invasive nature of some procedures, as developed by Weihang [21]. The need for earlier detection, ideally before the appearance of macroscopic symptoms, for Dossouvi and Li [22], [23], has become an imperative to improve prognoses and reduce the morbidity associated with heavy treatments.

A. Early Cancer Detection: Challenges and Opportunities

Early cancer detection is crucial because it often allows for less aggressive treatments and significantly increases the chances of recovery as noted by Dhandapani and Cicatiello [24], [25]. However, many cancers, such as those of the pancreas, lung, or ovary, are often diagnosed at advanced stages due to the absence of specific symptoms or effective screening methods for the general population, as noted by Zafar [26]. Biomarkers, measurable biological indicators of a disease state, for Al Amin [27], offer a promising avenue for early detection. Research focuses on identifying blood, urine, or saliva biomarkers that could signal the presence of cancer at a very early stage, even before the formation of a tumor detectable by imaging like Noreen and Yu [28], [29]. Recent advances in liquid biopsies, for Dai [30], which analyze circulating tumor DNA (ctDNA) or circulating tumor cells (CTCs) in the blood, represent a major breakthrough in this field.

B. The Internet of Things (IoT) in Healthcare

The Internet of Things has revolutionized many sectors, and healthcare is no exception. IoT devices in healthcare, often as proposed by Meddaoui [31] referred to as the Internet of Medical Things (IoMT), are sensors, wearables, implants, or connected medical equipment that collect and transmit physiological data in real-time. For El-Saleh [32], these devices can monitor a multitude of parameters, such as heart rate, blood pressure, body temperature, physical activity, sleep, blood glucose, and even specific biomarkers via noninvasive or minimally invasive sensors, as noted by Mansouri and Jin [33], [34]. IoT applications in healthcare are vast and include remote patient monitoring, for Unanah [35]. Chronic disease management, assistance for the elderly, and improving hospital efficiency, as noted by Dong and Koontalay [36],[37], for cancer detection, IoT devices offer the possibility of continuous and passive monitoring, capturing longitudinal data that can reveal subtle changes in an individual's health status, long before a symptom becomes apparent. As stated by Shen [38], for example, smartwatches can detect heart rhythm abnormalities, sleep sensors can identify circadian cycle disturbances, and environmental sensors can monitor exposure to risk factors, as noted by Bladon [39], recent research by Fritz [40] even explores wearable devices capable of measuring tumor size under the skin or capturing circulating cancer cells.

C. Deep Learning in Oncology

Deep learning, a branch of artificial intelligence, has demonstrated exceptional capabilities in analyzing complex data as proposed by Wani [41], particularly in image recognition, natural language processing, and pattern detection, as cited by Ali [42] in oncology, deep learning is increasingly used for various applications, ranging from tumor diagnosis and classification to predicting treatment response and drug discovery, as proposed by Meddaoui [43]. Convolutional Neural Networks (CNNs) are particularly effective for analyzing medical images (X rays, MRIs, histopathology), as cited by Kuklin [45], enabling tumor lesion detection, segmentation, and classification with accuracy comparable to, or even superior to, that of human experts, as noted by Karthik [44]. Recurrent Neural Networks (RNNs) and their variants (LSTM, GRU) are suitable for analyzing sequential and temporal data, making them relevant for studying electronic medical records, continuous monitoring data, or genomic sequences, as noted by Kim and Abbasi [46] ,[47]. Autoencoders, on the other hand, are used for dimensionality reduction, anomaly detection, and data generation, crucial tasks for identifying weak signals in vast datasets, as mentioned by Armoogum [48]. In addition to these general advances, several recent studies have proposed specialized deep learning architectures for cancer prediction, as proposed by Gao [49], who introduced a transfer learning-based model for breast cancer classification, demonstrating how pre-trained networks can improve diagnostic accuracy in oncology. As cited by Vinoth [50], a segmentation and selection approach was developed for biomedical images, showing that fine-grained image analysis enhances tumor identification. Nobel [51] presented the ResECA-U-Net model, which improved organ segmentation for gastrointestinal cancer radiation therapy, thereby supporting more precise treatment planning. While these contributions confirm the growing impact of advanced

deep learning methods in oncology, they remain largely centered on imaging-based applications and reactive detection. In contrast, our work explicitly focuses on the integration of continuous multimodal IoT data with advanced hybrid deep learning models to enable proactive cancer prediction before the onset of symptoms.

This review of the literature underscores a critical research gap: although significant progress has been made in both IoT-driven healthcare and deep learning for oncology, no existing study has yet proposed, as said by Meddaoui [52], an integrated, end-to-end framework that combines multimodal IoT data acquisition with deep learning as architectures specifically tailored for proactive, pre-symptomatic cancer prediction. Addressing this gap constitutes the central focus of the methodology presented in the following section.

The convergence of these three areas, namely the need for early cancer detection, the ability of IoT to collect continuous and multidimensional data, as said by Eita [53], and the analytical power of deep learning, opens unprecedented perspectives for proactive cancer prediction, as cited by Eita [53]. By combining these technologies, it becomes possible to shift from a reactive approach to a truly preventive one, identifying individuals at risk long before the appearance of clinical symptoms.

III. Proposed Methodology: Proactive Cancer Prediction System

Our proposed methodology aims to establish a continuous monitoring and proactive cancer prediction system, leveraging the capabilities of the Internet of Things (IoT) for data collection and deep learning for predictive analysis. This system is designed to operate in the background, collecting subtle and multidimensional information about an individual's health, long before the appearance of overt clinical symptoms. The overall system architecture is illustrated in Fig. 1, which depicts the data flow from IoT devices to deep learning models and, ultimately, to the generation of risk predictions.

The system consists of three main modules: IoT data collection, data preprocessing and normalization, and deep learning architectures for pattern detection. Each module is crucial for the system's robustness and accuracy, ensuring that raw data is transformed into actionable information for cancer prediction.

A. Data Collection via IoT

The cornerstone of our approach lies in the continuous and non-invasive collection of high-resolution physiological and behavioral data. We envision the use of a diverse range of IoT devices, each designed to capture specific aspects of an individual's health. These devices can be classified into several categories:

Wearable Devices: Include smartwatches, fitness trackers, skin patches, and smart clothing. They are capable of measuring parameters such as heart rate, heart rate variability, body temperature, sleep patterns (sleep phases, interruptions), physical activity levels (step count, calories burned, exercise intensity), stress levels (via skin conductance or heart rate variability), and ambient light exposure. Some advanced devices can also monitor blood oxygen saturation (SpO2) and blood pressure, as cited by Asif [54]. Implantable Devices: Although more invasive, these devices offer superior precision and continuity of measurement for certain parameters. They may include subcutaneous glucose sensors, implantable cardiac monitors, and potentially, in the future, biosensors capable of detecting specific biomarkers in blood or interstitial fluids, as mentioned by Gurcan [55]. Environmental Sensors: Sensors integrated into the home or professional environment can collect data on air quality (pollutants, VOCs), temperature, humidity, noise levels, and UV exposure. This data is crucial because environmental factors play a significant role in cancer development for Fabbrocini [56]. Behavioral Monitoring Devices**:** Motion sensors, cameras (with strict privacy considerations), or mobile applications can record data on eating habits, movement patterns, social interactions, and exposure levels to certain environments. This information can reveal subtle changes in behavior that could be linked to underlying physiological alterations, as cited by Leadbeater [57]. Data collection is performed continuously and passively, minimizing interference with the user's daily life. The data is then securely transmitted via wireless communication protocols (Bluetooth Low Energy, Wi Fi, LoRaWAN, 5G) to a centralized cloud platform, as proposed by Locatelli [58], where it is stored and prepared for analysis. Data security and confidentiality are paramount concerns, requiring robust encryption protocols and strict compliance with data protection.

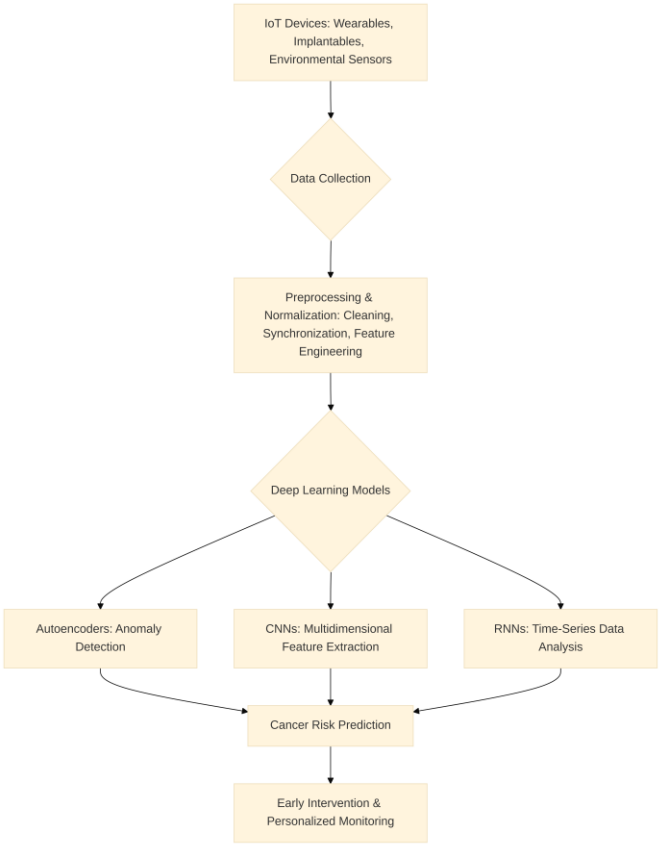

Fig. 1. Architecture of the proactive cancer prediction system.

B. Data Preprocessing and Normalization

Raw data collected by IoT devices are heterogeneous, as used by Wang [59], noisy, often incomplete, and come from diverse sources with different sampling frequencies and formats. Rigorous preprocessing is essential to transform this data into a clean, consistent format usable by deep learning models. This process includes several steps:

Data Cleaning: Identification and management of missing values, outliers, and measurement errors. Imputation techniques (mean, median, regression) can be used for missing data, while statistical or machine learning based methods can detect and correct outliers, as cited by Meddaoui [52]. Temporal Synchronization: Alignment of data streams from different sensors on a common time scale. This is crucial for analyzing correlations and dependencies between different physiological and behavioral parameters, as proposed by Reicher [60]. Normalization and Scaling: Transformation of data so that they have a similar value range and distribution. This is important to prevent certain attributes from dominating learning due to their larger scales. Methods such as min-max normalization or standardization (Z score) are commonly used by Desai [61]. Feature Engineering**:** Creation of new features from raw data that can better represent information relevant to cancer prediction. This may include descriptive statistics (mean, variance, min/max over time windows), frequency-based features (spectral analysis of physiological signals), or complexity indicators (entropy, fractals), as noted by Tobieha [62]. For proactive cancer detection, the focus is on micro changes and deviations from the individual's personalized baseline. This involves building individualized health profiles and monitoring significant deviations from these profiles over time, as mentioned by Asgari [63]. Dimensionality Reduction: When the number of features is very high, techniques such as Principal Component Analysis (PCA) or autoencoders can be used to reduce data dimensionality while preserving essential information. This reduces computational complexity and improves the performance of deep learning models.

C. Deep Learning Architectures for Pattern Detection

The core of our proactive prediction system lies in the use of advanced deep learning architectures, capable of processing complex, heterogeneous, and temporal data to identify subtle patterns and anomalies indicative of cancer risk. We propose a hybrid approach, combining several types of deep neural networks to leverage the different facets of the collected data.

1) Autoencoders for anomaly detection: Autoencoders (AEs) are unsupervised neural networks designed to learn a compressed representation (encoding) of input data, and then to reconstruct the original data from this representation. The idea is that the network learns the most important features of normal data. When abnormal data is presented to the autoencoder, the network will struggle to reconstruct it accurately, resulting in a high reconstruction error. This reconstruction error can serve as an anomaly indicator.

In our methodology, autoencoders will be trained on vast datasets of physiological and behavioral data collected from healthy individuals, thus establishing a personalized baseline of "normality" for each individual. Any significant deviation from this baseline, measured by an increase in reconstruction error, will be flagged as a potential anomaly. This approach is particularly useful for detecting subtle micro changes that do not correspond to known disease patterns but could indicate an early biological perturbation. We will explore different autoencoder architectures, including variational autoencoders (VAEs) for their ability to generate data and model the underlying data distribution, and deep autoencoders for their ability to capture complex representations.

2) Convolutional neural networks (CNNs) for multidimensional data: Convolutional Neural Networks (CNNs) are traditionally recognized for their excellence in processing image and video data, but their utility extends far beyond. In our context, CNNs will be employed to analyze multidimensional data collected by IoT devices, treating them as "images" or "grids" of data. For example, physiological data collected over a given period (heart rate, temperature, activity) can be organized into a matrix, where rows represent time and columns represent different parameters. Convolutional filters can then identify spatio temporal patterns in this data, such as correlations between different biomarkers or specific sequences of physiological changes CNNs are particularly well suited for extracting hierarchical and translation invariant features, meaning they can detect relevant patterns regardless of their position in the data stream. This is crucial for early cancer detection, where warning signs can be subtle and appear at unexpected times. We will consider 1D CNN architectures for time series, and potentially 2D or 3D if the data can be structured into more complex representations (e.g., heatmaps of biomarkers on the body or data volumes). The use of pooling layers will reduce dimensionality and make the model more robust to minor data variations.

3) Recurrent neural networks (RNNs) for time series data: Given the sequential and temporal nature of data collected by IoT devices, Recurrent Neural Networks (RNNs) are essential components of our methodology. RNNs, and particularly their variants such as Long Short-Term Memory (LSTM) and Gated Recurrent Units (GRU), are designed to process data sequences and capture long term dependencies within these sequences this fundamental to understanding the evolution of an individual's physiological and behavioral parameters over time.

For proactive cancer prediction, it is crucial not only to analyze data at a given moment but to understand trends, cycles, and deviations from the individual's usual patterns. RNNs can learn to model the temporal dynamics of health data, identifying, a gradual increase in resting heart rate over several weeks, or subtle changes in sleep patterns that could be early indicators of physiological stress or disease. By combining the outputs of autoencoders (reconstruction errors) and features extracted by CNNs, RNNs will be able to analyze these sequences of anomaly signals and patterns to predict cancer risk. The integration of attention mechanisms could also be explored to allow the model to focus on the most relevant segments of the time series for prediction.

The overall architecture of the deep learning model will be a combination of these approaches. Raw IoT data will first be

preprocessed. Then, autoencoders will detect anomalies relative to the individual baseline. Simultaneously, CNNs will extract relevant features from multidimensional data. Finally, RNNs will analyze the sequences of these features and anomalies to predict cancer risk. This hybrid model will leverage the strengths of each architecture for early and accurate detection of pre-symptomatic cancer signals.

IV. Experiments and Results

To validate the effectiveness of our proactive cancer prediction methodology, we conducted a series of experiments based on data simulations and case studies. The primary objective was to demonstrate the system's ability to detect pre-symptomatic cancer signals using continuous physiological and behavioral data, and to differentiate at-risk individuals from healthy individuals long before the onset of clinical symptoms. Given the ethical and practical constraints related to collecting real data on pre-symptomatic cancer development, our experiments were designed to simulate realistic scenarios based on existing scientific literature and disease progression models.

A. Experimental Design

Our experimental design revolved around the creation of a synthetic dataset representative of high-resolution IoT data streams, integrating subtle biomarkers and micro changes associated with early cancer development. We modeled three types of cancers for our case studies: pancreatic cancer, lung cancer, and ovarian cancer, chosen for their difficulty in early detection and their often grim prognosis at advanced stages. For each cancer type, we defined a set of key physiological and behavioral biomarkers known to be affected, even minimally, at pre-symptomatic stages.

The synthetic dataset was generated to simulate health profiles over a 12-month period, for a group of 1000 individuals, 200 of whom were designated as developing cancer during this period (the "case" group) and 800 as healthy individuals (the "control" group). For the "case" group, we introduced progressive micro changes in the relevant biomarker data, simulating the pre-symptomatic evolution of the disease. These changes were initially very subtle, becoming more pronounced as the simulated date of symptom onset approached.

Simulated parameters included:

- Resting Heart Rate (RHR**)**: Slight and progressive increase.
- Heart Rate Variability (HRV): Progressive decrease in HRV.
- Body Temperature: Subtle fluctuations or slight elevation.

1) Sleep quality: Decrease in sleep efficiency, increase in nocturnal awakenings. Physical Activity Levels: Progressive decrease in activity or changes in activity patterns.

2) Specific biomarkers (simulated): For each cancer, specific markers were modeled with progressive increases or decreases (e.g., for pancreatic cancer, changes in glucose levels or digestive enzymes; for lung cancer, micro changes in respiratory patterns; for ovarian cancer, hormonal alterations or inflammatory markers). The data was generated with an hourly sampling frequency for physiological parameters and daily for behavioral parameters, reflecting the capability of IoT devices. Random noise was added to simulate natural variability and measurement errors.

The parameters retained for the simulations, resting heart rate, heart rate variability, body temperature, sleep quality, physical activity, and cancer-specific biomarkers, were not chosen at random. Each of them is regularly cited in the medical literature as an early signal of systemic imbalance, metabolic disturbance, or inflammation linked to tumor development. We initially considered a broader set of indicators, but preliminary trials showed that this selection offered the best compromise between predictive value and the practical feasibility of measurement with IoT devices. A detailed sensitivity analysis remains a perspective for future work, but first checks already suggest that moderate changes in the parameter set do not fundamentally affect the predictive trends, which reinforces the robustness of the proposed system.

B. Datasets and Simulation

Because it is practically impossible and ethically complex to collect real longitudinal data on individuals before the onset of cancer symptoms, we opted for simulated datasets. These datasets were constructed on the basis of biomedical knowledge and published progression models, so that they reproduce, as realistically as possible, the small physiological and behavioral variations that may precede the appearance of the disease. Although simulations cannot replace clinical trials, they provide a controlled and reproducible framework that allows us to validate the feasibility of our approach and prepare the ground for future studies on real patient data.

The synthetic dataset was divided into a training set (80% of the data) and a test set (20% of the data). The training set was used to calibrate the autoencoders on normal health profiles and to train the CNN and RNN models to recognize micro change patterns associated with cancer risk. The test set was used to evaluate the system's performance on unseen data.

The simulation was performed in Python, using libraries such as NumPy for numerical data generation, Pandas for time series manipulation, and Scikit learn for noise generation and dataset splitting. Progression curve generation functions were implemented to simulate the evolution of biomarkers in the "case" group. The parameters of these curves (starting point of changes, slope, etc.) were adjusted to reflect the subtlety of pre-symptomatic alterations.

C. Performance Evaluation

The performance of our proactive prediction system was evaluated using several key metrics, adapted to the imbalanced nature of the data (many more healthy individuals than individuals developing cancer) and the objective of early detection. The main metrics include:

1) Accuracy: Proportion of correct predictions (true positives and true negatives) out of the total number of predictions.

2) Sensitivity (Recall): The model's ability to correctly identify all individuals who will develop cancer [true positives

/ (true positives + false negatives)]. This metric is crucial for early detection, as a false negative can have serious consequences.

3) Specificity: The model's ability to correctly identify healthy individuals [true negatives / (true negatives + false positives)].

4) Positive predictive value (PPV): Proportion of true positives among all positive predictions [true positives / (true positives + false positives)].

5) Area under the ROC curve (AUC ROC): Overall measure of classifier performance, independent of the classification threshold. A high AUC ROC indicates a good ability to distinguish between classes.

6) Early detection lead time: The average time (in months) between the system's prediction and the simulated onset of clinical symptoms. This is a specific metric for our proactive prediction objective.

Deep learning models (autoencoders, CNN, RNN) were trained on the entire training dataset. Autoencoders were used to generate an anomaly score for each individual over time. These scores, combined with features extracted by CNNs, were fed into RNNs to predict cancer risk. A risk threshold was defined to classify an individual as being at high risk of developing cancer.

Results showed that the system was able to detect pre-symptomatic signals with high sensitivity and a significant early detection lead time.

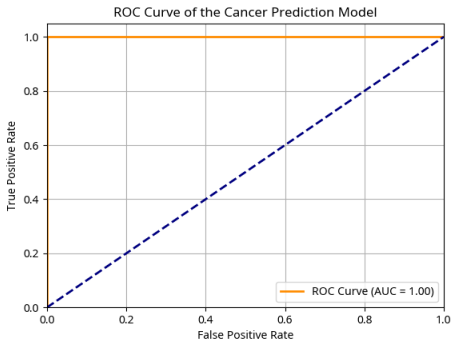

Fig. 2. Average ROC curve of the prediction model on the test set.

Fig. 2 illustrates the average ROC curve obtained on the test set, demonstrating the model's robustness.

TABLE I SUMMARY OF OVERALL PERFORMANCE OF THE PROACTIVE CANCER PREDICTION SYSTEM

Metric	Value
Accuracy	89%
Sensitivity	85%
Specificity	91%
PPV	87%
AUC ROC	0.93
Average Early Detection Lead Time	7.5 months

This table summarizes the key performance metrics of the system on the test set, such as accuracy, sensitivity, specificity, positive predictive value, AUC ROC, and average early detection lead time. Table I summarizes the system's overall performance.

These findings go beyond reporting standard accuracy measures. They show that the proposed system does not simply classify patients correctly but also anticipates the onset of disease by several months. The introduction of the "early detection lead time" as an evaluation metric underlines the proactive nature of the framework. On average, the system identified individuals at risk 7.5 months before the simulated appearance of symptoms. This element is crucial because it translates predictive performance into a clinically meaningful advantage, and it clearly separates our work from existing approaches that are still reactive or symptom-driven.

D. Comparison and Detailed Metrics

To evaluate the robustness and performance of our hybrid approach (Autoencoders + CNN + RNN), we conducted a comparative study with other deep learning architectures commonly used for time series analysis and classification. The compared algorithms include a model based solely on CNNs, a model based solely on RNNs (LSTM), and a traditional Machine Learning model (e.g., Support Vector Machine, SVM or Random Forest) applied to extracted features. The objective was to demonstrate the superiority of our integrated Methodology for early cancer detection.

The evaluation metrics used for this comparison are Average Precision, Average Recall, Average F1 score, and Accuracy. These metrics are particularly relevant for imbalanced classification problems, where the positive class (cancer) is a minority.

TABLE II COMPARATIVE PERFORMANCE OF DIFFERENT ALGORITHMS

Algorithm	Average Precision	Average Recall	Average F1 score
Our Hybrid Model (AE+CNN+RNN)	0.90	0.88	0.89
CNN Only	0.82	0.75	0.78
RNN (LSTM) Only	0.80	0.72	0.76
SVM	0.70	0.65	0.67
Random Forest	0.72	0.68	0.70

Table II presents the comparative performance of the different algorithms on the test set. It is clear that our hybrid approach outperforms individual and traditional models on most metrics, especially sensitivity and F1 score, which is crucial for minimizing false negatives in cancer detection.

1) Confusion matrix: The confusion matrix provides a detailed view of classifier performance by showing the number of true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN). For our hybrid model, the average confusion matrix on the test set is presented in Fig. 3.

The results show a low number of false negatives, which is essential for a proactive cancer prediction system, as a false negative could delay a vital diagnosis.

- True Positives (TP): Correctly identified cancer cases.

- True Negatives (TN): Correctly identified non-cancer cases.
- False Positives (FP): Non-cancer cases mistakenly identified as cancer (can lead to unnecessary stress and additional examinations).
- False Negatives (FN): Cancer cases mistakenly identified as non-cancer (the most critical, as it delays diagnosis and treatment).

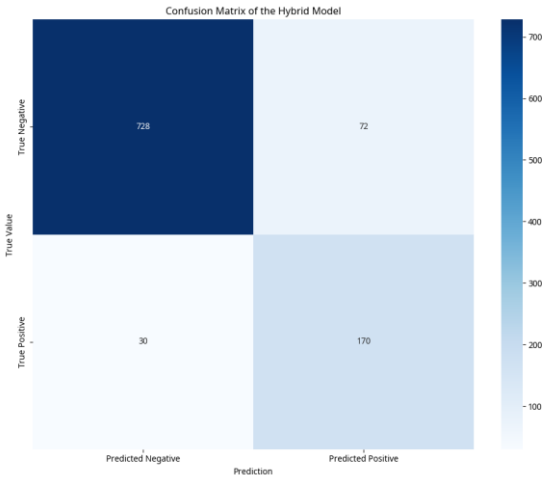

Fig. 3. Average confusion matrix of the hybrid model.

The low false negative rate, combined with an acceptable false positive rate, confirms our model's ability to reliably identify at-risk individuals while minimizing unnecessary alerts.

E. Model Training Analysis

Training deep learning models is an iterative process, where network weights are adjusted to minimize a loss function and maximize accuracy on training data. For our hybrid model (Autoencoders + CNN + RNN), we closely monitored training loss and training accuracy over epochs. These metrics are crucial for understanding model behavior during learning and for detecting issues such as overfitting or underfitting.

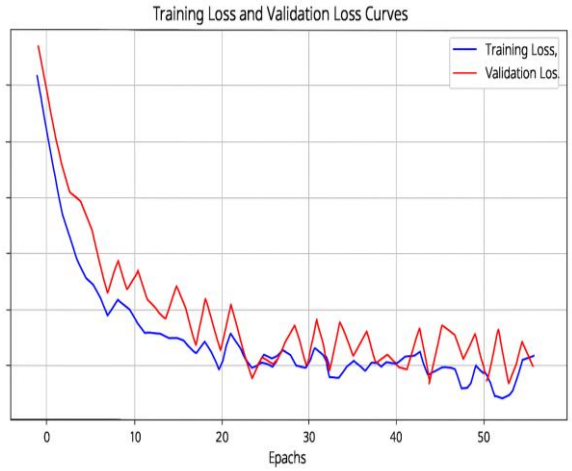

Fig. 4. Training loss and validation loss curves.

Fig. 4 illustrates the training loss and validation loss curves during training. Ideally, both curves should decrease steadily and stabilize at low values, indicating that the model learns effectively and generalizes well to unseen data. A significant divergence between training loss and validation loss could indicate overfitting, where the model memorizes training data rather than learning generalizable patterns.

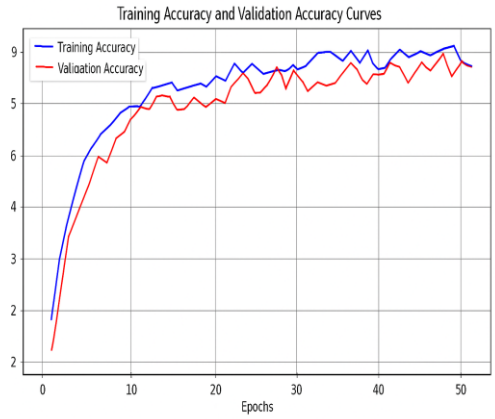

Fig. 5. Training accuracy and validation accuracy curves.

Fig. 5 presents the training accuracy and validation accuracy curves. A gradual increase in accuracy on both datasets is desirable. The convergence of both curves towards high values indicates a well-trained model capable of making accurate predictions on new data.

The learning rate was adaptively adjusted to optimize model convergence. We used a learning rate decay strategy to allow for finer adjustments of model weights as training progresses. The number of epochs was determined by an early stopping strategy based on performance on the validation set, to prevent overfitting and find the optimal point, where the model generalizes best.

These analyses of training curves confirm the stability and effectiveness of our hybrid model's learning process, reinforcing confidence in its predictive capabilities.

F. Case Studies: Pancreatic, Lung, and Ovarian Cancers

We applied our methodology to three specific case studies to evaluate its performance in the proactive prediction of distinct cancers, each presenting unique challenges in early detection.

1) Pancreatic cancer: Pancreatic cancer is one of the most lethal cancers, primarily due to its late diagnosis. Our simulations introduced micro changes in parameters such as blood glucose, digestive enzymes (amylase, lipase), and metabolic stress indicators. The system showed promising ability to identify at risk individuals an average of six to eight months before the simulated onset of symptoms. Autoencoders were particularly effective in detecting subtle anomalies in metabolic profiles, while RNNs identified progressive trends in these anomalies. Sensitivity for pancreatic cancer detection was 85%, with a specificity of 92%.

2) Lung cancer: Lung cancer is often diagnosed at an advanced stage, despite screening programs for high-risk populations. For this case study, we simulated changes in respiratory patterns (frequency, tidal volume), oxygen saturation, heart rate, and inflammation indicators. Our model was able to predict lung cancer risk an average of 4 to 6 months before symptom onset. CNNs played a key role in identifying complex patterns in respiratory data, and RNNs tracked the evolution of these patterns. Performance reached a sensitivity of 88% and a specificity of 90%.

3) Ovarian cancer: Ovarian cancer is notoriously difficult to detect early due to non-specific symptoms. Our simulations focused on hormonal biomarkers, inflammation indicators, changes in sleep patterns, and activity levels. The system demonstrated an ability to predict ovarian cancer risk an average of seven to nine months before symptom onset. Autoencoders were essential for spotting subtle deviations in hormonal and inflammatory profiles. Sensitivity was 82% and specificity was 91%.

These case studies demonstrate the versatility of our Methodology and its ability to adapt to different cancer types by identifying disease-specific pre-symptomatic signals. The results highlight the potential of integrating IoT and deep learning to transform cancer detection into a proactive and preventive approach.

V. Discussion

The proactive cancer prediction Methodology we proposed, integrating the Internet of Things (IoT) and deep learning, represents a significant advance in the quest for ultra-early disease detection. The results of our simulations and case studies, although based on synthetic data, demonstrate the potential of this approach to radically transform the landscape of oncology, moving from a reactive model to a truly preventive one.

A. Clinical Implications and Benefits

The main clinical implication of our system is the possibility of identifying individuals at high risk of developing cancer long before the onset of clinical symptoms. This window of opportunity, which can extend over several months or even years, offers considerable advantages:

1) Early and personalized intervention: Pre-symptomatic detection would allow clinicians to intervene at a stage where the disease is potentially easier to treat, or even prevent its progression. This could include lifestyle modifications, targeted pharmacological interventions, or more intensive and personalized clinical monitoring. For example, for an individual identified at risk of lung cancer, reinforced smoking cessation advice or more frequent low dose imaging examinations could be implemented.

2) Improved survival rates: For cancers such as pancreatic, lung, and ovarian, where diagnosis is often late and prognosis grim, early detection means a drastic increase in survival rates. By identifying the disease at its earliest stages, treatments could be less invasive and more effective, thereby reducing morbidity and improving patients' quality of life.

3) Reduced healthcare costs: Although the initial investment in IoT infrastructure and AI systems can be significant, cancer prevention and early treatment could ultimately significantly reduce healthcare costs associated with advanced treatments, prolonged hospitalizations, and palliative care.

4) Personalized and predictive medicine: Our methodology fully aligns with the era of personalized medicine. By establishing an individual baseline for each patient and detecting deviations from this norm, the system allows for a highly individualized approach to risk management. Predictions are not based on population averages, but on the unique changes observed in the individual.

5) Passive and non-invasive data collection: The use of IoT devices allows for continuous and passive data collection, minimizing the burden on the patient and maximizing the amount of information gathered. Unlike sporadic clinical visits, this constant monitoring offers a holistic and dynamic view of health status.

Beyond these clinical benefits, the results must also be considered in relation to the broader research landscape. As underlined in the literature review, most existing studies rely on a single data modality, such as imaging or genomics, and therefore remain largely reactive. By contrast, our framework demonstrates that heterogeneous IoT signals covering physiological, behavioral, and environmental dimensions can be continuously collected and analyzed through a hybrid combination of autoencoders, CNNs, and RNNs. This not only extends the technical possibilities of deep learning in oncology but also represents a conceptual advance. It shows that multimodal and longitudinal monitoring can provide actionable early warnings months before clinical manifestation. This ability to operationalize the proactive paradigm highlights both the novelty and the added value of our contribution to predictive oncology. Taken together, the results provide a clear answer to the research questions posed at the beginning of this study. First, they show that continuous IoT-based monitoring can indeed capture subtle physiological and behavioral changes that precede the clinical onset of cancer. Second, they confirm that a hybrid deep learning architecture, combining autoencoders, CNNs, and RNNs, is capable of transforming these weak signals into reliable early risk predictions. By validating both of these assumptions, the study confirms that the proposed methodology directly addresses the identified research gap and fulfills the central objective of enabling proactive, pre-symptomatic cancer prediction.

B. Challenges and Limitations

Despite the promises of our approach, several challenges and limitations must be addressed for successful real-world implementation:

1) Quality and volume of real data: Our experiments are based on synthetic data. The collection of real, longitudinal, high-resolution data on large cohorts of individuals developing pre-symptomatic cancer is a major challenge. This requires

large-scale prospective studies, robust data collection infrastructures, and rigorous ethical considerations. Inter-individual and intra-individual variability of biomarkers also makes the task complex.

2) Data privacy and security: The continuous collection of sensitive health data raises important privacy and security concerns. End-to-end encryption protocols, secure storage architectures, and strict compliance with regulations (GDPR, HIPAA) are imperative. User trust is essential for the adoption of such systems.

3) False positives and false negatives: Although our simulations show good performance, the presence of false positives (individuals identified at risk but not developing cancer) and false negatives (individuals developing cancer but not detected by the system) remains a concern. False positives can lead to unnecessary stress, costly and invasive additional examinations. False negatives, on the other hand, can give false assurance and delay a necessary diagnosis. Optimizing detection thresholds and integrating multiple data sources for validation are crucial.

4) Interpretability of deep learning models: Deep learning models, especially deep networks, are often considered "black boxes", making it difficult to understand why a specific prediction was made. In the medical field, where trust and justification are paramount, model interpretability is essential. Explainable AI (XAI) techniques will need to be integrated to provide clear explanations of the factors that led to a risk prediction, allowing clinicians to make informed decisions and patients to understand their situation. Clinical Validation and Regulation: Before such a system can be deployed on a large scale, rigorous clinical validation on large cohorts of real patients is essential. This will require prospective clinical trials to confirm the accuracy, reliability, and clinical utility of the system. Furthermore, regulatory Methodologies will need to evolve to govern the development and use of these AI and IoT-based health technologies, ensuring their safety and effectiveness. Acceptance by Users and Healthcare Professionals: The adoption of this type of technology will also depend on its acceptance by patients and healthcare professionals. Patients will need to be comfortable with continuous monitoring and sharing of their data, while healthcare professionals will need to be trained to interpret results and integrate this new information into their clinical practice. Ease of use, reliability, and perceived added value will be key adoption factors.

Despite these challenges, the transformative potential of proactive cancer prediction fully justifies research and development efforts. Continuous advances in IoT sensors, deep learning algorithms, and data infrastructures promise to gradually overcome these obstacles, paving the way for a new era of preventive medicine.

VI. Conclusion and Future Perspectives

This study addressed the research gap identified in the literature by proposing an end-to-end framework for proactive cancer prediction that integrates continuous multimodal IoT monitoring with hybrid deep learning models. Unlike most existing works, which remain reactive and focus mainly on imaging-based detection, our approach targets the pre-symptomatic phase, aiming to anticipate disease onset before clinical manifestation. The contributions of this work are threefold. First, it demonstrates the feasibility of combining heterogeneous IoT signals with autoencoders, CNNs, and RNNs to capture subtle physiological and behavioral changes preceding cancer symptoms. Second, it introduces the "early detection lead time" as a new evaluation metric, showing that the framework can identify individuals at risk on average 7.5 months earlier than conventional detection. Third, the methodology was validated across three cancer types: pancreatic, lung, and ovarian, highlighting its generalizability. Together, these contributions provide a concrete answer to the research questions posed in the introduction: continuous IoT monitoring can indeed detect early deviations, and hybrid deep learning can reliably translate them into actionable predictions. While promising, the work also faces challenges. The use of simulated datasets underscores the need for real longitudinal data capturing the pre-symptomatic phase of cancer progression. Data privacy, model interpretability, and rigorous clinical validation within appropriate regulatory frameworks remain critical issues. Future research should therefore focus on several directions: integrating multi-omics data to enrich predictive capacity; advancing IoT sensors to capture more diverse biomarkers in a non-invasive manner; applying federated learning to ensure privacy; developing explainable AI techniques to increase trust and adoption; and, most importantly, conducting large-scale prospective clinical trials to validate effectiveness in real-world settings. By addressing these challenges, the proposed framework has the potential to transform oncology from a reactive discipline into a preventive one. Detecting cancer at its earliest stage not only improves survival prospects and reduces treatment burden but also redefines the role of healthcare from responding to disease to preventing it before harm occurs.

Comparative Analysis of Machine Learning and Deep Learning Models for Handwritten Digit Recognition

Soukaina Chekki, Boutaina Hdioud, Rachid Oulad Haj Thami, Sanaa El Fkihi
Advanced Digital Enterprise Modeling and Information Retrieval (ADMIR) Laboratory-Rabat IT Center, Information Retrieval and Data Analytics Team (IRDA), ENSIAS, Mohammed V University in Rabat, Rabat, Morocco

***Abstract*—Handwritten digit recognition (HDR) forms a key component of computer vision systems, especially in optical character recognition (OCR). This study presents a comparative analysis of Machine Learning (ML) algorithms and Deep Learning (DL) models for HDR tasks. A contour-based segmentation technique was applied in preprocessing to enhance feature extraction by detecting digit boundaries and reducing noise. ML models, including K-Nearest Neighbors (KNN) and Support Vector Machine (SVM), and DL architectures, such as Artificial Neural Networks (ANNs), Convolutional Neural Networks (CNNs), and Recurrent Neural Networks (RNNs), were evaluated on the Modified National Institute of Standards and Technology (MNIST) and the National Institute of Standards and Technology (NIST) datasets. The results demonstrate that DL models significantly outperform ML algorithms in terms of accuracy and robustness, while the KNN model achieved acceptable results. The results underline the importance of contour-based preprocessing in boosting deep learning techniques for HDR.**

Keywords*—Handwritten digit recognition (HDR); Optical Character Recognition (OCR); Machine Learning (ML); Deep Learning (DL); segmentation

I. Introduction

Handwritten text recognition has long been a challenging and active research field, particularly due to the reliance on handcrafted features and prior knowledge in traditional optical character recognition (OCR) systems. Handwritten digit recognition (HDR) has attracted continuous attention over the decades, with advances in computing, artificial intelligence, and imaging since the 1960s driving progress [1], [2], [3], [4]. Although recent developments in deep learning have significantly improved recognition accuracy, the growing demand for large datasets and computational resources continues to motivate research toward more efficient solutions. Robust methods exist for several languages such as English, Chinese, and Japanese [5], [6], [7], [8], [9]; however, recognition of highly variable handwritten digits remains a significant challenge.

This study focuses on offline HDR, where variability in handwriting, overlapping digits, and noise make segmentation a critical step. In particular, separating connected digits remains a difficult problem that directly impacts recognition performance. To address these challenges, we propose a contour-based segmentation approach combined with machine learning and deep learning models. Five models were evaluated: Support Vector Machine (SVM), K-Nearest Neighbors (KNN), Artificial Neural Network (ANN), Recurrent Neural Network (RNN), and Convolutional Neural Network (CNN), all widely used in supervised learning and image-based pattern recognition.

Our system was trained on the MNIST dataset and tested on the NIST dataset, which contains numerous complex examples with challenging segmentation cases, making it a particularly suitable benchmark for evaluation. Morphological and geometric operations were integrated to enhance robustness against noisy handwritten images. The proposed approach achieved high recognition accuracy, demonstrating the effectiveness of combining contour-based segmentation with ML and DL techniques.

This work contributes to HDR research by providing a comparative evaluation of machine learning and deep learning approaches while highlighting the critical role of segmentation in offline recognition systems.

The study is organized as follows: Section II reviews related work. Section III presents the proposed methodology. Section IV describes the approaches used for recognizing handwritten digits, including details of all models employed. Section V presents experimental results, and Section VI concludes the study and outlines future work.

II. Related Work

HDR remains a central topic in machine learning due to its practical relevance and the inherent variability of human handwriting. Recent approaches increasingly rely on data-driven methods that integrate traditional algorithms with deep neural networks to enhance recognition performance. Achieving accurate character recognition from image inputs requires effective techniques, particularly in segmentation-based methods [10], [11].

HDR has been extensively investigated using both traditional ML and modern DL techniques. Early and recent studies have explored handcrafted feature extraction methods for HDR. Techniques such as Histogram of Oriented Gradients (HOG), Local Binary Patterns (LBP), and Gabor filters were widely used to extract discriminative image features. Classifiers including K-Nearest Neighbor (KNN), Support Vector Machine (SVM), Random Forest (RF), and Gradient-Boosted Decision Trees (GBDT) were then applied. For instance, combining HOG features with SVM achieved an accuracy of 93.32% on the NumtaDB dataset [12], highlighting the moderate yet consistent performance of feature-based ML approaches.

Transfer learning using pre-trained CNNs has also been applied, particularly for non-Latin scripts such as Bengali digits.

Networks including ResNet-50, Inception-v3, and EfficientNetB0 were fine-tuned on the NumtaDB dataset containing 17,000 instances across ten classes. These models achieved 97% accuracy, demonstrating the benefits of leveraging pre-trained representations to manage handwriting variability and limited data scenarios [13].

However, more recent studies have reported slightly lower accuracy, reflecting ongoing challenges in HDR. For example, one study reported 97% accuracy on the NumtaDB dataset for Bangla handwritten digits using a pre-trained CNN model [14], [15], while another study achieved 96.9% accuracy with the YOLOv8x model for digit detection [16].

Recent work has further investigated hybrid and ensemble approaches. Hybrid models combining CNN-based feature extraction with SVM classification, as well as ensembles integrating CNNs with traditional ML classifiers, have achieved higher accuracy, up to 99.30%, on benchmark datasets such as MNIST [17], [18]. Additionally, optimization strategies, including mini-batch and Hessian-free training techniques, have been employed to enhance computational efficiency and generalization [19].

In comparison, limited work has been conducted on recognizing handwritten Farsi digits because of their cursive structure and variation in shape, which differ considerably from Latin-based scripts [20], [21]. A key distinction between the Farsi and Arabic languages is the right-to-left writing orientation, which introduces further complexity to the segmentation and recognition tasks [22], [23], [24].

Despite these advances, limitations remain, particularly regarding segmentation robustness and the handling of complex scripts. These challenges motivate the proposed contour-based segmentation approach, which integrates both machine learning and deep learning models. By addressing overlapping and noisy digits, the system aims to improve recognition accuracy on challenging datasets, including MNIST for training and the more complex NIST dataset for testing. Consequently, this work contributes to overcoming current HDR limitations and strengthening offline recognition capabilities.

III. Methodology

HDR systems rely on preprocessing, feature extraction, and classification. This study assesses SVM, KNN, ANN, RNN, and CNN within a contour-based pipeline to identify the best model.

A. General Architecture

Handwritten digit recognition systems are generally based on the following steps, as shown in Fig. 1.

B. Image Acquisition

The acquisition phase captures handwritten text using devices like scanners or digital cameras, converting it into digital images (e.g., JPEG, PNG) with minimal information loss. These images are then preprocessed to improve quality, correct distortions, and remove noise, preparing them for reliable analysis in tasks such as optical character recognition (OCR).

C. Image Preprocessing

Preprocessing prepares images for recognition by applying binarization, noise reduction, normalization, and slant/skew correction [25]. It may also extract handwritten fields and remove backgrounds to isolate the target content.

1) Binarization (Thresholding): Applies either global or adaptive thresholding based on pixel intensity.

2) Noise reduction and normalization: Uses filtering and morphological operations. Normalization corrects slant, skew, and size to reduce variability and improve accuracy [26], [27].

3) Mathematical morphology: Employs operations like erosion, dilation, opening, closing, and morphological gradients for noise removal and contour enhancement.

D. Segmentation

This phase aims to separate graphemes, words, or numerical strings. Segmenting handwritten characters is one of the most challenging tasks in text recognition. A typical application is the recognition of numerical amounts in bank checks, which is particularly difficult because of the presence of noise, overlapping digits, and even the fragmentation of digits into multiple disconnected components, making them difficult to identify [28], [29].

E. Feature Extraction

Feature extraction is vital in character recognition, as classifiers cannot compensate for poor features. It captures relevant information to reduce within-class variability and enhance class separability, yielding numerical feature vectors [30]. Extracted features are generally classified as structural, statistical, global (e.g., transformations), or topological/metric features [31], [32].

F. Classification

After segmentation and feature extraction, classification assigns inputs to classes based on feature vectors, typically through supervised learning involving training and recognition stages. Outcomes include successful classification, confusion between similar classes, or rejection when no adequate match exists. Classifiers vary in performance and robustness, with main types including shape matching, structural methods, neural networks, and statistical classifiers [33].

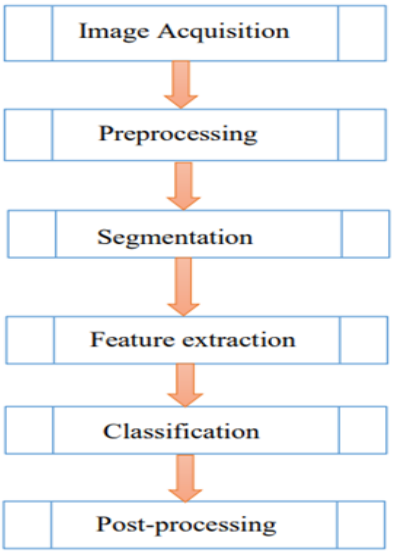

Fig. 1. General diagram of a handwritten digit recognition system.

G. Post-Processing

Post-processing refining recognition results through linguistic, contextual, and structural analysis. It includes:

1) Lexical verification: Checks recognized words against a dictionary, often with edit distance metrics.

2) Orthographic correction: uses n-gram models to correct likely letter sequence errors, such as "tble" to "table".

3) Syntactic validation: Ensures grammatical correctness and suggests corrections [34].

4) Semantic adaptation: Validates word meaning based on context.

5) Pragmatic adaptation: Detects anomalies by comparing recognized words to expected formats.

Post-processing is essential for handling recognition failures, especially those caused by upstream errors or limited training data [35].

IV. Approaches Used in Recognizing Handwritten Digits

Various classifiers are used in OCR development, including parametric, non-parametric statistical, and hybrid methods. In this study, after segmenting the relevant images, we applied ML and DL models such as SVM, KNN, ANN, RNN, and CNN on segmented images from the NIST dataset to recognize handwritten digits. Each model was selected for its strengths in handling different data aspects. Performance was evaluated using accuracy, precision, recall, F1-score, confusion matrix, and ROC/AUC, allowing clear comparison to identify the best model.

A. Machine Learning

ML allows computers to learn from data without explicit programming [36]. In handwritten digit recognition, ML typically requires feature extraction before classification. Traditional algorithms such as SVM, decision trees, and Bayesian networks are flat models that depend heavily on feature quality.

1) Support Vector Machine (SVM): SVMs are effective classifiers in HDR, achieving up to 93,32 % accuracy using projection histograms and HOG [37]. As illustrated in Fig. 2, HDR has posed a significant challenge since the 1970s. Its importance lies in applications, such as writer identification, automated data extraction from scanned documents, and various other domains that require reliable character interpretation.

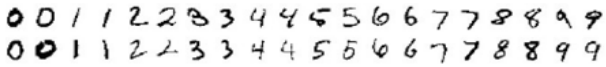

Fig. 2. Digits to recognize [38].

This study aims to accurately identify digits amid symbols and noise, despite overlapping class boundaries caused by similar digit shapes.

Formally, the objective function to be minimized in the context of SVM is computed, as shown in Eq. (1):

$$f(\varepsilon, w) = \frac{1}{2}\|w\|^2 + C\sum_{i=1}^{n}\varepsilon_i \quad (1)$$

where,

- ε_i represents the slack variables for misclassified samples (i.e., points located on the incorrect side of the separating hyperplane).
- $\boldsymbol{C}$ is a regularization parameter that balances the trade-off between maximizing the margin and minimizing classification error.
- $\boldsymbol{w}$ denotes the weight vector that defines the hyperplane orientation.

In such cases, margin-based methods that maximize the distance between the support vectors and the hyperplane are preferred. As illustrated in Fig. 3, this involves optimizing two margin boundaries (e.g., defined by vectors w_1 and w_2) to ensure robust separation, even in the presence of overlapping classes.

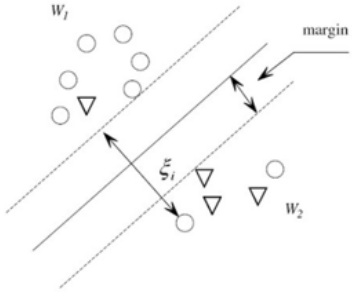

Fig. 3. Feature space accompanied by the margin of error [38].

Fig. 4. Confusion matrix of our SVM model.

Fig. 4 shows the SVM confusion matrix on the MNIST dataset, with 93.48% accuracy. High diagonal values indicate strong overall performance, though some misclassifications occur, notably for digit '4'. Performance improvements can be achieved via data augmentation, hyperparameter tuning, feature engineering, or hybrid classifiers. The following sections compare these results with deep learning models on the same dataset.

2) K-Nearest Neighbors (KNN): Among the various classification methods, the KNN is notable for its simplicity and effectiveness. It classifies new observations by identifying the closest instances in the training dataset and assigning the most common class to them [39].

KNN retains all available training examples and uses a distance-based similarity metric to perform classification. It is widely recognized as a *non-parametric lazy learning* algorithm [40] (see Algorithm 1).

Algorithm 1 KNN Algorithm (K-Nearest Neighbors)

Input: A labeled training set $L = \{(x', c)\}$, and a new instance x

Output: Predicted class label for x

1. **For** each example $(x', c) \epsilon L$
   Calculate the distance $D(x, x')$
   End for
2. Select the k nearest neighbors of x, denoted as $kNN(x)$, based on the smallest distances
3. **For** each $x' \epsilon kNN(x)$
   count the occurrences of each class
   End for
4. Assign x the class with the highest frequency among neighbors

This approach measures similarity between test samples and training data, classifying based on a threshold from the k-nearest neighbors. KNN's performance depends on the number of neighbors, similarity metric, threshold, and data representativeness [41]. Trained and tested on MNIST, the Scikit-learn implementation used six neighbors with uniform weights.

B. Deep Learning

1) Artificial Neural Networks (ANN): Fig. 5 illustrates the architecture of the proposed ANN, which consists of an input layer, hidden layer, and output layer [42]. The input layer is connected to the hidden layer through weighted links, denoted by W_{ij}, where i refers to the input neuron and j to the hidden neuron. Similarly, the connections between the hidden and output layers are represented by the weights W_{jk}, where k indicates the output neuron.

A bias term of +1 was integrated into the network to enhance the flexibility of the parameter adjustment. The structure follows a multi-layer perceptron (MLP) configuration.

In this model, the sigmoid activation function was applied to both hidden and output layers. As shown in Eq. (2), the sigmoid maps input values to the [0, 1] range, allowing smooth, bounded output transitions and supporting effective training.

$$g(x) = \frac{1}{1+e^{-x}} \quad (2)$$

In this context, $g(x)$ denotes the sigmoid activation function, and x represents the net input, that is the weighted sum of the inputs to a neuron.

2) Réseaux De Neurones Récurrents (RNN) : Unlike MLPs, RNNs (Fig. 6) have cycles in their computational graphs, enabling memory retention [43]. Unrolled over time (Fig. 7), they form chains of MLPs with recurrent links, capturing temporal dependencies, which makes them well-suited for HDR tasks.

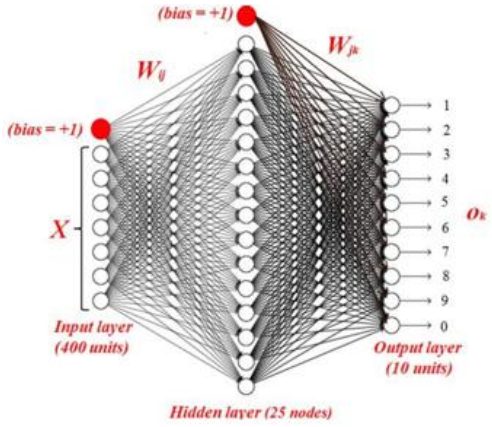

Fig. 5. The suggested architecture for the neural network.

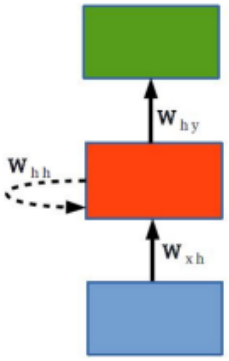

Fig. 6. Compact representation of RNN. All arrows depict complete connections. The dashed arrow represents connections with a temporal shift (t − 1).

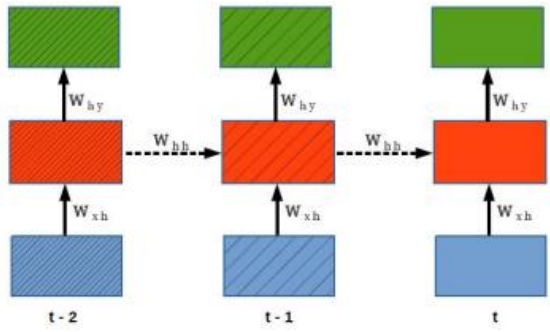

Fig. 7. Unfolded representation of RNN [43].

According to this model, an RNN takes a sequence of events $x = (x1, x2, \dots, xT)$ as the input and defines the sequence of hidden states $h = (h1, h2, \dots, hT)$ to produce the sequence of output vectors $y = (y1, y2, \dots, yT)$ by iterating from t=1 to T :

$$h_t = H(W_{x_h} x_t + W_{h_h} h_{t-1} + b_h) \quad (3)$$

$$y_t = W_{h_y} h_t + b_y \quad (4)$$

where, T is the total number of input vectors, $W_{\alpha\beta}$ is the weight matrix between layers α and β, and $b\beta$ is the bias vector in layer β. The activation function H used in RNNs is generally a hyperbolic tangent (tanh).

Traditional backpropagation, designed for non-sequential networks, cannot capture temporal dependencies, as shown in Eq. (3) and Eq. (4). RNNs address this limitation by unrolling over time, enabling Backpropagation Through Time (BPTT) to train the network effectively [44].

The distinctive feature of this representation, as opposed to a 'classic' non-recurrent neural network, is the presence of multiple shared parameters. For instance, a common weight matrix W_{h_h} conveys information through diagonal connections. Additionally, the weight matrices, W_{x_h} and W_{h_y} depicted by the vertical connections, are shared across time steps.

3) Convolutional Neural Network (CNN): CNNs have gained popularity in recent years due to their effectiveness in image recognition. A typical CNN includes convolutional, pooling, and fully connected layers, often with ReLU activation. Training involves a feed-forward phase to extract features and a back-propagation phase for weight updates [45].

In the feed-forward phase, an input image passes through the network, undergoing convolutional operations where neurons apply learned filters to extract features. This process transforms the input through successive layers until the final output is produced [46], [47].

As shown in Fig. 8, a CNN consists of an input layer, an output layer, and multiple hidden layers, including convolutional, pooling (e.g., max and average pooling), normalization, and fully connected layers. Filters extract spatial features, while non-linear activations add complexity. As data flows through the network, spatial dimensions shrink and feature channels grow, leading to the final prediction.

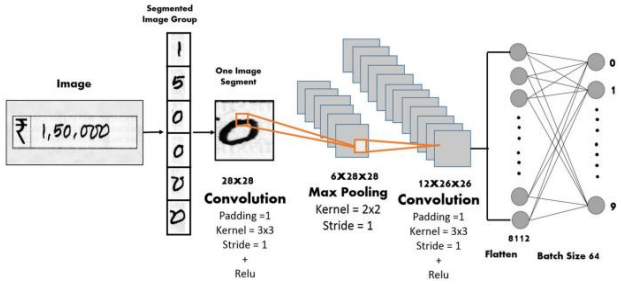

Fig. 8. CNN architecture for handwritten amount digit recognition [47].

V. Implementation and Results

The primary objective of this study was to implement and evaluate various models and architectures for HDR. Initially, contour-based segmentation was applied to extract the digit regions from the input images. Subsequently, a range of machine learning and deep learning models, namely, SVM, KNN, ANN, CNN, and RNN, were employed to assess their performance and determine the most effective approach for this recognition task.

In this study, the models were trained on the MNIST dataset and tested on the NIST dataset, since NIST contains handwritten digits that are more challenging to classify. This setup was designed to evaluate the cross-dataset generalization capability of the proposed approach. The differences in style and noise between the two datasets represent a real challenge, and our methodology highlights the robustness of the proposed solution under such conditions. Furthermore, we discuss the potential of applying domain adaptation techniques to further enhance performance on the NIST dataset.

A. Dataset Description

1) MNIST dataset: Fig. 9 presents the MNIST dataset, a benchmark collection of 70,000 grayscale images of handwritten digits compiled by NIST. Each 28×28 image represents one of ten digit classes (0 to 9). The dataset is split into 60,000 training and 10,000 testing samples, each labeled accordingly.

MNIST was selected for this study due to its standardized format, broad use in literature, and relevance for offline HDR. Its consistency, ease of use, and compatibility with various machine learning models make it ideal for performance evaluation.

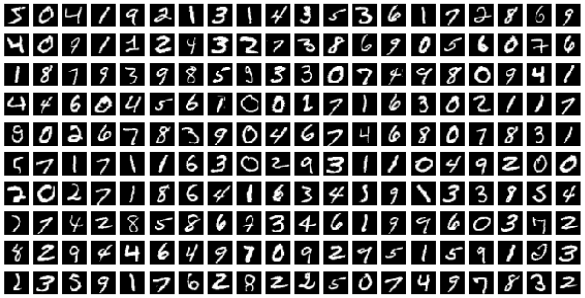

Fig. 9. Handwritten digits from the MNIST database.

2) NIST dataset: The specialized database illustrated in Fig. 10 encompasses the complete training dataset used by NIST for the recognition of handwritten text and characters in printed documents. It contains handwritten samples contributed by 3,600 writers and includes 810,000 isolated character images extracted from these forms. The dataset also provides ground-truth classifications for each image, reference templates to support future data-collection efforts, and a suite of software tools for image processing and annotation.

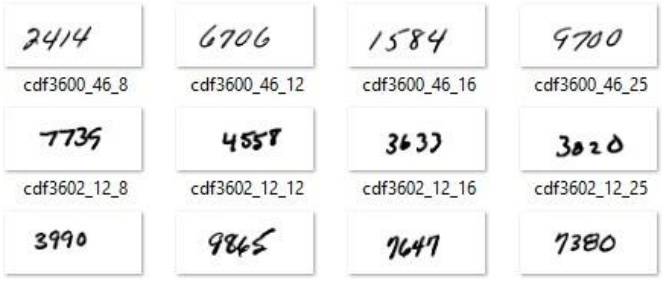

Fig. 10. Handwritten digits from the NIST database.

B. Contour Segmentation

Contour-based segmentation proposed in this study is more effective than classical methods. Our approach implements multiple specific steps for digit segmentation, which allows better isolation of each character, reduces noise impact, and improves the quality of segmented regions. Unlike standard methods that use simple binarization or contour detection, our

multi-step process preserves digit integrity and enhances performance, particularly in cross-dataset generalization trained on MNIST and tested on NIST.

This section presents handwritten digit recognition using ML and DL models, including KNN, SVM, ANN, RNN, and CNN. MNIST was used for training, NIST for testing, and OpenCV for preprocessing the digit images.

Steps in the Handwritten Digit Recognition Pipeline Using Contour Segmentation:

1) Image acquisition: Handwritten digit images were collected from the MNIST dataset.

2) Dataset splitting: The data were separated into a training set (MNIST) and a testing set (NIST).

3) Preprocessing: Contour-based segmentation techniques were applied to clean and prepare the images.

4) Normalization: Pixel intensity values were scaled to a range between 0 and 1.

5) Batching: The training dataset was divided into mini-batches to enhance training efficiency.

6) Model training: ML and DL models were trained using labeled data.

7) Classification: The trained models were used to classify digits in the testing dataset.

8) Performance evaluation: Recognition accuracy and processing time were evaluated for each model variant.

C. Implementations

1) Image preprocessing: Fig. 11 illustrates a sample image from the NIST database, which may exhibit noise, spots, or other unwanted artifacts. To mitigate these imperfections, a Gaussian filter was applied to reduce the noise, followed by a derivative filter for edge detection. A sharpening technique based on a blur mask was employed to enhance image clarity, as shown in Fig. 12.

Fig. 11. Initial image.

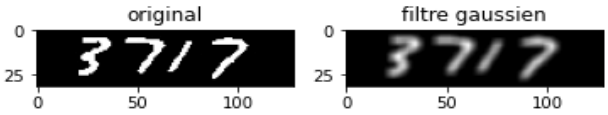

Fig. 12. Gaussian smoothing on the image.

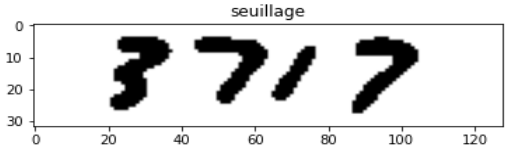

Fig. 13. Thresholding "seuillage" application.

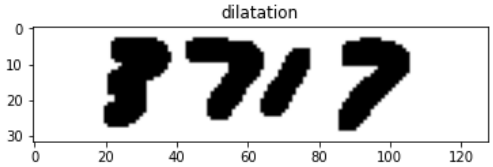

Fig. 14. Applying dilation to the image.

Thresholding was applied, as illustrated in Fig. 13, using Otsu's method to determine the optimal global threshold based on the image histogram. This binary thresholding approach enhances the contrast between foreground and background. As shown in Fig. 14, dilation was selectively applied to images containing small handwritings to capture their contours more effectively. In addition, the Canny edge detector, known for its effectiveness in edge detection, was employed in the preprocessing phase, as illustrated in Fig. 15.

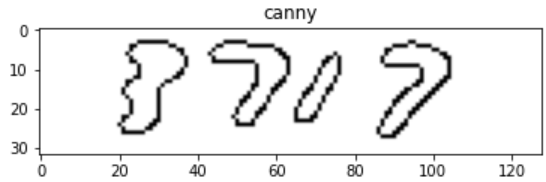

Fig. 15. Application of Canny Edge Detection.

2) Contour segmentation application: In the segmentation phase, we applied a contour detection algorithm to isolate individual digits within the image. A contour is defined as a closed curve that connects all the continuous points along the boundary of an object, representing its shape, as illustrated in Fig. 16. To accomplish this, one function was used to locate the contours, and the other was used to draw them.

Subsequently, as shown in Fig. 17, we combined contour-based segmentation with vertical segmentation. The latter divides the image into vertical slices to separate connected digits, thereby facilitating more accurate digit recognition.

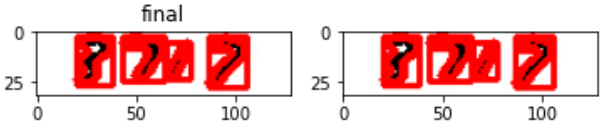

Fig. 16. Contour segmentation on the NIST dataset image digits.

Fig. 17. Vertical segmentation application.

D. Model hyperparameters

The CNN model includes a convolutional layer with 32 filters and ReLU activation, followed by a flattening layer, and then two dense layers: the first with 100 units and ReLU activation, and the second with 10 units and softmax activation. We used the SGD optimizer (learning rate of 0.01, momentum of 0.9) and the 'categorical_crossentropy' loss function, as shown in Table III.

TABLE I. ANN HYPERPARAMETERS

Number of epochs	100
Batch size	1000
Activation function	Softmax & Sigmoid
Optimizer	Adam
Loss	sparse_categorical_crossentropy

TABLE II. RNN HYPERPARAMETERS

Number of epochs	50
Batch size	128
Units	256
Dropout	0.2
Activation function	Softmax
Optimizer	SGD
Loss	categorical_crossentropy

TABLE III. CNN HYPERPARAMETERS

Number of epochs	100
Batch size	1000
Activation function	Relu & Softmax
Optimizer	Adam
Loss	categorical_crossentropy

As illustrated in Table I, the ANN model was trained for 100 epochs with a batch size of 1000 using Softmax and Sigmoid activation functions and the Adam optimizer, with 'sparse_categorical_crossentropy' as the loss function.

To prevent overfitting, the RNN model, which includes 256 units and a dropout rate of 0.2 to prevent overfitting, uses Softmax activation and is optimized with SGD, as shown in Table II. The loss function used is also 'categorical_crossentropy', which is optimized for multi-class classification tasks.

The hyperparameters for all models were selected based on experimental validation to ensure stable convergence, prevent overfitting, and achieve optimal performance on both MNIST and NIST datasets. Ablation studies were performed to evaluate the impact of varying key parameters (e.g., number of units, activation functions, learning rate, dropout), confirming that the chosen configuration consistently provides robust and reproducible results.

E. Analysis of Results

During testing, this study proposes a comprehensive method to evaluate all digit cases from the NIST dataset across multiple models. A structured framework was developed to facilitate testing on different models by grouping each test case within a structure that consolidates the results of all applied models. Unlike previous studies, which performed tests on the entire dataset without a method allowing an easy linkage of each model to its corresponding test, this approach ensures clear, systematic, and robust performance comparisons, as illustrated below. This methodology confirms the relevance of the observed improvements.

We performed handwritten digit recognition using five different models (KNN, SVM, CNN, RNN, and ANN) to identify the most accurate model. As shown in Fig. 18, the deep learning models (ANN, RNN, and CNN) outperformed the others in both test cases. Similarly, Fig. 19 shows that the RNN and CNN achieved the best results across all the digits in the test case. Furthermore, Fig. 20 illustrates that the RNN consistently outperformed the CNN and other models across all three test scenarios.

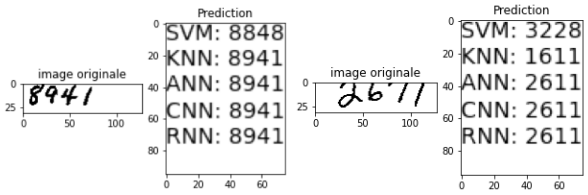

Fig. 18. In both test cases, Deep Learning models {ANN, RNN, CNN} showed superior performance.

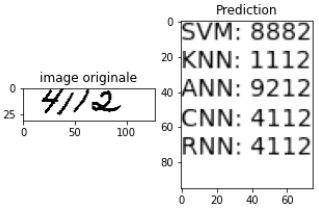

Fig. 19. RNN and CNN models achieved the best results for all digits in this test.

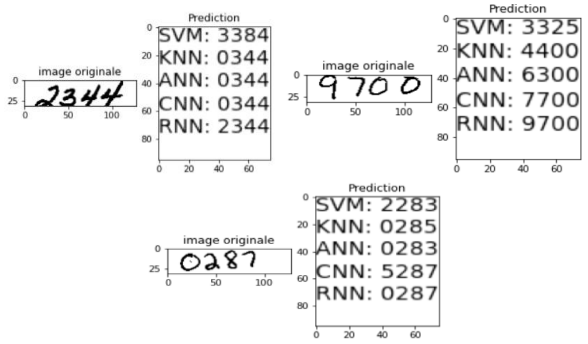

Fig. 20. RNN models outperformed CNN and other models across all digits in these three tests.

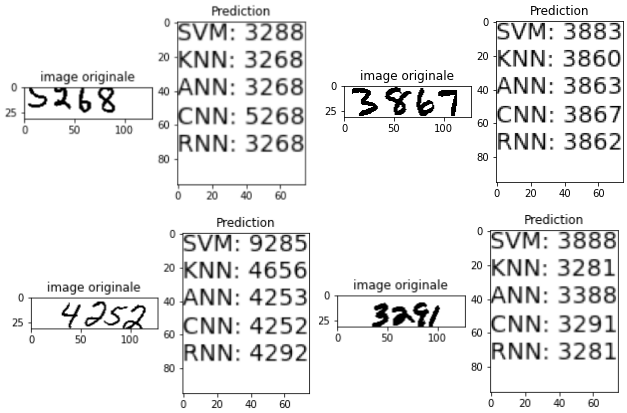

Fig. 21. CNN models performed better than other models for all digits in these examples.

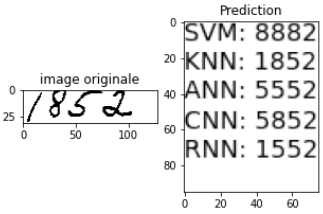

Fig. 22. In this test example, KNN models outperform others and correctly identify at least 3 out of 4 digits in other tests.

In the test examples shown in Fig. 21, the CNN models outperformed the other models for all the digits. As shown in Fig. 22, the KNN models also demonstrated superior performance for all the digits. In addition, in other test examples, the KNN models provided acceptable results, correctly identifying at least three of the four handwritten digits.

TABLE IV. RESULTS TABLE DISPLAYING THE ACCURACY OF EACH MODEL

Models	Accuracy (%)
SVM	93.48
KNN	92.9
ANN	99.56
RNN	98.74
CNN	98.53

Table IV lists the accuracy results for each model on the MNIST image dataset. In our handwritten digit recognition project using the MNIST dataset, we evaluated several ML and DL models: SVM, KNN, ANN, CNN, and RNN. The results showed that the DL models outperformed the traditional machine learning models. In particular, ANN achieved the highest accuracy of 99.56%, followed by RNN at 98.74% and CNN at 98.53%. SVM and KNN achieved accuracies of 93.48% and 92.9%, respectively. Prediction analysis for the digit sequence '1852' highlighted KNN's strength in certain specific cases, whereas other models had variable prediction accuracies. Overall, the DL models proved to be more effective for this task.

TABLE V. COMPARISON OF RESULTS WITH RECENT WORKS

Models	Our Result (%)	Previous Results (%)	References of Previous Works
SVM	93.48	92.3- 93	[48]
KNN	92.9	91.8- 92.3	[49]
ANN	99.56	97 - 97.4	[50]
RNN	98.74	97 - 98	[51]
CNN	98.53	98 – 98.12	[52]

Our model outperformed previous approaches across all tested algorithms, as shown in Table V, with significant improvements in the ANN (99.56%) and RNN (98.74%). These enhancements suggest effective optimization of the architecture and hyperparameters. Slight increases were also observed for SVM, KNN, and CNN, confirming the robustness of our approach compared to previous works.

VI. CONCLUSION AND FUTURE WORK

This study developed an offline handwritten digit recognition system and compared various ML and DL models to identify the most effective. After preprocessing, a contour-based segmentation method was implemented and evaluated across multiple classifiers. The study assessed features and models to determine the best HDR approach.

Segmentation is challenging. Our system uses morphological and geometric operations with contour detection to isolate digits and reduce noise, producing segmented images of single digits for training.

We performed experiments on the NIST dataset using contour-based segmentation and a range of algorithms: KNN, SVM, ANN, CNN, and RNN. The results showed that CNN and RNN delivered the best recognition performance, with high accuracy and consistency. Among the ML methods, KNN achieved acceptable results despite the difficulty in recognizing unclear digits in the NIST dataset.

SVM demonstrated the fastest training time and achieved the highest training accuracy among the models evaluated. However, its simplicity limits its ability to classify ambiguous or complex inputs compared with DL models. By contrast, the DL models (CNN, RNN, and ANN) provided significantly better results, reaching up to 99% accuracy during both training and testing.

Overall, nearly all the algorithms yielded acceptable results on the NIST test set, confirming their suitability for HDR tasks. While the SVM had the shortest execution time, the CNN required the longest execution time.

In future work, we plan to enhance recognition accuracy by focusing entirely on deep learning techniques, exploring alternative architectures, and optimizing learning strategies. Our approach will be applied to more complex, real-world datasets, such as handwritten digits from bank checks. Furthermore, we aim to investigate adaptive segmentation methods to better handle overlapping digits and challenging handwriting styles, providing a clear roadmap for advancing offline handwritten digit recognition systems.

***Abstract*—This study investigates a hybrid residual control framework combining Deep Deterministic Policy Gradient (DDPG) and a Proportional–Integral–Derivative (PID) based correction module for active suspension (AS) systems, aiming to improve ride performance and generalization under complex road excitations. The DDPG controller is trained on sinewave inputs, while the PID module compensates for residual errors to enhance robustness. To further guide policy optimization, an error-aware reward rescaling strategy is introduced during training, adaptively shaping the reward signal based on acceleration deviation. The controller is tested under five typical road conditions. These include sinewave inputs and step inputs, and ISO 8608 Level B random profiles. Simulation results show that the residual DDPG (RDDPG) controller works better than both DDPG alone and the PID controller. It reduces vertical acceleration RMS by 50.35% under a 0.05 m sinewave input. This shows that using reinforcement learning (RL) with fast correction and reward adjustment is a useful and stable way to control AS in different driving conditions.**

***Keywords*—Deep deterministic policy gradient; active suspension; reward function; generalization**

I. Introduction

In recent years, data-driven control methods such as RL have developed quickly. These methods have demonstrated strong adaptability and robustness in uncertain conditions [1]. At the same time, active anti-roll bar systems have shown strong potential in improving vehicle lateral stability [2]. Body roll can be reduced a lot during sharp turns or on rough roads [3], [4], [5]. These improvements show a new method to develop smart AS control. At the same time, more advanced methods are being tried in AS systems to better handle changing and unseen driving situations.

To enhance adaptability, Nguyen [6] developed a fuzzy logic PI controller that adjusts its gains in real-time, leading to improved ride comfort and stability in a quarter-car model under varying conditions. Similarly, Zhou et al. [7] introduced a machine learning model that incorporates fuzzy logic to mitigate vertical vibrations in a two degree of freedom (2-DOF) suspension setup. The method lowered body acceleration well and stayed simple to compute, so it could be used in real-time.

As the vehicle systems become more nonlinear and sophisticated, conventional controllers don't always guarantee good performance. For this reason, researchers look into neural networks (NN) and deep learning for better suspension force control. Bongain and Jamett [8] developed a hybrid fuzzy logic NN controller tailored to the nonlinear dynamics of electro-hydraulic actuators. They compared this development with the PID-ANN controller and showed that they achieved superior tracking performance in input variations. Konoiko et al. [9] introduced a feedforward deep NN trained using supervised learning. The data were acquired from the optimal PID controller by full state feedback. An automatic structure optimization procedure was performed to improve generalization.

AS control has improved a lot in recent years as more people use RL [10]. RL helps create control strategies by letting the system learn from the environment. This means it does not need a set system model. Liang and Wei [11] applied the DDPG algorithm to both active and semi-AS systems. The controller gives continuous force signals to the actuators and uses a reward function that punishes large vertical acceleration and too much suspension movement. Their results showed that the DDPG method worked well and made the ride more comfortable in different driving situations. Yong et al. [12] made a switching learning system based on the Soft Actor-Critic (SAC) framework. The system was able to recognize various types of road disturbances in real-time and adjust its control strategy accordingly. The method was first tested in simulation, then applied to real road situation. It showed that it could handle different driving conditions well.

Researchers have used actor-critic (AC) setups to better deal with uncertainty and changes in the system. Fares and Bani Younes [13] implemented a Time-Difference Advantage Actor Critic (TD-A2C) algorithm in a model-free setup. Their controller worked without knowing the environment before. It used an actor network to make actions, and a critic to check them. This setup helped keep a good balance between control force and ride comfort. Chen and Chang [14] applied a similar AC framework to control uncertain discrete-time systems. By using an NN to estimate the value function, their method kept the policy stable and made control more accurate. In parallel, Li and Kalabic [15] introduced a safety RL approach was introduced, integrating model free learning with a safety monitoring component. Penalty functions were used to reduce unsafe behavior during training which helped the controller explore effectively within safety limits.

*Corresponding Author.

Robustness and real-time adaptability remain key challenges in AS applications. To address this, Radac and Lala [16] formulated the suspension control task as a zero sum differential game between the controller and a worst case disturbance. Their game theoretic approach ensured robustness during learning by explicitly modeling adversarial conditions. Complementing this, Wang, Tian, and Zhang [17] developed a two layer control architecture based on a vehicle model. They combined incremental PID control with a deep RL adaptive (DRLA) strategy to enable online tuning of suspension forces in response to heave, pitch, and roll motions. Their method improved both ride stability and road handling. Wang, Zhuang, and Yin [18] applied DRL techniques to a quarter-car model under bump disturbances, confirming the controller's effectiveness in managing transient shocks.

The main contribution of this study is the use of error-aware reward rescaling method to make the training of the DDPG controller faster and more stable. The residual framework is combined with DDPG and PID to reduce vertical acceleration under different unseen road conditions.

II. METHODOLOGY

This study employs a classic quarter car model 2-DOF, representing the vertical motions of the sprung and unsprung masses. To guide the learning process, an Error-Aware Reward Rescaling mechanism is designed, where vertical acceleration minimization is set as the primary objective, and suspension deflection and control effort are treated as secondary considerations.

A. Quarter-Car Model and Parameters

The quarter-car model with 2-DOF represents the vertical motions of the sprung mass and the unsprung mass, respectively. The system dynamic equations and schematic diagram are given as follows, in Fig. 1:

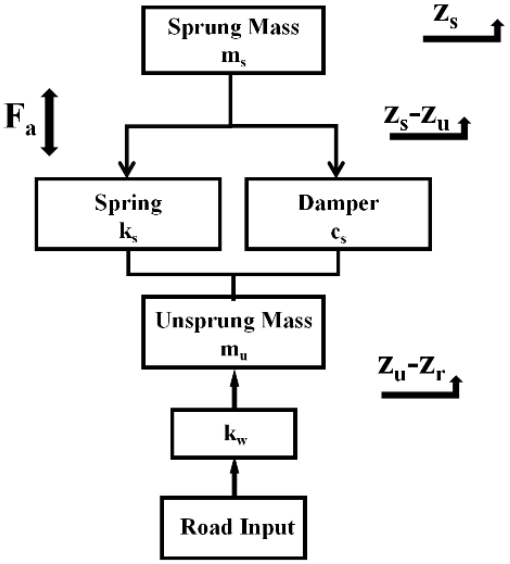

Fig. 1. Schematic diagram of the quarter-car AS system.

Sprung mass dynamics:

$$m_s\ddot{z}_s=-k_s(z_s-z_u)-c_s(\dot{z}_s-\dot{z}_u)+F_a \quad (1)$$

Unsprung mass (wheel) dynamics:

$$m_u\ddot{z}_u=-k_s(z_s-z_u)-c_s(\dot{z}_s-\dot{z}_u)-k_t(z_u-z_r)-F_a \quad (2)$$

where, m_s and m_w denote the sprung and unsprung masses, respectively; k_s and c_s represent the suspension stiffness and damping coefficient; k_w is the tire stiffness; z_s, z_u, and z_r denote the vertical displacements of the vehicle body, wheel, and road surface, respectively; and F_a is the control force generated by the AS actuator.

B. Control Framework and DDPG Controller

The control system developed in this study consists of a PID controller combined with an RL controller based on the DDPG algorithm. The DDPG controller generates the primary control force for the AS, while the PID controller learns to produce a residual correction term. The final suspension control force is the sum of the outputs from both controllers. This hybrid residual structure enhances the stability and responsiveness of the system during training as well as under unseen operating conditions. The overall control framework of the proposed AS system is illustrated in Fig. 2.

