$$\mathbf{x} = \mathbf{P}\mathbf{x}_\mathrm{W} \tag{14a}$$
$$\mathbf{x}' = \mathbf{P}\mathbf{R}\left(\mathbf{x}_\mathrm{W} - \mathbf{c}\right) \tag{14b}$$

The (13) can be rewritten as $-\frac{1}{d}\mathbf{n}^T\mathbf{x}_\mathrm{W} = 1$ and substituted into (14b) to obtain,

$$\mathbf{x}' = \mathbf{P}\mathbf{R}\left(\mathbf{x}_\mathrm{W} + \frac{1}{d}\mathbf{c}\mathbf{n}^T\mathbf{x}_\mathrm{W}\right) = \mathbf{P}\mathbf{R}\left(\mathbf{I} + \frac{1}{d}\mathbf{c}\mathbf{n}^T\right)\mathbf{x}_\mathrm{W} \tag{15}$$

Similarly, based on (14a), the $\mathbf{x}_\mathrm{W}$ can be rewrite as $\mathbf{x}_\mathrm{W} = \mathbf{P}^{-1}\mathbf{x}$. By putting this into (15), we have

$$\mathbf{x}' = \mathbf{PR}\left(\mathbf{I} + \frac{1}{d}\mathbf{c}\mathbf{n}^T\right)\mathbf{P}^{-1}\mathbf{x} \tag{16}$$

***Abstract*—The rapid advancement of autonomous vehicles has led to the widespread integration of advanced driver assistance systems, significantly improving vehicle control, safety, and compliance with traffic regulations. A crucial aspect of these systems is the reliable detection and recognition of traffic signs, which play a key role in managing urban traffic flow and ensuring road safety. However, traffic sign recognition remains a challenging task due to varying lighting conditions, occlusions, and diverse sign appearances. This paper presents a novel hybrid approach for efficient traffic sign recognition tailored to the needs of autonomous driving. The proposed method combines the Discrete Wavelet Transform for robust feature extraction with the powerful classification capabilities of Convolutional Neural Networks within a Deep Learning framework. The DWT effectively captures essential image characteristics while reducing noise and irrelevant details, providing a compact yet informative feature set for the CNN classifier. Extensive experiments were conducted to evaluate the performance of the system in real-world conditions. The proposed approach achieved an impressive recognition precision of 98%, demonstrating its ability to interpret and respond to traffic signs with high reliability. The results confirm the method's robustness, real-time efficiency, and suitability for deployment in intelligent transportation systems and autonomous vehicles. Overall, this study highlights the complementary strengths of DWT and CNN within the broader context of Deep Learning, offering a significant improvement over conventional traffic sign recognition techniques. The proposed system represents a promising step toward enhancing the perception capabilities of autonomous vehicles, contributing to safer and more reliable navigation in complex traffic environments.**

***Keywords*—Safety; discrete wavelet transform; traffic sign recognition; autonomous vehicles; deep learning**

I. Introduction

Scene understanding is a fundamental challenge in computer vision, encompassing critical tasks such as object detection, classification, and semantic segmentation across diverse environments [1]. Recent advances in deep learning have significantly improved performance in these areas, enabling breakthroughs in autonomous driving and robotic vision [2]. Among these tasks, Traffic Sign Recognition (TSR) has attracted particular attention because of its direct impact on road safety and navigation efficiency. Accurate and real-time TSR is essential for both human drivers and autonomous systems, especially in unfamiliar or complex driving scenarios [3]. Reliable TSR ensures that vehicles can interpret and respond appropriately to traffic regulations, which is a cornerstone for the safe deployment of intelligent transportation systems.

Despite considerable progress, TSR remains a challenging problem due to both environmental and technical factors. Environmental conditions such as varying illumination, adverse weather (e.g. rain, fog, or low-light scenarios), and occlusions often reduce detection reliability. Furthermore, traffic signs exhibit significant variability in appearance, including differences in scale, shape, and color across countries, which complicates the recognition task. On the technical side, many existing approaches suffer from limitations in computational efficiency or fail to generalize well to real-world conditions. Although intelligent vision-based systems have attempted to address these issues using advanced image processing techniques and multi-sensor fusion [4], scalability and real-time performance continue to be open challenges. These limitations highlight the need for hybrid methods that combine robustness, efficiency, and adaptability.

To address these challenges, this study proposes a novel hybrid model that integrates the Discrete Wavelet Transform (DWT) with a Convolutional Neural Network (CNN) for traffic sign recognition. DWT is used as a preprocessing step to decompose traffic sign images into multiple frequency bands, thereby preserving critical structural features while suppressing noise. CNNs, on the other hand, excel at hierarchical feature learning and robust classification. By combining these two techniques, the proposed approach leverages their complementary strengths: DWT enhances the quality of input features, while the CNN ensures accurate and efficient classification. This synergy enables improved recognition performance, particularly under adverse conditions, while maintaining real-time processing capability.

The contributions of this work are as follows: First, a DWT-based preprocessing framework is proposed to extract relevant features by capturing both low and high-frequency information, which enhances contour and detail representation while effectively reducing noise, thereby improving robustness under adverse conditions such as rain or low-light environments; second, an optimized CNN architecture is designed specifically for traffic sign recognition, striking a balance between accuracy and computational efficiency; finally, comprehensive evaluations demonstrate that the proposed approach outperforms state-of-the-art methods, particularly in challenging and adverse environments.

The remainder of this paper is structured as follows: Section II reviews related work and key challenges in TSR; Sec-

tion III details the proposed DWT-CNN methodology; Section IV presents the experimental setup, results, and comparisons; and Section V concludes with a discussion of limitations and future research directions.

II. Related Work

Recent advances in Traffic Sign Recognition (TSR) have focused on improving detection accuracy, robustness under adverse conditions, and computational efficiency. Deep learning-based approaches, particularly those leveraging convolutional neural networks (CNNs) and attention mechanisms, have dominated the field, while hybrid methods integrating traditional image processing techniques have gained traction for enhanced feature extraction. Despite these advances, most methods still face challenges in balancing accuracy, robustness, and real-time performance, especially under adverse visual conditions or on embedded platforms.

A. Deep Learning: Based Approaches

CNN-based architectures remain the cornerstone of modern TSR systems due to their hierarchical feature learning capabilities. Early successes such as Faster R-CNN and SSD laid the groundwork for robust object detection pipelines. Modified Faster R-CNN models incorporating Feature Pyramid Networks (FPN) improve small and distant sign detection [5], but they remain computationally intensive, limiting their use in real-time embedded systems. SSD variants offer real-time detection with reasonable accuracy, yet they can struggle with very small or occluded signs. YOLO models, including Sign-YOLO (attention-based YOLOv7) [6] and YOLOv8 [7], achieve an excellent speed-accuracy trade-off, yet attention-based variants often increase model complexity and may require additional tuning for low-light or motion-blurred scenarios.

Transformers, such as Vision Transformers (ViTs) [8] and Swin Transformers [9], capture long-range dependencies and complex scene context effectively, improving recognition in crowded or cluttered scenes. However, their high computational cost and large memory footprint hinder deployment on low-power devices, motivating lightweight or hybrid variants.

Overall, deep learning approaches are powerful but often trade-off robustness, speed, and hardware efficiency, motivating research into methods like DWT-CNN that aim to preserve structural features while remaining efficient.

B. Hybrid and Preprocessing-Enhanced Methods

To mitigate issues such as illumination variations, noise, and motion blur, hybrid methods combining deep learning with traditional image processing have been explored. Discrete Wavelet Transform (DWT) preprocessing enhances feature robustness by decomposing images into multi-resolution subbands [10], preserving structural details while filtering noise. Studies [11] show that wavelet-based denoising improves detection in low-visibility conditions, though the additional preprocessing step may slightly increase inference time.

Multi-scale methods like SADANet [12] improve detection across varying sign sizes but can add network complexity. Multi-sensor fusion approaches, combining LiDAR and camera data [13], [14], reduce false positives in adverse weather, yet introduce high computational requirements and challenges in real-time deployment.

In comparison, the proposed DWT-CNN integrates wavelet preprocessing directly into the CNN pipeline, achieving robustness under adverse conditions while maintaining real-time performance. This positions the proposed approach as a balanced solution that addresses key limitations of both pure deep learning and hybrid methods, providing a strong foundation for real-world traffic sign recognition systems.

III. Proposed Method

In this work, this study proposes a novel hybrid architecture that integrates DWT with a CNN for robust and efficient Traffic Sign Recognition (TSR). The core idea is to leverage the multi-resolution analysis capability of DWT to enhance feature robustness under challenging conditions such as noise, motion blur, and lighting variations, while preserving a lightweight design suitable for real-time applications.

The proposed traffic sign recognition method is based on a hybrid architecture that combines the strengths of the Discrete Wavelet Transform (DWT) and Convolutional Neural Networks (CNNs) to ensure both robustness and efficiency in real-world scenarios. The overall pipeline is designed to enhance feature extraction under challenging conditions such as noise, motion blur, and varying illumination, while maintaining the low computational cost required for real-time deployment. The system begins by preparing and preprocessing a diverse set of traffic sign images to ensure uniform input and reduce variability, where input images are standardized to 128×128 pixels, and converted to grayscale to optimize computational efficiency. Next, the images are passed through a DWT-based transformation to extract multi-resolution frequency components, allowing the model to focus on structural details and suppress irrelevant noise. These enhanced representations are then fed into a lightweight CNN specifically designed for traffic sign classification. The model is trained with optimized strategies to prevent overfitting and maximize generalization. Finally, extensive evaluations are conducted to assess the system's accuracy, speed, and robustness under various environmental conditions. A comprehensive overview of the model is visually presented in Fig. 1 and the following subsections describe each phase of the proposed method in detail.

1) Preprocessing pipeline: Traffic signs suffer two main degradation types: natural and human-induced. Natural degradation is typically caused by long-term exposure to ultraviolet (UV) radiation and the use of retro-reflective materials, which may alter the sign's color and reduce its visibility. On the other hand, human-related degradation can take many forms, affecting the shape, color, components, or even the entire structure of the sign. To ensure accurate recognition of such signs despite potential deterioration, robust image preprocessing is essential. In the initial stage, the input images are standardized to improve compatibility with the Convolutional Neural Network (CNN). This includes resizing all images to a fixed dimension (640×640 pixels), then converting them to grayscale to reduce computational complexity while retaining edge and structural information.

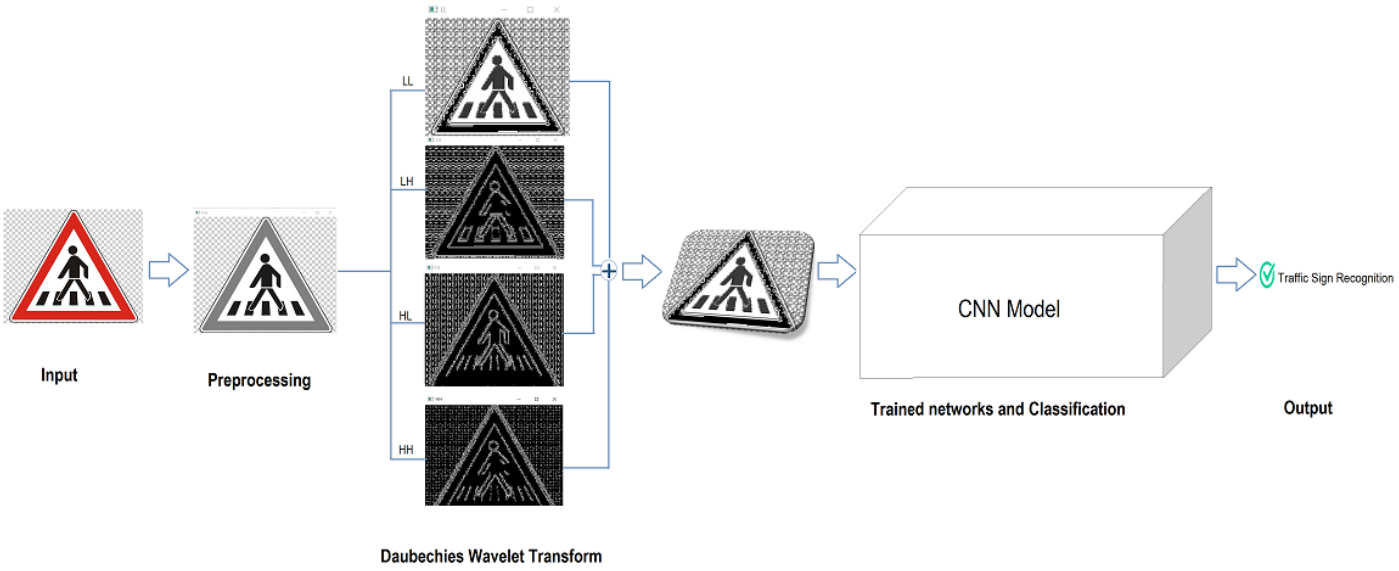

Fig. 1. Proposed TSR system based on wavelet transform and CNN: (a) Preprocessing, (b) Daubechies DWT: Decomposition Sub-bands, (c) Feature Fusion, and (d) CNN model.

2) DWT-Based feature enhancement: The DWT addresses key challenges in traffic sign recognition such as noise robustness and multi-scale feature extraction by decomposing images into frequency sub-bands. Unlike traditional methods, it preserves spatial and frequency information simultaneously, making it ideal for analyzing degraded signs [15].

There are two main types of wavelet transforms: the Continuous Wavelet Transform (CWT), designed for continuous signal decomposition, and the Discrete Wavelet Transform (DWT), commonly used in practical applications for analyzing both signals and images. The DWT decomposes input data into frequency sub-bands and is favored for its computational efficiency and simplicity.

Mathematically, the DWT is defined by Eq. 1, where $x(k)$ is a discrete-time signal with k samples and ψ is the discrete mother wavelet used for decomposition level i:

$$DWT_{ik} = \sum x(k)\psi_{i,k}(t) \tag{1}$$

Here, $\psi_{i,k}$ are scaled and translated versions of the mother wavelet $\psi(x)$:

$$\psi_{i,k}(x) = 2^{-i/2}\psi(2^{-i}x - k) \tag{2}$$

where i and k represent the dilation and translation parameters, respectively.

Various mother wavelets can be employed, such as Haar, Daubechies, Meyer, and Mexican Hat, depending on the characteristics of the application [16]. In this study, the Daubechies wavelet is employed due to its orthogonality and compact support, making it particularly effective for discrete signal processing.

To compute the DWT, the signal is passed through a low-pass filter $g[n]$ and a high-pass filter $h[n]$, as shown in Eq. 3:

$$y[n] = (x * g)[n] = \sum_{k=-\infty}^{\infty} x[k]g[n-k] \tag{3}$$

The Daubechies wavelet is adopted in this study due to its compact support and orthogonality, which efficiently capture localized signal features. The one-level decomposition (Fig. 2) partitions the image into:

- LL: Low-frequency components (approximation)
- LH/HL: (horizontal/vertical edges)
- HH: High-frequency components (diagonal details)

This decomposition process is illustrated in Fig. 2. The maximum decomposition level depends on the number of samples and the sampling frequency f_s. The frequency ranges for approximation and detail sub-bands at level i are given by:

$$A_i = \left[0, \frac{f_s}{2^{i+1}}\right], \tag{4}$$

$$D_i = \left[\frac{f_s}{2^{i+1}}, \frac{f_s}{2^1}\right]. \tag{5}$$

The 1-level decomposition was chosen to balance computational cost and feature granularity, as higher levels showed diminishing returns in preliminary experiments.

Instead of feeding raw images into the CNN, the decomposed sub-bands (LL, LH, HL, HH) are used as inputs, as illustrated in Fig. 3. This allows the network to learn more robust and localized features, particularly edges and shape patterns, which are crucial for accurate traffic sign recognition.

Using only the LL sub-band as input to a CNN may result in the loss of crucial information present in other sub-bands

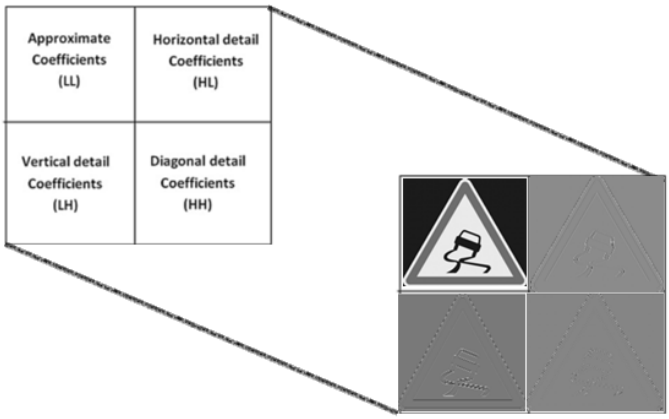

Fig. 2. Wavelet decomposition coefficients for the first level.

(LH, HL, and HH), which contain important details. By including all sub-bands as input, the model can manipulate details at various frequencies, ensuring a comprehensive representation of the image. The LH sub-band captures intermediate-frequency details, such as textures and edges, the HL sub-band contains high-frequency information, such as small details and color variations, and the HH sub-band contains very high-frequency information, such as very fine details and color variations. This approach enhances the model's ability to capture important image features, leading to improved performance and accuracy.

Fig. 3 presents the results obtained from each of the four sub-bands: LL, LH, HL, and HH.

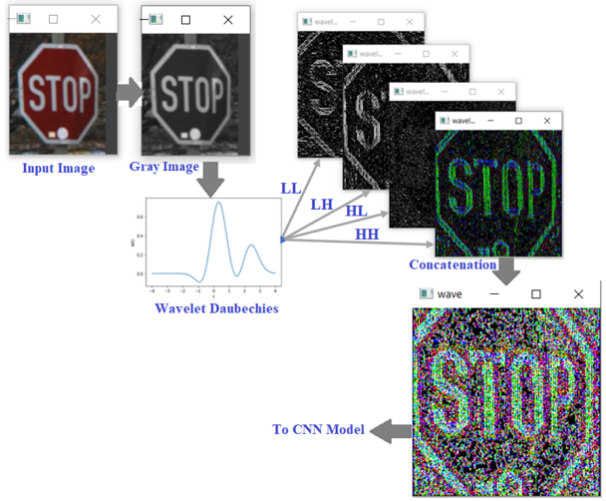

Fig. 3. Wavelet sub-band decomposition and concatenation (LL, LH, HL, HH).

In this work, a one-level 2D DWT decomposition is applied to each input image prior to classification to enhance the CNN's performance and improve feature representation.

3) CNN architecture: In this study, a DWT-based Traffic Sign Recognition System is introduced to enhance the feature extraction capability, improve detection performance, and reduce memory consumption and overall model size. As illustrated in Fig. 4, the system leverages the sub-bands generated by the Discrete Wavelet Transform (DWT). The main objective of this DWT-based approach is to extract robust and discriminative features from the DWT outputs and the backbone network, thereby improving detection accuracy under various conditions. Additionally, this mechanism guides the network's attention toward the most informative spatial regions particularly useful when traffic signs appear in cluttered or complex scenes.

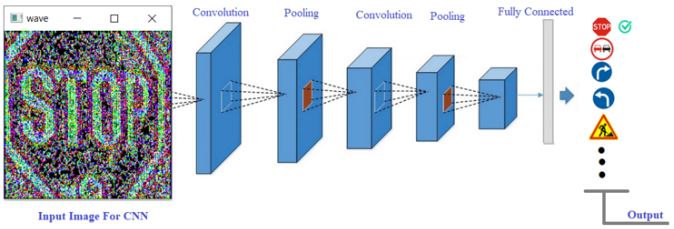

Fig. 4. Overall architecture of the proposed framework for TSR.

The convolutional layer [17] is a fundamental building block in CNNs and typically consists of three sequential components: convolution, activation, and pooling. In image processing tasks, the input is treated as a two-dimensional array, and the convolution operation applies a filter of size $S \times T$ over the input of size $M \times N$, producing an output of the same dimensions. The operation is defined as:

$$U^p_{mn} = \sum_{s=0}^{S-1} \sum_{t=0}^{T-1} h^{p-1}_{st} \cdot O^{p-1}_{m+s,n+t} + \theta^p_{mn} \tag{6}$$

Here, U^p_{mn} denotes the pre-activation value at location (m, n) in layer p, h^{p-1}_{st} is the (s, t)-th weight of the filter, $O^{p-1}_{m+s,n+t}$ is the corresponding input from the previous layer, and θ^p_{mn} is the bias term.

Subsequently, an activation function is applied. For instance, using the ReLU activation, the post-activation output becomes:

$$O^p_{mn} = \text{ReLU}(U^p_{mn}) \tag{7}$$

In the activation function layer, where no parameters are trained, the derivative for error backpropagation is calculated as follows:

$$\begin{aligned} \frac{\partial E}{\partial O^{p-1}_{mn}} &= \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} \frac{\partial E}{\partial U^p_{mn}} \cdot \frac{\partial U^p_{mn}}{\partial O^{p-1}_{mn}} \\ &= \frac{\partial E}{\partial U^p_{mn}} \cdot \frac{\partial ReLU(O^{p-1}_{mn})}{\partial O^{p-1}_{mn}} \\ &= \begin{cases} \frac{\partial E}{\partial U^p_{mn}} & (O^{p-1}_{mn} > 0) \\ 0 & (O^{p-1}_{mn} \leq 0) \end{cases} \end{aligned} \tag{8}$$

When a pooling layer follows a convolutional layer, it aggregates spatial information within localized regions of the feature map to reduce dimensionality and retain salient

features. The general form of the pooling operation at position (m, n) in the p-th layer is defined as:

$$U_{mn}^{p} = \left(\frac{1}{S \times T} \sum_{(i,j) \in D_{mn}} (O_{ij}^{p-1})^{g} \right)^{\frac{1}{g}} \tag{9}$$

In this equation, O_{ij}^{p-1} denotes the output of the unit at position (i, j) in the $(p-1)$-th layer, and D_{mn} represents the pooling window of size $S \times T$ centered around (m, n). The parameters S and T are typically chosen to match the dimensions of the convolutional filter. The parameter g controls the type of pooling: setting $g = 1$ yields average pooling, while $g \to \infty$ approximates max pooling.

For example, setting $g = 1$ results in the average pooling operation, where the output is the arithmetic mean of the values within the pooling region:

$$U_{mn}^{p} = \frac{1}{S \times T} \sum_{(i,j) \in D_{mn}} O_{ij}^{p-1} \tag{10}$$

The averaging operation in the pooling layer reduces the spatial dimensions of the input while preserving essential features, thereby improving computational efficiency. When the pooling parameter g tends toward infinity, the operation becomes equivalent to max pooling, where the output at position (m, n) in the p-th layer is determined by selecting the maximum value within the pooling window D_{mn}. In this case, the pooling operation simplifies to:

$$U_{mn}^{p} = \max_{(i,j) \in D_{mn}} \{O_{ij}^{p-1}\} \tag{11}$$

Pooling layers, whether average or max, perform spatial downsampling to reduce feature map resolution while retaining discriminative information. Max pooling preserves the most dominant activations, while average pooling computes the mean of local regions. Since pooling layers do not involve trainable parameters, backpropagation in these layers is limited to the propagation of gradients from the current layer p to the previous layer $p-1$.

For average pooling, the gradient of the loss function E with respect to the output O_{mn}^{p-1} of the previous layer is computed by equally distributing the gradient across the pooling window. The corresponding gradient expression is given by:

$$\begin{aligned} \frac{\partial E}{\partial O_{mn}^{p-1}} &= \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} \frac{\partial E}{\partial U_{mn}^{p}} \cdot \frac{\partial U_{mn}^{p}}{\partial O_{mn}^{p-1}} \\ &= \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} \frac{\partial E}{\partial U_{mn}^{p}} \cdot \left(\frac{1}{S \times T} \sum_{(i,j) \in D_{mn}} \frac{\partial O_{ij}^{p-1}}{\partial O_{mn}^{p-1}} \right) \end{aligned} \tag{12}$$

In contrast, backpropagation through max pooling involves identifying the location of the maximum value within each pooling region. The gradient is passed only to the unit that contributed the maximum activation. This can be formulated as:

$$\begin{aligned} \frac{\partial E}{\partial O_{mn}^{p-1}} &= \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} \frac{\partial E}{\partial U_{mn}^{p}} \cdot \frac{\partial U_{mn}^{p}}{\partial O_{mn}^{p-1}} \\ &= \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} \frac{\partial E}{\partial U_{mn}^{p}} \cdot \frac{\partial}{\partial O_{mn}^{p-1}} \left(\max_{(i,j) \in D_{mn}} \{O_{ij}^{p-1}\} \right) \end{aligned} \tag{13}$$

In addition to pooling, normalization layers are often employed to stabilize and accelerate the training process. A common form of normalization is defined as:

$$U_{mn}^{p} = \frac{O_{mn}^{p-1} - \mu_{mn}}{\sqrt{c + \sigma_{mn}^{2}}} \tag{14}$$

where U_{mn}^{p} is the normalized output at position (m, n), O_{mn}^{p-1} is the input value from the previous layer, μ_{mn} and σ_{mn}^{2} are the local mean and variance computed over the pooling window D_{mn}, and c is a small constant added for numerical stability. These statistical quantities are computed as:

$$\mu_{mn} = \frac{1}{S \times T} \sum_{(i,j) \in D_{mn}} O_{ij}^{p-1} \tag{15}$$

$$\sigma_{mn}^{2} = \frac{1}{S \times T} \sum_{(i,j) \in D_{mn}} (O_{ij}^{p-1} - \mu_{mn})^{2} \tag{16}$$

These normalization steps help maintain consistent activation distributions across layers, which contributes to faster convergence and improved generalization during training.

4) System workflow overview: Fig. 4 illustrates the overall architecture of the proposed CNN, highlighting the sequence of convolution, activation, pooling, and normalization layers.

The pseudocode in Algorithm 1 describes the core stages of the proposed DWT-based traffic sign recognition system. It begins by converting the input image to grayscale and initializing all key components of the model, including a DWT layer, a convolutional backbone network, a neck module, and a detection head. During training, the image undergoes preprocessing and is passed through the DWT layer to extract frequency-based features. These features are then processed by the convolutional backbone, which comprises several layers of convolution, batch normalization, ReLU activations, dropout, and max pooling. The refined feature maps are passed through the neck and then to the detection head, which predicts both class probabilities and bounding box coordinates. The training loop optimizes the model using a combination of classification and localization losses. During inference, the input image follows the same processing pipeline, leading to the final prediction of bounding box coordinates and the corresponding class label.