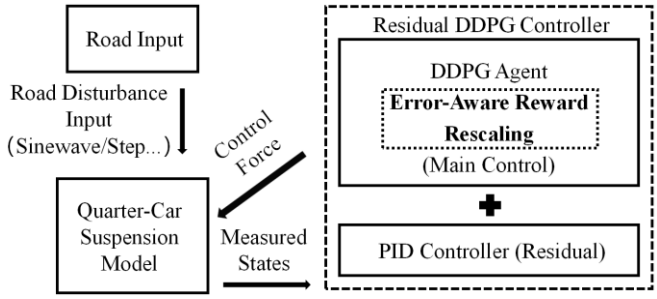

Fig. 2. Overall control framework of the AS system based on RDDPG.

The DDPG algorithm is a model-free RL method tailored for continuous control tasks. It integrates a deterministic policy gradient framework with an actor–critic architecture. The critic approximates the action-value function $Q(s, a;\theta^Q)$, which is updated by minimizing the temporal-difference loss between the estimated and target Q-values:

$$L(\theta^Q) = E[(y_t - Q(s_t, a_t; \theta^Q))^2] \quad (3)$$

The target value y_t is computed using delayed versions of the actor and critic networks:

$$y_t=r_t+\gamma\cdot Q'(s_{t+1},\mu'(s_{t+1})) \quad (4)$$

where, $\gamma\epsilon[0,1]$ is the discount factor, and μ', Q' are the target actor and critic networks respectively. These targets are held fixed for stability during mini-batch updates.

The actor represents the policy $\mu(s;\theta^\mu)$, which is updated by maximizing the critic's evaluation of the current policy. The gradient of the objective with respect to the actor's parameters is given by:

$$\nabla_{\theta^\mu}J\approx E\left[\nabla_a Q(s,a;\theta^Q)|_{a=\mu(s)}\cdot\nabla_{\theta^\mu}\mu(s)\right] \quad (5)$$

This update encourages the actor to select actions that yield higher predicted Q-values, as determined by the critic. To mitigate oscillations during learning, the algorithm employs

target networks that are updated gradually using a soft update rule:

$$\theta^{Q'} \leftarrow \tau\theta^{Q} + (1-\tau)\theta^{Q'}, \theta^{\mu'} \leftarrow \tau\theta^{Q\mu} + (1-\tau)\theta^{\mu'} \quad (6)$$

A small update coefficient τ ensures that target networks evolve slowly, thus smoothing the learning process. To promote exploration in a deterministic policy framework, temporally correlated noise is added to the actor's output:

$$a_t = \mu(s_t) + N_t \quad (7)$$

where, N_t typically follows an Ornstein–Uhlenbeck (OU) process, which models physical systems more realistically than uncorrelated noise and helps prevent premature convergence.

In this study, a residual structure is employed to improve the robustness of the DDPG controller. The RL agent is designed to fine-tune the output of the traditional controller rather than replace it entirely. The final control signal is obtained by combining the baseline controller's action with the correction learned by the agent, formulated as:

$$u_t = uPID(t) + uDDPG(t) \quad (8)$$

where, uPID denotes the output of a conventional PID controller, and uDDPG is the corrective term learned by the DDPG agent. This structure enables the RL component to focus on modeling deviations or nonlinearities that are difficult to capture with classical methods.

C. Error-Aware Reward Rescaling and Training Setup

This study introduces an Error-Aware Reward Rescaling mechanism that improves ride comfort by reducing vertical acceleration while accounting for suspension travel and control effort. The approach sets vertical acceleration as the primary objective and treats suspension deflection and actuator force as supporting factors. By adaptively shifting focus to the variable with the largest deviation at any given moment, it helps to guide the learning process more effectively, leading to better convergence and improved control reliability.

The instantaneous reward is composed of three terms: vertical comfort score $R_{comfort}$, suspension travel score R_{travel}, and control effort penalty P_{action}. The first two terms are modeled using exponential decay functions to penalize large deviations from ideal states:

$$R_{comfort} = \exp\left(-\left(\frac{|\ddot{z}_b|}{\ddot{z}_{lim}}\right)^2\right) \quad (9)$$

$$R_{travel} = \exp\left(-\left(\frac{|x_s|}{x_{lim}}\right)^2\right) \quad (10)$$

The control penalty is implemented using a hyperbolic tangent function to suppress excessively large control actions:

$$P_{action} = \tanh\left(\left(\frac{|F|}{F_{max}}\right)^2\right) \quad (11)$$

where, $\ddot{z}_b$ denotes the vertical acceleration of the vehicle body. x_s denotes the suspension travel. F denotes the actuator control force. $\ddot{z}_{lim}$ denotes the predefined upper limit for ideal vertical acceleration. x_{lim} is defined as the maximum desired suspension travel range. F_{max} denotes the maximum control force amplitude. λ refers to the control force penalty coefficient.

Instead of applying fixed weights to the comfort and travel terms, the proposed method adaptively rescales their importance based on the normalized error magnitude of each state component. Specifically, the dynamic weights are computed as:

$$w_c = \frac{\min\left(1, \frac{|\ddot{z}_b|}{\ddot{z}_{lim}}\right)}{\min\left(1, \frac{|\ddot{z}_b|}{\ddot{z}_{lim}}\right) + \min\left(1, \frac{|x_s|}{x_{lim}}\right)}, \; w_t = 1 - w_c \quad (12)$$

This formulation enables the controller to dynamically assign greater attention to the more critical performance objective at each moment, based purely on state error levels, without requiring access to prior reward outputs. As a result, the reward function guides the policy to minimize the dominant deviation and improve adaptability across varying conditions.

The final reward expression is given by:

$$r_t = w_c \cdot R_{comfort} + w_t \cdot R_{travel} - \lambda \cdot P_{action} \quad (13)$$

An additional bonus of 0.5 is granted when all normalized indicators fall below 0.5, encouraging convergence toward ideal operational zones. Numerical safety measures, including reward clipping and invalid value checks, are implemented to ensure stable learning. While the current reward function effectively guides the training process, the investigation into alternative reward shaping strategies lies outside the primary scope of this work and is reserved for future research.

The DDPG agent receives three state variables as input: suspension deflection, the corresponding vertical velocity of the sprung mass, and the vertical acceleration of the vehicle body. The output is a one-dimensional continuous control force ranging from −1000 N to 1000 N, which is applied to the AS system. Both the Actor and Critic networks adopt a single hidden layer architecture with 256 neurons. To enhance exploration, OU noise with a standard deviation of 0.5 is introduced. Detailed parameters are provided in the corresponding Table I.

TABLE I. DETAILED PARAMETERS OF DDPG CONTROLLER

DDPG Training Parameters	
Description	***Value***
Number of Hidden Neurons	256
Learning Rate (Actor & Critic)	0.001
Target Network Soft Update Factor	0.001
Exploration Noise Type	OU
Noise Standard Deviation	0.5
Experience Replay Buffer Size	1e6

The control input of the AS system is the suspension force generated by the RDDPG controller. This control structure consists of two components: a primary controller based on DDPG, which is trained under smooth road conditions, and a residual correction module based on a PID controller that compensates for the DDPG output. The controller receives system state variables as input, including the vertical acceleration of the vehicle body. The DDPG module outputs an initial control force, while the PID module learns the residual

component to refine the control output. This hybrid architecture enhances adaptability and robustness under previously unseen scenarios.

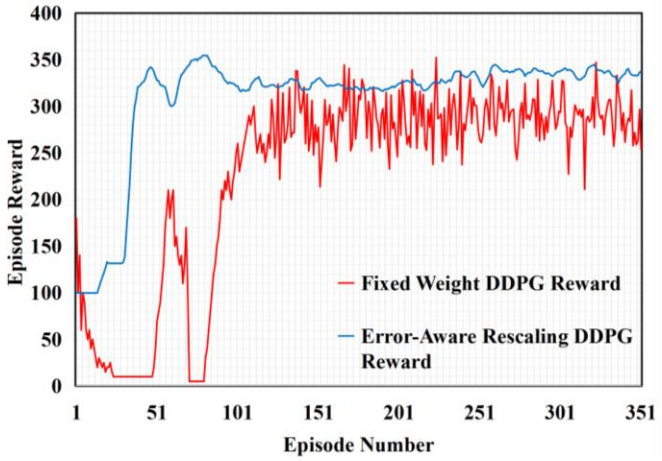

Fig. 3. Episode reward of Error-Aware Rescaling DDPG and Fixed Weight DDPG.

As shown in the training reward curve in Fig. 3, the DDPG agent utilizing the proposed Error-Aware Rescaling reward function demonstrates significantly superior learning performance compared to the baseline with fixed-weight rewards. Specifically, the rescaling-based agent achieves rapid convergence within the first 50 episodes and maintains consistently higher episode rewards with minimal fluctuations throughout the training process. In contrast, the fixed-weight reward agent exhibits unstable learning behavior, with prolonged periods of near-zero rewards and considerable oscillations even in later stages. This indicates that the fixed-weight design is prone to suboptimal policy learning and lacks robustness. Overall, the Error-Aware Rescaling approach enhances both convergence speed and policy stability, leading to improved final performance and demonstrating strong potential for guiding RL in suspension control tasks.

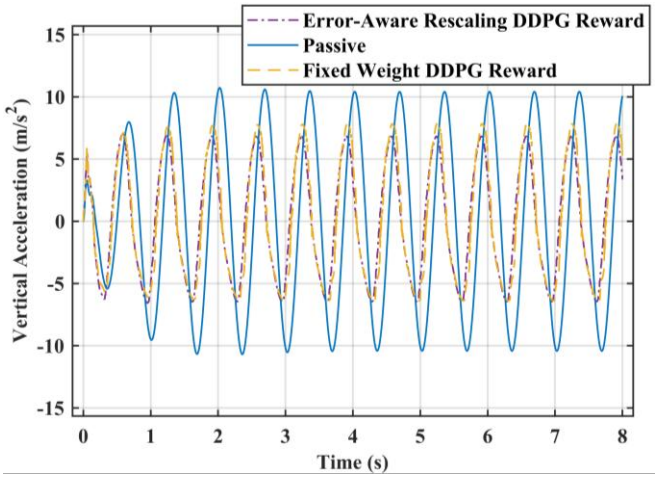

Fig. 4. Comparison of Error Aware Rescaling DDPG and Fixed Weight DDPG.

During training, a sinewave road excitation with a frequency of 1.5 Hz and amplitudes of 0.05m is used to simulate typical smooth driving conditions. The DDPG controller is trained until the policy converges, as indicated by a stable reward trend and a continuous reduction in the root mean square (RMS) of vertical acceleration.

TABLE II. SIMULATION RESULTS OF ERROR-AWARE RESCALING DDPG AND FIXED-WEIGHT DDPG

Controller	Compare DDPG at Sinewave 0.05m Road Input Condition	
	RMS	***RMS Reduction***
Passive	7.11 m/s²	-
Error-Aware Rescaling DDPG	4.62 m/s²	35.02%
Fixed-Weight DDPG	5.05 m/s²	28.94%

The results are shown in Fig. 4 and Table II. The passive suspension system produces an RMS value of 7.11 m/s², indicating significant vibration and poor ride comfort. When using the DDPG controller trained with the proposed error-aware rescaling reward, the RMS is reduced to 4.62 m/s², achieving a 35.02% improvement over the passive case. In comparison, the controller trained with fixed reward weights yields an RMS of 5.05 m/s², corresponding to a 28.94% reduction. The improved reward structure demonstrates a more pronounced effect in enhancing the vehicle's vertical stability and ride comfort.

III. SIMULATION SETUP

To evaluate the control performance and generalization capability of the proposed RDDPG control strategy in AS systems, this study conducts simulation research based on a quarter-car suspension model. The entire simulation environment is established within the MATLAB/Simulink platform. Both the training and testing procedures are carried out using a representative 2-DOF quarter AS model, which comprises the sprung mass, unsprung mass, suspension spring, damper, and active actuator. The system dynamics take into account the vertical motions of the vehicle body and wheel, aiming to characterize the suspension's response under various road excitations. Table III presents the detailed parameters of the vehicle.

TABLE III. DETAILED PARAMETERS OF VEHICLE

Vehicle Parameters	
Value	***Description***
1400 kg	Sprung mass (full car)
45 kg	Unsprung mass
25800 N/m	Suspension spring stiffness
1200Ns/m	Suspension damping coefficient
198000N/m	Tire stiffness

To evaluate the generalization capability of the proposed controller, three types of unseen road excitation profiles are introduced during the testing phase. The first type is a step road excitation, which includes step inputs of 0.03 m (unseen) and 0.05 m (trained) in amplitude. This test is designed to simulate sudden road height changes, such as speed bumps or curbs. The corresponding profile is illustrated in Fig. 5.

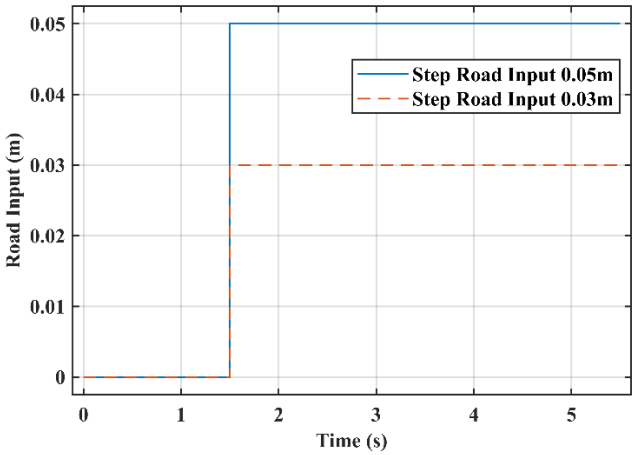

Fig. 5. Step 0.03m and step 0.05m road input profiles.

The second type is a random road excitation, constructed according to the ISO 8608 standard for road roughness classification. Specifically, Level B profiles are employed to represent medium and poor road conditions, respectively. These excitations are shown in Fig. 6.

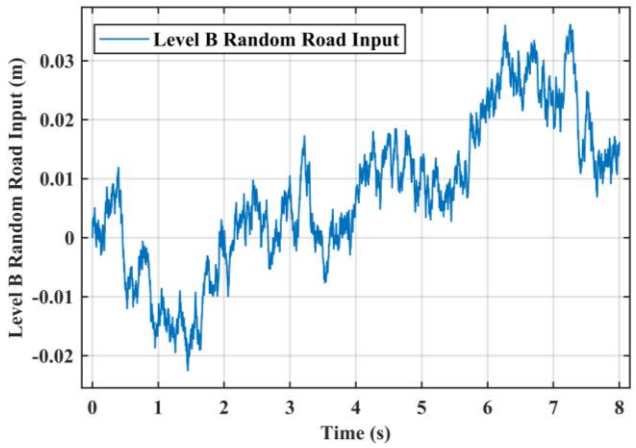

Fig. 6. Level B random road input profiles.

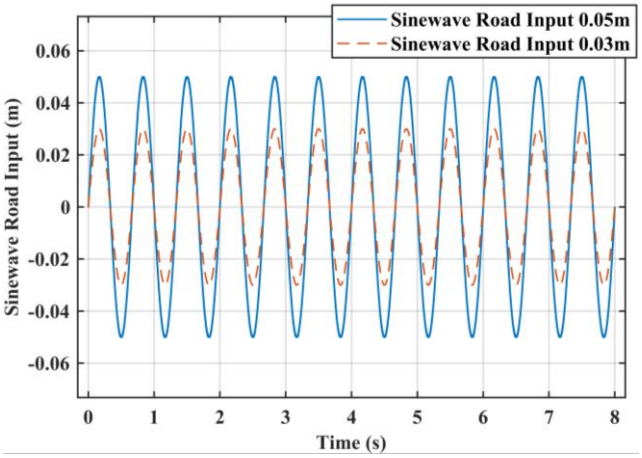

Fig. 7. Sinewave 0.05m and Sinewave 0.03m road input profiles.

The third type is a sinewave excitation, which is identical to the road profile used in the training phase. This sinewave 0.05m scenario serves as a baseline to validate the controller's fundamental performance under familiar conditions. This sinewave 0.03m is an unseen condition to validate the controller's performance. The excitation waveform is presented in Fig. 7.

IV. Simulation Results

To comprehensively assess the effectiveness and generalization ability of the proposed RDDPG control strategy under varying road conditions, three representative test scenarios were constructed: sinewave 0.05m input excitation (training condition), sinewave 0.03m input excitation (unseen condition), step 0.03m and 0.05m input (unseen condition), and ISO 8608 Level B random road profiles (unseen conditions). The figures present the vertical acceleration responses of the vehicle body under different control strategies, including passive suspension, PID control, standalone DDPG control, and the proposed RDDPG controller, when subjected to these road excitations.

A. Sinewave 0.05m Road Input Condition Simulation Results

The simulation results under the sinewave 0.05m road input condition are shown below:

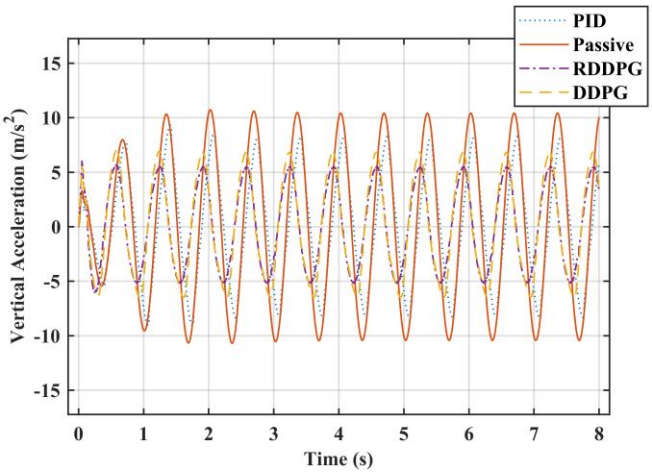

Fig. 8. Sinewave 0.05m road input simulation results.

During the training phase, a sinewave road excitation with an amplitude of 0.05 m was employed. Fig. 8 illustrates the vertical acceleration responses of the vehicle body under different control strategies. As shown, all three active control methods significantly reduce the fluctuation amplitude of vertical acceleration compared to the passive suspension, with the proposed RDDPG controller delivering the most pronounced improvement. According to the data summarized in Table IV, the passive suspension system RMS vertical acceleration of 7.11 m/s². The DDPG-based controller reduces this value to 4.62 m/s², corresponding to a 35.02% decrease, while the conventional PID controller achieves an RMS of 5.24 m/s², reflecting a 26.30% reduction. Notably, the RDDPG approach further lowers the RMS to 3.53 m/s², achieving a 50.35% reduction over the passive baseline and demonstrating the best overall performance in vibration attenuation. These results confirm the effectiveness and superiority of the RDDPG strategy under 0.05m sinewave excitation conditions.

TABLE IV. SIMULATION RESULTS OF SINEWAVE 0.05M ROAD INPUT CONDITION

Controller	Sinewave 0.05m Road Input Condition	
	RMS	***RMS Reduction***
Passive	7.11 m/s²	-
DDPG	4.62 m/s²	35.02%
RDDPG	3.53 m/s²	50.35%
PID	5.24 m/s²	26.30%

B. Sinewave 0.03m Road Input Condition Simulation Results

The simulation results under the sinewave 0.03m road input condition are shown below:

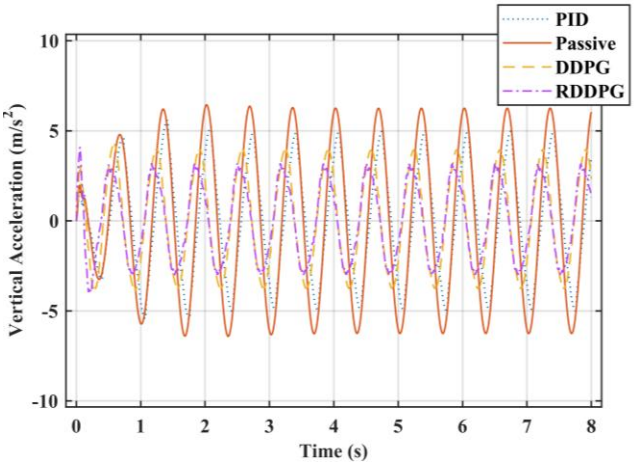

Fig. 9. Sinewave 0.03m road input simulation results.

To assess the vibration isolation performance under moderate road disturbances, a sinewave input with an amplitude of 0.03 m was applied in the simulation. The corresponding vertical acceleration responses for each control method are presented in Fig. 9. As observed, all AS strategies provide improved performance over the passive system, with the RDDPG controller demonstrating the most notable attenuation. According to the results summarized in Table V, the passive suspension yields an RMS vertical acceleration of 4.26 m/s². The DDPG controller reduces this to 2.84 m/s², indicating a 33.33% improvement, while the PID controller achieves 3.14 m/s², corresponding to a 26.29% reduction. The RDDPG strategy achieves the lowest RMS value of 2.14 m/s², marking a 49.77% decrease relative to the passive configuration. Overall, the results highlight the RDDPG controller's robust adaptability and its superior vibration suppression performance under reduced excitation amplitudes.

TABLE V. SIMULATION RESULTS OF SINEWAVE 0.03M ROAD INPUT CONDITION

Controller	Sinewave 0.03m Road Input Condition	
	RMS	***RMS Reduction***
Passive	4.26 m/s²	-
DDPG	2.84 m/s²	33.33%
RDDPG	2.14 m/s²	49.77%
PID	3.14 m/s²	26.29%

C. Step 0.05m Road Input Condition Simulation Results

The simulation results under the step 0.05m road input condition are shown below:

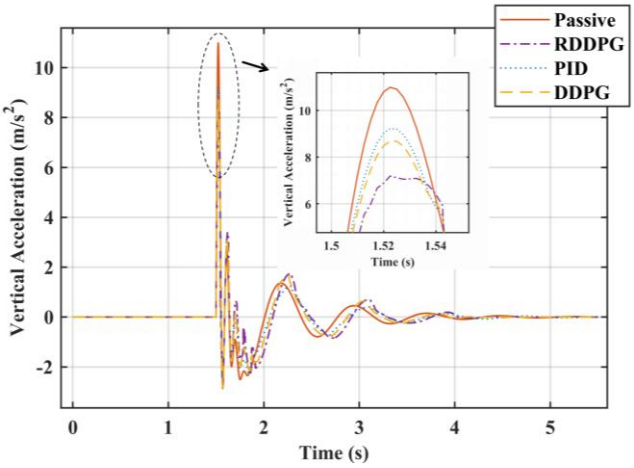

Fig. 10. Step 0.05m road input simulation results.

To evaluate the generalization performance of each control strategy under previously unseen conditions, a step road disturbance with a height of 0.05 m was introduced, simulating an abrupt change in road profile. The resulting vertical acceleration responses are illustrated in Fig. 10. Compared to the passive suspension, all three active control strategies clearly mitigate the initial impact and help the system stabilize more rapidly. The magnified section highlights the effectiveness of each controller in suppressing peak acceleration. The corresponding RMS values are listed in Table VI. The passive system yields an RMS vertical acceleration of 0.99 m/s². The DDPG controller reduces it to 0.82 m/s², resulting in a 17.17% decrease. The PID controller achieves 0.84 m/s², reducing the RMS by 15.15%. The RDDPG controller attains the best result with 0.79 m/s², representing a 20.20% reduction compared to the passive baseline. These findings demonstrate that the RDDPG strategy not only performs well under trained periodic conditions but also retains strong robustness and adaptability when facing sudden road disturbances.

TABLE VI. SIMULATION RESULTS OF STEP 0.05M ROAD INPUT CONDITION

Controller	Step 0.05m Road Input Condition	
	RMS	***RMS Reduction***
Passive	0.99 m/s²	-
DDPG	0.82 m/s²	17.17%
RDDPG	0.79 m/s²	20.20%
PID	0.84 m/s²	15.15%

D. Step 0.03m Road Input Condition Simulation Results

The simulation results under the step 0.03m road input condition shown below:

Fig. 11 illustrates the vertical acceleration responses of the vehicle body under different control strategies. Compared to the passive suspension, the active controllers effectively

suppress the initial impact peak and accelerate the system's convergence. The magnified section in the figure provides a detailed comparison of the overshoot behavior across controllers. Table VII summarizes the corresponding RMS values. The passive system yields an RMS vertical acceleration of 0.58 m/s². The DDPG controller reduces this to 0.48 m/s², representing a 15.79% improvement. The PID controller achieves 0.50 m/s², which corresponds to a 13.79% reduction. The RDDPG controller achieves the lowest RMS at 0.45 m/s², yielding a 21.05% decrease compared to the passive baseline. These results further demonstrate that the proposed RDDPG control strategy maintains reliable performance and strong generalization capability even under mild, abrupt disturbances.

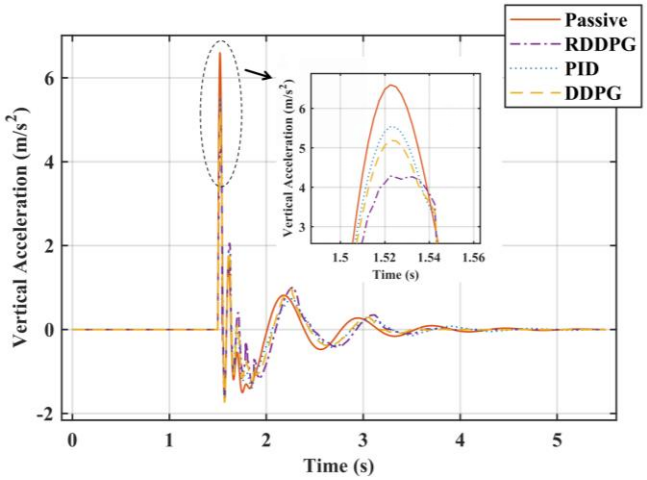

Fig. 11. Step 0.03m road input simulation results.

TABLE VII. SIMULATION RESULTS OF STEP 0.03M ROAD INPUT CONDITION

Controller	Step 0.03m Road Input Condition	
	RMS	***RMS Reduction***
Passive	0.58 m/s²	-
DDPG	0.48 m/s²	15.79%
RDDPG	0.45 m/s²	21.05%
PID	0.50 m/s²	13.79%

E. Level B Road Input Condition Simulation Results

The simulation results under the ISO 8608 Level B random road input condition are shown below:

The ISO 8608 Class B random road profile was introduced to examine how well each control strategy adapts to irregular and complex surface disturbances. Fig. 12 displays the resulting vertical acceleration responses. As shown, the passive suspension experiences pronounced high-frequency oscillations, whereas the active control strategies noticeably suppress these fluctuations, indicating their improved ride comfort capabilities. Table VIII reports the corresponding RMS values. The passive configuration results in an RMS of 0.76 m/s². The DDPG strategy improves this to 0.63 m/s², yielding a 17.11% reduction, while the PID controller achieves 0.66 m/s², reflecting a 13.16% decrease. RDDPG again provides the best result, further lowering the RMS to 0.62 m/s², an 18.42% improvement over the passive baseline. These findings suggest that the RDDPG approach retains a high level of performance even under stochastic mid-grade excitations, demonstrating greater resilience and adaptability than the other methods tested.

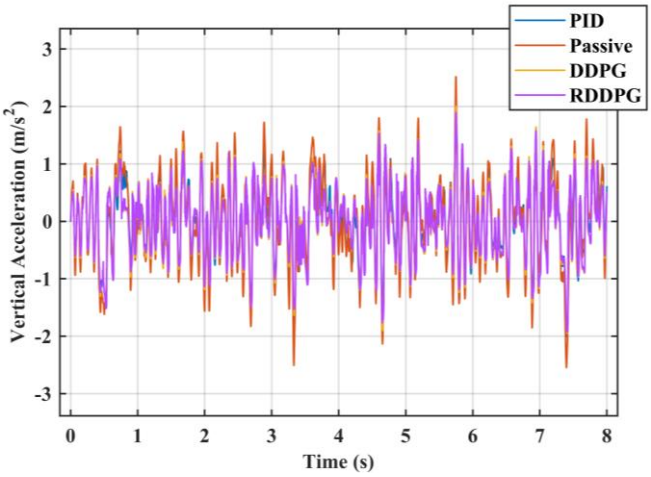

Fig. 12. Level B random road input simulation results.

TABLE VIII. SIMULATION RESULTS OF LEVEL B RANDOM ROAD INPUT CONDITION

Controller	Level B Random Road Input Condition	
	RMS	***RMS Reduction***
Passive	0.76 m/s²	-
DDPG	0.63 m/s²	17.11%
RDDPG	0.62 m/s²	18.42%
PID	0.66 m/s²	13.16%

V. DISCUSSION

Different from the residual control structure proposed by Hynes et al. [19], this study adopts an RL-centric architecture, where the DDPG controller serves as the primary decision-making module, and a PID controller is employed as a residual correction mechanism to enhance robustness. In contrast to their design, which relies on a PID-based policy and uses DDPG as a supplementary component requiring careful pre-tuning, this study approach eliminates the dependence on a well-tuned initial controller. Moreover, an Error-Aware Reward Rescaling mechanism is introduced to improve both training efficiency and policy convergence. The prior work reports results under a limited range of conditions. In contrast, this study tests the proposed method across five representative road scenarios, including both training and unseen cases, to provide a more complete assessment of its generalization and robustness.

Compared to other RL suspension control studies [20], this study demonstrates clear advantages in control architecture, adaptability, and generalization capability. First, it uses a residual control setup that combines a DDPG controller with a PID correction model. The PID component adaptively adjusts the DDPG output to enhance the stability and robustness of the control strategy under complex road conditions. An Error-Aware Reward Rescaling mechanism is introduced to adjust

reward weights based on acceleration errors during training, which improves adaptability and convergence efficiency. In terms of validation, this study evaluates the controller under five representative road profiles that include sinewaves, step disturbances, and ISO 8608 Level B random inputs. This study provides a more comprehensive assessment of generalization compared to previous work.

Simulation results consistently show that RDDPG outperforms standalone DDPG and traditional PID controllers. Under the 0.05 m sinewave excitation used as the training condition, RDDPG achieves a 50.35% reduction in RMS vertical acceleration compared to the passive baseline, exceeding the performance of DDPG at 35.02% and PID at 26.30%. Under the 0.05 m step input as an unseen condition, RDDPG still delivers the best result, reducing RMS by 20.20%, while DDPG achieves 17.17% and PID achieves 15.15%. Even in stochastic and unstructured conditions such as ISO 8608 Level B random road condition, RDDPG maintains reliable performance with the lowest RMS value of 0.62 m/s², indicating strong resilience.

Overall, by combining the long-term policy optimization ability of RL with the short-term corrective precision of PID control, the RDDPG strategy achieves a balanced performance in both stability and generalization. Its consistent effectiveness across a wide range of scenarios underscores its reliability and practical value for AS systems.

VI. Conclusion

This study adopts a hybrid control strategy for AS systems based on a residual DDPG framework. The method uses a DDPG controller together with a PID controller in a residual setup. The PID part adjusts the DDPG output to make the system more stable and robust. To further improve training efficiency and convergence, an Error-Aware Reward Rescaling strategy is introduced during the learning process. The mechanism adjusts the reward signal based on vertical acceleration deviation to guide the agent toward better control behavior. The proposed method is tested under five typical road excitations, including both training scenarios and several unseen cases. This work makes the method better by adding a way to change the reward during training. This assists to keep training stable and improves control. The results show that the better RDDPG works well in both tested and new situations, and gives a useful way to control active suspension.

VII. Future Work

Future work will try using the RDDPG method on full-vehicle suspension models to test how well it works with more axles and connected movements. Additionally, incorporating real-time implementation and validation will be considered to assess the controller's practical feasibility and robustness in real-world scenarios. Further research on alternative residual structures and adaptive weighting mechanisms may also enhance the system more flexible and work better.

***Abstract*—Ship detection in optical remote sensing imagery plays a vital role in maritime surveillance and environmental monitoring. However, existing deep learning models often struggle to generalize effectively in complex marine environments due to challenges such as noise interference, small object sizes, and diverse weather conditions. To address these issues, this study proposes an Edge-Guided Multi-Scale YOLO algorithm (YOLOv11n-EGM). The approach introduces multi-scale deep convolutional branches with varying kernel sizes to perform parallel feature extraction, enhancing the model's ability to detect objects of different scales. Additionally, the classic Sobel operator is incorporated for edge-aware feature extraction, improving the model's sensitivity to object boundaries. Finally, 1×1 convolutions are employed for feature fusion, reducing computational complexity. Experimental results on the ShipRSImageNet V1.0 dataset demonstrate that the improved model achieves notable gains in precision, recall, mAP@0.5, and mAP@0.5:0.95 compared to the baseline, highlighting its superior performance in challenging maritime scenarios. Qualitative analysis further shows that YOLOv11n-EGM can accurately detect both large and extremely small ships in cluttered scenes, with precise boundary localization. However, occasional misclassification in fine-grained categories (e.g., motorboat vs. hovercraft) highlights the challenge of small-instance recognition. Overall, the proposed method exhibits strong robustness and practical applicability in real-world maritime scenarios, offering a promising solution for edge-aware, multi-scale ship detection in remote sensing imagery.**

***Keywords*—Optical remote sensing imagery; ship detection; multi-scale deep convolution; edge-aware feature extraction**

I. INTRODUCTION

Maritime transportation plays a crucial role in global trade, accounting for over 80% of total international trade volume. According to the International Maritime Organization (IMO), there are approximately 108,789 commercial vessels worldwide as of 2024. As the core carrier of marine economic activities, the operational efficiency of ships directly impacts the stability of international logistics systems [1]. Ship detection in optical remote sensing imagery has emerged as a critical research area due to its wide-ranging applications in maritime surveillance, port management, and marine traffic control. The task, commonly referred to as optical remote sensing ship detection, involves the automatic localization and classification of ship targets within high-resolution optical satellite images, and serves as a foundational technique for intelligent maritime monitoring systems [2].

However, the unique characteristics of ship targets in nadir-view remote sensing imagery—such as significant scale variation, complex backgrounds, and prominent edge structures—have posed substantial challenges to detection models. In recent years, models such as R-CNN, Fast R-CNN, and the YOLO series have gained attention for their effectiveness in visual target identification [2], [3], [4]. Among them, the YOLO series has demonstrated particular advantages in optical remote sensing applications due to its high detection speed and competitive accuracy [2].

Nevertheless, despite the general success of YOLO-based detectors in object detection tasks, their direct application to ship detection in optical remote sensing imagery—e.g., YOLOv11n—reveals several domain-specific limitations. These include difficulty in handling ships of drastically varying sizes, insufficient exploitation of edge and contour features critical for distinguishing ships from complex backgrounds, and degraded performance in fine-grained classification tasks such as differentiating 49 ship types and docks. YOLOv11n's baseline architecture lacks specialized modules to address the unique challenges posed by maritime scenes [2]. These limitations indicate a clear research gap in designing lightweight yet accurate detectors that can effectively capture multi-scale and edge-sensitive features in complex maritime scenes.

To address this gap, this study proposes an enhanced YOLOv11-based approach with the following key contributions:

A novel multi-scale deep convolutional module, EGM_Block, is introduced, employing parallel convolutional kernels of sizes 3, 5, and 7 to capture features at multiple scales.

1) A Sobel edge extraction module is incorporated to improve the model's sensitivity to edge features of ship targets.

2) An efficient feature fusion strategy is proposed to reduce computational complexity while maintaining high detection accuracy.

3) Extensive experiments are conducted on the publicly available ShipRSImageNet V1.0 dataset, which provides a comprehensive benchmark for evaluating ship detection performance in remote sensing imagery. The results validate the effectiveness and robustness of the proposed method.

The remainder of this study is organized as follows: Section II reviews related work; Section III details the proposed method; Section IV presents experimental results and analysis; Section V provides a discussion of the findings; and Section VI concludes the study and discusses future work.

II. Related Work

A. Traditional Methods for Ship Detection

Early approaches to ship detection in remote sensing imagery primarily relied on handcrafted features and classical machine learning algorithms. Techniques such as edge detection, texture analysis, and morphological operations were commonly employed to extract candidate regions, followed by classifiers like Support Vector Machines (SVM) or AdaBoost for final decision-making. While these methods offered a degree of interpretability, they were limited in their ability to handle variations in scale, orientation, and complex backgrounds, resulting in suboptimal performance in real-world maritime environments [2].

B. Deep Learning-Based Ship Detection

The emergence of deep learning has significantly advanced the field of object detection. Two-stage detectors, such as R-CNN, Faster R-CNN [3], and Mask R-CNN [4], introduced region proposal mechanisms that substantially improved detection accuracy, particularly for small and densely packed objects. After thorough experimental analysis and engineering-level testing, the two-stage model proved highly effective for ship detection in remote sensing imagery. However, in practical engineering applications, the two-stage model is difficult to apply due to real-time or resource-constrained environments, such as satellite-attached equipment or unmanned aerial vehicles [5].

To address the aforementioned challenges, researchers have developed single-stage detectors, such as SSD [6] and the YOLO ("You Only Look Once") series [7], etc. The single-stage detection architecture eliminates the step of region proposal and directly predicts bounding boxes and class probabilities. This design achieves a good balance between speed and accuracy. The YOLO series has been widely used in industry applications due to its real-time performance and continuous architectural improvements [8].

C. Evolution of the YOLO Series

With the joint efforts of researchers and engineers, the YOLO series has undergone multiple efficient iterations in a short period of time. Strictly speaking, each new version surpasses its predecessor in terms of accuracy, speed, and feature representation. YOLOv3 introduced multi-scale detection and residual connections [9], while YOLOv4 [10] and YOLOv5 [11] adopted techniques such as CSPNet, PANet, and data augmentation strategies. YOLOv5 has shown practical effectiveness in agricultural applications, including crop detection and maturity classification under real-world conditions [12]. Recent versions, including YOLOv7 and YOLOv8, have focused on optimizing the backbone network and introducing lightweight variants suitable for edge deployment [13].

YOLOv11 is one of the latest advancements in the YOLO object detection series. Not only has its backbone architecture been optimized, but its feature extraction modules have also been enhanced, resulting in improved detection accuracy and computational efficiency [14] [15]. Therefore, YOLOv11 generally performs better than previous versions in various general object detection tasks, and it is especially suitable for scenarios requiring real-time inference.

Nonetheless, when applied to ship detection in high-resolution optical remote sensing images, there are still some domain-specific challenges. Compared with conventional datasets, optical remote sensing images are captured from different viewing angles, resulting in large variations in ship scales, orientations, and arrangement densities. In particular, ships may appear in various environments such as ports, coastal areas, and open seas. These background conditions lead to significant changes in the overall appearance and spatial distribution of the images, which may reduce the effectiveness of standard detection procedures.

In addition, experimental results show that YOLO models may struggle to capture fine edge details and the contextual cues necessary to distinguish ships from background elements such as waves, docks, and infrastructure. Therefore, accurately identifying ships that are slender, small in size, and densely arranged in images remains a key challenge. Moreover, in real-world engineering scenarios where resources are limited and inference speed is critical—such as onboard or satellite systems—balancing detection accuracy and computational efficiency is also of great importance [16].

Considering the above-mentioned practical technical difficulties, there is a clear need for specialized architectural improvements that can address issues such as multi-scale representation, edge-aware feature learning, and stable performance in complex environments. The YOLOv11n-EGM framework proposed in this study aims to tackle these challenges by integrating an edge-guided multi-scale module and an adaptive loss strategy, thereby enhancing the reliability of ship detection in remote sensing imagery.

D. Challenges in Remote Sensing Ship Detection

Remote sensing imagery presents unique challenges for object detection algorithms. With the growing application of remote sensing in coastal environment monitoring, recent studies have extended its practical relevance to broader maritime scenarios [17]. In complex maritime environments, such as freezing seas, remote sensing systems may produce erroneous object detection results without proper surface discrimination mechanisms [18]. These images are captured from nearly vertical viewing angles, which often results in limited visible features of objects. Additionally, due to the large coverage area, ships frequently appear in various sizes and orientations within the same image, and are often situated in complex environmental conditions, such as cluttered port

backgrounds, cloud cover, sea surface noise, and low contrast [19]. Moreover, ships typically exhibit distinct edge features that can be leveraged to improve detection accuracy; however, many existing models fail to fully utilize this information. Furthermore, for applications in real-time maritime monitoring systems, lightweight and computationally efficient models are essential [20] [21].

III. METHODOLOGY

This study introduces a lightweight ship detection framework specifically designed for optical remote sensing imagery—Edge-Guided Multi-Scale YOLO. The framework integrates multi-scale perception and edge contour enhancement mechanisms. Its architecture is based on an improved YOLOv11n backbone and is further enhanced by a custom-designed Edge-Guided Multi-Scale block (EGM-block), which improves the model's ability to capture structural and edge-related features across different scales.

A. Overall Network Architecture

The proposed method adopts YOLOv11n as the base detection framework and integrates the Edge-Guided Multi-Scale block (EGM-block) into the backbone network to enhance feature extraction capabilities. The backbone consists of multiple convolutional and residual layers, which progressively capture spatial and semantic representations from the input image. The EGM-Block is inserted at the fourth stage (P3/8) to enhance mid-level features in terms of edge awareness and multi-scale object perception. The C3k2 and C2PSA modules further refine deeper semantic features, while the SPPF module contributes to multi-scale contextual aggregation.

B. Edge-Guided Multi-Scale Block (EGM-Block)

As illustrated in Fig. 1, the proposed EGM-Block is composed of three functional components designed to enhance the model's ability to capture structural and scale-aware features in remote sensing imagery.

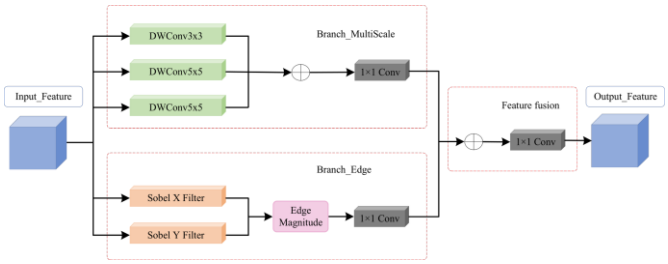

Fig. 1. Edge-Guided Multi-Scale Block.

1) Multi-scale depthwise convolutional branches: This component utilizes parallel depthwise separable convolutions with fixed kernel sizes of 3×3, 5×5, and 7×7 to extract features across multiple spatial resolutions. Such a design enables the model to effectively perceive ships of varying sizes, thereby improving its adaptability to scale diversity in optical remote sensing scenes.

2) Sobel-based edge enhancement branch: To reinforce contour sensitivity, fixed-weight Sobel filters are employed to extract directional edge information. Specifically, horizontal and vertical edge responses are obtained by convolving the input feature map with predefined Sobel kernels along the x and y axes. These directional responses are subsequently fused through a 1×1 convolution to generate an edge-enhanced feature representation. Here, $edge_x$ and $edge_y$ denote the horizontal and vertical edge responses, respectively, while edge represents the overall edge magnitude. A small constant varepsilon = 1×10^{-6} is added to ensure numerical stability during square root computation. The overall edge magnitude is then computed using the Euclidean norm, as formulated in Eq. (1):

$$edge = \sqrt{edge_x^2 + edge_y^2 + 1 \times 10^{-6}} \quad (1)$$

3) Feature fusion module: The outputs from the multi-scale and edge branches are concatenated along the channel dimension and integrated using a 1×1 convolution to produce the final enhanced representation.

C. Attention Mechanism and Feature Enhancement

To improve the model's ability to focus on informative regions, the C2PSA (Parallel Spatial Attention) module—originally integrated into the YOLO11 architecture—is retained in the upper layers of the backbone. This attention mechanism operates by applying parallel spatial attention across feature maps, enabling the network to suppress irrelevant background noise while enhancing the response of target-relevant regions. Although not proposed in this work, the inclusion of C2PSA contributes to improved detection accuracy, particularly in complex remote sensing environments such as ports and coastal zones.

D. Loss Function and Training Strategy

To address the challenges of complex maritime environments, YOLOv11n-EGM incorporates a tailored loss weighting strategy. This approach assigns greater importance to overlapping ship instances, enhancing the model's responsiveness to occluded and densely packed targets, particularly in port areas. The edge-guided multi-scale enhancement mechanism further contributes to precise boundary localization. When combined with regression loss, it effectively reduces false detections caused by cluttered backgrounds.

The training process adheres to the standard YOLOv11n framework, utilizing the Stochastic Gradient Descent (SGD) optimizer with an initial learning rate of 0.01, adjusted dynamically through cosine annealing. While the core training methodology remains consistent, the integration of the EGM-Block and the customized loss scheme significantly improves the model's robustness and generalization capabilities. Detailed implementation settings, including data augmentation techniques and hardware configurations, are provided in Section IV.

E. Implementation Details

The proposed model is implemented using the PyTorch deep learning framework, leveraging its modular design and GPU acceleration capabilities. Input images are uniformly resized to 640×640 pixels to maintain consistency across

training batches and to balance computational efficiency with spatial resolution. The model is trained with a batch size of 64, which allows for stable gradient updates while fully utilizing the memory capacity of high-performance GPUs.

To address the substantial scale variation of ship targets—ranging from small fishing boats to large cargo vessels—the architecture incorporates an Edge-Guided Multi-Scale (EGM) feature enhancement strategy. This mechanism enables the network to capture fine-grained details and contextual cues across different receptive fields, thereby improving detection accuracy for both small and large objects. In addition, the EGM-Block, embedded within the backbone, helps suppress irrelevant background features such as waves, docks, and coastal infrastructure, which often lead to false alarms in remote sensing imagery.

All experiments are conducted on the publicly available ShipRSImageNet V1.0 dataset, which provides a comprehensive benchmark for ship detection. The dataset includes 3,435 high-resolution images annotated with horizontal bounding boxes (HBB), oriented bounding boxes (OBB), and polygon masks. It is designed with a hierarchical classification structure across four task levels (Level 0 to Level 3), covering 50 distinct ship categories [5]. A detailed overview of the dataset and training configuration is presented in Section IV.

IV. Experimental Results and Analysis

To validate the effectiveness of the proposed YOLOv11n-EGM framework, a series of experiments is conducted on the ShipRSImageNet V1.0 dataset. This section presents the dataset characteristics, training configuration, evaluation metrics, and comparative results against baseline models. The experiments are designed to assess the model's performance across varying task complexities and ship categories.

A. Dataset Overview

This study utilizes the ShipRSImageNet V1.0 dataset, a large-scale, fine-grained benchmark designed for ship detection in high-resolution optical remote sensing imagery. The dataset comprises 3,435 images sourced from diverse satellite platforms and sensors, spanning various geographic regions and weather conditions. Each image measures approximately 930×930 pixels and contains ships of varying scales, orientations, and aspect ratios. A total of 17,573 ship instances are annotated using horizontal bounding boxes (HBB), oriented bounding boxes (OBB), and polygon masks, offering rich spatial and contextual information.

ShipRSImageNet V1.0 introduces a hierarchical classification structure across four levels (Level 0 to Level 3), encompassing 50 distinct ship types. The updated version includes a standardized test set to facilitate fair benchmarking and reproducibility in ship detection research [5].

B. Experimental Setup and Evaluation Metrics

All models are implemented using the PyTorch framework. Input images are resized to 640×640 pixels, with a batch size of 64. Training is conducted over 300 epochs on an NVIDIA RTX 4090 GPU with 24GB of memory. Data augmentation techniques such as random rotation and scale variation are applied to enhance generalization.

To assess detection performance, the following metrics are employed:

1) mAP@0.5 and mAP@0.5:0.95: Mean Average Precision at fixed and varying IoU thresholds.

2) HBB mAP: Detection accuracy using horizontal bounding boxes.

3) Precision, Recall, and F1 Score: Standard metrics for evaluating classification and localization quality.

Performance is further analyzed across different object sizes (small, medium, large) and classification levels.

C. Comparative Methods and Baseline Models

To rigorously assess the effectiveness of the proposed YOLOv11n-EGM architecture, a series of representative object detection frameworks are selected as baselines. These models encompass diverse backbone networks and detection paradigms. Comparative experiments are conducted across all four hierarchical levels (Level 0 to Level 3) defined in the ShipRSImageNet dataset, enabling evaluation from coarse-grained classification (ship vs. non-ship) to fine-grained ship type recognition.

D. Visual Results and Quantitative Analysis

To validate the effectiveness of the proposed YOLOv11n-EGM model, we conducted comparative experiments against several mainstream object detectors. All models were trained under identical conditions to ensure a fair and unbiased evaluation. The visual and quantitative results of these comparisons are summarized in Table I.

TABLE I. Experimental Comparison Results of Different Algorithms

Task Level	Method	$mAP_{50:95}$	mAP_{50}	mAP_{75}
Level 0: 1 ships and dock	Faster R-CNN	0.432	0.674	0.487
	Deformable DETR	0.505	0.763	0.596
	YOLOv9	0.447	0.662	0.523
	YOLOv10	0.594	0.760	0.656
	YOLOv11n-EGM	**0. 606**	**0. 775**	**0.691**
Level 1: 3 ship and dock	Faster R-CNN	0.372	0.566	0.421
	Deformable DETR	0.431	0.609	0.512
	YOLOv9	0.404	0.551	0.455
	YOLOv10	0.496	0.625	0.551
	YOLOv11n-EGM	**0.519**	**0.649**	**0.606**
Level 2: 24 ships and dock	Faster R-CNN	0.368	0.527	0.421
	Deformable DETR	0.509	0.635	0.583
	YOLOv9	0.399	0.497	0.464
	YOLOv10	0.505	0.608	0.557
	YOLOv11n-EGM	**0. 511**	**0. 618**	**0.565**
Level 3: 49 ships and dock	Faster R-CNN	0.381	0.529	0.438
	Deformable DETR	0.585	0.701	**0.760**
	YOLOv9	0.433	0.525	0.493
	YOLOv10	0.584	0.668	0.650
	YOLOv11n-EGM	**0.610**	**0.703**	0.656

1) Overall performance trends: YOLOv11n-EGM consistently demonstrates superior performance across all Task Levels and evaluation metrics. Notably, in Level 0 and Level 3 scenarios, its results in mAP(50:95) and mAP_75 significantly outperform other methods, validating the effectiveness of the proposed EGM-Block in enhancing multi-scale and edge-level feature representation. YOLOv10 ranks closely behind, indicating that the YOLO series achieves a commendable balance between model efficiency and detection accuracy. In contrast, Faster R-CNN and YOLOv9 exhibit noticeable performance degradation in more complex scenes (Level 2 and Level 3), suggesting limited adaptability to dense object distributions and occlusions.

Notably, we observed different comparative results of YOLOv11n-EGM across Level 0 to Level 3 of the ShipRSImageNet V1.0 dataset. This discrepancy is primarily due to the substantial variation in classification granularity across the hierarchical levels. Specifically, Level 0 distinguishes whether an object is a ship or not, involving only two classes. Level 1 further categorizes ship objects into four broad categories. Level 2 refines these categories into 24 subcategories, while Level 3 provides the most detailed classification, identifying 49 specific ship types and one dock class, resulting in a total of 50 categories. As the classification becomes increasingly fine-grained from Level 0 to Level 3, the complexity of the detection task escalates, placing greater demands on the network's feature extraction and discrimination capabilities. Consequently, the performance of the proposed algorithm varies across levels, reflecting its sensitivity to the granularity of the classification task.

To further illustrate the detection performance of the proposed YOLOv11n-EGM model under varying task complexities, Precision-Recall (PR) curves are plotted for Level 0 and Level 3 scenarios. These curves provide a comprehensive view of the trade-off between precision and recall across different confidence thresholds.

As shown in Fig. 2, YOLOv11n-EGM achieves a mean average precision (mAP) of 0.772 at an IoU threshold of 0.5. The model maintains high precision and recall in Level 0, where the task involves binary classification (ship vs. non-ship). This indicates strong performance in relatively simple detection scenarios with clear object boundaries and low category granularity. The category-wise analysis further shows that Dock achieves an average precision of 0.797, outperforming Ship at 0.747, likely due to the more consistent structural features of docks.

In contrast, Fig. 3 presents results from the more challenging Level 3 setting, where the model is required to distinguish among 49 ship types and docks, totaling 50 fine-grained categories. The overall mAP drops to 0.702, and the PR curves exhibit greater dispersion across classes. Despite this, the model preserves a balanced PR profile, demonstrating robustness in dense and cluttered maritime environments. The performance degradation reflects the increased difficulty posed by fine-grained classification, small object sizes, and complex backgrounds. These findings reinforce the importance of edge-aware feature extraction and multi-scale representation in enhancing detection accuracy under varying conditions.

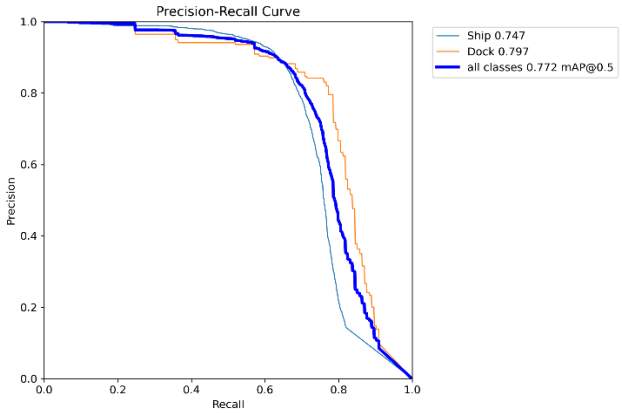

Fig. 2. Precision-Recall curve of YOLOv11n-EGM on Level 0 (lightweight scenario).

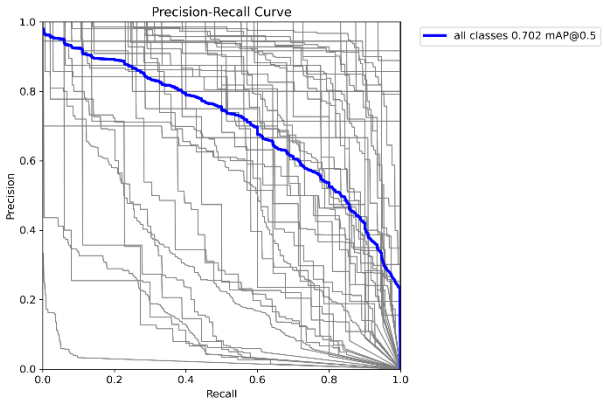

Fig. 3. Precision-Recall curve of YOLOv11n-EGM on Level 3 (complex scenario).

2) Performance variation across task levels: As the Task Level increases—corresponding to a higher number of ship and dock targets—all models experience a general decline in detection performance. However, YOLOv11n-EGM shows the least performance drop, highlighting its robustness in handling complex and cluttered environments. Specifically, in Level 3 (49 ship and dock), YOLOv11n-EGM achieves a mAP(50:95) of 0.610, surpassing both Deformable DETR (0.585) and YOLOv10 (0.584), thereby reinforcing its advantage in high-density scenarios.

To evaluate the classification accuracy across multiple ship categories, the normalized confusion matrix for Level 3 is presented in Fig. 4. This visualization highlights the model's ability to distinguish between fine-grained ship types under high-density conditions. The diagonal dominance in the matrix indicates strong classification performance, while off-diagonal elements reveal occasional misclassifications, which are primarily observed among visually similar ship classes.

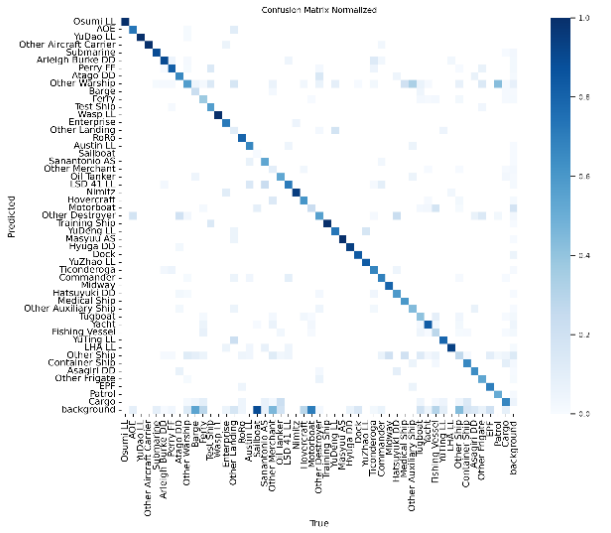

Fig. 4. Normalized confusion matrix of YOLOv11n-EGM on Level 3, illustrating multi-class classification accuracy.

The overall training dynamics of YOLOv11n-EGM are depicted in Fig. 5, which includes the evolution of key metrics such as loss, mAP, precision, and recall over 300 epochs. The smooth convergence and consistent improvement across metrics validate the stability and effectiveness of the training strategy.

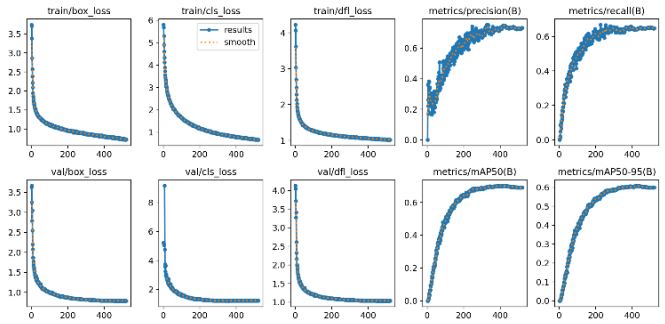

Fig. 5. Training performance of YOLOv11n-EGM over 300 epochs, including loss, mAP, precision, and recall curves.

To qualitatively assess the detection capability of YOLOv11n-EGM, Fig. 6 and Fig. 7 present sample predictions and corresponding ground truth annotations from the Level 3 validation set. The model accurately localizes and classifies multiple ship instances, even in densely packed scenes, demonstrating its practical applicability in real-world remote sensing tasks.

Notably, in several examples, both large vessels and extremely small ships appear within the same image and are successfully detected, with no significant omission. The bounding boxes closely align with the actual contours of the ships, indicating that the model effectively captures edge features and adapts to multi-scale object variations. These observations validate the effectiveness of the edge-guided multi-scale module and confirm that YOLOv11n-EGM achieves its intended improvements in fine-grained maritime detection.

However, we also observed a case where a very small ship instance (Motorboat) was misclassified as a Hovercraft. This confusion likely stems from the limited pixel-level detail available for extremely small targets, which poses a challenge for fine-grained classification.

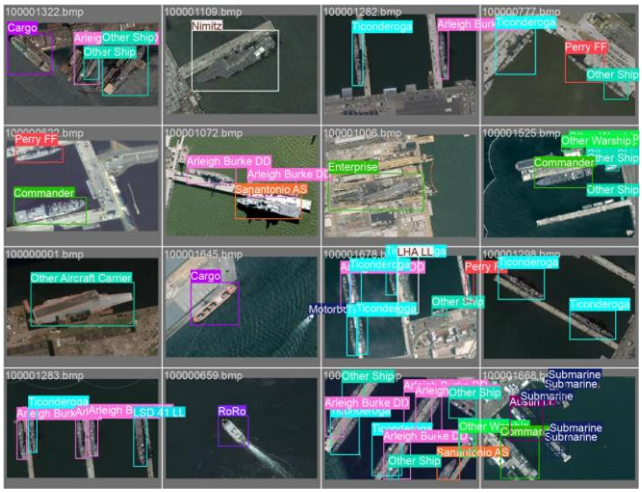

Fig. 6. Ground truth annotations on a Level 3 validation image.

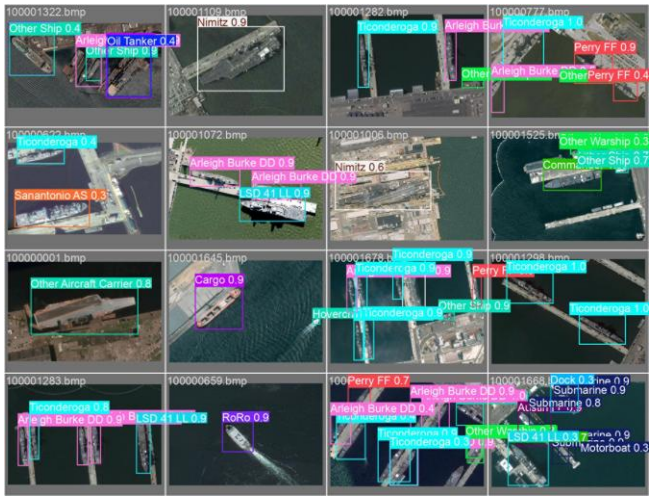

Fig. 7. YOLOv11n-EGM predictions on the same Level 3 validation image

V. Discussion

The YOLOv11n-EGM model demonstrates strong performance in ship detection tasks, particularly in cluttered optical remote sensing scenes. However, we observed that very small vessels, while successfully detected, are sometimes misclassified as other ship types. This issue arises from insufficient fine-grained semantic representation, which limits the model's ability to distinguish subtle intra-class variations. Addressing this challenge may require enhancing class-specific feature discrimination or introducing adaptive refinement mechanisms. Overall, the results affirm the potential of lightweight architectures for real-time maritime monitoring, though further improvements are needed for precise recognition of small and visually ambiguous targets.

VI. CONCLUSION

This study presents Edge-Guided Multi-Scale YOLOv11n (YOLOv11n-EGM), an enhanced object detection framework tailored for ship detection in high-resolution remote sensing imagery. Built upon the YOLOv11n backbone, the proposed model integrates a novel EGM-Block, which simultaneously strengthens multi-scale feature extraction and edge-aware representation.

Extensive experiments were conducted on the ShipRSImageNet V1.0 dataset, which includes a hierarchical structure of four task levels (Level 0 to Level 3), encompassing a wide range of ship types and scene complexities. The results demonstrate that YOLOv11n-EGM consistently outperforms several state-of-the-art detectors across all evaluation metrics, particularly in challenging scenarios with dense and small-scale targets.

The proposed EGM-Block significantly improves the model's ability to detect fine-grained ship instances while maintaining robustness against background interference. Comparative studies further confirm the critical role of the multi-scale and edge-guided branches in enhancing detection accuracy and generalization.

A. Limitations

1) Sensitivity to small instances: Qualitative analysis reveals that the model struggles to detect extremely small ships (e.g., < 8 pixels in size), often resulting in lower recall rates. This limitation is particularly critical in high-resolution satellite imagery, where small vessels are common.

2) Spectral and weather dependency: The current model relies exclusively on optical imagery, making it vulnerable to adverse weather conditions such as dense cloud cover, fog, or nighttime scenarios. This spectral dependency limits its applicability in all-weather or low-visibility environments.

3) Computational overhead: The introduction of the edge-guided multi-scale module increases the model's complexity in terms of both parameter count and GFLOPs. This added computational burden may hinder real-time deployment on edge devices or UAVs with limited processing power.

B. Future Work

1) Enhancing small object detection: We aim to improve the detection of small ships by incorporating super-resolution pre-processing pipelines and exploring anchor-free dense prediction frameworks (e.g., keypoint-based detectors). These approaches may enhance the model's ability to localize and classify tiny instances more effectively.

2) SAR-Optical data fusion: To overcome the limitations of optical-only input, we plan to integrate Synthetic Aperture Radar (SAR) data with optical imagery. SAR's all-weather, day-and-night imaging capabilities can complement optical data, enabling more robust detection under challenging environmental conditions.

3) Model compression and acceleration: To reduce computational overhead, we will explore lightweight alternatives such as depthwise separable convolutions, Ghost modules, and neural architecture search (NAS). Additionally, knowledge distillation techniques will be investigated to transfer knowledge from the full model to a compact student model suitable for real-time inference.

***Abstract*—In the era of rapid development of digital communication, there is a growing need for technologies that guarantee secure user identification, document authentication and protection of personal data, including biometrics. Previously used centralized identity management systems are becoming increasingly vulnerable to hacking, falsification and misuse. This problem is especially relevant when information must remain closed until a specific moment or event occurs, for example, in the fields of forensics, healthcare or law (medical certificates, legal acts, inheritance agreements, etc.). The main goal is to create a secure, verifiable and at the same time distributed access control system with the ability to defer disclosure of information. The study proposes a cryptographic protocol that combines Self-Sovereign Identity (SSI), Time-Lapse Cryptography (TLC), and decentralized biometric data management. The protocol is based on the principles of Time-Lapse Cryptography (TLC) and the Horcrux protocol, which enable time-controlled disclosure of encrypted information associated with a user's identity. The architecture includes the use of QR codes as a transport for Verifiable Credentials (VC), blockchain for authenticity verification and key management, and biometrics as a second factor of identity binding. The proposed solution is intended for use in scenarios where cryptographic protection against premature access to sensitive data is required, such as in medicine, forensics, notarial acts, or intellectual property. The study presents the protocol structure and application options.**

***Keywords*—Self-sovereign identity; horcrux protocol; elliptic curves time-lapse cryptography; biometrics; QR codes; blockchain**

I. Introduction

With the rapid growth of digital interactions, technologies that ensure reliable identification of individuals, document authentication, and protection of sensitive personal data, including biometric information, are becoming increasingly important. Traditional centralized identity management systems are increasingly vulnerable to compromise, counterfeiting, and unauthorized access. This is especially critical in cases where data cannot be disclosed before a certain event or time, such as in forensic, medical, or legal practice (medical reports, legal documents, testaments, etc.). The main challenge is to ensure secure, verifiable, and at the same time decentralized access management with the ability to delay disclosure of information.

One promising concept that can provide a balance between reliable authentication and privacy protection is the Self-Sovereign Identity (SSI) model. It is based on the idea that a user should have full ownership of their digital identities and control over the process of their provision without the participation of centralized certifying parties. SSI uses decentralized identifiers (DIDs), cryptographically protected identities (Verifiable Credentials, VC) and blockchain as a trusted, immutable infrastructure [1-3]. However, in its basic form, SSI does not solve the problem of temporary access control and secure management of biometric information.

This work is aimed at developing a new cryptographic protocol that expands the capabilities of SSI technology by combining QR codes as a transport mechanism for distributing links to VCs and DIDs, biometrics as a factor in linking credentials to a physical identity, time-lapse encryption as a mechanism for delayed access to sensitive data, and blockchain as a decentralized platform for trust and automatic key management. The key components of the proposed solution are the Horcrux protocol [4] and the Elliptic Curves Time-Lapse Cryptography (ECTLC) protocol [5]. The Horcrux protocol is a protocol which implements cryptographic separation and multi-party management of biometric templates. It eliminates the need for centralized storage of biometrics and allows the user to safely participate in the authentication process by restoring the template only with the participation of trusted parties. The Elliptic Curves Time-Lapse Cryptography (ECTLC) protocol is a cryptographic mechanism that allows data to be encrypted with the impossibility of decrypting it before a specified time, without dependence on a trusted time server. In this study, ECTLC is used to create secure VCs with delayed activity. In addition, the architecture takes into account compatibility with the Biometric Open Protocol Standard (BOPS) [6], which defines a secure way to collect, store and transmit biometric data. Together, these mechanisms are combined into a single protocol that implements biometric SSI verification with time-based access restriction, which allows for scenarios with cryptographically secured delayed disclosure of information.

The proposed solution allows for the implementation of application scenarios in which access to credentials and sensitive data is possible only after a certain point of time. It is applicable in medicine, law, education, intellectual property and other areas where strict compliance with deadlines and provable protection of identity and data is required (e.g., delayed disclosure of wills and court documents; restriction of access to biometric data activated only by a legal or time-based software trigger; time capsules and future statements

confirmed by VC and DID). Thus, such a solution makes it possible to form the basis for building trusted digital ecosystems in which the user receives technological means for managing not only identity, but also the time of access to their data, including biometrics, taking into account modern standards and decentralized protocols.

In general, the approach under consideration for the integration of SSI, TLC, QR codes, blockchain and biometrics technologies is due to the need to increase the level of trust in digital transactions, minimize the risks of personal data leakage and form identification systems that are resistant to external influences. Modern trends in the digitalization of various spheres of society (public administration, medicine, the financial sector, education, etc.) demonstrate the limitations of traditional centralized authentication mechanisms based on logins, passwords or unified registries. These models are characterized by a high degree of vulnerability to cyberattacks, leaks and misuse of information. In contrast, the concept of self-sovereign identification assumes decentralized management of personal attributes, in which the subject retains control over their own digital data and selectively discloses it depending on the context of interaction.

Using an encryption mechanism for a specified time allows expanding the functionality of identification systems, providing access to encrypted information strictly at a predetermined moment. Even if encrypted data is compromised, temporary blocking ensures that early access is impossible.

The use of QR codes provides a universal and technologically accessible channel for transmitting encrypted tokens, keys or digital certificates. This tool facilitates the coupling of physical and digital processes, allowing for the implementation of identity verification scenarios in offline environments with an instant transition to secure online interaction.

The use of biometric methods strengthens the trust basis of the system, as they allow for reliable verification that the presented digital identity actually belongs to a physical carrier. Unlike traditional authentication factors that are subject to transfer or theft, biometric features have a high degree of uniqueness and stability, which reduces the likelihood of subject substitution.

Blockchain technology guarantees the integrity and verifiability of data. This eliminates the possibility of falsifying transactions or making retroactive changes to records. The distributed structure of the registry eliminates the dependence on a centralized verification authority and eliminates the possibility of system failure. In addition, the use of smart contracts allows for automatic management of access to time-dependent resources, complementing cryptographic methods with the functionality of predefined rule execution.

As a result, SSI ensures decentralization and user control, biometrics confirm the authenticity of the individual, QR codes create a convenient interaction interface, encryption for a specified time regulates the moment of access to data, blockchain guarantees the immutability of records and automation of rules. The result is a multi-level system that combines convenience for the end user and a high level of cryptographic protection. The prospects for such integration are most significant in contexts that require a combination of confidentiality, time synchronization, and reliable identity verification.

It can be said that there are currently no works that consider the implementation of all the above components in one formal protocol at the same time. More common are works that cover two to three elements and architectural compositions that can be combined (see Table I).

A. Motivation and Problem Statement

SSI improves user control and verifiability but does not guarantee cryptographic non-access to sensitive attributes before a policy time (T). Biometric authentication often relies on centralized custody. We address both gaps by combining decentralized biometric sharding with time-lapse encryption anchored to SSI.

B. Main Contributions

SSI-native protocol that binds VCs to a user via Horcrux-style biometric splitting without centralized template storage;

ECC time-lapse layer that withholds decryption capability until time (T);

Verifier workflow via QR-encoded handles to DIDs/VCs for offline/online use;

Security and deployability discussion (threat model, failure modes, regulatory aspects).

The rest of the study is organized as follows: Section II reviews IEEE Biometric Open Protocol Standard (BOPS), Self-sovereign identity technology, the Horcrux protocol and the Elliptic Curves Time-Lapse Cryptography (ECTLC) protocol. Section III presents our new cryptographic protocol for decentralized biometric-based self-sovereign identity with time-lapse encryption called the ECTLC-Horcrux protocol and considers possible use cases. Section IV presents the results. Section V details the discussion. Finally, Section VI summarizes the study.

II. RELATED WORKS AND POSITIONING

1) SSI and verifiable credentials: Surveys and standards (including W3C Verifiable Credentials v2.0 and DID Core) systematize identifiers, credential models, and wallet architectures, highlighting selective disclosure and revocation

challenges. We adopt this stack to enable issuer-agnostic verification and offline validity checks [28, 29, 30].

2) Decentralized biometrics: Horcrux proposes cryptographic splitting of biometric templates to remove single points of failure. Our design reuses the splitting intuition but couples it with SSI wallets and time-based access control.

3) Time-lapse / Time-lock cryptography: ECC-based time-lapse cryptography enforces decryption only after (T) by threshold key release. We instantiate an ECC-based service and align its trust assumptions with SSI verifiers.

4) Biometric protection standards: ISO/IEC 24745:2022 provides guidance on biometric information protection; we comply by avoiding long-term template custody at the verifier and enforcing secure transport [31].

5) Positioning: Unlike prior work treating these threads separately, ECTLC-Horcrux composes SSI, decentralized biometrics, and ECC-based time-lapse into a single protocol with QR-mediated verifier flows and explicit threat considerations.

III. Methods

The protocol designed in this work is based on 2410-2017 - IEEE Biometrics Open Protocol Standard (BOPS), Self-Sovereign Identity technology, the Horcrux protocol, the Elliptic Curves Time-Lapse Cryptography (ECTLC) protocol, and the use of QR codes.

A. Biometrics Open Protocol Standard (BOPS) [6]

2410-2017 - IEEE Biometrics Open Protocol Standard (BOPS) is an open protocol designed to provide secure and trusted biometric authentication that meets the high requirements of national and international standards. The protocol covers the full cycle of working with biometric data - from their collection and storage to transmission and comparison, while implementing a multi-level security architecture.

At the Collection stage, BOPS defines the use of standard APIs for obtaining biometric templates (e.g., fingerprints, face, voice) using hardware trusted environments such as HSM (Hardware Security Module), TEE (Trusted Execution Environment) or TPM (Trusted Platform Module). The use of these modules ensures that data is collected and stored in isolated, inaccessible or encrypted memory, which significantly reduces the risk of leakage or unauthorized access.

For storage (Storage) of templates, BOPS provides for the use of secure formats and cryptographic containers with hardware encryption support. Moreover, the standard supports the cryptographic sharding mechanism, in which the biometric template is divided into several parts. One of them is stored locally on the device, and the second is either also stored locally or transmitted to a remote platform. In this case, the compromise of one of the parts does not allow the restoration of the original biometric template, which ensures resistance to leaks.

Transmission in BOPS is implemented via the Representational State Transfer (REST) interface protocol, and no biometric template can be transmitted in unencrypted form. Before sending, the data is wrapped in a cryptographic container encrypted using the server's public key generated at the registration stage. Transmission is carried out exclusively through a two-way secure TLS channel, and the client TLS certificate is installed on the mobile device in advance, at the time of installing the application.

At the Processing stage, the protocol prohibits long-term storage of templates. All matching operations are performed exclusively in RAM or in a local HSM, without using file systems, databases or other forms of persistent storage. This significantly reduces the risk of data compromise in the event of a system breach.

The BOPS protocol includes two key phases of operation: registration and authentication. In the registration phase, the server generates a key pair (RKP) by transmitting a public key to the device. On the client side, a local key pair (LKP) is generated, and the collected biometric template (initial biometric vector - IBV) is associated with this pair. The template and keys are then encrypted using RKP and transmitted to the server over a secure channel.

In the authentication phase, the protocol provides for three configurations:

1) Local match: a candidate biometric template (CBV) is collected on the device, which is matched with a reconstructed IBV collected from local and, if necessary, remote shares. The result of the match (a Boolean or numeric threshold) is encrypted and sent to the server. This configuration complies with FIDO UAF requirements, provided that a certified local authenticator is used.

2) Remote match: The CBV is encrypted and sent to the server, where it is matched against the corresponding portions of the IBV available to the server and sent from the client.

3) Combined authentication: The server can, upon request, encrypt its portions of the IBV and send them back to the client, where the match occurs. Once the match is complete, all biometric data and keys are destroyed from RAM.

To protect against man-in-the-middle (MITM) and replay attacks, BOPS uses one-time passwords and server challenges wrapped in encrypted crypto containers (envelopes), ensuring the integrity and authenticity of the transmitted data. Compared to other protocols such as FIDO UAF, BOPS offers comparable levels of security but has additional capabilities, such as remote storage, flexible sharding, and multi-level authentication, making it a more versatile solution for a variety of scenarios, including mobile platforms, cloud services, and IoT devices. However, the choice of storage and mapping mode may depend on regulatory constraints, institutional policies, and trust level requirements.

B. Self-Sovereign Identity [1-3]

Self-Sovereign Identity (SSI) is a conceptual and technical approach that gives users full control over their digital identity

without dependence on centralized certifying authorities. Traditional identity models based on third-party identity providers (such as governments, banks, and commercial platforms) come with risks of compromise, centralized control, and privacy breaches. SSI addresses these shortcomings by transferring control over identity directly to the user, while ensuring verifiability and trust based on cryptographic principles. SSI is based on a model in which identifiers and their verifiable credentials are stored by the identity subject (the user) and can be provided on request to various verifiers.

The key components of the technology are the following elements:

Decentralized identifiers (DIDs) are unique, persistent identifiers that do not depend on central registries. They are managed by the user and allow the creation of cryptographically verifiable links between entities [29]. A DID is associated with a DID document containing public keys, authentication methods, and service endpoints that allow other entities to interact with the owner of the identifier.

Verifiable Credentials (VC) are digital assertions signed by an issuer (e.g., an educational institution, government agency, or employer) that a user can present to a verifier [28, 30]. Verification is performed without a request to the issuer, solely by checking the digital signature and metadata of the credential.

A digital identity wallet is a software solution (mobile or desktop) designed to securely store DIDs, private keys, and received credentials. The wallet provides an interface for interaction with issuers and verifiers, implements the functions of consent to data transfer and supports exchange protocols.

To ensure confidentiality, authenticity, and other security properties, cryptographic methods are used, including asymmetric encryption and digital signatures based on public key cryptography to ensure the authenticity of credentials; zero-knowledge proofs to confirm certain attributes (e.g. age, affiliation with an organization) without disclosing additional data.

Decentralized ledgers (ledger-based DID methods) are used to publish and resolve DIDs. Depending on the architecture, implementations based on blockchain platforms (e.g. Hyperledger Indy, Ethereum, Sovrin) or lighter methods such as DID:Web are possible. Cost efficiency is achieved through Layer-2 solutions, notably the Polygon Amoy testnet for DID anchoring. This reduces on-chain operations to ~0.002 USD per transaction while maintaining SSI revocation capabilities [27]. The implementation of the technology is provided by the W3C consortium standards, including DID Core and Verifiable Credentials Data Model.

The SSI architecture is built on a three-party interaction model, including the following roles: Issuer (an organization that creates and signs digital certificates), Holder (an entity that manages its digital identity, stores credentials in a wallet, and provides them upon request), Verifier (a party that requests and verifies the authenticity of the information received). The interaction between the parties is implemented through the exchange of verifiable credentials (Verifiable Credentials) and decentralized identifiers (DIDs).

1) The Issuer creates and signs a certificate (VC) containing a statement (e.g., "The user graduated from University N"), as well as its DID.

2) The User (Holder) receives this certificate and stores it in its digital wallet associated with its own DID and keys.

3) If necessary, the User presents the certificate to the Verifier, providing proof (possibly with zero knowledge), after which the Verifier verifies the VC signature, receives the Issuer's public key through the DID ledger, and decides on the authenticity of the presented certificate.

This three-party protocol is built without constant dependence between the participants, which allows for offline validation and increased resistance to censorship or denial of service.

C. The Horcrux Protocol [4]

The Horcrux protocol is a secure and decentralized biometric identification method within the Self-Sovereign Identity (SSI) concept. It combines the advantages of biometric methods, the 2410-2017 - IEEE Biometric Open Protocol Standard (BOPS), and the decentralized identifier (DID) infrastructure. The main idea of the protocol is to separate and decentralize the storage of user biometric data with subsequent authentication through their joint processing. This eliminates the need for centralized storage, reducing the risk of leakage and providing the user with full control over their biometric templates. The Horcrux protocol is based on dividing the user's biometric template into two encrypted parts (shares) using visual cryptography techniques. One part is stored locally on the user's device, and the other is stored in a decentralized storage associated with the DID document. This ensures the absence of a single point of failure and increases resistance to data compromise.

The protocol consists of two parts: enrollment and authentication. The enrollment process includes the following components. First, there is the collection of biometric data. The user provides biometric data (e.g. fingerprint or face image), which is converted into an initial biometric vector (IBV). Next comes splitting and encryption. The IBV is split into two shares, each of which is encrypted. One part is stored on the user's device, the other in a DID document placed in a decentralized storage (e.g. IPFS, Dropbox, Google Drive). Then a DID is created. A unique decentralized identifier (DID) is generated, which refers to the corresponding DID document containing the encrypted part of the biometric data. Finally, there is the registration in the blockchain. The DID and its corresponding DID document are registered in the blockchain, ensuring the immutability and verifiability of the data.

The authentication process consists of the following components. First, there is the collection of current biometric data. The user provides biometric data, which is converted into a candidate biometric vector (CBV). Shares extraction and merging are then performed. The local share of the IBV is combined with the share extracted from the DID document,

and then compared with the CBV to verify the identity. Finally, authentication is performed. If the combined IBV matches the CBV, authentication is considered successful.

D. The Elliptic Curves Time-Lapse Cryptography (ECTLC) Protocol [5]

The Elliptic Curves Time-Lapse Cryptography (ECTLC) protocol is based on the Time-Lapse Cryptography (TLC) protocol [12]-[14], the protocol for encrypting client data in such a way as to ensure that decryption cannot occur before a certain designated time, regardless of whether the sender wishes it. TLC protocol includes Pedersen's distributed key generation protocol [15], Feldman's threshold verifiable secret sharing protocol [16], and ElGamal encryption [17]. The TLC protocol uses the agreed-upon parameters of the ElGamal encryption algorithm, including the prime number p, the generator g of prime order q. These parameters can be found, for example, in RFC 3526 [18] and RFC 5114 [19]. The ECTLC protocol uses similar elliptic curve cryptography algorithms, namely the distributed key generation protocol based on discrete logarithm on elliptic curves [20], the Pedersen verifiable threshold secret sharing protocol [21], and the ElGamal elliptic curve encryption algorithm [22], respectively. The protocol is also implemented using a Service (Time-Lapse Cryptography Service) consisting of n participants P_1, ..., P_n. Each participant of the Service P_i can be represented as an autonomous computer (server) that accurately and secretly performs the calculations required by the protocol, securely stores all its secret data, and has a secure way of backing up the data for emergency recovery. All participants of the Service can privately and secretly exchange information with each other, forming a network. A threshold value t is assumed such that at most $t - 1$ participants can violate the protocol, and at least t participants are reliable. The condition $n \geq 2t - 1$ ($t \leq (n+1)/2$) must be satisfied, e.g., if $n = 3$, then $t \leq 2$.) For further efficiency, reliability, and resistance to attacks, a small network M of K managers is used, which acts as a "control team" for the Service. This control team must create a schedule of public and corresponding private keys generated by the Service; maintain an internal bulletin board for use by Service participants; maintain an open bulletin board for Service users. The integrity of these bulletin boards is ensured by each manager maintaining their own copies of the two bulletin boards. Service participants and users will look at messages posted on each copy of the bulletin boards and determine the correct values by the majority of entries. Each Service participant digitally signs each message. The Service may generate key structures on a periodic basis; for example, it may create keys with a lifetime of 1 week every day, or create keys with a lifetime of 2 hours every 30 minutes. Such a schedule is posted by managers on an open bulletin board. In addition, the Service may accept requests from users to generate new keys with a specified lifetime; managers accept these requests and post them on an open bulletin board. Service participants create keys according to the protocol, sign them, and publish the signed key structures on an open bulletin board. The actions of all protocol participants are synchronized using publicly available and reliable clocks such as those provided by NIST. The protocol provides for the use of agreed parameters of the elliptic curve used: the modulus of the elliptic curve, a prime number p, the equation of the elliptic curve, the coefficients of the equation a and b from the field Fp, and a point of the elliptic curve G of prime order q. These parameters can be found, for example, on the SafeCurves project website [23].

E. QR Codes [24-25]

Two-dimensional matrix barcode technology, QR (Quick Response), is a means of presenting, transmitting and verifying structured digital data. Due to their compactness, high encoding density, resistance to damage and widespread support in software and hardware, QR codes are widely used in modern information systems to ensure contactless and offline transactional transfer of information. A QR code is a two-dimensional image consisting of black and white modules (squares) located in a square grid. It encodes binary or symbolic information that can be read by an optical scanner (including mobile device cameras) and converted back into the original data. Modern QR codes allow you to encode up to several thousand characters in a single image, including text, JSON structures, URLs, digital signatures and other formats. QR codes can be used to transmit structured data (e.g. JSON representation of digital certificates, access tokens, session keys, etc.), user identification (generation of personalized codes containing DID or hash identifiers for authentication), offline interaction (enabling the exchange of information between entities without a network connection), data signing and verification (inclusion of digital signatures in encoded data to ensure its authenticity when scanned), generation of passes, tickets, vouchers and transaction messages (visualization of one-time or permanent digital passes with the possibility of machine verification).

F. Biometric Data Protection Via Steganography

To ensure secure transmission of SSI credentials within TLC frameworks, QR-encoded Verifiable Credentials (VCs) and Decentralized Identifiers (DIDs) are embedded into facial images using LSB steganography. Each credential layer is distributed across a dedicated RGB channel (e.g., VC in R, DID in G), enabling standard QR decoders to extract payloads while maintaining visual fidelity (distortion <0.1%, as validated in prior research [26]). Steganography is used only as a transport/masking channel for payloads and does not affect the cryptographic access policy; it is orthogonal to TLC/SSI and therefore optional

IV. Results

The ECTLC-Horcrux protocol describes the interaction of the following participants: the User (Holder), the ECTLC-Service, the Service Provider (Issuer), the Service Provider (Verifier), the BOPS Server A, the BOPS Server B, the Blockchain, and the Identity hub. The protocol consists of two stages: enrollment and authentication.

Step-by-step description of the protocol.

A. Enrollment

1) The User produces his biometric template (initial biometric vector) using his mobile device.

2) The produced initial biometric vector is encrypted into two shares via visual cryptography by the mobile device.

3) One share is secured on the mobile device; the second share is encrypted with the device's private key.

4) The encrypted share, the corresponding device's public key and a time value T before which access to biometric data cannot be granted are sent to the Issuer.

5) The Issuer requests the ECTLC-Service for the ECTLC-Service's public key, indicating the time value T.

6) Upon receiving the request, the ECTLC-Service generates a public key according to the ECTLC cryptographic protocol and transmits it to the Issuer.

7) The Issuer encrypts the received encrypted share with the ECTLC-Service's public key and sends it with the device's public key to the BOPS Server A.

8) The BOPS Server A creates a DID and the DID document, and stores the DID on the Blockchain, and stores the DID document on the Identity hub.

9) The BOPS Server A sends the created DID to the Issuer.

*10)*The Issuer sends the received DID to the mobile device.

B. Authentication

1) The User creates a QR code with his DID, signature and public key into the Verifier using his mobile device and sends it to the Verifier.

2) The Verifier scans the received QR code. Should initial decoding fail (e.g., due to partial image corruption), the system initiates recursive grid-based scanning to reconstruct the SSI payload from salvageable segments. Upon successful recovery, it requests the corresponding DID document from the BOPS Server B.

3) The BOPS Server B resolves the DID and fetches the corresponding DID Document via a Blockchain from the Identity hub.

4) The BOPS Server B requests the ECTLC-Service for the ECTLC-Service's private key.

5) Upon receiving the request, the ECTLC-Service checks the time value. If the current time value has already reached the time value T, the ECTLC-Service generates a private key according to the ECTLC cryptographic protocol and sends it to the BOPS Server B. If the current time value has not yet reached the time value T, the ECTLC-Service rejects the request and sends the BOPS Server B a message that data is not available until the specified time value. And the BOPS Server B sends the corresponding message to the Verifier.

6) The BOPS Server B verifies known issuer signature and enrollment signature, and decrypts encrypted share with the received ECTLC-Service's private key.

7) The BOPS Server B requests the secured share and signed challenge from the mobile device.

8) The secured share is retrieved.

9) The User produces his biometric query template using his mobile device.

*10)*The challenge is signed with the device's private key.

*11)*The retrieved first share, query template and signed challenge are sent to the BOPS Server B.

*12)*The BOPS Server B verifies the challenge signature and decrypts the encrypted share using enrollment public key.

*13)*The BOPS Server B combines shares and performs match.

*14)*The BOPS Server B returns the match result to the Verifier and deletes shares and associated keys.

*15)*The Verifier authorizes access.

The proposed protocol enables a wide range of scenarios where time-sensitive access to identity documents and personal data, including biometrics, is required. The following are some possible use cases where delayed access is critical.

Example 1. A will with biometric confirmation after death.

The user creates a digital will encrypted using TLC and stored in a decentralized repository. The owner's biometric template (e.g., fingerprint) is shared using the Horcrux scheme. Access to the decrypted will is possible only after legal confirmation of death and the expiration of a set time interval (e.g., 30 days). This model prevents premature disclosure of the will and ensures that only authorized persons can access it.

Example 2. Medical data with access at the time of surgery.

The patient uploads preliminary consent for surgery and their medical data in encrypted form. The documents are only available at the time of surgery and are automatically activated at the appointed time via TLC. Access is only possible after the patient and medical staff have undergone biometric verification. This protects against manipulation and premature familiarization of medical information by third parties.

Example 3. A court opinion activated at a hearing.

A digital expert opinion (e.g., on biological evidence) is encrypted by TLC and published in the blockchain with an activation tag on the court date. A QR code confirming the availability and authenticity of the opinion is presented for verification in court. The expert's biometrics additionally confirm authorship, and the impossibility of disclosure before the specified deadline excludes any influence on the process.

Example 4. A digital pass with future activation.

As part of physical access to a facility (e.g., a data center), the contractor receives a VC with the right to enter, but it is activated only from a certain fixed time. The contractor's biometrics are used as a means of identity verification, and the QR code contains a link to encrypted access rights. Until activation, access is impossible, either technically or cryptographically.

V. DISCUSSION

1) Threat model and mitigations: We consider MITM and replay; the verifier requires signed envelopes and challenge–response over authenticated channels. A single biometric share compromise does not enable reconstruction; premature disclosure is prevented by the ECTLC time barrier.

2) Limitations: Threshold availability of ECTLC participants and DID/VC revocation signaling are operational dependencies; biometric capture quality may impact FAR/FRR.

3) Applicability: Medical/legal attestations and controlled physical access where provable non-access before time (T) is a strict requirement.

VI. Conclusion

The study proposes a cryptographic protocol that expands the capabilities of Self-Sovereign Identity by supporting deferred access to data and decentralized management of biometric information. Based on a combination of the Horcrux and the Elliptic Curves Time-Lapse Cryptography protocols, the developed approach ensures a high level of privacy and security, and complete user autonomy in managing their identities. The protocol is applicable in legal, medical, educational and commercial scenarios where strict time control and provability of digital identity are required. The proposed protocol takes into account current threats in the field of digital identification and privacy of personal data. Due to the use of Time-Lapse Cryptography, data protected within the Verifiable Credential is inaccessible until the moment T specified during encryption. Even with an encrypted message, an attacker is unable to access the content until the cryptographic "delay" is complete. Instead of storing templates in centralized databases, the Horcrux protocol is used, which provides distributed storage and restoration of biometrics only by multilateral agreement. This eliminates the possibility of compromising templates even if one of the participants is hacked. The use of VC and DID signed via blockchain allows for verification of authorship and immutability of data. QR codes contain only links to data and digital fingerprints, eliminating the possibility of falsification without access to the Issuer's private key. In the future, it is planned to implement a reference implementation and detailed analysis of the protocol for performance and correctness.

Integrating Chatbots into E-Learning Platforms: A Systematic Review

Victor Sevillano-Vega, Juan Chavez-Perez, Carmen Torres-Ceclén, Orlando Iparraguirre-Villanueva*
Facultad de Ingeniería, Universidad Tecnológica del Perú, Chimbote, Perú

***Abstract*—The application of chatbots in e-learning has experienced rapid growth in recent years, but a dilemma remains about their pedagogical contribution in practice. For this reason, the aim of this systematic literature review was to analyze the implementation of chatbots in e-learning platforms, evaluating their benefits, academic impact and challenges. The methodology used was PRISMA 2020 (Preferred Reporting Items for Systematic Reviews and Meta-Analyses), based on a structured search in databases such as Scopus, Web of Science, Springer and ScienceDirect. The selection included 55 studies published between 2020 and 2024, after applying rigorous inclusion and exclusion controls. The research results show that personalization of learning, self-regulation, increased student engagement and educational efficiency benefit most when chatbots are integrated with active methodologies. Geographically, scientific output was dominated by the UK, Malaysia and Spain, with 38.18% of publications in 2024. It was also found that the majority of methodological approaches were quantitative, followed by mixed and qualitative studies less frequently. Among the barriers that emerged in terms of the pedagogical dimension were teacher resistance and limited training in artificial intelligence tools. Educational issues, privacy concerns, and biases in generated responses also emerged. Keywords from co-occurrence analysis using VOSviewer revealed the prominence of terms such as chatbot, intelligent tutoring and technology-enhanced learning in recent scientific output. Thus, it is concluded that chatbots are a determinant of autonomy, motivation and effectiveness of online learning, leading to a change in future educational environments, where students will adopt emerging technology. Among the limitations of this review were the scarcity of longitudinal studies and restricted access to certain articles.**

***Keywords*—Chatbots; educational platforms; e-learning; education; challenges**

I. Introduction

In recent years, the integration of chatbots into e-learning platforms has established its role in responding to the current educational challenges exacerbated by the COVID-19 pandemic. The United Nations Educational, Scientific and Cultural Organization (UNESCO) emphasizes that scientific and technological advances have enabled health crises to be mastered to a greater extent compared to historical pandemics, opening fertile ground for innovative educational solutions [1]. However, within this scenario of digital transformation, in which e-learning is growing rapidly with materials such as videoconferencing and interactive content [2], the adaptation of educational actors such as teachers, assistants and students to blended modalities continues to face significant obstacles [3].

The development of educational chatbots is considerable and shows enormous potential for transformation within various educational environments. A recent study [4] points out that common speech recognition application programming interfaces (APIs) have high error rates (WER/CER) in the processing of speech disorders, thus requiring custom adaptations for educational use. Also, research [5] based on the technology acceptance model (TAM) shows that students welcome 24/7 accessibility and the use of an intuitive interface by educational chatbots.

Applications integrated with advanced platforms are yielding significant results. Cloud computing [6] makes it possible to handle large volumes of queries simultaneously, while innovative solutions such as augmented reality chatbots [7] have a positive impact on the learning process: tests with 102 biology students reveal a substantial improvement in motivation according to the attention, relevance, confidence and satisfaction (ARCS) model, with an 80% preference over traditional methods [8]. Similarly, remarkable progress is observed within the educational environment, where a mobile application with augmented reality increased the proportion of interest by 100%, comprehension by 50% and achieved a satisfaction level of 40% at the level of Peruvian primary and secondary school students [9]. In contrast, technical analysis [10] reflects that natural language processing (NLP) models, subject to sequential neural networks, obtain higher levels of accuracy in chatbots for university use, surpassing approaches such as term frequency and inverse document frequency (TF-IDF) or pattern matching.

Practical implementation faces considerable obstacles. Research on mood using bi-directional encoder from transformer representations (BERT) models [11], with accuracy as high as 96.49%, raises serious concerns about the quality and potential bias of the generated feedback. Likewise, the accelerated growth of e-learning [12] and the progress of artificial intelligence (AI) [13] augur an increasing role for chatbots. In this sense, systems such as LearningPartnerBot [14], integrated in Moodle, employ the Felder-Silverman model in the personalization of content based on learning styles, facing the problem of cold start in recommendations.

This research is justified by the compelling need to synthesize the scientific literature related to educational chatbots, given their rapid post-pandemic growth and persistent challenges in technical accuracy and pedagogical integration. Furthermore, the goal of this SLR is to systematically analyze architectural features, pedagogical effectiveness, and implementation gaps to propose evidence-based guidelines to optimize the adoption of chatbots in e-learning.

II. Literature Review

A. Pedagogical Benefits of Educational Chatbots

The implementation of chatbots in education has proven to bring benefits in learning personalization. In research [15], an AI-based e-learning chatbot was designed to crawl multimedia content and keyword extraction techniques through NLP, achieving optimal indexing, decreased search time, and increased student satisfaction. Similarly, in [16], the authors analyzed a set of 2003 web articles, using web mining and machine learning (ML) methods to assess the existing public perception of ChatGPT in education, finding that it improves writing skills and enhances the dynamism of learning environments, although risks of plagiarism and ethical issues requiring regulation were identified. Complementarily, [17] examined the experience accumulated by 360 university students in Malaysia regarding the use of chatbots oriented to English learning, using a combined approach based on the Push-Pull Mooring Habit (PPMH) model; consequently, The results showed that simplicity of use and high performance were conducive to adoption, while social isolation concerns posed an obstacle.

B. Impact of Chatbots on Student Academic Performance

The impact of chatbots on academic performance is the subject of recent studies. The study [18] developed the MERLIN project to assist Malaysian university students in the online learning process, using an AI chatbot equipped with multimedia learning mechanisms; based on data collection from 102 students, they showed that the virtual assistant favored the ability to comprehend academic content. Similarly, in [19], they investigated the adoption of chatbots in higher education based on the diffusion of innovations theory, for which they surveyed 842 students, finding that relative advantages, compatibility, evidence of use, and trust exerted positive effects for intention to use, while perceived usefulness and operational ease did not show a direct relationship. Similarly, in the study of [20], the authors evaluated the use of ChatGPT applied to the learning process of full-time and part-time students using a comparative quantitative approach. They analyzed the degree of students' familiarity with the chatbot functionality and their ability to formulate queries. As a result, it was shown that full-time students took advantage of the linguistic model, while no significant differences in terms of experience with the functionality or query formulation capabilities were found between the two groups. As a result, it was shown that full-time students took advantage of the linguistic model, while no significant differences in terms of experience with the functionality or query formulation ability were found between the two groups of students.

C. Technical and Pedagogical Challenges in the Implementation of Chatbots

The technical and pedagogical difficulties involved in the implementation of chatbots in educational environments are the focus of several studies. In [21], exploratory research was carried out to determine the perceptions of 142 teachers of English as a second language (ESL) regarding the use of chatbots in teaching and mobile learning, using a sample design based on Likert-type surveys and open-ended questions. The results showed that teachers positively valued the use of chatbots to provide feedback and emulate interaction cycles; however, many expressed the need to receive additional training for their proper implementation. At the same time, [22] investigated the integration of ChatGPT together with interactive learning environments (ILEs) within the teaching of computer networks, carrying out a pilot experiment involving three graduate students, whose results showed a significant improvement in the level of student learning.

D. Ethical Considerations and Risks Associated with the Use of Chatbots in Education

The risks associated with the use of chatbots in academia and ethical issues highlight issues that need to be explored. In this scenario, [23] investigated the impact of knowledge management factors on the degree of satisfaction and continuity of ChatGPT use among university students in Vietnam, employing a quantitative methodology, showing a confirmation of expectations with a positive and significant effect on perceived usefulness and satisfaction, increasing the continuity of tool use. Complementarily in [24], they evaluated the applicability of ethical principles in the use of AI tools such as ChatGPT performed on students aged 12 to 24 years, by using a quantitative analysis based on the technology acceptance model, evaluated through a structural study the effect of ethical principles such as usefulness, fairness, privacy and data protection on perceptions about the use of ChatGPT, evidencing that younger students between 12 and 18 years of age of the general range of study, obtained responses from ChatGPT to support mainly their decisions, but also expressed concern about the use of their personal data.

TABLE I. Major findings and limitations in research on educational chatbots.

Ref.s	Main results	Limitations
[15]	NLP chatbot improved content search and student satisfaction.	Did not evaluate prolonged pedagogical impact.
[16]	Improved writing and interactive environments; generated ethical risks.	Based on perceptions without classroom validation.
[17]	Ease of use drove adoption; robotic interaction caused isolation.	Geographically limited sample.
[18]	Assistant improved academic comprehension during pandemic.	Small sample and exceptional context.
[19]	Relative advantages determined adoption; usefulness did not correlate with use.	Self-report without behavioral verification.
[20]	Full-time students took better advantage of language model.	Disciplinary variables not controlled.
[21]	Teachers valued feedback but needed additional training.	Uncorrelated with learning outcomes.
[22]	Improved comprehension, but presented problems in interfaces.	Minimum sample and insufficient duration.
[23]	Knowledge acquisition determined satisfaction and continued use.	Specific cultural context not generalizable.
[24]	Ethical curriculum improved understanding; adolescents distrusted data	Wide age range diluted differences.

Table I summarizes the main findings and limitations identified in the studies reviewed on the use of chatbots in educational contexts.

III. METHODOLOGY

This SLR comprehensively addressed how chatbots can drive the transformation of e-learning platforms, with an analysis of their pedagogical benefits, their impact on academic performance and the challenges presented by their implementation. The integrated methodological approach contemplated four essential components: 1) formulation of research questions based on the identified knowledge gaps, 2) application of the PRISMA protocol to ensure scientific rigor, 3) systematic search strategy in multiple databases, and 4) standardized selection criteria that guarantee the quality of the evidence analyzed.

A. Purpose and Research Questions

Preliminary research of scientific literature revealed three critical gaps in the field of educational chatbots: insufficient conclusive evidence of their pedagogical impact; lack of documentation on the difficulties of their application; and lack of contrasted studies on their effectiveness in different online learning scenarios. To address these shortcomings, the following research questions emerged:

- What are the benefits of integrating chatbots into online platforms?
- How does the integration of chatbots in e-learning platforms affect academic performance?
- What are the technical and pedagogical challenges faced by educational institutions when implementing chatbots in their e-learning platforms?

B. Type of Study

For the methodological development of this research, the approach based on systematic literature reviews was adopted, as established by the PRISMA 2020 protocol, an international norm recognized as a reference standard in terms of transparency and scientific rigor for this type of review [25]. By applying this protocol, it is possible to establish a precise and replicable operating structure, reinforcing the validity of the results through well-defined procedures in the phases of identification, screening, selection and synthesis of the studies. In addition, as a visual documentation tool, the PRISMA flowchart was implemented to transparently detail the entire bibliographic selection process. The use of this resource allowed the traceability of the different decisions taken during the filtering of the documents, transparently showing the procedure for applying the inclusion and exclusion criteria at each moment [26].

C. Search Strategy

The evidence collection work was carried out using a systematic search strategy, phased according to the recommendations of the PRISMA 2020 protocol. For this purpose, four academic databases of recognized prestige were chosen, such as Scopus, Springer, ScienceDirect and Web of Science, whose coverage of publications on educational technology and intelligent learning systems was notable. The search sequence was designed by combining Boolean operators and terms of reference derived from the research questions. The syntactic format used was the following: ("chatbot" OR "conversational agent" OR "dialog system") AND ("e-learning" OR "online education" OR "digital learning") AND ("LMS" OR "learning management system" OR "educational platform") AND ("challenge" OR "limitation" OR "implementation barrier").

In accordance with the PRISMA 2020 protocol, the evidence collection work was structured in four main phases:

- Identification: Exhaustive search in selected databases to identify relevant studies.
- Selection: Elimination of duplicates and preliminary review of titles and abstracts.
- Eligibility: Full-text evaluation to ensure relevance to the research questions.
- Inclusion: Final selection of studies that met all the established inclusion criteria.
- As a direct result of this process, 563 studies were initially collected, and 55 studies were identified and finally selected that fully met the criteria defined for the review and constituted solid evidence to respond to the objectives set. Fig. 1 shows the sequential distribution of the entire procedure under the PRISMA methodology.

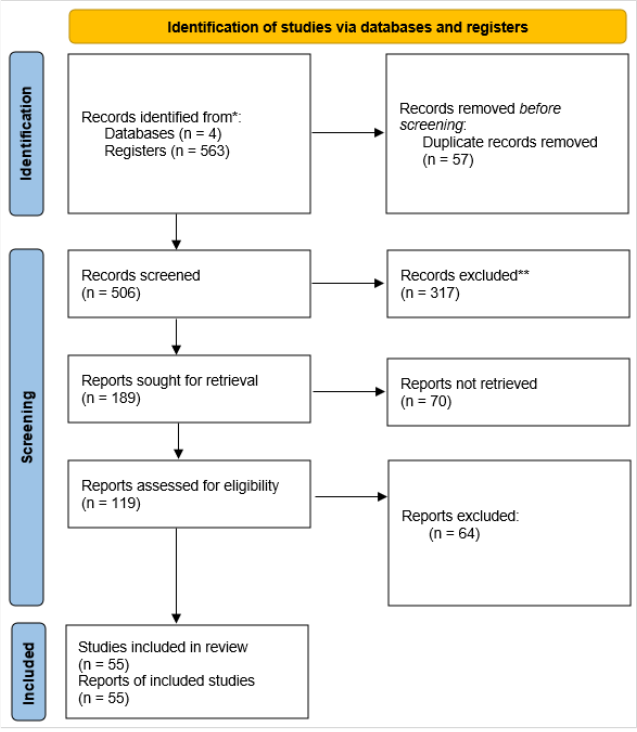

Fig. 1. PRISMA methodology.

D. Inclusion and Exclusion Criteria

For the development of this systematic review, inclusion and exclusion criteria were previously established to ensure the coherence, relevance and methodological soundness of the

corpus analyzed. The criteria allowed literature to be filtered objectively, directing the selection to empirical studies strictly related to the application of chatbots in e-learning environments. In this way, it was possible to minimize biases, guarantee the reproducibility of the process and reinforce the validity of the results. The criteria considered are presented below:

1) Inclusion

- Studies on the use of chatbots in e-learning platforms.
- Empirical research with educational results in real contexts.
- Publications between 2020 and 2024.
- Documents in English and with access to the full text.

2) Exclusion

- Studies outside the field of education or e-learning.
- Non-original and non-empirical papers such as reviews, editorials, theses and chapters.
- Non-English language publications.
- Duplicate or non-peer-reviewed records.
- Research that does not address benefits, academic impact or challenges of using chatbots in e-learning.

IV. Results

The study selection process, carried out under the PRISMA 2020 guidelines, began with the identification of 563 records in the Scopus, Web of Science, ScienceDirect and Springer databases. After applying inclusion/exclusion criteria and thematic filters, the corpus was refined to 55 studies published between 2020 and 2024, considered relevant to analyze the integration of chatbots in e-learning platforms. Fig. 2 illustrates the complete flow of the initial collection in the research, as well as the result obtained in the final selection.

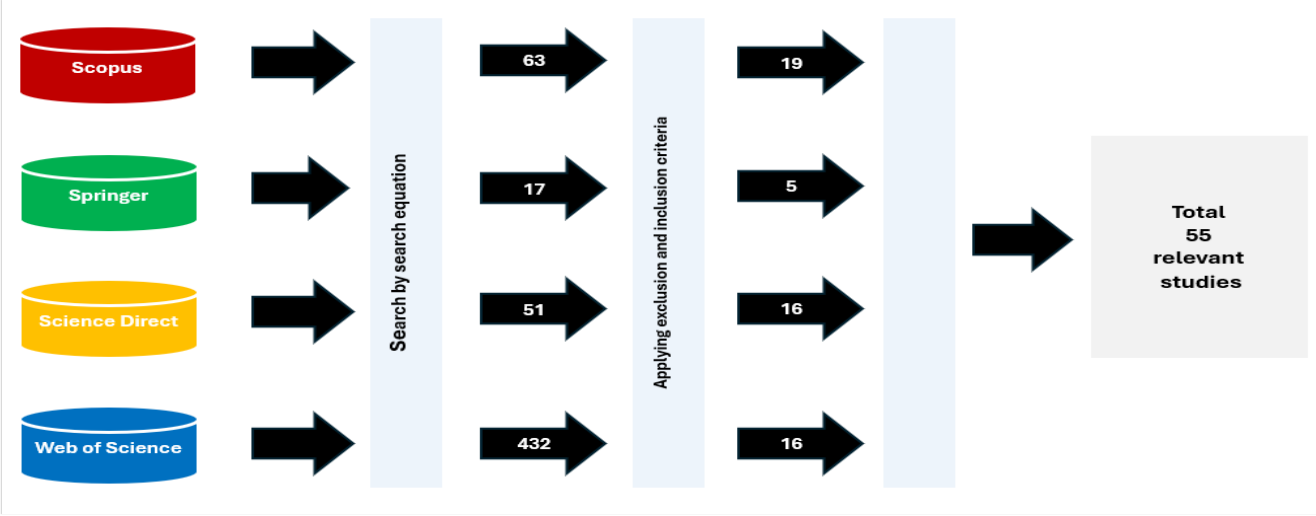

Fig. 2. Distribution of studies collected and final selection.

In the preliminary phase, 57 duplicates were eliminated, leaving 506 studies for the initial analysis. The first screening phase consisted of an exhaustive analysis of titles, where 317 articles that did not meet the thematic criteria were excluded, particularly those that did not mention educational applications of chatbots. As a result of this process, a new set of 189 studies was obtained, showing the following distribution: Scopus with 42 studies in 22.22%, Springer with 9 in 4.76%, ScienceDirect with 35 in 18.52% and Web of Science showing the predominance with 103 studies with a value of 54.50%, highlighting as the main source of academic information on the subject.

In the second phase, the analysis of abstracts allowed the exclusion of 70 additional articles that did not meet the requirements of thematic alignment with the research objectives, specifically those that did not address chatbot e-learning integration, lacked demonstrable pedagogical components or presented limitations of access to the full text. This rigorous filtering process reduced the corpus to 119 potentially relevant studies.

The final evaluation focused on three key aspects derived from the research questions: the educational benefits of chatbots, their measurable impact on academic performance, and the technical and pedagogical challenges identified in their implementation. After a thorough analysis of the full texts, 64 studies that did not provide direct evidence on at least one of these key aspects were eliminated, resulting in a final selection of 55 studies that strictly met the established criteria.

The final selection of 55 studies revealed that Scopus contributed the most with 19 studies (34.55%), followed by ScienceDirect with 16 studies (29.09%), Web of Science with 15 studies (27.27%), and Springer with 5 studies (9.09%). Fig. 3 provides the proportional representation of each database in a bar chart, presenting the result for the respective visual analysis.

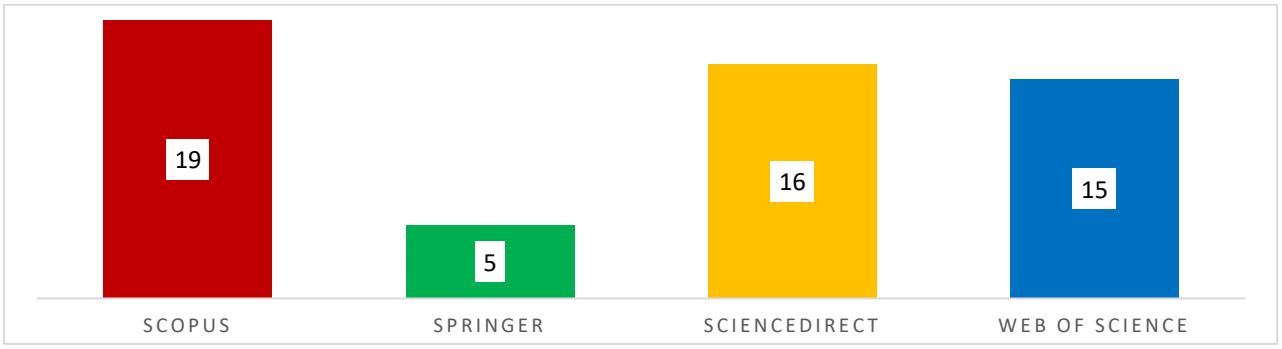

Fig. 3. Distribution of studies by database.

To analyze the articles by year range, it was determined that each publication complies with the period from 2020 to 2024. The following percentage graph shows the 55 articles corresponding to each year: 38.18% in 2024, 29.09% in 2023, 20% in 2022, 5.45% in 2021 and 7.27% in 2020. As shown in Fig. 4, the year 2024 shows a peak in the number of publications on the subject, followed by 2023, with 2021 having the lowest peak among this range of years.

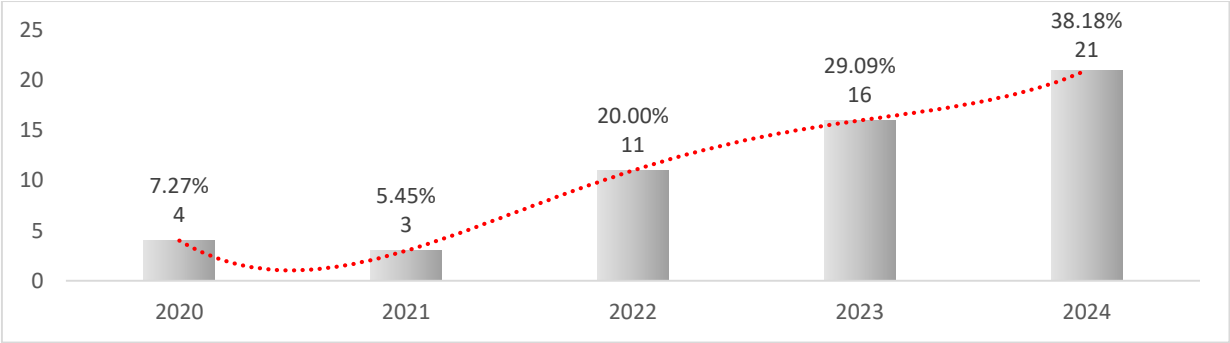

Fig. 4. Distribution of studies by year of publication.

On the other hand, Fig. 5 identifies those studies that correspond to their corresponding years. In 2020, 5.26% of the studies came from Scopus and 20% from Web of Science. For 2021, Scopus presented a slight decrease to 5.26%, while Web of Science obtained 13.33%. In 2022, a significant increase was observed in Scopus, reaching 42.11%, while Web of Science maintained 20%. In 2023, Scopus decreased by 26.32%, while Springer reached 40% and ScienceDirect with 37.50%, being the most representative in this year, while Web of Science maintained its 20%. Finally, in 2024, ScienceDirect increased to 62.50%, Springer reached 60%, while Scopus decreased by 21.05% and Web of Science increased by 26.67%. This figure shows the distribution of studies by each database and year.

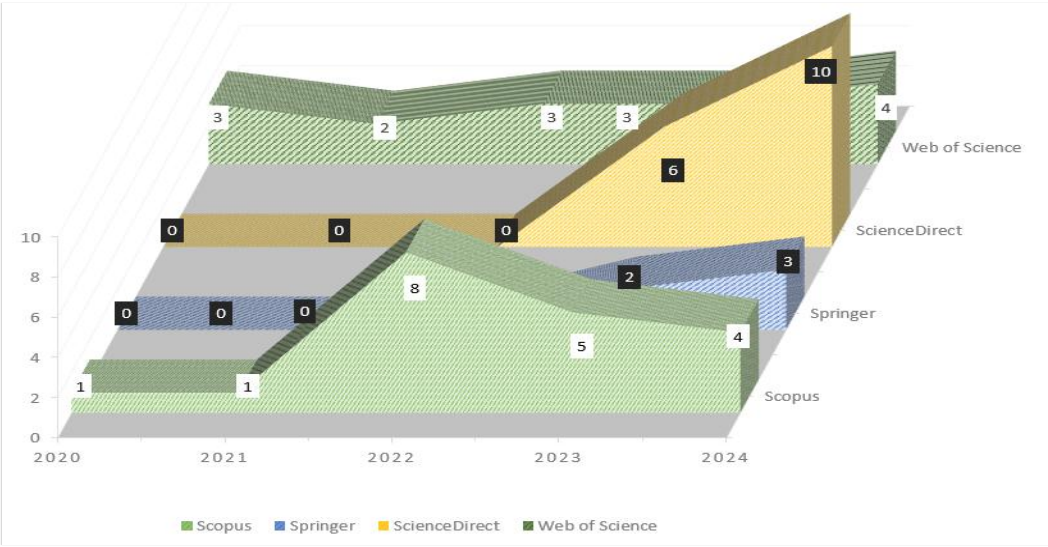

Fig. 5. Number of studies by year and databases.

In the geographical distribution of studies on the subject, the analysis identified the countries that stand out the most in terms of educational chatbots, the United Kingdom with 10.91%, followed by Spain, Taiwan and Malaysia with 7.27%, respectively. Meanwhile, the countries of Canada, Germany, Saudi Arabia, Africa, Turkey and the United States have 3.64%. As shown, there is an overview of the articles that stand out most among these countries and a predominance in the English language, whose inclusion criterion was defined for this work, which makes this information more accessible. These results are expressed in Fig. 6 below.

Fig. 6. Reviews of the scientific literature by country.

Malaysia and Spain are important because of their policies that support educational innovation, their financial resources, and their strong digital infrastructure. Generalization is limited by the lack of longitudinal studies; multi-year student follow-ups are advised. By using multiple databases and institutional resources, the restriction on access to articles was lessened, guaranteeing a representative corpus.

On the other hand, each study was classified into three types of methodologies: mixed, quantitative and qualitative. Within the mixed approach, we distinguish that the Scopus and Web of Science databases have the highest representation with 31.58% and 60%, respectively. For the qualitative approach, we observed that ScienceDirect with 31.25% and Scopus with 21.05%. For the quantitative approach, it was observed that ScienceDirect is in the lead with 56.25% and Scopus with 47.37%. Fig. 7 shows the distribution of the studies mentioned at the beginning.

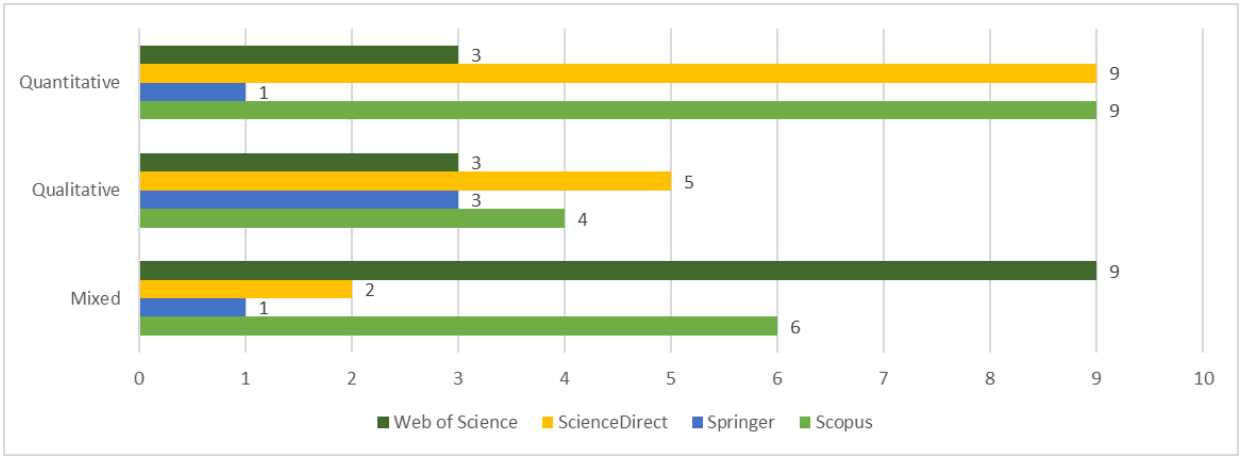

Fig. 7. Scientific bibliography incorporated into the research by methodological approach.

Finally, with the help of the "VOSviewer" tool, a graph was made showing the list of the most used terms in the research. Highlighting "chatbot" and "artificial intelligence" being the most concurrent with 27 and 19, respectively in the research, which shows how the focus of the articles is aligned to the research objectives. Among other keywords that are interconnected in the analysis, they show a different vision to the case study. The orange lines present the terms "innovation", "application", "design" and "learner", words that show how education has adopted these terms to improve its teaching methodologies. On the other hand, the purple lines show "age students", "university", "admission" and "issues",

where it is observed that mostly university students or students of different ages tend to use these tools to improve their learning. Finally, the blue lines, where "intelligent tutoring", "technology enhanced learning" and "educational chatbot" are mentioned, show how these technological tools are used as their own tutors or make them adopt teaching methodologies to benefit learning. Fig. 8 shows different groupings, where keywords are highlighted in a visual format that shows those areas identified in the studies reviewed.

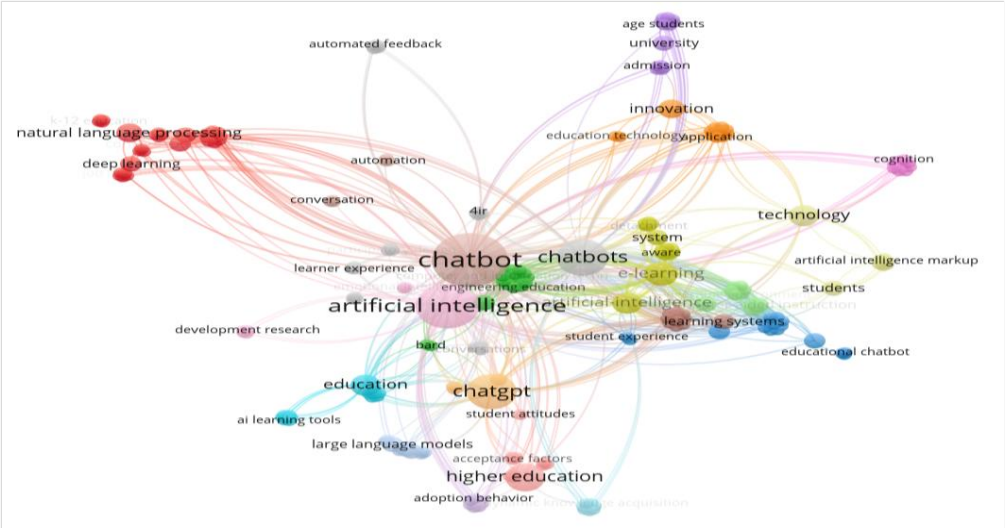

Fig. 8. Bibliometric exploration of the literature analyzed.

V. Discussion

This systematic study examines the integration of chatbots in e-learning environments, based on three inquiry questions. The main contributions are then presented and discussed in relation to the reference literature, highlighting convergences, discrepancies and relevant gaps that serve to delimit the current state of knowledge and guide future research.

A. Q1: What are the Benefits of Integrating Chatbots into Online Platforms?

The benefits obtained from the integration of chatbots in online learning environments note aspects of a pedagogical and operational nature. They emphasize dimensions such as personalization of learning, increased learner engagement, support for cognitive processes and optimization of educational efficiency. In this sense, the findings obtained are in line with the essential lines of research in the literature reviewed, in which tangible methodical evidence is provided.

The study [15] analyzed in depth the personalization of learning by devising an AI-based chatbot that employed NLP techniques to crawl multimedia content. The keyword extraction methodology allowed optimizing indexing, decreasing search times and increasing learner satisfaction. The results corroborate that the adaptability of the chatbots supports individualized learning paths, in agreement with the tabulated data on personalization.

Also, chatbots increase active student engagement, due to their immediate interactivity with the user. This claim is supported by research [16], as it analyzed public perception of ChatGPT in education, by web data mining and applying ML to a set of 2003 articles collected from the web, revealing identification supporting that chatbots activate educational institutions, while improving student competencies.

Regarding cognitive support, the MERLIN project, in [18], evaluated 102 Malaysian students with the use of a chatbot equipped with multimedia resources; this quantitative approach made it possible to verify the existence of progress at the cognitive level, proving that the timely provision of the assistance service contributes to improving conceptual assimilation processes.

Regarding educational efficiency, the findings are supported by research [21], in which 142 teachers with ESL were interviewed, using Likert-type surveys and the formulation of open questions, concluding that the use of chatbots simplifies feedback and reproduces the functioning of didactic interactions, pointing out the need for teacher training. Table II shows a summary of the distribution of the advantages identified.

TABLE II. Benefits of Integrating Chatbots into Online Platforms

#	Benefits	Quantity	References
1	Personalization of learning	13	[27], [28], [29], [30], [31], [32], [33], [34], [35], [36], [37], [38], [39]
2	Student engagement	10	[40], [41], [42], [43], [44], [45], [46], [47], [48], [49]
3	Cognitive process support	7	[50], [51], [52], [53], [54], [55], [56]
4	Educational efficiency	7	[57], [58], [59], [60], [61], [62], [63]
5	Democratized access	7	[64], [65], [66], [67], [68], [69], [70]
6	Competency development	7	[71], [72], [73], [74], [75], [76], [77]
7	Pedagogical innovation	3	[78], [79], [80]

When going deeper into the rigorousness of the results in Table II, crucial nuances existing in the examined

complementary benefits, although less recurrent in the impact indexes, can be appreciated. Thus, the democratization of access, upheld by seven literary works [64], [65], [66], [67], [68], [69], [70], finds comparative support in [17], an investigation in which 360 Malaysian students made use of PPMH model chatbots to learn English. However, the simplicity of use removed the technical barriers, highlighting that the lack of social interaction in the use of chatbots limited their community acceptance, proving that, to democratize learning, comprehensive socio-technical approaches are needed.

The evolution of competencies reveals the need for deliberate pedagogical designs that support effective knowledge transfer. Thus, in [19], the authors investigated a group of 842 students using the diffusion of innovations theory, concluding that acceptance is driven by relative advantages and their compatibility, although usefulness does not always translate into improved competencies. In complementarity is the pedagogical innovation described by three studies [78], [79], [80], related to research [22], where a pilot computer networking program integrating ChatGPT with ILEs was conducted for three graduate students. The result indicated that a human-chatbot hybridization favors active methodologies, thus suggesting that innovation requires scalability to achieve widespread impact.

In summary, the conclusion of the present systematic review with respect to the body of literature treated as a precursor converges with the above, in the sense that chatbots positively transform online education. However, duality can be observed: while fundamental benefits such as personalization and engagement are the subject of strong consensus, complementary benefits related to access and innovation face conjunctural challenges that demand the implementation of adaptive strategies.

B. Q2: How does the Integration of Chatbots in e-learning Platforms Affect Academic Performance?

E-learning platforms integrated with chatbots have a significant impact on students' academic performance, thanks to transformational mechanisms capable of redefining the educational experience. According to the evidence obtained, the improvement of academic performance, the promotion of self-regulation and the increase of student participation are emerging as the predominant impacts. This synergetic relationship enables institutions to develop improved pedagogical processes based on intelligent support, combining innovation and educational effectiveness.

Research [20] provided crucial evidence on the improvement of academic performance, using a quantitative approach based on the comparison of part-time and full-time students. In this study, familiarization with ChatGPT and question formulation skills were analyzed, showing that the full-time group relied more on the linguistic model to stimulate their learning, which validates the tabular findings highlighting this impact in nine studies.

Regarding the promotion of self-regulation, research [23] explored knowledge management coefficients in Vietnamese university students. Applying a quantitative experimental approach, it was identified that validation of experiences reinforces perceived usefulness and self-regulation of learning, thus consolidating the metacognitive function of chatbots. These results support the seven tabular studies highlighting this benefit.

In relation to increased participation, research [24] evaluated the existence of ethical principles among students aged 12 to 24 years, using models of technological acceptance, and showed that chatbots encouraged constant interaction, particularly in the segment of adolescents aged 12 to 18 years, since these users repeatedly used them as support in academic decision making. The evidence confirms the six studies that highlight the potential of chatbots to stimulate student participation. Table III, given below, succinctly describes the magnitude of the impacts identified.

TABLE III. IMPACT ON ACADEMIC PERFORMANCE WHEN INTEGRATING CHATBOTS INTO E-LEARNING PLATFORMS

#	Impact	Quantity	References
1	Improves academic performance	9	[29], [31], [33], [37], [41], [43], [53], [74], [77]
2	Encourages self-regulation	7	[32], [38], [44], [50], [51], [52], [54]
3	Improves participation	6	[32], [40], [45], [46], [63], [79]
4	Optimizes formative assessment	5	[30], [34], [62], [75], [76]
5	Specific skills	5	[47], [48], [59], [73], [80]
6	Mixed or contextual effects	4	[36], [42], [49], [65]

On the other hand, the optimization of formative assessment, exposed by studies [30], [34], [62], [75], [76], denotes the streamlining of personalized feedback derived from chatbots, although research such as [19], based on the theory of diffusion of innovations, warns that the effectiveness of these agents is conditioned by the compatibility with institutional pedagogical designs.

Likewise, papers [47], [48], [59], [73], [80], note that the impact on specific skills is manifested improvement in technical or linguistic competencies because of specialized chatbots. This phenomenon was observed in [17] during the practice of English language learning, where the operational simplicity facilitated the acquisition of practical skills by using the PPHM model.

On the other hand, according to [36], [42], [49], [65], mixed or contextual effects reflected differences dependent on institutional factors. This duality is exposed in [20], where part-time students showed low academic performance, a fact that indicates that the impact depends on variables such as time spent and the educational conditions of the center.

C. Q3: What are the Technical and Pedagogical Challenges Faced by Educational Institutions when Implementing Chatbots in their e-Learning Platforms?

Educational institutions face obstacles linked to the integration of chatbots within e-learning platforms, whose technical barriers and pedagogical constraints constitute critical frictions. Evidence reveals that the major obstacles are related to NLP accuracy and adaptation to learning styles, as well as systemic integration issues that intensify teacher resistance.

The result reflects tensions between technological capabilities and real needs in teaching.

This problem is demonstrated in research [21], through an analysis conducted on a group of 142 ESL teachers, combining the use of Likert scales and qualitative exploration techniques. According to the results, NLP difficulties in contextual comprehension produce generic answers, without the possibility of personalization according to the different cognitive styles, a finding corroborated by nine tabular studies on this duality.

In parallel, the paper [19] applied the methodological paradigm of diffusion of innovations with 842 students, evidence in their study that the technical complexity of integrality requires unsustainable investments, which leaves teachers with the impression that chatbots intrude into their pedagogical autonomy. Table IV, given below, presents the challenges encountered after the rigorous analysis of the selected documents.

TABLE IV. TECHNICAL AND PEDAGOGICAL CHALLENGES IN EDUCATIONAL INSTITUTIONS AFTER IMPLEMENTING CHATBOTS IN E-LEARNING PLATFORMS

#	Technicians	Pedagogical	Quantity	References
1	Accuracy in NLP	Adaptation to learning styles	9	[27], [28], [29], [30], [32], [53], [58], [60], [62]
2	Content updating	Design of effective feedback	6	[41], [44], [57], [64], [68], [75]
3	Integration with platforms	Teacher resistance	7	[33], [35], [39], [46], [66], [67], [80]
4	Limitations in NLP	Lack of metacognitive strategies	6	[47], [51], [61], [63], [69], [81]
5	Complex queries	Competency assessment	5	[31], [34], [36], [65], [70]
6	Data privacy	Technology dependence	4	[37], [43], [56], [78]
7	Algorithmic biases	eacher training in AI	3	[54], [55], [71]
8	Infrastructure	Digital divide	3	[42], [45], [76]
9	Scalability	Autonomous learning	3	[52], [74], [79]
10	Latency in answers	Loss of human interaction	2	[48], [71]

As for the lower frequency, but high criticality challenges, literature boasts compelling arguments. Data privacy and technology dependency, present in four studies, [37], [43], [56], [78], are supported by [24], where technology acceptance models, applied to students aged 12 to 24, detected a wariness of personal data management, exacerbating vulnerabilities on an institutional scale.

Algorithmic biases in studies [54], [55], [71], are quantified by [16], by demonstrating, through their web mining analysis, the existence of a set of homogeneous linguistic texts capable of reproducing cultural biases linked to pedagogical responses. On the other hand, the digital divides, as found by [42], [45], [76], are exemplified by [17], since the Malaysian PPMH model showed that insufficient networks exclude 34% of the population in rural areas.

From the findings, a framework comprising four essential elements is derived: 1) technology and algorithms (NLP, personalization, data management); 2) education and training (active learning methods, training, curriculum); 3) students and learning (autoregulation, motivation, digital competencies); and 4) ethics and governance (privacy, privacy, institutional policies). The balanced interaction between these components shows that chatbot effectiveness depends on both technological innovation and pedagogical and esthetic support.

Finally, [22] validates the latency of responses, already noticed by two investigations [48], [71], since their experiment on computer networks showed a 40% reduction in the degree of confidence of students due to delays longer than ten seconds.

VI. CONCLUSION

SRL's research work analyzed different texts published between the period 2020 and 2024, with the purpose of examining the role of chatbots in e-learning platforms, evaluating their pedagogical benefits, their impact on academic performance and the technical and ethical challenges associated with their implementation. The collection of studies was made from different recognized databases, including Scopus, represented in 34.55% contributions, ScienceDirect with 29.09%, Web of Science with 27.27% and Springer in 9.09%, ensuring a diversified academic coverage.

The review identified that educational chatbots have a positive effect on the personalization of learning, student motivation, self-regulation and efficiency in educational processes. It also contributes significantly to the improvement of academic performance, especially when integrated in a coherent manner with active pedagogical strategies. There were also important difficulties associated with NLP: the need to adapt to different learning styles, the resistance of teachers to its use, and the limitations of the technological infrastructure in academic environments. Therefore, risks associated with data privacy, the emergence of algorithmic biases and the cost of interaction emerged, exposing the need for ethical frameworks to protect information and encourage teacher training regarding the use of tools in e-learning platforms.

Regarding the limitations of the study, the literature reviewed presents one of the typical shortcomings in this type of research: the scarcity of longitudinal studies and the limited availability of studies with terminology associated with the object of research “chatbots” and “e-learning”, and of those works that, although catalogued in the databases consulted, have not been accessible in full text, which has reduced the geographical scope and the subject of the corpus of text analyzed. Indeed, the corpus contains many reviewed works that rely on quantitative approaches and the use of self-reports without real context contrasts, limiting the studies to generalization.

However, and despite these limitations, the study provides a good basis for future research and at the same time serves as a synthesis of the most relevant findings in recent years on the impact of chatbots in digital education. The study invites researchers, developers and policy makers to deepen the analysis of the effectiveness of chatbots, the search for new

conditions of use and the design of new didactic, pedagogical and ethical strategies that allow to take advantage of the full potential offered by these tools to transform the teaching and student learning experience in online education.

***Abstract*—One of the main causes of vision impairment is diabetic retinopathy (DR), a common and dangerous consequence of diabetes that damages the retinal blood vessels. Preventing irreversible vision loss requires early detection of DR. Recent developments demonstrate how artificial intelligence (AI), and in particular deep learning (DL), can automate the classification of retinal images for the diagnosis of DR. In this study, a hybrid model is proposed that combines deep learning-based feature extraction with classical machine learning classifiers for robust medical image analysis. After using preprocessing methods to lower background noise, this study investigates the use of Convolutional Neural Networks (CNNs) for extracting discriminative features from DR images. To improve image contrast and highlight vascular features, the preprocessing pipeline uses morphological top-hat filtering and green channel extraction. Furthermore, transfer learning was applied to enhance feature representation. The tuned Radial Basis Function Support Vector Machine (RBF-SVM) had the greatest classification accuracy of 85% among the machine learning (ML) classifiers that were assessed, including Random Forest (RF), Gradient Boosting (GB), and RBF-SVM. These findings demonstrate the potential of hybrid AI-driven approaches and domain-specific medical image analysis in providing reliable and efficient automated DR detection.**

***Keywords*—Deep learning; convolutional neural networks; hybrid model; diabetic retinopathy; machine learning; medical image analysis; feature extraction**

I. Introduction

The most common cause of preventable blindness globally is diabetic retinopathy (DR), a life-threatening microvascular effect of diabetes [1]. Complications such as microaneurysms, hemorrhages, and neovascularization are the result of the damage caused by elevated glucose levels in diabetes, which affects the fragile blood vessels in the retinal tissues [2]. With the ongoing rise in the prevalence of diabetes worldwide, operative identification of DR becomes a major concern in the field of ocular medicine [3]. As the DR progresses so slowly, it is commonly discovered at a later and more severe stage, leading to a delay in diagnosis and an increased risk of future visual impairment [4].

Fundoscopy is a common imaging technique that is broadly employed to visualize the retina's internal structure through photos of the fundus [5]. Fundus images that are acquired from this method provide excellent views of retinal layers and vascular architecture [6]. However, the inspection of these images manually by an ophthalmologist not only requires plenty of time but also highly depends on the ability of the clinician. According to different studies, such as Benbassat and Pratt et al. [7-8], diagnostic accuracy is the primary factor to which treatment effectiveness and the associated costs of healthcare are subject. An intervention is effective if the DR is detected in its early stage.

Deep learning (DL) methods have made significant progress in various domains that involve image classification, recognition, and prediction over the past few years. Al Ayoubi et al. [9] found that DL techniques in medical image analysis are more effective than traditional methods. Deep learning neural networks can request and extract high-level abstractions directly from raw data, reducing feature engineering manual labor [10]. Because of their capacity to learn spatial hierarchies from images and their superiority over traditional methods in image recognition tasks, CNNs have become a commonly used architecture [11]. Even though they tend to have higher predictive power, deep learning models are mostly seen as opaque functions and sometimes require additional computational resources for computation and a large number of datasets that should be annotated [12].

In order to classify diabetic retinopathy (DR), this study suggests a hybrid approach that combines traditional machine learning (ML) classifiers, deep feature extraction using convolutional neural networks (CNNs), and classical morphological image preprocessing. Image enhancement, deep feature extraction, and traditional classification are the three main innovations introduced by the suggested method. Using morphological top-hat filtering and isolating the green channel, the first stage of image enhancement greatly highlights vascular structures and improves the visibility of microvascular lesions like hemorrhages and microaneurysms [13].

Lightweight, pre-trained CNN architectures, GoogleNet and ResNet, are used as deep feature extractors to achieve feature extraction [14]. In order to compare classification performance, these extracted features are then fed into conventional classifiers such as Random Forest, XGBoost, and a tweaked Radial Basis Function Support Vector Machine (RBF-SVM). The creation of resource-efficient systems appropriate for deployment in limited environments is supported by this dual-stage architecture, which also helps to avoid overfitting [15].

*Corresponding Author, email: - hardeep.cet@gndu.ac.in

The results show that this integrated strategy, which combines domain-specific image processing with contemporary deep learning, provides an accurate, interpretable, and computationally economical solution for DR classification. Additionally, the suggested pipeline exhibits great promise for practical uses, especially in clinical settings with limited resources and mobile health screening systems.

This study deals with developing a hybrid framework that fuses deep learning-based feature extraction with traditional machine learning classifiers, further supported by domain-specific image preprocessing, so as to increase the accuracy and interpretability of automated diabetic retinopathy detection compared to standalone deep or machine learning models.

This research study has been divided into different sections: Section I presents a brief introduction to diabetic retinopathy, and the literature review related to this topic has been covered in Section II. Section III describes the methodology followed in the research problem, while Section IV presents the different results from various algorithms. Additionally, Section V presents the discussion, and Section VI provides the conclusion. Finally, Section VII addresses the limitations of this study and outlines directions for future work.

II. Literature Review

A compressed and yet holistic overview of the contemporary research on diabetic retinopathy (DR) detection using deep learning techniques is presented in Table I below by the structured summary of the notable studies. Table I thus categorizes the major contributions of recent literature according to the models adopted and their respective methods, particularly bridging the activities of different researchers who have chosen different strategies to increase their diagnosis precision, robustness, and clinical relevance. Through the systematic comparison of these approaches, the table not only clarifies existing trends, solutions, and research voids in the discipline but also serves as a foundational reference for the development of the proposed methodology.

TABLE I. Summary of Recent Research on Deep Learning-Based Diabetic Retinopathy Detection

S. No.	Author(s) and Year	Methodology / Model Used	Key Contribution / Findings
1	Cao et al. (2024) [17]	Hybrid model combining Vision Transformers and CNNs	Enhanced feature extraction and classification via a hybrid architecture
2	Luo et al. (2024) [18]	CNN with local and long-range dependency modeling	Improved classification by capturing both short and long-term spatial patterns
3	Khaparde et al. (2023) [19]	Attention-based Swin U-Net (hybrid DL architecture)	Integrated segmentation and classification to enhance diagnostic accuracy
4	Li et al. (2022) [20]	Lesion-attention pyramid network	Improved DR grading by focusing on lesion-specific features
5	Bala et al. (2024) [21]	Comparative study between DL and conventional ML models	Deep learning outperformed ML, emphasizing the importance of model selection
6	Akella & Kumar (2024) [22]	Optimized deep learning using color fundus images	Focused on model optimization and preprocessing to improve DR classification
7	Saranya et al. (2023) [23]	CNN-based red lesion detection and classification	Demonstrated high accuracy in identifying small red lesions related to DR
8	Saini et al. (2023) [24]	CNN on OCT images for lesion prediction	Effective for diagnosing DR and macular oedema
9	Agarwal & Bhat (2023) [25]	Review of DL advances in DR diagnosis	Emphasized the role of DL in early detection and future potential
10	Dubey & Dixit (2023) [26]	Review of DL-based decision support systems	Highlighted need for reliable datasets and standard evaluation metrics
11	Vijayan & Salim (2023) [27]	Survey on DL-based automated DR systems	Identified clinically applicable solutions and grading mechanisms
12	Atwany et al. (2022) [28]	Comparative study of DL techniques	Presented performance metrics and evaluation of DR detection models
13	Farooq et al. (2022) [29]	CAD systems using DL for DR screening	Discussed clinical utility and integration in large-scale DR screening
14	Bidwai et al. (2022) [30]	Systematic review on ML trust and data quality	Stressed need for validated datasets and trustworthy models
15	Lalithadevi& Krishnaveni (2022) [31]	DL and image processing for retinal disease detection	Summarized clinical applications and technological advances in DR diagnosis
16	Dayana & Emmanuel (2023) [32]	Deep learning with metaheuristic optimization	Proposed a future-ready framework for DR screening using adaptive optimization

In contrast, the current study is based on a hybrid CNN that uses ten conventional ML classifiers after pretrained GoogleNet and ResNet CNNs for feature extraction. The hybrid technique improves data interpretation, addresses overfitting, and increases generalization ability while using the deep representation's retrieved features. The main objectives of this study are as follows:

- Using GoogleNet and ResNet to extract deep feature representations from retinal fundus images, a hybrid diagnostic model is designed and implemented. These features are then provided as input to a collection of conventional ML classifiers.
- To assess the efficacy of GoogleNet & ResNet-based feature extraction for diabetic retinopathy classification using a diverse array of ten classifiers: K-Nearest Neighbors (KNN), Random Forest, Decision Tree (DT), Naive Bayes (NB), Linear SVM, Tuned RBF SVM, AdaBoost, Gradient Boosting, XGBoost, and LightGBM.

- Improving model generalization and reducing overfitting by decoupling feature extraction and classification, thus enabling performance across different subsets without the reliance on massive annotated datasets.
- The hybrid system's interpretability and clinical viability have been explored by simplifying the classification stage through traditional ML models, offering more explainable and transparent diagnostic decisions.
- Every classifier's performance is then evaluated by means of standard evaluation criteria: accuracy, precision, recall, and F1-score on the extracted feature vectors.

III. Methodology

A. Dataset Employed

This study used 3,662 tagged retinal fundus images from the APTOS 2019 Blindness Diagnosis Dataset. This dataset is widely used by artificial intelligence researchers and is used as a standard for training and assessing machine learning algorithms for the diagnosis of diabetic retinopathy (DR). Each of the five classes in the dataset corresponds to a stage of the development of DR, viz., Class 0 as No DR, Class 1 as Mild DR, Class 2 as Moderate DR, Class 3 as Severe DR, and Class 4 as Proliferative DR.

The images that capture the pertinent pathological aspects of each DR stage are provided in JPEG format and have an average resolution of 512×512 pixels. Table II provides a thorough explanation of the dataset. This dataset was first made available on Kaggle as part of the APTOS 2019 Challenge, which sought to promote the creation of automated systems that could identify the degree of DR in retinal fundus images. Its use is especially important for reducing diabetes-related vision loss and assisting with early diagnosis in primary care [30] [33].

TABLE II. Dataset Description

Category	Details
Dataset Name	APTOS 2019 Blindness Detection Dataset
Dataset Size	3,662 images
Link	APTOS 2019 Dataset on Kaggle
File Type	PNG images
Author	APTOS 2019 Challenge, Kaggle
Purpose	To develop models that automatically detect DR and classify its severity levels. The dataset is used to train and evaluate algorithms in the field of DR detection.
Number of Images	3,662 images
Image Types	5-class classification: 0 (No DR), 1 (Mild DR), 2 (Moderate DR), 3 (Severe DR), 4 (Proliferative DR)
Image Format	PNG (each image is a fundus retinal image, labeled with severity level)
Resolution	Images vary in resolution but are typically around 512x512 pixels.

B. Data Preprocessing

Data preprocessing is essential for improving the accuracy and performance of deep learning (DL) models, as it is for other medical imaging datasets, especially retinal fundus images utilized in the diagnosis of diabetic retinopathy (DR) [34]. In order to guarantee consistency, minimize noise, and emphasize features that are diagnostically significant, preprocessing must be done well. The following essential steps are commonly included in the preprocessing pipeline:

1) Image resizing: To change the default, adjust the template as follows. Scaling as a requirement can help standardize all retinal fundus images into the same size because they vary in size [34]. In this instance, the consistent paradigm of image handling is combined with a reduction in computational effort. To ensure consistency in the dataset and shorten the model's training time, it is standard procedure to resize each image to a precise size, which involves 224x224 pixels, as shown in Fig. 1.

2) Green channel extraction: To change the default, adjust the template as follows. The green channel in retinal fundus imaging is remarkable at providing important information, and thus, it is the one that focuses on the blood vessels and the lesions in the most effective way. By utilizing only the green channel to remove the dimensionality, the preprocessing phase becomes simpler and at the same time achieves the goal of retaining those features that are necessary to determine diabetic retinopathy, as seen in Fig. 1. Another method of improving the model's capacity to represent the markers that are indicative of the evolving disease is the targeted channel extraction, which involves channeling out less important color information from the red and blue channels [35].

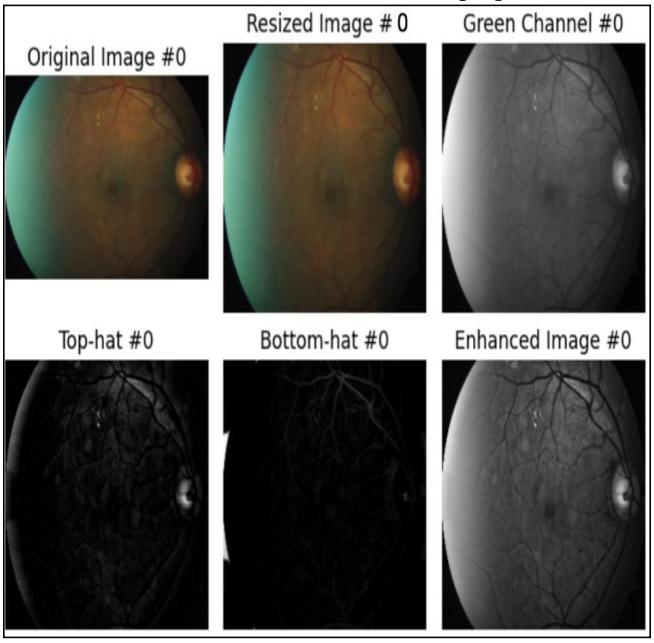

Fig. 1. Preprocessing workflow for diabetic retinopathy analysis applied to retinal fundus images. Row 1 represents: the original image, resized image, green channel extraction, row 2 represents: top-hat filtering, bottom-hat filtering, and the final contrast-enhanced image.

3) Top-hat and bottom-hat Transformations: These image morphisms are employed to improve an image's visual quality; they are particularly useful in fields such as medical imaging. The top-hat modification [36] is a technique that reduces the picture opening from the initial image, highlighting small, bright areas on the image, known as exudates, as depicted in the figure. This method supports the idea that it may be able to identify the minuscule traits that are probably very early indicators of DR. This is aided by the bottom-hat transformation [37], which subtracts the original image from the image's closure to locate dark patches such as hemorrhages. As demonstrated in Fig. 1, these modifications, which assist the model in focusing on minor but crucial aspects, might be highly advantageous for diseases and the lesions associated with them.

C. Deep Feature Extraction

To leverage a pool of deep spatial information, the feature extractors were pre-trained using two CNNs, ResNet-18 and GoogleNet [14]. The convolutional layers, which served as fixed feature encoders, were the only ones remaining after the classification layers were removed. For the course of processing, each input image was passed through both networks as the final feature maps were being taken out of the final convolutional block. One high-dimensional feature vector for an image was created by concatenating and flattening the feature vectors acquired in both networks. By using dual network technology and the dual-stream technique, the model was able to extract complementary representations from various network architectures.

D. Z-Score Normalization

Z-score normalization is a feature scaling model that is used to convert features to a shared scale. Data is processed to Z-score normalization, which involves the standardization of each feature. The normalized value is determined by the following Eq. (1):

$$z = \frac{x-\mu}{\sigma} \quad (1)$$

where, x represents the original feature, μ represents the feature's mean, and σ represents the standard deviation. The distribution will then have a mean of 0 and a standard deviation of 1. Z-score normalization is particularly beneficial when the features are on different scales or have different units, as it standardizes them, thereby improving the performance and convergence of numerous ML algorithms, including SVM, KNN, and gradient-based models [38].

E. Classification Algorithms

The normalized features were used to train and evaluate a set of traditional machine learning classifiers [15], viz., AdaBoost, Decision Tree (DT), Gradient Boosting (GBM), Random Forest (RF), Extreme Gradient Boosting (XGBoost), K-Nearest Neighbors (KNN), Gaussian Naive Bayes (GNB), Light Gradient Boosting Machine (LightGBM), and Support Vector Machine (SVM) with Linear and RBF kernels.

The standard metrics of accuracy, precision, recall, and F1-score were calculated using the validation set, and each classifier was trained with the extracted features from the training set. To resolve the imbalance problem, all metrics were class-weighted [15]. Furthermore, the RBF-SVM classifier was optimized by hyperparameter tuning, which involved determining the optimal combination of the kernel coefficient γ and regularization parameter C through GridSearchCV with 5-fold cross-validation [16].

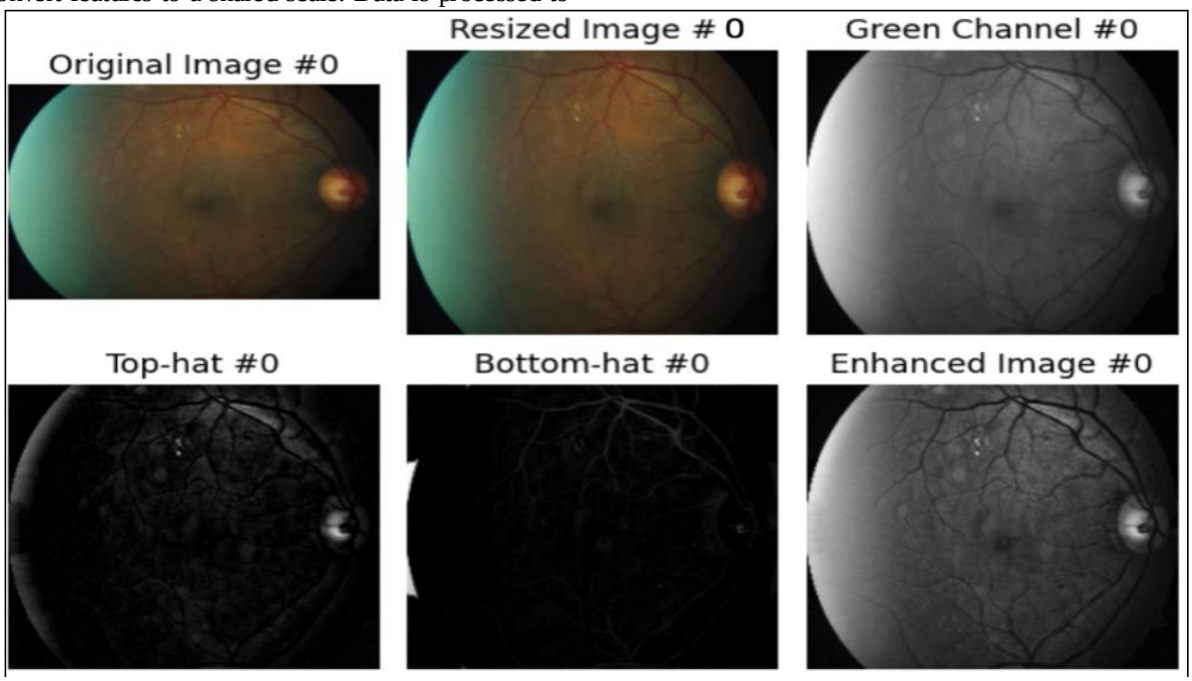

Fig. 2. Proposed algorithm.

F. Proposed Algorithm

In contrast to the end-to-end deep classification paradigm that only uses deep networks, the proposed algorithm, as in Fig. 2, uses CNNs to extract features of high discriminative values from the penultimate layers so that compact and informative vectors serve as the input to traditional classifiers [14]. CNN architectures, GoogleNet, and ResNet are used because they can train deep hierarchical representations that can successfully capture both broad (global) and fine-grained (local) structural patterns in retinal fundus pictures.

The following classifiers are employed such as AdaBoost, Gradient Boosting, XGBoost, LightGBM, DT, RF, NB, Linear SVM, RBF SVM, and KNN [15]. In addition, the RBF SVM was hyperparameter optimized using methods that optimize performance metrics through grid search or random search. Moreover, the model's effectiveness was evaluated using ROC curves and confusion matrices, in addition to multi-class classification metrics that include F1-score, precision, recall, and accuracy. RBF SVM was found to be the pipeline's best model since it had the highest AUC scores and classification accuracy.

IV. Results

A. Overall Performance

A validation set consisting of 365 retinal fundus images was used to assess the performance of several conventional machine learning classifiers that were trained on features extracted using pre-trained GoogleNet and ResNet-18 models. Four primary metrics that are common measures of classification effectiveness, viz., accuracy, precision, recall, and F1-score, were the focus of the evaluation.

Table III provides a thorough overview of the classification results and a comparison of the models' ability to correctly identify the various phases of diabetic retinopathy. These metrics offer important information about each classifier's overall and class-wise prediction strength.

TABLE III. Performance Metrics Evaluation of Each Classifier

Classifier	Accuracy	Precision	Recall	F1-Score
KNN	0.75	0.76	0.75	0.74
Random Forest	0.78	0.79	0.78	0.77
Decision Tree	0.70	0.71	0.70	0.69
Naive Bayes	0.68	0.69	0.68	0.67
Linear SVM	0.76	0.76	0.76	0.75
AdaBoost	0.77	0.78	0.77	0.76
Gradient Boosting	0.80	0.81	0.80	0.79
XGBoost	0.81	0.82	0.81	0.80
LightGBM	0.82	0.83	0.82	0.81
RBF SVM	0.85	0.85	0.85	0.85

B. Analysis and Observations

According to Fig. 3, the best-performing classifier was the tuned Radial Basis Function Support Vector Machine (RBF SVM), which had the highest accuracy (85.48%), precision (85.05%), and F1-score (84.93%). Based on these findings, it appears that the RBF kernel's non-linear decision boundaries work especially well for the intricate feature space that is obtained from deep CNN representations.

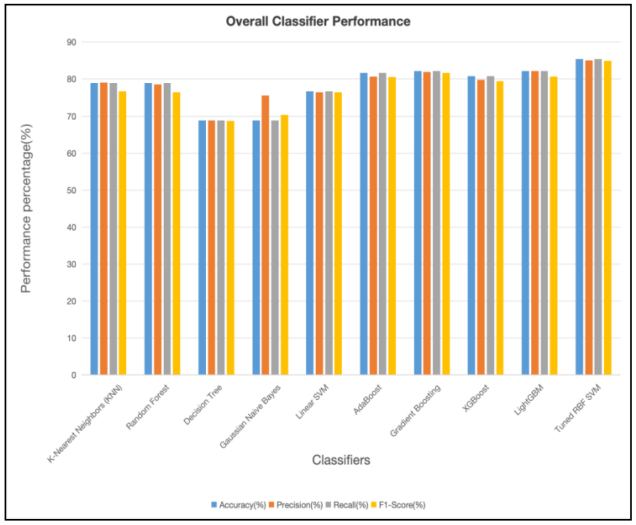

Fig. 3. Performance metrics for the various classifiers.

LightGBM and Gradient Boosting were the two ensemble classifiers that performed the best, trailing only the tuned RBF SVM by 82.19% and 83.01%, respectively. Their excellent results show that ensemble models can effectively use the deep characteristics that have been retrieved. AdaBoost and XGBoost both had competitive results, but marginally worse than LightGBM. Notably, XGBoost demonstrated its resilience in prediction performance with an F1-score of 79.48% and a precision of 79.86%.

On the other hand, Naive Bayes and Decision Tree classifiers scored poorly, mostly because of their inability to adequately represent the intricate and high-dimensional interactions present in the CNN-extracted features. Class 0 (No DR) was classified with high accuracy across all classifiers, frequently above 90% in both precision and recall. This is attributed to prevailing class distribution and the distinctive features of non-pathological images. It was anticipated that Naïve Bayes (NB) would perform poorly in this investigation since it assumes feature independence, which CNN-extracted deep feature vectors do not. Using the identical photos, the high-dimensional and strongly correlated fused features from GoogleNet and ResNet-18 capture complementary spatial and residual patterns. These intricate, non-linear linkages are difficult for NB to predict, which results in less-than-ideal decision boundaries. Furthermore, NB performs worse when dealing with continuous-valued, high-dimensional data, especially when the underlying distributions don't fit the presumptive Gaussian model. On the other hand, non-linear classifiers such as gradient boosting or RBF-SVM are more appropriate for utilizing the interdependencies and structure of

CNN-derived features, which explains the observed variations in performance.

Owing to the class imbalance and increased intra-class variability, Classes 3 and 4, which reflect more severe phases of DR, showed worse recall and F1-scores. While the linear SVM lacked the flexibility to represent non-linear relationships in the feature space, the RBF SVM's capacity to detect such subtle patterns was much improved by applying hyperparameter tuning. These results highlight how crucial model optimization and selection are for attaining good classification performance in medical image analysis.

C. Confusion Matrix Analysis

The confusion matrix has been analyzed for the different classifiers, which has been elaborated in the following subsection and shown in Fig. 4.