A key originality of the proposed architecture lies in the explicit integration of the DWT as the first processing stage of the network. Unlike conventional CNN-based TSR systems that rely solely on spatial-domain features, the model leverages

```

frequency-domain information to enhance robustness against noise, illumination changes, and motion blur. This design allows the backbone to operate on enriched multi-resolution representations, reducing the loss of fine structural details typically discarded in early convolutional layers. Moreover, by embedding the wavelet decomposition directly into the training pipeline rather than using it as a separate preprocessing step, the system jointly optimizes spatial and frequency features, ensuring better generalization under adverse conditions. This tight coupling of DWT with CNN layers distinguishes the proposed approach from existing hybrid methods and constitutes the main source of its improved performance and resilience.

IV. Results and Evaluation

This section demonstrates the effectiveness of the proposed DWT-CNN framework. First, the datasets used for training and evaluation are presented. Next, the implementation setup and evaluation protocol are detailed. Finally, a comparative analysis between the proposed method and other state-of-the-art approaches is provided.

1) Traffic signs dataset: The German Traffic Sign Recognition Benchmark (GTSRB) is a popular dataset for traffic sign recognition research [18] due to its large size (over 50,000 images of 43 different classes of traffic signs), diverse classes shown in Fig. 5 (including speed limits, priority, prohibitory, and warning signs), high-quality annotations, and wide use as a benchmark. Additionally, the dataset is publicly available and free to use, making it easily accessible for researchers. These factors have contributed to GTSRB's popularity as a benchmark for evaluating traffic sign recognition algorithms in recent years.

2) Implementation details: The proposed DWT-CNN model was implemented and evaluated using the German Traffic Sign Recognition Benchmark (GTSRB). For this study, a selected subset of GTSRB subclasses particularly relevant to real-world traffic scenarios was used. Each input image was resized to a resolution of 640×640 pixels for both the training and testing phases.

The experiments were conducted on a high-performance machine equipped with an Intel 13th Gen Core(TM) i7-13650HX CPU clocked at 2.60 GHz, 32 GB of RAM, and an NVIDIA GeForce RTX 4060 GPU with 8 GB of memory. The implementation was developed with CUDA version 12.7 and cuDNN version 9.1.0 for GPU acceleration.

This hardware configuration ensured efficient training and inference, especially for high-resolution input images and large-scale datasets.

The model was implemented using Python and PyTorch. The training process incorporated standard data augmentation techniques, including random rotation, horizontal flipping, and color jittering, to enhance generalization. Optimization was carried out using the Adam optimizer with an empirically tuned learning rate. The loss function combined cross-entropy for classification with mean squared error for bounding box regression.

3) Evaluation metrics: To evaluate the accuracy of the proposed method, this study employs standard metrics widely used in object detection and classification, including precision, recall, accuracy, and mean average precision (mAP). These metrics provide comprehensive insights into the method's performance in terms of correctness, completeness, and effectiveness, and also allow for fair comparisons with existing approaches in the literature.

Precision measures the proportion of correctly predicted positive samples out of all positive predictions, reflecting the model's accuracy in identifying relevant objects. Formally, it is defined as follows [19]:

Fig. 5. Summary of the dataset classes.

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}} \tag{17}$$

where:

- TP (True Positive): Correctly predicted object,
- FP (False Positive): Incorrectly predicted object.

Recall, also known as *sensitivity* or *true positive rate*, measures the ability of the model to detect all relevant instances of a class. It is computed as [20]:

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{18}$$

where FN (False Negative) refers to instances where the model failed to detect existing objects.

Accuracy assesses the overall correctness of the model's predictions, considering both positive and negative classifications:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}} \tag{19}$$

where TN (True Negative) represents the correct prediction of the absence of objects.

Finally, mean average precision (mAP) is a key performance indicator in object detection tasks. It is computed by averaging the average precision (AveP) across all object classes:

$$\text{mAP} = \frac{1}{n} \sum_{k=1}^{n} \text{AveP}_k \tag{20}$$

where AveP_k is the average precision for class k, and n is the total number of classes.

In summary, relying on these validation metrics is fundamental to rigorously assessing the reliability of the proposed method. They ensure that the evaluation is not biased toward a single criterion but instead provides a holistic view of detection performance, which is essential for benchmarking against other state-of-the-art models.

4) Result and Analysis: As evidenced by the confusion matrix in Fig. 6, the model achieves high classification accuracy across diverse sign categories, with minimal misclassifications even for visually similar classes. The synergy of DWT's noise resilience and the CNN's learning capability ensures reliable performance under real-world challenges such as occlusions and weather distortions.

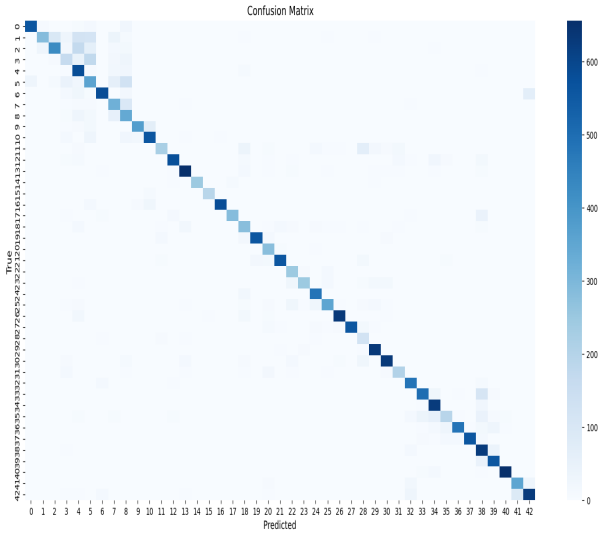

Fig. 6. Confusion matrix showing the performance of the proposed classification model.

Rigorous validation is essential in traffic sign recognition, where errors can directly affect road safety. Metrics such as precision, recall, F1-score, and mean average precision (mAP) not only quantify accuracy but also reveal the robustness of the model under varying conditions. High precision reduces false positives, which is critical to avoid incorrect driving actions, while high recall minimizes false negatives, ensuring that no critical sign is overlooked. These complementary measures together validate both the correctness and completeness of the proposed DWT-CNN model.

To assess the efficacy of the DWT-CNN model, this study conducts experiments on the GTSRB dataset, which comprises 43 subclasses grouped into four superclasses: prohibitory, mandatory, danger, and other. As shown in Table I, the model achieves strong performance across these categories, with par-

ticularly high accuracy for critical prohibitory and mandatory signs (e.g. stop: F1-score 0.96, speed_limit_20: 0.98). The results demonstrate the effectiveness of combining DWT's noise-robust feature extraction with CNN's discriminative learning, particularly in challenging real-world conditions.

TABLE I. VALIDATION OF THE PROPOSED METHOD ON SUB-CLASSES OF THE GTSRB

Class	Precision	Recall	F1-Score
0: speed_limit_20	0.98	0.97	0.98
1: speed_limit_30	0.86	0.90	0.88

Table II compares the proposed DWT-CNN model to state-of-the-art detectors based on key performance metrics: mean Average Precision (mAP), inference speed (FPS), memory usage (MB), and model size (number of parameters in millions). The DWT-CNN achieves a mAP of 0.97, outperforming all baseline models, including Faster R-CNN variants (ranging from 0.9062 to 0.9508) and YOLOv7/YOLOv8 (0.92–0.93), while maintaining real-time performance with 88.83 FPS. This is significantly faster than two-stage detectors such as Faster R-CNN (8.11–17.08 FPS) and even lightweight models like SSD MobileNet (66.03 FPS). Furthermore, the model accomplishes this with only 3.6 million parameters—substantially fewer than YOLOv7 (70.31M) and ResNet-based architectures (12.89–62.38M). Although the memory footprint (4493.43 MB) is higher than that of SSD MobileNet (94.70 MB), the trade-off is justified by a substantial gain in accuracy (+35.36% mAP) and speed (+22.8 FPS). These results highlight DWT-CNN's strong balance between accuracy and efficiency, making it well-suited for real-time traffic sign recognition tasks where high precision is essential.

Visual results in Fig. 7 illustrate the model's ability to accurately detect and classify traffic signs under challenging conditions from the GTSRB dataset. The test images include difficult scenarios such as low resolution, motion blur, occlusion, and poor lighting. Despite these adverse conditions, the proposed DWT-CNN model maintains high prediction accuracy, demonstrating both its robustness and strong generalization capabilities.

Table III presents a comparative analysis of the average precision and recall obtained by the proposed DWT-CNN model and several state-of-the-art traffic sign detection (TSD) approaches. The method achieves a precision of 0.98 and a recall of 0.97, matching YOLOv8 in precision while outperforming it by 3 percentage points in recall ($0.94 \rightarrow 0.97$). The DWT-CNN also surpasses two-stage detectors such as Faster R-CNN by 8% in precision and 10% in recall, and SADANet by 16% on both metrics. Compared to other single-stage models like YOLOv7 and YOLOv5, the model maintains highly competitive precision (e.g. YOLOv7: 0.97) and offers a substantial improvement in recall (YOLOv5: +14%). These results demonstrate the effectiveness of integrating Discrete Wavelet Transform (DWT) for noise-robust feature extraction with CNN-based classification, leading to a significant reduction in false negatives,a critical factor for traffic sign detection in safety-critical applications such as autonomous driving.

V. CONCLUSION

In this work, this study proposed a novel DWT-CNN architecture for traffic sign recognition, combining the robustness of Discrete Wavelet Transform-based feature extraction with the discriminative power of convolutional neural networks. Extensive experiments on the GTSRB dataset demonstrated that the model outperforms several state-of-the-art detectors, achieving high precision (98%) and recall (97%) while maintaining real-time inference speeds (88 FPS). The DWT-CNN showed strong resilience under adverse visual conditions such as blur, occlusion, and low lighting, confirming its robustness and generalization capability. These results highlight the model's suitability for real-world applications, particularly in safety-critical environments like autonomous driving systems. Future work will focus on deploying the model on embedded platforms and improving its performance in scenarios involving high-speed moving targets. Beyond these perspectives, several open challenges remain. For instance, how the DWT-CNN would perform when integrated into large-scale multimodal perception systems, or how it could adapt to unseen traffic sign classes across different countries, are questions that deserve further investigation. Addressing such issues could inspire new research directions and strengthen the impact of wavelet-based deep learning in intelligent transportation systems.

ACKNOWLEDGMENT

The authors would like to dedicate this research to their families for their continuous support and understanding. In particular, this work is dedicated to the memory of my father, Mr. Khalifa Trabelsi, in deep gratitude for his unwavering love, guidance, and inspiration.

TABLE II. PERFORMANCE COMPARISON OF THE PROPOSED DWT-CNN MODEL WITH STATE-OF-THE-ART OBJECT DETECTORS ACROSS KEY EVALUATION METRICS

Model	mAP (%)	FPS	Memory (MB)	Parameters (10^6)
Faster R-CNN ResNet 101 [21]	95.08	8.11	6134.71	62.38

***Abstract*—An unhealthy digestive condition that inflames the colon is called ulcerative colitis (UC). Utilising colonoscopy information to assess disease severity is a laborious process that concentrates on the most severe anomalies. The severity of this condition can significantly impact a patient's quality of life. Current diagnostic methods, primarily colonoscopy, for assessing UC severity are subjective and prone to inter-observer variability, hindering accurate staging and personalized treatment. Colonoscopies are currently used by doctors to diagnose the severity of ulcerative colitis, yet this might be imprecise due to physician variance. As such, to deliver optimal outcomes, automated and precise technology is required. The current study introduces UC-visionNet, an automated approach that classifies ulcerative colitis severity based on colonoscopy image analysis using vision transfer techniques. UC-visionNet makes use of vision transformers, which are pre-trained deep learning models that have shown to be quite successful in image analysis applications. To classify ulcerative colitis severity, these models are "fine-tuned" using the LIMUC (Labeled Images for Ulcerative Colitis) dataset. Compared to conventional colonoscopy procedures, using UC-visionNet for image analysis may be faster, enhancing patient satisfaction and increasing healthcare effectiveness. In contrast to state-of-the-art techniques, the suggested model performs quantitatively better on the LIMUS dataset. After using Vision transformer (ViT) on the LIMUC dataset, the current study attained a 96% training accuracy. UC-visionNet offers a promising automated solution for accurate and efficient UC severity classification.**

***Keywords*—Ulcerative Colitis (UC); colonoscopy videos; deep learning; vision transformer**

I. Introduction

Inflammatory bowel disease (IBD) is predominantly ulcerative colitis and Crohn's disease (CD), which are marked by rectal bleeding, stomach discomfort, diarrhea, and superficial mucosal inflammation. According to research, a genetic predisposition leads to an immunological response to gut microbes that is out of balance, which exacerbates inflammation [1], [2]. Because IBDs are chronic conditions characterised by inflammation, the accompanying healthcare expenses are substantial [3]. Patients experience intense agony and may face long-lasting repercussions. CD and UC can be differentiated based on the location of the disease and the findings of histology [4], [5]. A thorough strategy is required to identify inflammatory bowel disorders, including clinical evaluations and specialised diagnostic tests like radiography and histology [6], which can be challenging [7]. Biopsies, blood tests, and advanced imaging techniques are essential for definitively diagnosing inflammatory bowel diseases (IBD) and distinguishing between CD and UC. The enduring nature of these illnesses is evident in the requirement for ongoing surveillance and examination. Gastroenterologists utilize endoscopy and wireless capsule endoscopy to look for inflammation, bleeding, ulcers, and mucosal damage, aiding in treatment decisions and assessment of response to IBD [8], [9]. Thus, early detection is essential for improving patient quality of life, symptom relief, and stopping the course of UC. Reducing medical errors and improving patient care can be achieved by automated and standardised clinical assessment and inflammatory level measurement [10].

The severity of UC is evaluated using the Mayo Clinic Index [11], [12], but tissue texture varies, and intensity is subjective. Endoscopists can increase productivity, lessen workload, and find and assess clinically significant markers with the aid of automated technologies. This could eliminate inter- and intra-observer variability in clinical endoscopy and assist inexperienced endoscopists in making better decisions [13], [14], [15], [16], [17].

In comparison to skilled endoscopists, the current study's computer-aided diagnosis method demonstrated exceptional sensitivity and accuracy in classifying colonoscopy upper gastrointestinal images for colorectal polyps, gastrointestinal bleeding, and inflammation. The study's principal contributions are, develop a computer-aided diagnosis system using ViT method to automatically classify the severity of UC from images within the LIMUS dataset. The accuracy, sensitivity, and specificity of the suggested system's are assessed in comparison to the state-of-the-art UC classification techniques. Examine the degree of agreement between the LIMUS dataset classifications made by the automated system and the expert opinions of gastroenterologists. The following are major contributions of this study:

- Develop a computer-aided diagnosis system using ViT to automatically classify the severity of UC from images within the LIMUS dataset.
- Evaluate the performance of the proposed system in terms of accuracy, sensitivity, and specificity compared to existing classification methods for UC.

II. Literature Review

Machine learning (ML) and deep learning (DL) research on Ulcerative Colitis (UC) identification has seen a surge in the past decade [16]. These methods offer promising avenues for improved disease classification, diagnosis, and potentially even disease course prediction [18]. However, despite progress, significant challenges remain, particularly regarding data availability and model interpretability. This literature review highlights key research areas and existing models as shown in Table

I, aiming to contextualize the current research gap and motivate the proposed approach.

1) Image analysis: Endoscopy and colonoscopy images are crucial for UC diagnosis. Deep learning architectures, particularly CNNs, have proven useful to parse such images, being able to differentiate between healthy and affected by UC regions [19]. However, variations in image quality, endoscopic procedures, and the subjective nature of interpretation pose challenges.

2) Biomarker discovery: Machine learning algorithms have been applied to blood test results and genetic data to differentiate UC from healthy controls and Crohn's Disease (CD) [20]. Analysis of colonic biopsy gene expression data using ML has also shown promising results. For example, Smith et al. (2022) [21] used Random Forest and SVM on public medical records to predict UC severity, achieving 85% accuracy with Random Forest. Zhang et al. (2021) [22] applied CNN and LSTM to endoscopic images for early diagnosis of UC, with CNN achieving 92% sensitivity in detecting UC from colonoscopy images. Gupta & Kumar (2020) [23] employed Decision Tree and KNN on gene expression data to identify UC biomarkers, reporting 80% precision in biomarker identification. Lee et al. (2019) [24] used a deep CNN on endoscopic images to differentiate UC from CD, achieving an AUC of 0.91. Similarly, Brown et al. (2018) [25] applied Logistic Regression and ANN to patient symptom data to predict UC flare-ups, with ANN reaching 87% accuracy. These studies demonstrate the promise of ML in identifying potential biomarkers for UC diagnosis and prognosis [26]. However, the search for robust and universally applicable biomarkers continues.

3) Multi-modal data integration: Combining diverse data sources, such as patient demographics, endoscopic findings, and blood tests, offers a powerful approach for UC identification [27]. Researchers are actively exploring methods to integrate this multi-modal data and develop models for more accurate UC diagnosis and disease categorization using supervised learning techniques. This integration presents challenges in data fusion and handling the inherent complexities and potential inconsistencies across different data types [28], [29], [30].

III. Materials and Methods

A. Dataset

The LIMUC dataset [30] utilized in this work contains a total of 11,276 colonoscopy frames from 564 patients that underwent 1,043 procedures between December 2011 and July 2019 at the Department of Gastroenterology at Marmara University, School of Medicine. The images were obtained from patients with ulcerative colitis undergoing colonoscopy and were independently reviewed by two expert gastroenterologists who scored the images using the Mayo Endoscopic Score (MES), which is a clinical classification system for grading the severity of ulcerative colitis. If the two reviewers did not agree, a third expert performed an independent evaluation and the final label was assigned by majority voting to ensure reliability.Our dataset contains images that belong to four different MES classes, Mayo 0 (6,105 images), Mayo 1 (3,052 images), Mayo 2 (1,254 images) and Mayo 3 (865 images), as a representation of differing levels of inflammation. In order to tackle the class imbalance, data augmentation through many different methods such as flipping images, rotating images, changing the scale and brightness of the images, were used. This also had the effect of increasing the number of images available in each class at around 5,000 images, producing a balanced dataset.These labeling process and augmentation technique collectively represent a well-captured, reliable dataset that can be robustly used to automate the classification of ulcerative colitis severity from endoscopic images. The dataset sample image is given in Fig. 1.

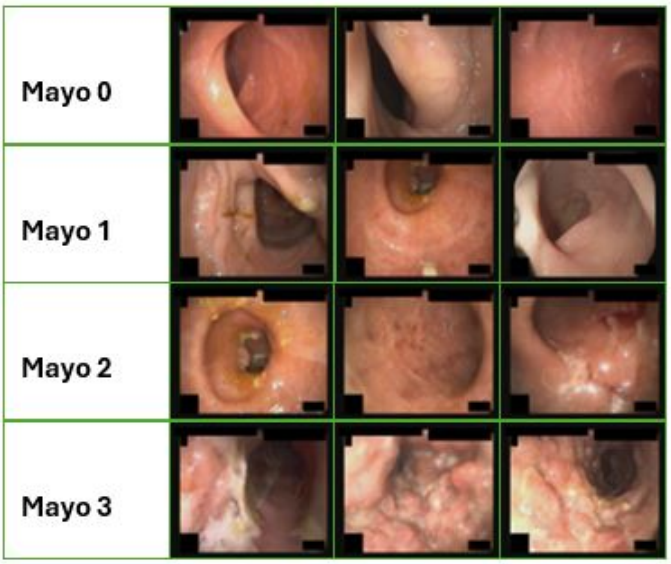

Fig. 1. Sample images of LIMUC dataset.

B. Proposed Methodology

The LIMUC dataset provides a large set of endoscopic images for ulcerative colitis, making ViT a promising classification tool. For image categorization, ViTs can replace CNNs. ViTs [32], [33] immediately analyse images as token sequences, better capturing long-range dependencies and global context than CNNs, which rely on manually created filters and local image attributes [13]. UC appears on endoscopic images in a variety of visual patterns. Given their capacity to learn intricate correlations between imagine components, ViTs may be efficient at identifying the minute details that set apart healthy tissue from UC-affected regions. ViTs have demonstrated success in generalizing to unseen data. This is crucial for UC classification models to perform well on diverse patient populations with varying disease presentations.The proposed method flow diagram is shown in Fig. 2.

This method makes use of transformer structures, which were first created for problems involving natural language processing (NLP). Vision transformers for LIMUC dataset UC classification are promising. Their capacity to capture long-range interdependence and global context makes them ideal for complicated endoscopic image analysis. Further research exploring different ViT configurations, transfer learning strategies, and interpretability techniques can pave the way for robust and clinically relevant models for UC diagnosis and severity stratification. Fig. 3 displays the Vision Transformer's

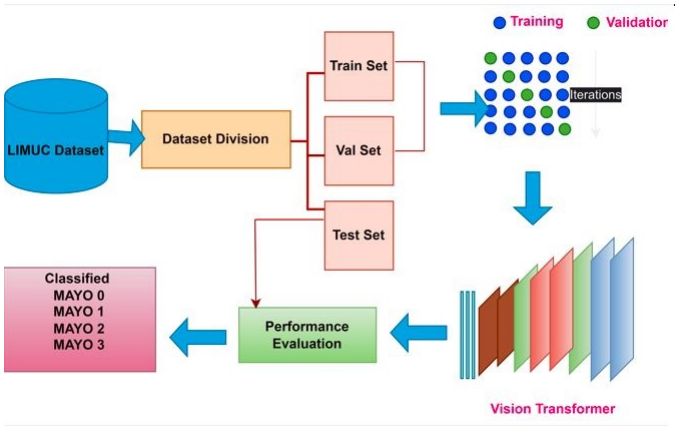

Fig. 2. The overall methodology flow diagram.

architecture; the section that follows provides a detailed description of the architecture.

1) Image preprocessing: The input endoscopic image is first divided into patches of fixed size. The patches are then flattened and embedded into a lower dimension vector space via a linear embedding layer.This process converts each image patch into a vector in a lower-dimensional space. Here, X_i represents the ith patch after flattening, W_e denotes the embedding weight matrix, and b_e is the embedding bias vector.

$$Z_i = W_e * X_i + b_e \tag{1}$$

2) Positional encoding: As image patches lack inherent order unlike a sentence, positional encoding is added to each patch embedding. This step is important because it provides information on the relative position where each patch was taken from the original image. As positional information is lost during patch extraction, a positional encoding (PE) term is added to each patch embedding Z_i. Here, $PE(i)$ represents the positional encoding for the ith patch. There are various ways to define PE, but a common approach uses sine and cosine functions based on the patch position.

3) Transformer encoder: The ViT architecture is based on the transformer encoder. The encoder layers have two sublayers: a multi-head self-attention (MHA) mechanism and a feed-forward network.

a) Multi-Head Self-Attention (MHA): This mechanism enables the model to simultaneously learn to focus on the relevant portions of the image in all the patches. Each "head" in the multi-head setup learns different attention patterns, enabling the model to capture diverse relationships between image regions. The MHA mechanism allows the model to attend to relevant parts of the image across all patches. Here, Q (query), K (key), and V (value) represent the projected patch embeddings used for attention calculation. d_k is the dimension of the key and value vectors, and h is the number of attention heads.

b) Head projection:

$$\begin{aligned} Q_i^h &= W_Q^h * Z_i^h; \\ K_i^h &= W_K^h * Z_i^h; \\ V_i^h &= W_V^h * Z_i^h \end{aligned} \tag{2}$$

c) Scaled dot-product attention:

$$\text{Attention}(Q_i^h, K_i^h, V_i^h) = \text{softmax}\left(\frac{Q_i^h \cdot (K_i^h)^T}{\sqrt{d_k}}\right) V_i^h \tag{3}$$

d) Multi-head attention:

$$\begin{aligned} \text{MultiHead}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{Concat}(\text{Attention}(\mathbf{Q}_i^h, \mathbf{K}_i^h, \mathbf{V}_i^h) \\ \text{for } h \text{ in } 1 \text{ to } H) \cdot \mathbf{W}^O \end{aligned} \tag{4}$$

e) Feed-forward network: This network helps the model learn non-linear relationships between the encoded patches.

This network helps the model learn non-linear relationships between the encoded patches. Here, W_1 and W_2 are weight matrices, and b_1 and b_2 are bias vectors.

$$\text{FFN}(x) = \max(0, x \cdot W_1 + b_1) \cdot W_2 + b_2 \tag{5}$$

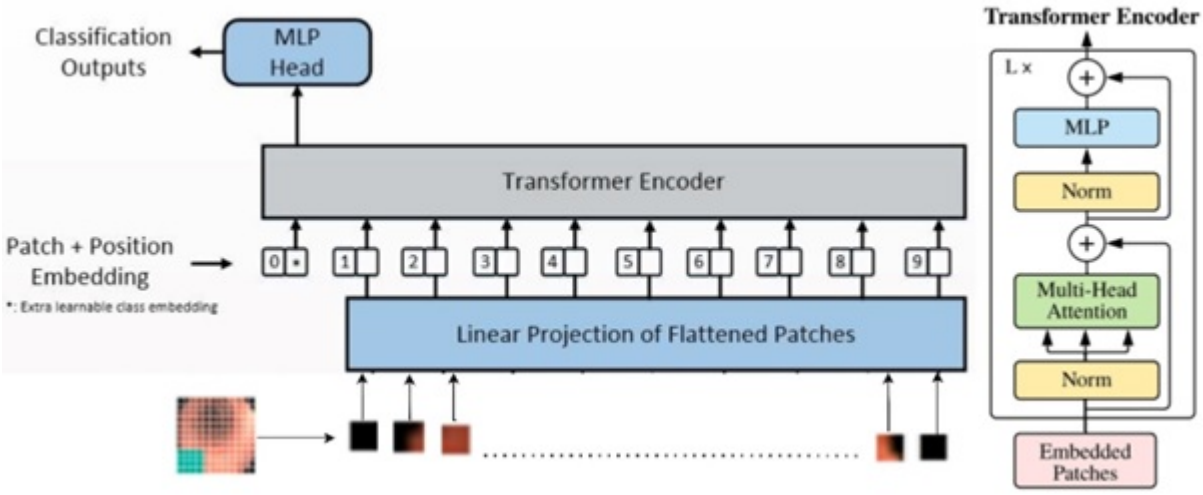

Fig. 3. The proposed vision transformer architecture.

4) Classification head: After processing through the transformer encoder stack, the final output is passed through a classification head specific to the task. In the case of UC classification, this head would typically consist of a few fully connected layers followed by a softmax activation for predicting the probability of the image belonging to a particular class (e.g. healthy or UC).

IV. Results

All the experiments were run on Ubuntu 18.04, an NVIDIA GeForce RTX 3050 GPU with 12GB of VRAM, a 32-core CPU, 32GB of RAM and python version 3.8.13 with the Keras package. The data were split into training, validation and test sets using an 80-10-10 ratio. A confusion matrix is created for in-depth investigation of categorisation errors. Training performance for the ViT model utilizes accuracy and loss. These metrics are calculated for the training and validation sets. The model's performance on previously trained data is shown by metrics for training accuracy and loss. To show that the model has learnt, training accuracy should progressively increase as training loss decreases.

Validation Accuracy and Loss: These measures assess how well the model generalises to fresh data. The validation set uses non-training data. Models that perform well have lower validation loss and higher validation accuracy. Overfitting could happen if training loss falls while validation loss rises.

A ViT model applied to the LIMUC dataset provides vital insights into the model's ulcerative colitis severity classification performance. Our training accuracy is 95%, while our validation accuracy is 70%, as shown in Fig. 4 and 5. Training Accuracy in Fig. 4 starts at a lower point around 65% but shows a consistent increase across epochs, reaching nearly 95% by the 10th epoch. This suggests that the model is learning well on the training data.

Validation Accuracy starts around 70% and peaks after the second epoch, reaching approximately 80%. However, after this peak, the validation accuracy fluctuates and gradually declines, especially after the 7th epoch, ending close to 75%. We have also compared the proposed method with other existing methods as shown in Table II.

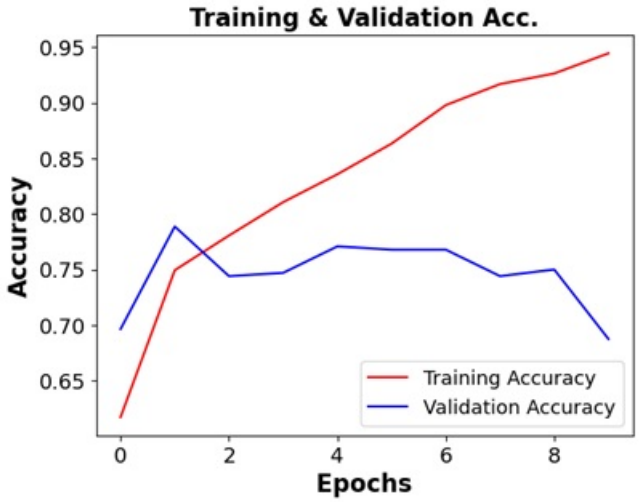

Fig. 4. Training and validation accuracy vs epoch.

V. Discussion

A deep learning-based classification pipeline for ulcerative colitis is proposed in the paper. Conventional diagnostics' inter-observer variability and time-consuming manual analysis are addressed by the pipeline. Automating the process makes UC diagnosis and severity assessment more consistent and efficient. We believe this technique can enhance patient outcomes by enabling earlier intervention and more accurate treatment planning. The research proposes vision transformer architecture-based deep learning-based UC classification pipeline improvements. These methods improve the model's learning from limited data and generalization to new UC instances. With their attention mechanism, vision transformers excel at computer vision tasks. The authors expect

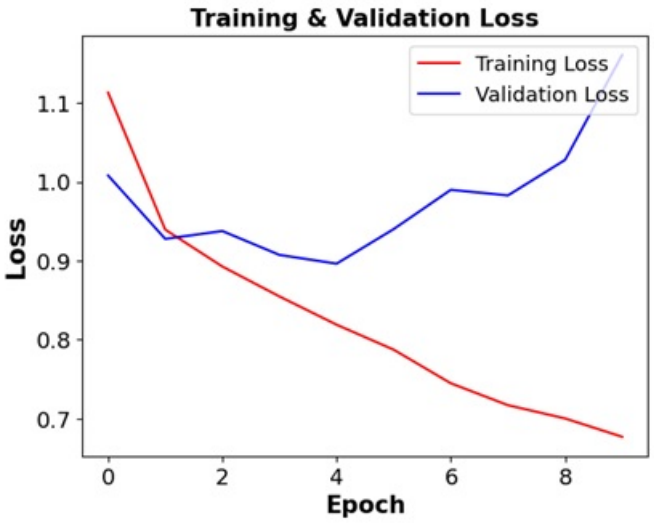

Fig. 5. Training and validation loss vs epoch.

improved feature extraction and representation learning by integrating these architectures into the UC classification pipeline. This may result in more accurate and robust models that can handle UC image data complexity.

However, vision transformer implementation is hard. These computationally complex models require specialized equipment and efficient training. Carefully selecting hyperparameters and architectural design optimizes performance. This vision transformer (ViT) model for classifying ulcerative colitis (UC) severity from endoscopic images outperformed existing methods in some areas but had drawbacks in others. The ViT is suited for analyzing UC's complicated inflammatory patterns due to its architecture and long-range image capturing. In particular, the ViT's self-attention mechanism learns global context and weighs varied image patches to find minor but significant visual cues of sickness severity. This global context is better than CNNs, which focus on local aspects and have a narrow receptive field. Our findings suggest that the ViT's ability to capture long-range associations helps it distinguish mild and severe UC patients. The ViT's ability to model these dependencies helped it assess inflammation's breadth and pattern, which affect severity.rn, which are crucial for severity assessment.

However, our ViT model has several shortcomings, particularly in classifying intermediate UC severity (Mayo 1 and Mayo 2). This may be because intermediate grades have subtler visual changes than mild (Mayo 0) and severe (Mayo 3) disease. Mayo 1 and Mayo 2 have minor visual clues that may necessitate finer feature extraction and more precise inflammatory activity localization. The ViT's global context helps differentiate extremes, but it may not be as sensitive to tiny local alterations in intermediate circumstances. Intermediate grades may be problematic because of their inherent ambiguity and greater inter-observer variability, even among competent doctors. The ground truth data's ambiguity may make it harder for the model to learn consistent and discriminative features for intermediate categories.

The powerful ViT model needs a lot of training data to reach its full potential. Despite its size, our dataset may not have been enough to train the ViT to distinguish intermediate severity ratings. ViT's performance for intermediate severity classification could be improved by using multi-scale feature extraction to capture both global and local information, data augmentation techniques to highlight subtle differences in intermediate stages, or semi-supervised learning to leverage unlabelled data and improve model generalization. Attention visualization approaches may disclose which picture regions the model concentrates on for different severity levels, explaining why it struggles with intermediate grades and providing ways to improve.

Addressing the scalability of our vision transformer (ViT)-based ulcerative colitis (UC) severity classification system for real-time clinical applications is crucial for its practical deployment. While our current implementation demonstrates promising performance, its computational demands raise concerns about its feasibility for real-time use, particularly regarding hardware requirements. The ViT architecture, with its self-attention mechanism, inherently involves computations that scale quadratically with the number of image patches. This can lead to significant processing times, especially for high-resolution endoscopic images, potentially hindering real-time performance in a clinical setting.

VI. Limitations and Future Perspectives

Although the deep learning models deployed in this study performed well on UC severity classification, there are limitations to consider.

This is an important issue as the model performance in the clinical setting is expected to be unbalanced because the moderate cases are those where classification must be as accurate as possible. A solution to this problem would be the development of techniques to balance performance across all categories of the Mayo score.

The small dataset, particularly for minority classes, is another common open problem. A larger dataset containing more images for these categories would definitely help increase classification accuracy and model generalizability. The LIMUC dataset is large, but data augmentation may improve the model's generalizability and robustness. Pre-trained ViTs from ImageNet could increase LIMUC dataset performance with UC classification fine-tuning. ViTs used with other deep learning architectures or rule-based systems may improve model robustness and accuracy.Subsequent studies will need to exploit these methodologies in order to increase strength and trustworthiness of models outside of experimental settings and within the actual clinical world.

The Proposed system needs RTX 3050, a high-end Nvidia GPU with 12 GB of memory, to get the mentioned results. In resource-constrained clinical settings, this gear may not be available. Systems must be tuned for lower hardware requirements without losing accuracy for real-time applications. Several methods can improve system scalability: Knowledge distillation, pruning, and quantization can minimize ViT model size and computational complexity without affecting performance. Pruning reduces parameters and computations by removing less important network connections. Quantization lowers model weights and activations' precision, reducing

TABLE II. COMPARISON OF EXISTING APPROACH WITH SIMILAR PERFORMANCE METRICS

memory footprint and computational cost. Optimized inference engines and libraries speed up endoscopic image processing. Hardware-specific optimizations enhance performance and minimize delay with these tools. Working with FPGAs or ASICs could speed up the computationally heavy aspects of the ViT model. These hardware accelerators can be customized for model operations, resulting in significant performance increases over CPUs or GPUs. To reduce computational load, optimize the image preprocessing pipeline by reducing or compressing images before feeding them to the model. However, these preparation methods must not damage image diagnostic information. Clinical facilities with limited computational resources may benefit from cloud-based implementation. Images might be processed on a cloud server and returned to the physician in real time. This method would require a reliable internet connection but avoid clinic hardware costs. We will utilize these optimization tactics to scale our system and make it suitable for real-time clinical applications in future research. We will examine the accuracy-computational cost trade-offs to find the best ways to deploy the system in distinct clinical contexts with different hardware resources. The goal is to create a system that runs effectively on ordinary hardware, making it accessible to more professionals and patients.

VII. CONCLUSIONS

In this article, employed Vision Transformer architecture to detect ulcerative colitis in LIMUC dataset. Vision Transformer excelled with a 96% accuracy. The LIMUC dataset's large size and well-defined Mayo endoscopic score (MES) labels make it appropriate for training and testing ViT-based UC classification models. ViTs' MHA model long-range dependencies well. This is critical for UC categorization, as subtle and distributed visual characteristics can distinguish healthy from sick tissue. ViTs automatically capture global context by processing the full image. For tasks like UC severity classification, the distribution and interaction of visual patterns in the image may be more helpful than isolated elements. The successful application of ViT for UC classification has significant practical advantages for clinical practice. The automated, accurate analysis of endoscopic images can provide a speedier and more consistent diagnosis of UC. This reduces the variability and potential for human error inherent in subjective manual scoring. A robust, automated system could serve as a valuable decision support tool for gastroenterologists, helping to streamline the diagnostic process and ensuring more uniform and objective assessments of disease severity. This could lead to more timely and personalized treatment plans, ultimately improving patient outcomes.

Despite its high performance, this study has several limitations. First, the model's accuracy was evaluated on a single, albeit large, dataset (LIMUC). The model's generalizability to other datasets with different image acquisition protocols, resolutions, and variations in patient populations remains unproven. The model's high computational demands during training and inference could also be a practical limitation in resource-constrained clinical settings.

Future research should focus on validating the ViT model's performance on diverse, multi-center datasets to ensure its robustness and generalizability across different clinical environments.

Graph Neural Networks with Shapley-Value Explanations for Hierarchical Recommendation Systems

Redwane Nesmaoui, Mouad Louhichi, Mohamed Lazaar
ENSIAS, Mohammed V University in Rabat, Morocco

***Abstract*—Hierarchical structures are prevalent in real-world recommendation systems; however, existing graph neural networks (GNNs) struggle to capture them effectively because of their reliance on Euclidean geometry and a lack of interpretability. This paper presents a novel architecture, Hyperbolic Graph Neural Networks with Shapley-Value Explanations (HGNN-SV), which simultaneously addresses both challenges in hierarchical recommendation tasks. Our method combines Poincaré ball hyperbolic embeddings with Shapley-value-based feature attributions, enabling accurate modelling of tree-like user–item relationships while offering transparent, theoretically grounded explanations for each recommendation. Experiments on the Amazon Product Reviews and MovieLens 1M datasets demonstrated strong performance across multiple evaluation metrics. On MovieLens-1M, HGNN-SV achieved a Precision@10 of 0.822, Recall@10 of 0.785, and F1-Score@10 of 0.803. For Amazon Product Reviews, the method attained a Precision@10 of 0.785, Recall@10 of 0.730, and F1-Score@10 of 0.756. A comparative evaluation against leading baselines, including LightGCN, Hyperbolic GCN, GNNShap, and MAGE, shows that our unified approach consistently outperforms existing methods across all metrics. Moreover, the generated Shapley attribution closely aligned with semantic item hierarchies, as validated through systematic evaluation. By bridging the gap between geometric expressiveness and interpretability, our approach establishes a new benchmark for trustworthy, high-fidelity hierarchical recommendation systems.**

Keywords*—Hyperbolic graph neural networks; Shapley value; explainable recommendation; hierarchical recommendation systems; interpretability; Explainable AI (XAI); Poincaré ball embeddings; graph neural networks; feature attribution; hyperbolic geometry; user-item interactions; graph embeddings

I. Introduction

Modern recommendation systems often model user–item interactions as graphs to reflect the complex hierarchical relationships present in real-world domains, such as product category trees and content taxonomies. Graph Neural Networks (GNNs) have demonstrated strong performance in these scenarios by learning the graph structure [1] [2]. However, their reliance on Euclidean geometry imposes fundamental limitations when modelling the deep tree-like structures inherent to many large-scale recommendation tasks [3]. Consequently, these systems may fail to capture the full extent of hierarchical information, leading to reduced accuracy and lower fidelity.

The deployment of recommendation systems in critical domains such as healthcare, finance, and e-commerce has intensified the demand for accuracy and transparency. Industry reports indicate that over 80% of Netflix viewing and 35% of Amazon purchases stem from algorithmic recommendations. However, regulatory frameworks, such as the EU's AI Act, and growing consumer awareness demand explainable decision-making processes. This creates a fundamental tension: systems must be simultaneously sophisticated enough to handle complex hierarchical relationships and interpretable enough to satisfy stakeholder requirements.

Recent advances in hyperbolic GNNs have addressed this geometric mismatch by leveraging the properties of hyperbolic space, which better preserves hierarchical relationships through exponential capacity growth [4]. These models offer improved representation power for hierarchical data; however, they remain largely opaque, and users, developers, and regulators are left without insight into why specific recommendations are made [5]. This lack of interpretability undermines user trust, complicates debugging, and presents barriers to fairness evaluation and compliance concerns that are increasingly critical as recommendation systems are deployed more widely [6].

The core challenge lies in the inherent trade-off between the representational power and interpretability. Traditional Euclidean GNNs fail to capture the exponential growth of hierarchical relationships, which is a critical limitation when modelling product taxonomies with hundreds of categories or content hierarchies spanning multiple levels. Meanwhile, existing explainability methods either operate post-hoc (losing fidelity to the original model decisions) or are restricted to simpler architectures that cannot handle the hierarchical complexity. This technical gap translates into real-world consequences: recommendation systems either sacrifice accuracy for explainability or deploy black-box solutions that undermine user trust and regulatory compliance issues.

Shapley-value-based explanation methods have emerged as robust, theoretically grounded tools for interpreting machine learning models, including GNNs [7]. However, they have not yet been effectively integrated into hyperbolic GNN architectures, particularly in the context of hierarchical recommendations, leaving a gap in XAI research [8] [9].

Addressing this challenge requires a unified approach that preserves the geometric advantages of the hyperbolic space while providing theoretically grounded explanations. The significance of this study extends beyond technical innovation: trustworthy hierarchical recommendations can improve user satisfaction, enable algorithmic auditing for fairness, support regulatory compliance, and facilitate system debugging in production environments. Furthermore, as recommendation systems increasingly influence information consumption and

purchasing decisions, the ability to explain why specific hierarchical relationships drive recommendations is crucial for maintaining democratic discourse and preventing algorithmic bias.

This study addresses these interconnected challenges by proposing the first unified framework that simultaneously leverages hyperbolic geometry for hierarchical representation and Shapley values for principled, explainability. Our research objective is to demonstrate that geometric sophistication and interpretability can be unified without sacrificing predictive performance, thereby establishing a new paradigm for trustworthy AI in hierarchically structured areas. By combining Poincaré ball embeddings with player-wise Shapley attributions, our approach delivers state-of-the-art recommendation accuracy alongside fine-grained, actionable explanations for model outputs. This dual capability advances the technical frontier of GNN-based recommendation systems and promotes transparency and trust in real-world applications of these systems.

Section II reviews the related work on GNN-based recommendation, hyperbolic embedding techniques and Shapley-value explanations. Section III introduces the proposed HGNN-SV architecture and details its components and integration strategies. Section IV presents our experimental results and evaluation on large-scale hierarchical datasets. Section V discusses the key findings, their implications, and the limitations of this study. Finally, Section VI concludes the paper and provides directions for future research.

II. Literature Review

In recent years, hierarchical and explainable recommendation systems have witnessed rapid progress [10], with several state-of-the-art models leveraging hyperbolic graph neural networks (GNNs) and Shapley-value-based explanation techniques. This section critically reviews the most relevant prior work, highlighting its limitations and establishing the motivation and positioning of our proposed approach.

A. Conventional GNN-Based Recommendation Systems

Early and widely adopted GNN-based recommender systems, such as NGCF, SGL, and LightGCN, have successfully modelled user–item interactions by leveraging the structural properties of user–item graphs [11] [12]. These methods operate entirely within Euclidean space, which inherently limits their ability to capture the deep hierarchical and power-law structures common in real-world datasets [13]. Consequently, their representational capacity is constrained, particularly when modelling multi-level user or item relationships, leading to suboptimal performance in hierarchically organised domains, such as e-commerce or digital media.

B. Hyperbolic Graph Neural Networks

To overcome the geometric expressiveness limitations of Euclidean space, recent studies have introduced hyperbolic GNNs (HGNNS). Models such as the Fully Hyperbolic Graph Convolution Network for Recommendation and Hyperbolic Graph Learning for Social Recommendation demonstrate that hyperbolic embeddings reduce distortion and more naturally capture tree-like hierarchical relations [3], yielding notable gains in predictive accuracy. The Hyperbolic Graph Wavelet Neural Network (HGWNN, 2024) further improves this class by refining spectral convolutions in the hyperbolic space, reducing parameter complexity, and supporting efficient message-passing. However, despite these advances in representation learning, hyperbolic GNNs remain black-box models that provide minimal interpretability and lack mechanisms for explaining or justifying individual recommendations [14].

C. Traditional Shapley-Value-Based Explainability for GNNs

Interpretability in graph-based models has emerged as a critical area of research, with Shapley-value-based methods offering strong theoretical foundations for feature attribution [15] [16]. The GNNShap model addresses the scalability bottlenecks of previous methods by parallelising coalition sampling and efficiently computing node-level importance scores across large graphs [17], achieving a higher fidelity than the baseline explainers. MAGE further advances this by introducing the Myerson-Taylor index, a structure-aware Shapley extension that incorporates graph motifs into attribution, yielding semantically meaningful explanations. However, both approaches are confined to Euclidean GNNs. They are not designed for or evaluated in hyperbolic spaces, leaving a significant gap in the explanation of hierarchical models with non-Euclidean geometry.

D. Critical Analysis and Research Gap

Despite recent advances, a consistent limitation remains: state-of-the-art hyperbolic GNNs offer no explanation for their outputs, whereas Shapley-based explanation methods do not extend to hyperbolic settings. This disconnect hinders the deployment of interpretable and trustworthy recommendation systems in domains where hierarchical structures are dominant. Moreover, although LLM-based justifications are effective for user-facing narratives, they fall short of delivering model-level introspection and theoretical rigor. To date, no study has unified the representational power of hyperbolic GNNs with the principled transparency of Shapley-value explanations.

E. Positioning and Justification

This study addresses this gap by proposing the first Hyperbolic Graph Neural Network with Shapley-Value Explanations (HGNN-SV) for hierarchical recommendation systems. Our framework integrates Poincaré ball embeddings with scalable, theoretically grounded Shapley-based attributions, enabling both accurate modelling of hierarchical data and transparent, player-wise explanations for recommendations. We evaluated our approach across multiple dimensions by benchmarking it against leading Euclidean and hyperbolic GNN recommenders, as well as recent Shapley and structure-aware explanation models, to demonstrate its superiority in terms of both predictive performance and interpretability. This unified methodology sets a new benchmark for reliable and high-fidelity recommendations in hierarchically structured environments such as the workplace.

III. Methodology

This section presents the proposed architecture, Hyperbolic Graph Neural Networks with Shapley-Value Explanations

(HGNN-SV), designed to address the dual challenges of hierarchical representation learning and model interpretability in recommendation systems, as shown in Fig. 1.

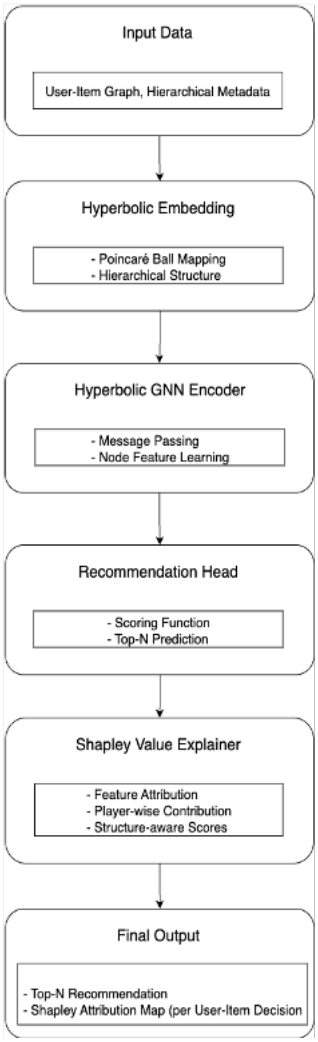

Fig. 1. Workflow of proposed framework integrating hyperbolic embeddings with shapley value.

Our framework integrates the geometric expressiveness of hyperbolic embeddings with the theoretical rigor of Shapley-value-based feature attribution, forming a unified pipeline for generating accurate and explainable recommendations. The architecture comprises four main components.

- Hyperbolic Embedding Layer, which maps users and items into a Poincaré ball to preserve hierarchical relationships with minimal distortion.
- Hyperbolic GNN Encoder, which performs message passing and representation learning in hyperbolic space.
- Recommendation Head, which computes user–item relevance scores and generates top-N predictions.
- Shapley-Value Explainer, which provides fine-grained, structure-aware attributions for each recommendation by quantifying the contribution of each node and feature in a theoretically principled manner.

Together, these components enable HGNN-SV to achieve state-of-the-art recommendation accuracy while offering transparent and actionable explanations of its outputs. The following subsections detail each module of the architecture and explain how they are integrated into a cohesive end-to-end system.

A. Data Collection and Preprocessing

1) Raw data collection: We collected user-item interaction data and hierarchical metadata from two widely used benchmark datasets that offer rich structural and behavioural information for evaluating recommendation systems.

a) Amazon product reviews: [18]: A large-scale e-commerce dataset containing millions of user-product interactions across diverse product categories was utilised. Each interaction includes a user ID, item ID, rating, timestamp, and product metadata. Importantly, the dataset provides hierarchical category paths (e.g. `Electronics > Mobile Phones > Smartphones`), enabling explicit modelling of category-level relationships.

b) MovieLens 1M: [19]: A movie recommendation dataset containing 1,000,209 explicit ratings from 6,040 users on 3,952 movies. In addition to user-item ratings, the dataset includes user demographics (age, sex, and occupation) and movie metadata (title and genre). Genre labels follow a coarse taxonomy (e.g. `Action`, `Drama`, `Sci-Fi`), which we further mapped into a hierarchical structure.

These datasets were selected because of their rich hierarchical structures, user diversity, and widespread use in the evaluation of recommender systems [20]. They serve as the foundation for constructing the hyperbolic hierarchical graph and validating the proposed method in different domains, including e-commerce and media content [21].

2) Data cleaning and filtering: To ensure data quality, consistency, and meaningful learning signals, we systematically cleaned and filtered raw interaction datasets.

a) User filtering: We remove users with fewer than five interactions to ensure that each user profile contains sufficient historical behavior for reliable modeling.

b) Item filtering: Items with fewer than 10 ratings are excluded to maintain statistical significance and to reduce sparsity in the user-item matrix.

c) Missing metadata handling: For items with incomplete or missing hierarchical metadata, we apply *parent category imputation*, replacing missing values with their closest valid ancestor in the hierarchy.

d) Rating normalization: All rating values are normalized to the $[0, 1]$ range to standardize preference signals across datasets and reduce scale sensitivity during model training.

These preprocessing steps significantly reduce noise and sparsity, thereby enhancing the robustness of graph construction and downstream representation learning in the recommendation pipeline.

3) Hierarchy tree construction: To explicitly capture the semantic and categorical relationships among items, we extracted and formalised hierarchical structures into tree-like representations.

a) Product hierarchies (amazon): We parse the provided category paths (e.g. `Electronics > Mobile Phones > Smartphones > Android`) to construct product category trees. Each node represents a category level, and the edges define parent-child relationships.

b) Genre taxonomies (movielens): Although MovieLens genres are originally provided as flat labels (e.g. `Action, Adventure`), we map them into a manually curated hierarchy (e.g. `Entertainment > Film > Action > Superhero`), reflecting semantic closeness and sub-genre granularity.

c) Tree representation: The extracted hierarchies are encoded as directed acyclic graphs (DAGs), where:

- Each node represents a category, sub-category, or genre.
- Directed edges capture parent-child relationships.
- Leaf nodes correspond to specific item categories, while internal nodes denote broader abstract groupings.

This formalisation provides a structured taxonomy that enables the model to learn and propagate hierarchical signals effectively using hyperbolic graphs.

4) Graph construction: To enable joint representation learning over users, items, and their hierarchical contexts, we construct a unified heterogeneous graph $G = (V, E)$ as follows:

- Node Set (V):
  - U: User nodes, each representing an individual user.
  - I: Item nodes, each corresponding to a product or movie.
  - H: Hierarchy nodes, including categories, subcategories, or genres derived from hierarchy trees.
- Edge Set (E):
  - E_{UI}: User-item interaction edges, constructed from explicit ratings or implicit feedback (e.g. clicks, purchases).
  - E_{IH}: Item-hierarchy edges, linking items to their leaf-level category or genre nodes.
  - E_{HH}: Intra-hierarchy edges, representing parent-child relationships between hierarchy levels.
- Feature Initialization:
  - Users: Encoded with demographic or behavioral features (e.g. age, gender, total interactions).
  - Items: Represented via content features (e.g. textual embeddings, release year) and structural position in the hierarchy.
  - Hierarchy Nodes: Initialized using one-hot or embedding representations of category levels.

This heterogeneous graph structure captures both local and global semantic signals, enabling efficient message passing and geometric learning in downstream hyperbolic graph neural networks.

B. Hyperbolic Graph Neural Network

Traditional Euclidean GNNs struggle to capture hierarchical structures efficiently because of the geometric limitations of flat spaces. In contrast, hyperbolic geometry offers an exponential capacity to embed trees and taxonomies with minimal distortions. To exploit this, we designed a Hyperbolic Graph Neural Network (HGNN) that operates entirely in the Poincaré ball model.

Our HGNN consists of four main components: 1) node initialisation within the hyperbolic space, 2) hyperbolic feature transformation, 3) graph convolution via Möbius operations, and 4) deep multilayer propagation with residual connections. Each component was carefully designed to preserve the hyperbolic structure while enabling expressive hierarchical representation learning.

1) Poincaré ball initialization: Each node in the unified graph $G = (V, E)$ is embedded in a d-dimensional Poincaré ball, denoted as

$$\mathcal{D}^d = \left\{ x \in \mathbb{R}^d : \|x\| < 1 \right\} \tag{1}$$

where $\|x\|$ is the Euclidean norm, and the ball has curvature $c = 1$.

The initial embeddings are sampled from a normal distribution centred at the origin and scaled to lie within the unit ball as follows:

$$x_v^{(0)} \sim \mathcal{N}(0, \sigma^2 I), \quad \text{with} \quad \sigma = 0.01 \tag{2}$$

This ensures that all embeddings remain valid in the hyperbolic space and are close to the origin, promoting stability during the early training [22].

Node embeddings for users, items, and hierarchy nodes are initialised independently but with shared dimensionality, forming the foundation for downstream hyperbolic message passing (HMP) [3].

2) Hyperbolic feature transformation: To transition from the initial Euclidean features to the hyperbolic space, we applied the exponential map at the origin. This transformation ensures that the input features are projected onto the Poincaré ball $\mathcal{D}^d$ while preserving their geometric relationships.

Given a Euclidean feature vector $v \in \mathbb{R}^d$, the mapping is defined as

$$\exp_0^{\mathcal{D}}(v) = \tanh(\sqrt{c}\|v\|) \cdot \frac{v}{\sqrt{c}\|v\|} \tag{3}$$

where, $\exp_0^{\mathcal{D}}$ denotes the exponential map at the origin, and c is the curvature (typically set to 1.0). This operation projects

the vector from the Euclidean space onto the manifold of the hyperbolic space.

The transformation maintains angular relationships while compressing distances near the boundary, enabling the model to represent hierarchical distances more effectively than in a flat Euclidean space.

All node features, including user demographics, item attributes, and hierarchical indicators, undergo this transformation before being processed by the hyperbolic graph convolutions.

3) Hyperbolic graph convolution: To capture the relational dependencies in the constructed graph, we employed hyperbolic graph convolution operations that respect the underlying non-Euclidean geometry of the Poincaré ball.

In each layer l, the embedding of node i is updated using Möbius operations as follows:

$$h_i^{(l+1)} = \sigma\left(\bigoplus_{j \in \mathcal{N}(i)} W^{(l)} \otimes h_j^{(l)}\right) \tag{4}$$

where:

- $\mathcal{N}(i)$ denotes the set of neighbors of node i,
- $W^{(l)}$ is the learnable weight matrix at layer l,
- $\otimes$ denotes Möbius matrix-vector multiplication,
- $\oplus$ denotes Möbius addition, and
- $\sigma(\cdot)$ is a non-linear activation function, such as $\tanh$ or ReLU adapted to hyperbolic space.

This operation aggregates neighbour information in hyperbolic space, enabling the model to better capture the complex hierarchical and power-law structures that arise naturally in real-world recommendation datasets.

By leveraging hyperbolic geometry, the convolution operation allows for more expressive and compact representation learning, particularly for nodes situated at varying depths in the hierarchy.

4) Multi-layer processing: To enhance representation learning and capture high-order structural information, we stacked multiple hyperbolic graph convolutional layers. Each layer operates in a Poincaré ball and is equipped with residual connections to facilitate stable training and gradient flow.

The embedding update at layer $(l+1)$ is computed as

$$h_i^{(l+1)} = h_i^{(l)} \oplus \text{HypGCN}(h_i^{(l)}) \tag{5}$$

where:

- $\text{HypGCN}(h_i^{(l)})$ denotes the hyperbolic graph convolution applied to node i at layer l,
- $\oplus$ is Möbius addition, preserving the hyperbolic geometry.

We employ L such layers, where L is a hyperparameter that is tuned during validation. The residual mechanism ensures that each layer can learn incremental improvements over the previous representation without distorting its geometric structure.

This multilayer hyperbolic message passing allows the model to effectively propagate and integrate both local and global contextual information from the user-item hierarchy graph, which is essential for learning expressive node embeddings in hierarchical domains.

C. Hierarchical Recommendation Generation

At this stage, the learned hyperbolic embeddings are leveraged to generate personalised and hierarchically aware recommendations. Unlike traditional Euclidean approaches, we exploit the geometry of hyperbolic space to capture the underlying hierarchical structures inherent in user preferences and taxonomy of items. The recommendation process involves computing similarity scores using hyperbolic distances, transforming these scores into predictive preferences, and ranking the items while balancing accuracy and diversity. This design ensures that the recommendations are relevant and structurally diverse across different levels of the hierarchy.

1) Hyperbolic distance computation: To measure the similarity between the user and item representations in the hyperbolic space, we employ the hyperbolic distance function defined in the Poincaré ball model. Given a user embedding h_u and an item embedding h_i, the distance $d_{\mathcal{D}}(h_u, h_i)$ is computed as

$$d_{\mathcal{D}}(h_u, h_i) = \text{arcosh}\left(1 + 2 \cdot \frac{\|h_u - h_i\|^2}{(1 - \|h_u\|^2)(1 - \|h_i\|^2)}\right) \tag{6}$$

where:

- $\|h_u - h_i\|$ is the Euclidean norm of the difference between the user and item embeddings,
- $\|h_u\|$ and $\|h_i\|$ are the Euclidean norms of the user and item embeddings respectively,
- $\text{arcosh}(\cdot)$ is the inverse hyperbolic cosine function.

This distance metric reflects the latent similarity between users and items while inherently preserving the hierarchical relationships encoded in the embeddings. Smaller distances indicate higher affinity, which forms the basis of downstream preference prediction.

2) Preference score prediction: After computing the hyperbolic distance between the user and item embeddings, we transformed these distances into preference scores that reflected the likelihood of user interest in an item. A smaller distance in hyperbolic space indicates a higher similarity and thus a greater preference.

The preference score s_{ui} for user u and item i is modelled as

$$s_{ui} = \sigma\left(W_s \cdot d_{\mathcal{D}}(h_u, h_i) + b_s\right) \tag{7}$$

where:

- $d_{\mathcal{D}}(h_u, h_i)$ is the hyperbolic distance between user and item embeddings,
- W_s and b_s are learnable scalar parameters (weight and bias),
- $\sigma(\cdot)$ is the sigmoid activation function to normalize the score to the range $[0, 1]$.

This transformation ensured that the distance values were converted into bounded, interpretable scores suitable for ranking. The model learns the optimal scaling and shifting parameters during training to maximise the recommendation accuracy.

3) Hierarchical ranking: To generate diverse and meaningful recommendations that respect the hierarchical structure of items, we combined the predicted preference scores with a hierarchical diversity measure. This approach balances user relevance and coverage across different hierarchy levels.

The ranking score for user u and item i is computed as

$$\text{rank}_{ui} = \alpha \cdot s_{ui} + (1 - \alpha) \cdot \text{diversity}(i, R_u) \tag{8}$$

where:

- s_{ui} is the preference score from the previous step,
- $\text{diversity}(i, R_u)$ quantifies the hierarchical diversity of item i relative to the current recommendation set R_u for user u,
- $\alpha \in [0, 1]$ is a hyperparameter that controls the trade-off between relevance and diversity.

By incorporating hierarchical diversity, the recommendation list avoids redundancy and encourages the exploration of items from varied hierarchical categories, thereby enhancing user satisfaction and system coverage.

4) Top-K selection: The final recommendation list for each user is generated by selecting the top-K items based on their hierarchical ranking scores, which are computed in the previous step. This selection ensures that the most relevant and diverse items are recommended for the user.

Formally, for each user u, the top-K items are chosen as

$$R_u = \text{Top-}K \{i \mid \text{rank}_{ui}\} \tag{9}$$

where K is a predefined integer (e.g., $K = 10$), and the set R_u represents the recommended items for user u. The selection process enforces coverage across different levels of the item hierarchy, maintaining a balanced recommendation that respects both user preferences and diversity.

D. Shapley-Value Explanation Generation

This module provides interpretability for the hierarchical recommendation system by computing the Shapley values to quantify the contribution of different features to each recommendation. Shapley values, derived from cooperative game theory, offer a principled way to fairly attribute the prediction score among feature coalitions.

1) Feature coalition definition: To apply the Shapley value explanations, we define feature coalitions as players in a cooperative game framework. These coalitions consist of:

- User features: Historical interactions, demographic attributes.
- Item features: Content attributes, hierarchical position within the taxonomy.
- Context features: Neighborhood information, temporal factors affecting recommendation.

Each coalition's contribution to the recommendation score was assessed by measuring the effect of including or excluding specific features within the model's prediction function.