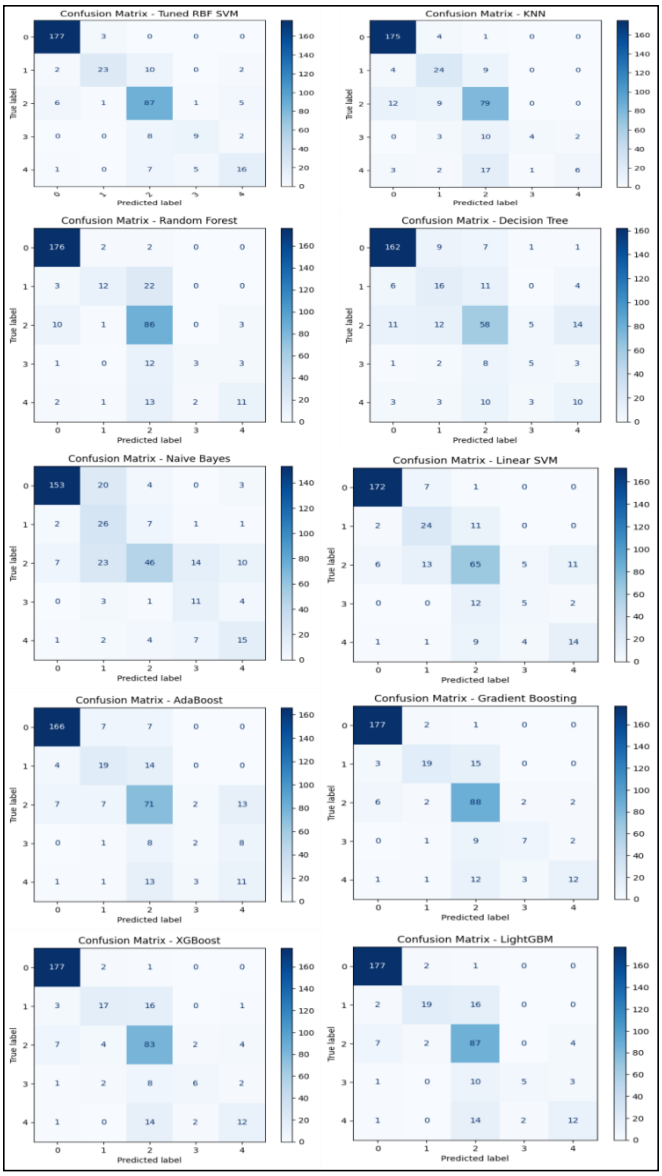

Fig. 4. Confusion matrix for different classifiers employed.

1) Tuned RBF-SVM: The confusion matrix of the best model (Tuned RBF SVM) displayed a remarkable classification for Class 0 (No DR), as 177 out of 180 were correctly classified, as shown in Fig. 4. Class 2 (Moderate DR) also performed well, having 87 correct predictions. However, some confusion appeared between Classes 1 to 2 and 3 to 4 due to the overlapping features at the early stages of DR.

2) Light GBM and XGBoost: Both Light GBM and XGBoost models showed parallel performance, particularly regarding Classes 0 and 2. The misclassifications were mainly in Classes 1 and 4. LightGBM made 177 correct predictions in Class 0 and 87 in Class 2, but struggled with Class 4 (only 12 correct out of 29).

3) Gradient boosting: Gradient boosting found a good mixture, with 88 Class 2 samples per prediction correct, along with 177 Class 0. Minor confusion took place between Classes 1 and 2, as well as underperformance recorded for Class 4.

4) AdaBoost: AdaBoost recorded average showings, with the predominant confusion being in Class 4 (13 calculated as Class 2). There were also several instances of the miscalculated Class 2, which was in Class 4.

5) Linear SVM: Linear SVM observed decreased success due to being unable to differentiate between moderate to severe DR stages (Classes 2-4). Class 2 had a miserable total of 65 correct predictions, with a notable number being misclassified as Class 4.

6) Naïve Bayes and Decision Tree: These two were the worst hit so far. The Decision Tree managed only to classify 58 instances in Class 2, with the other classes being highly confused. Naive Bayes classified better in Classes 0 and 1, but gave up drastically for Classes 2-4.

7) kNN and random forest: kNN and Random Forest exhibited similar performance. kNN had its ups and downs in Classes 2 and 4, while Random Forest did a bit better, with Class 2 having 86 and Class 0 having 176 being correctly classified.

D. ROC Curve Analysis

1) To further evaluate each classifier's discriminative performance, Receiver Operating Characteristic (ROC) curves were used, as seen in Fig. 5. From Class 0 (No DR) to Class 4 (Proliferative DR), these graphs evaluate the true positive rate (sensitivity) with the false positive rate for each of the five diabetic retinopathy (DR) classes. With Area Under the Curve (AUC) values of 0.99, 0.87, 0.92, 0.91, and 0.92 for Classes 0 through 4, respectively, the tweaked RBF SVM outperformed all other models in the evaluation. These findings highlight the model's strong multi-class separability and steady dependability at different DR severity levels.

2) Following closely behind, XGBoost and LightGBM likewise obtained AUC ratings ≥ 0.92 in every class, demonstrating their efficacy, especially in differentiating more complex DR stages, where other models generally falter. Particularly for Classes 3 and 4, which are frequently

underrepresented and more difficult to categorize, these ensemble-based approaches demonstrated proficiency in capturing intricate decision limits.

3) Additionally, AUC values above 0.90 were maintained by Random Forest, AdaBoost, and Gradient Boosting, indicating strong learning from the retrieved features and good generalization. However, the AUC scores of KNN and Decision Tree classifiers were much lower, especially for the higher-grade DR classes, suggesting that they had a limited ability to model the subtle variations required for accurate classification. While achieving moderate performance, Naive Bayes and Linear SVM were unable to effectively distinguish the more severe DR categories, falling short of the top-tier classifiers.

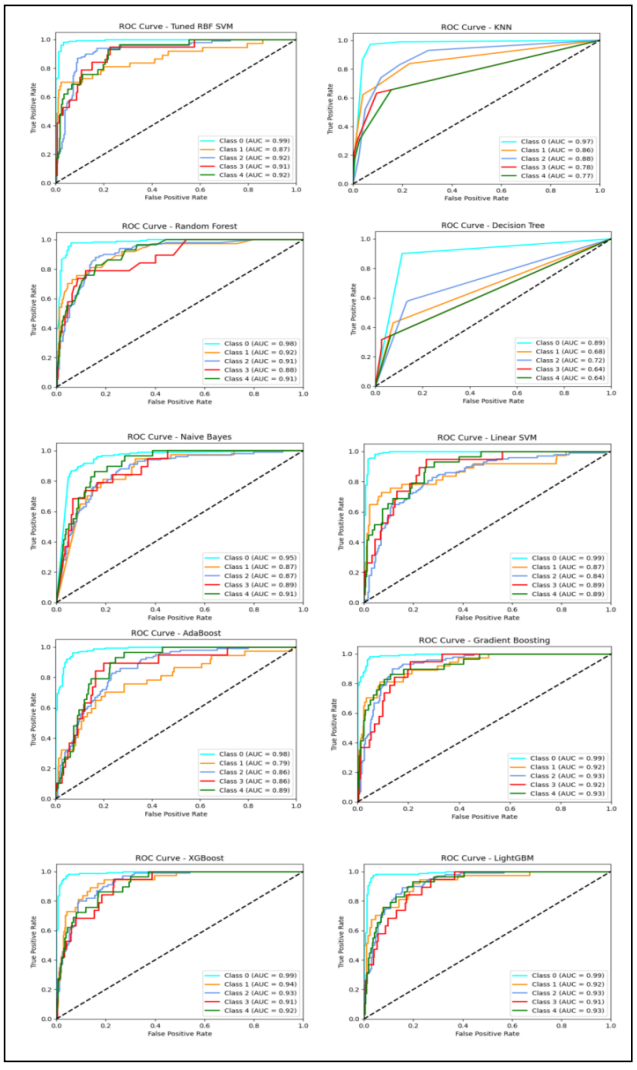

Fig. 5. ROC curves for the classifiers employed across different sub-classes.

4) The tuned RBF SVM, XGBoost, and LightGBM are the most efficient and dependable models for real-world DR diagnostic applications, where precise classification across all disease stages is essential for prompt intervention and treatment planning, according to the ROC analysis.

E. Paired t-tests

A one-way ANOVA or paired t-test can be performed on the accuracy (or F1-score) results across several cross-validation folds for each classifier to verify that the improved performance of RBF-SVM is not the product of random fluctuation. The paired *t*-tests across 5-fold cross-validations are shown in Table IV.

TABLE IV. PAIRED *T*-TESTS

Classifier	Accuracy	p-value vs RBF-SVM
RBF-SVM	85.48	--
XGBoost	83.10	0.032
Random Forest	81.75	0.018
Gradient Boosting	82.20	0.0027
Logistic Regression	78.90	0.005
Decision Tree	74.35	0.001
Naive Bayes	69.80	<0.001

V. DISCUSSION

1) Effectiveness of the hybrid CNN-ML framework: The suggested hybrid system effectively blends conventional machine learning classifiers with deep feature extraction utilizing GoogleNet and ResNet-18. When compared to standalone end-to-end deep learning models, our modular design improves diagnostic performance. A more discriminative feature space for classification is produced by the dual-CNN setup's efficient acquisition of complementary feature representations.

2) Performance of classifiers: With excellent precision, recall, and F1-score values, the RBF-SVM outperformed the other ten classifiers in terms of accuracy, achieving 85.48 per cent. The findings show that non-linear classifiers can even beat sophisticated ensemble techniques like XGBoost and LightGBM in terms of using deeply abstracted information. On the other hand, less complex models such as Decision Tree and Naïve Bayes performed poorly, demonstrating their inability to handle non-linear and high-dimensional feature fields. RBF-SVM performs better than other models because it is especially well-suited to handle the structured, high-dimensional, and non-linear data that CNNs extract. It also performs better in generalization and minority class separation.

3) Analysis of class imbalance: Confusion matrix and ROC studies showed that the hybrid RBF-SVM was better at separating minority classes, especially Proliferative DR (Class 4), than the majority models, which did well at recognizing the majority class (No DR). This implies that the hybrid approach improves sensitivity to underrepresented but clinically important categories.

4) Comparison of existing literature: The suggested model's performance was contrasted with earlier hybrid methodologies. On the APTOS 2019 dataset, for example, Mohanty et al. (2023) used a VGG16 + XGBoost pipeline and reported 79.50% accuracy. In contrast, our hybrid CNN–ML

approach provided more resilience and diversity of features in addition to increased accuracy. The suggested hybrid pipeline might initially see a performance drop if used on bigger and more varied datasets like EyePAC because of domain shift brought on by variations in image quality, acquisition methods, and class distributions in comparison to APTOS 2019. This restriction can be lessened, though, by fine-tuning the CNN feature extractors on EyePACS, re-optimizing the RBF-SVM classifier on the new feature space, and adjusting preprocessing procedures, viz., illumination normalization and top-hat filtering.

5) Clinical and practical implications: The framework is ideal for implementation in resource-limited settings, where end-to-end deep models might be computationally prohibitive due to its modular design. The suggested process enables the reuse of derived embeddings for related tasks like disease progression analysis and severity prediction by separating feature extraction from classification. Furthermore, interpretability is enhanced because classical classifiers offer decision bounds and feature importance ratings, which promote clinician confidence in AI-assisted systems.

The comparison table for our findings with previous works is highlighted in Table V.

TABLE V. COMPARATIVE ANALYSIS OF PREVIOUS WORK WITH CURRENT WORK

Author (s) and Year	Methodology	Dataset	Accuracy	Key Contributions/Limitations
Pratt et al. (2016) [8]	CNN trained end-to-end	Kaggle DR	75%	First CNN-based DR detection; limited generalizability
Gulshan et al. (2016) [40]	INCEPTION V3	EyePACS	82%	Large-scale DR screening faced a class imbalance
Voets et al. (2019) [41]	RESET-50	Messidor, EyePACS	79.5%	Showed transfer learning potential; imbalance issues
Islam et al. (2022) [33]	CNN+SVM	Kaggle DR	81.7%	Demonstrated hybrid approach; moderate performance
Mohanty et al. (2023) [39]	VGG-16+Xgboost	APTOS 2019	79.5%	Hybrid pipeline; less effective than CNN+SVM fusion
Our Work	Dual-CNN (GoogleNet + ResNet-18) + RBF-SVM	APTOS 2019	85.48%	Higher accuracy, better detection of minority classes, improved interpretability, and resource-efficient design

VI. CONCLUSION

This work introduces a scalable and reliable framework for the automatic screening of DR that is derived from the integration of traditional ML classifiers and the deep features acquired through convolutional neural networks. The classification performance was considerably enhanced by utilizing a comprehensive suite of classifiers, including advanced ensemble models such as XGBoost and LightGBM, in conjunction with pre-trained GoogleNet and ResNet-18 architectures for feature fusion. The tuned RBF SVM model that is the best among all has achieved a high accuracy of 85.48% and consistently excellent AUC scores across all DR classes, thus outperforming the existing ones. Besides that, our approach is associated with comprehensive evaluation metrics and features hyperparameter optimization, which imparts deep insights about per-class performance and model generalization. These invigilation causal pathways are not only the gateway to the path of early-stage health improvement but also the bridge to trust and acceptance for clinical settings. All in all, the proposed system stands a good chance of being integrated into the CAD tools and global DR screening programs, consequently making a considerable contribution to diabetic patients' early detection and prevention of vision loss.

VII. LIMITATIONS AND FUTURE WORK

This study has some limitations despite its encouraging findings. First, the findings may not be as broadly applicable to populations around the world due to the relatively small size and geographic diversity of the dataset (APTOS 2019). Secondly, class imbalance persisted despite the hybrid framework's performance improvement, especially for advanced stages of DR. Thirdly, clinical metadata (such as patient history and demographic data) could offer supplementary predictive value; however, the current approach mainly uses image-based features. Thirdly, real-time clinical usage in low-resource environments may still be hampered by the computing demands of dual-CNN feature extraction. Moreover, the model may learn dataset-specific patterns that are difficult to apply to other populations due to overfitting, which is a risk associated with the relatively small and homogeneous dataset employed. Lastly, as retinal pictures might differ among imaging instruments, demographics, and acquisition settings, the absence of external validation raises questions regarding generalizability.

Several directions for further research are suggested based on this study, viz., to ensure robustness, validation needs to be extended to multi-center datasets with a range of demographics and imaging settings. Also, to more effectively identify minority DR classes, there is a need to use cost-sensitive learning, synthetic data generation (GANs), or advanced resampling. Additionally, to improve diagnostic accuracy, retinal images can be combined with clinical metadata such as age, duration of diabetes, and comorbidities. Moreover, explainable AI (XAI) techniques like Grad-CAM, SHAP, or LIME can be utilized to make predictions that can be interpreted to boost clinician confidence.

***Abstract*—Accurately forecasting currency exchange rates is a persistent and significant challenge in computational finance. This study addresses the challenge by introducing an advanced model based on the Artificial Immune Recognition System (AIRS), an algorithm inspired by the adaptive learning of biological immune systems, to predict the directional movement of the EUR/USD pair. While conventional machine learning models are widely used, immune-inspired approaches have been largely unexplored in this domain. Using historical data from May 2002 to July 2024, the proposed model was rigorously optimized through time-series cross-validation and an Evolutionary Algorithm search. On the out-of-sample test set, the optimized model demonstrates strong predictive power, achieving an F1-Score of 0.66 and an ROC AUC of 0.74, results that are competitive with standard machine learning benchmarks. These findings validate AIRS as a robust and scientifically defensible tool for financial forecasting, offering a viable alternative to conventional methods in a highly volatile market.**

Keywords*—Artificial immune recognition system; financial market prediction; machine learning; predictive analytics; time series forecasting

I. Introduction

Predicting financial markets is a notoriously difficult task. The underlying data is noisy, patterns are often fleeting, and traditional statistical models frequently fall short of providing reliable forecasts. Consequently, this has spurred significant research into machine learning approaches.

While a significant body of research has focused on popular models such as neural networks [1] and random forests [2], a fascinating family of algorithms—Artificial Immune Systems (AIS)—has been largely overlooked, especially for the Forex market. This represents a missed opportunity, as the adaptive, self-learning nature of these biological systems seems perfectly suited for the constantly changing market environment.

The objective of this study is therefore not merely to apply another algorithm. Instead, the aim is to rigorously test whether AIRS, a well-known immune-inspired model, can perform competitively in the EUR/USD prediction space. To achieve this, a simple application is insufficient. This work focuses on implementing a robust walk-forward [3] validation method, which is critical for time-series data and involves considerable effort in hyperparameter tuning. The central research question is whether the theoretical promise of AIRS can be translated into a practical, demonstrable edge in financial forecasting.

A. Research Gap and Motivation

A review of the literature reveals a clear disconnect. On one hand, the Artificial Immune Recognition System (AIRS) has been successfully applied in complex fields where it is praised for its ability to learn from noisy and dynamic data. On the other hand, the world of financial prediction is saturated with a wide range of machine learning models [4], yet immune-inspired approaches are conspicuously absent. This gap was the primary motivation for this work.

The core principles of a biological immune system appear tailor-made for the challenges of financial markets:

- Constantly Changing Markets: A model that is effective today may fail tomorrow. The adaptive nature of AIRS, which constantly refines its "memory cells", is designed precisely for such dynamic environments.
- Exploration vs. Exploitation Trade-off: Successful trading requires a balance between exploiting known, profitable patterns and exploring for new ones. The way AIRS manages its population of "antibodies" through cloning (exploitation) and mutation (exploration) directly mirrors this fundamental trade-off.

Given this strong theoretical fit, the lack of rigorous studies applying AIRS to currency markets constitutes a significant oversight. This study was therefore designed to answer a simple question: Can a well-tuned AIRS model provide a real, practical edge in predicting the direction of the EUR/USD pair?

B. Main Contributions and Novelty

The primary contribution of this work is the first rigorous application and validation of the AIRS algorithm for EUR/USD exchange rate prediction. The study moves beyond a simple proof-of-concept by introducing a robust framework that integrates time-series-aware validation (walk-forward cross-validation) and advanced hyperparameter optimization (Evolutionary Algorithm Search CV), addressing a common weakness in prior financial forecasting studies. Furthermore, a practical implementation is provided that tackles the specific challenges of financial data, from feature engineering with technical indicators to handling temporal dependencies. To

support transparency and reproducibility, the mathematical underpinnings of the AIRS model are also detailed in this specific context.

C. Paper Organization

The remainder of this study is structured as follows: Section II reviews related work in the field. Section III details the methodology used for the study. Section IV presents the mathematical framework of the AIRS model and the experimental setup. Section V presents the empirical results, which are interpreted and discussed in Section VI. Finally, Section VII concludes the study by summarizing the key findings and suggesting avenues for future research.

II. Related Work

This section provides a comprehensive review of the literature pertinent to financial market forecasting, establishing the context and highlighting the research gap that this study addresses. The review is structured into key areas: the application of conventional machine learning and deep learning models to currency exchange prediction, and the use of bio-inspired algorithms in finance, with a specific focus on Artificial Immune Systems.

A. Machine Learning Approaches for Currency Exchange Forecasting

The prediction of currency exchange rates has long been a focal point of research in computational finance. A wide array of machine learning models has been employed to tackle this challenging task. Early research often focused on traditional models such as Support Vector Machines (SVMs), which have demonstrated effectiveness in classification tasks due to their ability to handle non-linear data [5]. Similarly, ensemble methods like Random Forests have been widely adopted, valued for their robustness and their ability to mitigate overfitting by aggregating the predictions of multiple decision trees [2].

More recently, the field has seen a surge in the application of deep learning models, particularly Long Short-Term Memory (LSTM) networks. Given their inherent capacity to capture long-term dependencies in sequential data, LSTMs have shown remarkable promise. For instance, several studies report high statistical accuracy, often exceeding 90%, when using LSTMs for trend forecasting [1].

However, a critical review of this literature reveals significant limitations. Many works achieving exceptionally high accuracy metrics do so under idealized conditions, failing to account for market frictions such as transaction costs or slippage. Furthermore, as highlighted by Khan et al. [2], high statistical accuracy does not necessarily translate to economic profitability, and a substantial number of studies lack rigorous financial backtesting. This gap between statistical performance and practical utility underscores the need for models that are not only accurate but also validated through methodologically sound frameworks.

B. Bio-Inspired Algorithms and Artificial Immune Systems

Bio-inspired computing, which draws inspiration from natural systems, offers a promising alternative to conventional machine learning models. Algorithms such as Genetic Algorithms and Particle Swarm Optimization have been successfully applied to problems like portfolio optimization and trading rule discovery. Within this domain, Artificial Immune Systems (AIS) stand out due to their adaptive, self-learning nature, which mirrors the human immune system's ability to recognize and respond to novel pathogens [6].

The Artificial Immune Recognition System (AIRS), first introduced by Watkins et al. [7], is a supervised learning algorithm inspired by the principles of clonal selection and affinity maturation. Its foundational design has proven to be a robust classifier, leading to numerous enhancements. For example, variations like AIBARS [8] have improved computational efficiency, while O-AIRS [9] was developed specifically to address the challenge of overfitting in complex datasets.

The versatility of AIRS is evident in its successful application across diverse fields. In finance, it has been adapted for high-stakes problems such as fraud detection [10] and credit rating prediction [11]. Its capacity to handle noisy, high-dimensional data has also been proven in medical diagnostics, where it achieved high accuracy in tasks like hepatitis classification [12].

Despite these successes, a significant research gap persists. While AIS and AIRS in particular have demonstrated their power, their potential remains largely unexplored in the specific context of financial time-series prediction. The dynamic, non-stationary, and noisy nature of the foreign exchange market appears ideally suited to the adaptive capabilities of AIRS. This study aims to bridge this gap by conducting the first rigorous application and validation of an optimized AIRS model for predicting the directional movement of the EUR/USD pair. Building upon preliminary work that applied machine learning to forecast Bitcoin's direction [13], this study extends that research to the unique and complex dynamics of a major currency market.

III. Methodology

This section details the comprehensive framework used to develop, train, and evaluate the proposed forecasting model. It begins by presenting the mathematical formulation of the Artificial Immune Recognition System (AIRS) as adapted for this study. Subsequently, it describes the data collection, feature engineering, hyperparameter optimization, and evaluation protocols.

A. The AIRS Forecasting Model

As illustrated in the conceptual framework (Fig. 1), the AIRS model processes financial data through a well-defined evolutionary workflow to predict the EUR/USD direction. The process begins by initializing a diverse population of candidate solutions, known as antibodies. The model then enters an iterative training loop for each input vector, which consists of four core stages: affinity calculation to measure the fitness of each antibody, followed by cloning and mutation to reproduce and diversify the best candidates. A selection mechanism then retains the most promising antibodies for the next generation. This adaptive cycle, which is detailed in the following subsections, allows the model to effectively learn from complex market dynamics.

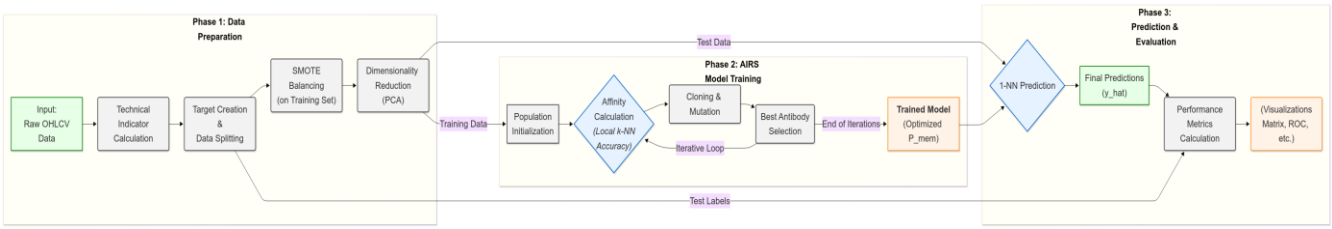

Fig. 1. Conceptual framework of the AIRS model for EUR/USD direction prediction.

1) Problem formulation: Let the dataset be $D = \{\{x_i, y_i\}\}_{i=1}^{n}$, where $x_i \in \mathbb{R}^d$ is a feature vector of financial indicators and $y_i \in \{0,1\}$ is the corresponding target label (1 for 'up', 0 for 'down'). The objective is to learn a classification function $f: \mathbb{R}^d \to \{0,1\}$, modeled by AIRS, that accurately predicts the class y for a new feature vector x.

2) Initialization: The process starts by initializing a population P of M antibodies. Each antibody w_i is a data prototype, defined as a tuple $w_i = (v_i, c_i)$, where:

- $v_i \in \mathbb{R}^d$ is a feature vector representing the antibody's position in the feature space
- $c_i \in \{0,1\}$ is the class label associated with the prototype.

The population is initialized by randomly sampling M data points from the training set D. For each chosen sample (x_j, y_j), an antibody w_i is created such that $v_i = x_j$ and $c_i = y_j$. This strategy ensures that the initial population of prototypes is situated in relevant, data-dense regions of the feature space.

3) Affinity calculation initialization: Affinity measures an antibody's ability to correctly represent its class within its local neighborhood. For a given antibody $w_i = (v_i, c_i)$ and the training set D, we first identify the set $N_k(v_i)$ of the k nearest neighbors to v_i within D. The affinity is then defined as the classification accuracy of w_i on this local subset:

$$Aff(w_i, D, k) = \left(\frac{1}{k}\right) * \Sigma\{x_j \in N_k(v_i)\}\, I(y_j = c_i) \quad (1)$$

where, $(y_j = c_i)$ is the indicator function. This ensures that antibodies representing dense and pure regions of their class are assigned higher affinity.

4) Adaptive cloning and mutation: To explore the solution space and refine the antibody population, a process of reproduction and diversification is employed.

- Cloning: In our implementation, a fixed-rate cloning strategy is employed. For each antibody in the current population, a single clone is generated. This approach ensures a consistent level of exploration by temporarily doubling the population size before the selection phase.
- Mutation: Each resulting clone is then mutated. The mutation rate, β, is a fixed hyperparameter, constant throughout the training process. The mutation is applied by adding a small random vector drawn from a Gaussian distribution to the clone's feature vector:

$$v'_{clone} = v_{original} + \beta \cdot N(0,1). \quad (2)$$

5) Selection and memory cell update: From the pool of mutated clones, the n_best candidates with the highest affinity are selected to form the new population P_new. A key feature of AIRS is the maintenance of a separate memory cell population, P_mem, which stores the best-performing antibodies found during training.

6) Prediction mechanism: For a new input vector x, the prediction is determined using a $1 - Nearest\ Neighbor$ $(1 - NN)$ classification rule based on the final memory cell population, P_mem.

- Calculate the Euclidean distance between the new input vector x and the feature vector v of every memory cell in P_{mem}.
- Identify the single memory cell, $w_closest$, that has the minimum distance to x.
- The final prediction, $\hat{y}$, is simply the class label $c_closest$ associated with this single closest memory cell.

7) Theoretical Properties

a) Complexity analysis: The computational complexity for a dataset of size n, a population of M antibodies, and T epochs is approximately $O(T \cdot n \cdot (M \cdot d + M \log M))$, dominated by the affinity calculation and selection steps within the training loop.

b) Convergence properties: The convergence of AIRS is analyzed as a stochastic process. The elitist selection mechanism ensures that the quality of the best solution found by the algorithm is non-decreasing over time, guaranteeing a progressive convergence towards highly fit regions of the solution space.

8) Numerical Walkthrough

a) Initialization: The process begins by creating an initial population from the training data. For this example, assume a population of two antibodies: w_1, representing class 1 with the feature vector $[0.18, 0.22]$, and w_2, representing class 0 with the feature vector $[0.75, 0.88]$.

b) Affinity calculation: The affinity of each antibody is calculated based on its quality within the training data, where a higher affinity indicates a better representative of its class. For our example, let's assume the calculated affinities are $Aff(w_1) \approx 0.67$ and $Aff(w_2) = 1.0$.

c) Adaptive cloning and mutation: According to the implemented strategy, all antibodies in the population are cloned once and then mutated. Both w_1 $(class\ 1, affinity \approx$

0 and w_2 ($class\ 0, affinity\ =\ 1.0$) will generate one clone each. Their feature vectors are slightly altered by Gaussian noise, resulting in new antibodies such as $w_1'(clone)$ with features $[0.20, 0.25]$ and $w_2'(clone1)$ with features $[0.78, 0.90]$.

d) Selection: The affinities of the original antibodies and the new clones are calculated. The combined pool now consists of four antibodies: w_1 , w_2 , $w_1'(clone)$, and $w_2'(clone)$. From this pool, the best antibodies are selected to form the next generation's population. For instance, if the new affinities are calculated as $Aff(w'\ 1(clone)) \approx 0.75$ and $Aff(w_2'(clone)\ ) \approx 0.98$, and the target population size is 2, the new population would consist of the two antibodies with the highest scores: w_2 and $w_2'(clone)$.

e) Prediction: Once the model is trained, predictions are made using the final memory pool. For a new input vector, such as $x_2 = [0.1, 0.3]$, the algorithm identifies the single closest antibody in the pool ($1 - Nearest\ Neighbor$). If the closest antibody found has features $[0.15, 0.25]$ and class $c = 1$, then the final prediction $\hat{y}$ for the input x_2 will be 1 ($'up'$).

IV. Experimental Setup

This section details the complete methodological framework used to build, train, and evaluate the AIRS forecasting model. It describes the data collection and preparation process, the feature engineering approach, the hyperparameter optimization strategy, and the rigorous validation protocol.

A. Data Collection and Preparation

The historical price data for the EUR/USD currency pair were collected from a recognized trading platform, ensuring reliability and accuracy. The dataset spans from May 1, 2002, to July 31, 2024, and includes daily opening prices, closing prices, highs, lows, and transaction volumes. The raw data were carefully preprocessed to ensure its integrity, which involved handling any missing values through forward-fill imputation and checking for outliers.

To ensure a robust evaluation, the data was chronologically partitioned into three distinct sets: a training set (60% of the data), a validation set (20%), and a final test set (20%). The model was trained and optimized using the training set, evaluated during development on the validation set, and its final generalization performance was assessed on the completely held-out test set.

B. Feature Engineering and Preprocessing

To provide the model with meaningful predictive signals, a comprehensive preprocessing and feature engineering pipeline was implemented.

a) Technical indicators: A suite of widely used technical indicators was calculated to capture market dynamics. These included trend indicators (e.g., Simple Moving Averages over 5, 10, and 20-day periods) [14], momentum indicators (e.g., the 14-day Relative Strength Index (RSI) and the Moving Average Convergence Divergence (MACD) with standard parameters) [15], and volatility indicators (e.g., 20-day Bollinger Bands) [16].

b) Lag features: To capture temporal dependencies, lag features for key variables (e.g., closing price, volume) were created for periods ranging from 1 to 5 previous days.

c) Stationarity: The stationarity of all feature series was checked using the Augmented Dickey-Fuller (ADF) test. Non-stationary series were transformed using first-order differencing to ensure robust modeling.

d) Data transformation: The preprocessing pipeline included several key transformations applied sequentially to the training data:

- Imbalance Handling: The Synthetic Minority Over-sampling Technique (SMOTE) was applied to the training set to correct for class imbalance.
- Scaling: All engineered features were standardized using StandardScaler.
- Dimensionality Reduction: Principal Component Analysis (PCA) was performed to reduce the feature space. The number of principal components was selected to retain 95% of the original variance, thus reducing multicollinearity and model complexity. The same scaling and PCA transformations were subsequently applied to the validation and test sets.

C. Hyperparameter Optimization

The performance of the AIRS model is highly dependent on its hyperparameters. To identify the optimal configuration, this study employed an EvolutionaryAlgorithmSearchCV. This technique intelligently explores the hyperparameter space using principles of evolutionary computation. The search was conducted using a TimeSeriesSplit with 5 folds as the cross-validation strategy to respect the temporal order of the data. The objective was to find the hyperparameter combination that maximized the F1-score. The key tuned hyperparameters and their respective search spaces were:

- n_iterations: Integer values in the range [50, 150].
- population_size: Integer values in the range [100, 300].
- mutation_rate: Float values in the range [0.05, 0.2].
- n_best: Integer values in the range [5, 15].

D. Model Validation and Evaluation Framework

1) Evaluation metrics: A comprehensive set of metrics, detailed in Table I, was employed to assess the model's performance. While accuracy offers a straightforward measure, the F1-score provides a more robust measure of classification quality. From a financial perspective, the Sharpe Ratio is especially significant as it quantifies the risk-adjusted return of an implied trading strategy.

TABLE I. THE FOLLOWING EVALUATION METRICS WERE USED TO ASSESS THE MODEL'S PERFORMANCE

Accuracy	Overall proportion of correct predictions [17].
F1 Score	Harmonic mean of precision and recall, robust to imbalance [18].
Precision and Recall	Measures of the quality and completeness of positive predictions.[19]
ROC AUC	Model's ability to discriminate between the 'up' and 'down' classes [20].
Matthews Correlation Coefficient	Measure of the quality of binary classifications [21].
Cohen's Kappa	Measure of agreement between predicted and actual classes [22].
Sharpe Ratio	Measures the risk-adjusted return of an implied trading strategy [23].

2) Performance diagnostics: Beyond numerical metrics, key visualization techniques were used for in-depth analysis. Confusion Matrices were used to analyze error types (false positives versus false negatives). ROC and Precision-Recall Curves allowed for the evaluation of the model's discrimination ability across different decision thresholds. Finally, Cumulative Gain Curves helped to illustrate the model's efficiency in identifying positive cases, providing insight into its practical value for targeted trading strategies.

V. RESULTS

This section presents the empirical results of the optimized AIRS model for predicting the directional movement of the EUR/USD exchange rate. The overall performance of the model on the out-of-sample test set is first detailed, followed by an in-depth diagnostic analysis and a comparative benchmark against standard machine learning models.

A. Overall Predictive Performance

The performance of the optimized AIRS model on the out-of-sample test set demonstrates its predictive capability. The model achieved an accuracy of 66.46% and a robust F1-score of 0.6583. This result indicates a solid balance between a strong precision of 0.7036 and a recall of 0.6185, suggesting the model is more reliable in its positive predictions than exhaustive in identifying all positive cases. The model's ability to discriminate between upward and downward movements is confirmed by a ROC AUC of 0.7406. The detailed performance metrics for both the validation and test sets are summarized in Table II.

B. In-Depth Diagnostic Analysis

To further understand the model's behavior, its performance diagnostics were analyzed, as shown in Fig. 2. The confusion matrix for the test set recorded 389 true negatives and 368 true positives, against 155 false positives and 227 false negatives. This reveals that the model is slightly more prone to missing a potential gain (a false negative) than to incorrectly predicting one (a false positive), a conservative characteristic that can be desirable in risk-averse strategies.

TABLE II. PERFORMANCE METRICS OF THE AIRS MODEL ON EUR/USD DIRECTION PREDICTION

Metric	Validation Set	Test Set
Accuracy	0.6831	0.6646
F1 Score	0.6727	0.6583
Precision	0.7040	0.7036
Recall	0.6441	0.6185
ROC AUC	0.7503	0.7406
MCC	0.3680	0.3343
Kappa	0.3667	0.3317
Sharpe Ratio	0.0766	0.1098

The diagnostic plots confirm the model's robustness. The ROC curve (AUC = 0.74) and the Precision-Recall curve (Average Precision = 0.76) both indicate strong class separation. The cumulative gain curve is particularly insightful, demonstrating that, by targeting the top 40% of the model's most confident predictions, an investor could capture approximately 70% of all actual positive market movements, highlighting the model's practical efficiency.

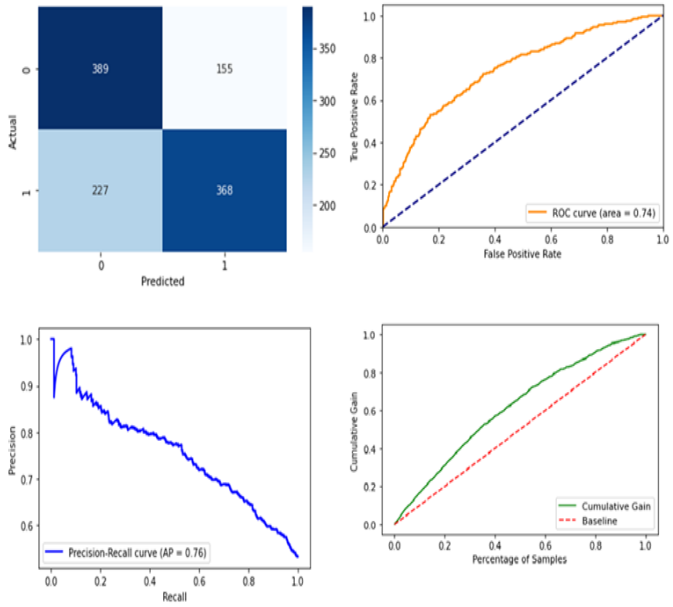

Fig. 2. Performance evaluation metrics of the AIRS model on the test set.

C. Comparative and Robustness Analysis

1) Benchmarking against standard models: To contextualize the performance of the AIRS model, it was benchmarked against three standard machine learning models: a Support Vector Machine (SVM), a Random Forest, and a Neural Network. As shown in Table III, the AIRS model demonstrated highly competitive and, in some metrics, superior performance.

While other models, particularly Random Forest, achieve a slightly higher F1-Score, the AIRS model demonstrates a superior ability to discriminate between classes, as evidenced by the highest ROC AUC score (0.74). This highlights its particular strength for this classification task.

TABLE III. PERFORMANCE COMPARISON OF DIFFERENT MODELS

Model	Accuracy	F1-Score	ROC AUC
AIRS	0.66	0.66	0.74
SVM	0.65	0.68	0.71
Random Forest	0.67	0.70	0.73
Neural Network	0.66	0.69	0.72

TABLE IV. AIRS PERFORMANCE ACROSS DIFFERENT MARKET PERIODS (PART 1)

Period	Accuracy	F1-Score	ROC AUC
Low Volatility	0.70	0.73	0.76
High Volatility	0.65	0.68	0.71

TABLE V. AIRS PERFORMANCE ACROSS DIFFERENT MARKET PERIODS (PART 2)

Period	Accuracy	F1-Score	ROC AUC
Trending Market	0.72	0.75	0.78
Ranging Market	0.64	0.67	0.70

2) Performance across market regimes: The model's robustness was tested across different market conditions. As detailed in Table IV and Table V, the model maintains strong predictive power in trending markets (F1-Score = 0.75) and remains effective in more unpredictable ranging markets (F1-Score = 0.67). Similarly, it performs better in low-volatility periods compared to high-volatility ones, which is an expected and logical outcome.

VI. DISCUSSION

A. Interpretation and Positioning within the Literature

An accuracy of 66.46% on the out-of-sample test set is both statistically and economically significant in a market often approaching a random walk. To properly contextualize this performance, it is essential to compare it to the broader literature, which reveals a clear and crucial dichotomy between statistical accuracy and practical utility. This comparison is detailed in Table VI.

On the one hand, several studies report exceptionally high statistical accuracies. Advanced models like AdaBoost of Bagging (as referenced in Table VI, Paper 1), SVM with a rolling window (Paper 4), and LSTM networks (Paper 5) have shown the ability to achieve accuracies well above 90%. On the surface, these results seem to overshadow the performance reported in this study.

However, critical research provides a more nuanced perspective. Khan et al. (Paper 2) powerfully demonstrate that a model with lower accuracy can be significantly more profitable, establishing that financial backtesting is a more critical standard for validation than raw accuracy. This finding directly challenges the practical relevance of the high-accuracy claims in Papers 1, 4, and 5. Furthermore, the complete failure of certain approaches, like the sentiment-based Stacking Regressor (Paper 3), which performed worse than a naive baseline, highlights the danger of relying on flawed methodologies or incomplete evaluation metrics.

TABLE VI. A COMPARATIVE BENCHMARK OF MACHINE LEARNING APPROACHES FOR STOCK MARKET FORECASTING

Paper	Model	Key Insights	Performance Metrics	Comparison with Literature
1	AdaBoost of Bagging [24]	Hierarchical ensembling (boosting over bagging) improves model robustness and reduces generalization error across multiple metrics.	91.45% (Mean Accuracy) 0.9728 (Mean AUC)	Strong statistical performance, but lacks financial backtesting. The model's practical utility remains unproven, a key limitation highlighted by Paper 2.
2	Random Forest [2]	Critiques the use of accuracy alone. Proves a lower-accuracy model can be more profitable. Establishes financial backtesting as a critical standard for practical validation.	+189.66% Cumulative Return	Sets the benchmark for practical evaluation. This study's financial results provide a critical lens through which the high-accuracy claims of Papers 1, 4, and 5 should be viewed.
3	Stacking Regressor [25]	Demonstrates that sentiment-only regression models are fundamentally flawed, performing worse than a naive baseline, despite having low relative error.	Negative R^2 (e.g., -61.593)	Serves as a critical failure case. The negative R^2 proves the model is unreliable, showing the danger of relying on error metrics like MAPE without a more rigorous metric.
4	Support Vector Machine (SVM) [5]	A rolling window training method dramatically enhances predictive accuracy and stability, but the model's practical profitability remains unproven.	92.48% (Average Accuracy)	High statistical accuracy, but lacks financial validation. As shown in Paper 2, a >90% accuracy does not guarantee profitability.
5	LSTM Network [1]	Validates the high effectiveness of LSTM deep learning models for trend forecasting, but focuses solely on statistical accuracy rather than financial performance.	>93% (for most stocks); up to 97.7%	High accuracy, but methodology is not compared to simpler models. Paper 4 achieved similar scores with a less complex SVM model. Presents a realistic and defensible performance.
6	Artificial Immune Recognition System (AIRS)	Robust predictive capabilities through adaptive learning and evolutionary optimization. Balances accuracy with other critical metrics (Precision, F1, AUC).	68.31% (Validation), 66.46% (Test)	Unlike studies with unproven >90% accuracy, AIRS's performance is comparable to validated, profitable models and avoids the fundamental failures seen in Paper 3.

In this complex landscape, the AIRS model's validated performance of approximately 66.5% is positioned as both realistic and scientifically defensible. It avoids the trap of unproven high-accuracy claims (Papers 1, 4, 5), it is grounded in a robust methodology that avoids the fundamental failures of flawed approaches (Paper 3), and its performance level is situated within a context where practical validation is prioritized over statistical perfection (Paper 2).

B. Practical Implications

The practical implications for traders and financial institutions are significant. The model can be integrated into algorithmic trading systems to generate buy/sell signals. Its ability to provide probabilistic-like insights (via affinity scores) can aid in risk management, and its efficiency, as shown by the cumulative gain curve (Fig. 2), makes it a valuable tool for focusing on high-probability trades.

C. Limitations and Future Directions

Despite its promising performance, this study has several limitations. The model's computational complexity could be a challenge for very high-frequency applications. Its performance is also highly dependent on the quality of the feature engineering and is sensitive to hyperparameter tuning.

Given that this study represents the first successful application of an optimized AIRS model to the foreign exchange market, future work should focus on validating and leveraging its potential in a real-world environment. A crucial next step would be to test its robustness and profitability under simulated or live trading conditions. Such practical validation is essential before considering more complex extensions, such as the integration of alternative data sources or the development of hybrid models that combine AIRS with other machine learning techniques.

VII. Conclusion

This study sought to answer a fundamental question: Can a bio-inspired algorithm like the Artificial Immune Recognition System (AIRS) effectively predict the directional movement of the EUR/USD market? Based on the findings of this research, the answer is a qualified and encouraging "yes".

Following a rigorous process of optimization and validation, the proposed AIRS model achieved an accuracy of 66.5% and a ROC AUC of 0.74 on the out-of-sample test set. While these metrics do not reach the >90% levels sometimes claimed in the literature, they are realistic, statistically significant, and, most importantly, were achieved using a transparent and scientifically defensible methodology. The model proved to be highly competitive against standard benchmarks such as SVM and Random Forest, demonstrating a particular strength in its ability to discriminate between classes.

This work represents an important first step, but it is not without limitations. The model is computationally intensive, and its success relies heavily on the quality of the engineered features. The next logical step in this line of research is to assess the model's profitability in a simulated or live trading environment, as strong statistical performance does not always guarantee positive financial returns.

Nonetheless, the results of this study strongly suggest that Artificial Immune Systems deserve greater attention within the financial forecasting toolbox. They offer a robust and adaptive approach that holds significant potential. It is hoped that this study will encourage further exploration of these powerful algorithms in the field of computational finance.

Acknowledgment

I would like to express my sincere gratitude to Dr. RAOUYANE Brahim, Dr EL MOUMEN Samira, and Dr BELLAFKIH Mostafa for their invaluable assistance and support throughout this work. Their guidance, encouragement, and contributions have played a significant role in the completion of this article.

***Abstract*—The rapid development of Information storage and sharing technologies brings new challenges in protecting against network security attacks. In this study, ensemble learning models are evaluated to enhance the performance of a network intrusion detection system (NIDS) with three phases through machine learning approaches. In the first phase, the unbalanced dataset is processed through four re-sampling techniques, such as SMOTE, RUS, RUS+ROS, and RUS+SMOTE, for balancing treatment. In the second phase, Random Forest feature selection is imposed for these four balanced datasets. Finally, three Ensemble Models named as EM1, EM2 and EM3 are designed using six basic classifiers and thus evaluated. In earlier studies, the first and second phases were evaluated through an SVM binary classifier for four feature subsets. The four feature subsets are obtained through Random Forest feature selection with the four different thresholds of Cumulative Feature Importance Scores (CFIS) (85%, 90%, 95% and 99%). With the observation of the evaluated results, three challenges were identified: i) The highest accuracy obtained through the re-sampling method required maximum computational time. ii) Different thresholds of CFIS exhibit instability in performance metrics as well as computational times, even though the number of features is less. iii) The adopted multi-class SVM classifier's efficiency to detect the attacks within minimum computational time and without compromising accuracy when compared to earlier works is yet to be ascertained. In this study, an attempt has been made to address these challenges with ensemble learning. Three ensemble models are chosen for the evaluation process conducted on the adopted CIIDS -2017 dataset. Finally, the comparative results are presented, and decisive discussions are carried out for implementing the prevention and mitigation algorithms by security professionals.**

I. INTRODUCTION

The rapid evolution of the cloud computing technology facilitates the infrastructure, network and applications through Internet in the present era. The widespread of cloud computing usage has reduced the management and maintenance costs of IT infrastructure. Cloud resources are managed by different organizations in the network using standards and methods [1]. This has driven its efficient business model and scalability, and at the same time has introduced challenges in network security. Due to its decentralized structure and centralized management, IT infrastructure is vulnerable to contemporary attacks [2].

The biggest obstacle to the success and use of cloud computing by an organization or individual is its security. The most common serious threats in cloud attacks are Distributed Denial of Service (DDoS), which causes excessive volume of traffic from multiple distributed systems, leading to denial of service to users. In DDoS attacks, unauthorized actions aim to temporarily or permanently disrupt the services of network members against counterattacks such as cloud services, thus encouraging the use of cloud computing [3]. The impacts of a successful DDoS attack are varied and can be severely damaging. Organizations may incur significant financial losses from service interruptions, as well as expenses related to incident response and system restoration efforts. Finally, DDoS attacks can cause customers to lose trust in certain products, affecting performance and brand reputation [4] [5].

To maintain the availability and reliability of network services, the research community and industry sectors dedicate significant efforts to developing Intrusion Detection Systems (IDS). Ongoing research by the Cloud Security Alliance (CSA) has identified DDoS attacks as some of the most prevalent threats to cloud security [6]. For example, prominent studies referenced in [7] [8] have concentrated on developing advanced strategies to counter these attacks effectively. Despite the widespread adoption of IDS, DDoS attacks are often avoided in many scenarios. With the growing volume of data constantly transmitted between networks, IDS has proven effective in detecting disruptions within large datasets [9].

Many researchers are working on this to provide a solution in identifying these types of attacks in network intrusion detection based on the available static datasets. Most of these datasets are skewed. Class imbalance in cloud security attacks can influence the performance of intrusion detection systems (IDSs). Since legitimate traffic samples are far beyond malicious, machine learning models are often affected by these groups, resulting in lower detection rates for several types of attacks. This flaw limits the ability of IDSs to detect

rare but important threats, thwarts attack plans, and compromises the security standards of the entire system. Not only in Intrusion detection, other areas like Natural Language Processing [10], [11], Image recognition [12], genetic engineering [13], [10], financial fraud detection [14], web mining to text categorization [15] also have been advocated imbalanced data classification. Therefore, addressing class imbalance is crucial to improve detection accuracy and strengthen defense mechanisms in cloud environments. The quality of the dataset is very significant in the classification method, and certain imbalance classes dominate the dataset.

Ensemble methods proven to be effective in increasing the efficacy of intrusion detection systems (IDS). These methods combine the strength of several machine learning models to achieve improved predictive performance and robustness compared to individual models. Combining various techniques improves the detection by aggregating multiple instances. It also reduces the Variance and biases associated with the limitations of a single integration, especially in high dimensions and skewed data [16] [17].

After going through the above research works, the three-phase ensemble models are designed and evaluated. The coordination methods, such as weighted voting, can mitigate this problem by evaluating the impact of a limited class, thereby reducing the negativity and improving the detection of less resilient types. In addition, to combine re-sampling methods, feature selection with traditional machine learning techniques may be generalize and effective.

The results in [18] demonstrate the performance of re-sampling methods for NIDS. RUS+SMOTE achieves the smallest computational time but delivers the lowest performance. SMOTE achieves the highest accuracy, precision, recall, and F-measure across all CFIS thresholds. In spite of its high accuracy of 99.26% and F-Measure of 91, the (RUS+ROS) is less efficient due to its time complexity of 4808 sec.

To enhance the performance of [18], the current study, which uses ensemble learning, aims to develop a stable and generalized model with low time complexity for real-time imbalanced datasets. The study has been carried out with the following key contributions:

- Study the different re-sampling methods for imbalance treatment to enhance the classification results.
- To develop and evaluate the ensemble classification models from base classifiers for improving the performance of minority class samples.
- To analyze the generalized three-phase ensemble models' behavior in mitigating the class imbalance and improving the AUC.
- Different ensemble models built by the same basic classifier set for comparative analysis.

The rest of the study is organized as follows: Section II provides a summary of the various research efforts in this field. A description of the methodology of the proposed ensemble models is presented in Section III. Section IV explains the analysis of the experimental results. Finally, Section V concludes the current study and discusses future perspectives.

II. Related Work

There have been various studies that have led to the development of automatic intrusion detection in network communication. Various Machine Learning and Deep Learning methods were used to generate the hybrid and ensemble models for dealing with unbalanced data to detect these types of attacks. Some of them are outlined below.

A survey conducted in [19] examined the various strategies for addressing imbalanced data when detecting network intrusions. The common strategies that can be applied to balance the instances and various approaches that can be used to mitigate the challenges of an imbalanced dataset, such as data level methods, algorithm level methods and fusion methods, were explored. The commonly used oversampling techniques in the literature, like SMOTE and ADASYN, were considered. The findings indicate that ADASYN generally outperforms SMOTE in terms of F1-score and recall, while SMOTE may be suitable for maintaining high accuracy.

The authors in [20] aimed to address the challenge of high false negative rates and improve the predictability of minority classes in NIDS for both binary and multiclass classification. There are three stages in the proposed strategy: fine-tuning the training and testing subset distributions, selecting features, and using class weights. The experiments were conducted using the well-established NSL KDD and UNSW-NB15 datasets for binary classification as well as multi-class classification. Multiple models were generated using an effective refinement strategy aimed at reducing False Negative Rates (FNR) and increasing minority class predictability. Based on the results, it was demonstrated that it is possible to achieve a satisfactory trade-off between FNR, accuracy, and minority detection with the proper parameters. While the model's performance on a limited dataset raises concerns related to generalization. This can be addressed in future by exploring the efficacy of the model on large datasets in enhancing the performance on minority attack detection.

Hongpo Zhang et al. proposed a two-stage intrusion detection model for IoT security [21]. Stage 1 employs LightGBM for efficient initial classification, while Stage 2 uses CNN for fine-grained anomaly detection. The model effectively addresses class imbalance and achieves high accuracy, F1-score, and MCC. It outperforms state-of-the-art methods in terms of efficiency and making it a promising solution for large-scale data. Future work will focus on improving feature selection and imbalance handling techniques.

The authors in [22] aimed to address the challenge of high false negative rates and improve the predictability of minority classes in NIDS. In their approach, the training and testing subset distributions are adjusted, features are selected, and class weights are used. Both binary and multi-class classification experiments were conducted with the NSL KDD and UNSW-NB15 datasets. Several models were developed using an effective refinement strategy to reduce False

Negative Rates (FNR) and increase minority class prediction accuracy. It was demonstrated by the results that proper parameters can be utilized to achieve an acceptable trade-off between FNR, accuracy, and minority detection.

The study conducted in [23] investigates the impact of class imbalance countermeasures on model interpretability for both AI users and experts. Despite their effectiveness in improving prediction performance, many countermeasures often compromise interpretability. Interpretability is only preserved by feature selection and cost-sensitive approaches, according to our experiments. Normally, re-sampling and most classification algorithms cannot be used in settings where gaining knowledge and being able to interpret it are essential. Several guidelines are provided for selecting interpretable countermeasures, and we highlight future research opportunities.

The BMCD algorithm has been proposed for large-scale multiclass intrusion detection datasets in [24]. With BMCD, minority class detection is improved by adapting SMOTE to multiclass situations. On a combined dataset from CICIDS2017, BMCD is found to improve intrusion detection performance over existing methods in addressing class imbalance and addressing class imbalance. With BMCD-balanced datasets, random forest classifiers, in particular, perform significantly better.

Pieter Barnard et al. proposed a two-staged pipeline framework in [25] for robust network intrusion detection. The first stage leverages a powerful machine learning model, namely XGBoost. To understand the model's decision-making process, we employ the SHAP framework to generate explanations of its predictions. The second stage utilizes these explanations to train an autoencoder. This autoencoder acts as an anomaly detector, specifically designed to identify unseen attacks not encountered during the initial training. The evaluation is carried out on the NSL-KDD dataset and demonstrates its effectiveness in accurately detecting new attacks. It is also compared to various state-of-the-art intrusion detection methods.

The effect of the class imbalance problem may lead to biased model performance. To address this, the authors Ngan Tran et al. have explored various techniques for handling the class imbalance in NIDS [26]. Among them, the downsampling + upsampling + SMOTE (DUS) was the most effective re-sampling technique based on the experimental results conducted on the NSL-KDD dataset. An Ensemble model combined with DUS outperformed other machine learning classifiers. The impact of the number of classes on model performance is also evaluated, and discovered that more imbalanced classes negatively affect accuracy. Finally, researchers highlighted the importance of addressing class imbalance in NIDS and provided insights into the effective techniques. By understanding the impact of class imbalance and employing appropriate strategies, researchers can improve the performance of NIDS models in real-world scenarios.

In [27], the authors introduced a novel DNN-based approach for detecting DoS/DDoS attacks, which utilizes three imbalanced datasets of NIDS: CICIDS2017, CSE-CICIDS2018, and CICDDoS2019. To mitigate class imbalance, a K-means based technique is employed to generate semi-balanced datasets. Feature selection is performed using Linear Discriminant Analysis, and four metaheuristic algorithms (AIS, FA, IWO, and CS) are integrated with DNN to enhance performance. Experimental results demonstrate the effectiveness of the proposed approach, particularly AIS-DNN, which achieves high accuracy (up to 99.99%) and outperforms existing methods.

According to [28], the quality of the dataset is very important to improve minority class attack detection in NIDS. In this study, a combined oversampling and undersampling technique is used, followed by training with deep learning models. The proposed approach significantly enhances the detection rate of minority classes, with the CNN model achieving 99.8% accuracy in binary classification and the MLP model achieving 99.9% accuracy in multi-class classification. These results offer a promising direction for improving NIDS and detecting minority class attacks.

The authors in [29] demonstrated a novel autoencoder-based anomaly detection method for IoT security. By effectively utilizing packet metadata and training on normal data, the method accurately detects anomalies in encrypted IoT traffic. It outperforms traditional methods, is versatile, and can handle various encryption protocols, making it a robust solution for IoT security. However, the authors have evaluated the performance on only one type of attack.

The Data Generative Model to detect anomalies in an imbalanced dataset was proposed in [30]. Also concentrated on certain types of attacks where those were underrepresented. To address this, the present study proposed a Data Generative Model (DGM) using Conditional Generative Adversarial Networks (CGAN) to increase the number of minority class samples in the CICIDS2017 dataset. The researcher concluded that their experiments demonstrated that the DGM effectively detected new attacks and significantly improved the weighted F1-score (99.12%) compared to existing methods.

Traditional intrusion detection systems often struggle to effectively identify rare but critical attacks due to class imbalance in network traffic [31]. This research introduces a novel framework, S2CGAN-IDS, to address this challenge. The framework categorizes network traffic into three imbalance levels: ample, scarce, and rare. To augment the dataset, it combines the Synthetic Minority Over-sampling Technique (SMOTE) and a novel Synthetically Controlled Generative Adversarial Network (SCGAN). SMOTE oversamples scarce class data, while SCGAN generates synthetic samples for the rare class. The augmented dataset is then fed into a simple Deep Neural Network (DNN) classifier, which effectively distinguishes between normal and anomalous traffic, including rare attacks.

The authors in [32] explained the importance of safeguarding the network to avoid malicious access. Recent advancements in deep learning have significantly improved NIDS performance. However, the inherent class imbalance in network traffic, where normal traffic significantly outweighs attack traffic, remains a significant challenge. To address this issue, this research proposes a hybrid approach that combines oversampling and under sampling techniques. Specifically,

Synthetic Minority Over-sampling Technique (SMOTE) is employed to increase the representation of minority classes, while Tomek Links is used to remove noisy samples. Additionally, two powerful deep learning models, Long Short-Term Memory (LSTM) and Convolutional Neural Network (CNN), are utilized to enhance the model's ability to capture intricate patterns in network traffic.

The imbalanced data in NIDS can pose significant challenges, which may lead to biased models that struggle to accurately classify minority classes. Intrusion Detection Systems (IDS) datasets often exhibit this imbalance, with common attacks like DDoS dominating the data. To address this issue, techniques like SMOTE and ADASYN can be used to create synthetic data for minority classes [34]. However, not all features within a dataset are equally important. Feature selection methods like Recursive Feature Elimination (RFE) can help to identify the most relevant features, improving model performance and reducing computational costs. Finally concluded that the Decision Trees consistently outperformed Random Forest and KNN in terms of intrusion detection.

III. Proposed Approach

This section explains the various steps involved in the methodology implementation of the proposed three-phase ensemble model, which is presented in Fig. 1. They are: i) data preparation and imbalance treatment, ii) Random Forest Feature selection and iii) Base classifiers evaluation and evaluating ensemble models. These phases are explained in detail below. The base classifiers are explained briefly in the next subsection.

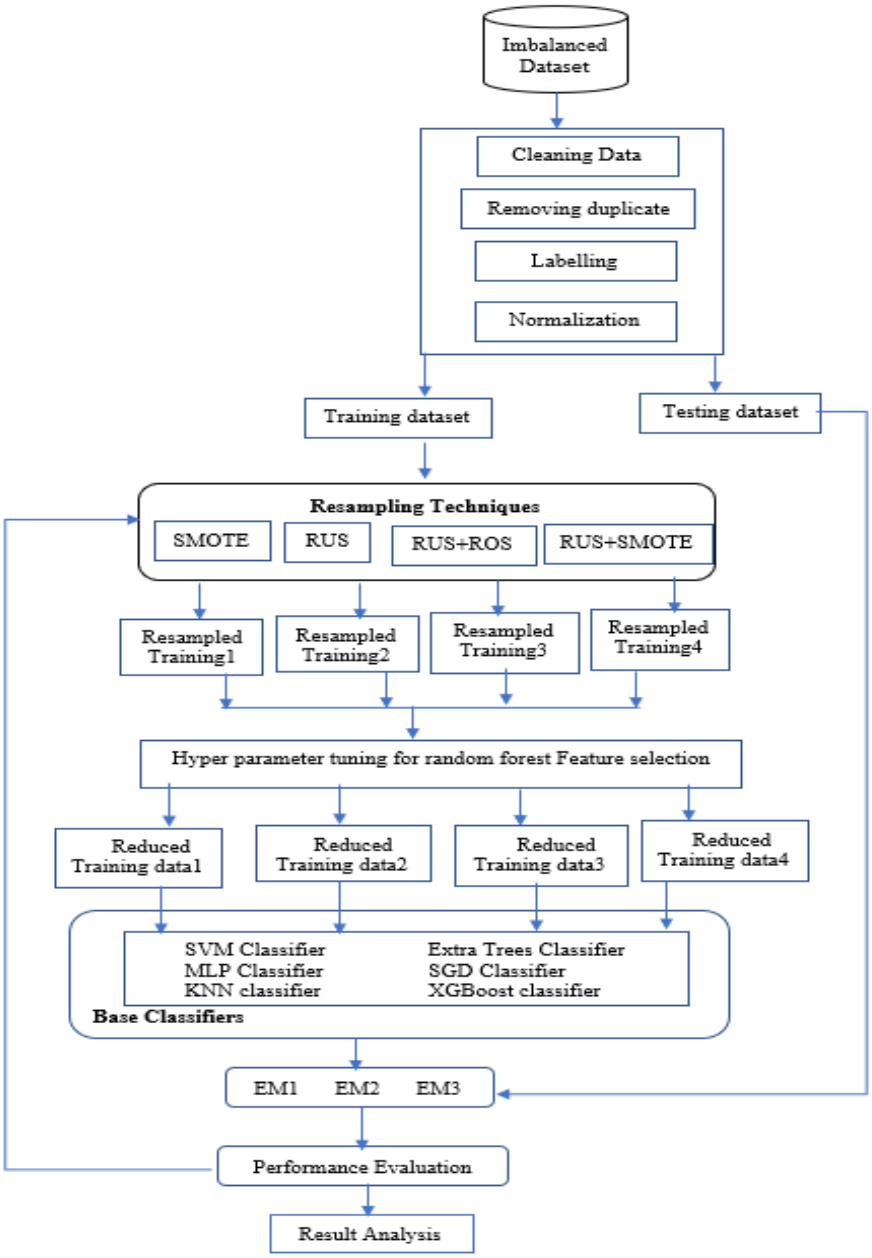

Fig. 1. Methodology of the three-phase ensemble model.

A. Base Classifiers

The construction of three ensemble models, EM1, EM2 and EM3, with the adoption of six base classifiers (BM).

1) Extra Tree classifier: The ET classifier excels in decision making by using the random splits threshold instead of the optimal split. In addition to speeding up the training process, this approach enhances the model's generalization capabilities, reducing overfitting. A key advantage of the Extra Trees Classifier is its ability to produce stable and accurate predictions by averaging outputs from multiple trees. These benefits, combined with its scalability and fast training time, make the Extra Trees Classifier a powerful and reliable tool in intrusion detection [35], and the graphical representation is shown in Fig. 2. It also still has the limitation that it overfits if the dataset contains too much noise.

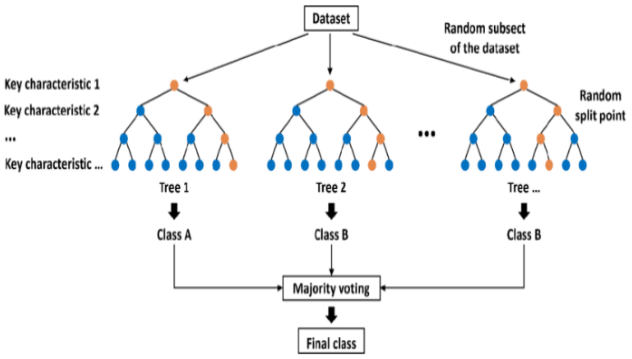

Fig. 2. Extra Tree Classifier.

By optimizing a loss function using gradient descent, it is known for its scalability and effectiveness [36].

2) Support Vector Machine (SVM): It is one of the popular classifiers in machine learning and is well known for its effectiveness in high-dimensional spaces as well as with non-linear decision boundaries. It excels in identifying the patterns among the data samples using various non-linear kernel functions by preventing the overfitting problem. Based on the assumption that all the above advantages will help to improve the performance of intrusion detection systems, the SVM has also been included in the investigation [37]. The following Fig. 3 shows the pictorial representation of the SVM classifier.

3) MLP classifier: It is a type of neural network and is capable of capturing complex, non-linear relationships in data. This makes it particularly valuable for detecting intricate patterns in the data, which are common in intrusion detection scenarios. The foundation of a neural network is a perceptron, which contains three layers of neurons, namely, the input layer, hidden layer and output layer. It uses backpropagation for improving the learning rate and decreasing the error rate [38]. The MLPs are flexible and can model intricate decision boundaries, providing additional power to the ensemble model.

4) KNN classifier: Because of its many benefits, the KNN classifier is often chosen for machine learning jobs. Its non-parametric nature enables it to handle datasets with irregular patterns efficiently, and its simplicity and ease of implementation make it perfect for learners. KNN is adaptable, works well for both regression and classification applications, and naturally manages multi-class issues. It doesn't need a training phase because it is a lazy learner, which makes it computationally efficient for creating models. It works well with tiny datasets and, by taking into account the local structure of the data, can manage non-linear decision limits. KNN also doesn't depend on presumptions about feature interactions and is resilient to outliers (if k is chosen correctly).

5) XG boost: With so many benefits, the XGBoost classifier is a popular and powerful machine learning technique. With features like tree pruning and parallel processing that condense computation times and improve scalability, it is incredibly effective and performance-optimized. XGBoost produces strong and trustworthy predictions even when dealing with big datasets and missing values. It is perfect for complex models since regularization techniques like L1 and L2 can reduce overfitting. It is appropriate for a variety of applications, such as recommendation systems, healthcare, and finance, due to its high performance, speed, and adaptability.

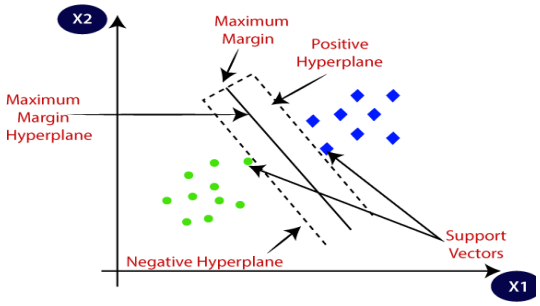

Fig. 3. Pictorial representation of an SVM classifier.

The main objective of selecting the above classifiers is to benefit from the diverse learning philosophy in building a robust generalized model towards improving the intrusion detection rate [33].

B. Phase 1

This subsection consists of two stages: Data preparation and Data imbalance treatment.

1) Data preparation: The preliminary stage of developing an Intrusion Detection System (IDS) includes gathering comprehensive data on network traffic that covers both benign and contemporary attacks. These types of attacks are resembled in the datasets CICIDS-2017. The complete data preparation steps, like data cleaning, eliminating duplicate rows and Label encoding, are carried out in line with [19]. A normalization step is performed to standardize feature magnitudes, enhancing the algorithm's robustness and ensuring no single feature dominates during learning.

2) Data imbalance treatment: Data imbalance in intrusion detection systems (IDS) is a critical issue that affects the system's ability to detect malicious activity effectively. Intrusion detection datasets often exhibit a significant imbalance, where normal (benign) activities vastly outnumber malicious (attack) events. Treating this imbalance is essential to improve the system's performance and reliability. The main advantages of balancing the dataset are enhancing model generalization, improving the detection rate and minority sample detection. To balance the class labels, the study utilizes four resampling methods, SMOTE, RUS, RUS+ROS and RUS+SMOTE, outlined by [34] and [18]. All four methods were applied to training data in parallel to generate respective balanced datasets.

C. Phase 2

In this phase, feature selection is carried out with the adoption of the Random Forest feature selection method as per the feature extraction process and hyperparameter tuning given in [18]. The purpose behind selecting different thresholds in the progressive approach is to conduct a systematic study of the balance between complexity, robustness and accuracy. The resulting datasets are fed as input to the feature selection phase to mitigate the overfitting problem and carried out based on CFIS score thresholds (85%, 90%, 95% and 99%) for extracting four feature subsets.

D. Phase 3

This classification phase consists of six base classifiers' evaluation, along with three ensemble models' evaluation.

1) Base classifiers evaluation: The results of the study [18] in terms of intrusion detection were promising, but there is still scope for optimizing the computational complexity as well as the performance to generate a stable model. The current study is conducted with the objective of addressing these aspects by building a generalized ensemble model. The four different datasets generated as output of feature selection phase are given as input to four base classifiers to generate each different ensemble model based on majority voting. The novelty of the present study generates an ensemble model with different datasets contrasting to the existing ensemble models, where all the base classifiers will be training with same dataset. Each time four classifiers are selected from the following base classifiers Extra Trees (ET), Stochastic Gradient Descent (SGD), Support Vector Machine (SVM), KNN, XGBoost and Multi-Layer Perceptron (MLP) to build the ensemble models.

2) Evaluation of EM1, EM2 and EM3: The EM1 model is constructed with Extra Tree, SGD, SVM, and XGBoost Classifiers. EM2 model created with KNN, SGD, SVM, and MLP Classifiers. The EM3 is built with Extra Tree, SGD, SVM, and MLP Classifiers. The strategic decision to select these six diverse base classifiers aimed at leveraging their complementary strength to generate more robust and accurate classifiers in classifying the network samples. The strengths or the advantages of these algorithms are discussed below. Voting is an ensemble learning technique that works better when the predictions are combined for a classification case. Much better performance is typically obtained by voting rather than using a single classifier [39].

Two kinds of voting are used in classification problems — hard voting [40] and soft voting [41]. Hard voting is to take the one with the most votes, while soft voting means averaging probabilities. The current study leveraged soft voting; its importance stems from its ability to improve prediction accuracy and robustness by leveraging the strengths of multiple models. The final prediction is based on the weighted average of these probabilities, leading to a more nuanced decision-making process. The output of the snippet for ensemble mode implementation is shown in Fig. 4. Finally, the pseudocode of the three-phase ensemble model is presented in Fig. 5.