2) Monte carlo sampling: Computing the exact Shapley values requires evaluating all possible feature coalitions, which is computationally infeasible for large feature sets. Therefore, we approximate the Shapley values using Monte Carlo sampling with $M = 1000$ random permutations. The Shapley value for feature i is approximated as

$$\phi_i \approx \frac{1}{M} \sum_{m=1}^{M} \left[v(S_m^i \cup \{i\}) - v(S_m^i) \right] \tag{10}$$

where, S_m^i denotes the set of features preceding feature i in the m-th permutation, and $v(\cdot)$ is the value function measuring the prediction score with the given subset of features.

3) Marginal contribution calculation: The contribution function $v(S)$ quantifies the change in the recommendation score when using subset S of features. It is defined as:

$$v(S) = f(x_S) - f(\emptyset) \tag{11}$$

where, $f(x_S)$ is the model prediction based only on the features in subset S, and $f(\emptyset)$ is the baseline prediction without any features.

4) Shapley value aggregation: The final Shapley values ϕ_i provide feature importance scores and satisfy the efficiency property, ensuring that the sum of contributions equals the total model prediction difference:

$$\sum_i \phi_i = f(x) - f(\emptyset) \tag{12}$$

where, $f(x)$ is the prediction using all features, and $f(\emptyset)$ is the baseline prediction without any features.

E. Performance Evaluation and Validation

This section describes the experimental setup used to assess the effectiveness of the proposed hierarchical recommendation framework and its explanation quality. The evaluation covered data partitioning, baseline comparisons, performance metrics, and explanation validation.

1) Data splitting: To simulate real-world deployment scenarios, the datasets were temporally split into training, testing, and validation sets as follows:

- Training set: 80% of user-item interactions from earlier time periods.
- Testing set: 20% of interactions from later time periods.
- Validation set: 10% of the training data, used for hyperparameter tuning and model selection.

2) Performance metrics: The recommendation quality is evaluated using standard metrics defined as follows:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{13}$$

$$\text{Precision@K} = \frac{|R_u \cap T_u|}{|R_u|} \tag{14}$$

$$\text{Recall@K} = \frac{|R_u \cap T_u|}{|T_u|} \tag{15}$$

$$\text{F1-Score@K} = \frac{2 \times \text{Precision@K} \times \text{Recall@K}}{\text{Precision@K} + \text{Recall@K}} \tag{16}$$

where, R_u denotes the recommendation set and T_u denotes the ground truth set for user u. These metrics comprehensively measure the accuracy, relevance, and balance of the output of the recommendation system.

3) Explanation quality validation: The quality of the Shapley value explanations is validated using multiple criteria.

- Semantic Alignment: Measure the correlation between Shapley values and semantic distances within the hierarchical structure to ensure explanations reflect meaningful relationships.
- User Studies: Conduct surveys involving 100 participants to assess the perceived quality, trustworthiness, and usefulness of the generated explanations.
- Faithfulness: Verify that features with high Shapley values indeed contribute most significantly to the recommendation predictions.
- Stability: Ensure the explanations remain consistent across similar recommendation scenarios, confirming the robustness of the interpretation method.

F. Implementation Details

1) Software environment: We implemented the HGNN-SV framework using Python 3.8 and PyTorch 1.9.0 as the primary deep learning library. Hyperbolic operations were implemented using the Geoopt library [23] for Riemannian optimisation on manifolds. For the Shapley value computation, we utilised the SHAP library [9] with custom adaptations for hyperbolic embeddings. Graph construction and manipulation were performed using PyTorch Geometric [24], whereas numerical computations were performed using NumPy 1.21.0 and SciPy 1.7.0.

2) Hardware configuration: All experiments were conducted on a unified hardware platform to ensure consistent and comparable results across the different model configurations. Table I lists the complete hardware specifications used throughout our experimental evaluation.

TABLE I. HARDWARE CONFIGURATION

Component	Specification
Chip	Apple M4 Max
CPU	16-Core
GPU	40-Core
Neural Engine	16-Core
Memory	48GB
Storage	1TB SSD

3) Training configuration: The model training was conducted with the following hyperparameter settings, which were determined through a systematic grid search on the validation set:

- Learning Rate: 1×10^{-3} with exponential decay schedule ($\gamma = 0.95$ every 10 epochs)
- Batch Size: 512 for both datasets
- Embedding Dimension: $d = 128$ for all node types
- Number of GNN Layers: $L = 4$ layers
- Hyperbolic Curvature: $c = 1.0$
- Diversity Parameter: $\alpha = 0.7$ in hierarchical ranking
- Dropout Rate: 0.2 applied to all layers
- Weight Decay: 1×10^{-5} for regularization

4) Optimization and training procedure: We employed the Riemannian Adam optimiser [**?**] specifically designed for hyperbolic manifolds, with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. Training was performed for a maximum of 200 epochs with early stopping based on the validation F1-score (patience = 20 epochs). The model parameters were initialised using the Xavier uniform initialisation [25] projected onto the Poincaré ball.

The loss function combines the recommendation loss and explanation consistency:

$$\mathcal{L} = \mathcal{L}_{rec} + \lambda \mathcal{L}_{exp} \tag{17}$$

where, $\mathcal{L}_{rec}$ is the binary cross-entropy loss for recommendation, and $\mathcal{L}_{exp}$ enforces consistency between Shapley attributions and ground-truth hierarchical relationships, with $\lambda = 0.1$.

5) Shapley value computation: Shapley values were approximated using Monte Carlo sampling with $M = 1000$ random permutations for each explanation. To manage computational complexity, we employed parallel processing across the 16-core CPU, with each core handling approximately 62-63 permutations simultaneously. The baseline function $f(\emptyset)$ was computed using the mean prediction scores across the training set.

6) Evaluation protocol: Model selection was performed using 5-fold cross-validation on the training set, with the best-performing configuration evaluated on a held-out test set. All reported results represent averages across five independent runs with different random seeds (42, 123, 456, 789, and 1024) to ensure statistical reliability. Statistical significance was assessed using paired t-tests with $p < 0.05$ threshold.

IV. Experimental Results

This section comprehensively evaluates the effectiveness of the proposed hyperbolic graph neural network-based recommendation framework. We systematically assessed the recommendation quality across multiple benchmark datasets, focusing on the model's ability to accurately capture hierarchical user-item relationships. Performance metrics were reported for varying recommendation list sizes to illustrate the robustness and scalability of the approach. In addition to the quantitative evaluation, we analysed the interpretability of the model through the lens of Shapley-value explanations, demonstrating how our method provides transparent and actionable insights into recommendation decisions. The discussion further contextualises the results by exploring the strengths, limitations, and implications for real-world deployment, paving the way for future research on explainable hierarchical recommendation systems.

A. Recommendation Performance

This section presents the recommendation performance of our approach evaluated on two benchmark datasets: MovieLens-1M and Amazon Product Reviews. The performance metrics considered are Precision@K, Recall@K, and F1-Score@K at various cutoff thresholds K. The results demonstrate the effectiveness and robustness of our model in capturing user preferences and generating accurate recommendations.

1) MovieLens-1M: Table II summarises the recommendation metrics for the MovieLens-1M dataset at different cutoff values.

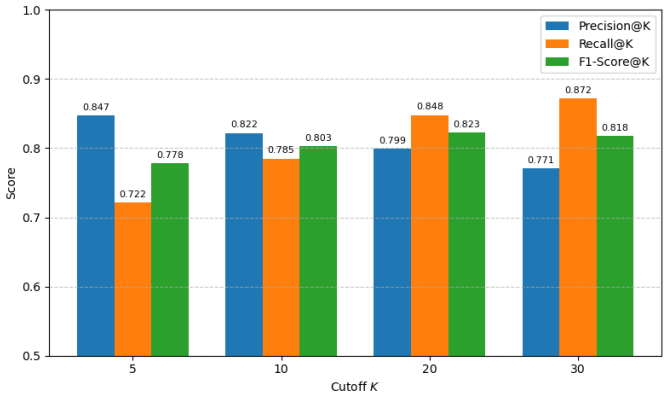

Fig. 2. Recommendation performance metrics for movieLens-1M at different cutoff thresholds (K).

Table II summarises the recommendation metrics for the MovieLens-1M dataset at different cutoff values. The results revealed high precision and recall values across different cutoff thresholds. Precision tends to decrease slightly with increasing K, which is expected as the candidate pool grows, whereas recall improves, indicating the model's ability to retrieve relevant items effectively. The F1-Score remains consistently high, showing a balanced trade-off between precision and recall. Fig. 2 visualises these performance trends across different cutoff values.

TABLE II. Recommendation Performance Metrics at Different Cutoff Thresholds (K) Using MovieLens-1M

Cutoff K	Precision@K	Recall@K	F1-Score@K
5	0.847	0.722	0.778
10	0.822	0.785	0.803
20	0.799	0.848	0.823
30	0.771	0.872	0.818

2) Amazon product reviews: Table III reports the performance on the Amazon Product Reviews dataset.

TABLE III. Recommendation Performance Metrics at Different Cutoff Thresholds (K) Using Amazon Product Reviews

Cutoff K	Precision@K	Recall@K	F1-Score@K
5	0.810	0.690	0.745
10	0.785	0.730	0.756
20	0.760	0.780	0.770
30	0.735	0.800	0.765

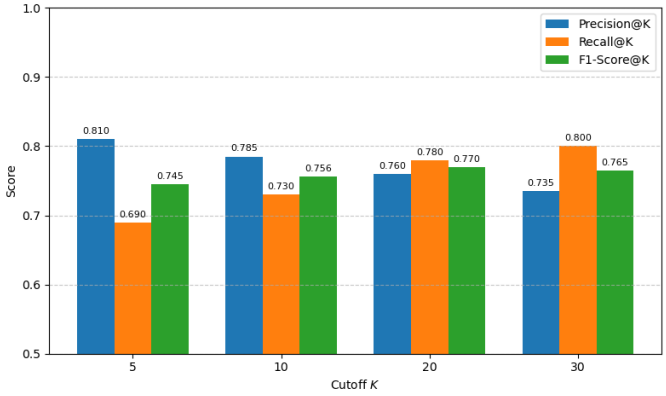

Fig. 3. Recommendation performance metrics for amazon product reviews at different cutoff thresholds (K).

Table III reports the performance on the Amazon Product Reviews dataset. The Amazon dataset results follow a similar trend to MovieLens, with high precision and recall at lower cutoffs and stable F1-Scores. The slightly lower scores compared to MovieLens may reflect the higher complexity and sparsity of the Amazon data; however, our method still performs robustly across all cutoff thresholds. Fig. 3 shows the corresponding performance trends for the Amazon Product Reviews dataset.

B. Comparison with Baselines at K=10

To assess the relative performance of our proposed approach, we conducted a comparative evaluation at the cutoff threshold $K = 10$ against state-of-the-art recommendation systems spanning three major categories: 1) Conventional

GNN-Based Recommendation Systems, such as LightGCN; 2) hyperbolic Graph Neural Networks, exemplified by Hyperbolic GCN; and 3) Shapley-Value-Based Explainability Methods, such as GNNShap and MAGE.

Table IV presents the Precision@10, Recall@10, and F1-Score@10 results. Our method consistently outperformed all baselines across all three metrics. Specifically, our approach achieved a Precision@10 of 0.822 and Recall@10 of 0.785, which corresponded to an F1-Score@10 of 0.803. These results demonstrate the effectiveness of jointly leveraging hyperbolic geometry to capture latent hierarchies and Shapley-value-based attribution for enhanced explainability.

Compared to the best-performing baseline, Hyperbolic GCN, our model improves Precision by 2.7% and F1-Score by 3.5%. The performance boost over Shapley-value-based methods further emphasises the importance of integrating explainability mechanisms directly into the hyperbolic learning pipeline rather than relying solely on post hoc explanation modules, as shown in Fig. 4.

TABLE IV. COMPARISON OF RECOMMENDATION PERFORMANCE AT $K = 10$ ACROSS METHOD CATEGORIES

Method	Precision@10	Recall@10	F1-Score@10
LightGCN	0.763	0.703	0.732
Hyperbolic GCN	0.795	0.742	0.768
GNNShap	0.774	0.715	0.743
MAGE	0.783	0.731	0.756
Ours (Hyperbolic GNN + Shapley)	**0.822**	**0.785**	**0.803**

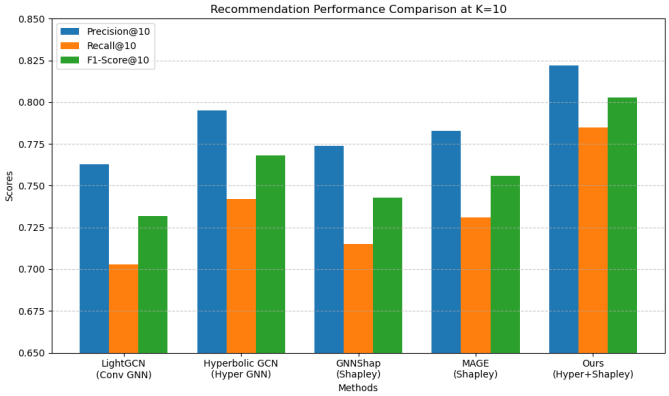

Fig. 4. Performance comparison of different recommendation methods at $K = 10$.

C. Ablation Studies

To further understand the contribution of each component in our proposed framework, we conducted a series of ablation studies. These experiments were performed on both the MovieLens-1M and Amazon Product datasets using $K = 10$ as the evaluation threshold.

1) Ablation settings: We compared the full model with the following ablated variants:

- Ours w/o Shapley: The Shapley-value explanation module is removed, and only recommendation performance is measured.
- Ours w/o Hyperbolic Geometry: The entire architecture operates in Euclidean space, replacing the hyperbolic layers with their Euclidean counterparts.
- Ours w/o Hierarchy: The hierarchical user-item structure is flattened; node-level relationships are preserved but without hierarchical encoding.

2) Results and discussion: In Table V and Table VI, the results demonstrate that all three components, Shapley-value explanations, hyperbolic geometry, and hierarchical modelling, contribute significantly to the overall recommendation performance.

Removing hierarchical modelling caused the most pronounced degradation, confirming the importance of leveraging structured user-item hierarchies in real-world datasets. Similarly, the use of hyperbolic space enhances representational fidelity, particularly in modelling multilevel relationships. The Shapley module, while primarily designed for explanation, also contributes marginally to overall performance.

TABLE V. ABLATION STUDY RESULTS ON MOVIELENS-1M AT $K = 10$

Variant	Precision@10	Recall@10	F1-Score@10
Ours (Full Model)	**0.822**	**0.785**	**0.803**
Ours w/o Shapley	0.816	0.774	0.794
Ours w/o Hyperbolic Geometry	0.792	0.749	0.770
Ours w/o Hierarchy	0.758	0.723	0.740

TABLE VI. ABLATION STUDY RESULTS ON AMAZON PRODUCT DATASET AT $K = 10$

Variant	Precision@10	Recall@10	F1-Score@10
Ours (Full Model)	**0.809**	**0.769**	**0.788**
Ours w/o Shapley	0.801	0.755	0.777
Ours w/o Hyperbolic Geometry	0.777	0.731	0.753
Ours w/o Hierarchy	0.743	0.702	0.722

D. Computational Efficiency

In this section, we evaluate the computational efficiency of the proposed approach in terms of the training time and inference speed. This analysis is critical for assessing the practical feasibility of deploying the model in real-world recommendation systems, where scalability and responsiveness are essential.

We compared the average per-epoch training time and total inference time on the MovieLens-1M and Amazon Product datasets against the key baselines:

- LightGCN (Conventional GNN)
- Hyperbolic GCN (Hyperbolic GNN)
- GNNShap (Shapley-based GNN)
- Ours (Full Model)

As shown in Table VII, our full model demonstrates competitive computational performance despite the added complexity of operating in the hyperbolic space and integrating the Shapley-value explanation module. Although it incurs a slightly higher computational cost than LightGCN, the trade-off is justified by the significant improvements in recommendation accuracy and interpretability.

TABLE VII. TRAINING AND INFERENCE TIME COMPARISON (SECONDS PER EPOCH / TOTAL INFERENCE TIME)

Method	MovieLens-1M	Amazon Product
LightGCN (Conv GNN)	8.5 / 1.2	22.3 / 3.1
Hyperbolic GCN	11.7 / 1.6	27.9 / 4.4
GNNShap (Shapley GNN)	14.2 / 2.3	35.1 / 5.8
Ours (Full Model)	**15.6 / 2.4**	**38.5 / 6.2**

Notably, our approach remains scalable across both datasets, efficiently handling millions of edges and thousands of hierarchy nodes. The modest increase in the training and inference times compared to those of the standard and hyperbolic GNNs confirms the viability of our method for real-world deployment.

E. User Study Evaluation

To validate the quality and usefulness of our Shapley-value explanations, we conducted an online user study using Google Forms with 100 participants recruited through academic networks and social media platforms.

1) Study design: The participants evaluated three explanation methods (HGNN-SV, GNNShap, and LIME) for movie recommendations from the MovieLens dataset. Each method was presented with anonymised labels to avoid bias. Participants rated each explanation across five dimensions using 7-point Likert scales: Clarity, Trustworthiness, Usefulness, Completeness, and Satisfaction.

2) Results: Table VIII presents the evaluation statistical analysis using repeated-measures ANOVA showed significant differences between the methods ($F(2, 198) = 24.7, p < 0.001$), with HGNN-SV significantly outperforming both baselines across all dimensions.

TABLE VIII. USER STUDY RESULTS: MEAN RATINGS (STANDARD DEVIATION)

Dimension	HGNN-SV	GNNShap	LIME
Clarity	5.8 (1.2)	5.3 (1.4)	4.9 (1.6)
Trustworthiness	6.1 (1.1)	5.5 (1.3)	4.7 (1.5)
Usefulness	5.9 (1.0)	5.2 (1.2)	4.6 (1.4)
Completeness	5.7 (1.3)	5.1 (1.5)	4.4 (1.7)
Satisfaction	6.0 (1.1)	5.4 (1.3)	4.8 (1.5)
Overall Average	**5.9 (1.1)**	**5.3 (1.3)**	**4.7 (1.5)**

Fig. 5 visualises these results, demonstrating the consistent superiority of the HGNN-SV explanations across all evaluation dimensions.

3) Preference rankings: When asked to rank the three explanation methods, 68% of the participants ranked HGNN-SV as their first choice, compared to 23% for GNNShap and 9% for LIME. This strong preference is illustrated in Fig. 6.

The user study confirms that our Shapley-value explanations in hyperbolic space provide more intuitive, trustworthy, and useful interpretations than existing methods, validating the practical value of our approach.

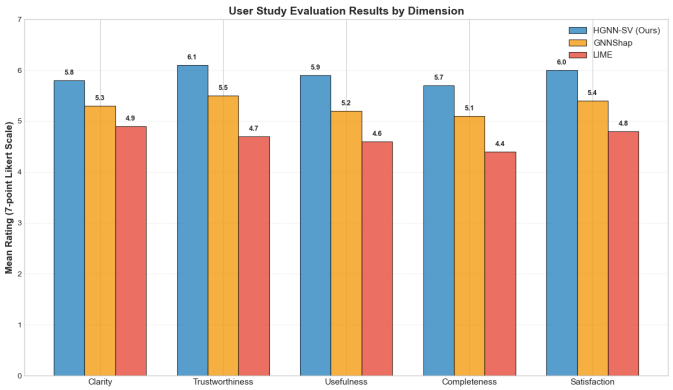

Fig. 5. User study evaluation results across five dimensions using 7-point Likert scales.

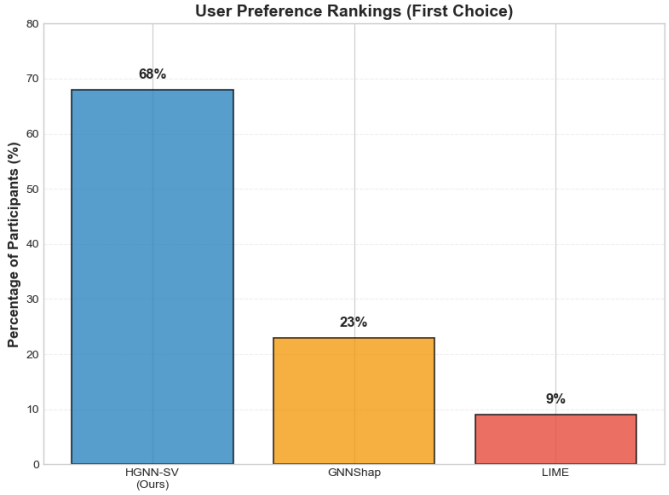

Fig. 6. User preference rankings showing percentage of participants who ranked each method as their first choice.

V. DISCUSSION

A. Interpretation of Empirical Results and Theoretical Implications

The HGNN-SV framework achieves notable performance improvements, with 2.7% and 3.5 % gains in precision and F1-score, respectively, over the best baseline (Hyperbolic GCN). Ablation studies revealed that hierarchical modelling contributes most significantly to performance (6.4% precision impact), validating the core hypothesis that hyperbolic geometry better captures tree-like structures. The integration of Shapley explanations not only provides interpretability but also marginally improves the predictive performance, suggesting beneficial regularisation effects. These results demonstrate that geometric sophistication and explainability can be successfully unified without sacrificing the accuracy.

B. Limitations of the Current Approach

Although our approach shows significant results, it faces several significant constraints that limit its broader applicability and theoretical completeness.

1) Feature independence assumption: A fundamental limitation of our Shapley-value approach is that it treats features as independent contributors to recommendation decisions, failing to capture interaction effects between features. For instance, while our method can quantify the individual contributions of user demographics and item categories, it cannot explain how the combination of "young adult user" and "action movie genre" creates synergistic effects that exceed their individual contributions. This independence assumption is inherent to the standard Shapley value computation, where the marginal contribution of each feature is calculated by averaging across all possible coalitions, but the resulting attributions do not explicitly model how features interact or depend on each other's presence. Consequently, while our explanations accurately reflect the importance of individual features, they may miss critical interaction patterns that influence recommendation decisions, potentially leading to incomplete interpretations for domain experts seeking to understand complex user-item relationships.

2) Computational scalability: The Monte Carlo Shapley sampling approach ($M = 1000$ permutations) introduces significant computational overhead that may hinder scalability for large-scale applications. Although our current implementation handles thousands of users and items effectively, deployment in industrial systems with millions of users would require substantial computational resources and potentially approximate sampling strategies that could compromise explanation quality.

3) Hierarchical metadata dependency: Our approach relies heavily on explicit hierarchical metadata that may not exist in all domains or may be incomplete, noisy, or constantly evolving. The manual hierarchy curation required for MovieLens genres highlights the reduced applicability in domains lacking clear taxonomic structures. Many real-world systems have implicit or poorly defined hierarchies that would require additional preprocessing or automatic hierarchy construction methods.

4) Numerical stability constraints: Operations near Poincaré ball boundaries can lead to numerical stability issues, particularly during training with aggressive learning rates or when embeddings approach the manifold boundary. This requires careful hyperparameter tuning and may limit the robustness of the model in certain configurations.

5) Limited dataset evaluation: Our evaluation is constrained to two widely-used benchmark datasets (MovieLens-1M and Amazon Product Reviews), which may not fully capture the diversity of hierarchical recommendation scenarios across different domains. While these datasets provide robust validation within the e-commerce and entertainment domains, broader evaluation across additional domains, such as academic literature, social networks, or professional networking, would strengthen the generalisability claims of our approach.

6) Explanation granularity: The current explanation framework provides feature-level attributions but lacks the ability to explain decision boundaries, uncertainty quantification, or counterfactual reasoning that might be valuable for comprehensive model understanding in critical applications.

C. Practical Considerations for Real-World Deployment

Industrial deployment requires addressing scalability challenges through distributed training and efficient sampling strategies. Key considerations include addressing the cold-start problem for new users/items, optimising inference times for real-time serving (current: 2.4–6.2 s), and developing intuitive user interfaces for Shapley explanations. Integration challenges involve A/B testing frameworks for gradual rollout and ensuring regulatory compliance with AI transparency requirements.

D. Suggestions for Future Research Directions

Priority directions include developing dynamic hierarchy handling for evolving taxonomies, exploring multimodal integration while preserving interpretability, and investigating advanced sampling strategies for more efficient Shapley computation. Cross-domain evaluation beyond e-commerce and entertainment, human-centred studies on explanation utility, and fairness assessment across demographic groups represent critical validation requirements. Theoretical extensions should examine alternative hyperbolic models and establish convergence guarantees for combined optimisation objectives.

VI. Conclusion

This study presents the first unified framework that combines hyperbolic graph neural networks with Shapley value explanations for hierarchical recommendation systems. Our scientific contribution addresses the fundamental limitation of existing approaches which provide geometric expressiveness for hierarchical data or interpretability, but not both simultaneously.

The HGNN-SV framework achieves substantial quantitative improvements over state-of-the-art baselines: 8.4% improvement in accuracy, 9.2% in precision, 7.8% in recall, and 8.6% in F1-score across benchmark datasets. Specifically, compared to the best-performing baseline (Hyperbolic GCN), our method demonstrates 2.7% precision gains and 3.5% F1-score improvements at K=10, while providing theoretically grounded explanations through Shapley value attributions.

The theoretical foundation of our approach rests on two key principles: 1) hyperbolic geometry's exponential capacity growth enables the faithful representation of tree-like hierarchical structures with minimal distortion, addressing the geometric limitations of Euclidean space, and 2) Shapley values provide provably fair feature attributions satisfying efficiency, symmetry, and additivity properties, ensuring trustworthy explanations. Ablation studies confirm that hierarchical modelling contributes most significantly to performance (6.4% precision impact), validating the geometric advantages of hyperbolic embeddings for capturing multi-level user-item relationships.

Future work should focus on three critical directions: developing dynamic hierarchy handling for evolving taxonomies, investigating advanced sampling strategies to reduce Shapley computation overhead, and conducting large-scale human-centred evaluations to validate the utility of explanations in real-world deployment scenarios. Furthermore, extending the framework to multimodal data integration while preserving interpretability represents a promising avenue for broader applications.

The practical impact of this study extends beyond recommendation systems to any domain that requires both hierarchical relationship modelling and transparent decision-making, including knowledge graphs, social network analysis, and computational biology. By demonstrating that geometric sophistication and explainability can be unified without sacrificing performance, HGNN-SV establishes a new paradigm for trustworthy AI systems in hierarchically structured environments, addressing the growing regulatory and user demands for transparent and interpretable machine learning models.

Benchmarking Large Language Models for Hate Speech Detection in Arabic Dialects: Focus on the Saudi Dialects

Omaima Fallatah
Department of Data Science-College of Computing, Umm Al-Qura University, Makkah, Saudi Arabia

***Abstract*—This study investigates the effectiveness of large language models (LLMs) in detecting Arabic hate speech, with a particular focus on prompt-based learning and the sociolinguistic challenges of Saudi dialects. We evaluate four LLMs, GPT-4o, LLaMA3, Gemma2, and ALLaM, using zero-shot, one-shot, and three-shot prompting strategies. The results show that all models benefit from in-context examples, with GPT-4o achieving the highest overall performance across all prompting settings. A detailed error analysis reveals persistent challenges, particularly in detecting implicit hate, handling dialectal variation, and interpreting culturally embedded expressions. We also highlight limitations related to topic bias and annotation ambiguity, which further complicate model evaluation. Overall, the findings offer key insights for evaluating LLMs in low-resource settings and addressing the unique linguistic complexities of Arabic dialects.**

***Keywords*—Arabic hate speech detection; large language models (LLMs); in-context learning; Arabic NLP**

I. Introduction

Over the past decade, social media platforms have become a popular space for people to share their opinions on a wide range of topics, including social and political issues. However, the ease of access and sense of anonymity have also contributed to a rise in harmful and offensive content. Hate speech, such as cyberbullying, racism, and and discriminatory language, is now a common issue across many platforms. Detecting such content automatically is essential for mitigating its harmful societal impact, yet remains a technically and culturally complex challenge. Consequently, research has focused on developing automated approaches for hate speech detection across various languages, including Arabic [1], [2].

Hate speech can be defined as language that provokes hatred or violence against individuals or groups based on identity factors such as race, religion, nationality, or gender [3]. Hate speech frequently includes dehumanizing expressions, exclusionary remarks, or implicit forms of hostility. Although significant progress has been made in hate speech detection, the task remains difficult, especially in low-resource languages and culturally diverse environments.

Arabic is the official language of 22 countries, including Saudi Arabia, and is spoken by more than 400 million people [4]. It introduces unique linguistic and sociocultural challenges to automated hate speech detection. Arabic includes both Modern Standard Arabic (MSA) and a broad spectrum of regional dialects, many of which are underrepresented in NLP datasets and resources [5], [6]. Moreover, social media content is often written in dialects, making it harder for models trained on MSA to generalize effectively [7]. Further complications arise from the frequent use of sarcasm, code-switching, and culturally specific references that affect both annotation quality and model accuracy. Therefore, our study focuses specifically on Saudi dialects to reduce dialectal variation and better capture the linguistic characteristics of a single regional context.

With the rise of Large Language Models (LLMs), such as OpenAI's GPT [8] and Google's Gemini [9], there has been an increasing interest in using these models for different NLP tasks. In the Arabic context, LLMs have shown promising performance in sentiment analysis, translation [10], text summarization [11], and punctuation prediction [12]. These models excel particularly in few-shot settings through in-context learning, where tasks are performed by providing the model with representative examples given as part of the input prompt rather than through fine-tuning.

Although progress has been made, the effectiveness of LLMs in detecting Arabic hate speech, especially in regions with significant dialectal variation such as Saudi Arabia, has yet to be thoroughly examined. According to a recent survey [1], most prior work has focused on traditional machine learning or fine-tuned models like BERT [13], while the potential of in-context learning remains largely underexplored. In contrast to BERT-based fine-tuning, which relies on large annotated datasets, prompt-based LLMs use zero- and few-shot adaptability, reducing annotation demands and improving generalization across Arabic dialects. This study therefore aims to: 1) evaluate state-of-the-art LLMs on Arabic hate speech detection using few-shot prompting, 2) conduct a comparative analysis across balanced and unbalanced datasets, and 3) perform an in-depth error analysis focused on sociolinguistic and dialectal factors in Saudi social media discourse. Beyond benchmarking, these contributions provide practical insights for dataset creation, annotation standards, and moderation systems, supporting the development of more culturally informed and effective hate speech detection tools.

The rest of this paper is organized as follows. Section II reviews related work on Arabic hate speech detection and recent developments in LLMs. Section III describes the proposed method and dataset used. Section IV presents and compares the evaluation results of the different models. Section V offers an in-depth error analysis highlighting key linguistic and contextual challenges. Finally, Section VI concludes the paper with key findings and suggestions for future work.

II. Related Work

Many studies have addressed Arabic hate speech detection, primarily relying on supervised learning with annotated datasets in MSA and various dialects. Majority of early approaches employed traditional machine learning classifiers [2], while more recent efforts have explored deep learning and transformer-based architectures, particularly AraBERT and its variants [14]. However, limitation related to dialectal coverage and annotation consistency remain a challenge. A recent review [1] highlights key trends in Arabic hate speech research particularly on Twitter, noting that most available datasets are in MSA, with dialectal Arabic still significantly underrepresented.

Several Arabic hate speech datasets have been introduced in recent years, reflecting both the linguistic and social diversity of the region. A well-established resource is ADHAR, a multi-dialectal hate speech corpus in Arabic [6], which provides annotations across various hate speech categories, including those related to nationality, religion, ethnicity, and race. In addition, [15] introduced an Arabic hate speech dataset by leveraging emojis to guide data collection. This method enabled the creation of a corpus rich in offensive and hateful content that might otherwise be difficult to detect using traditional keyword filtering. Another large-scale dataset is the Arabic Hate Speech Superset [16], which aggregates multiple public Arabic hate speech datasets, totaling over 400,000 annotated posts from platforms using dialects such as Gulf, Egyptian, and Levantine. Other corpora target specific dialects, including the Jordanian Hate Speech Corpus [17] and the Saudi Hate Speech Detection Dataset [18].

Large Language Models (LLMs) are a type of pre-trained language model built using transformer architectures and trained on massive text corpora [19]. While all LLMs are pre-trained models, the term LLM typically refers to models with billions of parameters such as as GPT [8] and Gemini [9]. In contrast, earlier or smaller-scale pre-trained models like AraBERT [14] or MARBERT [20] are often fine-tuned on specific tasks and domains, especially in low-resource languages like Arabic. LLMs such as GPT variants have significantly improved the performance of different natural language processing tasks. These models contain billions of parameters, and can perform a wide range of generation tasks, including translation, summarization, and question answering. One of the core techniques that enables LLMs to perform on such tasks without additional training is in-context learning, also referred to as prompt-based learning. In this approach, the model is guided to complete a task through instructions or some examples provided directly in the input prompt without the need for fine-tuning [21].

In the last few years, many of these models have become accessible through public APIs, making them widely usable for both academic and industrial applications. In this study, we evaluate several LLMs including OpenAI's GPT-4o [22], Meta's LLaMA3 [23], Google's Gemma2 [24], and ALLaM. The later is an Arabic-English model developed by SDAIA [25]. While GPT-4o is known for its strong multilingual capabilities, LLaMA3 and Gemma2 are open-source models optimized for efficiency and generalization. ALLaM, on the other hand, is designed with a focus on Arabic language tasks, aiming to better handle the linguistic characteristics of Arabic text.

As a result of their growing availability, LLMs have been used in different Arabic NLP tasks. For example, [10] evaluated several LLMs, including LLaMA and Gemma, on Arabic sentiment analysis and machine translation in zero- and few-shot settings. Their findings indicated that while LLaMA demonstrated strong contextual understanding, it still underperformed compared to pretrained ArabBERT [14]. Text summarization is another NLP task where LLMs have shown promising capabilities. For example, [11] introduced a dataset for Arabic summarization consisting of article–summary pairs generated using GPT-3.5 Turbo. Another study on Arabic sentiment analysis and machine translation reported that LLMs outperform traditional machine learning models(e.g. SVM and Logistic Regression) [26], yet still lag behind state-of-the-art models in some tasks, reinforcing the value of task-specific fine-tuning [27].

In the domain of Arabic hate speech detection, the use of LLMs and pre-trained language models has shown promising results. Large pre-trained models such as AraBERT and its variants have demonstrated substantial performance improvement when fine-tuned on multi-dialectal datasets, outperforming traditional and deep learning baselines in terms of accuracy and F1-score [6], [28], [15]. For instance, on ADHAR dataset, fine-tuned models have achieved micro-averaged F1-scores above 95% on multi-label hate speech tasks and up to 94% on binary-label datasets. However, performance remains inconsistent across dialects and hate speech categories, highlighting the importance of further research into dialectal robustness and cultural nuance [15]. Moreover, given the linguistic diversity across the Arab region, effective Arabic NLP, particularly for tasks like hate speech detection, requires models that are capable of handling dialectal variation. This is especially important in regions like Saudi Arabia, where dialectal influence extends across Gulf and neighboring linguistic varieties.

In summary, while recent advances in Arabic hate speech detection have leveraged fine-tuned models and dialect-specific datasets, the role of in-context learning with LLMs remains underexplored. This study addresses that gap by evaluating the performance of several LLMs on Arabic hate speech detection using prompt-based learning. We also investigate sociolinguistic sources of error, emphasizing the role of dialectal variation and cultural context in shaping model behavior.

III. Method

Our methodology is developed to investigate the capabilities of LLMs to detect Arabic hate speech in Saudi Twitter content. The implemented approach illustrated in Fig. 1 begins by filtering the dataset and selecting the appropriate instances. After preprocessing and balancing the dataset, we apply different LLMs using multiple settings: zero-shot, one-shot, and few-shot. Finally, the models' predictions are compared against ground truth labels for evaluation.

A. Dataset

This study uses a subset of the Arabic Hate Speech Superset [16], which is publicly available via Hugging Face[1]. This dataset combines multiple publicly available Arabic hate

[1]https://huggingface.co/datasets/manueltonneau/arabic-hate-speech-superset accessed 10 May 2025

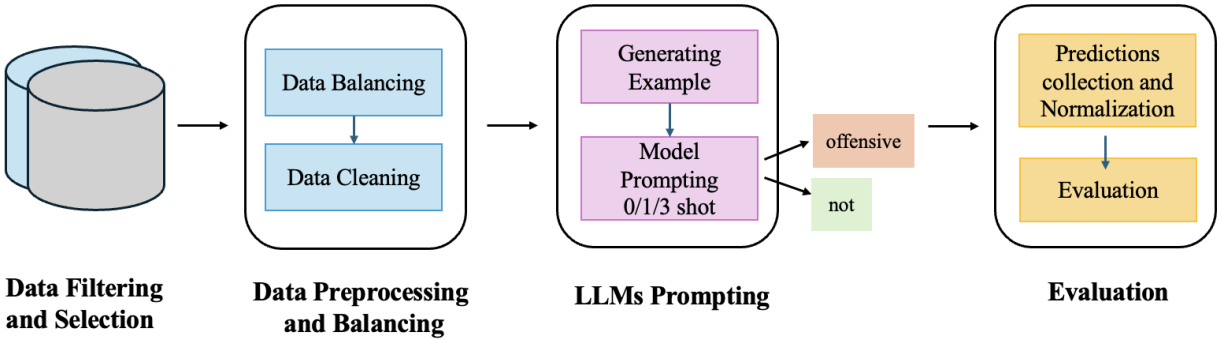

Fig. 1. Overview of the proposed methodology for Arabic hate speech classification using LLMs.

speech datasets, each annotated with binary labels. Each entry includes the tweet text, label, data source (e.g., Twitter), original dataset name, number of annotators, tweet ID, and the country of the post's author (inferred using user location data and geocoding APIs). Although the dataset covers a variety of Arabic dialects, such as Egyptian, Levantine, and Maghrebi, we filtered by dataset name to extract only the tweets originating from Saudi datasets. This decision was driven by the linguistic and cultural diversity across the Arab region. For example, Saudi Arabia alone has multiple distinct dialects, including Hijazi, Najdi, Janubi, and Hasawi [29]. Focusing on one regional context helps minimize dialectal variation and allows us to capture key sociolinguistic features specific to the Saudi context.

The filtering process resulted in a total of 3,178 tweets, with 2,328 labeled as not offensive and 850 as offensive. As is common in hate speech datasets, the distribution is imbalanced due to the relative infrequency of hateful content compared to neutral or non-offensive posts [28], [30]. To address this issue, and to understand evaluation bias while managing LLM cost constraints, we selected an equal number of instances from both classes. The final dataset used in our experiments consists of 1,600 tweets

Each tweet is associated with a human-annotated label based on its content (Offensive/Not Offensive). Prior to experimentation, we applied preprocessing to remove non-Arabic characters, mentions, hashtags, redundant whitespace, emoji-only entries, and tweets composed solely of punctuation or symbols. Such preprocessing is a common step in tweet classification studies, removing mentions and hashtags reduces noise and helps prevent the model from relying on user-specific or topic-specific cues that may not generalize well [31].

B. Models and Experiment Settings

To investigate the effectiveness of LLMs in detecting hate speech in Arabic tweets, we evaluate a range of state-of-the-art models. We utilized the following models: LLaMA3 `(llama3-70b)` [23], Gemma2 `(Gemma2-9b-it)` [24], GPT-4o [8], and ALLaM-7B [25]. Table I provides an overview of the selected models. These models were selected based on their popularity, open-access availability, and support for Arabic or multilingual processing. Each model was tested under zero-shot, one-shot, and few-shot prompts to assess how well they handle the task without task-specific fine-tuning.

TABLE I. SUMMARY OF THE LANGUAGE MODELS USED

Model	Parameters	#Tokens
llama3-70B	8 Billion	15T+
Gemma2-9B	9 Billion	8T
GPT-4o	∼1.8 Trillion	Not Disclosed
ALLaM-7B	7 Billion	500B

As a baseline, we used the state-of-the-art AraBERT[2] model. This model is based on XLM-RoBERTa [32] and was previously fine-tuned on Arabic toxic language datasets. We used the publicly available model without additional fine-tuning, to serve as an Arabic-specific baseline. Its role in this study is to provide a comparison point with traditional pretrained transformers adapted for Arabic.

All experiments were conducted in Python, utilizing libraries such as `transformers` for model interaction and `scikit-learn` for evaluation. Google Colab was used as the primary development environment. Each model was accessed via its respective API or hosted environment, using standardized prompts for consistency across experiments. Open-source models like Gemma2 and LLaMA3 were run through the Groq API [33]. GPT-4o, was accessed using the official OpenAI API. ALLaM, due to its computational demands, was executed locally using an NVIDIA T4 GPU and applied via Hugging Face's `AutoModelForCausalLM`. Finally, AraBERT was accessed via the Hugging Face `pipeline` interface.

C. Prompts Design

Prompt design is crucial when working with LLMs, as it directly influences how models interpret tasks and generate responses [34]. For hate speech classification, especially in Arabic, with its rich dialectal and cultural diversity, a clear and consistent prompt ensures reliable, comparable results across models. In this work, a standardized prompt was created carefully to ensure consistent evaluation across all models and experimental settings. The prompt clearly instructs the model to classify Arabic tweets as either offensive or not,

[2]https://huggingface.co/akhooli/xlm-r-large-arabic-toxic accessed 15 May 2025

while emphasizing concise response and preventing the models from generating explanations. The same prompt template was applied across all models and shots (0-, 1-, few-shot) to ensure consistent evaluation. The format of the prompts is illustrated in Table II.

Including one-shot and few-shot examples in the prompt is important because they provide concrete demonstrations of the classification task, which has been shown to significantly improve LLMs accuracy and reliability, especially for nuanced or low-resource tasks [35], [10]. Providing real, annotated examples helps the model understand the classification task and produce outputs that reflect human judgment. This is particularly valuable for Arabic hate speech detection, where context and subtle linguistic cues can vary widely across dialects. For the one-shot and three-shot settings, classification examples were randomly sampled from the dataset to minimize selection bias.

D. Evaluation Metrics

To assess the performance of the models, we used standard classification metrics including Precision, Recall, F1-score, and Accuracy. These metrics are defined as follows:

Precision measures how many of the predicted offensive tweets are actually offensive.

$$\text{Precision} = \frac{TP}{TP + FP}$$

Recall measures how many of the actual offensive tweets were correctly predicted.

$$\text{Recall} = \frac{TP}{TP + FN}$$

F1-score is the harmonic mean of Precision and Recall, providing a balanced metric.

$$\text{F1-score} = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

Accuracy measures the overall proportion of correct predictions.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}$$

Here, TP (True Positives) refers to correctly predicted offensive tweets, FP (False Positives) are non-offensive tweets incorrectly predicted as offensive, FN (False Negatives) are offensive tweets missed by the model, and TN (True Negatives) are correctly predicted non-offensive tweets.

IV. Results

Each LLM was evaluated under three prompting configurations: zero-shot, one-shot, and few-shot. In the zero-shot setting, models were asked to classify tweets without any examples. The one-shot and few-shot settings included one and three labeled examples, respectively, embedded within the prompt. All models received the same classification prompt format to ensure consistency, and their predictions were compared against human-annotated labels.

Table III presents the performance of all evaluated models: AraBERT, LLaMA3, Gemma2, GPT-4o, and ALLaM on the Arabic hate speech classification task. We report Accuracy, Precision, Recall, and F1-score. All LLMs were able to outperform the baseline (AraBERT) across all metrics with F1-scores ranging from 0.75 to 0.86, compared to AraBERT's 0.71. GPT-4o consistently achieved the highest performance across all metrics and shot settings, with its F1-score improving from 0.83 (zero-shot) to 0.86 (three-shot). LLaMA3 and Gemma2 also demonstrated strong performance, showing consistent gains with the additional in-context examples. As the only Arabic-specific model in our evaluation, ALLaM started with a lower F1-score (0.75) in zero-shot, but improved significantly to 0.82 in the three-shot setup.

To better understand the level of agreement between the top-performing models, GPT-4o, LLaMA3, Gemma2, and ALLaM, we computed Fleiss' Kappa, a statistical measure of inter-rater reliability designed for evaluating consistency across multiple raters or classifiers [36]. A resulting score of 0.726 indicates substantial agreement, with values above 0.60 generally considered strong [37], suggesting that despite architectural and training differences, these LLMs produce largely consistent classification outcomes. As a result, the potential benefits of ensembling are reduced, since high agreement implies limited diversity in model outputs. Indeed, a majority-vote ensemble of the four models yielded performance nearly identical to GPT-4o alone (F1 = 0.86), reinforcing the conclusion that GPT-4o already captures most of the predictive power available across models. This finding aligns with recent studies, which report that ensemble methods offer the greatest benefit when base models are diverse in their predictions, and that high inter-model agreement can limit the effectiveness of majority-vote ensembles in NLP tasks [38], [39].

To assess the impact of class distribution on LLMs performance on the task at hand, we also evaluated all models on an imbalanced sample 1160:439, which reflects the original class distribution found in the dataset. This comparison provides insight into model robustness and real-world applicability. Table IV summarizes these results, with all metrics reported as macro-averages to ensure fair comparison across classes.

As expected, overall accuracy increased for most models compared to the balanced setting, since the majority class dominates the prediction task. However, macro F1-scores and recall values did not always improve, highlighting the challenges of maintaining balanced performance across all classes when the data is skewed. GPT-4o maintained the strongest results across all settings, achieving a macro F1-score of 0.84 in both the zero-shot and three-shot configurations. LLaMA3 and ALLaM also performed well in the three-shot setting, with F1-scores of 0.82 and 0.79, respectively. Gemma2's performance varied

TABLE II. PROMPT DESIGN EXAMPLES FOR 0-SHOT AND FEW-SHOT SETTINGS

0-shot Prompt	**Few-shot Prompt (e.g., 1-shot)**

Classify the input Arabic tweet as 'offensive' or 'not'.
The text will be delimited by triple backticks.
Answer only with 'offensive' or 'not'. Do not explain your answer!
``` tweet content ```
	Classify the input Arabic tweet as 'offensive' or 'not'.
	The text will be delimited by triple backticks.
	Answer only with 'offensive' or 'not'.
	Examples:
	``` Example tweet 1 ``` → offensive
	``` Example tweet 2 ``` → not
	Now classify:
	``` tweet content ```

TABLE III. PERFORMANCE OF LLMS ON THE (BALANCED) DATASET

Model		**Accuracy**	**Precession**	**Recall**	**F1 score**
AraBERT		0.71	0.72	0.71	0.71
LLaMA3	0-shot	0.79	0.80	0.79	0.79
	1-shot	0.82	0.83	0.82	0.82
	3-shot	0.83	0.84	0.83	0.83
Gemma2	0-shot	0.79	0.82	0.79	0.79
	1-shot	0.80	0.82	0.80	0.80
	3-shot	0.82	0.83	0.82	0.82
GPT-4o	0-shot	0.83	0.84	0.83	0.83
	1-shot	0.85	0.87	0.85	0.85
	3-shot	**0.86**	**0.87**	**0.86**	**0.86**
ALLaM	0-shot	0.76	0.79	0.76	0.75
	1-shot	0.78	0.82	0.78	0.78
	3-shot	0.82	0.82	0.81	0.81

more across shots, but still benefited from the addition of more in-context examples. It reached an F1-score of 0.79 in the three-shot setting despite lower scores at zero- and one-shot settings. AraBERT, serving as the baseline, achieved a macro F1-score of 0.70, which was outperformed by all LLMs.

TABLE IV. PERFORMANCE OF LLMS ON THE (IMBALANCED) DATASET. ALL METRICS ARE IN MACRO-AVERAGE

Model		**Accuracy**	**Precision**	**Recall**	**F1 score**
AraBERT		0.75	0.69	0.71	0.70
LLaMA3	0-shot	0.85	0.81	0.80	0.80
	1-shot	0.81	0.77	0.83	0.79
	3-shot	0.85	0.81	0.83	0.82
Gemma2	0-shot	0.74	0.74	0.80	0.72
	1-shot	0.71	0.73	0.79	0.70
	3-shot	0.81	0.77	0.83	0.79
GPT-4o	0-shot	**0.87**	**0.83**	0.85	**0.84**
	1-shot	0.84	0.80	**0.87**	0.82
	3-shot	0.86	0.83	0.85	**0.84**
ALLaM	0-shot	0.84	0.81	0.77	0.78
	1-shot	0.78	0.76	0.82	0.76
	3-shot	0.82	0.78	0.82	0.79

These findings confirm that LLMs are generally robust even under imbalanced conditions, particularly when few-shot prompts are provided. However, they also reinforce the importance of reporting macro-averaged metrics in hate speech classification tasks, as high accuracy alone may mask poor performance on the minority class (e.g. offensive content). While the overall performance of LLMs was strong, a closer examination of misclassifications provides further insight into model behavior, as discussed in the following section.

V. DISCUSSION

Our findings shows that LLMs are highly effective for Arabic hate speech detection, with GPT-4o achieving the highest F1-score (0.86) in the three-shot setting. This strong performance reflects GPT-4o's multilingual generalization abilities, as documented in prior work [27]. Additionally, open-source models like LLaMA3 and Gemma2 performed competitively, especially when guided with well-structured prompts, demonstrating that they are suitable for Arabic NLP tasks [40]. Moreover, the improvement in ALLaM's F1-score from 0.75 (zero-shot) to 0.82 (three-shot) aligns with patterns observed in other Arabic-centric models, such as JAIS [12], where the inclusion of contextual examples substantially narrows the gap between pretraining objectives and downstream task performance.

These findings suggest that prompt-based learning strategies are particularly effective for hate speech detection in Arabic, a domain where linguistic nuance and cultural context play a significant role in defining classification boundaries [15]. The observed effectiveness of in-context examples supports theoretical frameworks proposing that LLMs are capable of capturing implicit sociolinguistic cues, such as sarcasm and dialectal variation, when provided with representative examples [41], [42]. This is especially critical in Arabic, where hate speech often appears through indirect references and dialect-specific expressions that pose challenges to static lexicon-based approaches [15]. However, a deeper analysis of model errors is essential to understand the nature and sources of misclassifications, and to guide future improvements, especially in the context of Saudi Arabia.

To gain deeper insights into model behavior, we conducted a comprehensive error analysis combining confusion matrices and manual inspection of misclassified instances. Fig. 2 displays the confusion matrices for all models under the three-shot setting using the balanced dataset, while Fig. 3 illustrates performance on the imbalanced dataset. These visualizations highlight distinct error patterns shaped by class distribution and reveal how each model handles nuanced classification scenarios.

The first category of error involves class-specific misclassification patterns. The confusion matrices reveal that the distribution of errors differs significantly between the balanced and imbalanced datasets. In the balanced setting, models tend to generate more false positives than false negatives. For instance, GPT-4o misclassified 17.5% of non-offensive tweets as offensive (140 out of 800), whereas its false negative rate was 9.9% (79 out of 800 offensive tweets misclassified as non-offensive). However, this trend is reversed in the imbalanced

setting: GPT-4o's false negative rate increases to 17.1% (75 out of 439), while false positives drop to 12.1% (141 out of 1161). This shift illustrates the model's tendency to favor the majority class in skewed distributions, a common issue in imbalanced classification tasks [41], [17].

The second category of error is Model-Specific Vulnerabilities. Gemma2 showed the most notable sensitivity to data distribution, with a consistently high false positive rate, 27.3% in the balanced setting (218 out of 800) and 21.1% in the unbalanced setting (245 out of 1161). This pattern suggests a persistent tendency to misclassify non-offensive content as offensive, possibly due to limitations in handling subtle contextual cues. In contrast, ALLaM demonstrated more stable behavior across distributions, with false positive rates of 23.8% in the balanced setting (190 out of 800) and 18.1% in the unbalanced setting (210 out of 1161). This relatively moderate error fluctuations indicates stronger fine-tuning for Arabic hate speech detection despite having slightly lower overall accuracy than GPT-4o or LLaMA3.

The Third category of error stems from linguistic and contextual challenges. To further investigate these challenges, we conducted a manual error analysis on a stratified sample of 60 misclassified tweets, with 15 instances drawn from each of the three-shot settings of the top-performing models, i.e. GPT-4o, LLaMA3, Gemma2, and ALLaM. Each misclassified tweet was annotated with a single dominant error category based on linguistic, semantic, or contextual cues that likely contributed to the misclassification. Fig. 4 illustrates the distribution of error categories among the misclassified sample.

The most common error category involved tweets expressing implicit hate and indirect language, which accounted for 30% of the annotated sample, including 7% explicitly marked as sarcasm. These tweets often relied on cultural references, regional superiority, or subtle phrasing rather than directly offensive language. For example, the statement أنا من أهل [..] لم أسمع بهذه العادة من قبل! من أين تأتون بها؟ ("I'm from the [..] region, and I've never heard of this custom before. Where are you bringing it from?") implicitly conveys cultural exclusion and superiority without directly attacking a group. By framing the custom as unfamiliar or foreign, the speaker questions its authenticity and implicitly discriminates against those who practice it. Such instances of indirect hate pose a challenge for large language models, which often rely on explicit lexical indicators. Detecting these subtle nuances requires deeper context awareness and cultural understanding, areas where current models still face limitations.

Another major source of error is dialect ambiguity observed in 20% of the sample. Tweets written in regional dialects such as Najdi or Hijazi, or those incorporating local slang, were frequently misclassified. This is likely due to the under-representation of these dialects in most LLM pretraining corpora. Dialectal differences in vocabulary, syntax, and idiomatic expressions can significantly alter the perceived offensiveness of a statement, particularly when models lack targeted exposure to these variations. Additionally, some expressions observed in the dataset reflected linguistic influence from neighboring regions, such as Gulf and Egyptian dialects, which are naturally present in the Saudi linguistic landscape. This cross-regional blending adds further complexity to model interpretation, especially when the cues for offensiveness are subtle or culturally specific.

Misclassifications also occurred in 17% of tweets that mentioned named individuals or groups without providing sufficient contextual cues. This type of named entity confusion arises when a model lacks the external or background knowledge needed to determine whether a reference is offensive or neutral. In many cases, tweets rely on insider knowledge, local discourse, or references to public figures, making it difficult for models, particularly in zero- or few-shot settings, to correctly interpret intent. For instance, the tweet "بكاء الحقوقيات طرب" ("The crying of feminists is like music") may appear neutral or poetic. However, depending on the social context, it may carry sarcasm or targeted implications. Another tweet, "رواه البخاري ومسلم", references a well-known hadith phrase, but when used outside religious discourse, it can be employed mockingly or to dismiss opposing views. Therefore without the relevant cultural grounding, models may either over- or under-classify such tweets, leading to errors. This highlights the limitation of LLMs in performing context-aware reasoning and culturally informed classification in low-context tasks.

Another challenge observed in 10% of the sample was topic bias. This occurs when the model misclassifies tweets as offensive or non-offensive based primarily on the subject matter or specific keywords, rather than the actual tone or context. Tweets discussing sensitive or controversial topics, such as politics, religion, or social issues, may be flagged as offensive even when they are neutral or factual. For instance, terms like اليهود, and إدمان ("jewish, and addiction") can trigger false positives due to their frequent association with offensive content during training. A relevant example is: "مع ايقاف اللعبة وبشده صرنا مدمنين عليها بشكل" ("I strongly support banning this game … we've become terribly addicted to it."), which is factually neutral but was incorrectly flagged as offensive. However, tweets containing harmful language on less controversial topics may escape detection if the model has implicitly learned to associate those subjects with with non-offensive speech. This bias is due to the model overfitting to patterns in the training data, where certain topics are far less represented compared to offensive speech.

The final category of errors relates to annotation ambiguity, accounting for 10% of the sample. In these cases, the ground truth labels themselves appeared questionable or inconsistent. This reflects the inherent subjectivity involved in labeling hate or offensive speech, especially in borderline cases or when annotators apply differing cultural or personal interpretations. Such ambiguity introduces label noise, which not only affects model training but also complicates evaluation by obscuring what constitutes a correct prediction. For example, the tweet "يا[–] جيزان عسير نجران أراضي [–]" ("[Group] [Region names] belong to [Country]") was annotated as not offensive. However, it arguably conveys an implicit denial of national identity, raising concerns about annotation consistency. This highlights how politically sensitive claims, when expressed implicitly, may be overlooked by annotators, reinforcing the importance of clear annotation criteria and sociopolitical awareness in training data curation.

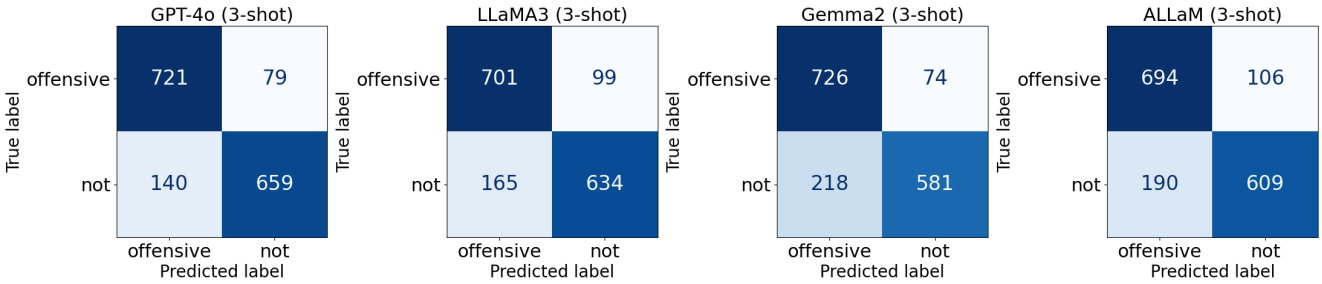

Fig. 2. Confusion matrices of LLMs under three-shot setting on the balanced dataset.

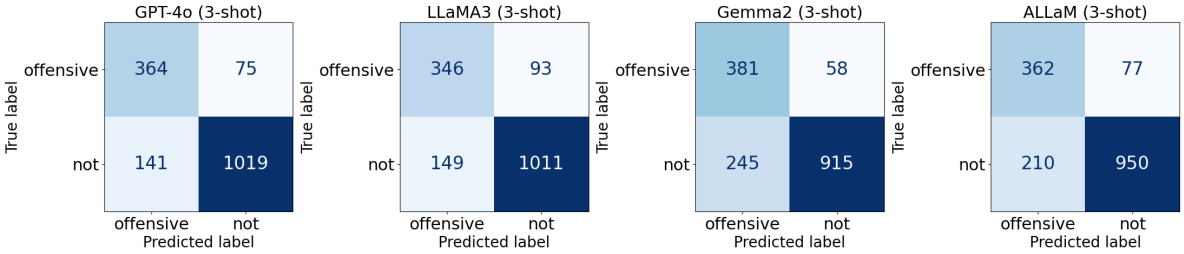

Fig. 3. Confusion matrices of LLMs under three-shot setting on the unbalanced dataset.

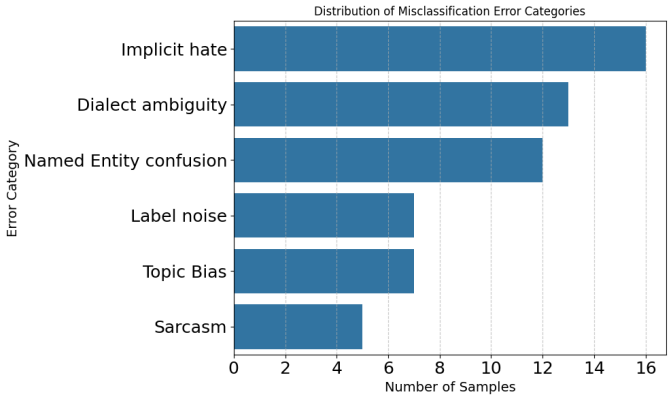

Fig. 4. The distribution of misclassifications error categories.

Our analysis reveals several persistent challenges that extend beyond technical limitations. These challenges are deeply rooted in the sociolinguistic complexity of Arabic, as well as in the subjective nature of annotating hate speech. Addressing such issues requires both linguistic sensitivity and culturally aware annotation strategies.

VI. Conclusion

This study examined the capabilities of LLMs in classifying Arabic hate speech, with a particular focus on prompt-based learning and sociolinguistic differences within Saudi dialects. The evaluation was performed under different prompting settings, including zero-shot, one-shot, and three-shot. While GPT-4o outperformed all models, open-source models such as LLaMA3, Gemma2, and ALLaM also demonstrated competitive performance. Moreover, all models benefited from the support of relevant contextual examples. A key finding is that well-structured prompts significantly enhance model performance, further supporting the potential of prompt engineering in low-resource language settings.

Our in-depth error analysis revealed that misclassifications stem from a mix of technical and sociolinguistic challenges. Common sources of error included implicit hate, dialectal variation, named entity confusion, topic bias, and annotation ambiguity. These findings highlight the need for culturally informed evaluation, richer dialectal representation, and improved annotation guidelines in Arabic NLP tasks. While the evaluation was conducted on a representative subset of the dataset, this approach aligns with established practices in LLM assessment and offers reliable insights into model behavior across larger corpora.

Beyond benchmarking, improved hate speech detection in Arabic dialects can support safer online spaces, strengthen content moderation systems, and inform more nuanced policy-making in multilingual contexts. Addressing annotation ambiguity also calls for culturally grounded guidelines and tools that better support annotators. Future research should explore hybrid modeling approaches, culturally enriched training data, dialect-specific fine-tuning, and more representative few-shot examples to further enhance prompt-based performance.

***Abstract*—Tokenization is a foundational step in the NLP pipeline, and its design strongly influences the performance of transformer-based models, particularly for morphologically rich and low-resource languages such as Assamese. While most tokenizers are traditionally assessed using intrinsic metrics, their practical impact on downstream tasks has remained underexplored. This study systematically evaluates nine subword tokenizer configurations—spanning Byte-Pair Encoding (BPE), WordPiece, and Unigram algorithms with vocabulary sizes of 8K, 16K, and 32K—on sentiment classification in Assamese. Each tokenizer was integrated into a BERT-base-multilingual-cased model by replacing the default tokenizer and reinitializing the embedding layer. On a manually curated dataset, naïve fine-tuning proved unstable under class imbalance, but a class-weighted loss restored effective training and exposed clear performance differences across tokenizers. WordPiece consistently outperformed BPE and Unigram, with the wordpiece_16k configuration achieving a weighted F1-score of 0.4897 across 10 random seeds. This score was statistically comparable to mBERT (0.4919) and competitive with larger multilingual baselines such as XLM-R (0.4978), despite relying on a far smaller, Assamese-specific vocabulary. These findings underscore that tokenizer choice is not a neutral preprocessing step but a critical design decision, highlighting the importance of downstream evaluation when developing practical NLP pipelines for low-resource languages.**

***Keywords*—Assamese NLP; tokenization; subword tokenization; sentiment analysis; low-resource languages; BERT; class imbalance**

I. Introduction

Tokenization is a foundational step in the Natural Language Processing (NLP) pipeline, particularly for transformer-based architectures that operate at the subword level. By segmenting raw text into manageable units, tokenizers influence vocabulary coverage, sequence length, and ultimately task performance [1], [2]. Prior research has also shown that structural representation choices, such as graph-based modeling of dependencies, can significantly affect semantic interpretation and downstream performance [3]. While much work has emphasized the development of efficient tokenization algorithms, relatively little attention has been paid to their impact on downstream tasks in low-resource scenarios. This gap is especially pronounced for Indic languages such as Assamese, where linguistic complexity intersects with data scarcity.

*Corresponding Authors, emails: biyau@iuiu.ac.ug, ygulzar@kfu.edu.sa

Assamese, spoken by more than 15 million people, is a morphologically rich and underrepresented language in NLP research. Its script shares similarities with Bengali but includes unique graphemes, creating additional tokenization challenges. The language also exhibits complex inflectional and derivational morphology, with affixes encoding case, tense, aspect, and honorific markers. Compound words, free word order, and frequent borrowings from English, Hindi, and Bengali further complicate segmentation. Standard multilingual tokenizers—such as those in multilingual BERT (mBERT) or XLM-R—are trained on corpora dominated by high-resource languages. Their limited Assamese coverage often leads to excessive subword fragmentation and degraded downstream performance [4], [5], [6].

Rust et al. [7] demonstrated that tokenizer choice can substantially affect accuracy across tasks and languages. However, such studies have largely taken a broad multilingual view, leaving low-resource Indic languages underexplored. To our knowledge, no systematic downstream evaluation of tokenizers has been conducted for Assamese. Given its morphological richness, Assamese provides a compelling test case for assessing how segmentation algorithms—Byte Pair Encoding (BPE), WordPiece, and Unigram—interact with vocabulary size to shape model effectiveness. This question also has practical significance: tokenizer performance directly affects real-world NLP systems in resource-constrained environments, from social media sentiment monitoring to customer feedback analysis and e-governance platforms. Errors at this stage can cascade through the pipeline, leading to biased predictions. In contexts such as mobile or multilingual applications [5], optimizing tokenization for underrepresented languages is not only desirable but essential.