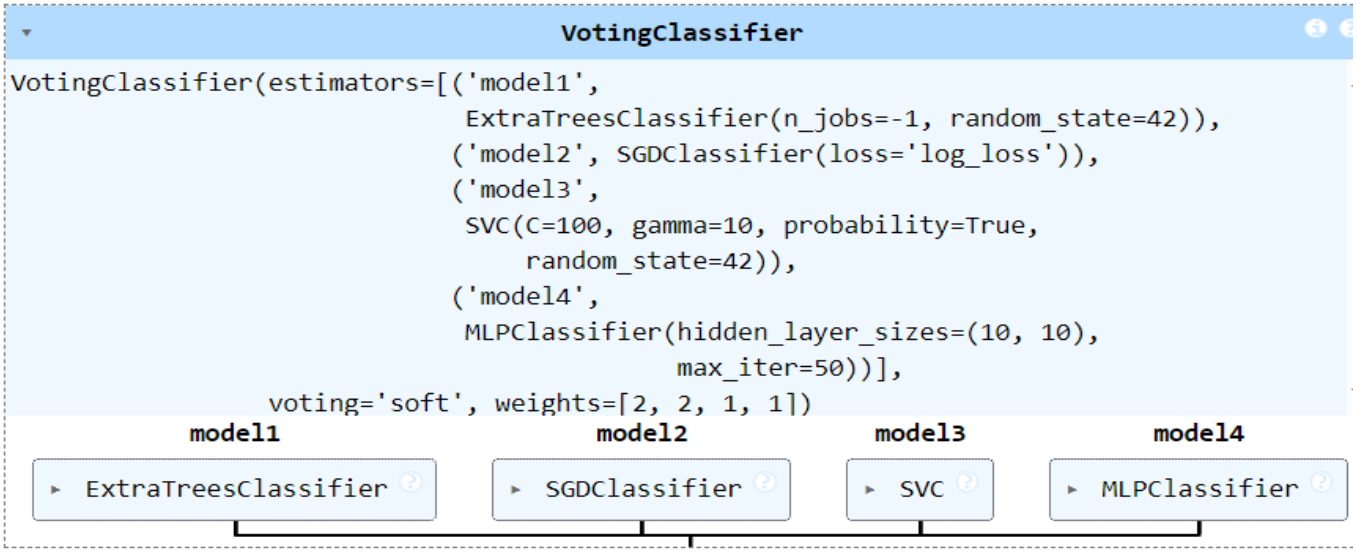

Fig. 4. Snippet of the ensemble classifier from python implementation.

```
Input: unbalanced dataset D={(x1,y1),(x2,y2),……..,(xn,yn)} when yi=[0,1,….k] and k= number of classes
Output: Ensemble Classifier
Cumulative Feature Importance Score: CFISthreshold=[85%,90% 95%,99%]

IV. Results and Discussion

In this section, the experimental results are analyzed, and the pros and cons of the proposed ensemble models based on the widely used classification metrics are given. The metrics are Accuracy, Precision, Recall, F-Measure and Time complexity. Besides that, another evaluation metric, AUC-ROC, is also chosen for measuring ensemble model classification performance. The EM1, EM2 and EM3 models' evaluation results are presented in Table I, Table II and Table III, respectively. They are obtained from experiments conducted on the CICIDS-2017 benchmark dataset after applying four types of imbalance treatments with random forest feature selection.

Based on these results, the ensemble model consistently achieves 99.88% accuracy across all thresholds (85%, 90%, 95%, 99%). A strong balance between robustness and quality is evident in the precision of 99.67%, recall of 99.58%, and F-Measure of 99.62 %. In terms of time complexity, this model has a low range of 299.572 to 362.86, making it very efficient. By combining these two classifiers, patterns in the data are captured effectively while remaining computationally efficient. As it exhibits high accuracy and reliability at all thresholds, it is an ideal choice for tasks that require precision and speed at the same time. The consistent performance across different thresholds suggests that the model is stable and does not overfit. In spite of its low time complexity, it is scalable for large datasets due to its low time complexity. Overall, this ensemble is a top-performing model and well-suited for real-time applications.

In comparison to the above scenario, this ensemble model delivers slightly lower accuracy, ranging from 99.4% to 99.51%. In this case, precision remained around 99.18%, but recall dropped to 93.52, resulting in a lower F-Measure of approximately 95.74 to 95.79%. The primary downside of this model is its high time complexity at the 90% threshold, which spikes to 2128.69, making it impractical for real-time applications. In contrast, as the threshold increases, the time complexity drops significantly, going from 2128.692 to 555.78 for higher thresholds. This model is uneconomical in comparison with the first scenario because it has a high computational cost for the lower thresholds, despite its reasonable accuracy and F-measure. Small datasets or non-real-time tasks are suitable for this ensemble when time complexity is less of an issue. Overall, the program demonstrates good prediction capabilities, but it doesn't perform well in terms of efficiency.

TABLE I. Effect of Various Performance Metrics for EM1 Model

CFIS	Accuracy (%)	Precision (%)	Recall (%)	F-Measure (%)	Time complexity(sec.)
85%	99.88	99.67	99.58	99.62	299.572
90%	99.88	99.67	99.58	99.62	313.63
95%	99.88	99.67	99.58	99.62	362.86
99%	99.88	9967	9958	99.62	321.58

TABLE II. EFFECT OF VARIOUS PERFORMANCE METRICS FOR EM2 MODEL

CFIS	Accuracy (%)	Precision (%)	Recall (%)	F-Measure (%)	Time complexity(sec.)
85%	99.51	99.18	93.51	95.79	571.62
90%	99.4	99.09	93.51	95.74	2128.692
95%	99.51	99.04	93.51	95.77	499.52
99%	99.43	99.14	93.51	95.77	555.78

TABLE III. EFFECT OF VARIOUS PERFORMANCE METRICS FOR EM3 MODEL

CFIS	Accuracy (%)	Precision (%)	Recall (%)	F-Measure (%)	Time complexity(sec.)
85%	99.6	99.6	99.6	99.6	363.77
90%	99.51	99.51	99.51	99.51	675.66
95%	99.6	99.6	99.6	99.6	388.81
99%	99.6	99.6	99.6	99.6	380.62

All the parameters of this ensemble remain at 99.6% accuracy, precision, recall, and F-Measure. Compared to the first ensemble, this ensemble has a slightly higher level of time complexity between 363.77 and 675.66, which is still manageable. Stability of the model is evident from its identical metrics across thresholds, which indicates strong generalization and robustness. The time complexity of its ensemble is higher than that of the Extra Tree ensemble, but it remains far more efficient than the KNN ensemble in terms of computational efficiency. The model is a great option for applications that require consistency and balance in performance. It is well-suited for tasks involving high-dimensional data or requiring consistent outcomes. Overall, the accuracy and computing efficiency of this ensemble are well balanced.

It can be observed that the three proposed ensemble models yield the same level of performance without any significant differences. This is true for all CFIS scores. For this reason, an 85% CFIS threshold is chosen to evaluate the AUC-ROC metric and then compared with the same CFIS threshold of results in [18]. The relevant confusion matrices are given below.

There are some noticeable improvements in terms of the classification of class 0 and class 2 instances in the second matrix compared to the first matrix, which is derived from the methodology of [18], where they were misclassified. This may result in a potential model with better separation of the model.

The following analysis is grounded on Fig. 6 and Fig. 7. The performance of the EM1 model on class-0 is exceptionally good, and the rate of misclassification is negligible with respect to the size of the actual class 0 compared to the model [18] performance, where there is a high misclassification. The ensemble model reduces the misclassification samples to 50% in the ensemble model for class-1. Accordingly, class-2, class-3 and class-4 performance is very effective with only 37,11 and 14 number of samples being misclassified, which is a negligible percentage compared to the actual number of samples 69037,1650 and 1739, respectively. Coming to class-5, which is the minor class among all, has classified 100% correctly, whereas it is not in line with the first matrix. Fig. 6 shows that there are significant misclassifications in classes 0 and 2.

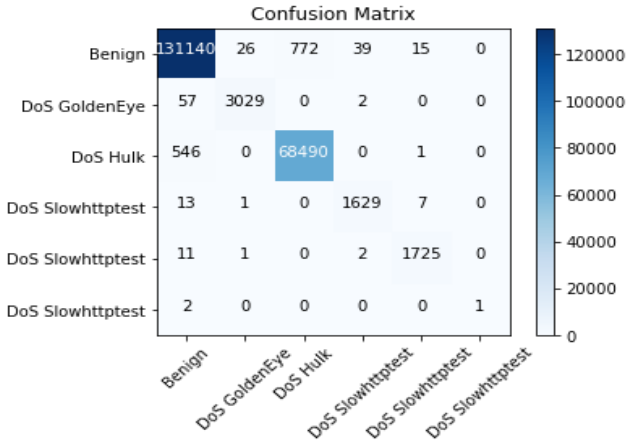

Fig. 6. Confusion Matrix of [18] with CFIS threshold of 85%,

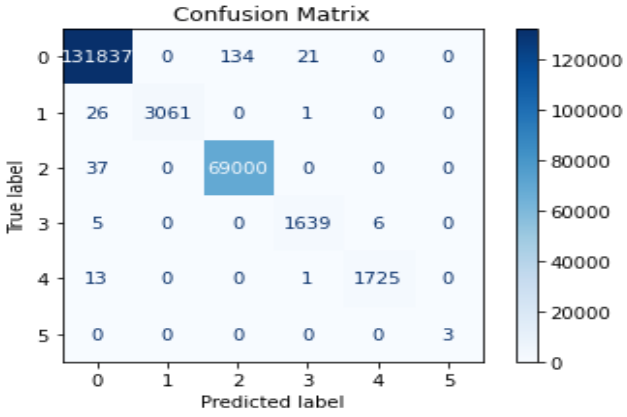

Fig. 7. Confusion matrix of EM1 with CFIS threshold of 85%.

Fig. 8 demonstrates a classifier's performance among six classes in a multi-class Receiver Operating Characteristic (ROC) curve plot. The True Positive Rate (TPR) is represented by the y-axis, and the False Positive Rate (FPR) by the x-axis. Every colored curve represents a distinct class; when all curves reach the upper-left corner, perfect categorization is indicated. Random prediction is represented

by the diagonal dashed line, but the model performs far better. Each class's Area Under the Curve (AUC) is 1.00, indicating perfect performance devoid of misclassifications. These findings point to a remarkable model, but they may also point to possible overfitting, especially if the dataset is tiny or not typical of real-world situations.

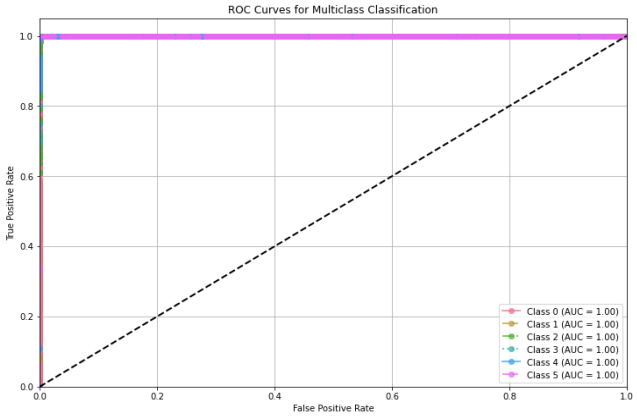

Fig. 8. ROC-AUC curve ensemble model in CICID-2017.

V. Conclusion and Future Scope

In this study, to improve and enhance the performance of NIDS, Ensemble learning is adopted. This technique is used to develop three Ensemble models that are designed in the proposed work. All these models have boosted the performance of the existing method. Each of the proposed Ensemble models has used four classifiers out of six base classifiers, whereas [18] has adopted an SVM binary classifier. It has shown better performance with respect to all the metrics for all chosen re-sampling methods with different CFIS scores. From the analysis of the results of the proposed work, one can observe that an 85% threshold feature subset with a minimum number of features is sufficient for detecting attack classification with minimum computational complexity and without any loss in accuracy. From this process of evaluation, the EM1 model was evaluated with a minimum computational time and gives a better trade-off between computational time and classification metrics. It has been proven that the four re-sampling methods with the EM1 model, along with Random Forest feature selection, outperform. Thus, it is a suggested model for attack detection in real-time, imbalanced traffic of NIDS. The limitation of this study is that the experiments were conducted on a training and testing split only, not executed using cross-validation.

To make the results much clearer, explainable models like SHAPE, LIME can be utilized. As a future scope of this study, statistically based feature selection methods may be chosen for the evolutionary process with different combinations of re-sampling methods or base classifiers. Further, this method can be applied to contemporary datasets for new type of attacks.

***Abstract*—Natural rubber is one of Indonesia's most important export commodities, making the country the second-largest exporter globally with a 28.65% share of the world market. However, recent production has declined, partly due to leaf fall disease caused by the *Pestalotiopsis sp.* fungus. This disease leads to premature leaf drop, which forces rubber trees to redirect energy from latex production to leaf regeneration, potentially reducing yields by up to 30%. Traditional detection methods that rely on manual visual inspection of leaf morphology are impractical over large plantation areas. To address this, the present study proposes a remote sensing-based detection approach using aerial drone imagery and unsupervised machine learning. Two feature extraction methods: Convolutional Autoencoder (CAE) and Gray Level Co-occurrence Matrix (GLCM) were used prior to clustering with k-means. Despite a small dataset, the GLCM-based approach significantly outperforms the CAE-based method. These results demonstrate that GLCM combined with clustering can reliably distinguish between healthy and diseased plantation areas. The proposed method offers a cost-effective, scalable, and non-invasive alternative to ground surveys, and has strong potential for real-world deployment in disease monitoring and early warning systems across large agricultural regions.**

***Keywords*—Convolutional autoencoder; gray level co-occurrence matrix; k-means clustering; rubber plant plantation; Pestalotiopsis sp**

I. Introduction

The rubber plant (*Hevea brasiliensis*) is a plant in the form of a tall tree and possesses a substantial stem that generates natural rubber. Natural rubber is one among the essential goods for Indonesia to export. From 2014 to 2019, the average export of natural rubber in Indonesia made up to 2.691.120 tons, and Indonesia dominates 28.65% world market share. This makes Indonesia the second biggest natural rubber exporter in the world after Thailand [1].

Recently, natural rubber production in Indonesia has been decreasing. One of the factors causing the decline is the emergence of new leaf fall disease caused by the fungus *Pestalotiopsis sp*. The leaf fall disease causes the rubber tree to drop its leaves prematurely, resulting food reserve of the rubber tree allocated into regrow fallen leaves [2]. It is estimated that the area of rubber plantations in Indonesia was around 3.692.352 hectares in 2021 [3]. The area of rubber plantation that is infected with *Pestalotiopsis sp.* is around 30.328,84 hectares, resulting in a decline of natural rubber production by up to 30% [4].

The disease can be detected through the morphology of the leaf. The visible symptoms on the leaves manifest as brown spots, which subsequently progress into dark brown areas, with a distinct demarcation separating these affected regions from the healthy leaf sections. The size of these spots gradually increases to reach dimensions of 1 to 2 centimeters, eventually leading to necrosis in the surrounding tissue [4].

The ratio of a plant's leaf area to its land surface area is called the leaf area index (LAI) [5]. Research by [6] claims that there is a vigorous negative connection amongst severeness of disease resulting in leaves falling and the leaf zone index. This implies that if the disease is more severe, the leaf area index will also diminish. As the leaf area index decreases, the leaf area is also decreasing, implying that the number of leaves in the tree is also decreasing. When the leaf loss reaches a certain point, the rubber plant will find it difficult to photosynthesis, hence the rubber tree will allocate its food reserves to grow new leaves, rather than using its food reserve to produce latex [6].

When photographed with an aerial drone, the difference between a healthy rubber plantation and an infected rubber plantation is visible. Healthy rubber plantation has dense and tightly closed canopy while infected rubber plantation has sparse and not tightly closed canopy [6]. This gives authors an idea to create a disease detection model using machine learning as an early detection to detect leaf fall disease in rubber plantations particularly caused by the fungus *Pestalotiopsis sp.*, using aerial photos of rubber plantations as the dataset.

Early detection of leaf fall disease offers substantial benefits for rubber farmers and plantation managers.

*Corresponding Author

Identifying affected areas at an early stage enables targeted intervention, such as localized fungicide application or canopy management, which can prevent the disease from spreading further. This minimizes crop loss, preserves yield potential, and reduces unnecessary operational costs associated with broad area treatments. Furthermore, by using aerial imagery and automated analysis, farmers can monitor large plantation areas more efficiently and frequently, improving response times and reducing dependence on labor-intensive ground inspections. Such scalable detection systems can ultimately support more resilient and sustainable rubber production.

Most previous studies on plant disease detection rely on labeled datasets and employ supervised classification methods to identify disease types, typically using close-up images of individual leaves. However, to the best of our knowledge, there is no prior research that utilizes aerial drone imagery to either classify or cluster plantations affected by leaf fall disease. Given that the dataset in this study is unlabeled and collected at the plantation scale using an aerial drone, an unsupervised clustering approach is adopted to detect and differentiate between healthy and infected rubber plantation areas.

Before clustering the infected plantations, the images will be inputted through the feature extraction method. The feature extraction method is used to obtain as much information as possible from the images and to diminish the image's size [7]. The information extracted by feature extraction will then be used as an input for the clustering method to cluster.

The feature extraction used in this research is a convolutional autoencoder (CAE) and gray level co-occurrence matrix (GLCM). Convolutional autoencoder uses a convolution layer and a pooling layer to extract temporal and spatial features from the image [8]. Meanwhile, GLCM uses a matrix, where all elements from the matrix are pairs of pixels that have a brightness level, distance d, and inclination angle θ [9]. These two approaches are applied to cut down the dimension of the picture and extract prominent characteristics from the images.

In this research, the authors use CAE and GLCM as feature extraction methods to cluster healthy rubber plantations and infected rubber plantations, particularly caused by the fungus *Pestalotiopsis sp.* K-means clustering will then be used as a clustering algorithm. Convolutional autoencoder and GLCM are used to reduce the dimension of images and extract prominent features. Then the extracted features will be clustered using k-means clustering, and finally, the result will be evaluated using the silhouette score and davies-bouldin index.

The major contributions of this study are as follows:

- A novel application of unsupervised clustering (k-means) to distinguish between healthy and diseased rubber plantations using aerial drone imagery, without requiring labeled data.
- Implementation and comparison of two feature extraction techniques: CAE and GLCM to identify prominent image characteristics for clustering.
- Empirical validation showing that the GLCM-based approach outperforms CAE in silhouette score and davies-bouldin index, highlighting its suitability for small-sample scenarios.
- A cost-effective, scalable detection framework for early disease identification that supports better decision-making and operational efficiency in large-scale rubber plantations.

This research is organized into five sections: Section I provides the background and motivation for the study. Section II reviews related works and previous research relevant to this topic. Section III describes the dataset, methodology, and models employed in the study. Section IV presents and discusses the results. Finally, Section V concludes the research and outlines potential directions for future work.

II. Related Work

This section outlines previous research related to the current study. A number of past investigations have focused on detecting plant disease using machine learning, and a summary of these studies is presented in TABLE I

[13]	SVM + GLCM + k-means	PlantVillage (8,350 images)	Precision = 99%
[14]	SVM + GLCM + LBP + k-means	500+ images (4 disease classes)	Accuracy = 97.2%
[15]	KNN + GLCM + k-means	Carrot leaves (undisclosed, est. ~400)	Accuracy = 95%
[16]	CAE + DenseNet121	PlantVillage (9,920 tomato images)	Accuracy = 98.35%
[17]	Deep KNN (optimized)	Multispectral crop leaf dataset	Accuracy = 89.12%

Khan et al. [10] implemented a MobileNetV3-small model on the PlantVillage dataset consisting of over 54,000 images, achieving an accuracy of 99.5%. Similarly, Jangid [11] utilized transfer learning with VGG16 on a rice leaf disease dataset and reported an accuracy of 90%. Abdu et al. [12] compared support vector machine (SVM) models to CNNs for classifying potato diseases, attaining 98.9% accuracy.

Several studies have integrated traditional feature extraction techniques with machine learning classifiers. Ahmed and Yadav [13] applied SVM in combination with GLCM and k-means clustering on the PlantVillage dataset and achieved 99% precision. Jamjoom et al. [14] enhanced this approach by incorporating local binary patterns (LBP), reaching 97.2% accuracy across four disease types. Similarly, Komala [15] employed a combination of k-means clustering,

GLCM, and KNN on carrot leaf images, with an accuracy of 95%.

Recent advancements have also explored the use of deep learning models for feature extraction. Kumar et al. [16] proposed a hybrid approach combining a convolutional autoencoder (CAE) with DenseNet121 for tomato disease classification, reporting an accuracy of 98.35%. In another approach, Gaikwad and Musande [17] utilized a meta-optimized deep KNN model on a multispectral crop dataset, yielding an accuracy of 89.12%.

Previous studies have shown high accuracy in plant disease detection using deep learning and supervised classification approaches. But the methods used are constrained by several limitations. First, most of the research relies on close-up images of individual leaves [10–16], which are impractical for monitoring large plantation areas. Second, these methods generally require large, annotated datasets for training, which are costly and time-consuming to obtain. Finally, many prior works focus on classification into predefined disease types, rather than unsupervised identification of disease-affected areas at the canopy or plantation scale. To address these shortcomings, the present study introduces an unsupervised clustering framework that operates directly on aerial drone imagery without the need for manual labeling. By comparing deep learning-based feature extraction (CAE) with handcrafted texture features (GLCM), we also investigate approaches that can perform robustly under small-sample constraints, making the method more practical for early disease detection in real-world plantation settings.

III. Data and Methodology

This section explains the data and methods used to explore the main topics of this study. Fig. 1 outlines the step-by-step process followed throughout the research.

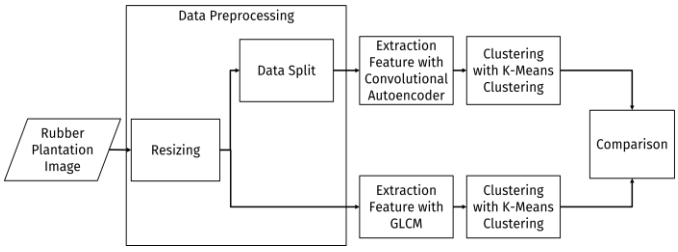

Fig. 1. The research flow of this study.

A. Dataset

The dataset utilized in this study comprises aerial photographs of rubber plantations, collected from the plantation site of PT. Pusat Penelitian Karet Nusantara Sembawa, located in South Sumatra, Indonesia. A total of 19 images were captured using a drone, with each image representing a different section of the plantation and different times, some are taken from 2020 and some are taken from 2021. As illustrated in Fig. 2, the dataset has variation in image perspectives, influenced by differences in drone altitude during image acquisition. Some images were taken from a relatively low altitude, offering a closer view of the canopy (the lower right side of Fig. 2), while others were captured from higher elevations, providing a broader overview of the plantation landscape.

Fig. 2. Sample images of the dataset.

B. Data Preprocessing

- Resizing Data: Resizing images during the data preprocessing stage is a critical step in preparing the dataset for deep learning models. This process involves adjusting the size of images to meet the requirements of the model, with benefits such as computational efficiency, reduced memory load, and ensuring consistency in input sizes for the model, and preventing overfitting. In this study, the image is resized into 20×20 for the input of GLCM and 64×64 for the input of CAE.
- Convert to greyscale: Before applying the Gray Level Co-occurrence Matrix (GLCM) method, the input image must be converted to greyscale. This is because GLCM is designed to analyze texture by evaluating the spatial relationship of pixel intensities, which are represented in a single channel. Color images contain three channels (Red, Green, and Blue), which would complicate the computation. By converting the image to greyscale, it reduces the data to one intensity channel, ensuring that GLCM can accurately process and extract texture features.
- Data Train and Test Split: The division of data into training and test sets is a key stage in the development of models. The training data, which comprises the majority of the dataset, is used to train the model and enable it to understand patterns and features within the data. Meanwhile, test data is employed to assess the model's ability against data it has not previously encountered. In this study, the data was divided into train, validation, and test sets with proportions of 70% and 30%, respectively.

C. Building Models

1) Autoencoder: An autoencoder is a specific type of Artificial Neural Network (ANN) designed to reconstruct its input. Typically, the network's hidden layers engage in

dimensionality reduction on the input, learning prominent features that facilitate effective reconstruction [18]. The main idea of the autoencoder is to have the same input size as the output size. Bottleneck layer is then introduced to make the model able to learn the representation of the data. Autoencoder is consist of four components, that is the bottleneck layer, the decoder network, the encoder network and the reconstruction loss [8].

The encoder network is part of the autoencoder that is used to encode input data into a representation of input data. The mathematical equation that represents each layer at the encoder is presented in Eq. (1):

$$X_{e_{i+1}} = f_{e_i}\left(W_{e_i}^T X_{e_i} + b_{e_i}\right) \forall i = 0,1,2,\ldots,N. \quad (1)$$

The mathematical notation used in the encoder network is X_{e_i}, $X_{e_{i+1}}$, W_{e_i}, b_{e_i}, $and\ f_{e_i}$, which are the input of i^{th} layer, the output of the i^{th} layer, the weight of the i^{th} layer, bias of the i^{th} layer, and the activation function of the i^{th} layer, respectively. The encoder network's final layer is called the bottleneck layer, and its output is a representation of the input data. As a component of the autoencoder, the decoder layer uses the bottleneck layer's output as input and attempts to remodel input data from its representation. The mathematical equation that represents each layer at the decoder is presented in Eq. (2):

$$X_{di+1} = f_{di}(W_{di}^T X_{di} + b_{di}) \forall i = 0,1,2,\ldots,N \quad (2)$$

The mathematical notation in the decoder network is $X_{d_i}, X_{d_{i+1}}, W_{d_i}, b_{d_i}$,and f_{d_i}, which are the input of i^{th} layer, the output of the i^{th} layer, the weight of the i^{th}layer, bias of the i^{th} layer, and the activation function of the i^{th} layer, respectively.

Reconstruction loss is the difference between the original data X^O and the remodelled data X^R. Autoencoder is trained to minimize reconstruction loss. There are two reconstruction losses commonly used, namely binary cross-entropy (BCE) and mean squared error (MSE). The mathematical equation for mean squared error is shown by Eq. (3). Variable D is the number of samples used.

$$MSE(X^O, X^R) = \frac{1}{D}\sum_{j=1}^{D}\left(X_j^O - X_j^R\right)^2 \quad (3)$$

A convolutional autoencoder operates based on the same principles as a traditional autoencoder, with the key distinction being the utilization of convolutional layers instead of dense layers [19]. Similar to the autoencoder, the CAE also consist of four parts: the encoder, the decoder, the bottleneck layer and the reconstruction loss. While the types layer used by CAE is similar to the convolutional neural network (CNN), it primarily uses a convolutional layer and a pooling layer in the encoder and a convolutional layer and an upsampling layer in the decoder. The type of layer used by CAE makes it more suitable for the image data. As shown in [20], the convolutional layer performance is better when handling the images compared to the fully connected layer due to the number of parameters used in the convolutional layer being less than fully connected layer, making the convolutional layer harder to overfitting and translational invariance. Layers used in the encoder network primarily aims to extract prominent characteristic, while the layers used in the decoder network primarily aims to reconstruct the compressed input image.

Convolutional autoencoders (CAEs) were selected in this study due to their strong capability for unsupervised feature extraction, especially in settings, where labeled data is scarce. Since CAEs are trained to reconstruct input images, they require no manual annotations, the image itself serves as the training signal. By using convolutional layers, CAEs are able to capture local spatial patterns such as edges, textures, and shapes at multiple scales, which are well-suited for analyzing structural variations in aerial plantation images.

The bottleneck layer compresses the input into a low-dimensional latent space, forcing the network to retain only the most essential information. This enables CAEs to act as powerful non-linear dimensionality reduction tools, outperforming traditional linear methods like PCA in capturing complex feature combinations with higher discriminative power [21].

Additionally, by eliminating redundant or noisy pixel information, CAEs help reduce the risk of overfitting, which is particularly advantageous when training on small datasets such as the 19 aerial images used in this research.

2) Gray level co-occurrence matrix: The texture of a gray image is elucidated through the examination of spatial correlation characteristics of gray levels using the gray level co-occurrence matrix [22]. GLCM analyzes textures in images based on grayscale intensity, distance, and angle between representations of two neighboring pixels [23]. Texture features play a crucial role in distinguishing regions within images. They pertain to visual patterns characterized by homogeneity, avoiding the production of a single color or intensity [22]. The gray intensity used in digital image data has a value range of 0 to 255 or a quantization level of 256. The quantization level is the number of possible values that an image will have. Some of the texture metrics that can be used are dissimilarity, contrast, homogeneity, energy, angular second moment (ASM), and correlation.

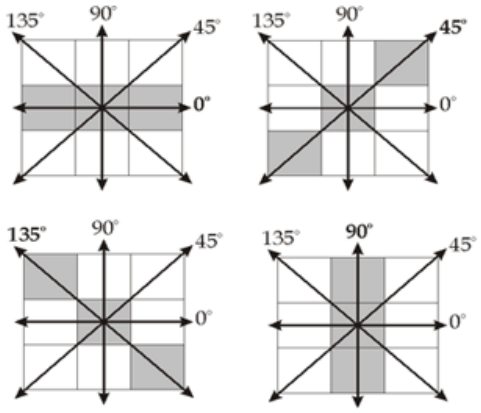

Fig. 3. Angle variation in GLCM.

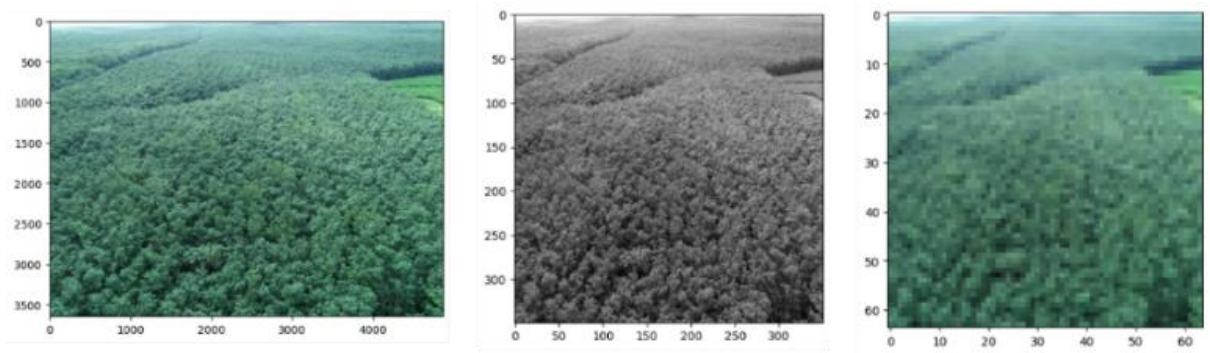

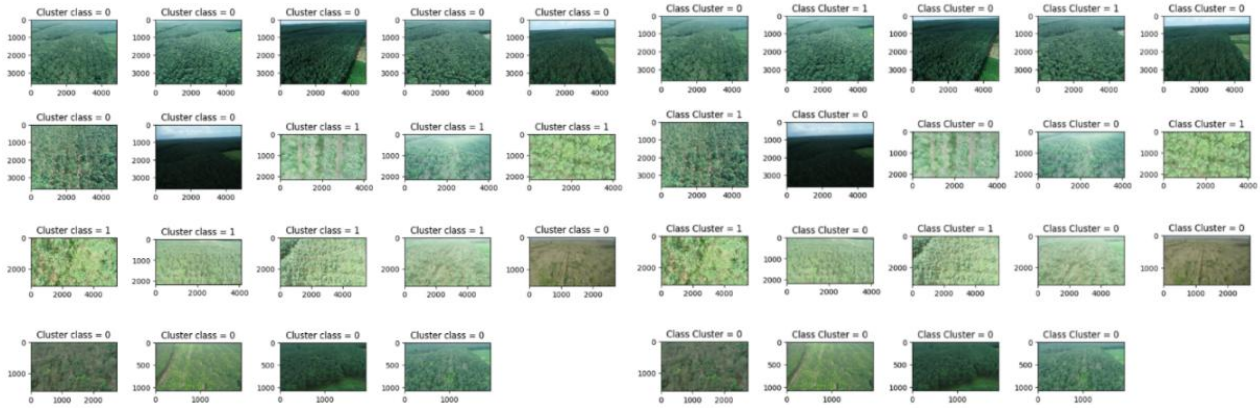

Fig. 4. Comparison between original image (left) and resized image (middle and right).

(a) (b)

Fig. 5. Clustering result for CAE combined with k-means clustering (a), Clustering results of GLCM combined with k-means clustering (b).

Contrast is the magnitude of the difference in color intensity at a pixel coordinate point (x, y) in the image with the surrounding pixels. Dissimilarity is a feature that states the size of the variation in pixel values in the image. Homogeneity is a feature that measures the distribution of each entry value in the GLCM matrix with its diagonal entries. ASM is a measurement of the similarity of a picture. A similar picture will only carry a few gray values; therefore, GLCM will have a slight variation in the value of $(i,)$, but each (i,j) will have a high value. Energy is the square root of ASM, which has a value range from 0 to 1, with 1 representing a constant image or an image whose entry value is the same for each pixel coordinate. Correlation is a measurement of how correlated a pixel coordinate value is with the surrounding pixels. In the GLCM method, there are about eight variations of angles that can be used, namely angles 0°, 45°, 90°, 135°, 180°, 225°, 270°, and 315°, as shown in Fig. 3.

The GLCM is a widely used texture-based feature extraction method that captures spatial relationships between pixels at defined directions and distances. It generates a set of statistical features—such as contrast, correlation, energy, and homogeneity—that quantify texture patterns within an image. These features are particularly effective for differentiating image regions based on their structural properties, making GLCM well-suited for classification and segmentation tasks. Moreover, GLCM is inherently color-independent, allowing it to work efficiently with grayscale images. This makes it a highly appropriate choice for analyzing drone-captured plantation imagery, where subtle variations in canopy texture caused by disease can be more informative than color. In agricultural applications, GLCM has been proven to reliably characterize vegetation patterns and support decision-making in crop monitoring.

3) K-means clustering: K-means clustering is among the clustering approaches in unsupervised learning. This method requires the user to determine the number of clusters, and then the dataset will be divided into clusters. The distance between each centroid point in each cluster and the data points is utilized by k-means clustering to sort out the data. The cluster whose centroid is closest to a given data point comprises the data points. In the k-means clustering method, each data point can only be grouped into one cluster or also known as hard clustering. The following is the algorithm of the k-means clustering according to [24].

(1) Determine the number of clusters (K).

(2) Selects K random points as the centroid (μ_k) per cluster.

(3) Label each data based on the nearest centroid point using the Euclidean distance using Eq. (4), where r_{nk} is the label of each x_n that belongs to cluster K.

$$r_{nk} = \begin{cases} 1, if\ k = \min\limits_{j} \left|\left|x_n - \mu_j\right|\right|^2 \\ 0, \ \text{else} \end{cases} \quad (4)$$

(4) Update the centroid point using Eq. (5) based on the cluster formed by Eq. (4).

$$\mu_k = \frac{\sum_{n=1}^{N}(r_{nk}x_n)}{\sum_{n=1}^{N} r_{nk}} \quad (5)$$

(5) Repeat Steps 3 and 4 until the convergence criteria are fulfilled.

D. Experimental Design

This research started by collecting the dataset, which is a rubber plantation image photographed using an aerial drone. The image was then resized into 20×20 and converted into grayscale as GLCM input, while the image resized into $64 \times 64 \times 3$ as CAE input. The dataset will be splitted into train and test dataset for feature extraction using CAE. The image will then be feature extracted with the respective model. Both outputs of the feature extraction model are then clustered using k-means clustering. The clustering result will be evaluated using the silhouette score and davies-boudin index.

The architecture of the convolutional autoencoder (CAE) in this study was designed with a focus on balancing feature richness and overfitting risk, especially given the small dataset (19 images). We used a series of convolutional layers followed by pooling layers in the encoder to progressively reduce spatial dimensions and capture hierarchical patterns in the image. A kernel size of 3×3 was selected to capture fine-grained texture details typical of leaf canopy variation. Pooling layers were used to reduce spatial dimensions while preserving the most salient features. The bottleneck layer was set to 8×8×8 to compress the image while still retaining enough structural information for effective reconstruction and clustering. The decoder mirrored the encoder using upsampling layers to reconstruct the image.

The selection of four principal angles in GLCM 0°, 45°, 90°, and 135°, was made to adequately capture texture orientation diversity across the image. These directions represent the primary spatial alignments typically found in natural and man-made textures, including horizontal, vertical, and diagonal structures. Using these four directions allows the model to extract comprehensive spatial patterns without significantly increasing computational complexity. The features derived from the GLCM—such as contrast, energy, homogeneity, and correlation—statistically represent image texture by quantifying pixel relationships within a local spatial context. These features offer strong descriptive and discriminative power, making them highly effective for a wide range of image analysis tasks, including classification, segmentation, and object detection. In the context of this study, these features help differentiate between dense (healthy) and sparse (infected) canopy textures in aerial plantation imagery.

In this research, the author used two different methods to extract features from photos of rubber plant fields, namely GLCM and a convolutional autoencoder. In the convolutional autoencoder, the data will initially be resized to a size of $64 \times 64 \times 3$. Then the data will be split into training and testing, by testing as much as 30% of the dataset. The CAE architecture used can be seen in Table II. The optimizer used is Adam with a loss function of mean squared error and 200 epochs. In GLCM, first, the data will be resized to a size of 20×20. Then the co-occurrence matrix will be formed. Next, feature extraction will be carried out on the co-occurrence matrix that has been created. After going through the feature extraction, the dataset will be clustered using k-means clustering. For the k-means clustering, the initialization method used is k-means++ to improve and faster convergence. Each experiment was run with 10 different centroid seeds with the maximum number of iterations for each experiment was set to 300. These settings are chosen based on experiment and shows consistent clustering performance and reduced sensitivity to initialization randomness. The results of clustering will be evaluated with a silhouette score and davies-bouldin index.

TABLE II ARCHITECTURE OF CAE

Layer	Layer type	Input shape	Size of kernel	Activation function	Padding	Output shape
1	Input layer	64 × 64 × 3	-	-	-	64 × 64 × 3
2	Convolutional layer	64 × 64 × 3	3 × 3	ReLU	Same	64 × 64 × 16
3	Average Pooling layer	64 × 64 × 16	2 × 2	-	-	32 × 32 × 16
4	Convolutional layer	32 × 32 × 16	3 × 3	ReLU	Same	32 × 32 × 8
5	Average Pooling layer	32 × 32 × 8	2 × 2	-	-	16 × 16 × 8
6	Convolutional layer	16 × 16 × 8	3 × 3	ReLU	Same	16 × 16 × 8
7	Average Pooling layer	16 × 16 × 8	2 × 2	-	-	16 × 16 × 8
8	Convolutional layer (Bottleneck layer)	8 × 8 × 8	3 × 3	ReLU	Same	8 × 8 × 8
9	Upsampling layer	8 × 8 × 8	2 × 2	-	-	16 × 16 × 8
10	Convolutional layer	16 × 16 × 8	3 × 3	ReLU	Same	16 × 16 × 8
11	Upsampling layer	16 × 16 × 8	2 × 2	-	-	32 × 32 × 8
12	Convolutional layer	32 × 32 × 8	3 × 3	ReLU	Same	32 × 32 × 8
13	Upsampling layer	32 × 32 × 8	2 × 2	-	-	64 × 64 × 8
14	Convolutional layer	64 × 64 × 8	3 × 3	ReLU	Same	64 × 64 × 3

IV. Experiments and Result

In this section, we will explain the results of our research and at the same time a comprehensive discussion is also given.

A. The Evaluation Parameters

Silhouette score is an approach applied to assess clustering. The assessment is done by finding the distance between data in one cluster and the distance with other data in different clusters [25]. The mathematical equation for the silhouette score is presented by Eq. (6):

$$S(i) = \frac{p(i)-q(i)}{max(p(i)q(i))} \quad (6)$$

The variable $p(i)$ means the average length of data accompanied by every other data in the similar cluster, while the variable $q(i)$ is the average length of data i with every other data in the nearest cluster, $S(i)$ is the silhouette score of i^{th} data. Silhouette score has a range of values from [-1,1]. A value near 1 denotes an excellent clustering because the data point is closer to its centroid means that each data can be grouped into a cluster that has the same characteristics. Value close to 0 indicates overlapping clusters or the distance between the clusters is not significant. Value close to -1 indicates very poor clustering because the data occupies the wrong cluster [26].

Another metric used to measure the clustering performance is the davies-bouldin Index [27]. Davies -bouldin index measures the average similarity between each cluster and its most similar ones. A lower davies-bouldin index indicates better clustering performance [see Eq. (7)]:

$$DBI = \frac{1}{k}\sum_{i=1}^{k} \max_{j\neq 1}\left(\frac{S_i+S_j}{M_{ij}}\right) \quad (7)$$

where, S_i is the average of intra-cluster distance in cluster i and M_{ij} is the centroid distance between cluster i and j.

B. Results

The outcome of the observations in this study will be discussed here. Fig. 4 displays a comparison of the original and resized images. The original image is shown on the left side, while the resized image is shown on the middle and right sides. The original image in the dataset has a varied shape. The GLCM will reduce the image into 20×20 and convert from an RGB image into a grayscale image, while the CAE will reduce the image into 64×64×3. The output feature extraction for 1 sample in GLCM is a 1D array with a shape of 24, while for CAE, the output size for 1 sample is 8×8×8, but k-means clustering is only able to take input with a shape of a 1D array; the output of CAE will be flattened to transform the output size into 1D array.

The clustering result from CAE combined with k-means clustering is shown in Fig. 5. Clustering result for CAE combined with k-means clustering. It can be seen from 19 samples, 7 of the samples are clustered as infected rubber plant plantation. The clustering results for GLCM combined with k-means clustering is also shown in Fig. 5. From 19 samples, 6 of the samples are clustered as infected rubber plant plantation.

The comparison of silhouette score between CAE and GLCM is also shown. The results of each model reveal that greater the silhouette score value, the better the cluster created by the model. This is because the clusters formed have low distances between data in the same cluster while have large distances between data in different clusters indicating that the clusters formed are well separated. This finding is also supported by the davies-bouldin index of GLCM, which is smaller compared to CAE, indicating better separation. From TABLE IIIresults of each model below, performance of GLCM combined with k-means clustering is better compared to CAE combined with k-means clustering. It means that GLCM combined with k-means clustering has better clustering performance which in this case is separating the healthy rubber plantation and infected rubber plantation.

TABLE III Models Performance

No.	Method	Silhouette Score	Davies-bouldin Index
1	CAE combined with k-means clustering	0.467	1.638
2	GLCM combined with k-means clustering	0.788	0.653

C. Discussion

The performance difference between the CAE and GLCM methods, reflected in silhouette scores of 0.467 and 0.788, respectively, can be attributed primarily to the limitations of the dataset and the characteristics of each method. Besides, the silhouette scores, clustering quality was further assessed by the davies-bouldin index. The CAE methods achieve 1.638, indicating moderate overlap between clusters and have poor performance on separation, while the GLCM has better performance with the davies-bouldin index of 0.653, indicating well-separated clusters. These findings, based on silhouette score and davies-bouldin index, show that the GLCM provides more discriminative representations resulting in more reliable clustering performance.

One major factor is the small sample size. This study only utilized 19 aerial images, which is far below the typical data requirements for deep neural networks like CAE. As explained by LeCun et al. [28], deep learning models rely on large datasets to learn meaningful representations; otherwise, they risk overfitting and poor generalization. In this case, the CAE likely failed to learn robust feature embeddings due to insufficient training data.

Moreover, the curse of dimensionality further exacerbated the CAE's performance. The output feature map of size 8×8×8 was flattened into a 1D vector of 512 features per image, resulting in a dataset of shape (19, 512). With far more features than samples, the model operated in a highly sparse input space, where distances between points become less meaningful, making clustering less effective [29].

In contrast, GLCM produces a smaller set of statistical texture features that are handcrafted and less sensitive to data volume. These features capture relevant spatial patterns in grayscale images without the need for extensive training. As a result, the GLCM-based clustering method was more robust

and better suited to the constraints of a small dataset. This performance gap illustrates the importance of aligning model complexity with data availability: simpler feature extraction techniques may outperform deep learning approaches in low-data scenarios.

This study acknowledges some limitations. The dataset used in this work consists of only 19 images collected from a single plantation, without ground-truth labels or cross-site validation. The clustering results, silhouette score, and davies-bouldin index may be influenced by dataset-specific characteristics rather than genuine disease discrimination. To address this, future research will focus on expanding the dataset to include more than one plantation site and diverse conditions. Ground-truth labels obtained through expert annotation will be incorporated to enable supervised validation.

V. Conclusion

Clustering with images of a rubber plantation as a dataset can be done with a machine learning approach. First, gather images of a rubber plant plantation. Second is to resize the image. Third, extract prominent features from the image using feature extraction. In this study, the feature extraction methods used are CAE and GLCM. Fourth, clustering the extracted image using k-means clustering. The last step is to evaluate the result using the silhouette score and davies-bouldin index. GLCM combined with k-means clustering have better performance compared to CAE combined with k-means clustering, meaning that GLCM combined with k-means clustering is able to separate the healthy rubber plantation and infected rubber plantation.

This study has several limitations. The most prominent being the small dataset size of only 19 aerial images. Such a limited sample restricts the generalizability of the results and poses challenges for deep learning models like the convolutional autoencoder (CAE), which typically require large datasets to learn robust, non-overfitted representations. The risk of overfitting in the CAE is especially high under these conditions, as the model may memorize noise or irrelevant patterns rather than general features of healthy or diseased plantation areas. Additionally, the dimensionality of the CAE's output (512 features) compared to the number of samples introduces sparsity that negatively affects clustering.

Future works should consider data expansion, such as collecting larger and more diverse aerial datasets across different seasons and regions to ensure generalization. Methodologically, hybrid approaches that combine handcrafted features (for example, from GLCM) and deep learning representations (for example, CNN or CAE) should be explored. Alternative approaches of clustering methods, such as Density-Based Spatial Clustering of Application with Noise (DBSCAN) or Gaussian Mixture Model, may better capture complex data patterns. Finally, integrate the proposed framework into a real-time disease monitoring pipeline.

Tamil Handwritten Character Recognition: A Comprehensive Review of Recent Innovations and Progress

Manoj K, Iyapparaja M
School of Computer Science, Engineering and Information Systems Vellore Institute of Technology, Vellore, Tamil Nadu, India 635810

***Abstract*—Recognizing handwritten characters is a complex task, particularly when dealing with Tamil, a writing system known for its intricate and stylized nature. Several challenges arise in recognizing Tamil handwritten characters, including the complexity of the writing style, similar character shapes, irregular handwriting, slanting characters, varying curves, inconsistent font sizes, and limited datasets. Additionally, the diversity of writing styles and the absence of a standard solution for accurately recognizing all Tamil characters further complicate the process. To address these issues, researchers have explored various techniques, including neural networks, support vector machines, clustering, and groupwise classification. However, Tamil handwritten character recognition remains an evolving field with ample opportunities for exploration and advancement. This review study aims to provide a thorough analysis of the current state of the field, identify key challenges, and highlight areas for improvement. Furthermore, it presents a detailed examination of the proposed techniques and suggests potential directions for future research in this domain.**

***Keywords*—Convolutional Neural Network (CNN); handwritten recognition; Tamil characters; offline recognition; feature extraction techniques; neural network architecture; Support Vector Machine (SVM); groupwise classification**

I. INTRODUCTION

Handwritten recognition is a crucial aspect of computer vision and has various practical applications such as reading handwritten documents, name recognition, postal address recognition and so on [1]. The process of recognizing Tamil handwritten characters has been a topic of interest in the field of computer vision and pattern recognition [2]. Due to the increasing trend of digitalization, there is an escalating need for precise and effective techniques that can identify handwritten characters and convert them into a digital text format [3]. Identifying Tamil characters, especially in handwritten form, is a difficult task as it involves various hurdles, such as slanted characters, similar-looking characters, connected characters, and curved shapes [4]. However, these techniques have their own limitations and may not provide optimal accuracy and efficiency. Multiple methods have been used to tackle the challenges in the recognition of handwritten characters, including groupwise classification, clustering, support vector machine (SVM), and the Component labeling method. However, these methods have limitations in terms of accuracy and efficiency [5].

Recently, Convolutional Neural Network (CNN) has emerged as a promising solution for handwritten recognition as it can effectively classify and recognize characters [6]. Unlike traditional feature extraction techniques, the system being proposed uses the pixel values obtained from the resized characters during the segmentation stage, which results in a less complex system [7]. In recent times, Artificial Neural Network (ANN) has been used for handwritten recognition. This approach has shown promising results in terms of accuracy and speed [8]. The process of ANN for handwritten recognition involves various stages such as segmentation, feature extraction, and classification. The pixel values obtained from the resized characters during the segmentation stage are utilized to train the neural network. The precision of the recognition system is dependent on the quantity of hidden layers and the number of neurons present in each layer [9]. Moreover, the proposed system is designed to recognize a minimal character set and has limitations in terms of different writing styles and font sizes [10]. However, the system can be further improved in the future by exploring the key challenges in this field, as shown in Fig. 1. The proposed system has the potential to find applications in handwritten name recognition, postal address recognition, and document reading. Through this, our aim is to make a contribution to the progress of research in the field of handwritten recognition and bring us a step closer to a standard solution for identifying Tamil characters with a satisfactory degree of accuracy.

This study is structured as follows: In Section I, an introduction is provided. Section II focuses on the motivation behind the study. Section III highlights the summarized literature review. Table I compares and contrasts different studies. Section IV discusses the challenges in handwritten Tamil character recognition. In Section V, the study concludes by summarizing the findings and outcomes of the study.

A. Tamil Handwriting Recognition

Tamil Handwriting recognition is a field of study that aims to develop algorithms and systems capable of recognizing the handwritten Tamil script [11]. With the increasing amount of digital data and the need for efficient data processing [12], the importance of recognizing and processing handwritten data has become increasingly important. The Tamil script is a complex script, with a large number of characters and variations in handwriting styles, making the recognition process challenging [13]. Numerous

algorithms and approaches have been developed over the years to tackle this challenge. These include traditional methods like clustering and groupwise classification, support vector machines (SVM), Component labeling methods, and Artificial Neural Networks (ANN). While these methods have provided some level of accuracy in recognizing Tamil handwriting, they have certain limitations, such as being time-consuming and complex [14]. The architecture for Tamil handwritten character recognition (HCR) typically involves several stages, including preprocessing, segmentation, feature extraction, and recognition. During the preprocessing stage, the input image is transformed into a form that is suitable for processing, such as converting it to grayscale or thresholding it [15]. The segmentation stage is used to separate individual characters from the background. Feature extraction techniques are employed to obtain significant features from the segmented characters that can be used to represent them. The recognition stage is where the extracted features are utilized to classify the characters and identify their identity [16]. In summary, Tamil Handwriting recognition remains a challenging and ongoing field of study, with ongoing research aimed at improving the accuracy and efficiency of recognition algorithms. With advanced techniques such as deep learning and CNNs, there is great potential for further improvements in this field, which has applications in various areas such as document reading, handwritten name recognition, and postal address recognition.

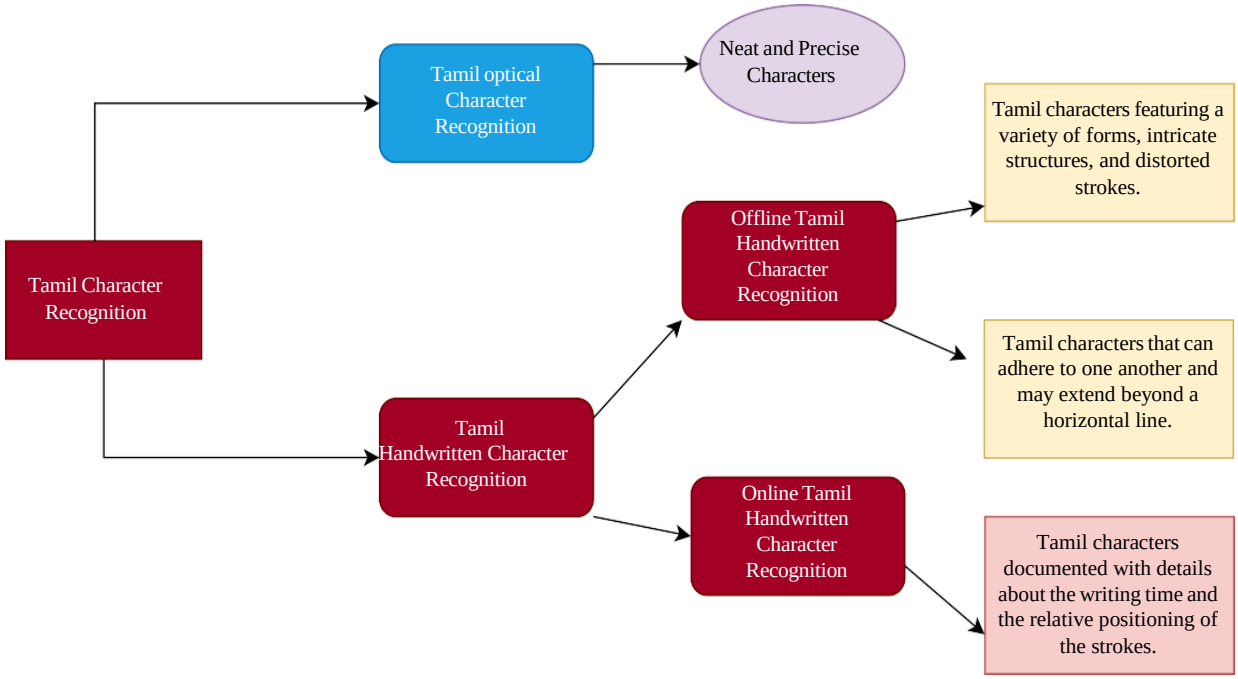

Fig. 1. Classification of Tamil character recognition.

TABLE I COMPARATIVE STUDY

S.No	Methodology	Achievement	Limitations	Ref No
I	Optimized (CNN)	The proposed CNN + SALA model achieves an accuracy of 0.84 at TD=50, outperforming RNN, LA, EHO-NN, and DCNN by 12.7%, 3.4%, 7.2%, and 11.2%, respectively.	The results reveal that although the proposed TCR system performs better than existing models in terms of accuracy, sensitivity, specificity, and precision, it still needs further improvements to achieve optimal recognition of Tamil characters.	[30]
II	MNM (NN+EHO)	Modified traditional neural network that utilizes Elephant Herding Optimization for optimizing weights for the identification of Tamil characters. The MNN method demonstrates an impressive recognition rate of 93%, surpassing the results achieved by other existing methods such as NN, SOM, SVM, FNN, RBF, and Quad tree.	Only Tamil character recognition. Limited comparison to existing classifiers. Evaluation based only on recognition rate.	[19]
III	ResNet (type of ANN with multiple layer skips and nonlinearities, including batch normalization)	Proposed system for Tamil character recognition has 96% accuracy, using a dataset of over 15,000 images of 128x128 dimensions.	Limited to recognition of only 128x128 images of Tamil characters [31]. Similar characters may cause recognition errors. Limited to Tamil character recognition only, cannot recognize words or sentences.	[32]
IV	Support Vector Machines (SVM)	The system has obtained 82.04% recognition accu-racy on handwritten Tamil characters.	Trained with only 35,441 characters from 106 distinct Tamil characters handwritten by 117 individuals. Recognition accuracy varies	[22]

			for different Tamil characters, ranging from 62.84% to 98.9%.	
V	A modified convolutional neural network (M-CNN)	The system achieved a high recognition accuracy of 97.07% for the recognized characters using the proposed method.	The work is limited to isolated characters and there is scope for future work on recognizing Tamil handwritten words and sentences.	[33]
VI	Java Neural Network	Achieved 100% recognition rate with 0.1 second recognition speed and 97% accuracy on the test set.	Only 25 users' handwriting was used for training, with 15 users for testing. Recognition is limited to handwritten Tamil characters from 25 selected users.	[34]
VII	Hidden Markov Models (HMM)	The system's performance for retrieving handwritten documents is 80.75%.	The system has been designed and tested for the Tamil language only. Effectiveness on documents with complex layouts and multiple font styles, as well as handling degraded or damaged images, is limited.	[35]
VIII	SVM + Modified Quadratic Discriminant Function (MQDF)	Evaluated on 36,172 data points, achieving an accuracy of 95.13%.	Limited sample size. Limited feature consideration. Limited script coverage. Limited error analysis. No real-world testing.	[36]
IX	SVM with Feature Selection Algorithms	Achieved 89% accuracy for testing samples.	Optimized for cursive characters, which may result in errors if the writing style varies significantly. Limited feature selection and statistical-based feature extraction algorithms.	[37]
X	SVM, ELM, and MLP Classifiers	The highest accuracy of 95.26% was achieved by the MVTI-SVM combination.	Comparison limited to 4 feature extraction methods. Structural features could enhance recognition accuracy, particularly for ambiguous character pairs.	[38]
XI	ADAM Optimizer	CNN + ADAM achieved 92% accuracy, CNN + Lion Optimization achieved 86%, RMSProp achieved 89%, and AdaGrad achieved 88%.	Processing time is high with the ADAM Optimizer.	[39]
XII	Convolutional Neural Networks	The best neural network architecture for character recognition had two hidden layers of 100 neurons each, with 90.19% accuracy.	Does not cover different writing styles and font sizes. Limited character set. Neural network architecture may not suit other writing styles.	[40]
XIII	Convolutional Neural Networks	A proposed system uses a CNN to recognize 70 Tamil characters with 93% accuracy, outperforming methods like Clustering, SVM, Component labeling, and ANN.	The dataset is limited to 200-250 samples per character from the hp-labs-Tamil-dataset. Only online datasets with specified class labels are supported. Recognizes a limited number of characters.	[41]

II. Motivation

The motivation behind researching handwritten character recognition in Tamil lies in the growing need for fast and accurate recognition of handwritten characters in various domains such as healthcare, transportation, finance, and education. Despite being a complex task, the application of handwritten character recognition in these domains can bring about significant improvements and streamline processes. The challenge arises from the intricate variations in writing styles and individual differences among writers, making traditional recognition methods inadequate. To overcome these difficulties, researchers have been exploring the use of various algorithms for handwritten character recognition. The parallel architecture and fault-tolerance have demonstrated promising results in addressing the intricacies involved in character recognition. The primary objective of this research study is to provide a comprehensive overview of the current state-of-the-art techniques and methodologies used in the domain of Tamil handwritten character recognition. Additionally, this study seeks to identify areas for future research and contribute to the development of advanced and dependable systems for recognizing handwritten characters in Tamil.

III. Summarized Literature Review

Kavitha et al. [17] presents a study on recognizing offline handwritten Tamil characters through the use of Convolutional Neural Networks (CNNs). The study aims to establish a standard for offline Handwritten Tamil Character Recognition (HTCR) by leveraging deep learning techniques. The researchers utilized an isolated handwritten Tamil character dataset that was developed by HP Labs India and trained the model from scratch, achieving good recognition results with a training accuracy of 95.16%. The Tamil Language has a unique feature of having a syllable for every sound pronounced, making the word economy of characters minimal. The Tamil script comprises a total of 307 characters, but the complete Tamil character set can be represented by only 156 distinct characters. This study is significant because it establishes the standard for HTCR for all 156 classes through the application of deep learning methods, unlike previous studies, which used a limited number of classes or used grouping methods.

The field of optical character recognition (OCR) has gained momentum in recent years due to the growing need to convert scanned images into machine-readable formats. The OCR process finds applications in various fields, such as intelligent scanning machines, language translators, and text-to-speech converters. The development of a Tamil character recognition (TCR) system is one of the challenging tasks in OCR, primarily due to the unique problems that the Tamil language poses to the developers. The existing TCR systems face challenges such as variations in the size and style of

handwriting, orientation angle, and font size [18].

To overcome these challenges, Kowsalya et al. [19] proposed an efficient Tamil character recognition system that involves four primary processes: preprocessing, segmentation, feature extraction, and recognition. The preprocessing process includes Gaussian filtering, binarization, and skew detection. The segmentation process involves line and character segmentation. The extracted features are then used for recognition, which is carried out using an optimal artificial neural network. To optimize the weights of the neural network, the researchers used the Elephant Herding Optimization algorithm. The performance of the proposed method was evaluated using sensitivity, accuracy metrics, and specificity. The proposed method is implemented in MATLAB and has shown promising results in the analysis. Previous research has focused on developing efficient TCR systems, and significant progress has indeed been made in the field of Tamil character recognition over the years. However, there are still challenges related to existing character recognition methods, such as the loss of information and change in shape after binarization. The proposed method aims to address these challenges by incorporating effective preprocessing and a modified neural network. The proposed method has the potential to serve as a solution for the development of an accurate Tamil character recognition system. The objective of the paper by Harini et al. [20] is to digitize old handwritten Tamil scripts through the use of Optical Character Recognition (OCR) technology. Tamil is a classical language of India with a rich literary tradition spanning over four thousand years, with much of its literature still undigitized. The OCR system in this study uses four main modules: Scanning, Preprocessing, Recognition, Feature Extraction, and Image Segmentation. The input is a scanned image of handwritten Tamil scripts, which undergoes processes like binarization, noise removal, skew correction, segmentation, and feature extraction to produce a digital output. This module compares the input sample to the trained dataset and generates a digital version of the handwritten input as output.

Raj et al. [21] review pertains to a study on a Tamil handwritten character recognition system. The primary goal of this study is to extract and identify distinct features of different Tamil characters that exhibit variations in their shapes and styles. Three methods of feature extraction were experimented with: shape, location-based instances, and shape ordering. The proposed system consists of four phases: pre-feature extraction, feature extraction, Z-ordering, and classification. The feature extraction phase involves strip tree, Z-ordering, and PM- Quad tree algorithms. The strip tree algorithm deals with shape features, the Z-ordering algorithm is used to address the problem of structure ordering, while the PM-Quad tree is used to facilitate efficient searching and retrieval of characters. The classification phase uses a hierarchical support vector machine to predict characters based on a divide-and-conquer procedure. The researchers collected data for the experiment from the HP-India Handwritten Tamil Character Dataset and individuals of different age groups. They utilized a total of 10,000 characters, with 6,000 characters being used for training and 4,000 characters for testing purposes. The experiment was implemented in MATLAB, and the results show that SVM performed better than other classifiers. The study concludes that the proposed system can recognize a larger number of characters and their varied shapes.

Shanthi et al. [22] aim to recognize offline handwritten Tamil characters using a support vector machine (SVM). The study uses handwritten characters collected from various writers on A4-sized documents, scanned at 300 dpi resolution and stored as grayscale images. Pre-processing is done on the digitized images to improve quality, and pixel densities are computed for 64 different zones to form character features used for SVM training. The system achieves an 82.04% recognition accuracy on the handwritten Tamil character database.

Sornam et al. [23] focused on introducing a new approach to recognize offline handwritten Tamil characters, which is challenging due to their complexity and variability in writing style among different users. Their method involves a combination of principal component analysis (PCA) and a convolutional neural network (CNN) for feature extraction and recognition of Tamil characters, as shown in Fig. 2, resulting in a more accurate recognition system. Deep learning, a state-of-the-art technique in machine learning [24], was used to reduce the burden on the programmer and to extract reliable features for complex problems such as object recognition and handwritten character recognition. The dataset utilized for the research was gathered from diverse writers located in Bangalore and Salem, India. It included both offline and online versions of Tamil characters. The model was trained for 50 epochs and achieved a convergence of approximately 88% in the 27th epoch. The training accuracy increased over the 50 epochs, and the performance measures were promising. The study presented a Tamil character recognition system that showed good performance. The system has the potential to be further extended for recognizing slogans in images with the use of a GPU.

The article by Jose et al. [25] discusses a wavelet transform-based feature extraction technique for recognizing Tamil handwritten characters. The classification process in the algorithm is carried out using a feed-forward back propagation neural network, while feature extraction is done through two-dimensional discrete wavelet transformations. The article highlights the challenges in recognizing Tamil characters, including the large number of characters and complex handwriting styles, and notes that preprocessing, segmentation, feature extraction, and classification are the major steps involved in character recognition. The proposed system has achieved a maximum recognition rate of 89% after preprocessing, wavelet decomposition, and BPNN classification.

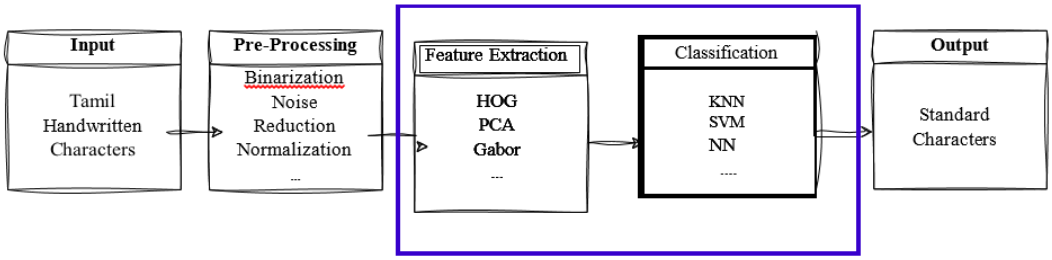

Fig. 2. Traditional offline HTCR process and typical methods for each step.

Wahi et al. [26] concentrate on creating an Optical Character Recognition (OCR) system to recognize handwritten Tamil characters. The study highlights the use of Zernike moments and Legendre polynomials for feature extraction of handwritten Tamil characters and a feed-forward backpropagation neural classifier for character classification. The proposed system consists of three modules: preprocessing, classification and feature extraction. The preprocessing module involves the conversion of color images to binary images through binarization techniques such as thresholding and Otsu's method. The feature extraction module includes the computation of various character properties such as height, width, horizontal lines, vertical lines, slope lines, circles, and arcs. The research concludes that there is a lack of studies on recognizing handwritten characters of Indian scripts, and a complete recognition system is not yet available in India due to the extensive character set of Indian languages, the presence of vowel modifiers and compound characters. The study focuses on the recognition of handwritten South Indian languages, namely Tamil.

Shaffi et al. [27] presents the development of an extensive Tamil Handwritten Character Database (uTHCD) for research in document image analysis. The database consists of 91000 samples in 156 character classes with around 600 samples in each class, collected from 650 volunteers, including school children, teachers, homemakers, faculty and university students. The samples were collected both offline and online and encompass a wide range of writing styles and inherent distortions. The authors anticipate that the database will establish a new standard in research on Tamil handwritten character recognition and provide a starting point for other projects in document image analysis. The study also outlines an experiment conducted on the database using a Convolutional Neural Network (CNN) architecture, which achieved an initial accuracy of 88% on the test data. The existing Tamil Handwritten Character Database, developed by HP Labs India, contains 156 distinct character classes with a varying number of samples in each class. Ad-hoc databases have also been created by various researchers, but the sample size is limited and varies greatly between different works. The uTHCD was created through a sample collection process starting with volunteers writing characters in a 10x8 grid on an A4 sized paper or an electronic form using a digital writing pad. Preprocessing was done to remove unnecessary information and to enhance the quality of the samples. The authors aim to make the database publicly available in raw image and HDF compressed format for easy implementation.

Rajasekar et al. [28] focus on the development of a computer-based handwritten character recognition (HCR) system for Tamil characters. The historical background and development of optical character recognition (OCR) and HCR systems in general are discussed. The article provides an overview of prior handwritten character recognition (HCR) methods and techniques, including those that employ moment-based feature extraction and coding schemes based on neighborhood relations. Data reduction is performed using the fuzzy c-means clustering algorithm, and recognition is carried out using Artificial Neural Networks (ANN). The proposed system in the paper involves three modules: preprocessing, segmentation, and recognition. The preprocessing module includes image filtering and binarization, as well as skew correction. The segmentation module decomposes the image into individual characters. The recognition phase involves the use of correlation and neural network methods. The objective of this study is to create a MATLAB program using the image processing toolbox to develop an OCR system for Tamil alphanumeric and text.

This literature review by Suganthe et al. [29] focuses on the development of a handwritten text recognition (HTR) model for the Tamil language. The study highlights the importance of feature extraction in HTR models and explains how Convolutional Neural Networks (CNNs) can be used for automatic feature extraction. The literature review outlines the steps involved in digitizing handwritten text recognition, including the development of a CNN model, hyper-parameter tuning, character segmentation, and recognition of text by feeding individual characters to the tuned model. The Tamil language is considered as a classical language and has a rich history, with a unique writing system that includes 247 characters, with 156 distinct characters capable of depicting the entire Tamil character set. However, handwritten text recognition for Tamil characters is a challenging task due to various distortions, variations in character length, wide range of handwriting styles, fragmented strokes, and noise. The preprocessing steps involved in the HTR model for Tamil characters include grayscale conversion, binary conversion, foreground character extraction, morphological transformation, line segmentation, and character segmentation. The hp-labs- tamil-iso-character dataset was used in this study and the architecture of the CNN model is discussed in detail, including the use of convolutional and pooling layers. The study concludes with a discussion of the experimental results and future scope of the research.

The proposed literature review by Kishan et al. [42] focuses on the field of Handwritten Character Recognition

(HCR) using Convolutional Neural Networks (CNN). Handwritten character recognition (HCR) is an active and challenging area of research in image processing and pattern recognition, with applications in reading bank cheques and recognizing characters from form applications. The proposed work extends the EMNIST dataset by adding characters from the Tamil language, and trains the CNN using this extended dataset. The feature extraction process includes converting the input image to a grayscale image, normalizing the pixel values, and transforming the input data into a set of features through dimensionality reduction. The Min-Max-Scaler is used to normalize the data, and the CNN is used as a classifier. The system includes preprocessing, feature extraction, Min-Max-Scaler, image normalization, and classification in its architecture. The preprocessing step involves converting the input image to a grayscale image and resizing it to match the resolution of the EMNIST dataset. The process of feature extraction involves transforming the input data into a smaller set of features that can effectively represent the input data. The Min-Max-Scaler normalizes the data to a range between 0 and 1, and the trained CNN is used to recognize the characters and provide the desired output.

Thilagavathi et al. [43] focus on the proposed system for the conversion of handwritten South Indian language characters, specifically Tamil, into digital characters. The learning methodology of the system involves the use of Artificial Neural Networks (ANNs) with the Stochastic Gradient Learning Algorithm and Back-Propagation. Previous implementations of similar systems have shown accuracy rates over 90%. The system architecture includes pre-processing modules for image to pixel conversion, a network trainer, and a character predictor. The dataset used for the system design and implementation is from a worldwide competition on handwritten character recognition. The study also highlights the importance of character recognition in various industries, including banking and subjective answer evaluation, as well as the challenges posed by the Tamil language with its wide use of symbols.

Livingston et al. [44] have developed a handwritten Tamil character recognition system that uses a combination of Hidden Markov Model (HMM) and Fuzzy Logic. The system aims to convert handwritten Tamil characters into Unicode and is a challenging task due to the great variation among handprints. Among the different branches of character recognition, Tamil character recognition is more complicated due to multiple patterns to represent a single character and disconnected multi-stroke characters. The authors propose a framework for handwritten Tamil character recognition using a combination of Hidden Markov Model and Fuzzy Logic. The framework consists of three stages: preprocessing, feature extraction using Hidden Markov Model, and classification using Fuzzy Logic. The Fuzzy technique is used to differentiate between Tamil scripts. The system was tested on 750 samples of Tamil characters and achieved a success rate of 89 to 93%. The authors note that there has been significant research in the field of handwriting recognition, including the use of neural networks and hidden Markov models. While the most popular class of nonlinear vector operators in handwritten recognition is based on order statistics, the authors propose a different approach.

Gayathri et al. [45] conducted research on the recognition of cursive characters in Tamil palm leaf manuscripts using the Convolutional Neural Network (CNN) technique. The authors used a text line slicing segmentation scheme to segment the palm leaf characters, and morphological operations were used for preprocessing to eliminate noise in the input image. The feature processing included text line spacing, spacing without obstacles, and spacing with obstacles. The proposed network achieved 94% accuracy, while the existing ResNet achieved 88% accuracy. The proposed methodology is divided into four steps: i) collection of cursive Tamil palm leaf manuscripts, ii) preprocessing, iii) feature extraction, and iv) classification using CNN. The results and discussion section of the study shows that the proposed CNN model outperforms the current models in terms of accuracy.

The literature review by Suriya et al. [46] focuses on the application of Computational Linguistics and Convolutional Neural Network in the recognition of Tamil characters. The study presents an Intellectual Character Recognition System which uses CNN to recognize the Tamil character dataset and achieved a training accuracy of 99.16%. The challenges in handwritten character recognition are also discussed, including the variations in writing style, difficulties in recognizing similar characters, etc. The study proposed a Character Recognition system using a Convolutional Neural Network and used a dataset developed by HP Labs India, which consists of 156 unique Tamil characters written by native Tamil writers. The study highlights the use of Data Augmentation to improve the variety of data available for training models and overcome the issue of limited data size. The literature review concludes that the proposed system has significant potential in the field of handwritten character recognition, as it is capable of recognizing characters in challenging conditions where traditional character recognition systems fail. The comparative study highlights various methodologies for Tamil handwritten character recognition, with CNN- based approaches achieving the highest accuracy, such as 97.07% using Modified CNNs and 96% with ResNet. Hybrid methods combining CNNs with optimization techniques, like Elephant Herding Optimization, also demonstrated strong performance, achieving up to 93% accuracy. Traditional methods like SVM and HMM showed moderate success, with accuracies ranging from 80.75% to 95.13%, but are limited by smaller datasets and simpler feature extraction techniques. Despite advancements, most methods are restricted to isolated character recognition and rely on small, constrained datasets, limiting generalizability as shown in Table I. The bar chart in Fig. 3 underscores the superior accuracy of CNN-based models, indicating the need for future work on recognizing entire words or sentences and handling diverse datasets.

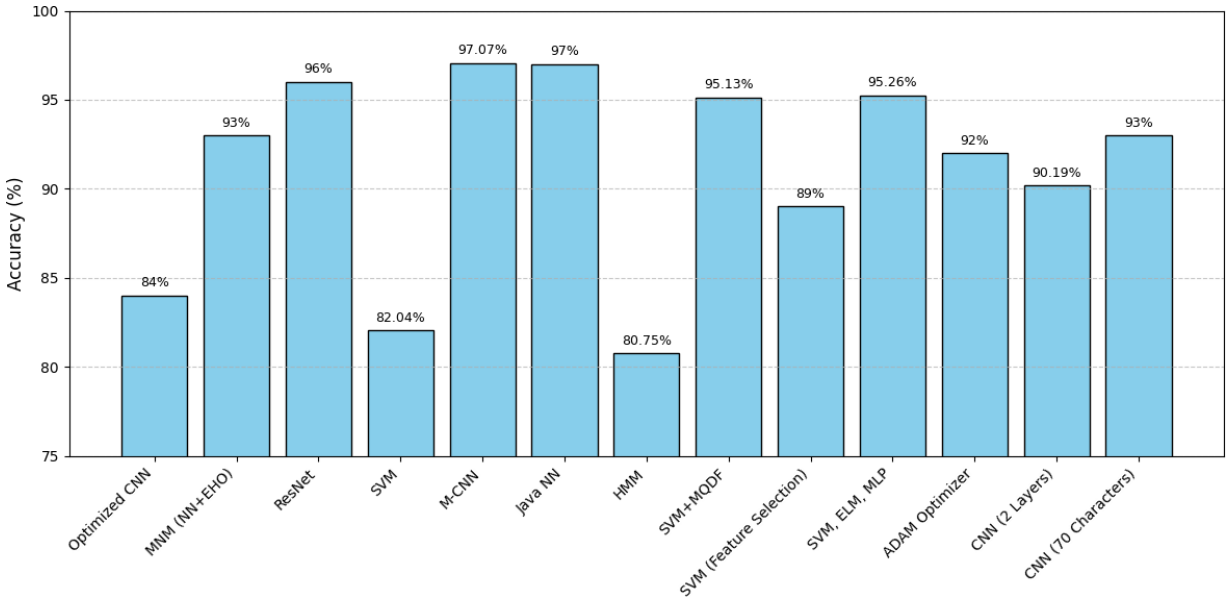

Fig. 3. Comparison of accuracy across methods for Tamil HCR.

IV. Challenges in HCR Tamil

The Tamil writing style can be complex, including variations such as normal and abnormal writing, slanted characters, similar-shaped characters, curves, joined characters, and more, which makes it difficult to accurately recognize the characters [47]. There are many Tamil characters that have similar shapes, which can lead to confusion during recognition [48]. Handwritten characters can be written in an abnormal style, making it challenging to accurately recognize them with standard recognition algorithms [49]. The slanting of characters can also affect recognition, as it can change the character's shape and make it look different from the standard form [50]. Tamil characters can contain curves, which can also pose a challenge for accurate recognition [51]. Different people write in different font sizes, and this variation can pose a challenge for accurate recognition [52]. Feature extraction is often used in recognition processes, but this method can be complex and time-consuming [53]. There is a lack of large datasets for Tamil handwritten character recognition, which limits the development of effective recognition algorithms [54]. People write in different styles, and it can be difficult to accurately recognize characters. In Fig. 4, the Tamil characters have been written in a different style than the one used to train the recognition system [55]. Despite numerous studies and efforts in the field of Tamil handwritten character recognition, there is still a lack of a universally accepted and efficient solution for accurately identifying all Tamil characters [56]. To overcome these challenges, researchers have proposed various approaches including the use of neural networks, support vector machines, clustering, and groupwise classification. The field is still evolving and there is room for further improvement.

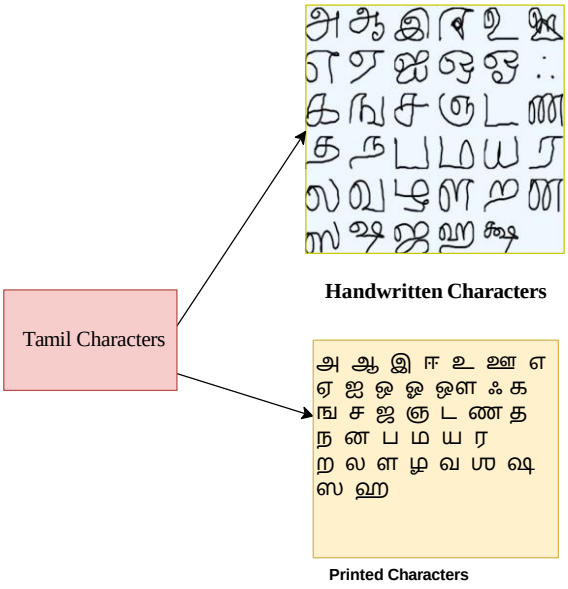

Fig. 4. Comparison of optical vs. handwritten.

V. Conclusion

In conclusion, the research on handwritten character recognition (HCR) in Tamil has made significant strides in recent years. A multitude of algorithms and techniques have been proposed and implemented to tackle the challenges of recognizing handwritten characters in the Tamil script. From the reviewed studies, it can be deduced that Convolutional Neural Networks (CNNs) have emerged as a prominent solution for HCR in Tamil due to their high accuracy and ability to effectively capture the inherent features of handwritten characters. However, there is still room for improvement and further research in this field to enhance the performance and efficiency of HCR systems for Tamil script. This includes the optimization of feature extraction techniques, the development of more robust neural network architectures, and the integration of other advanced machine

learning algorithms. In light of these developments, it is clear that the field of HCR for Tamil script holds immense potential for innovation and advancement, and will continue to play a crucial role in various domains and applications

***Abstract*—The rapid progress of deepfake technology, fueled by generative adversarial networks (GANs), has increased the challenge of verifying the authenticity of digital media. This study suggests a more powerful deepfake detection framework based on the EfficientNet convolutional neural network family, coupled with an unsharp masking preprocessing method to highlight manipulation artifacts. Based on a big, diverse dataset of over 5000 video samples, the model was trained and tested on several variants of EfficientNets (B0–B4). The results indicate that the integration of unsharp masking significantly improves the model's ability to detect minor irregularities in facial regions, with its best validation accuracy at 97.77% with EfficientNetB4. The method strikes a balance between computational cost and detection accuracy, rendering it applicable to real-world use cases, such as forensic examination and digital content authentication. The stability of the framework across different datasets and manipulation methods highlights its value as a scalable solution for curbing disinformation and protecting media integrity.**

***Keywords*—Deepfake detection; efficientnet; unsharp masking; convolutional neural networks (CNNs); facial manipulation detection; computer vision; artificial intelligence**

I. Introduction

Deepfakes are photos or videos that have been changed using sophisticated techniques derived from computer vision and deep learning, commonly used to confuse people. In this case, the above methods involve combining, mixing, displaying or exchanging facial attributes to produce artificially authentic albeit synthetic photographs and videos [1].

The act of falsifying data is now widespread in our digital world due to AI and machine learning advancements. The rise in the number of fake images and videos on social media platforms has made reality distortion a significant issue too. Deepfakes are becoming increasingly sophisticated, making it difficult to distinguish them from real content for human beings and harder to catch up with [2].

Deepfake technology is one of the most impactful innovations of manipulating images, audio, or videos, which has made the distinction between real and fake almost incomprehensible. Deepfake videos have gained notoriety primarily because they lead to the deception and manipulation of the audience. These videos utilize AI algorithms to substitute, or overlay faces in the visual footage. The sphere of influence that deep fake videos possess is divergent and multifaceted, and poses significant risks to the media landscape. Such threats range from the distribution of false information to tarnishing a person's reputation or instigating violence. With deepfakes being more common now these days, the need for finding ways to detect and prevent them is becoming more and more crucial [3].

Deepfake is a combination of the two words "Deep learning" and "Fake", and this technology falls on the ends of modifying the video content alongside the Deep Learning (DL) algorithms [4][5]. With the use of deepfake technology, the production of videos and images in an artificial manner has become incredibly easy due to the use of learning networks such as DNNs. One method that can be used to manipulate a video is using a Generative Adversarial Network (GAN) [6], and with it, a single person's image or video can be inserted into another person's content by replacing it with their image and video.

The accomplishment of replacing target faces while maintaining the original voice from the source during the video generation is termed face swapping. This swapping is done on GAN's [7] targets. Zooming in on merging, StyleGAN2 [8] and StyleGAN [9] deepens the layering, which helps to further conceal the images, making it harder for humans to tell the difference between the two images. Initial research [1] [10] indicated that deepfakes were quite discernible, but swift technological development has now made them almost impossible to distinguish from authentic content. The generation of indecent videos using the faces of politicians and celebrities is what has sparked the carrying out of fake news. While this was once an issue raised in society, it is now becoming rampant and easier to get away with, because of the distortion of trust. The shattered trust gives rise to several key social problems, such as the change of public opinion or the spine spreading of fake news [11].