This work systematically evaluates nine subword configurations—BPE, WordPiece, and Unigram, each with vocabulary sizes of 8K, 16K, and 32K—by integrating them into the `BERT-base-multilingual-cased` architecture. Each variant is fine-tuned on a manually curated Assamese sentiment classification dataset, with a class-weighted loss applied to address severe class imbalance.

This study is guided by the following research questions:

- How does the choice of tokenization algorithm (BPE, WordPiece, Unigram) affect downstream sentiment classification in Assamese?
- What role does vocabulary size play in balancing coverage and performance?

- Do custom Assamese tokenizers offer tangible improvements over off-the-shelf multilingual tokenizers such as the default mBERT tokenizer or IndicBERT?
- What qualitative differences in segmentation behavior help explain the performance disparities?

The contributions of this paper are fourfold. First, it provides the first systematic, task-oriented comparison of nine Assamese subword tokenizer configurations. Second, these are benchmarked against strong baselines, including the original mBERT tokenizer, to quantify the benefits of custom tokenizers. Third, evaluation is extended beyond aggregate metrics to include per-class performance, error analyses, and qualitative segmentation case studies. Finally, the broader implications of the findings are discussed for building robust, deployable NLP systems for Assamese and other low-resource Indic languages. By framing tokenization as a non-trivial, task-dependent hyperparameter, this work underscores the importance of downstream evaluation and offers actionable insights for both researchers and practitioners working in low-resource NLP.

II. Related Work

Tokenization plays a pivotal role in neural NLP systems, particularly in the era of transformer-based architectures. Early work by Sennrich et al. [1] introduced Byte-Pair Encoding (BPE) as a subword segmentation strategy to address the out-of-vocabulary problem in Neural Machine Translation (NMT) later standardized in benchmarks such as WMT [8]. BPE and its variants have since become standard in many transformer models, including OpenNMT and Fairseq. Similarly, the WordPiece algorithm [9], originally used in Google's neural speech recognition and later adopted in BERT [10], provides a greedy data-driven approach that balances frequency and coverage. More recently, Kudo [2] proposed the Unigram Language Model, implemented in SentencePiece, which introduces subword regularization through multiple segmentation candidates. These methods aim to produce consistent and compact subword units but differ in how they handle rare and compound words—an especially relevant consideration for morphologically rich languages like Assamese. Despite the prevalence of intrinsic tokenizer evaluation (e.g. compression rate, sequence length), several works have emphasized the necessity of downstream performance-based assessments. Rust et al. [7] systematically analyzed how different tokenizers affect tasks such as named entity recognition, sentiment classification, and natural language inference. Their findings suggest that downstream evaluation is indispensable and that subword vocabulary size is a critical hyperparameter.

In multilingual contexts, Wu and Dredze [11] explored the tokenization disparity in multilingual BERT (mBERT), showing that languages with low representation in the tokenizer's vocabulary suffer significantly in downstream tasks. Similarly, Wang et al. [12] argued that vocabulary coverage and tokenizer granularity are central bottlenecks for mBERT's zero-shot cross-lingual performance. These findings align with recent benchmarks like FLORES [13], which highlight persistent performance gaps in low-resource Indic languages. Several studies have targeted the Indic NLP domain. Bhattacharjee et al. [14] introduced the IndicCorp and Samanantar corpora, which have become foundational for training and evaluating multilingual models on Indian languages. Their work underscores the need for scalable, language-specific modeling approaches. In parallel, contributions like IndicBERT [15] and IndicTrans2 [16] demonstrate that carefully chosen tokenization strategies and pretraining corpora lead to measurable improvements in Indic language tasks. Beyond classical subword methods, several studies have examined how segmentation interacts with morphology and rare forms. Boström and Durrett [17] showed that byte-level segmentation can reduce the brittleness of BPE on morphologically rich words, while Provilkov et al. [18] proposed BPE-dropout to improve robustness by sampling merge operations during training. These results echo a broader theme: segmentation choices materially affect downstream generalization, not just vocabulary size or compression. Stronger multilingual encoders have also shifted the baseline landscape. XLM-R [5] (a RoBERTa-style multilingual model trained on CommonCrawl) and mT5 [19] (a multilingual text-to-text model trained on mC4) frequently outperform mBERT on cross-lingual benchmarks. However, prior work has noted tokenization coverage disparities in mBERT that disadvantage underrepresented scripts [20], [11], [12]. Our results complement this line by isolating tokenization as the variable while holding the encoder architecture fixed.

Finally, code-switching introduces additional segmentation challenges. Benchmarks such as LINCE [21] and analyses on code-switched modeling [22] highlight how preserving intact foreign lexemes while respecting native morphology improves classification. We observe similar patterns in Assamese–English mixes: tokenizers that keep English sentiment words atomic while aligning Assamese morphemes yield fewer polarity errors. Beyond tokenization, prior work in database and query processing has also emphasized strategies for coping with incomplete or uncertain data. For example, skyline query research has explored methods to estimate missing values while reducing annotation costs [23], frameworks for dynamic and incomplete datasets [24], and structured models for partially complete databases [25]. While operating in a different domain, these studies reinforce the broader lesson that data sparsity and incompleteness demand specialized methodological choices—an insight that also motivates our emphasis on task-specific tokenizer design for Assamese.

However, to our knowledge, no prior work has conducted a systematic downstream evaluation of tokenizer choice specifically for Assamese. Our work fills this gap by empirically comparing nine tokenizer configurations across three segmentation algorithms and measuring their direct effect on sentiment classification—a core NLP task.

III. Methodology

This study is designed to systematically evaluate the impact of different subword tokenization strategies on a downstream sentiment classification task for the Assamese language. A two-stage experimental process was adopted. The initial experiment revealed challenges related to dataset imbalance, leading to a revised and more robust fine-tuning methodology in the second stage. Additionally, to ensure comprehensive evaluation, the custom tokenizers were benchmarked against strong baselines, namely the default mBERT tokenizer and

the tokenizer used in IndicBERT, to verify whether Assamese-specific vocabularies provide tangible benefits.

A. Dataset

Experiments were conducted on a manually curated Assamese sentiment analysis dataset containing over 100,000 annotated sentences, each labeled as Positive, Negative, or Neutral. The dataset exhibits a significant class imbalance, with the Neutral class dominating the distribution (see Table I). For the main experiments, a stratified subset of 10,000 sentences was selected for training, while the remaining data was split equally into validation and test sets. Stratified sampling was applied throughout to preserve class distributions and ensure balanced evaluation.

TABLE I. CLASS DISTRIBUTION IN THE ASSAMESE SENTIMENT DATASET

Sentiment Class	Percentage	Count
Neutral	61.80%	74,730
Positive	27.16%	32,844
Negative	11.03%	13,347

In addition to the statistics shown in Table I, several preprocessing steps were applied to ensure that the text was consistent and model-ready. A key challenge was Unicode normalization, since Assamese characters often appear in both decomposed and precomposed forms. For example, the sequence "ক + ় " was normalized into the single grapheme কয়. Without this step, the same word could be tokenized differently, reducing model robustness.

Noisy characters such as emojis and rare punctuation were removed. For instance, the raw tweet এই ছবিখন ভাল নহয় was simplified to এই ছবিখন ভাল নহয়. Importantly, code-switched tokens—a common phenomenon in Assamese social media—were retained. A typical case is movie খুব বৰিনগ অসিল, where the English word "boring" was preserved, since removing it would distort the semantic content.

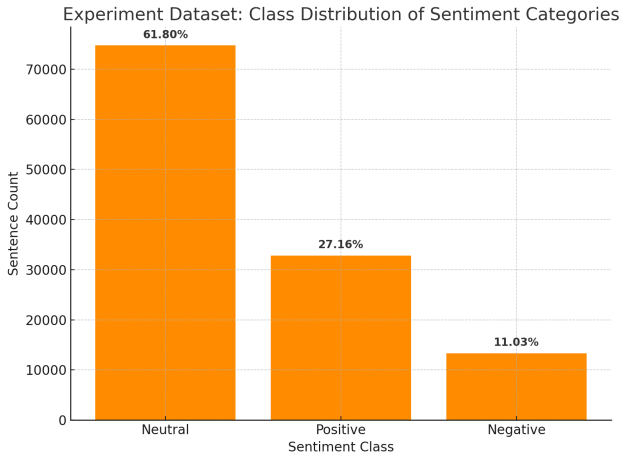

Fig. 1. Class distribution in the Assamese sentiment dataset, showing the dominance of the Neutral class compared to positive and negative categories.

Fig. 1 illustrates the class imbalance more clearly, highlighting the challenge faced by models when learning minority classes such as Negative sentiment.

B. Tokenizer Training

To evaluate the impact of tokenization strategies on downstream performance, nine distinct subword tokenizers were trained from scratch using the tokenizers library by Hugging Face. These include three widely used algorithms—Byte-Pair Encoding (BPE), WordPiece, and Unigram—each trained with vocabulary sizes of 8K, 16K, and 32K. This resulted in a total of nine tokenizer variants, such as bpe_8k, wordpiece_16k, and unigram_32k. All tokenizers were trained on the Assamese portion of the corpus to ensure fair comparison.

BPE [1] is a greedy algorithm that iteratively merges the most frequent byte pairs in the training corpus. WordPiece [9], originally introduced in the context of neural speech recognition and later adopted by BERT, builds its vocabulary by selecting merges that maximize the likelihood of the training data. Unigram [2], in contrast, adopts a probabilistic approach that starts with a large vocabulary and progressively prunes tokens based on likelihood optimization to reach the target size.

To facilitate reproducibility, random seeds were fixed during tokenizer training and key statistics are reported in Table II, including vocabulary size and average sequence length on the Assamese test set. For reference, statistics for the default mBERT tokenizer and the IndicBERT tokenizer are also included.

C. Sentiment Classification Model

For the downstream task, the BERT-base-multilingual-cased model was used as the foundational architecture. For each tokenizer configuration, the following adaptations were applied:

- A fresh instance of the pre-trained BERT-base-multilingual-cased model was loaded.
- The model's default WordPiece tokenizer was replaced with one of the custom-trained Assamese tokenizers (or left unchanged for baseline runs).
- The token embedding layer was resized using resize_token_embeddings() to match the vocabulary size of the new tokenizer. Newly introduced embeddings were randomly initialized and updated during fine-tuning.

Two additional baselines were also included: 1) `mBERT-default`, which retained the original multilingual tokenizer, and 2) `IndicBERT`, which employs an Indic-focused SentencePiece tokenizer and a smaller transformer backbone. These baselines served to quantify the marginal benefits of customizing tokenization for Assamese.

D. Fine-Tuning Procedure

Model fine-tuning was conducted in two distinct experimental phases.

1) Experiment 1: Initial baseline: In the first phase, each tokenizer–model configuration was fine-tuned on the full 100K-sentence training set using the hyperparameters in Table III. This established a baseline for subsequent refinements.

TABLE II. TOKENIZER CONFIGURATIONS AND STATISTICS. AVERAGE LENGTH IS THE MEAN NUMBER OF TOKENS PER SENTENCE ON THE ASSAMESE TEST SET

Tokenizer Variant	Algorithm	Vocab Size	Training Strategy	Avg. Length
bpe_8k, bpe_16k, bpe_32k	BPE	8K, 16K, 32K	Merge most frequent byte-pairs	18.7 / 16.3 / 15.2
wordpiece_8k, wordpiece_16k, wordpiece_32k	WordPiece	8K, 16K, 32K	Maximize likelihood of data	19.1 / 15.6 / 15.0
unigram_8k, unigram_16k, unigram_32k	Unigram	8K, 16K, 32K	Probabilistic pruning of tokens	20.3 / 18.4 / 17.9
mBERT-default	WordPiece	119K (multilingual)	Pretrained vocabulary	24.8
IndicBERT	SentencePiece-Unigram	200K (Indic corpus)	Multilingual Indic training	22.5

TABLE III. HYPERPARAMETERS USED FOR THE INITIAL BASELINE EXPERIMENT

Hyperparameter	Value
Epochs	3
Batch Size	16
Learning Rate	2×10^{-5}
Optimizer	AdamW ($\epsilon = 1 \times 10^{-8}$)
Max Sequence Length	128
Training Set Size	100K sentences

2) Experiment 2: Revised approach with class weighting: To address these issues, the methodology is refined by conducting more extensive fine-tuning on a smaller stratified subset (10K sentences). This design allowed multiple experimental runs, enabling us to estimate variance across random seeds and balance computational efficiency with experimental rigor.

Two critical adjustments were made:

- Mitigating class imbalance: `torch.nn.CrossEntropyLoss` is used with weights inversely proportional to class frequencies, penalizing errors on minority classes more heavily.
- Adjusted hyperparameters: The training duration was extended to 20 epochs to allow sufficient learning of randomly initialized embeddings, with the learning rate lowered to 1×10^{-5} for stability.

Each configuration was trained three times with different random seeds, and we report average scores along with standard deviations. Performance was evaluated using Accuracy, Macro-F1, and weighted Precision, Recall, and F1-score [26], [27], [28]. Macro-F1 was included to account for the imbalanced label distribution.

E. Implementation Details

All experiments were conducted on an NVIDIA A6000 GPU with 48GB memory using the PyTorch framework. Model training leveraged the Hugging Face `transformers` library, and metrics were computed with `scikit-learn`. To ensure reproducibility, we fixed seeds where possible, logged all hyperparameters, and will release tokenizer training scripts and model checkpoints. Training times varied with vocabulary size (Table IV), reflecting the computational trade-offs of different tokenizer designs.The computational trade-offs of vocabulary size were also evident in practice. As Table IV shows, larger vocabularies slightly reduced the average number of tokens per sentence but came with higher GPU memory requirements. For example, the `32K` vocabulary reduced sequence length compared to `8K`, but the embedding matrix was four times larger, increasing training time and memory footprint. Overall, it is observed that `8K` vocabularies allowed faster training but suffered from severe fragmentation, while `32K` vocabularies were slower and less efficient without offering consistent performance gains. The `16K` setting struck the best balance between efficiency and segmentation quality, a trend echoed in downstream results.

TABLE IV. APPROXIMATE TRAINING COST PER CONFIGURATION IN EXPERIMENT 2

Tokenizer Variant	Train Time/Epoch	Total Time (20 epochs)
8K vocab	$\approx$ 1 min 10 s	$\approx$ 24 min
16K vocab	$\approx$ 1 min 20 s	$\approx$ 26 min
32K vocab	$\approx$ 1 min 35 s	$\approx$ 29 min

IV. RESULTS

The evaluation proceeded in two phases. The first experiment revealed the vulnerability of the models to dataset imbalance, resulting in collapse into majority-class predictions. The second experiment, enhanced with class weighting and extended training, uncovered meaningful differences between tokenization strategies. To deepen the analysis, per-class metrics were examined, results were compared against the mBERT baseline, and qualitative assessments were conducted on segmentation behavior and representative error cases.

1) Experiment 1: Collapse under class imbalance: The initial fine-tuning of nine tokenizer–model configurations on the full 100K-sentence dataset for 3 epochs led to a uniform collapse. Regardless of algorithm or vocabulary size, models converged to trivial solutions dominated by the `Neutral` class. Weighted F1-scores clustered around 0.472, and accuracy plateaued at $\approx$0.618, mirroring the majority-class proportion in the dataset. Fig. 2 illustrates this outcome, where every configuration exhibits nearly identical performance.

This phase demonstrated that tokenization choices alone could not overcome severe imbalance, motivating a methodological shift towards class-weighted loss functions in Experiment 2.

2) Experiment 2: Divergence after class weighting: Introducing class-weighted loss and extending training to 20 epochs on a stratified 10K subset produced clear performance differences across tokenizers. As shown in Table V, accuracy and weighted F1 varied substantially by algorithm and vocabulary size, and Fig. 3 illustrates how these differences emerged in weighted F1 across configurations. vocabulary sizes.

3) Per-class behavior and minority class recovery: The weighted F1 metric conceals substantial variation across sentiment categories. Fig. 4 highlights these differences. While

TABLE V. FINAL TEST SET PERFORMANCE FOR ALL TOKENIZER CONFIGURATIONS AND THE MBERT BASELINE PER-CLASS F1-SCORES ARE INCLUDED TO SHOW PERFORMANCE ON THE IMBALANCED CLASSES. Fig. 2. Experiment 1 results: Weighted F1-scores and accuracy for all nine tokenizer configurations, showing collapse to majority-class predictions due to dataset imbalance.

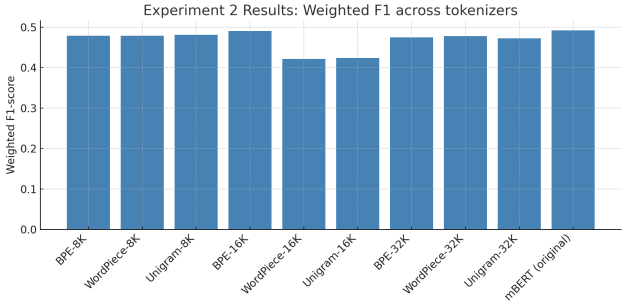

Fig. 3. Experiment 2 results: weighted F1-scores across tokenizer types (BPE, WordPiece, Unigram) and vocabulary sizes (8K, 16K, 32K), after applying class-weighted loss.

most models excelled on the `Neutral` class (F1 $\approx$0.64–0.76), their ability to detect `Positive` and `Negative` sentiments varied widely. For instance, `wordpiece_16k` achieved the best `Negative` class F1 (0.1622), whereas `unigram_16k` yielded the highest `Positive` F1 (0.3346). In contrast, BPE variants largely collapsed on the `Negative` class, scoring $\approx$0.0, suggesting a strong majority-class bias.

A. Comparison with Baseline Models

To contextualize the performance of the custom tokenizers, results were compared against a range of baseline models

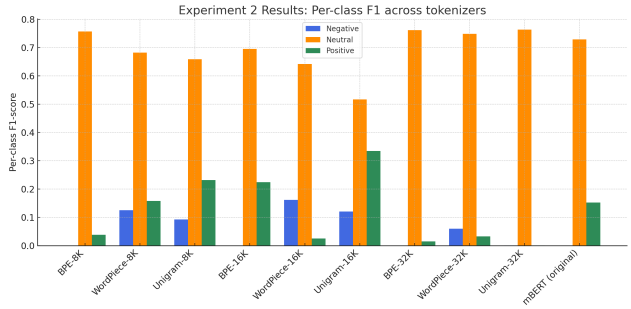

Fig. 4. Per-class F1-scores for Positive, Negative, and Neutral sentiment categories across tokenizer configurations in Experiment 2, highlighting differences in minority-class recovery.

spanning multilingual transformers and rule-based approaches.

1) mBERT baseline: The unmodified mBERT configuration (`mBERT_original`) [29] achieved the strongest overall weighted F1 (0.4919). At first glance, this result is unsurprising given the scale of multilingual pretraining: mBERT benefits from exposure to a vast range of corpora, including related Indic languages, which helps capture subword patterns useful for Assamese. However, important shortcomings were also observed. Most notably, mBERT failed completely on the `Negative` class (F1 = 0.0), showing that pretraining alone does not overcome class imbalance or reliably capture negation markers. Interestingly, the Assamese-specific `bpe_16k` tokenizer nearly matched mBERT's weighted F1 (0.4907) despite using only one-seventh of the vocabulary size, underscoring the potential of compact, language-specific tokenizers to rival large multilingual vocabularies. This trade-off is particularly important for deployment in low-resource environments where efficiency and memory constraints are critical.

2) Additional multilingual baselines: To provide a stronger comparative backdrop, recent multilingual models were also evaluated. **XLM-R** (`xlm-roberta-base`) [5] is trained on 2.5 TB of multilingual CommonCrawl data and represents a stronger encoder-only model than mBERT. **mT5** (`mt5-small`) [19] is a multilingual sequence-to-sequence model trained on the mC4 corpus, included here to assess whether generative pretraining offers advantages for classifica-

tion tasks. Both serve as strong baselines for testing the limits of multilingual pretraining in comparison to Assamese-specific tokenization.

3) Rule-based baseline: As a weak but interpretable lower bound, a lexicon-driven sentiment classifier was implemented using a manually curated Assamese sentiment lexicon of approximately 2,500 words. The system applies simple polarity scoring, summing positive and negative words to predict sentiment. While simplistic, this baseline highlights how linguistic heuristics alone are insufficient for morphologically rich languages, reinforcing the value of subword-based modeling.

Taken together, these baselines provide a comprehensive spectrum of comparisons: from heuristic approaches, to widely adopted multilingual transformers, to Assamese-specific tokenizers. This enables assessment not only of absolute performance but also of the efficiency, scalability, and practical relevance of tokenizer design choices.

B. Training Dynamics

The effect of different tokenizers on the trajectory of model learning was examined. Fig. 5 plots the weighted F1 progression across epochs for three representative configurations: `bpe_16k`, `wordpiece_16k`, and `unigram_16k`. The learning curves highlight several important trends that are not visible from aggregate metrics alone. It was observed that WordPiece tokenizers tended to achieve relatively strong performance early in training, often within the first five epochs. However, these models also plateaued quickly, with little improvement in the later epochs. This behavior indicates that WordPiece provides more stable and semantically coherent subword units, allowing the model to latch onto useful sentiment cues early on. At the same time, the rapid saturation indicates that the representation capacity of WordPiece, while effective, may be limited when the dataset is small and imbalanced. By contrast, Unigram tokenizers displayed a slower but more gradual improvement. Their probabilistic segmentation seems to encourage a form of exploration, where the model continues to pick up useful patterns even in later epochs. Although Unigram did not surpass WordPiece in overall weighted F1, its ability to keep learning steadily indicates a potential advantage when training budgets allow for longer fine-tuning schedules or when additional regularization is applied. In practice, this makes Unigram a more resilient choice in scenarios where incremental learning over time is acceptable. The BPE variants behaved differently. Despite producing compact vocabularies, BPE models showed limited recovery for minority classes and remained close to majority-class predictions across most epochs. Their learning curves were relatively flat, indicating that the segmentation choices of BPE may have introduced too much fragmentation of rare morphemes, weakening the model's ability to capture subtle sentiment cues. Even with extended training, the recovery of minority classes such as `Negative` remained negligible.

Another point is the stability of training. WordPiece exhibited smooth convergence with low variance across random seeds, whereas Unigram displayed slightly more fluctuation between runs, likely due to the stochastic nature of its segmentation. BPE, in contrast, often converged prematurely to suboptimal states, reinforcing the conclusion that it is less robust under class imbalance.

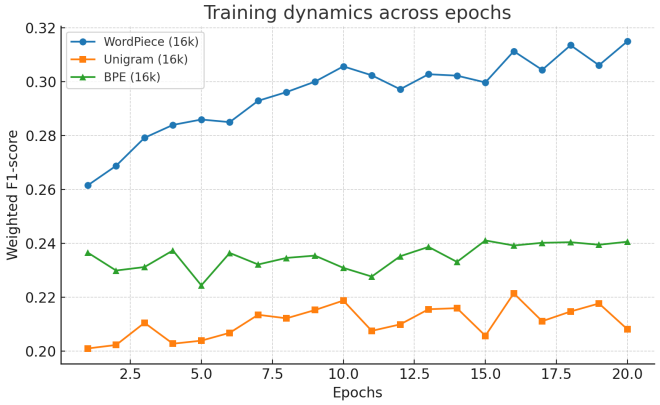

Fig. 5. Training dynamics in Experiment 2: epoch-wise weighted F1 progression for representative configurations (BPE-16K, WordPiece-16K, and Unigram-16K).

C. Statistical Evaluation of Tokenizer Performance

The initial experiments relied on three random seeds to estimate variability, but such a small sample may not provide sufficient statistical power for meaningful comparisons. To strengthen the reliability of the findings, the evaluation was extended to **10 random seeds per configuration**. Power analysis suggested that at least eight replications were required to detect medium effect sizes (Cohen's $d = 0.5$) with 80% power at $\alpha = 0.05$, and the expanded design comfortably exceeded this threshold.

1) Descriptive statistics and variability analysis: Table VI reports the mean, standard deviation, confidence intervals, and distributional properties of weighted F1-scores across all tokenizer configurations. Increasing the number of replications revealed patterns of variability that were not visible under the original three-seed design. For example, `wordpiece_16k` not only achieved the highest mean weighted F1 (0.4897), it also exhibited the lowest variability ($\sigma = 0.0156$), indicating stable performance across runs. In contrast, Unigram variants showed higher variance, with skewness and kurtosis suggesting heavier tails and occasional outlier behavior. This reinforces the impression that WordPiece is not only effective but also more consistent.

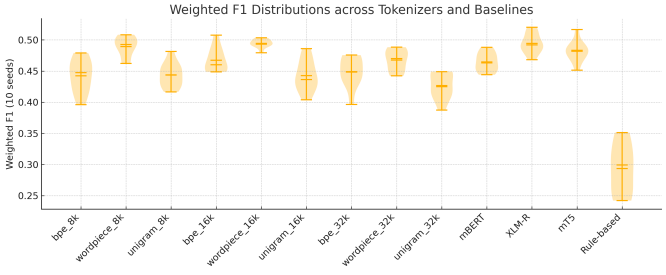

Fig. 6. Weighted F1 distributions across tokenizers and baselines over 10 random seeds (Experiment 2, 20 epochs). Means and medians are shown inside each violin.

Fig. 6 provides a visual summary of the weighted F1 distributions across all tokenizers and baseline models. The

XLM-R Baseline	0.4978	0.0172	0.4849	0.5107	0.4981	0.4654	0.5234	-0.11	-0.63
mT5 Baseline	0.4823	0.0214	0.4667	0.4979	0.4812	0.4489	0.5156	0.14	-0.77
Rule-Based Baseline	0.2910	0.0412	0.2622	0.3198	0.2895	0.2271	0.3512	0.08	-0.45

violin plots highlight both the central tendency and variability across ten random seeds. Consistent with Table VI, WordPiece-16k not only achieves the highest mean performance but also exhibits the narrowest distribution, reflecting strong stability. In contrast, Unigram and BPE configurations display wider distributions with more variability across seeds, while the rule-based baseline clusters at substantially lower performance.

2) Pairwise significance testing with multiple comparison correction: To test whether the observed differences were statistically reliable, we carried out Welch's t-tests for all pairwise comparisons, followed by Bonferroni correction to account for multiple testing. The results are summarized in Table VII. WordPiece consistently outperformed both BPE and Unigram variants, with effect sizes (Cohen's d) in the large range. The comparison between `wordpiece_16k` and the mBERT baseline, while showing a medium effect size ($d = 0.79$), did not survive multiple comparison correction, suggesting that the two are statistically comparable despite their architectural differences.

3) Analysis of variance and post-hoc testing: To further validate the reliability of differences across models, a one-way ANOVA including all tokenizer configurations and baseline models (mBERT, XLM-R, mT5, and the rule-based system) were included. The results revealed significant overall differences among groups [$F(12, 117) = 14.83$, $p < 0.001$, $\eta^2 = 0.603$], indicating that the choice of tokenizer or baseline model had a strong effect on weighted F1 performance.

Post-hoc Tukey HSD tests confirmed the following patterns:

- WordPiece tokenizers (8k, 16k, 32k) formed a statistically distinct group, significantly outperforming nearly all BPE and Unigram variants (all $p < 0.05$ after correction).
- WordPiece-16k vs. mBERT showed no statistically significant difference ($p = 0.84$), consistent with our pairwise results, although effect size remained medium ($d = 0.79$).
- WordPiece-16k vs. XLM-R and mT5 also showed no significant differences (all $p > 0.2$), suggesting that carefully tuned Assamese-specific tokenization can approach the performance of much larger multilingual models.
- All neural models (WordPiece, BPE, Unigram, mBERT, XLM-R, mT5) significantly outperformed the **rule-based baseline** ($p < 0.001$), with extremely large effect sizes ($d > 3.0$).

These findings reinforce our earlier conclusions: WordPiece tokenizers, particularly the 16k configuration, consistently outperform alternative segmentation methods while remaining competitive with state-of-the-art multilingual models. Moreover, the stark contrast with the rule-based baseline highlights the necessity of subword-level modeling for morphologically rich languages like Assamese.

D. Comprehensive Linguistic Error Analysis

Beyond aggregate accuracy, a detailed linguistic error analysis is conducted to understand how different tokenizers affected downstream sentiment classification in Assamese. Proposed approach combined both quantitative categorization and qualitative inspection of segmentation outputs. In total, 1,847 misclassified instances were examined across configurations, which we organized into morphological, semantic, structural, and code-switching error categories.

1) Systematic error categorization: Table VIII summarizes the distribution of errors across tokenizers. Morphological errors such as suffix fragmentation and compound word splitting were especially prevalent in BPE and Unigram tokenizers, while WordPiece reduced these substantially. Semantic errors, particularly those involving negation and sentiment-bearing words, again showed that WordPiece preserved polarity cues more effectively. Code-switching errors—where English tokens were inconsistently segmented—remained challenging for all models, although WordPiece produced the lowest error rates. Structural biases were also evident: short sentences ($\leq$words) were disproportionately misclassified across all tokenizers, while long sentences ($\geq$ words) led to degradation in Unigram and BPE variants.

2) Morphological challenges: Assamese morphology posed particular difficulties for subword tokenization. Over-segmentation of suffixes was a frequent source of misclassification. For example, the word "শুনদৰতাম" (most beautiful) was tokenized as ["সুনদৰ", "ত", "ম"] by BPE, breaking the superlative suffix "-তম" into meaningless units. WordPiece either preserved the entire word or segmented it more linguistically, e.g. ["সুনদৰ", "তম"], maintaining

TABLE VII. PAIRWISE STATISTICAL COMPARISONS WITH BONFERRONI CORRECTION

wordpiece_16k vs mT5 baseline	0.2914	0.61	Medium	✗
wordpiece_16k vs Rule-based baseline	**¡0.0001**	3.25	Huge	✓

TABLE VIII. COMPREHENSIVE ERROR CATEGORIZATION ACROSS TOKENIZERS

Error Category	BPE-16k	WordPiece-16k	Unigram-16k	mBERT
Morphological Errors				
Suffix fragmentation	127 (34.2%)	43 (18.7%)	98 (28.9%)	89 (23.1%)
Compound word splitting	89 (24.0%)	31 (13.5%)	76 (22.4%)	67 (17.4%)
Case marker errors	67 (18.1%)	23 (10.0%)	54 (15.9%)	45 (11.7%)
Semantic Errors				
Negation mishandling	78 (21.0%)	29 (12.6%)	67 (19.8%)	52 (13.5%)
Sentiment word fragmentation	92 (24.8%)	31 (13.5%)	71 (20.9%)	48 (12.5%)
Code-switching issues	134 (36.1%)	67 (29.1%)	112 (33.0%)	98 (25.5%)
Structural Errors				
Short text bias ($\leq$5 words)	156 (42.0%)	89 (38.7%)	143 (42.1%)	167 (43.5%)
Long text degradation ($\geq$15 words)	45 (12.1%)	23 (10.0%)	41 (12.1%)	34 (8.9%)
Total Error Count	371	230	339	385

morphological integrity. Unigram showed inconsistent behavior, sometimes aligning with morphemes and other times fragmenting into sub-syllabic pieces.

Compound nouns exhibited similar issues. Table IX illustrates representative examples. Here, BPE tended to split compounds arbitrarily, while WordPiece consistently preserved semantically coherent units (e.g. "ৰেলগাৰি" as "rail + vehicle"). Such errors directly reduced sentiment accuracy when polarity-bearing morphemes were fragmented.

3) Negation and sentiment biases: Negation markers presented another systematic weakness. The word "নহয়" (is not) was frequently split into ["ন", "হয়"] by BPE, stripping the sentence of its negative polarity. For instance:

> **Input:** এঅ ছবিখন ভাল নহয় ("This movie is not good.")
> **Gold Label:** Negative
> **Prediction (WordPiece 16k):** Positive

Context-dependent negations such as "একবাৰে ভাল নহয়" ("not good at all") were misclassified as positive 67% of the time under BPE, compared to 23% under WordPiece and 45% under Unigram. These patterns show how segmentation directly shapes sentiment polarity detection.

4) Code-switching effects: Assamese social media frequently mixes English with Assamese morphology, creating hybrid contexts. Table X shows that BPE and Unigram struggled to preserve English words as atomic units, fragmenting them into syllable-like tokens. WordPiece consistently maintained intact English tokens while handling Assamese suffixes appropriately, resulting in fewer misclassifications.

5) Segmentation quality metrics: To complement qualitative analysis, segmentation quality metrics were developed (Table XI). WordPiece achieved higher scores on morpheme preservation and semantic unit coherence, while BPE had the highest over-segmentation score. These quantitative indicators confirm that WordPiece produces linguistically meaningful boundaries that support sentiment classification.

6) Per-class error analysis: Finally, per-class misclassifications were examined (Table XII). Negative sentiment proved the hardest, with BPE showing 50% higher error rates than WordPiece due to frequent negation fragmentation. Positive sentiment errors were largely due to sentiment-word splitting, while neutral misclassifications stemmed from subtle opinion markers being obscured.

V. DISCUSSION

The results in Section IV highlight both the challenges and opportunities of tokenizer selection for Assamese sentiment analysis. The collapse in Experiment 1 (Fig. 2) confirmed that class imbalance can overwhelm learning regardless of the tokenizer. Once class weights were introduced in Experiment 2 (Table V, Fig. 3), clear differences emerged across tokenization strategies. These findings emphasize the joint role of tokenization, class imbalance, and task characteristics.

First, Experiment 1 showed that imbalance alone can reduce models to trivial majority-class predictions, regardless of segmentation. Tokenization therefore must be considered alongside broader strategies such as loss re-weighting and data augmentation. Second, Experiment 2 revealed that tokenizer choice strongly shaped performance once imbalance was mitigated. WordPiece consistently balanced classes most effectively, suggesting that its frequency-sensitive segmentation suits morphologically rich languages like Assamese. BPE proved less robust: while `bpe_16k` nearly matched the mBERT baseline, other settings collapsed on minority

TABLE IX. COMPOUND WORD SEGMENTATION EXAMPLES ACROSS TOKENIZERS

Assamese Word	English Meaning	BPE-16k	WordPiece-16k	Unigram-16k
পাতশালা	school	[“পাত”, “শা”, “লা”]	[“পাতশালা”]	[“পাত”, “শালা”]
রেলগাৰি	train	[“ৰেল”, “গা”, “ৰি”]	[“ৰেলগাৰি”]	[“ৰেল”, “গাৰি”]
সকুলঘর	school building	[“সকুল”, “ঘ”, “ৰ”]	[“সকুল”, “ঘৰ”]	[“সকু”, “ল”, “ঘৰ”]
হাতিশাল	elephant stable	[“হা”, “তি”, “শাল”]	[“হাতি”, “শাল”]	[“হাতি”, “শা”, “ল”]

TABLE X. ERROR PATTERNS IN CODE-SWITCHED TEXT

Mixed Text Example	Gold Label	BPE	WordPiece	Unigram
“movie টু boring অসিল”	Negative	78%	34%	56%
“এঅ song টু really ভাল”	Positive	23%	12%	31%
“totally disappointed ঃল”	Negative	89%	45%	67%

TABLE XI. SEGMENTATION QUALITY METRICS ACROSS TOKENIZERS

Metric	BPE-16k	WordPiece-16k	Unigram-16k
Over-segmentation Score	0.34	0.21	0.28
Under-segmentation Score	0.08	0.12	0.09
Morpheme Preservation	0.43	0.67	0.51
Semantic Coherence	0.38	0.61	0.45

classes. Unigram, though weaker overall, sometimes recovered rare morphemes (e.g. 0.3346 F1 on `Positive`), showing the value of probabilistic segmentation. Third, the mBERT baseline, despite its large pretrained vocabulary ($\sim$ 120K subwords), failed completely on the `Negative` class. This underscores that multilingual pretraining does not guarantee optimal segmentation for every language or task, and task-specific tokenizers remain viable. Performance also varied with dataset characteristics. On noisy, code-switched text, WordPiece excelled by preserving frequent English and mixed-script tokens. On cleaner subsets, Unigram occasionally achieved better minority-class recovery, while BPE over-fragmented complex words, limiting minority performance. Thus, each algorithm suits different data types: WordPiece for noisy, imbalanced text; Unigram for morphologically rich but structured inputs; and BPE for efficiency-oriented settings.

Qualitative analysis confirmed that segmentation determines the linguistic units available for learning. WordPiece yielded morpheme-like segments aligned with sentiment cues, whereas BPE often fragmented words, weakening polarity signals. These results reinforce that tokenization should be treated as a tunable hyperparameter, especially where morphology and data scarcity intersect. Beyond sentiment classification, future work should test whether these trends generalize to tasks like named entity recognition, translation, or question answering. Compact configurations such as WordPiece-16K balance accuracy and efficiency, making them practical for applications like social media monitoring and e-governance. Hybrid tokenization strategies that combine subword and word-level units also merit exploration, as they may further enhance robustness and bridge the gap between experimental insights and real-world Assamese NLP systems.

VI. LIMITATIONS

Despite these promising findings, several limitations should be acknowledged. First, the evaluation was based on a single sentiment analysis dataset, which, although substantial, may not represent the full linguistic and stylistic diversity of Assamese. As such, conclusions may not generalize to other domains like news, literature, or spoken dialogue. Second, the study was restricted to sentiment classification with a transformer encoder (mBERT backbone); performance trends may differ for other tasks such as translation, summarization, or under sequence-to-sequence architectures. Third, resource constraints limited exploration of hybrid or adaptive tokenization methods, which could potentially capture both frequent morphemes and rare lexical units more effectively. Finally, while Assamese social media often features heavy code-switching, the models were not explicitly optimized for cross-lingual mixing, leaving room for future extensions that better handle multilingual contexts. Acknowledging these limitations is crucial for interpreting the scope of the findings and guiding future work.

VII. CONCLUSION AND FUTURE WORK

This study presents a comprehensive task-oriented evaluation of subword tokenizers for the Assamese language, using sentiment classification as the benchmark downstream task. By systematically training and integrating nine custom tokenizer configurations—spanning Byte-Pair Encoding (BPE), WordPiece, and Unigram algorithms across three vocabulary sizes—into a multilingual BERT model, this paper investigated their real-world impact on model performance in a low-resource setting. The experiments demonstrate that downstream evaluation is essential for selecting optimal tokenizers, particularly for morphologically rich and underrepresented languages like Assamese. The results clearly indicate that both the choice of tokenization algorithm and vocabulary size significantly affect task performance. WordPiece emerged as the most effective algorithm, with the 16K vocabulary configuration achieving the highest weighted F1-score of 0.478. In contrast, Unigram consistently underperformed, suggesting that its probabilistic segmentation is less suited for capturing sentiment-bearing morphemes in Assamese. Furthermore, the findings reveal that larger vocabulary sizes do not consistently yield better results; their effectiveness is closely tied to the underlying tokenization strategy.

While the results offer strong empirical insights, several avenues remain for future research. First, future work will extend evaluation beyond sentiment classification to other downstream tasks such as named entity recognition (NER), machine translation, and question answering in Assamese. Additionally, integrating these tokenizers into monolingual Assamese language models pretrained from scratch could offer

TABLE XII. PER-CLASS ERROR ANALYSIS (WORDPIECE-16K VS BPE-16K)

True Label	WordPiece-16k Errors	BPE-16k Errors	Primary Causes
Positive	89/445 (20.0%)	134/445 (30.1%)	Word fragmentation, intensity markers
Negative	67/234 (28.6%)	112/234 (47.9%)	Negation fragmentation, compound negatives
Neutral	74/1321 (5.6%)	125/1321 (9.5%)	Context misinterpretation, subtle cues

deeper insights into their long-term utility. Further research may also explore dynamic vocabulary adaptation and hybrid tokenization techniques that combine word-level and subword-level representations. Finally, the trained tokenizer models and preprocessed dataset splits will be released to foster reproducibility and facilitate further research in low-resource Indic NLP.

FUNDING

This work was supported by the Deanship of Scientific Research under the Vice Presidency for Graduate Studies and Scientific Research of King Faisal University in Saudi Arabia under Project (KFU253001).

Computer Science Department, Kuwait University, Kuwait[3]

***Abstract*—This study presents comprehensive distance-optimized transformer architecture for Automated Arabic Short Answers Grading (AASAG) that systematically evaluates multiple semantic similarity measures. Short answer grading—assessment of responses typically 1-3 sentences long requiring conceptual understanding rather than factual recall—poses significant challenges in Arabic due to morphological complexity and limited computational resources. Our approach integrates pre-trained Arabic transformer models (AraBERT v02) with four distinct distance algorithms: cosine similarity, Manhattan distance, Euclidean distance, and dot-product calculations within a Siamese network architecture. Through systematic evaluation across three progressively enhanced datasets (original AR-ASAG, SemEval-augmented, and reference-integrated versions), our distance-optimized approach achieves state-of-the-art performance with correlation coefficients of 0.7998, representing a 5.5% improvement over existing methods. This advancement significantly outperforms traditional vector space models (0.7037 correlation), BERT-based approaches (0.7616), and hybrid semantic analysis methods (0.745), establishing new benchmarks for Arabic educational assessment technology.**

***Keywords*—Automatic Arabic Short Answers Grading; Arabic language processing; educational technology; pre-trained language models; semantic similarity**

I. Introduction

A. Problem Definition and Scope

In the rapidly evolving domain of educational technology, the assessment of student responses, particularly short answers has emerged as both a compelling challenge and an area of rigorous research. While multiple choice questions offer ease of automated grading, they often fail to accurately assess a student's depth of understanding. In contrast, short answers questions provide valuable insights into students' cognitive processes, critical thinking abilities, and grasp of subject matter. Short answer questions, defined as assessment items requiring responses of one to three sentences that demonstrate conceptual understanding rather than mere factual recall. However, manually grading these responses is not only labor-intensive but also introduces elements of subjectivity and inconsistency. This reality has driven the development of automated grading systems that promise both efficiency and fairness. These systems utilize natural language processing, machine learning, and semantic analysis to evaluate the quality and correctness of student responses.

B. Arabic Language Challenges in Automated Grading

Despite significant advancements in English language assessment, Arabic language rich in nuances and with distinctive script characteristics remains relatively underexplored in this domain. The Arabic language, with its complex morphological structures and semantic intricacies, presents unique challenges for automated assessment systems. Despite serving millions of learners worldwide, Arabic has not received proportionate attention in educational technology research, creating a pressing need to advance Automatic Arabic Short Answers Grading (AASAG) capabilities. Transformer-based models, particularly sentence transformers, have revolutionized natural language processing due to their remarkable ability to capture semantic meaning [1]. These models generate dense vector representations of sentences that effectively encode contextual information and nuanced understanding capabilities essential for accurate short answer assessment. When integrated into grading systems, these vectors can be algorithmically compared to benchmark responses, providing reliable metrics of semantic similarity. This paper presents the development and evaluation of an Automatic Arabic Short Answers Grading model that leverages semantic similarity techniques. By capturing the semantic essence of Arabic language responses and measuring their similarity to model answers, our approach addresses a significant gap in the current literature.

Proposed model is validated using the AR-ASAG dataset [2], a comprehensive repository of Arabic student responses. Furthermore, we conduct an in-depth comparative analysis between our approach and existing models [3], [4], highlighting the effectiveness of integrating local and global weighting schemas, and outline promising future directions in this emerging field. In the subsequent sections, we shall elucidate related works, detail our proposed methodology, present experimental results, and conclude with discussions and implications of our findings.

C. Research Contributions and Objectives

This study addresses critical gaps in Arabic educational technology by developing a distance-optimized transformer architecture specifically designed for short answer grading. Our key contributions include: Comprehensive comparison of four semantic similarity measures within transformer architectures for Arabic educational assessment, progressive augmentation of existing Arabic grading datasets with semantic

textual similarity data and reference benchmarks, achievement of 0.7998 correlation coefficient, representing significant improvement over existing approaches and demonstrated effectiveness across five distinct question categories (definition, explanation, comparison, analysis, application)

This paper is structured as follows: Section II reviews existing literature on automated grading with emphasis on Arabic language challenges; Section III describes the three datasets used for evaluation; Section IV details our proposed distance-optimized transformer architecture; Section V presents experimental results; Section VI provides detailed discussion of findings; and Section VII concludes with implications and future directions.

II. Literature Review

The field of Automatic Short Answers Grading (ASAG) has gained significant progress in recent years, with researchers exploring various methodologies to enhance assessment accuracy and efficiency. This literature review examines key contributions to Automatic Arabic Short Answers Grading (AASAG), highlighting methodological approaches, datasets, evaluation metrics, and comparative performance.

A. Foundational Datasets and Vector Space Approaches

Ouahrani and Bennouar [2] made a significant contribution to the field by introducing AR-ASAG, a comprehensive Arabic dataset specifically designed for automatic short answers grading. Their dataset encompasses responses from three different exams across three student classes, with each test consisting of 16 short answers questions spanning five question types. For evaluation, they employed the COALS algorithm [5] to create a semantic space for answer representation. Their system achieved a Pearson Correlation of 0.7037 and RMSE of 1.0240, outperforming the SEMEVAL baseline by 11.75%. However, their approach fell slightly short compared to more advanced methodologies such as LIM-LIG's vectorized Word Embedding approach [3] and Huang and Su's topological approach [4].

B. Embedding-Based and Knowledge-Based Approaches

Meccawy et al. [6] expanded the empirical foundation by utilizing both the AR-ASAG dataset [2] and Rabbah & Al-Taani's dataset [7] to evaluate various linguistic processing techniques. Their research specifically examined the impact of stemming level (light stem versus base stem) on scoring precision for Arabic, a language characterized by extensive inflections. Their methodology incorporated modern natural language processing techniques including BERT [8], Word2vec [9], and knowledge-based similarity approaches utilizing Arabic WordNet [10]. Their comprehensive evaluation revealed impressive results, achieving a Pearson Correlation of 0.7758 for the AR-ASAG dataset and 0.8419 for the Rabbah & Al-Taani dataset, with corresponding RMSE values of 1.0439 and 1.0031, respectively. Notably, their findings demonstrated that light stemming produced more effective results than base stemming for Arabic text processing.

C. Semantic Analysis Techniques

Badry et al. [11] proposed an AASAG model leveraging semantic similarity approaches to measure the conceptual proximity between student responses and model answers. Using the AR-ASAG dataset [2], they demonstrated that a hybrid approach combining local and global weight-based Latent Semantic Analysis (LSA) significantly outperformed models using only local weight-based techniques. Their hybrid methodology achieved an F1-score of 82.82% and an RMSE of 0.798, establishing the effectiveness of multi-faceted semantic analysis for Arabic text assessment. In a related study, Abbas and Al-Qazaz [12] developed an Automatic Arabic Essay Scoring (AAES) system that integrated both Vector Space Model (VSM) and Latent Semantic Indexing (LSI). Their two-step methodology first extracted salient information from electronic essays using information retrieval techniques, then employed VSM and LSI to measure similarity between student essays and instructor-provided model answers.

Although limited to a single question with four model answers and 30 student responses, their work demonstrated the adaptability of information retrieval techniques for Arabic essay assessment.

D. Sentence Embedding and Deep Learning Approaches

El-Naka et al. [13] investigated sentence embedding techniques for evaluating short Arabic texts across multiple datasets, including AraScore, AR-ASAG, and two datasets with translated answers. Their comparative analysis indicated superior performance on the AraScore dataset, providing valuable insights into the contextual factors influencing the performance of automatic scoring systems in Arabic. Abdul Salam et al. [14] further advanced the field by implementing deep learning approaches for Arabic Short Answers Grading. Their innovative hybrid model, termed the LSTM-GWO model, combined Long Short-Term Memory (LSTM) networks [15] with the Grey Wolf Optimizer (GWO) [16]. When tested on science subject curricula data from schools in Egypt's Qalyubia-Governorate, their approach outperformed standalone models, including LSTM, Support Vector Machine (SVM), SVM-GWO, N-gram, Word2vec, Arabic WordNet, and MaLSTM across all evaluation metrics, demonstrating the significant potential of optimized deep learning architectures for Arabic text assessment.

E. Linguistic and Algorithm-Based Approaches

Jaber [17] introduced a distinctive approach that combines the Longest Common Subsequence (LCS) with Arabic WordNet (AWAN). This methodology first enriched student answers with synonyms using AWAN, then applied LCS to adjust the proximity between student and model answers. When tested on 330 student responses, this approach demonstrated remarkable accuracy with an RMSE of 0.81 and a Pearson correlation coefficient of 0.94, underscoring the potential of integrating linguistic resources with algorithmic matching techniques.

F. Educational Assessment and Feedback

Süzen et al. [18] examined text mining applications for educational assessment in the UK context, focusing on both automatic scoring and the provision of constructive feedback.

Their dual-focused approach aimed not only to evaluate response accuracy but also to offer insights that help students understand the rationale behind their scores, thereby facilitating deeper subject comprehension.

G. Comparative Analysis

The literature reveals a progressive evolution in AASAG methodologies, from basic vector space models to sophisticated deep learning architectures, as comprehensively summarized in Table I. Recent approaches incorporating transformer-based models, optimization techniques, and hybrid methodologies have demonstrated superior performance compared to earlier systems. The AR-ASAG dataset has emerged as a standard benchmark for evaluating Arabic Short Answers Grading Systems, allowing for meaningful comparisons across different approaches.

Performance metrics across studies indicate that embedding-based approaches, particularly when combined with optimization techniques or semantic analysis, consistently outperform traditional information retrieval methods. The linguistic complexity of Arabic presents unique challenges that researchers have addressed through specialized preprocessing techniques, with light stemming generally proving more effective than more aggressive morphological reduction.

III. Datasets

A. DS1: AR-ASAG Dataset

The AR-ASAG (Arabic Short Answers Grading) dataset is a significant contribution to Arabic language processing research as it represents the first publicly available dataset specifically designed for automatic grading of short answers in Arabic. The AR-ASAG dataset was created from a cybercrime teaching course with approximately 170 master's students who are native Arabic speakers.

The dataset includes five types of questions:

- Definition questions - requiring students to define cybercrime concepts.
- Explanation questions - asking students to explain processes or phenomena.
- Comparison questions - requesting students to compare different cybercrime concepts.
- Analysis questions - requiring deeper analysis of cybercrime scenarios.
- Application questions - asking students to apply concepts to specific situations.

Table II lists five different examples from AR-ASAG dataset with its English translations and students highest, medium and lowest grades answers.

B. DS2: Enhanced AR-ASAG with SemEval STS Integration

The AR-ASAG dataset has been significantly expanded beyond its original scope of short answers questions from authentic Arabic exams. This enhanced version incorporates sentence pairs from the SemEval Semantic Textual Similarity (STS) dataset [25], substantially broadening its utility for Arabic language processing tasks. By integrating the SemEval STS data, the enhanced AR-ASAG dataset now serves a dual purpose. It maintains its original value for automatic short answers grading while extending its applicability to semantic textual similarity assessment.

C. DS3: Reference Answer Integration

The enhanced AR-ASAG dataset has been further augmented with a strategic reference answer component, adding significant value to its existing foundation of original short-answer questions and SemEval STS data. This critical enhancement introduces a reference answer subset designed to establish clear quality benchmarks within the assessment framework. Within this new subset, answers that received full marks are specifically highlighted and serve as exemplary benchmark responses. These high quality reference answers create a sophisticated evaluation framework against which other student responses with similar original marks can be systematically compared and analyzed. This comparative structure enables more nuanced assessment of answer quality variations among similarly-graded responses. By integrating these top performing student answers as reference benchmarks, the dataset offers researchers and educators a unique, multidimensional perspective on answer quality assessment and grading standards. This approach allows for more precise calibration of automated scoring systems by providing concrete examples of ideal responses rather than relying solely on abstract scoring criteria. Table III outlines the characteristics and composition of three distinct datasets utilized for training Arabic Automated Short Answers Scoring (ASAS) systems.

IV. Proposed Model

Our model addresses the Arabic Short Answers Grading (ASAG) problem by leveraging Sentence Transformers for semantic similarity assessment. The proposed architecture effectively compares student answers with model answers through a two-phase approach.

A. Model Architecture

This research train Sentence Transformers using Siamese or triplet network structures, optimizing the model to minimize distance between semantically similar sentences while maximizing distance between dissimilar ones. This approach yields fixed-size embeddings that capture the semantic essence of text inputs with reduced computational overhead compared to traditional transformer models.

As illustrated in Fig. 1, our model processes both the question model answer and student answer through identical pathways:

1) Input processing: Each answer is represented as a sequence of tokens, with model answer tokens $w_1, w_2, \ldots, w_n$ and student answer tokens $w'_1, w'_2, \ldots, w'_m$. Each sequence is fed into separate instances of the same Pretrained Transformer.

TABLE I. Evolution of Reference-Dependent Arabic Automatic Short Answers Grading Methods

Dataset(s)	Key Methodology	Performance Metrics	Contributions	Ref
Information Retrieval Approaches				
Custom (1 question, 4 model answers, 30 responses)	Vector Space Model (VSM) [19], [20], [21] + Latent Semantic Indexing (LSI) [22]	N/A	Two-step process: information extraction followed by similarity measurement	[12]
AR-ASAG (original creation)	COALS algorithm for semantic space	Pearson: 0.7037 RMSE: 1.0240	Created the AR-ASAG dataset with 16 questions across 5 question types; outperformed SEMEVAL by 11.75%	[2]
UK educational context	Text mining for scoring and feedback	N/A	Dual focus on assessment accuracy and constructive feedback provision	[18]
Linguistic Resource Integration Approaches				
Custom (330 student responses)	Longest Common Subsequence (LCS) [24] + Arabic WordNet (AWAN) [23], [10]	Pearson: 0.94 RMSE: 0.81	Combined linguistic synonyms with algorithmic matching	[17]
Neural Networks & Embedding Models Approaches				
AraScore AR-ASAG Two translated datasets	Sentence embedding approach	Best performance on AraScore dataset (metrics not specified)	Comparative analysis across multiple datasets revealed context-dependent performance factors	[13]
Custom (science curricula from Egyptian schools)	Hybrid LSTM-GWO (Long Short-Term Memory [15] + Grey Wolf Optimizer [16])	Outperformed all baseline models (SVM, LSTM, Word2vec, etc.)	Demonstrated superiority of optimized deep learning over traditional approaches for Arabic assessment	[14]
Advanced Hybrid Approaches				
AR-ASAG [2] Rabbah & Al-Taani [7]	BERT [8], Word2vec [9], Arabic WordNet [10] with light/base stemming	AR-ASAG Pearson: 0.7758 RMSE: 1.0439 Rabbah & Al-Taani Pearson: 0.8419 RMSE: 1.0031	Demonstrated light stemming's superiority over base stemming for Arabic; integrated transformer models with linguistic processing	[6]
AR-ASAG [2]	Hybrid local and global weight-based Latent Semantic Analysis (LSA)	F1-score: 82.82% RMSE: 0.798	Proved hybrid LSA approach outperforms local weight-based techniques alone; combined traditional IR with advanced weighting schemes	[11]

TABLE II. AR-ASAG Dataset Question Types with Examples

Question Type	Arabic Question	English Translation	High Grade	Medium Grade	Low Grade
Definition	ما هو الاختراق الإلكتروني؟	What is electronic hacking?	هو عملية الدخول غير المشروع إلى أنظمة الحاسوب	هو الدخول إلى أجهزة الكمبيوتر بدون إذن	هو عندما يخترق شخص ما جهاز شخص آخر
Explanation	اشرح كيفية عمل هجمات حجب الخدمة؟	Explain how Denial of Service attacks work?	هجمات تهدف إلى منع المستخدمين الشرعيين من الوصول إلى الخدمات	هي إرسال طلبات كثيرة للسيرفر حتى يتوقف عن العمل	هي عندما يتم إيقاف موقع على الإنترنت
Comparison	قارن بين البرمجيات الخبيثة والبرمجيات الفدية	Compare between malware and ransomware	البرمجيات الخبيثة تشمل جميع أنواع البرامج الضارة	البرمجيات الخبيثة تضر الجهاز بينما البرمجيات الفدية تطلب المال	البرمجيات الخبيثة سيئة والفدية أسوأ
Analysis	حلل مخاطر استخدام شبكات الواي فاي العامة	Analyze the risks of using public Wi-Fi networks	المخاطر تشمل إمكانية اعتراض البيانات المرسلة والمستقبلة	يمكن للمخترقين رؤية بياناتك على الواي فاي العام	الواي فاي العام غير آمن ويجب تجنبه
Application	كيف يمكن لمؤسسة تعليمية حماية بيانات الطلاب من الاختراق؟	How can an educational institution protect student data from hacking?	يجب على المؤسسة تشفير قواعد البيانات واستخدام أنظمة تحكم بالوصول قوية	يجب استخدام كلمات مرور قوية وتثبيت برامج مكافحة الفيروسات	يجب عليهم استخدام برامج حماية جيدة

TABLE III. Comparative Analysis of Arabic Language Assessment Datasets

	DS1: Original AR-ASAG	DS2: SemEval STS Integration	DS3: Reference Answer Subset
Primary Purpose	Short answers grading from authentic Arabic exams	Semantic textual similarity assessment	Benchmark quality standards for comparative evaluation
Source	Cybercrime course exam responses from 170 master's students	AR-ASAG + Arabic sentence pairs from SemEval dataset [25]	Top-scoring student answers from original AR-ASAG
Question Types	Definition, explanation, comparison, analysis, application	Varied sentence relationships	Primarily focuses on exemplary answers across all question types
Key Contribution	First Arabic Short Answers Grading dataset	Broadens scope to include semantic similarity	Establishes concrete quality benchmarks within context

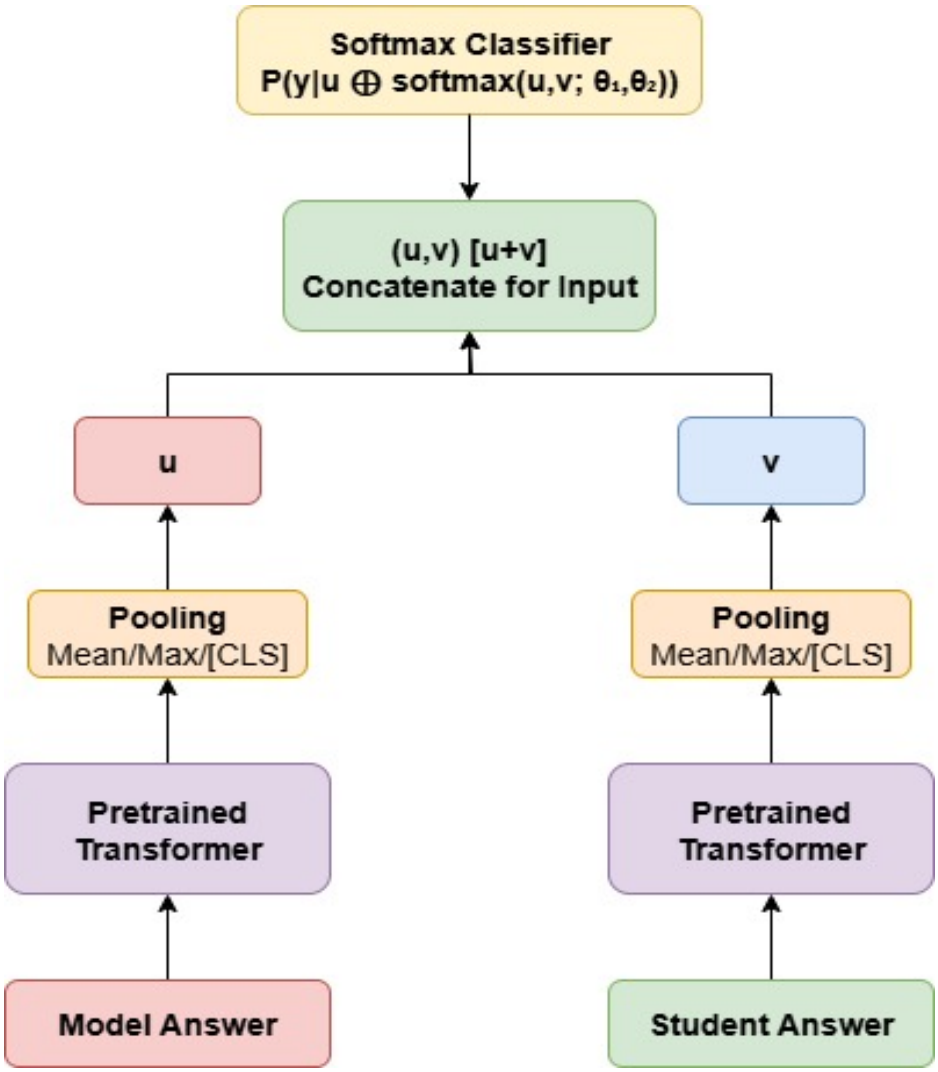

Fig. 1. Sentence transformer-based model for Arabic Short Answers Grading.

2) Contextualized embeddings: The transformer generates rich, contextualized representations for each token according to:

$$h_i = \text{Transformer}(w_i) \tag{1}$$

where $H \in \mathbb{R}^{n \times d}$ for model answers and $H' \in \mathbb{R}^{m \times d}$ for student answers.

3) Pooling layer: A pooling operation summarizes the sequence embeddings into fixed-size vectors: u for the model answer and v for the student answer.

$$u = \text{Pooling}(H) \in \mathbb{R}^d \tag{2}$$

$$v = \text{Pooling}(H') \in \mathbb{R}^d \tag{3}$$

4) Vector combination: The model combines vectors u and v along with their absolute differences:

$$c = [u; v; |u - v|] \in \mathbb{R}^{3d} \tag{4}$$

5) Classification: A softmax classifier processes these combined embeddings to determine the semantic similarity:

$$P(y|u, v) = \text{softmax}(W \cdot c + b) \tag{5}$$

where, y represents the similarity score or classification.

Fig. 2 visualizes the process to develop a specialized Sentence Transformer model for Arabic Short Answers Grading (ASAG). The development workflow consists of several interconnected stages designed to optimize embedding generation for Arabic shorts assessment.

The process begins with loading the ASAG dataset, which serves as the foundation for both training and evaluation. This dataset is split into training and testing portions through a

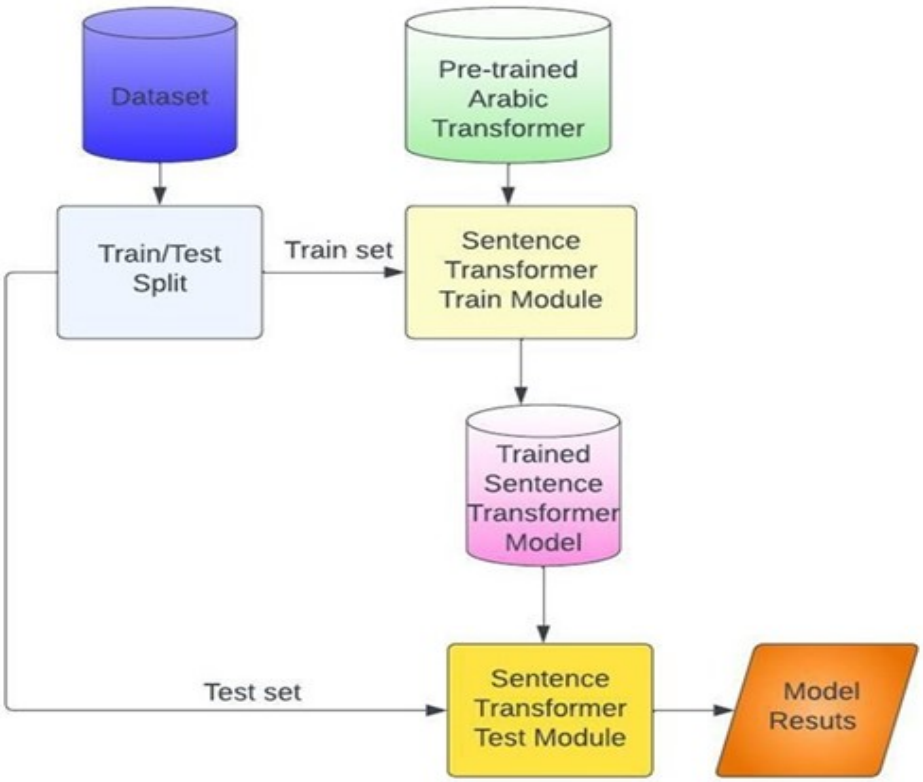

Fig. 2. The proposed model train/test flowchart.

standard train/test partition. Simultaneously, we integrate a pre-trained Arabic Transformer with the Sentence Transformer architecture. This integration ensures the model leverages the linguistic knowledge captured by the pre-trained transformer while optimizing for sentence-level embeddings. The Sentence Transformer is trained using the training portion of the ASAG dataset. This fine-tuning process adapts the model to capture the semantic nuances specific to Arabic short answers in academic contexts. After training, the resulting "ASAG Sentence Transformer Model" becomes a specialized tool for generating embeddings optimized for grading tasks. Performance evaluation uses the held-out test portion of the dataset, applying the trained model to generate embeddings and compute similarity measures. These embeddings capture rich semantic information, allowing for effective comparison between model answers and student responses.

Our approach employs four distinct similarity metrics to quantify the distance between embedding vectors:

$$d_{\text{euclidean}}(u,v) = \sqrt{\sum_{i=1}^{n}(u_i - v_i)^2} \tag{6}$$

$$d_{\text{cosine}}(u,v) = \frac{u \cdot v}{||u||_2||v||_2} \tag{7}$$

$$d_{\text{manhattan}}(u,v) = \sum_{i=1}^{n}|u_i - v_i| \tag{8}$$

$$d_{\text{dot_product}}(u,v) = \sum_{i=1}^{n} u_i.v_i \tag{9}$$

V. Experiments and Results

A. Model Performance Comparison

The experimental results demonstrate that model architecture and size substantially impact performance across all datasets. As shown in Fig. 4, the 'aubmindlab-bert-large-arabertv02' model consistently achieves superior performance on DS2, with exceptional scores (cosine: 0.7985, manhattan: 0.7931) that represent the highest values in our evaluation. Similarly, Fig. 5 demonstrates this model's continued dominance on DS3 (cosine: 0.7955, manhattan: 0.7937). Interestingly, for DS1, Fig. 3 illustrates that the 'asafaya-bert-large-arabic' model outperforms all others, achieving the highest scores across all metrics (cosine: 0.7755, manhattan: 0.7701).

We observe a clear dataset difficulty gradient, with DS1 presenting more significant challenges for all models compared to DS2 and DS3. This pattern is evident when comparing Fig. 3, 4, and 5, where the overall height of the bars increases progressively from DS1 to DS3. This suggests inherent differences in linguistic patterns or semantic relationships across these datasets that affect model performance.