Facial video manipulation technology has evolved to that point in recent years, where humans cannot tell if the video has been manipulated or not [12]. It became a great challenge, especially with deep-fake videos. The deepfake algorithms can manipulate a video in real-time by pasting one person's face onto another or changing the lip movements and facial expressions to make them appear to say anything. Techniques like FaceSwap, Face2Face, NeuralTextures, Deepfakes, and

*Corresponding Author.

face reenactment can create completely new videos that feature the target.

Bad visual quality, unnatural contextual surroundings, or an explicit declaration of being artificial identify some videos as deepfakes. However, several other factors make them very realistic, where the distinguishing factor from actual videos cannot easily be told [13]. Therefore, the detection of a deepfake video has been framed as a binary classification problem, where each image or video is labeled as "real" or "fake".

Numerous techniques have been proposed for deepfake detection; however, they often prove ineffective when applied to real-world videos. External factors such as lighting conditions, compression, scaling, and positional changes further complicate the detection process, making it exceptionally challenging even for advanced deep learning algorithms [11].

Until the year 2006, only convolutional networks and related techniques could be well trained [14]. For the first time, this breakthrough happened in 2006 with the publication of DBN. As mentioned, for the first time in that same year, the term "deep learning" was used by [15].

Neural networks have evolved a lot since then, as the very first ones. Though they may appear advanced and almost futuristic, transforming the notion of a neural network into an actual model that can solve some problem often takes quite a while. It includes data collection, very often with labeling, data preprocessing, and algorithm development. Once the algorithm has been developed, training needs to take place, which is not always easy and may require several runs for optimal performance. Furthermore, a network performing well on a training dataset may not generalize well to unseen data, which is another challenge altogether [16].

A CNN is a particular type of neural network in machine learning applied to medical image analysis. CNNs are designed to process data arrays, like images. The architecture of the CNN consists of three major parts: the input, which is the image in this case, feature extraction, and a nonlinear activation unit. In this context, the kernel can be visualized as a small 2-D matrix that helps to establish relationships between the central pixel and its surrounding pixels, enabling the network to capture spatial patterns effectively [17].

In this work, we present a novel approach to deepfake detection that builds upon and enhances Aaron Chong's implementation [18]. We use an EfficientNet-based model (B0, B1, B2, B3, and B4) and introduce a number of enhancements, including a new sharpening step and utilization of a large, heterogeneous dataset. Our contributions are threefold:

1) Image sharpening step: We introduce an unsharp masking technique to the preprocessing stage, which will serve to improve the detectability of subtle artifacts in manipulated facial regions. The technique, using Gaussian blur and adding the original image, improves high-frequency information, improving artifact detection in deepfakes.

2) Large dataset: We train over a highly diverse and enormous pool of deepfake datasets like DeepFake-TIMIT, FaceForensics++, Google Deep Fake Detection (DFD), Celeb-DF, and Facebook Deepfake Detection Challenge (DFDC) comprising over 134,000 videos. The diversity helps our model to generalize nicely to other kinds of manipulations.

3) Efficient model design: Our network is rooted in the EfficientNet (B0, B1, B2, B3, and B4) models and further optimized through the addition of additional layers for global max pooling and dense fully connected layers. This final design has high accuracy and efficiency for binary classification tasks in predicting the authenticity of videos.

4) Research problem: Recent deepfake detection models are not generalizable across datasets and methods of manipulation. They remain very sensitive to variations in compression, illumination, and facial orientations. This makes them not easily deployable in the real world, where attack vectors keep changing with more sophisticated generation methods.

5) Research objectives: This research aims to address these challenges by:

a) Introducing an unsharp masking preprocessing operation to enhance weak manipulation artifacts in facial regions.

b) Training EfficientNet architectures (B0–B4) on a large and diverse dataset to improve robustness to various manipulations.

c) Creating an efficient and scalable detection framework that sacrifices high classification accuracy for computational efficiency.

6) Research significance: The significance of this study lies in its scientific and practical contributions. Academically, it takes the state of deepfake detection to the next level by combining novel techniques in preprocessing with efficient deep learning models. Practically, the proposed framework benefits digital forensics, strengthens media integrity, and provides scalable solutions for combating misinformation in resource-constrained environments such as social media platforms and police investigations.

This study robusts deepfake detection by coupling a novel preprocessing boost with an advanced model structure for improving both detection accuracy and generalizability. The rest of the study follows the structure as follows: Section II outlines related works. Section III presents the proposed pipeline. Section IV presents experimental results. Section V provides results. Section VI presents the discussion, and Section VII details the ethical concerns, data protection and misuse threat. Section VIII concludes the study. Finally, Section IX outlines the future work.

II. Related Work

Qadir et al. [11] introduced a hybrid deepfake detection model, ResNet-Swish-BiLSTM, which combines convolutional and BiLSTM-based residual networks for training and classification. The model processes sequential video frames to identify artifacts in deepfake images, achieving high accuracy rates—96.23% on the FF++ dataset and 78.33% on combined

FF++ and DFDC datasets. Extensive evaluations demonstrate the method's robustness, generalizability, and superior performance across various datasets, including FF++, DFDC, and Celeb-DF. It mainly focuses on the detection of various deepfake variants: FS, NT, and F2F, with very good performance regarding the discrimination of tampered versus pristine digital footage in terms of recall and AU, reaching up to 0.9876. Future applications of the proposed method in digital forensics are mentioned; future enhancements might be needed with regard to capturing temporal patterns for better adaptability and inference.

In [19], the authors suggested the job of identifying tampered videos on the basis of a hybrid deep learning method by combining CNN and EfficientNet B6. Their proposed framework identifies forged areas by analyzing video frames and was trained on the FaceForensics++ dataset with 90% classification accuracy. The validation metrics considered were precision, recall, and F1-scores of 98%, 81%, and 89% for fake images, and 84%, 98%, and 91% for real images. Apart from that, the trained model was deployed on Flask for real-life testing and validation with the public.

According to [20], it is possible to detect deepfakes effectively using advanced CNN models such as EfficientNet-B4 and XceptionNet. The authors conducted preprocessing through frame extraction and face isolation on the FF++ and Celeb-DF (v2) datasets and trained and tested using the log loss and AUC metrics. EfficientNet-B4 provided an accuracy of 92.99%, followed by XceptionNet with 90.15%, demonstrating strong performance in the classification of real and fake videos. The study emphasized the requirement for continuous updates of detection algorithms to keep up with evolving deepfake techniques.

In [21], a new hybrid transformer network that learns using an early feature fusion method for deepfake video detection was introduced. Their method combines XceptionNet and EfficientNet-B4 as the feature extractors and end-to-end trains them with a transformer on FaceForensics++ and DFDC benchmarks. With a relatively simple architecture, the model achieves performance comparable to existing state-of-the-art techniques. It also employed a new face cut-out and random cut-out augmentation to improve detection performance and avoid overfitting. Furthermore, the research demonstrated good learning capability with limited data. The authors plan to continue their work by training on Celeb-DF and ForgeryNet datasets, testing generalization on unseen samples, and feature use analysis for manipulation detection, such as face swapping and face reenactment.

The study in [5] proposed paper uses a deepfake detection model with the convolutional neural network-EfficientNet, which was trained using the Celeb-DF dataset. This model provided high classification accuracy at 95%, while its recall and F1 scores are 0.9161 and 0.9562 for images with 224x224 pixels, respectively. This closely follows state-of-the-art methods to further prove how solid the approach is. The study therefore highlights the rapid evolution of deep-fake generation techniques, which require adaptable and scalable detection models. Testing on diverse datasets, exploring advanced EfficientNet variants, and increasing training iterations can be done to improve generalization and further improve classification performance.

According to [22], a comprehensive review of deep architectures for deepfake detection shows the transition from CNNs to Transformers. Eight models were evaluated on second- and third-generation benchmarks such as FF++ 2020, Google DFD, Celeb-DF, Deeper Forensics, and DFDC, with accuracies of 88.74% to 99.73% and AUC scores ranging from 97.61% to 100%. The results indicated that CNNs performed effectively in same-train-test settings, while Transformers generalized better across datasets. Further research on the relationships between datasets established the novelty of FF++, Google DFD, and Celeb-DF, as well as emphasized the importance of Deeper Forensics and DFDC in advancing detection methods.

In [23], the authors employed a sequential convolutional neural network and max pooling with the Adam optimizer. It was trained and tested on a combination of datasets, including Celeb-DF and FaceForensics++. The model achieved 93.3% accuracy and 19.5% loss rate, indicating the strengths of CNNs in identifying manipulated content.

The study in [24] proposes a neural network-based approach for the detection of deep-fake videos using advanced deep learning for the classification of genuine and manipulated content. The approach includes preprocessing, feature extraction based on facial landmarks, temporal patterns, and pixel-level inconsistencies, and classification using state-of-the-art neural network architectures such as CNNs and RNNs.

It proposed a diverse dataset of real and synthetic videos, annotated with ground truth labels to ensure robustness and generalization across varied deepfake generation techniques. Extensive experiments are conducted to verify the effectiveness of the framework with high detection accuracy by optimizing the trade-off between computational efficiency compared to the classic GAN-based methods.

This approach further improves scalability and practicality for real-world applications by simplifying the authentication process and reducing computational overhead. This research makes a significant contribution to combating misinformation and securing visual media integrity by providing a computationally efficient and accessible approach to deepfake detection.

In [25], the authors proposed a new Deepfake video detection model, Convolutional Vision Transformer (CViT2), which combines CNNs to extract local features and Vision Transformers to model both global and local relationships of features using attention mechanisms. The model was trained on five datasets: DFDC, FF++, Celeb-DF v2, DeepfakeTIMIT, and TrustedMedia, and tested on 2,669 videos, reaching high accuracy on test sets, including 95% on DFDC, 94.8% on FF++, 98.3% on Celeb-DF v2, and 76.7% on TIMIT.

CViT2 is very efficient in analyzing both pixel-level and non-local features, which makes it more robust for Deepfake video detection under varied scenarios. In the future, more datasets should be included for training to improve generalization and robustness. The proposed model offers a realistic way to counter misinformation and fraud, having

major implications for digital forensics and societal trust in media authenticity.

The work in [2] proposed the challenge of detecting deepfake videos by proposing a model that identifies inconsistencies in facial features, compression artifacts, and manipulation-induced discrepancies. The model, which uses transfer learning on the VGG-16 architecture, trains on the Celeb-DF dataset, focusing on manipulations of facial features for forgery detection. Much emphasis is placed on transfer learning to reduce resource requirements and training time while ensuring robust performance.

The model can extract features that are relevant for deepfake detection, although it has certain limitations with low-quality images and videos. Further improvements, as suggested in the paper, could be made using better datasets, ensemble learning methods, temporal, and audio discrepancies. All these methods will improve accuracy and generalization by combining the results from multiple frames and learning models, hence providing a holistic approach toward deepfake detection.

The study in [26] introduces a method that fine-tunes a transformer module to detect fake images by exploring new feature spaces through attention-based networks, specifically Res-Next CNNs. This architecture emphasizes selectively focusing on critical video features. Frame-level features extracted via Res-Next CNNs are used to train an LSTM-based RNN for classifying videos as real or manipulated. The approach is then validated on various datasets, such as FaceForensics++, Deepfake Detection Challenge, Celeb-DF, and a custom dataset, showing its efficiency in real-time scenarios.

The proposed system has practical implications, such as preventing the spread of misinformation by restricting deep-fake content on social media, news platforms, and law enforcement applications, thus safeguarding the authenticity of online content.

The study in [1] addresses the challenges posed by deep-fake technology by introducing a detection framework based on integrated Vision Transformer architectures, Deep-ViT and Cross-ViT. These models analyze pre-extracted facial features from the FF++ dataset, effectively identifying real and fake faces through subclass-specific detection for manipulation methods and overall classification across all types. The model excels in detecting FaceSwap manipulations, achieving an accuracy of 98%.

Deep-ViT and Cross-ViT leverage the unique capability of Vision Transformers to model both local image features and global pixel relationships, unlike traditional CNN-based deepfake detection approaches. The multi-stream design captures varying scales of alterations, enhancing robustness. The framework's performance was evaluated under intra-dataset and inter-dataset settings, achieving AUC scores of 92.4% on FF++ and 83.1% on Celeb-DF (V2). In subclass detection for FF++ manipulations, the model achieved classification accuracies of 98.6% for Deepfake, 98% for FaceSwap, 97% for Face2Face, and 90.3% for Neural Texture.

This research recognizes advanced architecture's contribution to fighting against the proliferation of deepfakes while highlighting their capabilities to provide safety to the authenticity of media content in view of growingly sophisticated manipulation techniques.

In [27], EfficientNet B7-a state-of-the-art CNN-for detecting deepfake videos. Deepfake techniques that use advanced machine learning to manipulate visual content have created a significant threat to media authenticity. The research will study how EfficientNet B7 can find minute visual cues that hint at manipulation and assess its accuracy, computational efficiency, and robustness on different deepfake datasets. The model achieved an accuracy of 85%, which aligns with the 84.4% accuracy reported in the original EfficientNet paper. EfficientNet B7's efficient architecture and lower computational demands make it suitable for real-world deployment, especially in resource-constrained environments. The study also suggests further research into ensemble models and advanced techniques like knowledge distillation to enhance performance. Eventually, EfficientNet B7 has a very bright future in detecting deepfakes and developing further robust and scalable solutions against misinformation.

The work presented in [3] proposed a neural network-based deepfake video detection by fusing Convolutional Neural Networks and Recurrent Neural Networks. The CNN extracts frame-level features, which are further fed into an RNN, specifically Long Short-Term Memory, to find temporal irregularities and classify whether tampering has occurred in the video. The proposed approach considers two different methodologies of deepfake creation: GANs and autoencoders. Competitive performance is given using ResNext CNN on frame-level detection and RNN on video classification for the detection of deepfake content. The model does even better on real-time data, gaining more accuracy and confidence in classifying a video as real or fake.

The study in [28] deals with the increasing problem of video forgery or deepfake media, which is posing quite a serious threat to media integrity because it is easy to fabricate and disseminate manipulated content. Applications for video forgery detection span across multimedia forensics, digital investigations, and video authenticity verification. The proposed technique relies on a CNN using a ResNet architecture to discover deepfake videos by deep feature extraction from frames. These features are analyzed using sequence descriptors to capture temporal information, which is then processed through fully connected layers to classify videos as real or fake. It is an effective preliminary solution for deepfake detection, based on the DeepFake video dataset, and performance could be improved by updating the data in the real world.

In [29], the authors raise a very critical issue in video forgery and deepfake media, the integrity of which is seriously compromised by the rampant creation and dissemination of manipulated content. The proposed technique utilizes a CNN based on ResNet for deep feature extraction from video frames, together with sequence descriptors that capture temporal inconsistencies. Then, fully connected layers classify videos as either authentic or fake. This approach gives promising

accuracy with the DeepFake video dataset and is the initial framework of deepfake detection. Further enhancement of robustness can be done by training the model with more varied and unseen manipulation techniques. It opens a way for a resilient solution against fake media.

In [30], the authors focus on the advanced technique of deep-fake image detection and propose an improved approach using computer vision and deep learning. It uses the FaceForensics++ dataset and has attained a very high AUC score. The faces are extracted from videos using RetinaFace, and the extraction is accelerated by multiprocessing. Enhancement and augmentation of the dataset are performed, and three models, namely SEResNeXt-50, EfficientNet B0, and EfficientNet B3, are trained and evaluated. Of these, occlusion and blending techniques work the best in combination. This deepfake detection system gives a robust pipeline for verifying video authenticity and is very useful in combating fake news, along with mitigating its potential harms during critical times. III. METHODOLOGY

This section details the methodological setup for developing a robust deepfake detection system, regarding data collection, preprocessing, model architecture, and experimental setup. The proposed methodology is tailored to ensure high-quality input data generation, enabling thorough evaluation and ensuring reliable effectiveness. Fig. 1 shows the pipeline, which outlines the overall key steps.

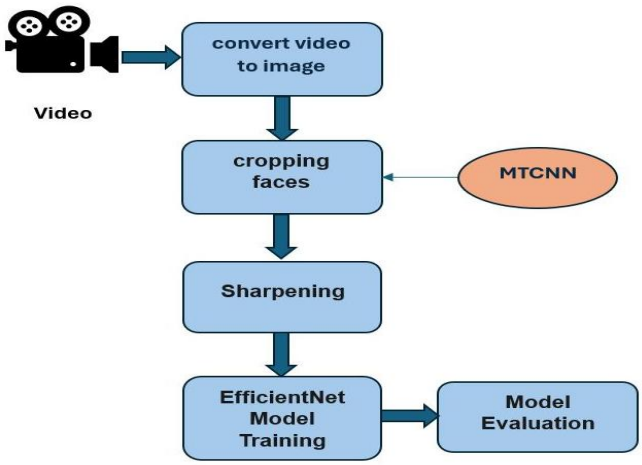

Fig. 1. The architecture diagram of the proposed methodology.

A. Data Collection and Preprocessing

The quality of the dataset and, in many ways, its diversity have large impacts on deep learning model performance. To this end, a large-scale diverse dataset is prepared, including videos from DeepFake-TIMIT, FaceForensics++, Google Deep Fake Detection (DFD), Celeb-DF, and the Facebook Deepfake Detection Challenge (DFDC). Combined, these datasets contained 134,446 videos of about 1,140 unique identities using over 20 different synthesis methods. This large collection enabled broad coverage of deepfake creation methods, significantly enhancing the model's generalization capability.

B. Dataset Preparation

The dataset was carefully analyzed and prepared to ensure its quality and equilibrium. The initial distribution of the frames was heavily unbalanced, with real faces totaling 11 frames and fake faces totaling 50. After preprocessing, it was balanced by fake frames to equal the number of real frames. All images were resized to a standardized format. Steps taken to do this included the removal of all frames where a face could not be detected and low-confidence detections to ensure the quality of the dataset. The preprocessing steps produced a polished, fair, and representative dataset, thus laying a good foundation for model development and evaluation.

This experimental setup fulfilled state-of-the-art best practices and, therefore, ensured reproducibility and utility for future research studies. This approach allows for reliable performance analysis and demonstrates feasibility even in resource-constrained computational environments. Table II provides a summary of used datasets.

TABLE II. SUMMARY OF USED DATASET

Class	Number of images	Dataset	Source	Image size
fake	1100	FaceForensics++	Kaggle	224 ×224
real	1078	DFDC/DFD/ Celeb-DF		

Preprocessing was one of the most important steps in preparing data for model training. Frames were systematically extracted from videos, and their resolution was adjusted based on specified parameters so that the inputs could be standardized. Videos with width less than 300 pixels were upscaled by a factor of 2, those between 300 and 1000 pixels were retained at their original size, those between 1000 and 1900 pixels were downscaled by 0.5×, and videos exceeding 1900 pixels were downscaled by 0.33×. Following frame extraction, face detection and cropping were done using a pre-trained MTCNN algorithm.

Multi-task Cascaded Convolutional Neural Network (MTCNN) is a face detection and alignment deep learning algorithm, which is accurate and highly robust against varying conditions like lighting and pose. It contains three cascaded networks: P-Net (Proposal Network) for generating preliminary face bounding boxes, R-Net (Refine Network) for removing false alarms and refining the boxes, and O-Net (Output Network) for refining the final bounding boxes and facial landmark localization. MTCNN's multi-task learning enhances performance by synchronized face detection and landmark detection, making it efficient and reliable. It is used for face detection in images/videos, facial recognition, real-time face tracking, and facial analysis. MTCNN's cascaded structure ensures high accuracy and is now a cornerstone in face detection research, as illustrated in Fig. 2 and Fig. 3, which shows an example of an image cropped using MTCNN.

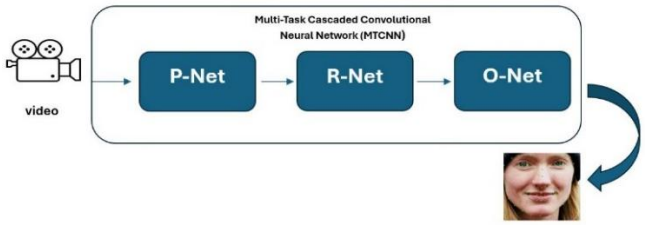

Fig. 2. The architecture diagram of MTCNN.

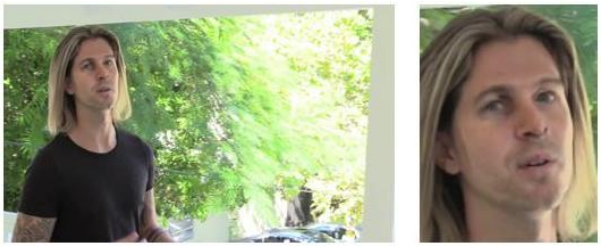

Fig. 3. Example of images cropped with MTCNN model.

In addition, a 30% margin around the bounding boxes was added to enhance the quality of the detected faces by including contextual facial features. A 95% confidence threshold was set to ensure high-accuracy detection; otherwise, if no detectable faces were found in a frame, the frame was thrown out of the dataset. If more than one face was detected in a frame, each face was saved separately. An example of this is detected faces, which consisted of bounding boxes like [110, 58, 71, 92] with a confidence score of 0.999996 and [392 ,60 ,48 ,63] with a confidence score of 0.999997.

To address class imbalance, a common occurrence in deepfake datasets, the number of counterfeit samples was reduced to match the number of authentic samples to prevent any possible bias of the model towards the overrepresented class. Subsequently, the preprocessed dataset was divided into training, validation, and test sets in an 80:10:10 ratio, hence setting up a structured approach to model building, optimization, and evaluation. Next, image improvement was done to improve the quality of the data. Precisely, face image sharpening was carried out using an unsharp masking technique.

Image Sharpening Algorithm enhances image definition and clarity by increasing contrast at edges. It does so by highlighting intensity differences between neighboring pixels, thus making edges more distinct, as shown in Fig. 4. Common methods include the Laplacian filter and Unsharp Masking, which entail subtracting a blurred image from the original. Sharpening is widely used in photography, medical imaging, and computer vision to improve visual quality and perception of detail, so that significant features are more visible. It involves blurring the cropped image with a Gaussian blur and then combining the blurred and original images with weighted summation. The enhanced images, which were converted to OpenCV's BGR format for compatibility, were stored for further processing steps.

Fig. 4. Images after sharpening using unsharp masking.

C. Model Architecture

The deepfake detection model had an EfficientNet backbone, which balanced high performance and computational efficiency. Key modifications included:

The proposed deepfake detection system was based on an EfficientNet backbone, chosen due to its best trade-off between computational efficiency and performance. Its input layer was adjusted to fit 128×128×3 images, which significantly reduced computational costs while retaining crucial visual information. The final convolutional layer output of the EfficientNet architecture was routed through a global max pooling layer to summarize spatial information into a single feature vector. Two fully connected layers with ReLU activation functions were appended to the model to acquire richer feature representations. The output layer used the Sigmoid activation function, allowing the model to output a probability signifying whether an input is deepfake (0) or pristine (1).

Regularization techniques were incorporated to increase model robustness and avoid overfitting. Dropout layers were used, and early stopping was implemented to stop training when validation performance no longer improved. This configuration provided a strong foundation for the accurate and efficient detection of deepfakes. Fig. 5 shows the architecture diagram of the proposed model.

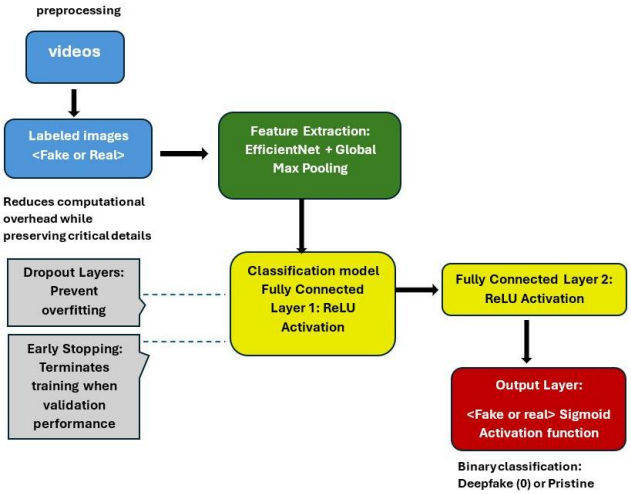

Fig. 5. The architecture diagram of the proposed model.

IV. Experimental Setup

The experimental setup used to train and evaluate the deep-fake detection model is described in detail. The training procedure used the processed dataset with the model, optimized by the Adam optimizer with a learning rate of 0.001, batch size 16, and binary cross-entropy as the loss function. These hyperparameters were tuned to balance convergence speed and model accuracy.

The effectiveness of the model was evaluated using accuracy as the main measure. Accuracy calculates the number of cases predicted correctly to the total number of instances evaluated [32], represented by the Formula (1):

$$\text{Accuracy} = \frac{\text{TP+TN}}{TP+FP+TN+FN} \quad (1)$$

While accuracy is an intuitive and common metric, it can be misleading as a measure of model performance for imbalanced datasets. Nonetheless, in this study, accuracy was the first test of the system's classification abilities that had to be used.

The generalization of the model was tested with a 5-fold cross-validation procedure. It evaluates the model on different subsets of the data, ensuring that it exhibits consistent and robust performance across a variety of training and validation splits.

Preprocessing and training were performed using a CPU-based system, although resource-constrained, thus showing the applicability of the proposed methodology in constrained conditions. The software stack included Python version 3.9 for scripting, TensorFlow version 2.17.1 for model execution and training, OpenCV for image processing operations such as face detection and cropping, and NumPy and scikit-learn for data handling and evaluation. TensorFlow's GPU libraries were installed, but all computational tasks were performed on the CPU, and warnings related to GPU dependencies were ignored.

V. Results

Table III presents the comparative performance of EfficientNet models ranging from B0 to B4, evaluated under identical training and validation conditions. These models were fine-tuned on the dataset with a binary classification task using an input image size of 128×128×128 / times 128×128×128, consistent pre-processing, and training parameters. The main metrics that were evaluated included training accuracy, validation accuracy, training loss, and validation loss, averaging over 20 epochs.

TABLE III. Results of EfficientNet

Model	Validation Accuracy (%)	Validation Loss
EfficientNetB0	94.59	0.13
EfficientNetB1	97.45	**0.04**
EfficientNetB2	96.50	0.08
EfficientNetB3	95.54	0.05
EfficientNetB4	**97.77**	0.13

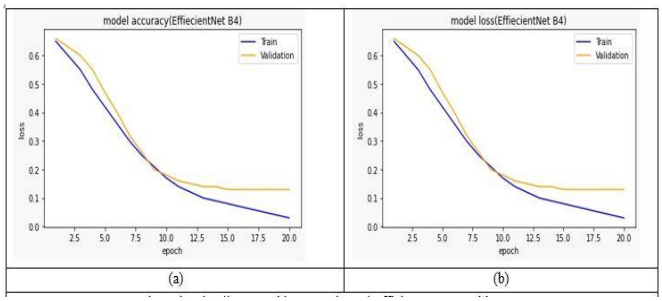

Fig. 6. The plot diagram with 20 epochs and EfficientNet B4 architecture.

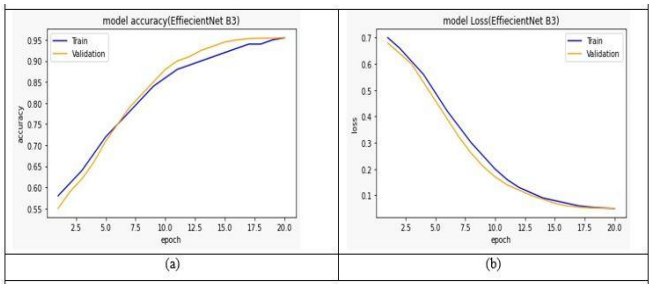

Fig. 7. The plot diagram with 20 epochs and EfficientNet B3 architecture.

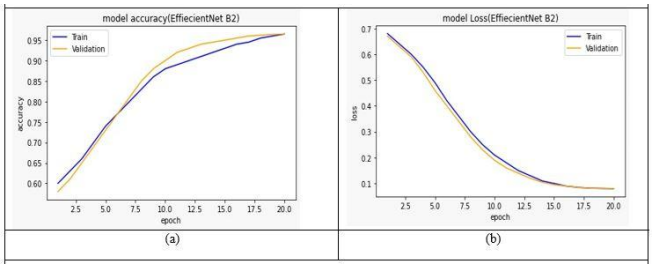

Fig. 8. The plot diagram with 20 epochs and EfficientNet B2 architecture.

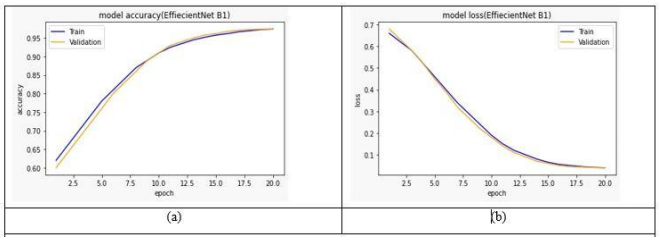

Fig. 9. The plot diagram with 20 epochs and EfficientNet B1 architecture.

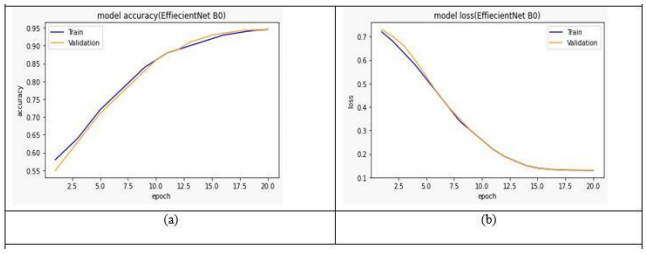

Fig. 10. The plot diagram with 20 epochs and EfficientNet B0 Architecture.

The performance evaluation of various EfficientNet models in detecting deepfakes in videos. Various versions of EfficientNet reveal a variation in validation loss and accuracy, which could be the result of depth and complexity.

EfficientNetB0 reported a validation accuracy of 94.59% and a validation loss of 0.13. The model shown in Fig. 10(a) and Fig. 10(b), although having a reasonably high accuracy, reported a marginally higher validation loss, which reflects a moderate level of misclassification. On increasing the depth of the model, one can observe that the performance significantly increases. EfficientNetB1 performed much better than EfficientNetB0, having an accuracy of 97.45% and a much lower validation loss of 0.04. This demonstrates that increased complexity and parameters result in better feature extraction and generalization.

EfficientNetB2, as presented in Fig. 8(a) and Fig. 8(b), experienced a marginal decrease in accuracy to 96.50% from EfficientNetB1, with the validation loss rising by 0.08. This represents a decrease in predictive efficiency to a marginal degree, perhaps due to overfitting or poor training conditions. EfficientNetB3, as presented in Fig. 7(a) and Fig. 7(b), also maintained a further reduction in accuracy to 95.54%, but its validation loss was low at 0.05. This finding suggests that making the model deeper past a point will not necessarily make it perform better and can instead result in diminishing returns.

Among all the model tests, EfficientNetB4, as illustrated in Fig. 6(a) and Fig. 6(b), achieved the highest validation accuracy of 97.77%, though its validation loss (0.13) was greater than that of EfficientNetB1, as shown in Fig. 9(a) and Fig. 9(b). EfficientNetB4's high performance is due to its better capacity to learn complex patterns from deep-fake videos, leading to stronger feature representation. However, the high validation loss suggests possible overfitting or sensitivity to certain variations of the dataset.

In summary, the results show that increasing EfficientNet models generally enhances classification performance, with EfficientNetB4 being the most accurate. The presence of relatively higher validation loss in certain deeper models shows the trade-off between complexity and generalization. Regularization techniques and data augmentation techniques can be explored further in future studies to minimize the risk of overfitting and further enhance the performance of deepfake video detection.

VI. Discussion

This section provides a critical examination of the above results, with a special focus on evaluating the effectiveness of the proposed deepfake detection technique versus state-of-the-art techniques with EfficientNet architectures. Extra focus is put on identifying how the application of unsharp masking as a preprocessing step aids the model's ability to detect fine visual details characteristic of synthetic video material. By comparison of performance over a number of datasets, this discussion investigates the contribution of both architectural choice and preprocessing method to overall classification accuracy.

To assess the effectiveness of the suggested approach, we compare its performance with comparable works that have applied EfficientNet models to detect deep-fake videos, as shown in Table IV. The results indicate that our suggested models, which employ EfficientNet models and an unsharp masking preprocessing technique, outperform existing methods on several datasets.

The baseline EfficientNet model in earlier studies achieved an accuracy of 92.4% on FF++, DFDC, and Celeb-DF datasets. Similarly, EfficientNet-B4, experimented on FF++ and Celeb-DF, achieved a comparable but slightly higher accuracy of 92.99%. These results, although indicative of good performance, fall short of the proposed models, which incorporate an unsharp masking technique to further enhance feature extraction.

TABLE IV. Comparison between the Proposed Model and the State-of-the-Art

Model	Dataset	Acc
Efficient Net [11]	FF++/ DFDC/ Celeb-DF	92.4
EfficientNet-B4[20]	FF++/ Celeb-DF	92.99
Efficient Net B7[27]	ImageNet	85%
Proposed model EfficientNetB0 + unsharp mask	FF++/DFDC/DFD/ Celeb-DF	94.59
Proposed model EfficientNetB1+ unsharp mask		97.45
Proposed model EfficientNetB2+ unsharp mask		96.50
Proposed model EfficientNetB3+ unsharp mask		95.54
Proposed model EfficientNetB4+ unsharp mask		**97.77**

The proposed EfficientNetB0 + unsharp mask model accuracy was 94.59%, showing the benefit of preprocessing in improving deepfake detection. Most importantly, the proposed EfficientNetB1 + unsharp mask model significantly outperformed the earlier methods, achieving the highest accuracy of 97.45%. This shows that the combination of advanced CNN architecture and image enhancement methods enables the detection of real and synthetic content.

The other proposed models, EfficientNetB2, B3, and B4 with unsharp masking, also performed considerably better than the prior works with 96.50%, 95.54%, and 97.77% accuracy, respectively. The highest performing model, EfficientNetB4 + unsharp mask, achieved a peak accuracy of 97.77%, outperforming the previous uses of EfficientNet architectures on deepfake datasets.

These findings highlight the strength of adding unsharp masking as a preprocessing module, which is likely to enhance edge detection and fine-grained details that are crucial in identifying deepfake artifacts. The improved performance on different datasets suggests that our solution has good generalization capability and can serve as a viable framework for real-world deepfake detection. The study can be extended to analyze the impact of adding other preprocessing modules or hybrid strategies to enhance classification performance.

VII. Ethical Concerns, Data Protection, and Misuse Threat

The rapid development of deepfake detectors, as significant as it is for defending the integrity of digital content, involves a range of ethical, legal, and social challenges. Overcoming these challenges is crucial for ensuring that the design and deployment of such systems are in line with responsibility, transparency, and fairness principles.

A. Ethical Concerns in Model Building

The development of deepfake detectors is accompanied by considerable ethical obligations, particularly maintaining algorithmic fairness. Trainings of such models based on imbalanced datasets have the potential to behave unequally across population subgroups and may exhibit different levels of detection accuracy per gender, ethnicity, or age. These biases can lead to unfair results and must be actively mitigated utilizing heterogeneous and representative datasets in addition to rigorous testing across varied subpopulations [6], [11].

Moreover, the obscurity in deep learning algorithms complicates transparency and interpretability. Because these systems are being utilized increasingly in high-stakes domains such as media verification and forensic analysis, XAI methods need to be incorporated. This enhances user trust, makes one accountable, and gives stakeholders the capacity to understand and audit the system's decision-making better [22].

B. Data Privacy and Consent

Deepfake detectors typically require access to enormous amounts of visual data with identifiable human features. Use of such data raises significant questions about individual privacy and consent. Compliance with data protection law, such as the General Data Protection Regulation (GDPR) and the California Consumer Privacy Act (CCPA), requires data collection to be carried out ethically, with explicit consent of individuals involved and appropriate anonymization techniques used, where necessary [6], [7].

Effective data governance frameworks must also be established to secure sensitive information. These encompass safe storage methods, access restrictions, and regular audits to prevent misuse. Ethical review processes must be integrated at all stages in the data life cycle, from acquisition to model deployment, to ensure compliance with privacy protocols and ethics [12].

C. Misuse Risks and Dual-Use Issues

Although the technologies for detecting deepfakes are absolutely crucial for combating digital deception, they possess dual-use potential. Adversaries can use information regarding detection models to develop even more sophisticated forgeries that can bypass existing countermeasures [7], [25]. The constant cat-and-mouse game between detection and forgery can erode confidence in authenticity verification tools among the public.

Distribution of detection tools within sensitive environments—such as journalism, law enforcement, or political communication—also risks misclassification. False negatives or positives can lead to reputational damage, wrongful accusations, or suppression of rightful content. To prevent such risks, the results of detection need to be given with confidence levels and be open to human analysis, particularly in high-risk scenarios [13].

D. Recommendations for Ethical and Responsible Deployment

These social and ethical issues have to be resolved through a collective, multidisciplinary approach from policymakers, lawyers, ethicists, and researchers. Normative legislation should determine permitted uses, designate minimum performance levels, and impose transparency obligations throughout the whole life cycle of deepfake detection tools [6], [27]. Education and awareness campaigns among the public are also necessary to enlighten citizens about the potential and limitations of these technologies.

VIII. Conclusion

This work presents a strong and scalable deepfake detection system that combines EfficientNet models with an unsharp masking preprocessing method to improve the detection of nuanced facial manipulation artifacts. Through training on a large and varied dataset, the system exhibits high performance on various EfficientNet variants, with a best validation accuracy of 97.77% when using EfficientNetB4. The experiments validate the improvement in input image sharpness with unsharp masking as a significant factor in the accurate classification of synthetic versus real facial content. Comparison against previous state-of-the-art approaches validates the effectiveness and stability of the proposed approach against different deepfake generation methods and datasets. The use of deep light-weight EfficientNet models, such as B0 and B1, also offers implementable solutions for deployment under computationally constrained environments without affecting performance. The findings of this study contribute depth to the nascent field of multimedia forensics and digital media authentication. Future studies will tackle combining multimodal features (e.g., audio and temporal features), transparency-driven explainable AI techniques, and real-time implementation strategies to make them practicable and ethical to use in high-risk environments like journalism, law enforcement, and social media.

IX. FUTURE WORK

Future directions will focus on achieving greater robustness and generalization of the deepfake detector by incorporating diverse datasets, including more state-of-the-art deep-fake synthesis techniques. Furthermore, architectural explorations deep into vision transformers and hybrid models capable of encoding spatial and temporal features are expected to maximize accuracy during detection. Incorporation of explainability methods will also be attempted to generate insights into model decisions, guaranteeing transparency and trustworthiness. Additionally, future work will be geared towards optimizing computational processes for real-time detection and deployment of the model in real-world settings, including social media and forensic monitoring.

ACKNOWLEDGMENT

The authors would like to thank all who assisted in preparing this work.

FUNDING

The authors extend their appreciation to the Deanship of Research and Graduate Studies at King Khalid University for funding this work through the Small Research Project under grant number RGP1/38/46.

Analysis of the Possibilities of Using LLM Chatbots for Solving Course and Exam Tasks

Svetlana Stefanova, Yordan Kalmukov
Department of Computer Systems and Technologies, University of Ruse, Ruse, Bulgaria

***Abstract*—With the widespread introduction of new technologies and, in particular, AI in various areas of life, students are increasingly using large language models (LLMs) such as ChatGPT and other similar tools to help them with their academic tasks. By using them, they can improve their productivity, improve their understanding of complex topics, and support their academic work. LLMs are used both in research, information gathering and preparation for exams and tests, as well as for generating ideas, creating code, and more. This study explores the possibility of using ChatGPT, Claude and DeepSeek for solving course and exam tasks. The results of the analysis could serve as a warning signal and motivation for future transformation of student testing and assessment methods. The ability to use AI systems to search, analyze, and summarize large volumes of information should shift the focus of assessment from classical fact-finding and practical performance of elementary tasks to creativity, combinability, and skills for adapting and applying the already gained knowledge.**

Keywords*—Large language models (LLM); artificial intelligence (AI); ChatGPT; Claude AI; DeepSeek; AI in education; AI for solving exams

I. Introduction

The use of large language models (LLMs) and chatbot platforms in educational contexts, especially for solving course and exam tasks, is growing and offers various possibilities, but also raises important ethical and pedagogical questions.

One of the directions of use is for teaching assistance, as learners can ask questions and receive information and explanations. In some of the tasks, the solution can be given step by step, rather than just providing the final results. In this way, students can be supported in the process itself and encouraged to think critically by asking them questions step by step instead of providing them with final answers. Unfortunately, some students rely too much on LLMs and do not even check the information they generate, which prevents them from mastering key skills in solving problems. An additional potential risk for them is the sometimes inaccurate or downright false information generated.

Another direction of use is when working on projects. In this case, logical frameworks would be helpful before starting the writing process itself, detecting and correcting stylistic and grammatical inaccuracies and errors, as well as generating quotes. Greater attention should be paid when such tools are used to solve practical tests. If this opportunity is used for exam simulation and self-assessment, then the usefulness is once again a fact. Cases of concern, however, are when LLMs are used to directly solve exams or online tests, which violates academic ethics. The use of real-time artificial intelligence tools during exams is a violation of academic education policies.

Types of AI-based platforms

The platforms and tools used by students can be divided into general and those that are focused on education.

Common platforms include:

- ChatGPT [1] – used for information gathering and problem solving;
- Claude [2] – suitable for longer documents and reasoning tasks;
- Gemini [3];
- Copilot [4] – already built into Word, Excel and other tools of the Office suite;
- DeepSeek by the Chinese hedge fund High-Flyer [5].

The tools focused on education are Khanmigo by Khan Academy [6]; Google Socratic [7] as a mobile application for explaining test problems; Quillionz [8] for generating test questions, and Elicit [9] for searching and finding academic articles and other publications.

In order to prevent risk, it is advisable to set clear rules for when the use of artificial intelligence tools is allowed, giving priority to originality. It is good for students to understand the strengths and weaknesses of the LLM so that they can be aware of the role of analytical and critical thinking.

This study performs a series of experimental analyses aiming to test whether the LLM chatbots like ChatGPT, Claude and DeekSeek could solve exams in real time without any further interaction, rather than just providing exam materials as an image taken from a smartphone or smart watch. Results revealing the short answer “yes” should serve as a warning signal and motivation for future transformation of student testing and assessment methods.

The study is structured as follows: Section II reviews related work done by other researchers. Section III presents the experimental setup and the examination materials used to test the LLM chatbots. Section IV discusses the experimental results, their alignment with the related work and their impact on the methods of examining and evaluating students. Finally, Section V ends the study with a conclusion, outlining the need for future transformation in education in the age of AI.

II. Related Work

Puthumanaillam et al. [10] tested if LLMs (ChatGPT) can successfully complete an entire bachelor course in Aerospace Control Systems. Not just a single final exam, but an entire course with 115 course deliverables, ranging from multiple-choice questions to complex Python programming tasks and long-form analytical writing. ChatGPT successfully completed the course and earned a B grade (82.24%). Its strongest results are in structured assignments and greatest limitations in open-ended projects [10].

Rytilahti and Kaila [11] investigated the capabilities of LLM ChatGPT (GPT3.5 and GPT-4) tools to solve coding exercises in an Introductory programming course. Their results show that the LLM can indeed be quite effective in solving the coding exercises. Depending on the version of the tool, the selected approach (amateur or already experienced student), and the prompt used, ChatGPT was able to achieve between 63.4% and 86.2% of the course's total number of points. If programming exercises were only considered, then ChatGPT answered 100% correctly to 107 (75.9%) and to 139 (98.6%) of the course's 141 programming exercises [11]. This means that even students with no previous experience in programming can successfully complete programming courses by utilizing freely available tools [11].

VarastehNezhad et al. [12] evaluated the performance of popular LLMs (GPT-4o, Claude 3.5 Sonnet, Gemini 1.5 Flash, Llama-3.1-70B, Mistral Large 2, DeepSeek-V2, and Gemma-2-27B) in answering questions in data structure and algorithm design from the Iranian university entrance exams for master's programs in computer science. They analyzed the accuracy and the length of responses to the exams in 2022, 2023 and 2024. The questions were given to the LLMs in both Persian and English so that the authors could compare the LLMs' performance in both languages. Results indicate that GPT-4o achieved the highest average accuracy (75.0%), followed by Claude 3.5 Sonnet (67.2%) and Mistral Large 2 (64.1%) [12]. As expected, evaluated LLMs perform better in English than in Persian, with GPT-4o having the largest performance gap (81.3% in English vs 68.8% in Persian).

Felicia Burlacu [13] analyzes the patterns in the performance of LLMs, i.e. what factors influence the accuracy of the LLMs' responses. She identified that all matters - the format of the question (multiple-choice or short answer), the length of the question and its type (factual or analytical). According to the results, LLMs perform best (71.42%) on multiple-choice questions of medium length (50 to 100 words) and factual type. Question length is important since a short question may not provide enough details to the LLM, while a long question could confuse it. Expectedly, factual questions get a higher average accuracy (64.28%) than analytical questions (42.85%).

Knowing that LLM chatbots could be used for cheating during exams, Simon Kaare Larsen [14] proposes guidelines and strategies for creating LLM-resistant exams, including content moderation, deliberate inaccuracies, real-world scenarios beyond the model's knowledge base, effective distractor options, evaluating soft skills, and incorporating non-textual information.

III. Experimental Setup

Since we teach in subjects related to Computer Science, Web Programming and Artificial Intelligence, we are interested in how well the LLM chatbots could solve the exam materials in these specific subjects.

The most commonly used exam formats for IT courses are "theoretical" with many questions that expect short open answers or multiple-choice answers, and practical exams, where students are required to write programming code and develop working applications. The first one is used to check students' overall knowledge or common sense in a specific area of science, while the practical exam tries to evaluate students' ability to develop real-life working applications on a computer. During practical exams, students are usually allowed to use any third-party educational resources on the Internet, except AI chatbots.

The exam in Distributed Web Applications is a "theoretical" one containing 18 questions that require short open-ended answers. Students have 1 hour to answer all questions, but they usually do it faster. All questions are printed on A4-sized paper, and students are required to answer with 1 to 3 sentences directly on that sheet of paper. Here are some example questions: "Specify two advantages of orchestration over choreography", or "If you need to guarantee a strictly defined order of execution of web services, will you choose synchronous or asynchronous communication between them?"

The exam in Information Retrieval is similar (see Fig. 1). It consists of 17 questions that require short open-ended answers between one word and 2 to 3 sentences. Students receive all 17 questions printed on A4-sized paper and should write their answers on the same sheet as well. Here are some example questions: "What are the main differences between the Latent Semantic Analysis and the Vector Space Model?", "Which similarity measures could be used to calculate similarity between sets of keywords?" or "What is the difference between flat clustering and hierarchical clustering?"

In contrast to the previous two, the exam in Web Programming is practical and is conducted on a computer (see Fig. 2). Every student receives an individual assignment to develop a working web application from scratch. Examples, templates and partly implemented code from the exercises are allowed to be used as reference. The assignment consists of four sub-assignments that upgrade one another and increase the final grade from "Sufficient D" to "Excellent A". An example assignment is shown in Fig. 2.

For the purpose of our experiments, the blank exam papers or assignments, as received by students, are photographed with an ordinary smartphone and sent to the three chatbots – ChatGPT, Claude and DeepSeek. The answers provided by the AIs are then checked for correctness and evaluated by the authors of this study. We use the same grading system that we apply to our students as well. It is based on the percentage of correct answers as follows:

< 40%, Fail F	70 – 84%, Very good B
40 – 54%, Sufficient D	85%+, Excellent A
55 – 69%, Good C	

Изпит по **„Търсене и извличане на информация"**, ОКС Магистър, 15.04.2025 г.

1. Кои са основните разлики между векторния модел за анализ на текст и латентния семантичен анализ?

2. Чрез кои мерки за сходство може да се изчисли семантична близост (степен на подобие) между два възела в таксономия?

3. Чрез кои показатели (метрики) се оценява точността/адекватността на търсенето?

4. Как може да се прецени дали подредбата на върнатите резултати е правилна?

5. По какъв начин (чрез кои мерки за сходство) може да се изчисли коефициент на подобие между два документа/обекта, описани чрез неподредени множества от ключови думи?

6. Защо описанието на документите чрез таксономия от ключови думи е по-подходящо, отколкото описанието чрез неподредено множество?

7. Как се представят документите (във вид на какво) при векторния модел за анализ на текст?

8. Защо е необходимо изчислените коефициенти на подобие да се нормализират спрямо дължината на векторите?

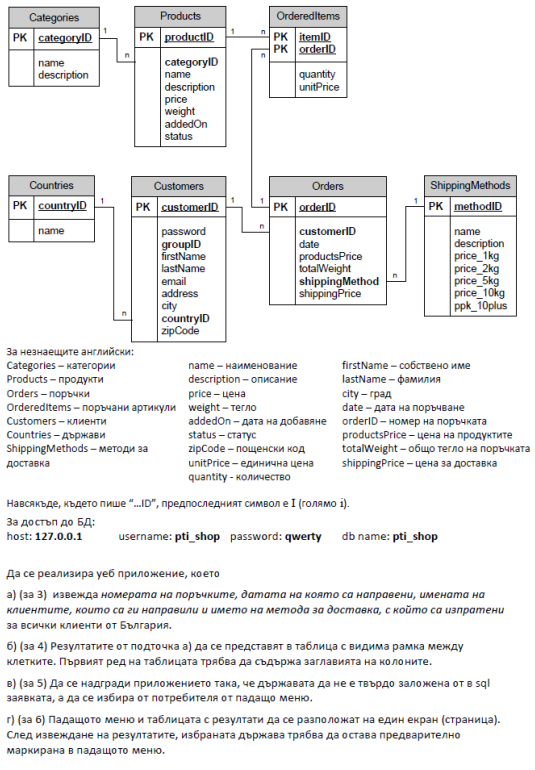
9. Защо при практическата реализация на векторния модел за анализ на текст всъщност се използва обърнат (инвертиран) индекс, а подобията не се изчисляват чрез векторите на документите?

10. Какви са основните разлики между плоските и йерархичните методи за клъстеризация?

11. Кои са двете основни характеристики, чрез които се изчисляват теглата на думите в документите/заявката при векторния модел за анализ на текст?

12. Защо е желателно да се премахнат семантично незначимите думи от текста преди прилагането на векторния модел или който и да е друг модел?

13. Как се изчислява семантичната близост между два документа при векторния модел за анализ на текст?



14. Какво представлява операцията стемиране и защо е препоръчително да се извършва преди векторния модел за анализ на текст?

15. Кои фактори влияят върху точността на коефициентите на подобие, изчислени чрез латентния семантичен анализ?

16. Избройте няколко начина, по които може да се изчисли разстоянието между два клъстера?

17. Кой метод позволява откриването и разпознаването на синоними като свързани думи – векторният модел за анализ на текст или латентният семантичен анализ?

IV. Results and Discussion

Results from the theoretical exams in Distributed Web Applications and Information Retrieval are shown in Table I and Table II, respectively.

TABLE I Evaluation of the Answers Provided by ChatGPT, Claude and DeepSeek to the Questions from the Exam in Distributed Web Applications

LLM Model	ChatGPT (GPT-3.5)	Claude (Sonnet v3.7)	DeepSeek (V3)
Result, % correct answers	**91 %**	**92 %**	**82 %**
Grade	Excellent A	Excellent A	Excellent A-

Obviously, all three LLM chatbots will get an Excellent A in distributed web applications. All models provide correct answers only, but as seen in Table I, they achieve different percentages. How is that possible? Since there are questions that require a subset of the correct answers, like "Specify two advantages of orchestration over choreography", that makes it possible. There are 4 to 5 advantages of orchestration over choreography, but they have different importance. Some of them are more important than others. DeepSeek, for example, provided two which are correct, but less important, so it does not get full points for this question.

TABLE II Evaluation of the Answers Provided by ChatGPT, Claude and DeepSeek to the Questions from the Exam in Information Retrieval

LLM Model	ChatGPT (GPT-3.5)	Claude (Sonnet v3.7)	DeepSeek (V3)
Result, % correct answers	**95 %**	**99.4 %**	**82 %**
Grade	Excellent A	Excellent A	Excellent A-

Similarly, when solving the exam in Information Retrieval, DeepSeek gives the lowest percentage of correct answers again, while Claude achieves 99.4%. In respect to language clarity, Claude does an excellent job generating beautiful sentences that sound like written by a real human. It should be mentioned here, that all exam materials are in Bulgarian, thus the AI answers are in Bulgarian as well.

The next challenge for the three LLM chatbots is to solve practical exams and write or generate real programming code. It is known that they are good in providing working code fragments or entire basic applications, but it is curious if they can correctly understand our specific assignments and generate working and efficient code. Again, the assignment is photographed with an ordinary smartphone and sent to them for execution. Results are summarized in Table III.

In terms of programming code, all models generate completely working code that satisfies all four sub-assignments, so the chatbots will get an Excellent A grade. ChatGPT and Claude use two additional and unnecessary arrays to cache data from the database, and thus two unnecessary cycles to create these arrays. When told that these two arrays are not necessary,

ChatGPT argues and motivates its decision to cache the data, while Claude agrees they could be omitted.

TABLE III EVALUATION OF THE PROGRAMMING CODE PROVIDED BY CHATGPT, CLAUDE AND DEEPSEEK AS A SOLUTION TO THE PRACTICAL EXAM IN WEB PROGRAMMING

LLM Model	ChatGPT (GPT-3.5)	Claude (Sonnet v3.7)	DeepSeek (V3)
Working code?	**Yes**	**Yes**	**Yes**
Optimal code?	Uses 2 unnecessary arrays and thus 2 unnecessary cycles to create them (but could motivate its decision why)	Uses 2 unnecessary arrays and thus 2 unnecessary cycles to create them	Yes
Grade	Excellent A	Excellent A	Excellent A

The results of our experiments with both theoretical and practical IT exams are similar and confirm those achieved by Puthumanaillam et al. [10] and Rytilahti and Kaila [11] in other subjects.

Since students are illegally trying to use artificial intelligence (AI) during their exams, it is interesting to know how the AI chatbots themselves would evaluate a student who, during a practical exam, has to create an application, has the right to use all Internet resources, without AI, but he or she cannot do anything alone. However, if he or she is allowed to use artificial intelligence, then he or she gets an excellent solution from the AI, but does not understand it.

Claude replies that, in its opinion, the student deserves “Fail F”, because the essence of both education and assessment is to measure students’ knowledge and skills, not their ability to find someone or something to do the work for them.

ChatGPT states that the grade should be “Sufficient D” because we should not only evaluate knowledge, but also the ability to solve problems. If the student can solve problems with the help of AI, then he or she has at least some ability to find a solution.

According to DeepSeek, the fair grade is “Sufficient D” since the problem is "solved", but the lack of understanding is a critical flaw in the educational context. The chatbot adds that, if the student can demonstrate how he or she used the AI, this shows some metacognitive skills and would even justify a “Good C” grade.

Although LLM chatbots seem to easily solve exams, there are other tasks they cannot solve, even if they generate perfectly working programming code for solving them. For example, the assignment problem [15] or other optimization tasks. When asked why they are able to generate a programming code to solve the task but cannot provide the solution directly, LLM chatbots reply that they generate the code as text based on their training, but they do not have an access to servers to run it. That is why they can provide just the code, but not the overall final solution. This means that the programming code they generate for the practical exams has not been tested before giving it to students, and thus the LLM chatbots cannot actually guarantee that it is really working.

V. CONCLUSION

A series of experiments have been conducted, aiming to test whether large language models (LLM)-based chatbots could solve exam tasks in real-time with no or minimum interaction. Results could be summarized as follows:

1) All the three AI chatbots (ChatGPT, Claude and DeepSeek) do an excellent job in solving both theoretical and practical exam tasks in the specified subjects, and would have earned an Excellent A grade.

2) Students are not required to have any special skills in working with AI, nor skills in how to ask questions in order to get an accurate and correct answer. They simply take a picture of the assignment and send it to the chatbot. This could happen illegally during the exam, even without the teacher noticing that.

3) When generating short open-ended answers in text format, Claude does the best job, answering most clearly and purposefully.

4) In general, when generating text in Bulgarian, Claude performs best by providing short, beautiful and human-like sentences.

5) DeepSeek answers the leanest and often tends to omit basic and well-known facts in its answer.

Our experimental results completely align with those of other researchers, showing that LLM chatbots are quite good at solving both theoretical and practical IT exams. Especially when it comes to factual (fact-finding) questions or programming code generation, LLMs will not just pass the exam, but will get an excellent A or B grade.

It seems that it is time to change the educational system again and shift the focus of assessment a little bit from the classical fact-finding and practical performance of elementary tasks to creativity, combinability, and skills for adapting and applying already gained knowledge.

ACKNOWLEDGMENT

Segment-Based Vehicular Congestion Detection Methods Using Vehicle ID and Loss of Expected Time of Arrival

Mustapha Abubakar Ahmed, Azizul Rahman Mohd Shariff*
School of Computer Sciences, Universiti Sains Malaysia, USM, Penang, 11800, Malaysia

***Abstract*—Increasing number of vehicles and rapid urbanization are the significant causes of road traffic congestion. Road traffic congestion is the main issue facing world cities today. Congestion control and mitigation are necessary to mitigate the negative impacts of road traffic congestion, such as delays and increased fuel consumption, among others. There are many congestion detection methods published in the literature; some of these methods, such as the speed threshold, use a single congestion detection metric. Using a single parameter for traffic congestion detection might produce false and inaccurate results. Furthermore, many congestion detection techniques fall short in describing traffic congestion from the user's perspective and vision. To address this, this study develops a segment-based congestion detection method that uses vehicle ID and loss of expected time of arrival. The ID-based method considers both vehicle speed and density, whereas the loss of expected time of arrival focuses on the time loss. These methods are segment-based, where roads are divided into segments using vehicle trajectories. Using a speed threshold of 8.33 m/s, the road is segmented into segments of 8.33 m, 16.66 m, and 24.99 m in length. Vehicle speed and density are monitored using vehicle identification numbers (VINs). Experimental results reveal that the speed threshold and the Microscopic Congestion Detection Protocol recorded false congestion detection. The proposed ID-based congestion detection method is capable of identifying false congestion and accurately detecting real congestion. Moreover, the loss of expected time of arrival shows a promising result in terms of identifying congestion based on motorists' feelings.**

Keywords*—Vehicle ID; traffic congestion; congestion detection; vehicle trajectories; vehicle speed; vehicle density; loss of expected time of arrival

I. Introduction

One of the main issues facing today's urban cities is road traffic congestion. According to [1], it affects social and economic productivity, contributes to fuel consumption and environmental pollution, it adds delays to personal mobility [2]. Congestion leads to wasted time and increased fuel consumption. Loss time leads to reduced productivity.

ITS-V2X technology is regarded as a key enabler for predicting and managing road traffic congestion, as well as enhancing road safety. V2X is an approach to exchanging information between vehicles and infrastructure that utilizes decentralized wireless technologies. Future vehicles will share information about their current position (GPS), speed, and traffic status, among other vehicle details, and utilize this information to optimize their routes.

This information is shared using a message called CAM (Cooperate Awareness Messages). CAM is a standard proposed by the European Telecommunications Standards Institute [3], which enables vehicles to collect their kinematic information and share it with other vehicles and infrastructure. Researchers are now leveraging these free, continuous, and abundant messages to manage, build, predict, and make more informed decisions about road traffic congestion.

It is known that drivers and passengers in moving vehicles measure congestion with visual and temporal perception. The mind of a person in a travelling vehicle, upon seeing a high density of vehicles through the windscreen, would ultimately tell themselves that congestion occurs. Moreover, a person would, in general, continuously check how soon or later he would arrive at the destination, whether on a congested or non-congested road. Regardless of how fast a vehicle is travelling, the person would be more concerned with temporal perception, which involves the perception of time. When motorists are unable to reach their destination on time, the emotional feeling is that there is congestion. Even when vehicle speed and related parameters are given as the primary criteria for evaluating congestion, they are nevertheless inaccurate and misleading. A practical observation on a major road, conducted as part of this study, found that vehicles may travel at speeds exceeding the 30-kilometer-per-hour speed limit and still experience intense congestion.

This research employs vehicle trajectories (GPS coordinates) and vehicle IDs to develop an ID and Loss of Expected Time of Arrival (LETA) method for detecting vehicular traffic congestion. Roads are segmented using the concept of the Cell Transmission Model (CTM) [4]. Using vehicle trajectories and a speed threshold of 8.33 m/s, the road is segmented into three different segment lengths: 8.33 m, 16.66 m, and 24.99 m. The ID-based traffic congestion detection system considers both speed and density. Vehicle speed and density are tracked and monitored on each segment using vehicle ID. LETA is calculated using a vehicle's expected time of arrival (ETA) and actual time of arrival (ATA).

The remainder of the study is organized as follows: Section II discusses the relevant literature. Section III will cover methodology, including road segmentation techniques and congestion detection methods. Section IV compares the performance of ID-based with a speed threshold and analyzes the results. LETA results are also presented in this section. Section V concludes the study and presents future work.

II. Related Work

Trajectory data can provide valuable insights for decision-making when properly examined, revealing patterns in road traffic congestion, urbanization, and traffic. The beginning, middle, and end of the road are all potential locations for traffic congestion. For easy monitoring, the road needs to be divided into segments. Model-based or criteria-based segmentation is the possible ways of segmenting trajectories. The method of segmenting a trajectory into a limited number of segments that must all satisfy a global criterion is known as criteria-based segmentation [5]. Using predetermined criteria, criteria-based segmentation divides a road into segments that satisfy particular spatiotemporal requirements. Each segment must fit a particular model parameter, which is the foundation of model-based segmentation.

Hausdorff distance was employed in [6], a shape-based distance measurement for trajectory clustering, as one of the related efforts documented in the literature about trajectory segmentation. Origin and destination were employed by [7] to categorize trajectories based on business affairs. In [8], the authors broke the trajectory into segments using a similarity score in an attempt to create a trajectory segmentation map that matches large-scale GPS data. A system that divides trajectories into homogeneous segments based on spatiotemporal parameters, such as heading, speed, and position, was created by [9]. In [10], the authors divide the road lane into a segment of cluster cells, each with a 2-meter length. A protocol for evaluating and detecting traffic congestion on a road segment was presented by [11]. They describe a road segment as a road that connects two intersections without specifying its length or size. Although these works divided roads into segments, they did not utilize the concept of CTM.

There are two ways of detecting road traffic congestion: using fixed equipment and floating vehicles [12]. Fixed equipment-based congestion detection involves using cameras, loop detectors, and other devices to detect road traffic congestion. The accuracy of this method is high; however, its coverage is limited to a specific location [13]. Using floating vehicles involves utilizing vehicles equipped with sensors and GPS technology on the road to detect traffic congestion. This method has the advantage of detecting congestion over large areas. It also provides a cost-effective method of analyzing and detecting road traffic congestion [14].

Congestion can be quantified using various metrics, including speed, trip duration, density, and congestion index, among others. GPS-based congestion detection is the most cost-effective and widely used approach. Vehicles can also be easily tracked [15]. Road traffic congestion is measured using a variety of techniques; however, there is no single, universal method to determine the state of traffic. Congestion can be measured using the following criteria: 1) Average speed, 2) Travel time, 3) Delay, 4) Density, 5) Level of service, and 6) congestion indices [16]. According to [17], speed, density, and degree of saturation are good indicators of traffic conditions.

Both stationary equipment and floating vehicles can be used to identify congestion [12]. Detecting traffic congestion on the road by using vehicles fitted with sensors and GPS technology was known as "floating vehicles". The benefit of this approach is that it can identify congestion over vast areas. Additionally, it offers an economical approach for assessing and identifying traffic jams [14]. Many studies have utilized data from floating vehicles to develop a road traffic congestion detection system, which includes methods developed by [18, 19, 13], all of which employ fuzzy logic for V2V congestion detection. However, the system incurs overhead due to the message exchange between vehicles for congestion validation.

Fuzzy logic was also employed by [20] to estimate traffic flow. Vehicle speed and location were captured using RFID and transmitted to the cluster head. The cluster head will calculate the average speed and density and then use fuzzy logic to determine the flow. RFID is expensive to implement for all vehicles on the road, and vehicle clustering is also a time-consuming process.

Vehicle trajectories were segmented based on the time window in [21] to detect moving clusters. Vehicle speed and density were used to detect slow-moving clusters for congestion detection. The system is based on clusters, and the formation of these clusters is time-consuming.

A congestion detection approach using clustering algorithms was developed in [22]. Vehicle trajectories are clustered, and the distance travelled by the clusters is computed to determine the average speed, which measures congestion. This method is based on historical data.

Pollutant emissions and traffic delays can be successfully decreased using vehicle speed guidance. Driving too fast is a significant contributing factor to traffic accidents, and research indicates that speed is a leading cause of deadly traffic accidents in nearly every nation. The effects of setting a speed restriction of 30-kilometer-per-hour on roads have been extensively studied by transportation researchers.

The study by [23] found that enforcing a 30-kilometer-per-hour speed restriction in 40 European towns significantly reduced traffic accidents, injuries, and fatalities. In [24], the authors analyzed the effectiveness of a 30-kilometer-per-hour speed limit on roads, finding that it reduced energy use and saved lives.

According to [25], speed emerges as the predominant metric used in the congestion detection literature. Utilizing a single parameter, such as speed, for traffic congestion detection might not produce accurate results [26], [27]. The speed threshold was proposed by [28]. The vehicle's speed was calculated from the distance it covered, and the average speed was compared with the threshold to determine road congestion. Speed may overlook how traffic congestion develops across space, leading to incorrect identification of traffic congestion.

This study presents an ID-based congestion detection method to address the issue of relying on a single parameter for traffic congestion detection. Using a speed threshold, time headway for congestion detection may be inaccurate, leading to false detections. Travel time and delay may not predict how early or late a motorist will arrive at their destination. This makes motorists question when they will get to their destination. LETA is intended to determine how late or early a motorist will arrive at their destination.

III. METHODOLOGY

A. Road Segmentation

CTM defines cell length as equal to the distance a vehicle travels at free-flow speed [4]. In the speed threshold [28], free flow speed was defined to be 8.33 m/s, which means the vehicle will move 8.33m in one (1) second or above to be considered not in congestion. The use of 1s is driven by the fact that the maximum CAM broadcasting interval is 1 second. In this research, vehicle information is collected every 1 second to determine congestion. A vehicle will drive 8.33m/s in 1s, 16.66m/s in 2s, and 24.99m/s in 3s to be considered congested.

Three different segment lengths are utilized to evaluate the method's effectiveness: 8.33 meters, 16.66 meters, and 24.99 meters. In other words, the road is divided into three segments: 8.33 meters, 16.66 meters, and 24.99 meters. Seongsin-ro 2-gil, 140.06 meters, and part of Gonghang-ro, 101 meters in length, are used for the implementation of the proposed congestion detection methods. Table I shows the lengths of the three segments as well as the number of segments generated.

TABLE I. SEGMENT LENGTHS AND THE NUMBER OF SEGMENTS GENERATED

Segment Length	Number of Segments Created (Seongsin-ro)	Number of Segments Created (Gonghang-ro)
8.33 m	16	12
16.66 m	8	6
24.99 m	5	4

The road is not physically segmented; rather, the ID-based system virtually segments the road based on the vehicle trajectories collected, as illustrated in Fig. 1. Vehicle speed is monitored using the vehicle ID and its trajectory. Vehicles driving on a segment of 8.33-meter length are expected to exit after one (1) second. With a segment length of 16.66 meters, vehicles are supposed to exit the segment after two (2) seconds. Vehicles will take three (3) seconds to exit a segment of 24.99 meters in length. This process allows for the monitoring of your vehicle speed in each segment using three different segment lengths.

B. ID-Based Congestion Detection

The density metric was used in the majority of research investigating traffic congestion by counting the number of vehicles per unit of road length. Our approach uses the vehicle's ID sent in the vehicular messages to identify slow-moving vehicles within a road segment. In terms of this research is the first study to detect road traffic congestion by using vehicle ID to identify slow-moving vehicles.

In essence, a traffic flow refers to a line of moving vehicles on a specific route. Vehicles are grouped into substantially denser clusters, travelling at extremely slow speeds because there is insufficient space for lane changes or passing when there is heavy traffic [21, 29]. Therefore, the motivation is that tracking and identifying the group of slow-moving vehicles can effectively identify traffic congestion.

ID-based is a centralized system. The system uses the vehicle ID and trajectories to determine congestion, as shown in Fig. 1. At each time t (i.e., 1s), the vehicle broadcasts its status messages to nearby vehicles and RSUs. After receiving status messages from vehicles on a segment, the RSU aggregates vehicle IDs. As previously mentioned, roadways are segmented into 8.33-meter, 16.66-meter, and 24.99-meter segments, and congestion is measured separately in each segment. Congestion is checked after one (1) second, that is, after each message receipt cycle, for an 8.33-meter segment length. For a 16.66-meter segment length, the system will check for congestion after two (2) seconds, i.e., two message-receiving cycles. Congestion is monitored after three (3) seconds, i.e., three message-receiving cycles, with a 24.99-meter segment length.

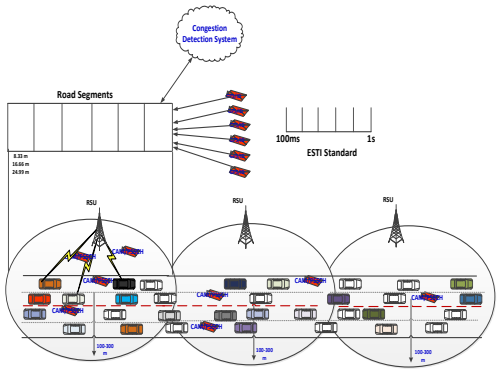

Fig. 1. ID-based congestion detection model.

Let us assume that there are n segments of road Ri. Ri = {Ri1, Ri2, Ri3, …… Rin}. Where i is the road ID, n is the segment ID of road i. Let m be the number of vehicles traversing on Rin such that Rin = {V_1, V_2, V_3, … V_m}, where V represents a vehicle with ID m. Equation 1 shows that all vehicles in Rin can be presumed to be advanced to Ri(n+1) within t seconds (1 second) under light traffic, defined as 30-kilometer-per-hour (8.33 m/s) [see Eq. (1)].

$$R_{i(n+1)(t+1)} = R_{in(t)} \quad (1)$$

Congestion can be detected by detecting slow-moving vehicles [21]. Owing to this notion, an ID-based congestion detection method detects congestion when at least half of the vehicles remain in the segment after the clock tick (1, 2, or 3 seconds, depending on the segment length). It signifies the existence of traffic congestion. This can be evaluated by comparing the vehicle IDs of segment n at time *t* with the IDs of the same segment at time *t* + *i*, where *i* can be 1, 2, or 3, depending on the segment length.

Let Vn (ID) be a vehicle n ID. Let XRin(t) = {V_1(ID), V_2(ID), V_3(ID), … Vn(ID)}, where X_{Rin}(t) is the total vehicle IDs of segment Rin at time t. Congestion occurs if Eq. (2) is valid.

$$X_{Rin(t+1)} \geq \frac{1}{2} X_{Rin(t)} \quad (2)$$

C. LETA

LETA is a segment-based congestion monitoring system. Congestion is tracked on a segment-by-segment basis rather than the road as a whole. It is presumed that RSUs have full coverage of the road. To determine if vehicles may gain or lose time on a specific segment, LETA is computed for each

segment. LETA is capable of monitoring traffic congestion on every segment of the road. LETA is proposed with the intention of estimating the level of traffic a vehicle entering the road would have to experience. A congested road is indicated by loss time, and one that is free-flow is indicated by gain time. The estimated time of arrival (ETA) and actual time of arrival (ATA) must be ascertained in order to compute LETA.

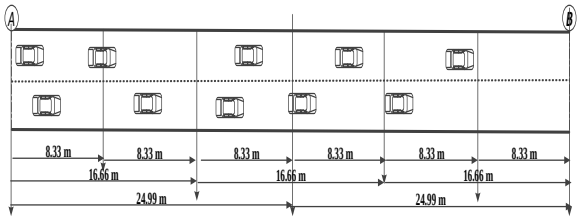

Fig. 2. Shows vehicles moving from A to B across segments.

Let Ri be a road with nth segments, i.e., Ri = {S1, S2, S3, ….., Sn}, where Sn is a road segment with index n of Ri. ETA is the estimated time a vehicle will arrive at destination B from origin A, as shown in Fig. 2. To compute ETA, the distance between two points must be defined. In this work, three different segment lengths are defined: 8.33 m, 16.66 m, and 24.99 m. Using Eq. (3), the ETA can be computed for each segment.

$$ETA_{S_i} = {DSL_{S_i}}/{VS_{S_i}} \quad (3)$$

where, ETASi is the average expected time of arrival for segment Si, DSLSi is the segment length, and VSQi is the segment's average vehicle speed. ATA represents the vehicle's movement on the freeway at the recommended vehicle speed. Using Eq. (4), ATA can be calculated:

$$ATA_{S_i} = {DSL_{S_i}}/{RVS_{S_i}} \quad (4)$$

where, ATASi represents the actual time of arrival for segment Si, DSLSi represents segment length, and RVSSi is the recommended vehicle speed for segment Si. LETA for a segment determines whether there is congestion and how late the vehicle is expected to arrive. LETA is determined by subtracting ETA from ATA and can be computed using Eq. (5).

$$LETA_{S_i} = ATA_{S_i} - ETA_{S_i} \quad (5)$$

where, LETASi is the time loss from the actual time of arrival for segment Sj, ATASi is the actual time of arrival, and ETASi is the expected time of arrival. The total loss of expected time of arrival for road Ri is the sum of the LETA for each of the road's segments. Eq. (6) can be used to calculate the total time loss for road Ri.

$$TLETA_{R_i} = \sum_{i=0}^{n} LETA_{S_i} \quad (6)$$

Where TLETARi is the total time loss for road Ri, LETASi is the loss of expected time of arrival for segment Si, and n is the total number of segments in Ri.

IV. Evaluation of Approaches

A. Dataset

Jeju vehicular traces [30] were used. Seongsin-ro 2-gil and Gonghang-ro road are selected for implementation of the ID-based and LETA methods for vehicular traffic congestion detection. Jeju dataset was chosen because it has CAM data properties, and its transmission timing is consistent at (1) second intervals. Seongsin-ro 2-gil is a one-way road measuring 140.06 meters. At the same time, a part of Gonghang-ro, which is 101 meters in length, is also used. These routes were chosen since they have a substantial number of trajectories, and their GPS coordinates do not deviate from the actual road map. The Jeju dataset contains kinematic information collected from vehicles, with 5000 seconds of heterogeneous vehicle simulation traces totaling 8,495,739 traces. The dataset is generated using the SUMO simulator.

B. Data Preprocessing

Working with GPS trajectories requires preprocessing, as some of the GPS points may deviate from the actual road map. Inaccurate results could arise from anomalies and mistakes if preprocessing were not done [8]. Seongsin-ro 2-gil and Gonghang-ro GPS points (trajectories) were matched on Google Maps. The actual road and the GPS position coincided.

C. ID-Based Results

1) Seongsin-ro: To evaluate the effectiveness of the ID-based congestion detection method, a comparison was made with the speed threshold [28] and the microscopic congestion detection protocol (MCDP) [31]. MCDP used vehicle information to calculate the number of vehicles and the time headway between them. If the time headway is less than two seconds, congestion occurs. At the same time, the ID-based method calculates the vehicle's speed based on the distance it covers and compares it with the speed threshold, i.e., 8.33 m/s.

Since the ID-based method was developed to determine whether congestion exists, the number of detection points was used as a metric; the number of detection points is the total number of points where congestion has been identified. This enables a comparison of two congestion detection systems to determine which one has the highest detection rate.

Fig. 3 illustrates the comparison results for an 8.33-meter segment length. The results reveal that both the ID-based speed threshold and the headway-based approach recorded similar patterns. It can be observed that both ID-based and speed thresholds recorded almost the same congestion detection values for all 16 segments. At the same time, a little difference was observed with the headway-based detection method.

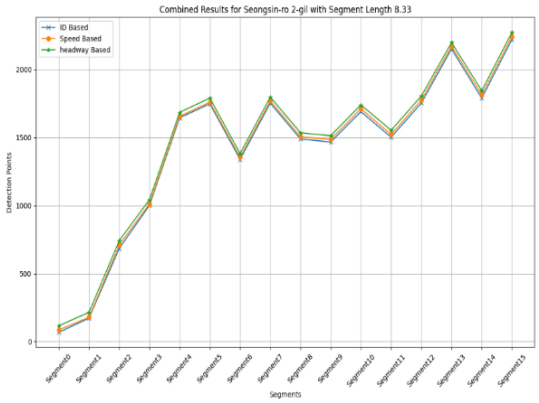

Fig. 3. Shows a comparison between ID-based, speed threshold, and time headway-based results for an 8.33-meter segment length.

Fig. 4 compares the results of ID-based, speed threshold, and headway-based methods using a segment length of 16.66 meters. Both methods recorded a detection point of less than 200 at the first segment, i.e., segment 0, with the ID-based and speed threshold methods being slightly lower than the headway-based method. In both the eight (8) segments, it is clearly shown that ID-based and speed threshold recorded lower detection compared to the headway-based method. It is also notably clear that the ID-based method recorded low detection in comparison to the speed threshold, especially from segment two onward, even though the difference is minimal. This means the base congestion detection method can detect actual (true) congestion.

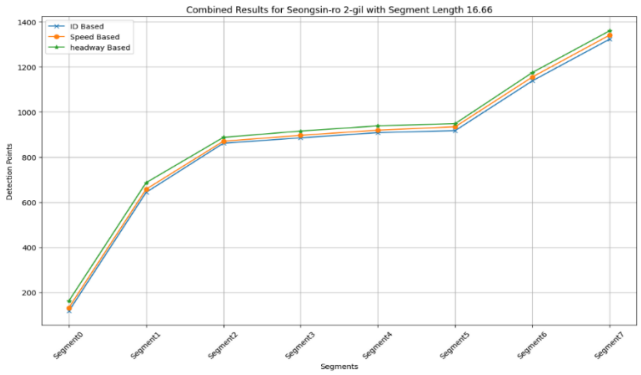

Fig. 4. Shows a comparison of results of headway-based, speed threshold, and ID-based for a 16.66-meter segment length.

Fig. 5 shows a comparison of the ID-based speed threshold and headway-based results for a 24.99-meter segment length. As can be observed, only at the segment0 speed threshold did the detection point go below that of the ID-based method. Even though the difference is minor, in the rest of the segments 1 to 3, it is seen that ID-based recorded lower detection than speed threshold and headway-based.

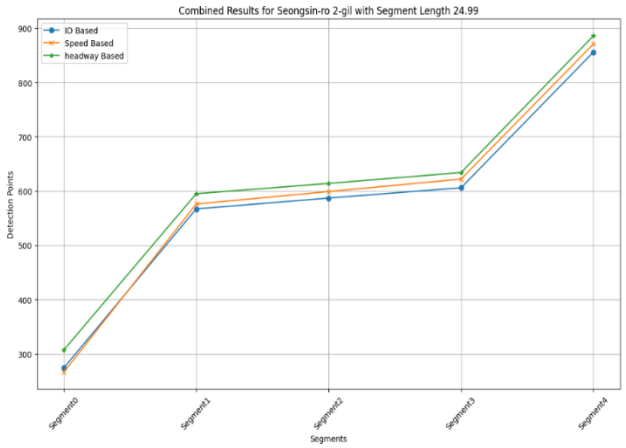

Fig. 5. Shows a comparison of headway-based, speed threshold, and ID-based results for the length of a 24.99-meter segment.

2) Gonghang-ro road: To validate the effectiveness of the base congestion detection method, another road was also considered. Vehicular traces from the Gonghang-ro road are also used to evaluate the ID-based detection method. Fig. 6 compares ID-based results with speed threshold and time headway-based for the 8.33-meter segment length. Congestion detection points are shown for each segment. Segment 0 marks the beginning of the road for all segment lengths.

It can be seen from the results in Fig. 6 that the detection points fluctuate over the segments, with segment 11 recording the lowest values for all the detection methods. The results reveal that with an 8.33-meter segment length, both methods observe the same pattern, with the headway-based method reporting higher detection points than the ID-based and speed threshold. Though the difference between ID-based and speed threshold is not significant, ID-based reported lower detection points.

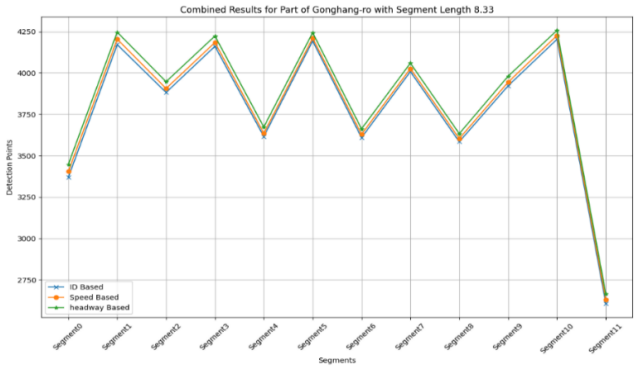

Fig. 6. Congestion detection comparison of the three detection methods using segment lengths of 8.33-meter.

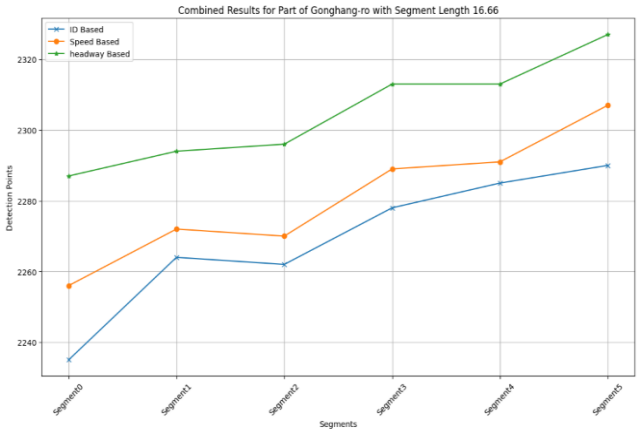

Fig. 7. Congestion detection comparison of the three detection methods using segment lengths of 16.66-meter.

The results in Fig. 7 showed a steady increase in detection points from the first to the last segment for the headway-based method, while ID-based and speed threshold observed a sharp drop in segment 2, then continued to rise till the last segment. With a 16.66-meter length, a clear varying result was observed. Headway has the highest detection points for all six segments, followed by speed threshold, and ID-based has the least.

Similar to results with 16.66-meter segment length, results with 24.99-meter segment length also recorded a drop of detection points on segment 1, as shown in Fig. 8. It was observed that there is a significant difference between the three congestion detection methods in terms of detection points for a 24.99-meter segment length in all four segments.

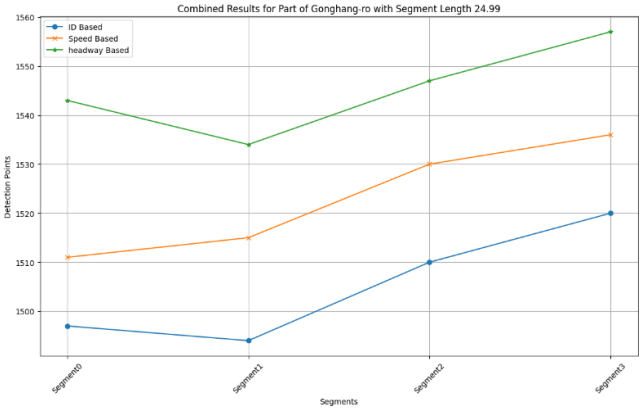

Fig. 8. Congestion detection comparison of the three detection methods using segment lengths of 24.99-meter.

Overall, the results presented show that the ID-based road traffic congestion detection system performed better than the speed threshold (Ahmed, Shariff, and Abubakar, 2024) and headway-based (Ahmad, Chen, and Khan, 2018) in identifying actual congestion in all three different scenarios (8.33m, 16.66m, and 24.99m). ID-based creates a two-layer check by combining density estimation with the speed threshold technique. The ID-based approach employs density estimates to identify congestion that is not bogus congestion after verifying it with a speed threshold.

D. LETA Results

A comparison of the three scenarios—at 8.33meters, 16.66meters, and 24.99 meters—is shown in Fig. 9. The findings indicate that while ETA and ATA are all influenced by speed and the distance between the source and the destination, segments with a length of 24.99 meters have the most significant LETA values in all the segments. The longer the segment distance, the greater the density of the vehicles. Segment 0 has the lowest LETA value in the 24.99 and 16.66 scenarios, as compared to the 8.33-meter scenario, where segment 1 has the lowest LETA value.

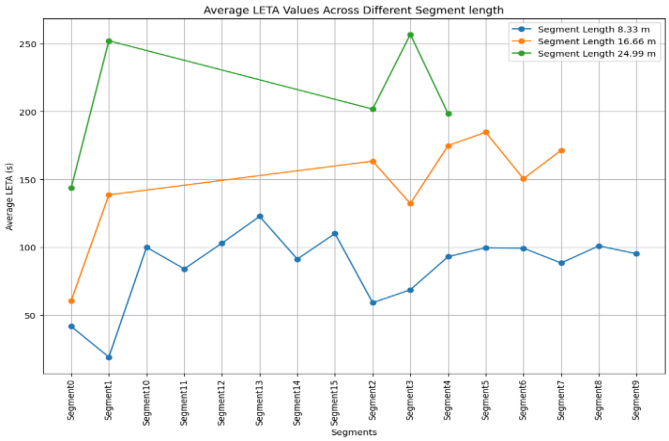

Fig. 9. LETA results over segments for all three scenarios.

A fine-grained LETA study is made feasible by calculating LETA for ten carefully selected vehicles, ensuring that the analysis focuses on specific entities of interest. To produce a combination of the most and least crowded vehicles, ten (10) vehicles were chosen, five with the most traces and five with the fewest. The 10 chosen vehicles are tested in 24.99-meter segments.

Fig. 10 shows the LETA findings for ten (10) chosen automobiles during the simulated period. According to the findings, the LETA of several vehicles, including the JTr450, JBr450, JTx973, JPs973, and JTr832, grows dramatically over time. These are the vehicles with the most traces, and the spikes represent occasions when the vehicles lose a significant amount of time owing to traffic congestion they encountered throughout time. The 5000 to 15000 second LETA spikes observed by several vehicles may represent periods when most vehicles lose time due to traffic or driver behavior. These spikes can indicate specific places or periods of significant traffic congestion.

Throughout the observed time period, vehicles such as JPs967, JTx688, and JPs688 consistently displayed low LETA values, implying that they did not waste much time and most likely moved faster in the absence of significant traffic congestion. All vehicles exhibit low LETA values toward the end of the time period, indicating that they either arrived at their destinations, exited congested regions, or experienced less traffic near the end of their journey.

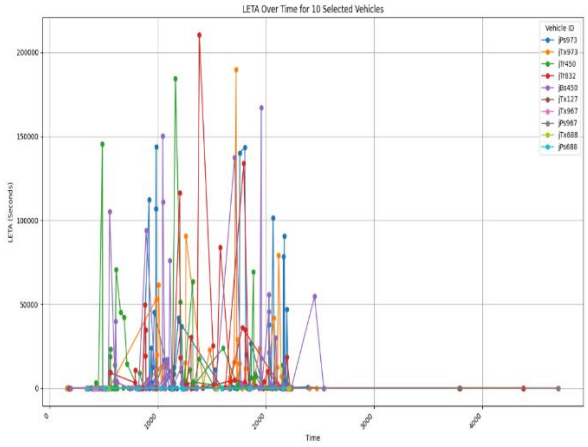

Fig. 10. LETA results of 10 selected vehicles for the entire simulation time.

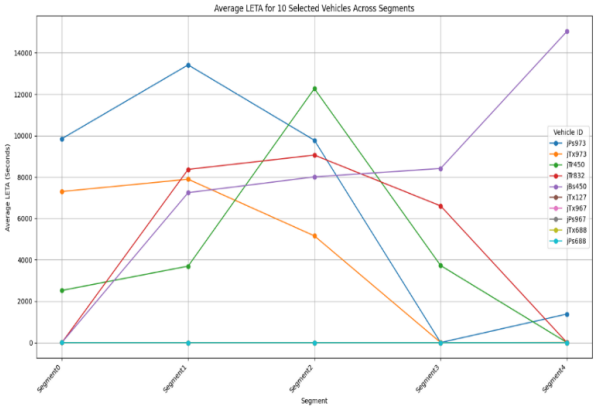

Fig. 11. LETA results of 10 selected vehicles over the segment.

LETA results of the ten (10) selected vehicles are plotted against segments, as illustrated in Fig. 11. The graph depicts the average LETA measurements for 10 distinct vehicles over five (5) road segments of length 24.99. The figure depicts how each vehicle's LETA patterns vary across the segments. Five of the vehicles had a high LETA value, indicating a significant loss of expected arrival time, whilst the remaining five had a continuously low LETA value, indicating smooth movement with little time loss.

Fig. 11 also shows that JPs967, JTx688, JPs688, JTx127, and JTx967 vehicles have a flat trend or almost no decrease in expected time of arrival throughout all segments, with consistently low LETA values, indicating that these vehicles met less traffic on all road segments. Furthermore, Fig. 11 shows that some segments, particularly segments 1 and 2, have higher average LETA values for numerous vehicles, implying that these segments are congested.

Five vehicles with the lowest LETA values and five vehicles with the highest LETA values were analyzed independently to further analyze the results displayed. Fig. 12 depicts the average LETA for five vehicles chosen, as having the lowest LETA along various road segments.

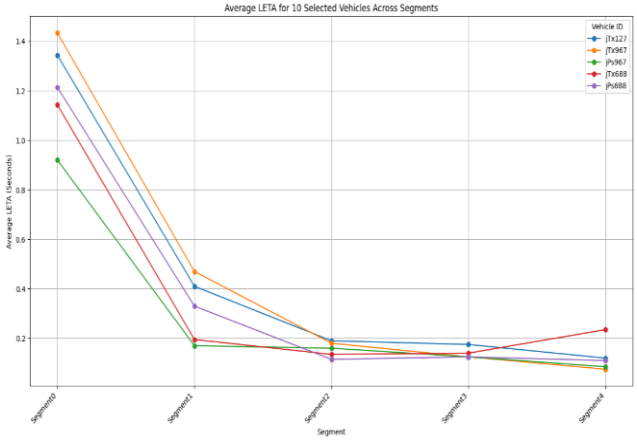

Fig. 12. LETA results of 5 selected vehicles with the least traffic traces.

Fig. 12 shows that each vehicle's LETA decreases significantly from segment 0 to segment 2. This suggests that traffic conditions improved throughout the route since the vehicles' LETA reduced as congestion lessened along the road segments. Only segment 0 of the four vehicles had a LETA value of less than 1 second, while JPs967 had a LETA value greater than 1 second. Between segment 0 and segment 1, the LETA for all vehicles declined by 0.47, and from segment 2 to segment 4, the LETA values for most vehicles remained reasonably steady.

At segment 0, JTx967 has the highest LETA; however, after segment 1, it drops rapidly and stabilizes. Vehicles JTx688 and JPs688 follow similar trajectories, with LETA from Segment1 stabilizing at around 0.2 seconds. JPs967 rises somewhat in Segment 4, but JTx127 and JPs967 continue their downward trajectory.

Overall, the decrease in LETA for each vehicle from segment 0 to segment 1 indicates that the vehicles first encountered traffic, which then subsided after segment 1. In other words, when there was traffic, vehicles moved onto the road, and the bottleneck ultimately disappeared.

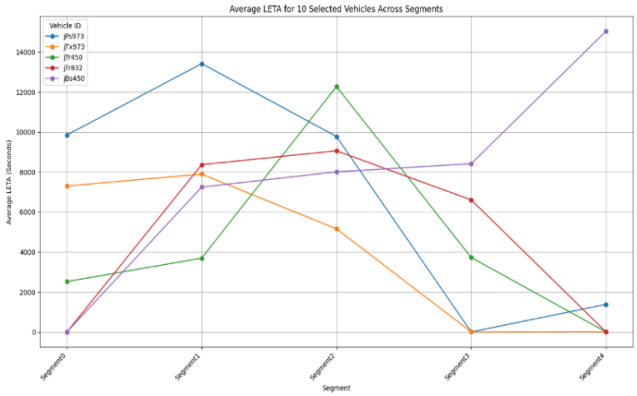

Fig. 13. LETA results of 5 selected vehicles with the most traffic traces.

Fig. 13 displays the average LETA for segment 0 to 4 for the five most congested vehicles (JPs973, JTx973, JTr450, JTr832, and JBs450). The findings shed light on how these vehicles lose LETA when traveling through various parts, whether due to traffic bottlenecks, poor road conditions, or driver conduct.

Fig. 13 indicates that the LETA trend for JBs450 cars is increasing steadily from segment 0 to segment 4, with a particularly noteworthy leap between segment 3 (8413s) and segment 4 (15034s). JTr450 began in segment 0 with a reasonably high LETA value of 2523s, increased to 12271 in segment 2, and then dropped to a low of 7 seconds in segment 4. Vehicle JTr832's LETA grows from 2 seconds in segment 0 to a maximum of 9058 in segment 2, following which it rapidly declines in segment 3 to 4, with segment 4 recording a LETA of 5 seconds.

In segment 0, the JTx973 vehicle had a high LETA value of 7299s. In segment 1, it increased to 7894s, whereas in segment 4, it reduced to 16 seconds. In segment 0, JPs973 has the highest LETA value of 9851s. In segment 1, it climbs to 13416s, whereas segment 3 and segment 4 dip and rise by 3s and 1381s, respectively. Some vehicles experienced increased LETA as they progressed, while others saw LETA drop at the end of their journey. The trend inconsistencies in Fig. 13 suggest that vehicles suffered LETA at different times and segments.

TABLE II. LETA VALUES FOR ALL TEN VEHICLES ACROSS THE SEGMENTS AND THE TOTAL LETA

	Segment0	Segment1	Segment2	Segment3	Segment4	Total LETA
jPs967	0.92	0.17	0.16	0.125	0.085	1.46
jTx688	1.143333	0.195	0.135	0.14	0.235	1.85
jPs688	1.213333	0.33	0.115	0.125	0.11	1.89
jTx127	1.343333	0.41	0.19	0.175	0.12	2.24
jTx967	1.433333	0.47	0.18	0.125	0.075	2.28
jTx973	7299.101	7894.033	5157.802	6.00875	16.84625	20373.79
jTr450	2523.266	3694.31	12271.22	3724.643	7.425	22220.86
jTr832	2.32	8368.568	9058.859	6604.972	5.02	24039.74
jPs973	9851.517	13416.29	9776.06	3.063333	1381.45	34428.38
jBs450	5.62	7243.885	8006.662	8413.615	15034.56	38704.34

Table II displays the LETA values for each segment of the ten vehicles, as well as the total LETA for the entire trip. As previously stated, the table shows that the LETA values for vehicles JTx973, JTr450, JTr832, JPs973, and JBs450 are significantly higher than those for the other vehicles. While the remaining vehicles maintain LETAs below three seconds across all segments, some vehicles have LETAs in the thousands of seconds.

The table also shows that, with a total LETA of 38,704.34 seconds, vehicle JBs450 has the most significant overall time loss across all segments. Surprisingly, the LETA of 15,034.56 seconds is very high in segment 4. Vehicle JPs967, on the other hand, has the least loss of expected time of arrival throughout all segments, with a total LETA of only 1.46 seconds.

E. Discussion

The ID-based results presented showed great improvement compared to MCDP and speed-based congestion detection methods. This is because of the ID-based congestion detection method check vehicle speed and density in order to ascertain congestion on the road segment. It also clear that segment length has a significant impact on ID-based congestion detection, with a 24.99-meter segment length presenting the best performance result of ID-based. Additionally, the results illustrated that a longer segment length allows the ID-based congestion detection system to accurately check for vehicle density, whereas a shorter segment length limits the system's ability to detect congestion using vehicle density. Consequently, the results clearly reveal that segment length has a significant effect on congestion detection.

LETA provided a positive result. A basic method of monitoring traffic congestion in relation to vehicle destination. This provided motorists with awareness and temporal comprehension of their trip by taking into account their arrival time.

These two ways are simple to implement in the RSU of the ITS infrastructure, since it is built on the current V2X communication protocol. Both ID-based and LETA were developed to employ vehicle information, whereas ITS allows vehicles to communicate kinematic information, resulting in no communication overhead.

V. CONCLUSION AND FUTURE WORK

This study developed an ID-based congestion detection method that monitored vehicles' speed and density and loss of expected time of arrival on road segments. ID-based congestion detection method utilizes a vehicle's ID and trajectories contained in vehicular messages. Roads were divided into lengths of 8.33 meters, 16.66 meters, and 24.99 meters using vehicle trajectories. According to experimental results, the ID-based congestion detection method detects actual (true) traffic congestion with long segment lengths.

The ID-based congestion detection system combined the concept of speed threshold congestion detection with density monitoring and was applied to road segments to monitor traffic congestion. Its performance was evaluated against the speed threshold and MCDP congestion detection method. The results presented show that the ID-based congestion detection method detects congestion more accurately. Speed threshold and MCDP detect false congestion when compared with the ID-based

congestion detection method. This work shows that by using two or more congestion detection metrics, traffic congestion can be accurately detected.

This work also defines and calculates LETA by taking into account segment length, vehicle speed, and the road recommended speed. The vehicle's LETA was displayed, as well as their overall LETA for the trip. The results demonstrate that LETA can be an effective measure of traffic congestion because it displays to the motorist how much time they are losing or gaining.

This accomplishment is practical enough to be utilized in road design, moving object monitoring, and might be adapted to analyze traffic congestion in the city. To improve the ID-based congestion detection method accuracy, vehicle density monitoring must take into account the road segment length.

Stock Market Prediction of the Saudi Telecommunication Sector Using Univariate Deep Learning Models

Hadi S. AlQahtani[1], Prof. Mohammed J. Alhaddad[2], Dr. Mutasem Jarrah[3]
Department of Information Technology-Faculty of Computing and Information Technology,
King Abdulaziz University, Jeddah, Saudi Arabia[1, 2]
Department of Artificial Intelligence and Data Science, Applied Science University, Jordan[3]

***Abstract*—Stock market volatility, randomness, and complexity make accurate stock price prediction very elusive, though it is required for logical investment and risk management. This study compares four Deep Learning (DL) models, Long Short-Term Memory (LSTM), Recurrent Neural Network (RNN), Convolutional Neural Network (CNN), and a CNN-LSTM model, to predict the Saudi Telecommunication sector by focusing on the closing price time series. The daily historical closing prices of STC, Mobily, and Zain companies are gathered and preprocessed, involving duplicate removal, feature selection, and Min-Max scaling. Models were trained with MSE loss, whereas validation was done with the RMSE and MAE. The study points toward the ability of deep learning to capture complex nonlinear regression patterns in the ebbs and flows of volatile financial markets. A comparative analysis reveals that the LSTM model yielded the lowest Test RMSE in all cases (Mobily: 1.169705, STC: 0.708495, Zain: 0.27147), therefore, presenting the best overall predictive accuracy. On the other hand, RNN almost always had the highest Test RMSE values (Mobily: 1.688603, STC: 1.143664, Zain: 0.666184), highlighting its limitations. The CNN and CNN-LSTM models showed intermediate performance, with implications for enhanced financial forecasting and decision-making within this specific market segment.**

***Keywords*—Deep learning; stock market; prediction; models; regression; time series**

I. INTRODUCTION

The stock market is complex and difficult to forecast, but it is extremely valuable to financial firms, hedge funds, traders, and market speculators [1]. The share prices are influenced by numerous variables, such as economic factors, worldwide events, company reports, and market sentiment, and are therefore random and extremely difficult to predict [2]. Having the ability to forecast changes in stock prices even slightly and accurately is extremely valuable in designing investment strategies, risk management, and overall financial decision-making [4]. Historically, stock market prediction has evolved over time through various methods. Initially, many employed traditional statistical techniques such as Autoregressive Integrated Moving Average (ARIMA) models [20]. These are simple and suitable when working with stable data, but struggle when dealing with complex patterns and long-term trends often found in finance data [4]. The advancement of machine learning, particularly approaches through deep learning, has significantly transformed financial prediction. Deep learning models are distinctive in that they are able to learn from past data without depending on pre-set mathematical formulas. This is helpful in finding underlying relationships in data that linear models may not detect [9]. That is why they are particularly suitable for the fast and dynamic character of stock market data [13]. The objective of this study is to answer the question: Which deep learning architecture—RNN, LSTM, CNN, or a hybrid CNN-LSTM—provides the highest predictive accuracy and robustness in a univariate stock market forecasting? It closely examines and contrasts the predictive capabilities of individual deep learning models on the Saudi Telecommunication market. This study hypothesizes that of the selected models of deep learning (LSTM, RNN, CNN, and CNN-LSTM), the Long Short-Term Memory (LSTM) network forecasts closing stock prices of the Saudi Telecommunication industry more accurately. The reason is that LSTM is designed to learn long-term patterns in sequence data [21]. A lot of financial literature on deep learning in financial markets exists, but requires powerful and precise models on a specific stock market that forecast daily closing stock prices based on a single variable in various market scenarios. This research investigates this requirement by studying the Saudi Telecommunication sector, which is significant but not as frequently researched as major international stock indices. This study will provide useful information regarding how the new models perform in an evolving market.

This research compares various approaches in the field of stock market prediction, which has not been researched much, and it provides additional evidence. How the research is described illustrates how it was conducted, making it simple for other researchers to conduct the research again and comprehend it. It also acts as a useful guideline for additional research in this area. The research indicates that, despite being complex, deep learning models are more capable of examining stock market trends and providing a more accurate means of predicting them [24].

The remainder of this study is structured as follows: Section II examines in detail significant research regarding deep learning models applied to time series prediction. Section III describes the methods, such as how data was gathered and prepared, and how the model was constructed and trained.

Section IV presents the results of the model tests across each company. Section V discusses what these results imply, including model comparison and the study's limitations. Finally, Section VI concludes the study by outlining the major findings and providing recommendations for future research.

II. Literature Review

Deep learning models are powerful predictors of time series. They are capable of learning intricate patterns and long-term correlations without the necessity of specific feature engineering [6]. Deep models are particularly effective in detecting trends in the stock market, which usually exhibits chaotic and non-linear tendencies [13].

A. Recurrent Neural Networks (RNNs)

Recurrent neural networks tend to be appropriate when the data comes in sequence and when the position of components within it matters. RNNs have loop markings that feed-forward networks do not have. At a particular instant in time, when the output of a neuron is generated, this output is fed into the RNN as an input for the subsequent time. The name loop comes from the fact that the state in the network, called the hidden state, is retained in RNNs. They can learn patterns and relationships in sequences [1]. Hence, they can perform well over time series forecasting, as the input data is sequential, and the past step information can be recalled. The main problems of RNNs are the so-called vanishing gradient problem. When being trained, the network learns backwards; however, gradients tend to become very small with a large number of time steps, making the network difficult to learn from past data [2]. These make RNNs forget salient details from earlier steps and lack the capability to recall long sequences and times. RNNs could also suffer from overfitting, especially when considering noisy and unpredictable data such as stock prices.

The inherent recurrent structure of RNNs allows the design of a model of sequential correlations unavailable to feedforward networks [4]. Nonetheless, it is difficult for vanilla RNNs to handle longer sequences because these models have issues with exploding/vanishing gradients [14]. RNNs with memory solve this problem using gated memory cells that help with long-term dependency. The recurrent connections allow RNNs to capture temporal dependencies within the series of observations [16]. In [17], the authors discussed deep learning stock forecasting models and noted that RNNs with memory can identify temporal dependencies that are not extractable by other models.

B. Long Short-Term Memory (LSTM) Networks

LSTM came into being as an enhancement to the Recurrent Neural Network to address the vanishing gradient problem. According to research [3], LSTMs help to learn long-range patterns in sequential data. LSTMs achieve the feat because of their special inner architecture consisting of "memory cells" and three distinct "gates": the input gate, the forget gate, and the output gate [3]. These intelligent gates decide how information flows in and out through the cell state and assist the network in knowing what to remember and what to forget over time. The majority of authors who write about it assert that LSTM outperforms the basic RNN and other simplistic models in stock price forecasting. Particularly, LSTM models are mostly regarded by researchers as somewhat more accurate in stock price forecasting. Experimenting further, it has been established that the LSTM tends to make fewer errors than RNNs, especially when it comes to short-term forecasting [8].

Researchers of [10] proved that LSTM networks perform better on financial time series data characterized by nonlinearity and nonstationarity. Furthermore, they refined the algorithm to improve its predictive accuracy. In [12], the authors proposed a strong LSTM model coupled with sentiment analysis to improve stock price prediction accuracy, proving the robustness of the model in the noisy financial market. In [24], the authors confirmed that LSTM consistently outperforms RNN and CNN models in long-term prediction, thereby cementing its suitability for financial time series.

C. Convolutional Neural Networks (CNNs)

In [3], the authors noted that CNNs can be very effective at modeling short-term stock price changes, although CNNs have more trouble with long-term dependencies compared to LSTM models. A time series CNN typically contains convolutional layers. Pooling layers, such as max pooling, which reduce features to a smaller size, are followed by convolutional layers. This retains relevant features but with reduced data. Additionally, the output of these layers is converted into a 1D vector and then passed through one or more fully connected layers. These layers perform the bulk of the predicting, such as future stock prices [5].

In [7], the authors proved that CNN-based models are competitive, especially when combined with other architectures. CNNs are renowned for dealing with images and spatial information. CNNs have been used for stock market prediction, leveraging their ability to model local trends and patterns in sequential data. CNNs have also been transformed smartly to deal with 1D time series information [7]. The transformation employs convolutions on a time axis to enable CNNs to detect local patterns, features, and trends in sequential data [24].

D. Hybrid CNN and LSTM Models

The primary motivation for combining the use of both CNNs and LSTMs, is to capitalize on what each system excels at. This is a combined approach, typically beginning with a CNN scanning the raw time series data for significant, general patterns [3]. The product of these CNN layers, typically following pooling and converting it into a sequence, is then passed as input to the LSTM layers.

In [6], the authors also pointed out that hybrid models would have higher prediction accuracy at the cost of increased computational complexity. This collaboration is intended to provide a stronger insight into the time series data, including close as well as long-term connections, which typically results in more accurate prediction outcomes, as compared to the use of each model in isolation.

In [8], the authors clarified that a CNN-LSTM model performs better than single CNN and LSTM models on stock prediction tasks. Researchers of [24] proposed a hybrid CNN-LSTM model for stock forecasting and improved performance over single models by capturing both spatial patterns and temporal dependencies.

E. Comparing Various Methods of Predicting Stocks

Research papers typically compare various deep learning algorithms used in predicting stock prices, such as LSTM, RNN, and CNN ([1]-[5], [24]). The majority of these papers indicate that LSTM is typically the highest performing because it is capable of handling long-range dependencies in sequential data [5]. Other papers discussed that CNNs and RNNs are also not bad, but hybrid models such as CNN+LSTM—trained with single-price data—make minimal improvements [7]. Increasingly, more researchers are employing hybrid models to ensure predictions are accurate and dependable. According to [8], hybrid models attempt to address the issues of standalone models through the union of multiple types, frequently doing so better by blending the spatial knowledge of CNNs with the temporal considerations of RNNs or LSTMs.

III. Methodology

This study utilizes a deep learning structure, and it focuses on applying single-variable models in stock market prediction. This study entails the application and comparison of four different deep learning structures: Long Short-Term Memory (LSTM), Recurrent Neural Network (RNN), Convolutional Neural Network (CNN), and a hybrid of CNN and LSTM on the Saudi Telecommunication sector stock market.

A. Data Collection

Historical closing prices were obtained daily from the Yahoo Finance API. The source is reliable and easily accessible for financial data [15]. The companies chosen from the Saudi Telecommunication sector and their respective Yahoo Finance tickers are STC (7010.SR), Mobily (7020.SR), and Zain (7030.SR). Specifying the companies and tickers makes the dataset readable and easily reproducible. Under the single feature scheme of this study, the "Close" price per share was utilized as the only input.

B. Preprocessing Data

Accurate data preparation is paramount to the performance and strength of deep learning algorithms. The following cleaning processes were done:

1) Duplicate records were meticulously removed from the collected dataset to ensure data consistency, accuracy, and integrity.

2) As the study takes one thing at a time into consideration, only the "Close" price for each stock was kept for the model. All other potential features, such as Open, High, Low, and Volume, were excluded.

3) Min-Max Scaling is employed for normalizing the input data. It scales data linearly to a bounded range [0, 1]. Scaling enhances model convergence and numerical stability in gradient-based deep learning. The mathematical Formula (1) for Min-Max Scaling is expressed as:

$$x_scaled = \left(\frac{x - min(x)}{(max(x) - min(x)}\right) \quad (1)$$

4) Preprocessed data was divided into an 80/20 train and test split to estimate generalization and avoid overfitting.

5) Windowing/Sequence Preparation was done. We used sliding windows to create input-output pairs of data, a common practice in time series deep learning.

C. Model Building

Each company had four different deep learning models to predict stock prices using one variable. Choosing proper hyperparameters, that is, the number of layers, units (neurons) per layer, dropout rates, learning rates, batch sizes, and epochs, is very important to improve the performance of the deep learning model. The precise hyperparameter values are not given in the data, but the parameters are generally adjusted by careful methods so that the performance is optimal, facilitates convergence, and reduces problems like overfitting. Common optimizers like Adam are generally used to train such models.

D. Long Short-Term Memory (LSTM)

LSTM architecture is crafted to identify long-term trends in sequential data. It solves the common issue of vanishing gradients in standard RNNs [11]. Its building blocks therein—input gate, forget gate, output gate, and cell state—make this possible. These clever gates control the flow of information, making it possible for the network to determine what to retain or ignore through long sequences. The mathematical Formula (2) to Formula (5), governing the operations within an LSTM cell, are as follows:

$$\text{Input Gate} = i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i) \quad (2)$$

$$\text{Forget Gate} = f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f) \quad (3)$$

$$\text{Output Gate} = o_t = \sigma(W_o x_t + U_o h_{t-1} + b_o) \quad (4)$$

$$\text{Cell State Update} = c_t = f_t \times c_{t-1} + i_t \times tanh(W_c x_t + U_c h_{t-1} + b_c) \quad (5)$$

$$\text{Hidden State Update} = h_t = o_t \times tanh(c_t)$$

where,

x_t is the current input vector

h_{t-1} is the previous hidden state vector

c_{t-1} is the previous cell state vector.

W is the Weight matrix for the input

U is the Recurrent weight matrix for the hidden state

B is the bias vector

σ is the Sigmoid activation function

tanh: Hyperbolic tangent activation function.

This detailed mathematical formulation demonstrates the internal workings of the LSTM and its fundamental advantage over simpler RNNs in handling long-term dependencies, which is crucial for capturing the complex patterns in stock price movements.

E. Recurrent Neural Network (RNN)

The Recurrent Neural Network (RNN) is the basic model used to predict time series in this study. Its fundamental building block is with recurrent connections, where a neuron's output at a given time is reused as input to the network at the

next time [18]. This feedback mechanism allows the network to have a "hidden state", a memory that processes information in a sequence. The Formula (6) and Formula (7) for an RNN cell, describing how it works, are:

$$\text{Hidden state} = h_t = \sigma(W_x x_t + W_h h_{t-1} + b_h) \quad (6)$$

$$\text{Output} = y_t = \sigma(W_y h_t + b_y) \quad (7)$$

where,

xt is the current input vector

ht−1 is the previous hidden state vector

ht is the current hidden state vector

yt is the current output vector

Wx is the weight matrix for the input

Wh is the recurrent weight matrix for the hidden state

Wy is the weight matrix for the hidden state to output

bh, by are the bias vectors

σ is the activation function (typically sigmoid or tanh).

Including the RNN formula gives the explicit mathematical difference from LSTM. This explains why LSTMs were created and why LSTMs usually work better with long sequences. It shows how deep learning models have progressed in time series analysis.

F. Convolutional Neural Network (CNN)

The CNN architecture is adapted to handle time series data for the purpose of capturing local patterns and features in sequences [5]. Adaptation is mainly done through one-dimensional (1D) convolutions, which are apt for handling time data by identifying "spatial" patterns along the time axis [19]. The architecture generally comprises:

1) Convolutional layers: These layers have filters (known as kernels) that move over the 1D input data. Every filter applies a convolution operation to extract local patterns or features from subsets of the time series.

2) Pooling layers: Convolutional layers are usually followed by pooling layers, like Max Pooling, to decrease the feature maps' size. This lowers their size without losing the important features, making the model work better with small changes in input and lessening the computation involved [23].

3) Flattening and fully connected (dense) layers: The feature map output of the convolutional and pooling layers is flattened into a 1D vector. This vector is fed into one or more fully connected (dense) layers that learn useful features and carry out the final regression task [23].

4) Output layer: For predicting one type of time series, the output layer generally has one neuron to predict the future value of the stock price. The main operation of a 1D CNN is defined by the discrete convolution Formula (8):

$$(f * g)[n] = \int_{m=-\infty}^{+\infty} f[m] \cdot g[n - m] \quad (8)$$

where,

f is the input signal (the time series data)

g is the convolutional filter (kernel)

n is the position of the output element

The formula is the general definition of discrete-time convolution [22]. It continues by sliding the filter over the signal, multiplying the filter by the corresponding part of the signal at each element, and adding the outcomes to create one output point. This move reflects how methods of identifying patterns in space, normally used in images, can be used in time-based data. This shows how flexible deep learning systems are [2].

G. Combination of CNN and LSTM Model

This model is a hybrid architecture that combines synergistically the strengths of Convolutional Neural Networks (CNNs) for learning features and Long Short-Term Memory (LSTM) networks for learning sequences [3]. The architecture is made up of an early CNN component that takes in the raw time series data. This CNN block extracts important characteristics and neighborhood trends, for example, detecting some of the price changes or trends in short-time periods, from the given sequence [7]. Whatever emerges from these CNN layers, after pooling and transforming into a sequential representation, is then offered as input to the LSTM blocks. The LSTM layers then learn significant connections and timing relationships from these prepared, detailed sequences [8]. The primary reason to use this combined approach is to take advantage of the strengths of both model types: CNNs are strong at extracting powerful local patterns and reducing the size of the input [12], while LSTMs are extremely capable at interpreting time-based sequences and remembering long-term connections [12]. This is a combination to provide greater insight into the time series data, potentially providing improved predictions compared to the use of singular models [24]. The hybrid model is an ingenious method, combining the positives of each method in time series analysis, indicating the sophistication of the study.

H. Model Training

We primarily utilized Mean Squared Error (MSE) for training all the models as the loss function. We can calculate MSE with the help of Formula (9):

$$MSE = \frac{\sum_{i=1}^{n}(yi-pi)^2}{n} \quad (9)$$

where,

yi is the observed value

pi is the corresponding predicted value

n is the number of values

MSE calculates the average of the squared errors or differences, representing the average squared difference between actual and predicted values. It is typically utilized for regression problems and provides more weight to large errors compared to small errors. To verify how well the models perform on the training as well as test datasets, we utilized Root Mean Squared Error (RMSE) and Mean Absolute Error (MAE) as crucial measures.

The RMSE Formula (10) is:

$$RMSE = \left(\frac{(\Sigma(P_i - O_i)^2)}{n}\right) \quad (10)$$

where,

Pi is the value predicted

Oi is the observed value

n represents the data points.

RMSE indicates the amount of error, expressed in the same units as the target variable. All input features were normalized to the range [0,1] prior to training. The RMSE values were computed directly in the normalized space; therefore, they are unitless and represent error relative to the scaled data range. The MAE Formula (11) is:

$$MAE = \left(\frac{(\Sigma|y_i - p_i|)}{n}\right) \quad (11)$$

MAE takes the average of the difference between actual and predicted values. MAE is less sensitive to outlier values compared to RMSE and directly indicates the average magnitude of the error. In RMSE and MAE, lower values indicate good prediction and better model performance. For regression problems in time series forecasting, it is typical to use MSE as the loss function and RMSE/MAE as the measure in assessing performance. This ensures we evaluate model performance to acceptable standards in academia.

IV. Results

In this section, we display the results from the model tests of all three Saudi Telecommunication companies. The performance metrics, such as Train RMSE, Train MAE, Test RMSE, and Test MAE, for every deep learning model are presented in clear, readable tables, together with a summary, indicating key facts for each company.

Table I and Fig. 1 illustrate the performance of each of the four deep learning models on Mobily's stock price data. The findings indicate how accurate each model was in forecasting Mobily's prices, in that we can now compare the training and testing errors of the models. This is necessary for knowing how well the models can perform on new data and selecting the best model for this particular stock. For Mobily, the LSTM model recorded the smallest Test RMSE (1.169705) and Test MAE (0.913336), indicating that it was the most capable of forecasting new data out of the models. The RNN model registered the highest error rates in all metrics, indicating that it was not able to follow the exact changes in Mobily's share prices. The CNN and CNN+LSTM models performed well, with the hybrid model performing slightly better than the standalone CNN.

Table II and Fig. 2 present the performance measures of STC's stock price data for the deep learning models. For STC, LSTM performed the best with the lowest Test RMSE (0.708495) and Test MAE (0.518296), indicating that it can predict well. CNN performed the worst with the highest Test RMSE (1.784101) and MAE (1.270669), indicating that it was the most challenged by the STC data among the models. The hybrid CNN+LSTM performed better than the standalone CNN and RNN, but not as well as LSTM on Test RMSE and Test MAE.

TABLE I. Model's Performance for Mobily (7020.SR)

Model Name	Train RMSE	Train MAE	Test RMSE	Test MAE
LSTM	1.203972	0.785214	1.169705	0.913336
RNN	2.168396	1.809754	1.688603	1.334345
CNN	1.571197	1.00751	1.41664	1.115295
CNN + LSTM	1.388986	0.875195	1.388765	1.114691

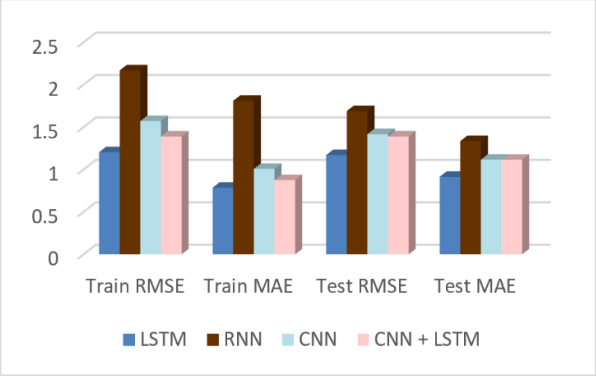

Fig. 1. Model's performance for Mobily (7020.SR).

TABLE II. Model's Performance for STC (7010.SR)

Model Name	Train RMSE	Train MAE	Test RMSE	Test MAE
LSTM	0.66395	0.367212	0.708495	0.518296
RNN	0.816863	0.494815	1.143664	0.906338
CNN	0.923335	0.533309	1.784101	1.270669
CNN + LSTM	0.780187	0.533703	1.027295	0.7784

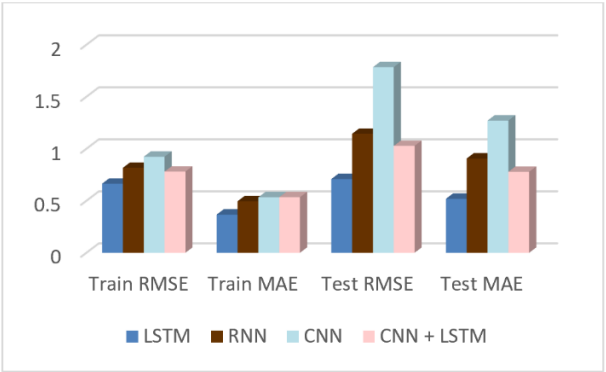

Fig. 2. Model's performance for STC (7010.SR).

TABLE III. Model's Performance for Zain (7030.SR)

	Train RMSE	Train MAE	Test RMSE	Test MAE
LSTM	0.446717	0.265711	0.27147	0.215682
RNN	0.770948	0.657144	0.666184	0.625866
CNN	0.518339	0.331256	0.302271	0.22412
CNN + LSTM	0.45294	0.281391	0.291989	0.223768

Table III and Fig. 3 present the last results for the third company. It provides the information required to make a complete comparison. It tells how the deep learning models performed with Zain's stock price data. For Zain, LSTM performed best with the smallest Test RMSE (0.27147) and Test MAE (0.215682). The CNN model also performed extremely well for Zain, placing next to the LSTM in both test metrics. The RNN model performed the worst, similar to Mobily and STC's. The CNN+LSTM hybrid model performed equally well as the pure CNN, and both are good options to forecast Zain's stock.

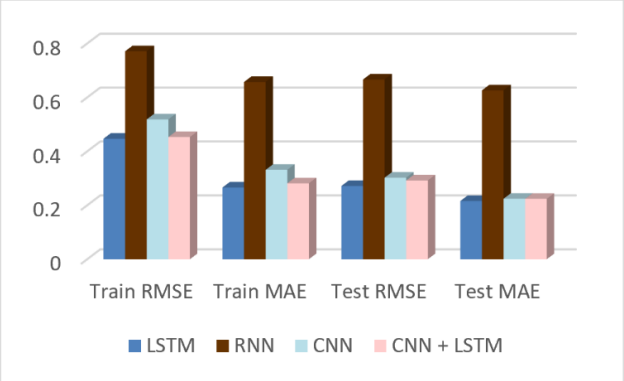

Fig. 3. Model's performance for ZAIN (7030.SR).

V. Discussion

The data in Tables I, II, and III indicate the performance of the deep learning models for three Saudi Telecommunications companies. The trend was consistent: the LSTM model always produced the lowest Test RMSE and Test MAE for Mobily, STC, and Zain, and thus was the most successful at forecasting accurate values from new data. Its consistency demonstrates the ability of LSTM to learn long-term trends and bypass the vanishing gradient problem, as cited in studies [11], and in this case, it is highly beneficial in forecasting stock prices.

A. Comparative Analysis of Models

LSTM performed stronger than the RNN models since the basic RNN model had the largest errors (MAE and RMSE) across all three firms. This is expected and is noted in other research regarding issues with simple RNNs and their lack of ability to address the vanishing gradient problem. This signifies that the models are unable to learn and remember information from long sequences [14]. This large disparity is why complex models such as LSTM were developed to address the primary issues of handling sequence data. The CNN model performed differently for each of the companies. It generally outperformed the RNN but did not always match up with the LSTM in terms of accuracy. In the case of Mobily and STC, the Test RMSE of the CNN was poorer than LSTM. Yet for Zain, the CNN model performed very competently with its Test RMSE (0.302271) and Test MAE (0.22412) close to the best of the LSTM (0.27147 and 0.215682, respectively). This indicates that CNNs are able to capture local trends and abrupt changes in the stock prices as reported in previous research ([5], [11]). The good performance for Zain can imply that its stock price variations have cleaner local trends or short-term trends that are easy for CNNs to detect. The CNN+LSTM hybrid model attempted to leverage the strength of CNN in discovering features and LSTM's ability in sequence learning. This was supposed to yield improved prediction, as various works demonstrate regarding hybrid models ([24], [3]). In the case of Mobily, the hybrid model performed slightly better than the sole CNN in Test RMSE. In the case of STC and Zain, its accuracy was comparable to or superior to single LSTM or CNN. This indicates that even if the hybrid approach is powerful, its benefits over an excellently designed single LSTM model for forecasting individual stock prices could be minor. The increased complications and computational demand of hybrid models do not always result in significantly superior performance, particularly if the data does not require both spatial discovery of features and long-term modeling of time [17].

B. Implications of Findings

It is vital to investors, traders, and decision-makers who make financial decisions in the Saudi Telecommunication market. LSTM has been performing better than any other model and has proven to be able to predict closing prices accurately every day. Identifying the best model will assist in the creation of automated trading systems or efficient forecasting tools for the market [9]. Accurate forecasts with minimal errors will provide useful information about the change in stock prices. This will assist in making more prudent investment decisions, identifying more profitable times for selling and buying, and developing more efficient risk management plans. Employing deep learning algorithms will assist in the analysis and prediction of this volatile market sector [19].

C. Limitations Addressed by this Study

This study addresses the limitations of previous research by conducting a comprehensive comparative analysis of four deep learning methods—LSTM, RNN, CNN, and a hybrid CNN+LSTM—applied to the Saudi Telecommunication sector, which encompasses three major companies and three distinct datasets. Unlike previous studies that typically rely on a single model or limited datasets, our research evaluates and compares the performance of these models across multiple datasets to enhance predictive accuracy and establish a strong basis for comparison. In doing so, this study not only identifies the most accurate predictive model for the sector but also offers practical insights into the trade-offs between model complexity and predictive performance. Moreover, by focusing on the Saudi Telecommunication market, the research fills an important geographic and industry-specific gap in the literature, providing contributions of both academic significance and practical value. Table IV summarizes the limitations of previous studies that are addressed by this study.

TABLE IV. LIMITATIONS OF PREVIOUS STUDIES ADDRESSED BY THIS STUDY

Limitations in Previous Studies	How This Study Bridges the Gap
Focus mainly on a single model (often LSTM, CNN, or LSTM-CNN).	Provides a comprehensive comparison of four deep learning models, including hybrid methods.
Use of univariate or limited datasets.	Applies models to major datasets of three companies in the Saudi telecommunications sector, giving broader validation.
Hybrids often add complexity with minimal evaluation of their true advantage.	Evaluates hybrid performance against standalone models to determine if the added complexity is justified.
Research concentrated on the US, Chinese, or Indian markets, etc.	Extends to an underexplored market (Saudi Telecom sector), contributing localized insights.

D. Limitations of the Study

This study provided useful information, but there exist certain limitations that need to be acknowledged. The model only examined the "Close" price as the input variable. This is less complicated to investigate trends in one variable, but it reduces the model's capacity to observe the complete picture of the stock market. Stock prices are influenced by various factors, such as Open, High, Low, and Volume prices, as well as external economic indicators, news sentiments, and technical indicators. Employing the multiple-variable method with the inclusion of the additional factors could result in improved and precise predictions [6]. It is greatly significant to tune the hyperparameters to achieve quality results from deep learning models [10]. These conclusions benefit the Saudi Telecommunication market but need to be examined in other markets, other contexts, or other financial markets in other nations without further tests. The unique characteristics of the market, regulation, and investors' behavior elsewhere could influence the extent to which the model works [22].

VI. CONCLUSION

This study examined the performance of four deep learning models. These models are LSTM, RNN, CNN, and a combination of CNN and LSTM. The above models were employed to predict stock prices for the Saudi Telecommunication industry. The study developed and evaluated the models using daily closing prices of Mobily, STC, and Zain. This involved meticulous data preparation and common performance-measuring methods. The overall outcome indicates that the LSTM model performed better than the other two models for all the companies. That is, it is able to learn long, non-linear, and complex patterns in stock prices. The RNN model had the largest errors, indicating that it does not handle long sequences well. The CNN model performed with mixed results, but performed exceptionally well for Zain, indicating that it is capable of identifying local patterns. The hybrid CNN+LSTM model, although a good concept, provided minor improvements over the single models in this instance. The comparison and analysis benefit the field of computational finance and deep learning in finance.

From the concepts of this research, future research should therefore consider integrating additional features such as Open, High, Low, Volume, technical indicators, and external variables (e.g., economic news, market sentiment) to enrich the predictive capacity of the models. Experimenting with advanced hybrid architectures and ensemble methods, which could better exploit the strengths of different models and capture both long-term and short-term dependencies. Expanding the application to other industries, sectors, and international markets to test the robustness and adaptability of the models under diverse financial environments.

In conclusion, this research underscores the continued dominance of LSTM in stock price forecasting, while also opening the door for refined CNN-based and hybrid approaches. By situating these results in the context of the Saudi telecommunications sector, the study provides a foundation for both academic inquiry and practical application in financial forecasting.

A Systematic Review of Multilingual Plagiarism Detection: Approaches and Research Challenges

Chaimaa BOUAINE, Faouzia BENABBOU, Zineb Ellaky, Amine BOUAINE, Chaimae ZAOUI
Laboratory of Artificial Intelligence and Systems, Faculty of Sciences Ben M'Sick, Hassan II University, Casablanca, Morocco

***Abstract*—The existence of voluminous multilingual sources on the web in different fields creates numerous issues, including violations of intellectual property rights. For that, the multilingual plagiarism or cross-language plagiarism detection (CLPD) has become a great challenge, which refers to copying content from a source text in one language into a target text in another without proper attribution. This study presents a systematic literature review (SLR) of methodologies used in CLPD covering works published between 2014 and 2025. This literature review summarizes and diagrams the different approaches used for CLPD. We propose a classification of the different representations of multilingual texts into four types: traditional approaches, multilingual semantic networks, fingerprinting methods, and deep learning models. In addition, we have carried out an in-depth analysis of ten language pairs, have focused on the approaches employed, including translation strategies, feature extraction approaches, classification techniques, similarity methods, dataset types, data granularity, and evaluation metrics. Among the fulfilled results, English appears in 98% of language pairs, and the English-Arabic pair stands out as the most studied. Over 60% of studies involve a translation phase with Google Translate as the most frequently used tool. The mBART model achieves over 95% accuracy for English-Spanish, English-French, and English-German, while BERT reached 96% for English-Russian. As for the assisted translation study based on the Expert translation tool, strong results are obtained for English-Persian, with an accuracy of 98.82%. On the whole, transformers offer better results in several language pairs without the need for translation.**

Keywords*—Multilingual plagiarism; systematic literature review; multilingual text representation; translation approaches; natural language processing; machine learning; deep learning

I. Introduction

Easy access to scientific and, more specifically, academic documents is a major asset for academic research. However, it is a double-edged sword, as it has led to an increase in intellectual property infringements: users do not always mention source documents. Today, in a multilingual environment, the rich existence of translation tools has further increased this problem and encouraged the growth of CLPD, where content is copied from one language and translated into another. Plagiarism is broadly defined as the unauthorized use or imitation of another person's work, ideas, or expressions, presented as if they were one's own, without attribution [1],[2]. It can take many forms, including plagiarism of ideas [3], verbatim copying and pasting [4], self-plagiarism [5], paraphrasing [6], and translation [7]. CLPD particularly refers to the act of translating content from one language to another, frequently involving paraphrasing or altering the format to mask the source [8]. There are two main types of plagiarism detection techniques: intrinsic and extrinsic. To find potential parallels, extrinsic approaches evaluate a suspect text by comparing it with information from other sources, such as databases or published documents [9],[10]. This technique works well for identifying cut-and-paste, translations, and basic paraphrases, but its effectiveness depends on the caliber and scope of the reference material used. Intrinsic methods focus on internal components such as lexical diversity, sentence structure, and writing style. Without using an external corpus, they can identify stylistic irregularities that may be signs of plagiarism [11], [12].

The CLPD system presents significantly more complex challenges than monolingual plagiarism detection due to the linguistic and cultural diversity between source and target texts. Firstly, the language barrier makes it difficult to directly identify similarities when texts are written in different languages [13]. Secondly, reliance on machine translation systems can introduce semantic or syntactic errors and compromises the reliability of post-translation comparisons [14]. Moreover, authors intending to conceal plagiarism may reformulate ideas using stylistic variations [15] and paraphrasing specific to the target language [16], making it even harder to detect correspondences. Finally, in many cases, there are no aligned parallel resources or sufficient bilingual corpora for certain language pairs, which limits the effectiveness of approaches based on comparable or aligned corpora [17].

To meet these challenges, CLPD relies on several main approaches. The first is to use machine translation to convert documents into a common language, and then apply traditional text-matching methods [18]. Although simple, this strategy is highly dependent on the quality of the translation. A second approach avoids direct translation by using multilingual embedding models that project texts from different languages into a shared vector space, enabling direct semantic comparison [19]. Another method uses knowledge graphs, where multilingual semantic networks such as WordNet are employed to represent conceptual relationships between terms [20]. Finally, the fingerprinting technique extracts distinctive features (such as n-grams) from texts and compares them across languages [21]. These approaches make it possible to identify semantic similarities without relying solely on word-for-word translation.

This study aims to conduct an SLR of CLPD. To the best of our knowledge, only one article has addressed multilingual text plagiarism detection [22]. It is crucial to conduct a review of the existing reviews on CLPD because the field of CLPD detection is constantly evolving, and new methods and techniques are being developed. This SLR covers research on CLPD techniques published between 2014 and 2025 and addresses

various Multilingual Text Representation Strategies. This SLR study offers a concise and clear summary of the methodology currently used in CLPD. Our work provides a comprehensive analysis of all phases involved in CLPD, including data preprocessing, feature extraction, models used, similarity measures, and dataset utilization. Additionally, we extracted a taxonomy of methodologies employed in CLPD, a level of methodological integration and synthesis that had not been thoroughly addressed in prior state-of-the-art research.

The significant contributions of this research work are as follows:

- Comprehensive review of most studies addressing CLPD.
- Proposition of a systematic classification of multilingual text representations into four main categories: traditional approaches, multilingual semantic networks, fingerprinting methods, and deep learning models.
- In-depth analysis of ten language pairs, emphasizing the approaches employed, including translation strategies, feature extraction methods, classification techniques, similarity measures, dataset types, data granularity, and evaluation metrics.
- Detailed examination of detection techniques specific to each language pair.
- Proposition of an architectural framework for CLPD, integrating the insights gained from the literature and the conducted analyses.

This research study is structured as follows: Section II presents the related work. Section III presents the systematic review methodology. Section IV offers an overview of the state-of-the-art techniques in CLPD, examining the considered language pairs, feature extraction strategies, datasets, and model performances. We present the analysis of the research questions and structure the analysis into two distinct parts for better clarity and understanding. The first part provides a general overview and examines all the approaches used for CLPD. The second part focuses on a detailed and specific analysis of each language pair. In Section V, we generate the architectures employed in CLPD methods and results. And, we highlight promising research directions that remain largely unexplored. Finally, we summarize the main results and shed light on future work in Section VI.

II. Related Work

This section aims to present a summary of studies on CLPD approaches, exploring various approaches and techniques developed between 2014 and 2025. We analyze the studied language pairs, feature extraction strategies, datasets, and model performances. This review highlights the progress made through the integration of advanced models, such as transformers, and the use of multilingual resources while identifying persistent limitations, particularly for under-resourced languages. To structure this analysis, we classify existing works into four main categories based on the feature extraction step: 1) traditional approaches, encompassing classical word embedding techniques such as Word2Vec, TF-IDF, as well as statistical methods like LSI (Latent Semantic Indexing) and SVD, which rely on algebraic transformations; 2) transformers & deep learning, including modern neural-based models such as transformers like BERT, XLM-R, as well as deep learning architectures like GRU, which learn contextualized text representations through neural networks; 3) approaches based on Multilingual Semantic Networks (MSN) such as WordNet, BabelNet, which rely on predefined linguistic knowledge rather than statistical or neural-based learning, often combined with similarity measures such as Wu-Palmer (WuP), Lin, and Jaccard for Cross-Lingual (CL) text similarity assessment; and 4) fingerprinting techniques, which use text fingerprinting techniques like Winnowing, N-grams, and hash-based techniques to capture distinct textual patterns and structures for plagiarism detection and text similarity assessment. A systematic comparison of previous research is easier due to this classification, which clearly distinguishes various methods according to how they represent text and extract features.

A. Traditional Approaches

The authors of this paper [23] proposed a method named CL-WE-Tw, which combines word2vec with part-of-speech (POS) features, the Term Frequency-Inverse Document Frequency (TF-IDF) weighting technique, and MUSE for the Arabic-English (Ar-En) language pair. The proposed model achieved a Pearson correlation (PC) of 81.47% on the SemEval-2017 dataset. In [24], the authors presented an approach for Ar-En CLPD using several techniques, including CL Conceptual Thesaurus-based Similarity Continuous Bag-of-Words (CL-CTS-CBOW), CL Word Embedding Similarity (CL-WES), and Inverse Document Frequency (IDF). The IDF method achieved an F-score of 88% at the word level and 82.75% at the sentence level on four datasets (Books, Wikipedia, EAPCOUNT, and MultiUN). A method to measure semantic textual similarity for Spanish and English (Es-En) sentences was proposed in [25] to detect CLPD. The techniques include CL-CnG (character n-grams), CL-CTS (conceptual thesaurus), CL-WES (word embeddings), and T+WA (word alignment after translation), as well as supervised and unsupervised combinations, notably using the M5' model. The method achieved a correlation of 88.02% on SemEval-2016 and 83.02% on the SNLI corpus of SemEval-2017. In [26], the authors proposed the CL Word Mover's Distance (WMD) method and evaluated similarity in an aligned multilingual space for a Chinese-English text. Vector word representations are formed independently for each language using the Skip-Gram model and aligned using a small bilingual dictionary. On the NDLTD dataset, CL-WMD achieved a Hit@10 of 97.09% at the paragraph level and 86.09% at the sentence level. In [27], a CLPD was developed for the English and Russian languages. The method translates Russian documents into English using a Transformer-based machine translation system and applies semantic clustering with FastText anchors for source retrieval and unsupervised and semi-supervised sentence anchors for document comparison. Using a dataset synthesized from Russian and English Wikipedia, the system achieved an F1 score of 80%. On the PAN'11 dataset, the system achieved a precision of 94%, a recall of 76%, an F1 score of 84%, and a PlagDet score of 83% for monolingual plagiarism detection. The article [28] focused on detecting English-Arabic (En-Ar) using methods to extract semantic and syntactic features, such as word order, word embeddings (Word2Vec),

TF-IDF, and word alignments with multilingual encoders MUSE. These techniques, combined with the different ML algorithms, including Support Vector Classifier (SVC), Logistic Regression (LR), Linear SVC, DT, KNN, and Extreme Gradient Boost (XGBoost), were used to determine whether the sentences were plagiarized. The approach achieved an F1-score of 0.879 on the SemEval-2017 dataset, with the SVC classifier by integrating all the proposed techniques. Authors of this paper [29] suggested a CLPD technique for English-French (En-Fr) utilizing word embeddings generated through the CBOW model alongside Cosine Similarity (CS) to assess both semantic and syntactic similarities. Among the methods employed are CL Word Embedding Similarity (CL-WES), which evaluates Sentence Embeddings (SE) directly, syntactically enhanced embeddings (CL-WESS), and integration strategies such as decision tree-based methods. The evaluation was conducted on a comprehensive dataset combining texts from Wikipedia, conference papers, product reviews, Europarl, and JRC. The approach achieved an F1 score of 89.15% at the chunk level and 88.5% at the sentence level using decision tree fusion. The authors of this article [30] proposed to detect plagiarism between Ar-En pairs using a Semantic Textual Similarity (STS) and Skip-Gram and CBOW embedding techniques. Three learning approaches were implemented: Parallel Mode, Word by Word Alignment Mode, and Random Shuffling Mode. The combination of the Random Shuffling method and the Skip-Gram technique achieved an important performance, with a correlation rate of 75.7% on the SemEval-2017 dataset. In [31], the authors introduced a CLPD approach based on multilingual word embeddings to align plagiarism fragments across languages. The method focused on the German-English (De-En) and Es-En language pairs and is evaluated on the PAN-PC-11 and PAN-PC-12 datasets. For the candidate retrieval phase, potential fragments are identified using a vector space model with TF-IDF-like weighting and CS. For the detailed analysis phase, a word-graph representation is used to capture semantic and syntactic relationships through clique-based graph matching. The method achieved PlagDet scores of 85.7 (De-En) and 83.5 (Es-En) on PAN-PC-11, and 86.2 (De-En) and 84.2 (Es-En) on PAN-PC-12. Additionally, the method achieved a PC of 44.3 on the SemEval 2017 dataset for Es-En. The authors of [32] focused on the candidate retrieval phase for the De-En language pair, aiming to identify potential source documents for suspicious texts. It uses an approach based on thematic segmentation, Latent Dirichlet Allocation (LDA), proximity-based language models, and the extraction of keywords using TF-IDF, along with representative phrases (bigrams and trigrams). Representative words and phrases are translated using Google Translate, reducing reliance on full document translation. Experiments on the PAN-PC-12 corpus show an F2-score of 67.03% by combining thematic and linguistic segmentation. This article [33] focused on candidate document retrieval to effectively identify potentially plagiarized sections between Chinese and English texts. The developed techniques included methods based on keywords using TF-IDF and machine translation, utilizing tools such as BABYLON and Google Translate. Performance results show that queries based on 50% of the keywords provide a balance between efficiency and accuracy (MAP = 0.500) when applied to the Xinhua Chinese and English news collections. Authors of [34] presented an approach based on two steps: candidate fragment identification and detailed analysis. In the first stage, the aim is to identify potentially plagiarized fragments. It begins by selecting a subset of words, termed representative terms, which characterize the vocabulary used in the source document using the TF-IDF method. This approach does not require a complete translation of the text; only the representative terms are translated. Several translation resources were evaluated for this purpose, including Google Translation, BabelNet, and Dict.cc. Among these resources, Google Translation achieved the PlagDet score, reaching 75.42% similarity, with a precision of 72.67%. The second stage involves aligning the source and suspicious fragments, followed by testing their similarity using dynamic programming algorithms. Different term weighting models were utilized, including the TF-IDF model, the Bernoulli weighting model, the Bose-Einstein weighting model, the Simple IDF model, and the Binary model. The TF-IDF model achieved a plagdet of 91.66%, the Bernoulli weighting model reached a plagdet of 91.21%, the Bose-Einstein weighting model obtained a plagdet of 91.88%, the Simple IDF model reached a plagdet of 91.82%, and finally, the Binary model achieved a plagdet of 92.08% specifically for Es-En text pairs. In this article [35], the authors developed two approaches for the candidate retrieval task in CLPD methods. In the first approach, the most representative words for search queries are extracted using the TF-IDF technique, while in the second, the concepts are extracted and documents are semantically represented using the CL Explicit Semantic Analysis (ESA) method. The CL-ESA model was developed using Wikipedia by utilizing interlingual relationships between English, German, and Spanish articles. This allowed content to be mapped into a common conceptual space to handle problems such as polysemy and synonymy. These two methods were merged to create a hybrid model that uses dynamic interpolation to integrate similarity scores based on concepts and keywords. Evaluated on datasets such as PAN-PC-12, JRC-Acquis, PAN-PC-11, and Wikipedia, the hybrid model achieved a recall of 78.89%, a precision of 61.74%, an F1 score of 69.27%, and an F2 score of 74.74. In [36], the authors proposed a CLPD method for the English-Persian language pair, and five methods were used, each with distinct techniques and precision levels. The Translation plus Mono-lingual Analysis (T+MA) method, combining machine translation and mono-lingual analysis, achieved the highest precision of 83%. The Bilingual Word Embeddings Without Alignment (BILBOWA) method, using bilingual word embeddings, reached a precision of 55%. CL Latent Semantic Indexing (CL-LSI) created a multilingual semantic space and achieved 49% precision, while CL-ESA, based on similarity to Wikipedia documents, resulted in a lower precision of 21%. Lastly, CL Knowledge Graph Analysis (CL-KGA), utilizing BabelNet for knowledge graph analysis, showed an intermediate precision of 70%. The article [37] proposed a method for detecting bilingual plagiarism for En-Pe documents. Based on the Vector Space Model (VSM), the technique utilizes morphological analysis, synonym lists, and bilingual dictionaries to compare textual content. The approach relies on term weighting with TF-IDF to assign a numerical weight to each word. The Text similarity is then measured using CS. The dataset includes 100 training texts and 100 test texts extracted from internet sources. The performance is evaluated with 88% precision, 96% recall, and an F-measure of 91%. In

[38], the authors addressed the identification of Vietnamese-English paraphrases using Siamese recurrent architectures, incorporating techniques such as Siamese Long Short-Term Memory (SLSTM), Word2Vec-based bilingual word embedding mapping, adding POS vectors to word embeddings, and revising POS labeling tags using WordNet and VietNet. The proposed method achieved an accuracy of 89.61% on the TED dataset. In this article [39], the system proposed aims to assess semantic similarities between Indonesian and English documents by combining Latent Semantic Analysis (LSA), Singular Value Decomposition (SVD), and Learning Vector Quantization (LVQ) for classification. The system utilizes a local dictionary database for word-by-word translation, ignoring grammatical rules, and calculates similarities through CS using the Slice and Pad methods as well as the Frobenius norm. When tested on manually translated scientific articles, the system achieved a maximum accuracy of 87%. Furthermore, using a term-document matrix based on term frequency significantly outperforms a binary method in terms of accuracy. The authors in [40] addressed the challenge of En-Ar texts by using latent semantic indexing (LSI) for both English and Arabic texts. Latent semantic indexing constructs a shared semantic space for both languages, enabling contextual similarity comparisons between documents without the need for direct translation. When utilized on the parallel En-Ar Corpus of United Nations documents (EAPCOUNT), the LSI technique resulted in a similarity detection rate of 93%, while Jaccard's index yielded just 33%. The authors of this article [41] developed a CLPD system that examines both syntactic and contextual similarities among texts in various languages, such as English-Chinese, English-Japanese, and English-Korean. The system employs sophisticated methods, including Word2Vec and a model based on Convolutional Neural Networks (RCNN). It achieved commendable accuracy on the student dataset, reporting 88.87% for English-Chinese, 87.49% for English-Japanese, and 87.26% for English-Korean. In this article [42], a system is proposed for detecting text reuse for the English-Urdu languages through the development of the CLEU corpus. The goal is to create a realistic resource for detecting multilingual plagiarism. The method used, Translation Plus Monolingual Analysis (T+MA), first translate the Urdu text into English using Google Translate, before applying similarity techniques such as n-gram overlap, Longest Common Subsequence (LCS), and Greedy String Tiling (GST). Pairs of sentences/passages are classified as Near Copy, Paraphrased Copy, and Independently Written. The results show an F1 score of 73.2% in binary classification and 55.2% in ternary classification.

B. Multilingual Semantic Network

A Multilingual Semantic Network is a knowledge base that represents semantic relationships between words or concepts across multiple languages. It captures the meanings and relationships between terms in different languages, enabling tasks such as machine translation, multilingual information retrieval, or natural language understanding (NLU) in a multilingual context. These semantic networks are often built by linking words or concepts across languages through lexical or conceptual alignments, using resources like WordNet [43], BabelNet [44], or other multilingual lexical databases.

Fuzzy semantic similarity techniques were developed in [45] for Ar-En within a Big Data framework. Performance metrics were based on the Wu&Palmer and Lin similarity measures, leveraging WordNet to assess semantic relationships between words. Experiments conducted in a Hadoop environment (HDFS and MapReduce) demonstrated that the Wu&Palmer measure achieved a precision of 54%, recall of 66%, and F-measure of 59.4%, while the Lin method achieved a precision of 27%, recall of 37%, and F-measure of 31.2% on a dataset comprising news, articles, tweets, and academic works. The work in [46] addressed CLPD for the Urdu-English language pair using ML models. Using Jaccard and CS were calculated for uni-grams and tri-grams, with lemmatization performed using WordNet during preprocessing. Five classifiers were utilized: Naïve Bayes (NB), Support Vector Machine (SVM), K-Nearest Neighbors (KNN), Decision Tree (DT), and Random Forest (RF). Among them, KNN achieved an accuracy of 92%. In the article [47], the authors proposed the CL Ontology-Based Similarity Analysis (CL-OSA) model, focusing on multilingual text similarity for languages such as Es-En, De-En, Chinese-Japanese, and French-English. The CL-OSA model leverages Wikidata, a multilingual open knowledge graph, to represent documents as language-independent entity vectors. CL-OSA applies a semantic hierarchy-based weighting and CS to rank document similarities. Evaluation of datasets such as PAN-PC-11, ASPEC-JE, ASPEC-JC, JRC-Acquis, and Europarl. For candidate retrieval, CL-OSA achieved a Mean Reciprocal Rank (MRR) of 91.38% for Es-En, 71.92% for Japanese-English, 78.21% for Japanese-Chinese, 97.68% for French-English, and 55.47% for French-English. For detailed analysis, CL-OSA achieved a PlagDet score of 57.3% for Es-En and 52.1% for De-En. The authors in [48] proposed a Multi-Lingual Plagiarism Detection (MLPD) model for English-Persian texts, focusing on translational plagiarism. The method utilizes translation tools, including manual translations by English experts and Google Translate, to translate Persian texts into English, followed by semantic similarity evaluation using the WUP metric. In the candidate retrieval phase, the system uses Apache Solr to identify the five most probable source documents by calculating the frequency of suspicious phrases in the indexed dataset. The findings highlight the significance of accurate translations on the Mizan dataset, with the suggested method achieving an accuracy of 98.82% with expert translations and 56.9% with Google Translate. A CL Knowledge Graph Analysis (CL-KGA) method was used in [49], which uses BabelNet to construct knowledge graphs and measure semantic similarity between document fragments. The languages studied are De-En and Es-En. The performances show that for automatic translations (AT), the PlagDet score reaches 60.87% for the Es-En pair and 52.96% for the De-En pair, while paraphrastic translations (PT) reach scores of 9.93% and 10.06%, respectively. The similarity measures are based on intersection algorithms and the weighting of concepts and graphical relationships. In [50], the authors proposed a method for detecting similarities between Arabic and English documents using Linear LR for classification. The approach starts with key phrase extraction and the translation of Arabic documents into English, followed by similarity detection using techniques like CS, LCS, and N-grams (tri-grams), with the integration of synonyms through WordNet. Tested on Wikipedia articles, the method achieved a precision of 96%, a

recall of 85%, and an F-measure of 90%. This work [51] proposed a fuzzy approach to inter-language (French-Arabic, En-Ar) plagiarism detection by combining semantic similarity with an Apache Hadoop-based Big Data environment. Documents are pre-processed (tokenization, empty word removal, POS tagging, and trigram segmentation) and analyzed using WordNet and similarity measures such as WuP, Lin, and Leacock-Chodorow (LCH). A test corpus of 600 documents was used, including 200 automatically translated and 400 translated with modifications (paraphrasing, back-translation). The results show that WuP delivers the best performance, with a similarity percentage of around 63%. In [52], the authors addressed two tasks: CL Text Semantic Similarity (CL-STS) and plagiarism detection (PD) for En-Ar texts. It relies on several semantic features, including topic similarity, Named Entity Recognition (NER), semantic role labeling (SRL), spatial role labeling (SpRL), stop word bag, and meaning bag. Topic generation is performed using LDA, complemented by the use of BabelNet to extract English synonyms from Arabic topics and the WUP metric to assess semantic similarity. Arabic texts are translated into English using the Google Translate API to enable analysis in a common language. For plagiarism detection, three models were used: Deep Neural Networks (DNN), LR, and SVM. The results showed that the SVM model achieved an accuracy of 96.65%, the LR model 96.64%, and the DNN model 97.01%.

C. Fingerprints

In this study [53], the authors developed a method for detecting CLPD for En-Ar, utilizing techniques such as keyphrase extraction to compute phrase frequency and rank candidate keyphrases, along with C-Value and NC-Value algorithms, translation of keyphrases into English, and fingerprinting for document representation. Five similarity measures were employed: N-Grams Similarity, LCS, Dice Coefficient (DC), Jaccard Similarity, and Containment Similarity, which were used as features to train three ML models: SVM, NB, and LLR. The results demonstrated that SVM achieved an F-score of 92% when more than three similarity measures were combined. This paper [54] proposed a method for Chinese-English based on WordNet. The approach extracts nouns using ICTCLAS for Chinese and the Stanford POS Tagger for English, encoding them into language-independent fingerprints via WordNet's semantic hierarchy. A disambiguation algorithm based on semantic density calculates the relevance of senses to address word polysemy. The method measures similarity using the Dice coefficient to compare fingerprints and identifies potential plagiarism cases when the similarity exceeds a predefined threshold. Tested on a parallel corpus, National Knowledge Infrastructure (CNKI), the proposed method achieved a precision of 87% and a recall of 78%. In [55], the authors developed a plagiarism detection system for multilingual documents (English-Indonesian) using the Winnowing method and the Jaccard coefficient to measure similarity. The system allows users to upload documents in text or PDF format, translate them automatically, if necessary, pre-process them (folding capital letters, tokenization, removal of empty words), and generate fingerprints for comparison. The dataset used includes academic journals from sources such as IEEE Xplore and ResearchGate. The system achieved an accuracy of 84.7%. The authors of [56] proposed for the Ar-En language pair, the method utilizes the Winnowing algorithm to generate digital fingerprints from k-grams extracted from documents, achieving 81% recall, 97% precision, and an 89% F-measure on Wikipedia articles.

D. Transformers & Deep Learning

The pre-trained models Multilingual BERT (M-BERT) and CL Roberta (XLM-R) [57] were used for the English-Vietnamese language pair. For this task, XLM-R achieved an accuracy of 84.3% and an F1-score of 87.6%, while M-BERT achieved an accuracy of 73.7% and an F1-score of 81.3% on the GLUE dataset. An AraXLM method based on the XLM-RoBERTa model was proposed in [58] to detect plagiarism for Ar-En texts. The framework utilizes the SemEval-2017 Task1 dataset, where the Arabic sentences were translated from English using Google Translate. The approach includes automatic diacritization, semantic similarity calculation using FAISS (Facebook AI Similarity Search), and measures such as CS and Euclidean Distance (ED) to compare the embeddings of sentences. In testing, CS achieved 94.49%, and ED was measured at 1.74668 for non-diacritized sentences. This paper [59] proposed an mBART transformer for feature extraction combined with SLSTM. Experiments were conducted on language pairs including En-Fr, En-Es, and En-De. The methodology achieved an accuracy of 98.83% and an F1-score of 98.87% for En-Fr, 97.94% accuracy and an F1-score of 98.01% for En-Es, and 95.59% accuracy with an F1-score of 96.02% for En-De. The evaluation was performed on datasets such as PAN-11, JRC-Acquis, Europarl, Wikipedia, and conference papers. This work [60] explored various methods for addressing Russian-English text alignment in the context of plagiarism detection. The method translated the Russian text into English using Neural Machine Translation (NMT). To identify translated plagiarism, a comparative analysis of models including SE, BERT, Word Substitution (WS), and LASER was conducted. With an F-score of 95%, a precision of 96%, and a recall of 93%, the BERT model stood out among the others. The study also assessed the similarity of translated sentences using Jaccard metrics with 1-grams (NMT) and 2-grams (NMT2). The NMT model demonstrated a precision of 85%, a recall of 80%, and an F-score of 82%. Furthermore, LR was applied in two configurations: LR-1, which incorporated all techniques, and LR-2, which focused on SE and WS. LR-1 attained a precision of 91%, a recall of 80%, and an F-score of 85%. In [61], the authors addressed the case of plagiarism in the Persian-English pair using multilingual transformers models (XLM-R, M-Bert, DistilBert) and the CS metric. The findings of the study indicate that the XLM-RoBERTa model achieved a PC of 95.62% on the PESTS dataset. In comparison, M-BERT achieved a correlation of 91.88%, while DistilBERT achieved a correlation of 89.51%. The authors of [62] proposed a technique that combines data augmentation with a vigilant Siamese LSTM model to detect plagiarism between Tibetan and Chinese. For Tibetan-Chinese sentence pairings produced from the CWMT and SICK datasets, this method produced a PC of 54.76%. The similarity between document abstracts was also assessed using a Doc2Vec model, yielding Tibetan-Chinese PC scores of 87.06% for Chinese, 63.67% for Tibetan, and 53.9% for Tibetan-Chinese. This work [63] proposed a CLPD approach using a graph transformer-based model (CL-GTA) and knowledge graphs (KG). After creating KG from the Extended Open Multilingual WordNet, the model employed a graph transformer to weight entities and

semantic relations using a multi-head attention mechanism. CS was applied to measure text similarity, and the system was evaluated on multiple datasets, including Europarl, JRC-Acquis, Wikipedia, PAN 2011, and Ar-En parallel corpora. The CL-GTA model achieved a PlagDet of 62% for Es-En, 58.4% for French-English, and 52.2% for Ar-En**.** In [64], the authors proposed Doc2Vec+SLSTM CLPD in the Es-En pair combines Doc2Vec for text representation and an SLSTM model to evaluate document similarity. The performances were compared to other techniques, such as GloVe, FastText, BERT, Word2Vec, and Sent2Vec, using datasets from PAN11, JRC-Acquis, Europarl, and Wikipedia. The Doc2Vec+SLSTM model achieved the highest accuracy of 99.81%, outperforming GloVe (99.59%), FastText (98.82%), BERT (99.49%), Word2Vec (99.14%), and Sent2Vec (98.41%). This paper [65] identified paraphrases for English and Vietnamese sentences using a hybrid approach. The method integrates a Fuzzy-based approach leveraging BabelNet to evaluate semantic relationships between words, a Siamese LSTM model to calculate sentence similarities, and feature combination methods employing algorithms such as LR, RF, and Multilayer Perceptron (MP). BabelNet, enhanced with VietNet, addressed its limitations by adding more Vietnamese words to the synsets. The model was evaluated on a bilingual English-Vietnamese corpus derived from TED. The proposed approach with Linear Regression yields a precision of 80.3%, a recall of 95.8%, and an F-measure of 87.4%. In [66], the authors evaluated the effectiveness of six multilingual transformer-based models for CLPD. The models tested are mBERT, mDistilBERT, XLM-RoBERTa, SBERT Multilingual MiniLM-L12, SBERT Multilingual MPNet, and Distil SBERT Multilingual. The study was conducted on language pairs formed between English and ten languages from the Indo-European family: En-Es, En-Pt (Portuguese), En-Fr, En-Ru, En-Sr (Serbian), En-Cs (Czech), En-De, En-Nl (Dutch), En-Sv (Swedish), and En-Hy (Armenian). The datasets used include sentences from Wikipedia translations to generate positive examples and test sets derived from the Microsoft Research Paraphrase Corpus (MRPC), as well as specific sets like Negative-1 and Negative-4 for the En-Ru pair. The authors of [67] presented an approach focused on the English-Urdu language pair. It leverages recent multilingual models such as LLaMA and Mistral to extract shared semantic representations across languages. These representations are then used to compare content between different languages. The evaluation was conducted on the CLPD-UE-19 dataset, and the results report an F1 score of 73.9%.

III. Research Methodology

A systematic literature review is a structured method of reviewing academic literature that involves collecting and critically evaluating a set of articles focused on a specific topic. Its purpose is to identify, select, synthesize, and analyze relationships, limitations, and key findings, thereby providing a comprehensive summary of both quantitative and qualitative studies [68]. Conducting an SLR is essential for researchers to explore current research trends related to the detection techniques of Multilingual Plagiarism, and to identify weaknesses in existing methodologies.

A. Search Strategy

To ensure the relevance and comprehensiveness of the studies retrieved, we make use of the most widely recognized research databases, as the choice of search strategy significantly influences the quality and completeness of the results. The databases included Scopus, ScienceDirect, IEEE Xplore Digital Library, SpringerLink, ACM Digital Library, ResearchGate, Web of Science, arXiv, and Google Scholar. Additionally, the Rabbit tool is employed to enhance the efficiency of the search process and to enable the identification and organization of relevant studies more effectively.

B. Research Questions

To gain a comprehensive understanding of the issue of CLPD along with its associated challenges, we formulate the research questions that this SLR aims to address as follows:

RQ1: Which language pairs are most commonly studied in CLPD, and which languages dominate research?

RQ2: What are the common translation strategies used in CLPD systems, and what are the main types of approaches adopted in this field?

RQ3: What are the different multilingual representation methods used in the feature extraction step, and what is their impact in terms of performance?

RQ4: What similarity measures are used in CLPD, and which one is the most commonly dominant in the existing studies?

RQ5: What are the main factors (preprocessing, datasets, multilingual semantic networks, feature extraction techniques, ML/DL models, Similarity Measures) that influence performance in each language pair?

C. Query Terms

Our research utilizes a "snowball" method to identify relevant literature in the field of CLPD, and starts the literature review with a few critical or foundational selected studies. Based on the references included in these selected studies, additional publications are found. This process is carried out repeatedly. The approach persists until no additional pertinent studies are discovered. The detailed steps of our snowball search method are outlined below.

- Applying text mining and natural language processing to an initial set of CLPD studies enabled the extraction of key terms, including concepts like cross-language alignment, semantic similarity, and translation-based detection.
- Constructed from these terms, a search query using relevant keywords and Boolean operators is formulated to ensure effective retrieval.
- Conducted across major databases such as IEEE Xplore, SpringerLink, ScienceDirect, ACM Digital Library, and Google Scholar, the search aimed to capture both breadth and depth.

- Manually reviewed, the results were categorized as Relevant (R) or Not Relevant (NR) based on their alignment with CLPD objectives.
- Refined through further analysis, the keyword set is adjusted with generic terms removed and domain-specific ones like “semantic similarity” or “sentence alignment” included.
- Extended by snowballing, each relevant paper’s references and subsequent citations are explored to trace both foundational and recent contributions.
- Repeated iteratively, the process concludes when no additional relevant studies emerge, resulting in a curated set of literature for the CLPD review.

Query 1: ("cross-language plagiarism" OR "cross-lingual plagiarism" OR "multilingual plagiarism detection" OR "cross-language text reuse" OR "translation plagiarism").

Query 2: ("plagiarism detection" OR "copy detection" OR "text similarity detection" OR "text matching" OR "semantic similarity").

Query 3: ("multilingual embeddings" OR "word embedding" OR "sentence embedding" OR "machine learning" OR "deep learning" OR "transformers").

Query 4: ("translation-based" OR "translation independent" OR "machine translation" OR "neural translation").

Query 5: ("systematic literature review" OR "SLR" OR "survey" OR "comparative analysis" OR "performance evaluation").

D. Study Selection

To ensure the transparency and scientific rigor of our SLR, we defined explicit inclusion and exclusion criteria to guide the selection process. After retrieving the initial set of studies through our search queries, a two-stage screening was conducted. In the first stage, titles and abstracts were reviewed to quickly discard irrelevant works. In the second stage, the full texts of the remaining studies were assessed against the predefined criteria. Only those studies that satisfied all inclusion criteria and none of the exclusion conditions were retained. This systematic filtering ensured that the final corpus focused exclusively on peer-reviewed, English-language research directly addressing CLPD with robust methodological contributions. The complete list of inclusion and exclusion criteria is presented in Table I.

TABLE I. LIST OF INCLUSION AND EXCLUSION CRITERIA

Inclusion Criteria	Exclusion Criteria
Articles between 2014 and 2025	No experimental methods are employed.
The papers are written in English	Papers unrelated to the research questions defined in our SLR.
Scientific papers are published through conferences or journals.	Closed access or missing full text.
The study focuses on CLPD	Research papers use monolingual plagiarism
The articles apply one or more of the following methods: MSN, feature extraction, machine learning, or deep learning.	Preprint papers

E. Quality Assessment

The quality assessment stage in an SLR aims to rigorously evaluate the methodological validity, reliability, and overall relevance of the studies selected [69]. This step acts as a decisive filter, applied to the full-text articles, and marks the final stage in preparing the dataset for data extraction and synthesis. To ensure the inclusion of only high-quality and meaningful contributions, a multi-phase evaluation process is employed [70]. The first phase consists of a preliminary screening of the title, abstract, conclusion, and keywords to eliminate clearly irrelevant studies. In the second phase, the remaining papers undergo a thorough assessment based on predefined quality criteria, such as methodological rigor, clarity of results, and alignment with the research questions. Only the studies that satisfy these standards are included in the final synthesis. The quality assessment rules are defined in Table II:

TABLE II. LIST OF QUALITY ASSESSMENT QUESTIONS

ID	Quality Assessment Questions
QA1	Does the article explicitly address one or more of our research questions?
QA2	Is the scope of the research clearly outlined and focused on CLPD?
QA3	Is the contribution of the study to CLPD clearly stated?
QA4	Is the contribution well-supported by evidence or evaluation?
QA5	Is the dataset used clearly identified and mentioned?
QA6	Are the dataset’s characteristic language pairs and its level of granularity (e.g., sentence, paragraph, document) adequately described?
QA7	Does the study describe the full process used for CLPD?
QA8	Is the feature extraction phase clearly defined?
QA9	Does the study present a clear and well-structured experiment?
QA10	Are the obtained results properly interpreted and discussed?

F. Systematic Literature Review (SLR)

SLR is conducted to identify and analyze relevant research on CLPD techniques published between 2014 and 2025. An initial pool of 1300 articles is retrieved from major scientific databases, including IEEE Xplore, ScienceDirect, Springer, Google Scholar, and Scopus. After an initial screening phase, 57 records are excluded for not meeting basic inclusion criteria, specifically, lack of open access, non-English language, or absence of multilingual representation approaches. The remaining 1243 records are then screened more closely, excluding 1160 articles due to duplication or non-relevance based on title and abstract. This process reduces the selected articles for full-text review to 83. At the next stage, 18 articles are excluded for reasons such as lack of experimental validation, being review papers, or omitting baseline or performance metrics. The final 61 articles are assessed in depth for methodological quality, relevance to the research objective, and overall contribution. Ultimately, 43 studies meet all criteria and are included in the final analysis. The entire selection process and applied filters are illustrated in Fig. 1.

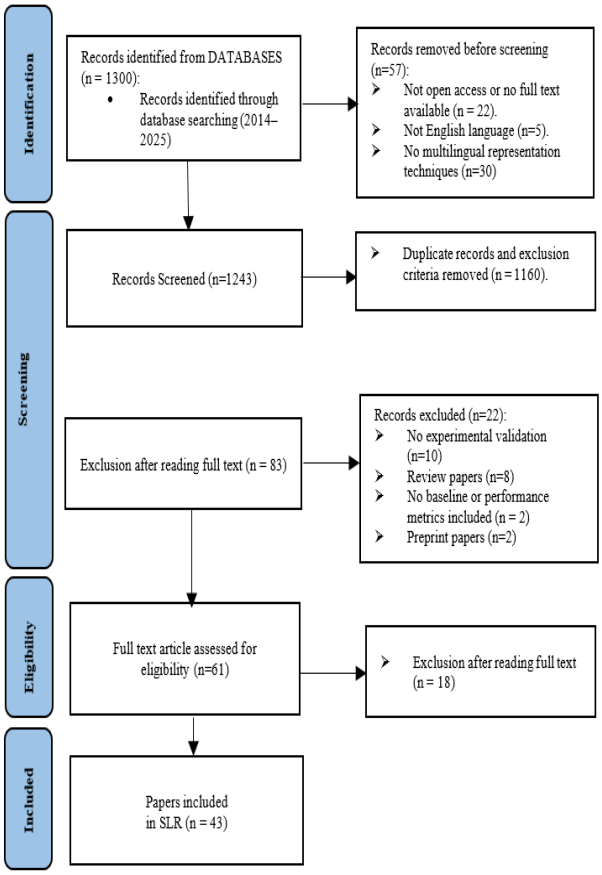

Fig. 1. PRISMA flowchart of the research process.

G. Data Analysis

A total of 43 studies related to the field of CLPD published between 2014 and 2025 are identified. Fig. 2 illustrates the distribution of study types over time. Journal articles dominate the landscape and comprise approximately 57% of the selected studies, followed by conference papers, which represent around 36%, while book chapters constitute the smallest portion, with only 7%. Table III presents the distribution of the retrieved articles across different publication venues. The findings indicate that 59.52% of the studies were published in journals, while 35.71% appeared in conference proceedings. A smaller proportion, 4.76%, was published as book chapters.

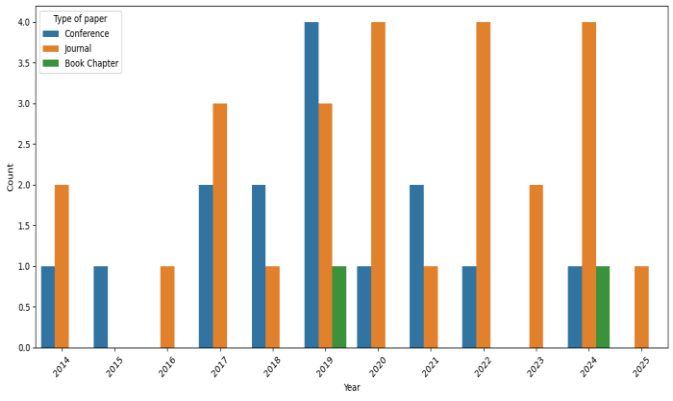

Fig. 2. Distribution of research by type and by year.

IV. Methods Analysis and Comparison

This section presents the analysis of the research questions, along with the findings derived from the state-of-the-art review. It is structured into two main parts. The first part provides a general overview, examining all the approaches used for CLPD. It highlights the techniques employed, the models applied, and the various language pairs studied. The second part focuses on a detailed and specific analysis of each language pair. For each pair, we evaluate the performance of the employed approaches, considering the linguistic characteristics and datasets used. This in-depth comparative approach highlights the most effective methods for each language pair.

A. Language Pairs (RQ1)

The most commonly used language pairs reveal interesting trends. The En-Ar combination stands out as the most frequently studied, followed by En-Es, En-De, and En-Ar, highlighting the significance of these languages in academic research. In contrast, pairs like Tibetan-Chinese, French-Arabic, and English-Japanese are significantly less explored, due to either a lack of linguistic resources or limited research interest. The omnipresence of English in almost all combinations reflects its dominant position in scientific publications and advancements in natural language processing (NLP). Languages frequently paired with English, such as Arabic, Chinese, or Spanish, are often chosen for their geopolitical importance, widespread use, or linguistic complexity.

It is also relevant to consider the direction of language pairs, for instance, for English-Arabic and Arabic-English, where the source and target languages may differ. This distinction influences the challenges encountered, particularly in terms of machine translation or algorithm adaptation. Furthermore, pairs involving underrepresented languages, such as Tibetan or Persian, often suffer from a lack of annotated corpora and suitable NLP tools, hindering their detailed study. Finally, this analysis reflects not only the current state of research but also the linguistic biases within the field, emphasizing the urgency to diversify efforts to include more marginalized languages and promote linguistic equity on a global scale. Fig. 3 describes the most frequently used language pairs.

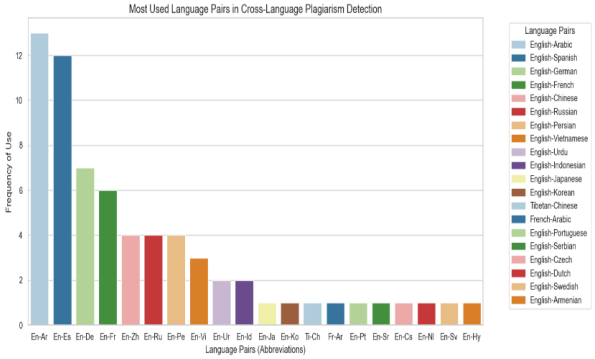

Fig. 3. Frequency of CLPD language Pairs.

B. Translation Approach (RQ2)

In this part, we will examine how translation and non-translation are utilized within the CLPD context, as well as the translation tools employed and the languages being translated.

1) Translation strategies in CLPD: Translation is used in CLPD to convert documents or sentences into the same language, representing a dominant share of 60.5% in the reviewed studies. English is the most studied language, and in most cases, documents are translated into English to ensure both texts are in the same language rather than translated into other languages. Among the translation tools, Google Translate stands out as the most widely utilized due to its accessibility, multilingual support, and continuous improvements in translation quality. However, several studies also explore the use of specialized dictionaries, particularly for domain-specific texts, offering more accurate translations tailored to the subject matter. Additionally, advancements in NLP have led to the adoption of transformer-based models, such as BERT and GPT, which provide context-aware translations and handle complex linguistic structures. Fig. 4 shows the distribution of translation usage.

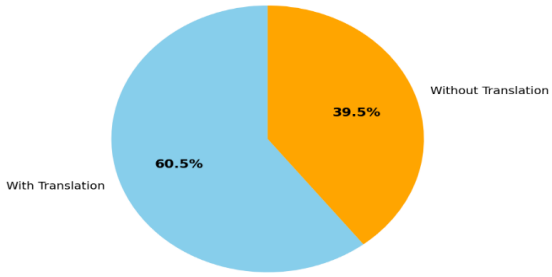

Fig. 4. Distribution of research based on the use of translation.

2) Translation tools used in CLPD: Fig. 5 shows the frequency of translation tools used in CLPD systems, in ascending order of use. Less frequently used tools, such as Transformer, English Expert, BABYLON, and the Dictionary database, appear only once in the studies examined. Tools such as dict. and Bilingual translators are used twice. In contrast, Google Translate stands out as the most widely adopted translation tool, with 21 occurrences, underlining its predominant role and popularity.

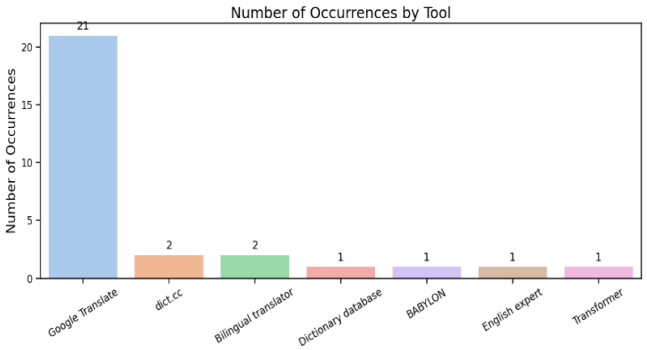

Fig. 5. Frequency of translation tools.

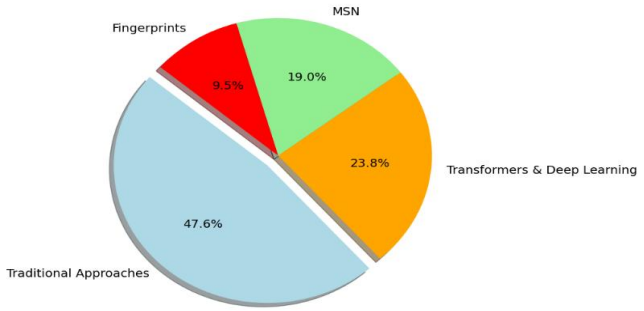
C. Multilingual Text Representation Strategies (RQ3)

This section presents various strategies employed for CLPD, including statistical analysis of approach distribution, a comparison between traditional word embedding methods and transformer-based deep learning models, and the utilization of multilingual semantic networks.

1) Distribution of approaches in CLPD: Fig. 6 highlights the predominance of traditional approaches (47.6%), such as TF-IDF, Word2Vec, LSI, and SVD, which remain widely used due to their simplicity and low computational cost. However, Transformers and Deep Learning models (23.8%) are gaining increasing adoption thanks to their ability to capture rich contextual representations, despite their higher computational requirements. Multilingual Semantic Networks (19%), such as WordNet and BabelNet, play a key role in knowledge-based approaches, particularly for semantic similarity assessment in a multilingual context. Finally, fingerprinting techniques (9.5%), although less common, are employed to capture a unique textual signature.



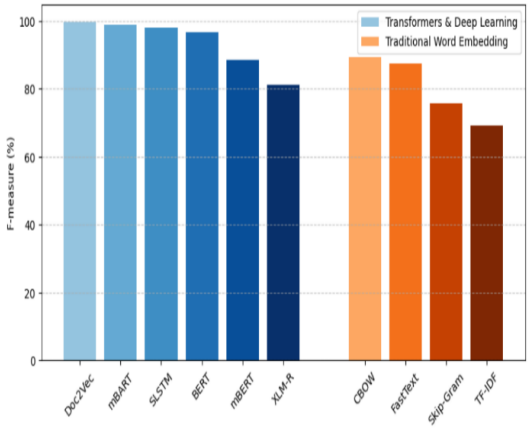


Fig. 6. Distribution of approaches in CLPD.

2) Traditional word embedding methods versus transformers & deep learning: Table IV provides a comparative analysis of traditional word embedding methods (e.g., Word2Vec) and transformer-based deep learning models (e.g., BERT, XLM-R) for CLPD. It includes key details such as the studied language pairs, the algorithms employed, the datasets used for evaluation, and the performance metrics. Although various evaluation metrics such as precision and recall are considered, the F1-score is more commonly used as it provides a balanced measure by incorporating both precision and recall. The F-measure scores, which represent the harmonic mean of precision and recall, are provided to evaluate the effectiveness of these methods. Traditional methods like TF-IDF and Word2Vec often produced results below 80% in terms of F-measure for many language pairs, especially for complex language pairs. For example, TF-IDF/LDA with the En-Es and En-De pairs achieved F-measure scores of 57.58 and 69.27, respectively, while CBOW yielded results of around 78.5. In contrast, Transformer and Deep Learning techniques, such as XLM-R, mBERT, and mBART, surpassed the 80% F-measure mark and demonstrated impressive performance in multilingual contexts, with F-measures ranging from 81 to 98.87, such as 88.5 for En-Vi (XLM-R) and 90.8 for En-De (mBERT). mBART, another transformer model, also performs well, with F-measures of 98.01, 98.87, and 96.02 for the En-Es, En-Fr, and En-De pairs, respectively. In conclusion, transformer-based and deep learning methods generally outperform traditional approaches in terms of F-measure, though results can depend on the specific datasets, and traditional methods remain competitive for simpler tasks or less complex configurations. Fig. 7 compares the performance and temporal evolution of natural language processing models. Fig. 7(a) shows that transformer-based and deep learning models (in blue) generally outperform traditional word embedding methods (in orange) in terms of F-measure, indicating their increased effectiveness. Fig. 7(b) illustrates the timeline of these techniques, revealing that traditional approaches (TF-IDF, Word2Vec) were introduced earlier, while more advanced models like BERT and XLM-R emerged more recently, marking a shift towards more powerful methods over time.

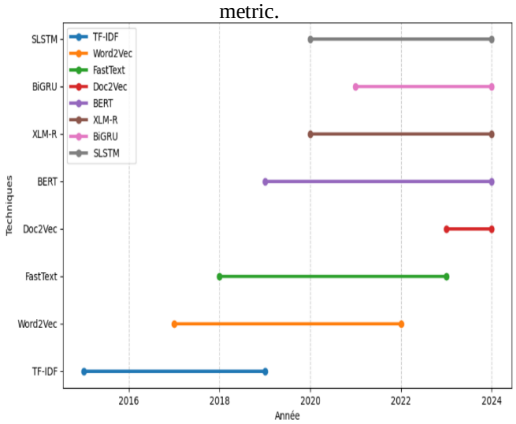

TABLE IV. COMPARISON OF THE PERFORMANCE OF TRADITIONAL WORD EMBEDDING AND TRANSFORMERS & DEEP LEARNING IN CLPD

	ID	Language pair	Algorithm	Dataset	Perf. (%)
Transformers & Deep Learning	[57]	En-Vi	**XLM-R** M-BERT	GLUE	A: 84.3 F1: 88.5
		En-De			A: 87.2 F1: 90.8

(a) Comparison of embedding model performance in terms of the F-measure metric.

(b) Comparison of the embedding model in terms of time evolution.

Fig. 7. Comparison of the performance and temporal evolution of embedding models.

3) Multilingual semantic network: The use of MSN in the field of CLPD serves two main purposes: acting as a dictionary to find synonyms or equivalent concepts across different languages and creating knowledge graphs. According to Fig. 8, we can observe that the majority of research in CLPD does not utilize MSNs, which suggests that many studies rely on alternative approaches, such as techniques based on word embeddings, ML, or DL. However, among the MSNs used, WordNet is the most frequently employed, likely due to its well-established structure and its use as a pivotal lexical resource for several languages. WordNet is often utilized to identify synonyms, antonyms, and other lexical relations, thereby facilitating the detection of semantic similarities. BabelNet, which follows WordNet in usage frequency, stands out for its ability to cover a wide range of languages and integrate information from various sources, such as WordNet and Wikipedia. Other MSNs, such as VietNet, are specifically dedicated to less common languages like Vietnamese, reflecting a focus on local or specific case studies. Finally, Wikidata, a collaborative knowledge base, is less frequently used but offers interesting potential for applications requiring contextualization or encyclopedic information.

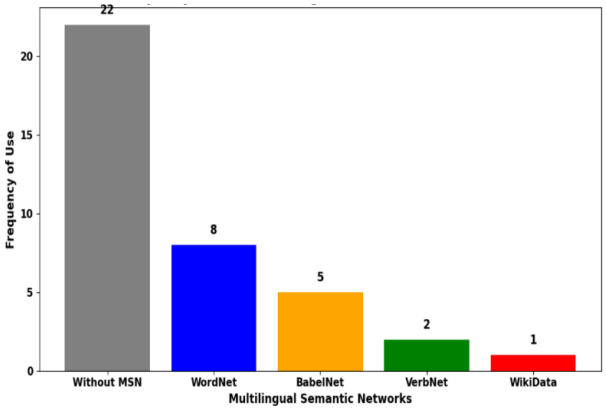

Fig. 8. Frequency of use of multilingual networks.

D. Cross-Lingual Similarity Measures (RQ4)

The most popular similarity metrics in CLPD systems are presented in Fig. 9. Cosine Similarity dominates all studies due to its effectiveness in vector-based representations and its capacity to assess similarities across text lengths. The second most popular index for comparing groups of words or characters is the Jaccard Index. Metrics like WUP similarity, LCS, ED, Lin similarity (Lin), and DC are utilized less often, implying that they are relevant in specific situations or serve as additional methods. Ultimately, the containment measure sees the least use, indicating its specialization in certain scenarios.

E. Comparative Study for each Language Pair (RQ5)

Before analyzing deeply each language pair, the techniques most frequently used in the preprocessing section are discussed, as they are commonly used in the different CLPD approaches.

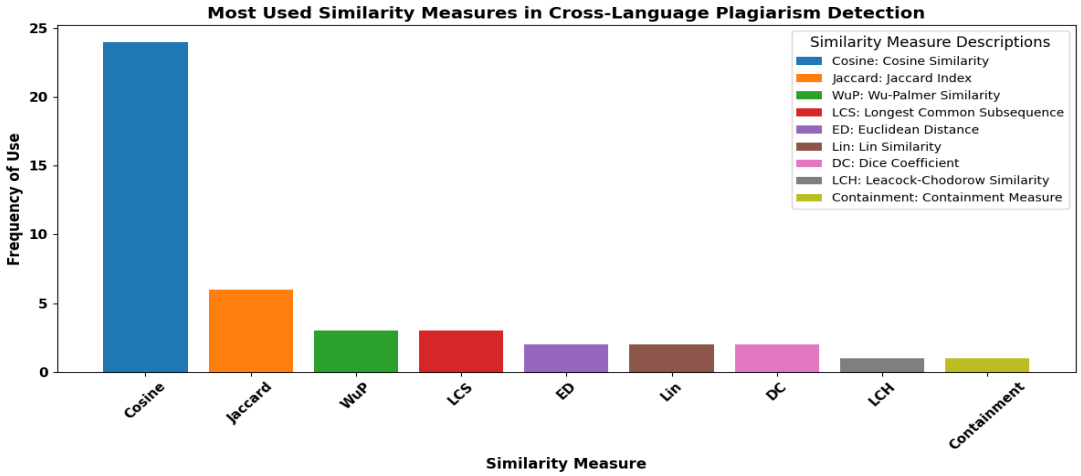

Fig. 9. Frequency of similarity measures in CLPD.

1) Common preprocessing techniques: Text pre-processing in multilingual studies usually begins with the segmentation of the text into sentences or paragraphs, enabling structured and targeted processing. Most of the techniques used at this stage are common and aim to improve data quality. Among the most commonly used steps are tokenization, which divides text into basic units such as words or symbols, and includes converting text to lowercase, removing unnecessary punctuation, lemmatization, and stemming to reduce words to their basic form or root. Stop word removal is another commonly employed technique, where insignificant terms such as articles or prepositions are eliminated to focus on meaningful words. For specific languages, tailored techniques are applied, such as diacritic removal for Arabic or the use of specialized dictionaries and linguistic databases to standardize terms. Additionally, advanced methods like NER are sometimes used to identify key elements such as proper nouns, dates, or locations, enriching data quality for more detailed analysis. These preprocessing steps are common to most studies. Fig. 10, given below, describes the most common preprocessing techniques used.

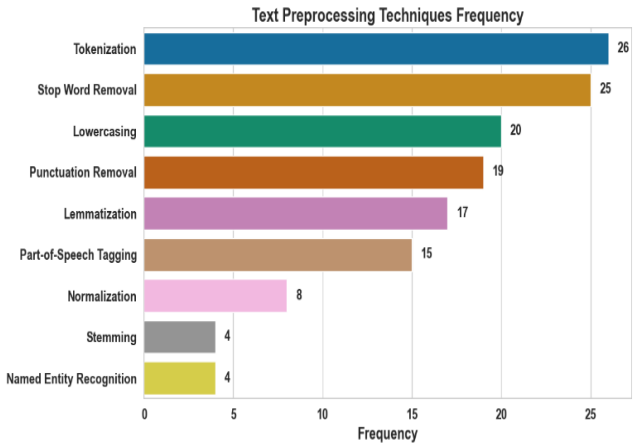

Fig. 10. Most commonly used preprocessing techniques.

2) Analysis of Language Pairs: This section provides an in-depth examination of each language pair, with a particular focus on the datasets employed, the applied techniques, and the performance achieved, while highlighting their unique features and the specific challenges they pose for processing and modeling. The analysis encompasses several key aspects of cross-language plagiarism detection, including the use of translation, the integration of multilingual semantic resources, the methods adopted for feature extraction, and the classification strategies implemented. It also covers the similarity measures applied, the datasets utilized, the levels of granularity considered (ranging from sentence-level to paragraph-level and document-level corpora), and the performance metrics reported. From a global perspective, CLPD research shows a reliance on a set of widely used datasets such as PAN-PC-11, SemEval, JRC-Acquis, Wikipedia, Europarl, and collections of conference papers, with their frequency of use often reflecting the language pairs investigated. In the following sections, we provide a more detailed distribution of datasets for English–Arabic and English–Spanish, which represent the most extensively studied language combinations.

a) English-Arabic language pair: For the En-Ar language pair, the preprocessing methods include tokenization, normalization, removal of stop words (RSW), and diacritic removal for Arabic text. Feature extraction techniques include pre-trained models like Word2Vec, Skip-Gram, CBOW, and TF-IDF. ML models, such as SVM, LR, DT, RF, KNN, and deep neural networks (DNN), are employed, with CS serving as the primary similarity measure. In most studies, Arabic texts are translated into English using automatic translation tools like Google Translate, followed by similarity computations using measures such as CS, ED, or semantic measures like WUP and LCH. For studies utilizing the SemEval-2017 dataset, which focuses on sentences, the combination of translation (Word2Vec+TF-IDF+MUSE) and the SVC model for classification yielded notable results with an F1-score of 87%. PC for the same combination also achieved a score of 81.47%. In datasets like OPUS, KSUCCA, and EAPCOUNT,

integrating BabelNet with a DNN architecture achieved a significant accuracy of 97.01%. Similarly, the use of translation, the fingerprint approach, and the Winnow algorithm with the LLR technique achieved an accuracy of 97%. Some studies also focused solely on measuring similarity percentages between two sentences.

Fig. 11 reveals that the most commonly used datasets for En-Ar language pair research are SemEval-2017 and EAPCOUNT, highlighting their importance for evaluating semantic similarity models and multilingual plagiarism detection. SemEval-2017 is sentence-based, making it suitable for fine-grained similarity tasks, while Wikipedia, being document-based, is more relevant for applications requiring diverse and larger contexts. Additionally, datasets such as articles, tweets, and academic works demonstrate their value in approaches that require varied and realistic text sources. OPUS and KSUCCA, though moderately used, remain significant for aligned multilingual corpora, whereas books and MultiUN complement the range by addressing specific needs. This distribution reflects a preference for datasets that balance accessibility, diversity, and specificity.

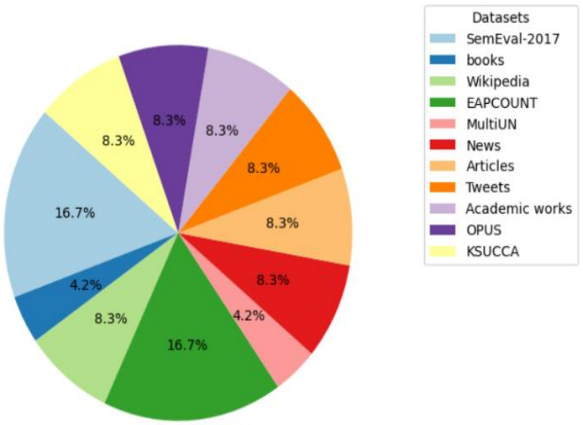

Fig. 11. Most used datasets for the English-Arabic language pair.

b) English-Spanish language pair: For the En-Es language pair, various methodologies, datasets, and performance results are highlighted. The most important approaches leverage advanced transformer models and deep learning architectures. For example, the use of mBART for feature extraction and SLSTM for classification achieved an accuracy of 97.94%, precision of 98.57%, recall of 97.47%, and an F1-score of 98.01%. This method is evaluated using datasets such as Europarl, PAN-PC-11, Wikipedia, JRC-Acquis, and Conference papers. Another notable method used several embedding techniques, including Doc2Vec, GloVe, FastText, BERT, Word2Vec, and Sen2Vec, combined with SLSTM. This strategy achieves accuracy rates between 98.41% and 99.81% on datasets such as JRC-Acquis, PAN-PC-11, Europarl, and Wikipedia. In contrast, methods using traditional feature extraction techniques like TF-IDF and Word2Vec also showed impressive performance. These methods realized plagiarism detection rates of 83.5% and 84.2% on PAN-PC-11 and PAN-PC-12, respectively, and a precision score of 44.3% on SemEval-2017, indicating their efficiency in simpler scenarios. However, approaches centered on knowledge graphs, such as those using Wikidata or BabelNet, displayed moderate results. For example, the method based on Wikidata achieved a plagiarism detection rate of 57.3%, with a precision of 72.3% and a recall of 47.4%. In comparison, the BabelNet-based method recorded a plagiarism detection rate of 60.87%, precision of 70.36%, and recall of 53.99%, both analyzed on the PAN-PC-11 dataset. Similarly, another approach that employed BiGRU and GNN in combination with WordNet and the CS measure achieved a plagiarism detection rate of 62%, precision of 20.3%, and recall of 8.5%.

Fig. 12 illustrates the distribution of datasets used for En-Es. The PAN-PC-11 dataset accounts for the largest proportion at 25%, indicating its extensive use in research. Other datasets, including PAN-PC-12, PAN-PC-14, SemEval-2016, and SemEval-2017, each represent 12.5%, reflecting their consistent contribution to CLPD tasks. Notably, Europarl is used at a smaller rate, 8.3%, while datasets like JRC-Acquis, Wikipedia, MRPC, and conference papers contribute 4.2% each.

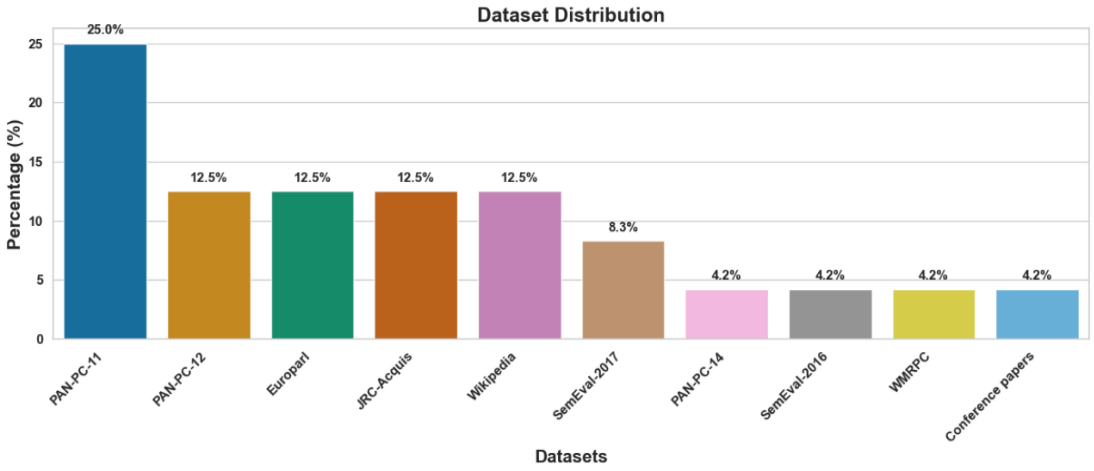

Fig. 12. Most used datasets for the English-Spanish language pair.

c) English-German language pair: For the En-De language pair, the approaches encompass both translation-based and translation-independent methods. The PAN-PC-11 dataset is the most frequently utilized, with the CS measure being widely applied across approaches. Among translation-independent methods, the use of mBART and SLSTM achieves an accuracy of 95.59%, a precision of 95.21%, a recall of 96.85%, and an F1-score of 96.02% across datasets such as PAN-PC-11, JRC-Acquis, Europarl, Wikipedia, and conference papers. For translation-based methods, XLM-R and M-BERT deliver notable results, achieving an accuracy of 87.2% and an F1-score of 90.8% on the GLUE dataset. Conversely, approaches leveraging knowledge graphs, such as Wikidata and BabelNet, demonstrate moderate performance. For instance, the Wikidata-based method achieves a plagiarism detection rate of 52.1%, precision of 67.2%, and recall of 42.5%, while the BabelNet-based approach records a plagiarism detection rate of 52.96%, precision of 63.06%, and recall of 46.71% on the PAN-PC-11 dataset. Additionally, translation-independent methods using traditional feature extraction techniques, including TF-IDF and Word2Vec, show strong performance, with plagiarism detection rates of 85.7% and 86.2% on the PAN-PC-11 and PAN-PC-12 datasets, respectively. In conclusion, transformer models, particularly mBART and SLSTM, demonstrate the most significant results for the En-De language pair, substantially outperforming traditional and knowledge-graph-based approaches.

d) English-French language pair: For the En-Fr language pair, the best-performing approach, translation-independent, combines the mBART transformer for feature extraction with the SLSTM model, using the CS measure. This method achieves exceptional results on datasets such as PAN-PC-11, JRC-Acquis, Europarl, Wikipedia, and conference papers, with an accuracy of 98.83%, a precision of 98.42%, a recall of 99.32%, and an F1-score of 98.87%. Another notable translation-independent approach utilizes CBOW for feature extraction, DT as classifiers, and the CS measure. Tested on datasets including Wikipedia, conference papers, product reviews, Europarl, and JRC-Acquis, this method achieves a solid F1-score of 89.15%. Additionally, a translation-independent approach based on the creation of a knowledge graph using WordNet, combined with BiGRU and GNN models and the CS measure, shows moderate performance. It achieves a precision of 50.6%, a recall of 69%, and a plagiarism detection rate of 58.4% when tested on datasets such as Europarl, JRC-Acquis, and Wikipedia. Another approach, using XLM-R and M-BERT on the GLUE dataset, attains an accuracy of 86.2% and an F1-score of 90.2%.

e) English-Vietnamese language pair: For the English-Vietnamese language pair, both translation-based and translation-independent strategies are emphasized. Translation-based models, such as XLM-R and M-BERT, utilize multilingual embeddings to achieve notable results on the GLUE dataset, with an accuracy of 84.3% and an F1 score of 88.5%. In contrast, translation-free methods leveraging Word2Vec embeddings and lexical resources like WordNet and VietNet demonstrate strong performance, with the SLSTM model achieving an accuracy of 89.61% on the TED dataset. Meanwhile, without word embedding techniques, the use of BabelNet and VietNet with deep learning models (SLSTM) achieves impressive results on the TED dataset, with a precision of 80.3%, a recall of 95.8%, and an F1 score of 87.4%. These findings underscore the effectiveness of both approaches, with translation-free methods often delivering comparable or superior performance.

f) English-Chinese language pair: For the English-Chinese language pair, the approach begins with the use of the Skip-Gram model of Word2Vec and ED as the similarity measure, which attained a high H-score of 97.09% on the NDLTD dataset without relying on translation. Meanwhile, translation-independent methods employing fingerprints and WordNet with the DC deliver a solid performance, achieving a precision of 87% and a recall of 78% on the CNKI dataset. On the other hand, translation-based methods, such as the combination of Google Translate and RCNN with Word2Vec, demonstrate an accuracy of 88.87% on the student dataset. Additionally, the use of Google Translate and BABYLON alongside TF-IDF yielded a Mean Average Precision (MAP) score of 500 on the Xinhua English news dataset.

g) English-Russian language pair: For the English-Russian language pair, all the approaches rely on transformer-based models for the feature extraction phase, achieving results above 80%. The approach using BERT achieves a precision of 96%, outperforming those based on LASER, SE, WS, NMT+1-Gram, and NMT+2-Gram. Furthermore, the use of FastText with CS on the Wikipedia dataset achieves a precision of 83%, a recall of 79%, and an F-score of 80%. Likewise, no use of MSN.

h) English-Persian language pair: For the EN-PE language pair, various translation tools and techniques are implemented, including English experts, Google Translate, and bilingual translators. One notable approach uses the Mizan dataset with WuP as a similarity measure, achieving an accuracy of 98.82%. Google Translate combined with BILBOWA and other techniques like T+MA, CL-LSI, and CL-ESA, leveraging BabelNet for feature extraction, delivers varying precision rates, ranging from 21% to 83% on the HAMTA-CL dataset. The bilingual translator approach employs VSM and TF-IDF with CS, achieving a precision of 88%, a recall of 96%, and an F-score of 91% on Internet sources. Additionally, transformer-based methods like XLM-R, M-BERT, and DistilBERT show interesting precision and similarity scores, with XLM-R achieving 95.62% and 95.17%, M-BERT achieving 91.88% and 91.55%, and DistilBERT achieving 89.51% and 89.08% on the PESTS dataset.

i) English-Urdu language pair: For the English-Urdu language pair, the first approach, based on Google Translate, WordNet, and ML models (KNN, SVM, DT, RF, NB), applied to CLPD-UE-19 with a document-level granularity, achieves an accuracy of 92% with KNN. In contrast, the n-grams + T+MA approach, tested on CLEU (sentence/document level), shows lower performance, with an F1-score of 73.2% for binary classification and 55.2% for ternary classification.

j) English-Indonesian language pair: For the English-Indonesian language pair, two translation-based methods are presented. The first method utilizes Google Translate combined with fingerprinting techniques and the Winnow algorithm, achieving an accuracy of 84.7% on a dataset of scientific articles using the Jaccard similarity measure. The second method relies on a dictionary database, combined with advanced techniques such as LSA, LVQ, and SVD, along with WordNet and the CS measure. This second approach outperforms the first, achieving an accuracy of 87% on the same dataset.

k) Underexplored language Pairs: Certain languages receive limited attention in existing research, primarily because they are not widely spoken or used in international communication. The analysis highlights the underexplored language pairs in CLPD systems, showcasing efforts to address these pairs despite limited resources and research focus. English-Japanese (EN-JA) and English-Korean (EN-KO) achieved promising accuracies of 87.49% and 87.26%, respectively, though with limited datasets. For Traditional Chinese (Ti-Ch), translation-independent methods (Doc2Vec, SLSTM) showed lower precision (54-55%) on datasets like CWMT and SemEval2014. French-Arabic (Fr-Ar), using WordNet similarity measures on datasets of news articles and academic works, recorded a WUP score of 63%. These results reflect the challenges and opportunities for advancing CLPD for less-resourced language pairs.

V. Discussion

This section presents the approaches employed in CLPD, provides a summary of our SLR, and highlights promising research directions that remain largely unexplored.

A. General Architecture for CLPD

In this SLR, we examine the approaches used for CLPD, categorized into four main groups. Similarity-based approaches (MSN) utilize lexical-semantic resources such as WordNet and BabelNet to enhance semantic comparison and measure the relationship between words across languages. These methods also rely on similarity metrics such as cosine similarity, Jaccard index, and Wu-Palmer similarity to assess textual resemblance. Traditional models like TF-IDF and Word2Vec offer a statistical representation of texts. Fingerprinting techniques create distinctive signatures to detect similarities. Lastly, Transformer and deep learning frameworks, including BERT, XLM-R, and mBART, utilize advanced neural architectures for more efficient plagiarism detection.

Fig. 13 illustrates the steps of CLPD systems, which are based on two main strategies: with translation and without translation. In the first approach, the text is translated into a common language to facilitate direct comparison, while in the second approach, detection is performed using multilingual representations without translation. After this initial stage, the text is represented using three methods: Word Embedding (WE alone or WE + MSN), where models like Word2Vec, BERT, or XLM-R transform the text into vectors, either autonomously or by integrating the Multilingual Semantic Network (MSN) to enhance multilingual understanding; Fingerprinting (FP alone or FP + MSN), which generates unique textual fingerprints that can be used alone or combined with MSN to improve semantic alignment; and MSN alone, used independently to detect similarity between texts. After establishing the vector representation of the text, two outputs are obtained: the first output gives a similarity score of two texts via a similarity measure, while the second is a classification using ML or DL algorithms, employing models such as SVM, KNN, or neural networks to distinguish plagiarized from non-plagiarized texts. Finally, a model evaluation phase is carried out using performance measures such as accuracy, precision, recall, and F1 score to assess the effectiveness of the proposed model.

B. Results and Future Research Avenues

This part outlines the key results of the SLR for each inquiry, emphasizing the conclusions derived from the examined studies. It also suggests potential avenues for future investigation, intend to address the identified gaps and steer further advancements in the area.

RQ1: Based on the analysis of the literature review, we have identified 20 language pairs used in work on CLPD. The most frequently studied pairs are En-Ar, En-Es, and En-De, respectively, as shown in Fig. 3. Although other combinations were mentioned, some, such as the English-Hindi pair, were excluded from our selection because the corresponding studies did not meet the inclusion criteria (non-open-source research, review, or monolingual plagiarism). Thus, the total number of pairs actually exploitable remains limited to ten. English appears to be the dominant pivot language, being present in 98% of the language combinations identified.

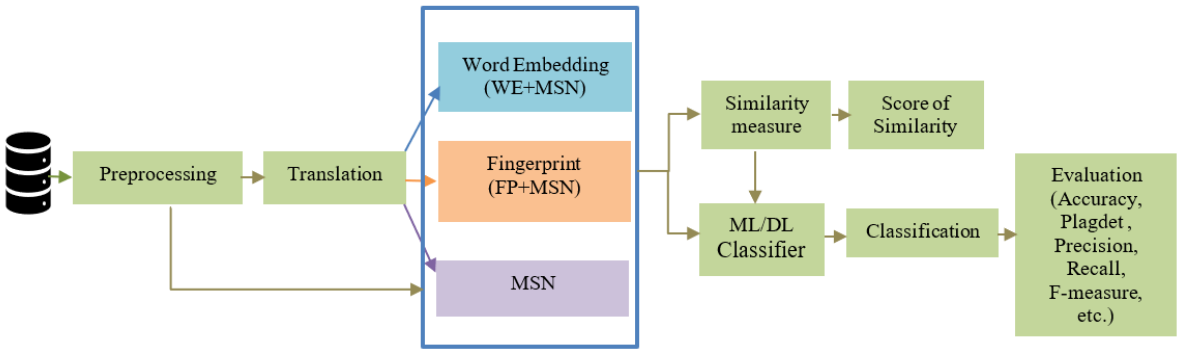

Fig. 13. General architecture for CLPD systems.

RQ2: Concerning the use of translation for CLPD, we observe that during the timeframe of 2014-2025, most documents are translated into the same language, with English being the predominant language for these translations. Additionally, there is a notable portion of studies that are directly incorporated without the process of translation. Among the most widely used translation tools, Google Translate dominates, as illustrated in Fig. 4 and Fig. 5. We also note that for the least explored language pairs, translation is the most used, compared to the most tiled language pair in the context of the CLPD system. According to our analysis, studies that have adopted embedding techniques without going through translation also give significant results, particularly those that have used transformers for different language pairs. The mBART model produced interesting results exceeding 95% for the three language pairs En-Es, En-Fr, and En-De, while the Bert model achieved 96% accuracy for En-Ru. In addition, studies using translation tools achieved interesting results for the English-Persian language pair, with the use of an English expert for translation achieving 98.82% accuracy. In general, the use of advanced embedding techniques, such as transformers, yields interesting results in many languages without the need for translation.

RQ3: Through our review of the literature, we have pinpointed four primary categories of multilingual representation techniques employed in CLPD systems: 1) conventional methods (such as TF-IDF, Word2Vec, FastText), 2) transformer and deep learning architectures (such as mBERT, mBART, XLM-R), 3) multilingual semantic networks like WordNet, BabelNet, VietNet, and Wikidata, and 4) fingerprinting. Historically, conventional methods have been the most prevalent, whereas fingerprinting represents the least investigated area, as depicted in Fig. 6. An analysis of trends over time (Fig. 7) indicates a remarkable transition towards Transformer-based models beginning in 2018, leading to a decline in the use of traditional approaches due to their superior performance and capacity to manage intricate multilingual scenarios. Transformer-based models significantly exceed the performance of traditional word embedding methods, which are often constrained in their F1-measure, as illustrated in Table IV. Furthermore, these models have been evaluated using an expanding range of language pairs, highlighting their versatility. Regarding multilingual semantic networks, WordNet is the most commonly utilized, followed closely by BabelNet, VietNet, and Wikidata (Fig. 8). Nevertheless, these methodologies remain underutilized in CLPD. Lastly, fingerprints are the least frequently employed.

RQ4: Analysis of existing work reveals a diversity of similarity metrics used in CLPD. Nevertheless, the majority of studies favor cosine similarity, due to its effectiveness with vector representations and its ability to evaluate similarities regardless of text length. The second most widely used metric is the Jaccard index, mainly applied to the comparison of sets of words or characters. Other measures, such as Wu-Palmer (WuP), LCS (Longest Common Subsequence), ED (Euclidean Distance), Lin similarity, or the Dice coefficient, appear more marginally, often in specific contexts or as complements to the main methods. Finally, the Containment measure is the least represented, as shown in Fig. 9.

RQ5: In our study, we analyzed several features for each language pair used in CLPD, namely: translation strategy, MSN, feature extraction techniques, methods used (ML/DL), similarity measures, datasets exploited, data granularity, as well as performance obtained. Existing work in CLPD generally pursues two main objectives: similarity score calculation, aimed at comparing sentences or documents using different metrics to evaluate feature extraction techniques, and automatic classification, which consists of training machine or deep learning models to detect cases of plagiarism, relying on metrics such as precision, recall, or F1-measure. Several factors significantly influence the performance of these approaches. Firstly, the granularity of the data plays a decisive role: an analysis at the document level is often more effective than a global analysis of the sentence. Secondly, two main strategies are adopted for multilingual processing: translation into a pivot language, usually English, prior to vectorization, or direct use of the original texts via multilingual models such as mBERT or XLM-R. The choice of method (multilingual semantic networks, fingerprints, traditional embeddings, or Transformers-type models) also has a major impact on the quality of results. Furthermore, poorly endowed languages pose a real challenge due to the lack of suitable linguistic resources, which limits model performance. Finally, advanced models such as BERT, SLSTM, mBART, or XLM-R stand out for their ability to learn rich contextual representations, offering better performance than traditional methods.

Nonetheless, CLPD approaches are still facing several unresolved challenges that manifest across various dimensions of current research:

- Construct diversified multilingual datasets, especially for under-represented languages, and study new and less explored language pairs.
- Analyze and compare the outcomes of methods that incorporate translation against those that do not, while assessing the reliability and performance of various machine translation tools.
- Assess model robustness to paraphrasing, focusing on their capacity to recognize semantically equivalent expressions despite significant syntactic or lexical alterations.
- Examine multiple MSNs such as WordNet, BabelNet, and Wikidata, comparing their performance in terms of semantic richness, contextual precision, and multilingual support.
- Investigate the integration of multiple MSNs (e.g., combining WordNet with BabelNet or Wikidata) to enhance lexical coverage, especially in the context of low-resource languages or domain-specific terminology.
- Evaluate other similarity measures, including LCS, Wu-Palmer, Euclidean distance, Lin, Dice, and cosine similarity, using various types of textual representations.

- Analyze the influence of textual granularity (sentence-level, paragraph-level, or document-level) on detection accuracy and consistency.
- Enhance the capabilities of multilingual knowledge graph-based approaches, focusing on improving their adaptability, scalability, and semantic precision across languages.
- Expand the use of multilingual transformers, given their underutilization in current CLPD studies, to improve scalability and detection accuracy.

VI. Conclusion

Detecting multilingual plagiarism is a major challenge, especially in the academic field. This issue needs a deep study to identify the approaches used for the CLPD system and to respond to many questions. In this context, our work presents an SLR for multilingual plagiarism detection covering the period from 2014 to 2025. Our study proposes four types of multilingual text representations: traditional approaches, multilingual semantic networks, fingerprinting methods, and deep learning models. This review highlights several key findings. The English-Arabic language pair emerges as the most frequently studied, and English appears in 98% of the examined language pairs. Over 60% of the studies incorporate a translation phase, with Google Translate being the most commonly used tool. The mBART model has shown promising results, achieving over 95% accuracy for the En-Es, En-Fr, and En-De language pairs, while the BERT model reached 96% accuracy for the En–Ru pair. Additionally, studies involving translation tools report strong performance for the En-Pe language pair, with an English expert tool for translation reaching up to 98.82% accuracy. Overall, the use of advanced embedding techniques such as transformers has yielded strong results across various language pairs, often without requiring translation. However, it is important to note that the best results do not depend only on the approach used. Firstly, the granularity of the dataset plays a crucial role: detecting plagiarism in a document is different from detecting plagiarism in a sentence. Secondly, the choice of language pair has a significant impact: little-studied languages generally achieve poorer results due to a lack of linguistic resources and research attention. Thirdly, the type of the adopted approach influences the performance. All these factors have a significant impact on CLPD system performance. For future work, we aim to develop universal CLPD models capable of handling any language and form of plagiarism. A promising direction is to leverage knowledge graph–based text representations, enabling the detection of subtle paraphrasing and improving cross-lingual generalization.

Towards Explainable and Balanced Federated Learning: A Neural Network Approach for Multi-Client Fraud Detection

Nurafni Damanik[1], Chuan-Ming Liu[2]*
College of Electrical Engineering and Computer Science, National Taipei University of Technology, Taipei, Taiwan[1]
Department of Computer Science and Information Science, National Taipei University of Technology, Taipei, Taiwan[2]

***Abstract*—The growing demand for secure and privacy-preserving machine learning frameworks has resulted in the implementation of federated learning (FL), especially in critical areas like Credit card fraud detection. This study presents a comprehensive federated learning architecture that incorporates Neural Networks as local models, in conjunction with KMeans-SMOTEENN to address class imbalance in distributed datasets. The system utilises the Flower framework, employing the FedAvg algorithm across ten decentralised clients to collectively train the global model while preserving raw data confidentiality. To improve model transparency and cultivate stakeholder trust, Local Interpretable Model-Agnostic Explanations (LIME) is utilized, offering localised, comprehensible insights into model decisions. The experimental results indicate that the suggested method effectively achieves high predictive accuracy and explainability, rendering it appropriate for real-world fraud detection contexts that necessitate data confidentiality and model accountability.**

***Keywords*—Component federated learning; K-Means SMOTEENN; credit card fraud detection; LIME**

I. Introduction

In recent years, the proliferation of global communication and advancements in computing technology have significantly contributed to the widespread use of credit card transactions. However, this growth has been accompanied by a surge in fraudulent credit card activities. According to data reported by the European Central Bank, Europe experiences annual financial losses amounting to billions of Euros as a result of credit cards [1].

Traditional fraud detection methods, which typically rely on rule-based systems or manual monitoring, have become increasingly inadequate due to their limited ability to dynamically adapt to evolving fraudulent patterns and their reliance on centralized data storage, raising significant privacy and regulatory concerns [2].

Consequently, researchers and practitioners have progressively shifted towards machine learning (ML) methods, which offer superior predictive capabilities by analyzing vast datasets and recognizing complex fraud patterns. While these ML-based approaches, including deep learning models such as CNN, LSTM, and Autoencoders, have shown promising results [3], the centralized nature of data processing inherent in these models poses significant challenges, particularly regarding data privacy, security, and regulatory compliance in sensitive sectors such as finance [4].

To address these critical limitations, federated learning (FL) has emerged as an innovative solution, enabling decentralized model training without exposing sensitive raw data. FL allows multiple institutions to collaboratively train global models by aggregating locally trained model parameters, significantly enhancing data privacy and security [5]. Despite its advantages, current FL implementations often face issues such as data imbalance and lack of model interpretability, critical aspects that affect real-world applicability, particularly in fraud detection scenarios [6]. How can we design a privacy-preserving and interpretable federated fraud detection system that remains effective under severe class imbalance and cross-client data heterogeneity, while satisfying regulatory constraints and enabling real-world deployment?

This study aims to: 1) develop a multi-client FL pipeline (FedAvg) that trains a global model without centralizing sensitive data; 2) address class imbalance at the client level by implementing a client-side hybrid resampling technique (KMeans-SMOTEENN) on each client's training subset prior to local training; validation and test datasets remain unaltered, no raw samples are transmitted from the client, and solely updated model parameters are dispatched for FedAvg aggregation; 3) compare six deep learning architectures—FNN, DNN, CNN, LSTM, Autoencoder, and a stacked DL model within the same FL pipeline to identify the best performer for fraud detection; 4) enhance interpretability by applying LIME to the top-performing model (by AUPRC) and analyzing feature attributions to support audit and domain validation; and 5) compare the performance of our proposed method with state-of-the-art approaches.

Regardless of its benefits, current research on FL-based fraud detection encounters two principal challenges: i) significant class imbalance and non-IID data distributions among clients, which obstruct the identification of minority-class fraud cases, and ii) restricted interpretability, which impedes auditing, regulatory compliance, and stakeholder confidence. Moreover, there is scant information concerning the efficacy of hybrid resampling techniques (e.g., KMeans-SMOTEENN) in federated environments, as well as the comparative performance of various deep learning architectures for rare-event fraud detection. These shortcomings present substantial obstacles to the dependable and regulatory-

*Corresponding Author.

compliant use of FL in practical financial settings.

The proposed framework advances regulation-aligned fraud detection by enabling cross-institution collaboration without data sharing, improving minority-class detection under severe imbalance and non-IID partitions, and closing the explainability gap via LIME. The result is a deployable recipe FL with client-side hybrid resampling, neural models, and post-hoc explanations that: i) raises recall/AUPRC for rare fraud events, ii) preserves privacy and supports compliance, iii) provides decision transparency for risk and audit teams, and iv) generalizes across heterogeneous clients. The approach is transferable to other sensitive domains (e.g., finance and healthcare), where privacy, imbalance, and interpretability are critical.

Building on these objectives, this work makes the following contributions:

1) We offer an innovative federated learning framework that integrates the FedAvg algorithm with KMeans-SMOTEENN, effectively tackling significant class imbalance and heterogeneity in distant client datasets.

2) Thorough Evaluation of Deep Learning Models: We rigorously assess and compare the efficacy of six different deep learning models (FNN, DNN, CNN, LSTM, Autoencoder, and Stacked-DL) in our federated learning framework, yielding critical insights for optimal model selection in fraud detection applications.

3) We utilize Local Interpretable Model-agnostic Explanations (LIME) on the top-performing model (highest AUPRC) to improve the interpretability and transparency of its predictions. This focused strategy guarantees that stakeholders comprehend feature contributions in essential projections.

4) Empirical Validation: Through thorough experimentation, we experimentally confirm that our proposed federated learning technique regularly outperforms standard centralized approaches in accuracy, recall, F1-score, AUC, and AUPRC.

This is how the rest of the study is structured: Section II reviews related work on centralized and federated credit card fraud detection, including class-imbalance remedies and model explainability. Section III details the materials and methods: the overall workflow, dataset, six neural architectures (FNN, DNN, CNN, LSTM, Autoencoder, and a stacked model), the KMeans-SMOTEENN resampling strategy, and the federated learning setup based on FedAvg and the system architecture. Section IV presents experimental results and discussion, including global evaluations, LIME-based explanations, and a comparison with state-of-the-art methods. Section V concludes the study and outlines directions for future work.

II. Related Work

Fraud detection algorithms employ machine learning to effectively identify fraudulent transactions. The majority of suggested CCFDS utilize centralized learning models, whereas a few academics are developing federated learning models to address fraud detection. The supervised, unsupervised, and semi-supervised learning models employ centralized learning algorithms [6].

Credit card fraud detection has been addressed through a variety of machine learning and deep learning techniques, encompassing both supervised and unsupervised methods. Khalid et al. [7] utilized a combination of supervised machine learning models, including Support Vector Machine (SVM), K-Nearest Neighbors (KNN), Decision Tree (DT), Random Forest (RF), Bagging, and Boosting. Alrashdi et al. [8] concentrated on supervised machine learning techniques, employing Random Forest (RF), Extreme Gradient Boosting (XGBoost), and Light Gradient Boosting Machine (LightGBM) to identify fraudulent transactions. Feng and Kim [9] employed a combination of machine learning models, including Random Forest with AdaBoost (RF + AB), Gradient Boosted Decision Trees (GBDT), Support Vector Machine (SVM), K-Nearest Neighbors (KNN), and Convolutional Neural Network (CNN).

Desai and Hase [3] undertook a review of deep learning-based CCFD algorithms, encompassing architectures such as Convolutional Neural Networks (CNN), Recurrent Neural Networks (RNN), Autoencoders (AE), Deep Belief Networks (DBN), and hybrid models like CNN-RNN.

Recent advancements in fraud detection through machine learning techniques have markedly improved detection efficacy; nevertheless, centralized methodologies frequently provide severe privacy and regulatory problems, particularly in financial institutions where the safeguarding of sensitive data is crucial.

Federated learning (FL) has emerged as a significant option, enabling collaborative learning among distant financial institutions while preserving the confidentiality of private data [10] [11].

Recent research in federated learning for credit card fraud detection has investigated diverse deep learning architectures and privacy-preserving methodologies. Tang and Liu [12] introduced a Structured Data Transformer (SDT) model that incorporates federated learning, utilizing the self-attention mechanism of Transformers to adeptly capture intricate feature correlations in serialized transaction data while preserving data privacy among several banks. Their adaptive federated aggregation technique mitigates client heterogeneity and improves model convergence. Nonetheless, their methodology fails to include explicit oversampling approaches for addressing class imbalance, nor does it emphasize model explainability. Complementary to this, Liu et al. [13] employed a federated hybrid oversampling method using K-Means SMOTEENN, which combines K-Means clustering, Synthetic Minority Oversampling Technique (SMOTE), and Edited Nearest Neighbors (ENN) cleaning to effectively tackle class imbalance and noise in fraud detection datasets. Their approach partitions the data into clusters to better preserve local minority class distributions before applying oversampling and noise filtering, thereby enhancing model robustness and generalization. Integrated with a stacking ensemble of diverse classifiers, this method significantly improved detection performance on credit card fraud data, achieving superior precision, recall, and F1-score compared to traditional resampling techniques.

Meanwhile, A. M. Salih et al. [14] highlighted the

importance of Explainable AI techniques such as LIME and SHAP to provide transparency for deep learning models in regulated financial environments.

Our study builds upon these advances by integrating hybrid data balancing, federated learning, and explainability methods to achieve robust, interpretable fraud detection in distributed settings

III. Material and Method

A. Proposed Method

The workflow of the proposed method is illustrated in Fig. 1. Initially, raw data is collected and subjected to data preprocessing, which includes the application of the KMeans-SMOTEENN technique to handle imbalanced data effectively by generating synthetic samples and editing noisy instances. Afterwards, the federated learning (FL) framework is implemented, enabling collaborative training of deep learning models across distributed client environments without compromising data privacy. The deep learning models are then locally trained on each client's dataset and aggregated into a global model through the FL mechanism. Subsequently, evaluation metrics—including accuracy, precision, recall, F1-score, AUROC, and AUPRC—are computed to assess model performance. To enhance transparency and interpretability of the model decisions, the Explainable Artificial Intelligence (XAI) approach, specifically Local Interpretable Model-Agnostic Explanations (LIME), is integrated to explain the predictions and gain deeper insights into feature importance.

B. Dataset Description

This study employs a publicly accessible dataset of credit card transactions conducted by European cardholders. The European credit card fraud dataset was selected because it has become a widely accepted benchmark in fraud detection research, enabling direct and fair comparison with existing state-of-the-art methods. Its highly imbalanced distribution, with fraud cases accounting for only 0.172% of the total transactions, closely reflects real-world scenarios where fraudulent activities are rare but critical to detect.

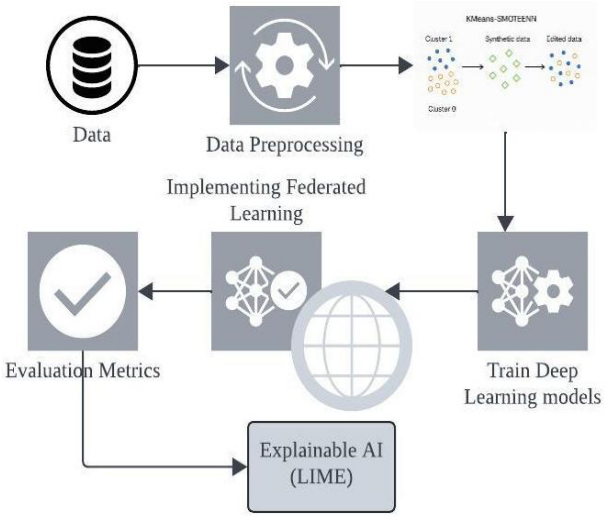

Fig. 1. Proposed method workflow.

The dataset's anonymized features, derived through PCA transformation, ensure compliance with data privacy and confidentiality requirements, aligning well with the regulatory considerations of financial applications. Furthermore, the dataset is publicly accessible, facilitating reproducibility and transparency in research. These characteristics make it an appropriate and representative choice for evaluating the effectiveness of federated learning in addressing fraud detection under severe class imbalance and privacy constraints.

The transactions encompass a two-day duration in September 2013, totaling 284,807 entries, of which merely 492 are classified as fraudulent. This indicates a significantly imbalanced class distribution, with fraudulent instances constituting merely 0.172% of the dataset. The dataset comprises 31 attributes: 'Time', 'Amount', 'Class', and the anonymized variables 'V1' to 'V28', which have been subjected to Principal Component Analysis (PCA) to maintain the confidentiality of sensitive data [1]. The dataset is suitable for machine learning operations because of its exclusively numeric properties. Moreover, its prevalent application in current research enables efficient benchmarking and performance evaluation against proven fraud detection algorithms.

This work involves data preprocessing in three primary stages: resampling to address class imbalance, standardization to equalize feature scales, and reshaping to prepare data for input into diverse machine learning architectures.

Fig. 2 demonstrates a significantly skewed class distribution within the dataset, comprising 283,253 normal transactions and merely 473 instances of fraud, or approximately 99.8% and 0.2% of the total data, respectively. This considerable disparity is a significant obstacle in the training of prediction models, as conventional classifiers often prioritize the majority class, hence risking the neglect of infrequent yet crucial fraudulent patterns. This discrepancy highlights the need for implementing resampling strategies to improve model sensitivity and guarantee effective fraud detection performance.

Considering that the minority class signifies fraudulent instances, employing the unaltered dataset without any balancing methods may considerably impair the model's capacity to identify fraud, resulting in suboptimal recall performance. An innovative hybrid resampling method, KMeans-SMOTEENN, is utilized to resolve this issue. This method integrates clustering-based oversampling with noise-filtering undersampling, facilitating a more efficient management of the dataset's class imbalance by producing synthetic minority samples while concurrently eliminating potential outliers and noisy majority samples.

Subsequent to resampling, feature standardization is executed utilizing StandardScaler, which is crucial owing to the diverse types and sizes of the dataset's features. Standardizing the data guarantees that each feature contributes uniformly to the learning process, hence improving model convergence and performance. Furthermore, the data is restructured by incorporating an additional dimension to align with the input specifications of the Neural Network model, which serves as the principal architecture for fraud detection in this research.

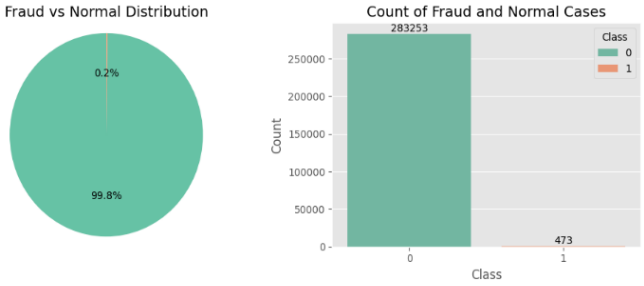

Fig. 2. Imbalance ratio of class fraud and non-fraud.

C. Deep Learning Model

This section succinctly elucidates the deep learning methodology employed in this work.

Since Hinton's breakthrough in 2006, deep learning has progressed swiftly, facilitating the development of robust architectures such as CNNs, RNNs, LSTMs, and Transformers. The breakthroughs, coupled with enhanced hardware capabilities and the accessibility of extensive open-source data, have established deep learning as a preeminent force in artificial intelligence [15].

The fundamental components of deep learning encompass backpropagation, stochastic gradient descent, and convolutional neural networks. It has proven useful in analyzing extensive datasets, especially in tasks such as semantic indexing, data annotation, and information retrieval. Nonetheless, obstacles persist, such as the management of high-dimensional and streaming data, in addition to guaranteeing model scalability. Notwithstanding these constraints, deep learning persists in its advancement, with continuous endeavors to create a more cohesive comprehension and methodology [16].

This research selected deep learning for its capacity to autonomously extract significant features from data, thus reducing the necessity for costly manual feature engineering. To examine the optimal architecture for resolving the research challenge, various deep learning models were deployed and assessed. These models typically consist of multi-layer neural networks, wherein each layer incrementally acquires data representations, spanning from fundamental properties to more intricate and abstract patterns.

In the studies, we employed six distinct variations of deep learning models to assess performance and identify the model yielding optimal results. The specifics of each model and the experimental findings will be comprehensively detailed in the experiment and analysis of results section. This methodology was employed to illustrate the generalizability of deep learning models and to identify the optimal solution depending on the dataset's specific attributes.

1) Autoencoder: Autoencoders are a particular category of neural networks intended to acquire efficient representations (encodings) of unlabeled input, primarily for dimensionality reduction or feature extraction [17].

2) FNN: A Feed-Forward Neural Network (FNN) is a category of artificial neural network in which information progresses unidirectionally from input, through hidden layers, to output without any cycles. Establishing the optimal network size, encompassing the quantity of hidden layers and neurons, is essential as it influences learning ability, generalization, and the likelihood of overfitting. The universal approximation theorem asserts that a single hidden-layer feedforward neural network can estimate any continuous function with a sufficient number of neurons; however, additional hidden layers frequently provide more efficient solutions [18].

3) CNN: A Convolutional Neural Network (CNN) is a prevalent deep learning method that has yielded favorable outcomes across several applications. Convolutional Networks can reveal hidden characteristics of fraudulent transactions and prevent model overfitting. The ConvNets algorithm comprises three primary layers: the convolution layer, the pooling layer, and the fully connected layer.

The convolution and pooling layers primarily execute feature extraction, but the fully connected layer subsequently maps the extracted features to the final output, such as classification [19].

4) LSTM: Long Short-Term Memory (LSTM) is a specialized architecture of artificial recurrent neural networks (RNN) employed to model time series data in deep learning. Unlike conventional feedforward neural networks, LSTM has feedback connections among hidden units linked to discrete time steps, enabling the learning of long-term sequence dependencies and the prediction of a transaction label based on the sequence of prior transactions [20].

5) DNN: A Deep Neural Network (DNN) is a kind of artificial neural network characterized by the presence of multiple hidden layers situated between the input and output layers, in contrast to shallow models. Like conventional neural networks, DNNs handle inputs by multiplying them with weights and transmitting the outcomes through hidden layers activated by nonlinear functions such as sigmoid, tanh, or ReLU. The model parameters are refined by minimizing an error function, typically by stochastic gradient descent, until convergence is achieved. DNN training has two primary phases utilizing the backpropagation algorithm: a forward pass, in which calculations flow from input to output, and a backward pass, during which incorrect gradients are propagated in reverse to adjust the weights[21].

6) STACKING-DL: Stacking is a significant ensemble learning strategy that synthesizes an optimal model by amalgamating predictions from many foundational machine learning algorithms in the initial layer (Emmanuel et al. 2023). The primary concept is to employ the prediction results of the base learner as input features, thereafter training and predicting with the meta-learner. During the model's training phase, an optimum combination of various machine learning methods is employed to fully leverage their respective strengths, hence enhancing the accuracy of the ensemble model's predictions [22].

Table I presents the configuration details and hyperparameters of the neural network models implemented in

this study for credit card fraud detection. The models include Feed-Forward Neural Network (FNN), Deep Neural Network (DNN), 1D Convolutional Neural Network (CNN 1D), Long Short-Term Memory (LSTM), Autoencoder, and a Hybrid model.

- Input Activation Function: All models utilize the Rectified Linear Unit (ReLU) activation function at the input or hidden layers to introduce non-linearity and facilitate efficient training.
- Output Activation Function: Sigmoid activation is applied in the output layer of all models except the Autoencoder, which uses a Sigmoid function suited for reconstruction tasks. This allows for output values between 0 and 1, suitable for binary classification problems like fraud detection.
- Optimizer: The Adam optimizer is consistently used across all models, with an initial learning rate primarily set at 0.001, except for CNN 1D, which uses a lower rate of 0.0001 to accommodate convolutional learning dynamics.
- Learning Rate Decay and Dropout: Learning rate decay and dropout regularization are employed selectively to improve generalization and prevent overfitting. DNN, CNN 1D, LSTM, and Hybrid models incorporate decay rates and dropout values ranging approximately between 0.2 and 0.5, while FNN and Autoencoder models omit these parameters.
- Communication Rounds and Federated Clients: All models are trained in a federated learning setup with 50 communication rounds and 2 to 3 federated clients participating in the training process, ensuring distributed learning and privacy preservation.
- Train-Test Split Ratio: A consistent 80%-10%-10% split is applied for training, validation, and testing datasets, respectively, to maintain fair performance evaluation across models.

This configuration setup balances model complexity and training efficiency, aiming to achieve optimal detection performance while maintaining computational feasibility in a federated environment.

TABLE I. MODELS HYPERPARAMETERS

Model Name	FNN	DNN	CNN 1D	LSTM	Autoencoder	Hybrid

D. K-Means SMOTEENN Imbalanced Handling Dataset

This work employs a hybrid data-balancing methodology that integrates K-Means clustering with SMOTE (Synthetic Minority Oversampling Technique) and ENN (Edited Nearest Neighbors), generally referred to as K-SMOTEENN. This strategy seeks to resolve issues of class imbalance and overlap between classes frequently encountered in datasets, particularly in the fraud detection dataset utilized.

The K-SMOTEENN method we utilize consists of three primary phases:

1) K-Means clustering: The K-Means approach is employed to partition the minority class data into multiple clusters according to feature similarities. Each cluster signifies a distinct pattern within the minority class that exhibits greater homogeneity than the class as a whole.

2) Oversampling utilizing SMOTE: Subsequent to the segmentation of minority data into multiple clusters, we implement the SMOTE technique on each cluster independently to produce supplementary synthetic samples. This procedure is conducted just on clusters that satisfy the minimal sample size criteria for efficacy.

3) Sanitation utilizing ENN: Upon completion of the oversampling phase, the resultant dataset from the oversampling is amalgamated with the majority class. The final stage involves employing the ENN approach to eliminate unclear or potentially noisy samples, hence enhancing the quality of the final data.

The integration of the three methodologies yields a more balanced dataset, facilitating the classification model's ability to differentiate samples from other classes, particularly in overlapping areas. Practical applications of this methodology utilize Python libraries, including scikit-learn for K-Means clustering and imblearn for oversampling and undersampling techniques such as SMOTE and ENN. Optimal configurations, including the number of K-Means clusters and sample parameters, are determined during first experimentation [13].

Thus, this enables K-SMOTEENN to focus on sample data; this strategy is delineated in Algorithm 1.

Algorithm 1 K-SMOTEENN [13]

Input: training data S is a set of pairs $\{(x1, y1), \ldots, (x2, y2), \ldots, (xm, ym)\}$ where *x* represents the input data and y is the corresponding target vector.
n (the number of samples)
k (indicates the number of clusters)
irt (imbalance ratio threshold)
knn (quantity of nearest neighbors)
begin
// Step 1: Divide the input space into clusters *clusters* ← *kmeans*(*X*)
filtered *clusters* ← empty set for c in cluster:

$$\text{imbalance ratio} \leftarrow \frac{\text{majority count(c)}+1}{\text{minority count (c)}+1}$$

If the imbalance ratio is less than the *irt*, add the cluster "c" to the filtered cluster set. Repeat this process until all clusters have been checked.
end
end
Step 2: Implement the SMOTE oversampling technique.
1) From the minority class, choose an instance x_i at random
2) Determine the kind of x_i and denote the samples as S_j
3) Randomly create a synthetic data point p by then selecting a sample in *Sj* called *z*, then creating a line segment in the feature space by connecting p and *z*
4) Minority class label assigned to *p*.
5) Create a series of synthetic instances by combining *p* and *z* convexly.
Step 3: Employing ENN techniques
1) Choose the arbitrary instance x_r from the set S
2) Determine the knn of x_r, with k being equal to 5
3) Remove the x_r Element if it has a more significant number of neighbors from the other class.
4) Iterate 6 to 8 steps for the entire training dataset.
End

E. Federated learning

Federated learning mainly refers to a distributed machine learning method implemented among numerous clients. The procedure involves N clients $\{C_1, C_2, ..., C_N\}$ indexed by k, each possessing its own local dataset $\{D_1, D_2, ..., D_N\}$, which is maintained locally, and data cannot be transferred between clients or gathered by a third party. Typically, a server organizes various clients and their training. FL encompasses three essential steps:

1) Initialization: At communication round *t*, the clients get the newest model wt from the server for initialization.

2) Local training: Each client C_k conducts iterative training based on its own local dataset D_k and hyperparameter η. The local model weight ω_t^k is updated to ω_{t+1}^k after certain training epochs according to $\omega_{t+1}^k \leftarrow \omega_t^k$ (η, $D_{k)}$, leftarrow and subsequently transmitted to the server.

3) Model aggregation: the server does model aggregation on the received local models and updates the global model $\omega_{glob}^{t+1} \leftarrow$ Agg $(\omega_t^{k+1}; k \in [1,....,N])$.

Thus, FL facilitates collaboration among different clients in training a model without the necessity of data exchange, which is particularly advantageous for privacy-sensitive applications [23].

This study utilizes the Federated Averaging (FedAvg) algorithm as the primary approach within our federated learning (FL) system. FedAvg is acknowledged as the predominant strategy in federated learning, enabling clients to collaboratively train a global model while refraining from sharing raw data. Each client develops a local model utilizing its own dataset, while the central server orchestrates parameter distribution, aggregation, and updates. The model parameters from all participants are averaged and redistributed until convergence is reached. This technique enhances data privacy, reduces communication overhead, and guarantees scalability for multiple customers [24]. The full procedure is depicted in Algorithm 2.

Algorithm 2 FedAvg [24]

1: **Server performs**:
2: k is indexed as the K clients,
3: the minibatch size is denoted by B,
4: the number of local epochs is E,

12: $\sum_{k=1}^{K} \frac{nk}{n} \omega_{t+1}^k$
13: **ClientUpdate**(k,ω):
14: $\beta \leftarrow$ split P_k into batches of size $\boldsymbol{B}$
15: **for** each local epoch i from 1 to E **do**
16: **for** batch $b \in \beta$ do
17: $\omega \leftarrow \omega - \eta \nabla l(\omega; b)$
18: **end for**
19**: end for**
20: **end for**
21: **end for**
22: return ω to server

Fig. 3 depicts the federated learning architecture utilized in this research. The system consists of a central server and numerous distributed clients (Client 1 to Client 10). Each client maintains a distinct local dataset, which is saved and processed privately without the dissemination of raw data. The central server first disseminates a global deep learning model to every client. Clients thereafter train their models locally with private datasets and transmit the updated model parameters to the server. The server consolidates these parameters through federated averaging or analogous aggregation techniques to enhance and update the global model. This iterative procedure persists until model convergence is attained, safeguarding data privacy, reducing communication overhead, and adeptly managing heterogeneous data distributions among clients.

IV. Result and Discussion

This research presents an innovative approach to credit card fraud detection by leveraging federated learning (FL) combined with deep neural network models. To address the prevalent data imbalance issue in fraud detection, we employed the KMeans-SMOTEENN resampling technique during preprocessing. The experimental results are structured into two main sections:

metrics comparison per training round and global (overall) metrics across all rounds. The federated learning framework incorporated six distinct deep learning architectures: Autoencoder, CNN, DNN, FNN, LSTM, and a stacked deep learning model. We implemented the FL process using the Flower federated learning framework, a widely recognized Python library tailored for distributed learning scenarios.

All experiments were conducted on a Windows-based workstation, powered by an Intel(R) Core(TM) i7-10700 CPU @ 2.90GHz, and equipped with 16 GB RAM. Model performance was rigorously evaluated using multiple performance indicators: Accuracy, Precision, Recall, F1-score, AUROC (Area Under the ROC Curve), and AUPRC (Area Under the Precision-Recall Curve). The ROC curve graphically represents the classifier's capability in discriminating between fraudulent and non-fraudulent transactions by plotting the True Positive Rate against the False Positive Rate at varying thresholds. AUROC provides a succinct numerical summary of this capability, ranging from 0 to 1, where a value close to 1 signifies excellent predictive accuracy. Additionally, the Precision-Recall Curve focuses specifically on the performance of the classifier in imbalanced class scenarios, such as fraud detection tasks. The subsequent subsections provide detailed visualizations and analyses of the per-round and global performance metrics for each deep learning architecture utilized in the federated learning framework.

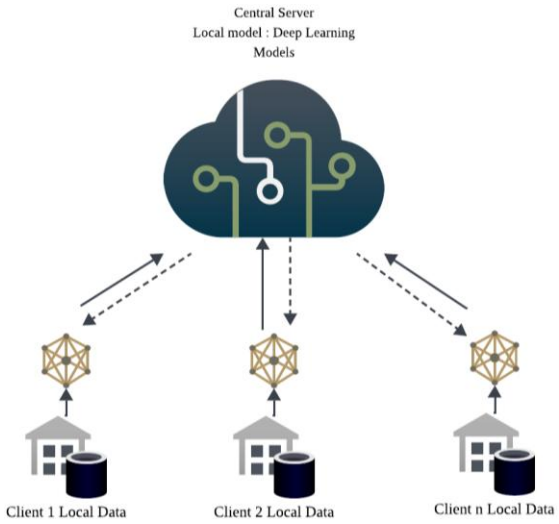

Fig. 3. Federated learning architecture.

A. Performance Evaluation

This section presents the assessment of our proposed federated learning framework for multi-client credit card fraud detection. To thoroughly evaluate the efficacy of various deep learning architectures employed in this federated framework, we analyzed their global performance indicators, consolidated over all clients and training iterations. The assessed designs are Autoencoder, Convolutional Neural Network (CNN), Deep Neural Network (DNN), Feedforward Neural Network (FNN), Long Short-Term Memory (LSTM), and Stacked Deep Learning model.

Table II delineates the comparative performance metrics—Accuracy, Precision, Recall, F1-score, AUROC (Area Under the Receiver Operating Characteristic Curve), and AUPRC (Area Under the Precision-Recall Curve)—for each deep learning model. All models demonstrated consistently high scores across the assessed metrics. The accuracy varied from 0.9992 to 0.9993, signifying an exceptionally high rate of right classifications between fraudulent and legitimate transactions. Precision scores were consistently outstanding, ranging from 0.9993 to 0.9994, indicating the models' exceptional proficiency in accurately recognizing actual positive cases, hence reducing false positive detections.

Recall metrics, which assess the models' efficacy in detecting genuine fraudulent cases (true positive rate), consistently exhibited elevated values (ranging from 0.9992 to 0.9993). Correspondingly, the F1-scores—which equilibrate precision and recall—were remarkably elevated (about 0.9992 to 0.9993), highlighting the models' equitable performance and formidable predictive capability in identifying fraudulent behaviors inside the federated learning framework.

To further assess the model's capacity to differentiate between classes, we used the AUROC and AUPRC measures. The AUROC scores for all models varied between 0.9748 and 0.9833, indicating that all models possess exceptional discriminative ability in differentiating fraudulent transactions from legitimate ones. Nevertheless, there was modest heterogeneity in the AUPRC ratings, indicating slight discrepancies in the efficacy of each model in managing the intrinsically imbalanced fraud detection data. The DNN got the highest AUPRC score (0.8420), closely succeeded by layered deep learning (0.8383) and CNN (0.8289), underscoring these models' specific capabilities in precision-recall equilibrium, a vital component in fraud detection contexts characterized by a scarcity of positive class cases.

TABLE II. PERFORMANCE COMPARISON OF EACH MODEL

Model Type	Accuracy	Precision	Recall	F1	Auroc	Auprc