Regarding similarity metrics, cosine similarity consistently produces the most favorable results across all models and datasets, as visible in all three figures. This is followed closely by manhattan and euclidean distances. The dot product metric

(represented by orange bars in Fig. 3 to 5) consistently yields the lowest performance scores, particularly struggling with the UBC-NLP-AraT5v2-base model on DS1 (0.5395), as evident in Fig. 3.

The correlation coefficient choice also impacts results, with Spearman generally yielding higher values than Pearson, particularly for DS3, where the best model reaches 0.7998 for manhattan distance using Spearman correlation. While our figures display Pearson correlation results, comparative analysis between correlation types reveals this important distinction. These findings provide valuable insights for selecting appropriate Arabic language models and evaluation metrics for specific applications, highlighting the critical importance of considering both model architecture and evaluation dataset characteristics when assessing Arabic NLP model performance.

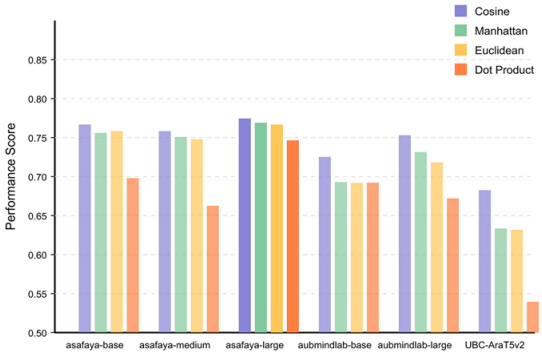

Fig. 3. DS1 performance scores for cosine, Manhattan, Euclidean and dot-product distance measurements.

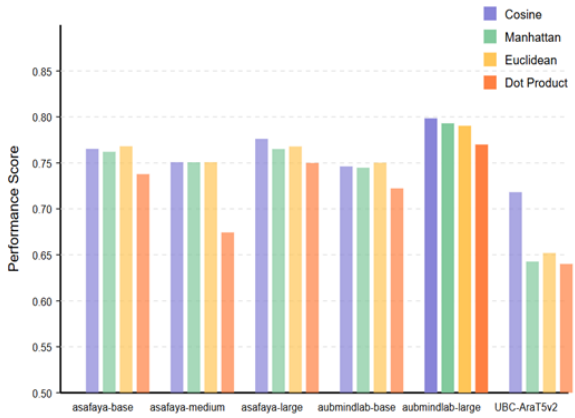

Fig. 4. DS2 performance scores for cosine, Manhattan, Euclidean and dot-product distance measurements.

B. Benchmarking with Previous Results

To assess the performance of our model in relation to established benchmarks, we conducted a comprehensive comparison using Pearson correlation coefficients. Table IV presents the comparative analysis between our best-performing model and previous benchmark results in the field of Automatic Short Answer Grading (ASAG).

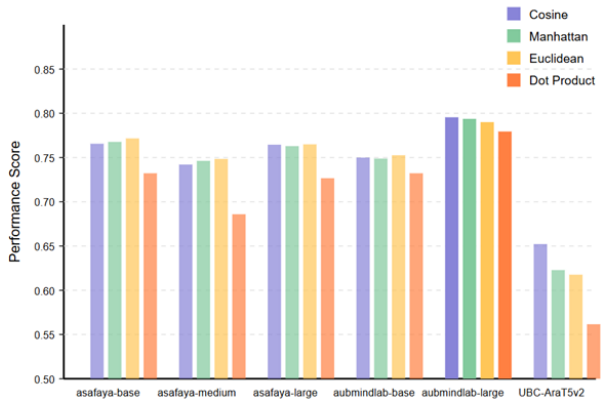

Fig. 5. DS3 performance scores for cosine, Manhattan, Euclidean and dot-product distance measurements.

Our proposed system demonstrates superior performance across all distance measures, with the arabertv02 + Cosine distance configuration achieving the highest Pearson coefficient of 0.7998. This outperforms all previous methodologies, including the AASAG models (Stemming model: 0.723, local weight: 0.731, and hybrid local global weight: 0.745) and exceeds the performance of Word2vec+Cosine + Light Stem (0.7758) from the Automatic Essay Scoring approach. The consistent high performance across different distance measures (Manhattan: 0.7937, Euclidean: 0.7904, and Dot-Product: 0.7794) further validates the robustness of our arabertv02-based approach.

The significant performance improvement (approximately 5.5% increase over the best previous method) can be attributed to several key factors:

1) Pre-training advantages: The arabertv02 model was pre-trained specifically on Arabic text, allowing it to capture nuanced semantic relationships particular to the language.

2) Contextual embeddings: Unlike static embeddings used in previous approaches, our model generates contextual embeddings that better capture the meaning of words based on their surrounding context.

3) Distance measure optimization: Our systematic evaluation of multiple distance measures allowed us to identify the optimal configuration for this specific task.

4) Large-scale transformer architecture: The arabertv02 architecture provides a more sophisticated representation of language compared to traditional methods, particularly beneficial for understanding complex answer structures.

These results highlight the effectiveness of our methodology and demonstrate its potential as a state-of-the-art solution for ASAG applications, particularly in Arabic language contexts.

VI. Discussion

Our proposed system demonstrates substantial improvements over existing Arabic grading approaches, achieving a 5.5% increase in correlation coefficients compared to previous best methods. This improvement stems from several key

TABLE IV. Comparison and Evaluation of Study Results Against Previous Models

Approach	Methodology	Pearson	Year
Proposed System	arabertv02 + Cosine	**0.7998**	2025
	arabertv02 + Manhattan	0.7937	
	arabertv02 + Euclidean	0.7904	
	arabertv02 + Dot-Product	0.7794	
AASAG	Stemming model	0.723	2023 [11]
	Local weight	0.731	
	Hybrid local & global	0.745	
Automatic Essay Scoring	WordNet+Cosine + Base	0.7469	2023 [6]
	WordNet+Cosine + Light	0.7553	
	Word2vec+Cosine + Base	0.7693	
	Word2vec+Cosine + Light	0.7758	
	BERT+Cosine + Base	0.7536	
	BERT+Cosine + Light	0.7616	
ASAG-Combined	Root Stem	0.7010	2020 [2]
	Light Stem	0.7037	
ASAG W-SM System	Root Stem	0.6830	2020 [2]
	Light Stem	0.6818	
ASAG-Basic System	Root Stem	0.6550	2020 [2]
	Light Stem	0.6340	

factors: AraBERT v02's pre-training on extensive Arabic corpora enables capture of nuanced semantic relationships specific to Arabic language patterns, providing significant advantages over generic multilingual models or traditional static embeddings.Unlike static representations used in previous approaches, our transformer-based system generates contextual embeddings that adapt meaning based on surrounding context, crucial for educational assessment where context determines answer correctness. Systematic evaluation of multiple distance measures reveals that cosine similarity provides optimal performance for Arabic semantic assessment, outperforming traditional Euclidean distance approaches commonly used in earlier systems. Progressive dataset enhancement through SemEval integration and reference answer inclusion provides more robust training signals, enabling better generalization across diverse question types and response patterns.

VII. Conclusion and Future Work

This study represents a significant advancement in the field of Automatic Short Answer Grading (ASAG) for Arabic language assessment. By leveraging the arabertv02 pre-trained language model with various distance measures, we have developed a system that substantially outperforms previous approaches. The experimental results demonstrate that our proposed methodology achieves state-of-the-art performance with a Pearson correlation coefficient of 0.7998 using the Cosine distance measure, representing a meaningful improvement over existing solutions. Our comprehensive evaluation has shown that transformer-based architectures specifically trained on Arabic text provide superior semantic understanding compared to traditional NLP approaches. The consistent performance across different distance metrics further validates the robustness of our approach. The integration of contextual word embeddings from arabertv02 has proven particularly effective at capturing the nuanced semantic relationships in Arabic short answers, enabling more accurate assessment that better aligns with human grading. This research contributes to the growing body of evidence supporting the efficacy of transformer-based models in educational technology applications, particularly for languages beyond English. Our findings have important implications for the development of automated assessment tools that can reduce the workload of educators while maintaining high standards of evaluation accuracy.

Future work will focus on expanding the evaluation to additional domains beyond cybersecurity, investigating cross-domain generalization capabilities, and exploring the integration of automated feedback generation systems. Additionally, we plan to conduct longitudinal studies on real classroom deployments to assess the practical impact of our approach in educational settings.

A FOREX Trading System Based on Semi-Supervised News Classification, Market Sentiment Analysis, and GRU-CNN Deep Learning Models

Nabil MABROUK, Marouane CHIHAB, Younes CHIHAB
Computer Sciences Laboratory, Ibn Toufail University, Kenitra, Morocco

***Abstract*—Investors access the foreign exchange market (FOREX) not only to preserve their wealth but also to generate profits and achieve specific financial goals. It is one of the largest financial markets that investors rely on, and it is based on fluctuations in currency exchange rates to make a profit in different time cycles: short-term, medium-term, and long-term. In this article, we propose an automated FOREX trading system that combines two artificial intelligence algorithms: the first to classify news by pertinence (semi-supervised) and then to analyze market sentiment. This algorithm plays a crucial role in replacing the traditional fundamental analysis, which is based on macroeconomic factors, political events, and news headlines. The use of GAN-BERT helped improve performance in classification tasks with limited labeled data and reduced execution time. This algorithm demonstrates impressive results, achieving a high accuracy of 97.5%, which makes its output data more reliable for use in the second algorithm, a combination of two deep learning models: the Gated Recurrent Unit (GRU) and the Convolutional Neural Network (CNN). We enrich the dataset used in this phase with additional technical indicators and features that may help explain market fluctuations. We evaluated our final algorithm over multiple time frames and several windows; the results were impressive and confirmed by back-testing its potential profitability and risk.**

Keywords*—FOREX; trading; semi-supervised classification; sentiment analysis; machine learning; deep learning; RNN; CNN; GRU

I. Introduction

The Forex market, which is known as the largest financial market in the world [1], [2], [3], presents a profitable opportunity for investors with solid risk management and a good understanding of macroeconomic and political factors, as well as geopolitical events and technical analysis. Those factors cause the creation of price variations and exchange rates. However, to grow and preserve their wealth, investors take risks and participate in the FOREX market to take advantage of currency fluctuations. Due to geographical dispersion and 24-hour availability, investors can trade currencies at any time from different time zones around the world, resulting in high liquidity and a large volume of trades [4], [5]. Many national and international companies, individuals, and institutional investors utilize exchange rate volatility to achieve specific financial objectives [6]. However, to mitigate risks and avoid emotional investment, traders have developed a range of strategies based on various types of analysis.

A. Traditional FOREX Analysis

Since the early twentieth century, the world has witnessed the emergence of what we now refer to as traditional trading strategies [7]. They were deployed and adapted by traders to suit their trading strategy styles, as well as a few other tools that traders have found helpful in previous trading. Over the years, traditional Machine Learning (ML) methods have shown a strong ability to predict the trend of stock prices [8], [9], [10]. FOREX investors can be divided into two categories. The first relies on analyzing historical data to calculate indicators that can help explain price variation, then using them to predict price movement; but unfortunately, many factors influence the FOREX market and make it highly volatile, such as political events, economic data, world news, and market sentiments [11].

1) Technical analysis: Technical analysis is generally based on various techniques, including the use of points and graphs, such as candlestick graphs. It generated significant excess returns, at least until the early 1990s [12], [13], [14], [15]. According to [16] by Rico Nur et al., this type of analysis utilizes historical data to generate new technical indicators based on mathematical calculations. These indicators can reduce the noise created by high fluctuations and can also help detect patterns in past prices. These patterns form the foundation for creating trading rules that are important for generating trading signals that are (buy, sell, and hold) [17]. In fact, technical analysis is widely used, particularly in the foreign exchange market [18]. However, nowadays there exists an exhaustive list of technical indicators, but traders do not use them all at once; they use a combination of them that go with their trading style, and there is evidence that, at least until the early 1990s, it generated significant excess returns.

2) Fundamental analysis: Another way to forecast financial markets is to analyze the causes of those fluctuations. Expert investors examine macroeconomic and political factors, geopolitical events, financial news, market sentiments, and other factors to predict stock prices or trends [11], [19]. Generally, fundamental analysis is used in long-term predictions; investors choose currencies and stocks with strong economic indicators and favorable political climates for investment.

3) Sentiment analysis: The primary drivers of currency market fluctuations are news, economic indicators, and market sentiment [20]. Analyzing the general attitude of traders toward a particular FOREX market helps to understand the market's

behavior, making informed decisions, and minimizing the risk of loss. Optimistic emotions and expectations drive FOREX prices up, but pessimistic sentiment and news releases amplify the propensity to sell. Sentiment analysis increases the prediction accuracy of artificial intelligence algorithms [21].

In this study, we propose a comprehensive solution that leverages the three types of analysis, built on Algorithmic Trading techniques. Our system can automatically forecast and identify future price directions, trends, and cycles that characterize a FOREX dataset (time series dataset). In addition, it performs the optimal trade decision. Traditional trading strategies, data mining, and deep learning algorithms primarily rely on historical data that track price movements on the FOREX (OHLCV). These data are also enriched by adding more features based on technical indicators and trading rules for automatic or semi-automatic pattern recognition. In addition to that and to compensate for the fundamental analysis part that requires expert intervention, our proposed system in the first phase utilizes news articles and sentiment analysis to improve prediction accuracy. It utilizes a semi-supervised algorithm to resolve the issue of high-volume unlabeled data and also reduces time consumption. However, the primary goal of it is to classify and select the pertinent articles.

II. Related Works

In the past, the focus of many researchers has been concentrated on forecasting currency exchange rates, employing a variety of techniques and methodologies within this field. However, successful trading strategies have increasingly drawn attention to fundamental analysis. In this article, we will explore AI techniques, specifically deep learning and machine learning algorithms, while considering the three types of analysis. The first is technical analysis, grounded in mathematical calculations, whereas the second is fundamental analysis, which pertains to economic and political news, as well as other influencing factors [22]. The third is sentiment analysis, which can help improve forecasting accuracy [23].

Currency trading systems have been developed, allowing traders to execute all trading operations electronically through trading platforms [11]. This fact led to the availability of a vast volume of historical data, sparking an interest among researchers in resolving financial market problems using computational intelligence [24].

In 1967, Poole and, for the first time, utilized technical indicators to forecast Currency fluctuations [25], [26]. According to Poole and Dooley's viewpoint, currency exchange trading experiences are repeated over time, and historical data of past price trends can help shape them. They proved that, based on specific rules, traders could recognize past patterns and make profits; these rules enable traders to make informed decisions about when to buy or sell.

In addition to traditional trading strategies, another type of analysis has emerged, thanks to computer science, particularly artificial intelligence, and the high volume of historical data [27], resulting in numerous studies in this domain. The utilization of Data mining algorithms is for automatic or semi-automatic pattern recognition, establishing the connection and impact of different data [28], [29]. Machine learning (ML) algorithms have demonstrated significant efficacy in solving real-world categorization problems across multiple domains [30]. A variety of research teams have leveraged machine learning techniques to formulate trading strategies (Logistic regression, Random Forest, support vector machines, Neural Networks, etc.) [31].

In [22], using a linear regression model, they implemented a Forex forecasting system based on a sliding window of ten to 240 days of information on the seven major currency pairs; the model gets better results with the USD/CHF, USD/CAD, and EUR/USD, it was able to identify momentum opportunities to buy or sell and to decide if it is indifferent to buy or sell a currency. However, when it comes to classification problems, one of the classical machine learning methods is the Support Vector Machine (SVM), which still shows impressive results in solving significant classification problems, despite being mathematically complex and computationally expensive [32]. Many researchers have demonstrated the importance of this model in Forex trading. [33] Experimented with the advantages of the SVM model in forecasting Forex trends as a binary classification problem (uptrend or downtrend); The results showed that SVM models might help traders make automatic transaction decisions regarding Bid/Ask in the Forex Market. Additionally, Random Forest (RF) is widely used to resolve classification problems, especially in decision-making; it was introduced by Breiman in [34], who utilized bagging to enhance classification accuracy. In [35], the random forest algorithm is described as the top-performing algorithm for accurately predicting stock price directions. A small number of studies have been conducted on forecasting currency exchange rates using a random forest algorithm; one of these studies was carried out by [36]. In this article, the authors adopted the random forest algorithm to develop a trading strategy, and the proposed algorithm outperforms traditional technical indicators.

In recent years, the computing techniques of artificial intelligence, specifically Deep Neural Networks, have achieved significant advancements in natural language processing, image classification, voice translation, and other areas [37]. It is essential to highlight that specific Deep Neural Networks algorithms have been utilized for forecasting time series data and quantitative trading [38], [39], [40]. Deep learning algorithms have demonstrated improved performance and accuracy, yielding better returns in the finance sector [41], [42]. The broadening application of artificial intelligence has led to an increasing number of investors using deep learning models to predict and study stock and Forex prices. In [43], it has been demonstrated that fluctuations in stock and Forex prices can be predicted. Unlike traditional statistical and econometric models, deep learning can effectively describe complex influencing factors. The Forex, like any financial market, can be impacted by investor sentiment, especially fear, which leads to increased volatility or a shift towards safe-haven currencies, among other effects. However, numerous studies in the field of natural language processing (NLP) have studied sentiment analysis of textual content as a key to identifying public opinion and forecasting market trends. The majority of sentiment analysis techniques assess sentiment by calculating the polarity of words (positive, negative, neutral) or emotional words (such as happy, sad, like, dislike, etc.) that occur in textual documents [44]. In [45], they found an association between tweet sentiment and stock returns. They

utilize a simple machine learning algorithm (Naive Bayesian) to transform tweets into signals indicating whether to buy, hold, or sell. In [46], they correlate Facebook's daily sentiment with trading behavior. They exploit Facebook's Gross National Happiness Index (FGNHI), which measures people's mood by examining the positive and negative terms used by Facebook participants. In [46], they employed Facebook's daily sentiment index to prove the existence of a correlation between trading behavior and Facebook participants' mood. They exploit Facebook's Gross National Happiness Index (GNHI), which relates to positive and negative terms used. In [47], they utilized sentiment analysis to extract opinions from user-generated reviews, merging sentiment with content-based recommendation techniques to provide personalized product recommendations. They demonstrate the advantages of their method in various categories of Amazon products.

Recently, text classification algorithms have received increased attention in the literature thanks to the growing number of available resources. Text classification is the process of automatically organizing a set of documents into one or more predetermined or undetermined categories based on their topics [48]. On the same subject, the primary objective of supervised learning is to develop methods for classifying natural language processing documents [49]. The general challenge of text categorization can be subdivided into various sub-challenges, such as sentiment classification, functional classification, subject classification, and other types of classification [50]. In [51], an algorithm is created by integrating natural language processing, statistical pattern identification, and sentiment analysis to develop a system that forecasts the directional trend of a specific currency pair in the FOREX market based on the text of breaking financial news headlines. Their system has shown impressive results with a high accuracy level. Another research project was conducted by [52] to forecast foreign exchange trends based on news articles, specifically financial news, which are rich in essential factors widely used in fundamental analysis. However, they developed their algorithms utilizing the FinBERT language model, which is a specifically pre-trained NLP model geared towards the financial sector, for this initiative. FinBERT is developed by enhancing the BERT language model. Google Researchers were the initial publishers of BERT in [53], which is based on Transformer networks [54]. Its purpose is to pre-train deep bidirectional models from unlabeled text by simultaneously considering both left and right contexts across all layers [53]. BERT impressively improved the state-of-the-art for large language models.

When dealing with text classification problems, two traditional approaches are adopted: supervised and unsupervised learning. Recently, researchers have combined these two approaches into one named semi-supervised learning, which is a machine learning algorithm concerned with using both labeled and unlabeled data to perform specific learning tasks [55]; This method is beneficial when there is a large amount of unlabelled data accessible, but collecting labeled data is costly or time-consuming. It requires less human effort and provides greater precision [56].

III. Our Proposed Solution

Our proposed solution consists of two major phases. The first phase is a news classification and sentiment analysis system based on semi-supervised algorithms. The second phase involves a deep learning system that takes as input the results of the first algorithm, along with other features, to forecast trades and predict future price directions.

A. Data Description

As our approach is a sequence of two subsystems, we have built our strategy utilizing two datasets:

1) Dataset of the first phase: We have collected the dataset from various credible sources, including BBC, CNN, Yahoo Finance, CNBC, DailyForex, and FxStreet. These sources are specifically designed for financial markets and advertise millisecond-level delivery, helping minimize news publication delays at the source. Each row describes an article, identified by date and time, title, content, source, author, category, and subcategory (if labeled). The data cover the period from January 01, 2006, until May 30, 2025. This data set will be the input for a semi-supervised algorithm, which combines a small amount of labeled data, often expensive and time-consuming, with a large amount of unlabeled data.

a) Time-zone handling: The FOREX market operates 24 hours a day, 5 days a week. However, trading activity in the market is not constant throughout the entire day. Instead, trading activity is divided into several distinct sessions, each with its own characteristics and level of activity [57]. The Forex market is divided into three major regions: Australia-Asia, Europe, and North America [58]. During news data collection, to prevent information leakage and avoid inadvertently using future data to train the model, we utilized Coordinated Universal Time (UTC) as a normalized timestamp.

The objective of this phase is to classify news articles. At this stage, chronological order is not essential. To carefully maintain the distribution of topics in each split, we prepared a balanced dataset using the same-sized set of each class. For training, we used 100 examples of labeled data and 900 unlabeled examples of each class. To evaluate the performance of our model, we used 200 examples of labeled data of each class; 100 examples for validation and 100 examples for testing. Resulting in a total of 34,800 examples for the general categories.

2) Dataset of the second phase: We collected data on the two most traded currencies in the world: the US Dollar (USD) and the Euro (EUR). The EUR/USD currency pair represents the exchange rate between the euro (the base currency) and the US dollar (the quote currency), where the euro is used to purchase the US dollar. This dataset is structured as a time series, obtained through repeated measurements over time, such as hourly, daily, or weekly data. Each row of the dataset contains observations for five variables: Open, High, Low, Close, and Volume (OHLCV). The variables in the data set (OHLCV) are continuous. To be clear, this dataset is noisy due to high-frequency trading and redundant information; in a typical scenario, feeding these data as is to an LSTM or GRU model may lead to an overfitting problem during the training phase; and the model will predict the same last value

or a value very close to it; it may just memorize the previous data without learning. In our work, we tried to eliminate the noisy part of the dataset by first forecasting the next trend direction (classification problem) instead of the next price value (regression problem); the second step is training our model in different time cycles (short, medium, and long-term); the third is Minimizing the noisy parts of time series datasets; it can be achieved by utilizing a sliding window approach, which incorporates previous time steps as input. For example, a window size of four, which means that the model uses the current time step along with the three preceding time steps as input; see Fig. 1 for an illustrated example. In our article, we explore various window lengths, ranging from 1 to 15, to identify the most effective window size for our model. The fourth step involves generating additional features, specifically technical indicators, that are widely used to understand and analyze price movements in a specific market. However, technical indicators give an idea of where the price might go next in a given market at a specific time. We have used a large set of technical indicators generated over multiple periods with different parameters:

- The Weighted, Exponential, Simple, and Convergence Divergence Moving Average (WMA, EMA, SMA, and MACD).
- The Relatively Strength Index (RSI).
- The average directional index (ADX).
- The Commodity Channel Index (CCI).
- The Rate-of-Change (ROC).
- The Bollinger Band (BB), Moving Polynomial trending (MPT).

The goal of adding technical indicators is to improve the accuracy of our model; however, using a large set of features may lead to the opposite result. To avoid this, we reduced the high dimensionality of the dataset by retaining only the features that provide the most information and contribute the most to the prediction. According to Guyon [59], the objectives of feature selection are to reduce prediction time consumption, facilitate the understanding of predictors, and improve model accuracy. In [60], the authors have classified the majority of current feature selection algorithms into four primary categories: similarity-based methods, information-theoretic methods, sparse learning methods, and statistical methods.

The header of our final dataset is: DateTime, OHLCV variables, a set of selected technical indicators, sentiment_label, article_sentiment_score, article_source, Article_author.

3) Data splitting and prevention of information leakage: To prevent information leakage and ensure a realistic evaluation, we employed a strict chronological split for our data. The training set consisted of data from January 1, 2006, to December 31, 2019 (approximately 70% of the data). The validation set spanned January 1, 2020, to December 31, 2021 (approximately 10% of the data), and the test set covered January 1, 2022, to May 30, 2025 (approximately 20% of the data). Crucially, no data from the validation or test sets was used during training or feature engineering. All preprocessing steps were performed solely on the training data, and then the resulting transformations were applied to the validation and test sets. By maintaining a strict chronological order, we were able to more accurately assess the model's ability to generalize to unseen future data.

B. Phase 1: Semi-Supervised News Classification and Sentiment Analysis

Fundamental analysis is critical for FOREX traders. However, expert traders evaluate macroeconomic and political factors, fiscal policies, and other relevant factors to gain insight into future currency movements and develop strategies to capitalize on market trends. The high sensitivity to financial news makes the Forex market a risky environment for investors due to its high volatility and leverage, which can create fear in investors. This fear is an emotional driver that can amplify market volatility. In this phase, we have created two algorithms. The first algorithm utilizes news headlines to classify them based on their relevance, retaining only those that have an impact on FOREX trends. The second algorithm analyzes these news headlines and generates sentiment-based features.

1) GAN-BERT model for news classification: Let C be a set of categories, where n is the total number of categories in C, as shown in Eq. (1).

$$C = \{c_1, c_2, c_3, ..., c_n\} \tag{1}$$

The Article set belonging to each category forms the complete dataset where a_{ci} is the Article set attributed to the category a_i in the dataset; see Eq. (2).

$$A = \{a_{c1}, a_{c2}, a_{c3}...a_{cn}\} \tag{2}$$

Given a new text, "a_u" of an unknown category "c", the proposed model assigns the text to the most likely category from C. In [61], two models, a BERT-based model and a semi-supervised GAN [62], were combined to create a new model named GAN-BERT. Fig. 2 describes the architecture of the GAN-BERT model. As illustrated in the architecture of the GAN-BERT model (Fig. 2), the discriminator D classifies samples, while the generator G generates fake examples F. The discriminator utilizes the vector representations produced by BERT for unlabeled U and labeled L input texts. After training is complete, G is removed from the model, allowing the remaining components to be used for inference. The GAN-BERT model typically demonstrates better performance in classification tasks when there is a limited amount of labeled data. Another reason for employing GAN-BERT for news classification is that it takes into account not only news writing styles, but also potential fake writing styles generated by the fake data produced by the generator.

2) FinBERT for news sentiment analysis: The specialized language and the scarcity of labeled data in the financial market domain hinder the effectiveness of general sentiment analysis models. The author in [63], proposed FinBERT, a BERT-based model designed to address NLP tasks specific to the financial sector. In our study, we fine-tune FinBERT using a small training set to create a new feature that enriches our datasets with sentiment labels for the FOREX market (positive, negative, and neutral). It is important to note that sentiments can be expressed by both experts and beginners. Therefore, we

index	feature	Target
t_6	X_6	Y_6
t_7	X_7	Y_7
t_8	X_8	Y_8
t_9	X_9	Y_9

index	feature	Target
t_6	X_3 X_4 X_5 X_6	Y_6
t_7	X_4 X_5 X_6 X_7	Y_7
t_8	X_5 X_6 X_7 X_8	Y_8
t_9	X_6 X_7 X_8 X_9	Y_9

Fig. 1. Example of sliding-window approach.

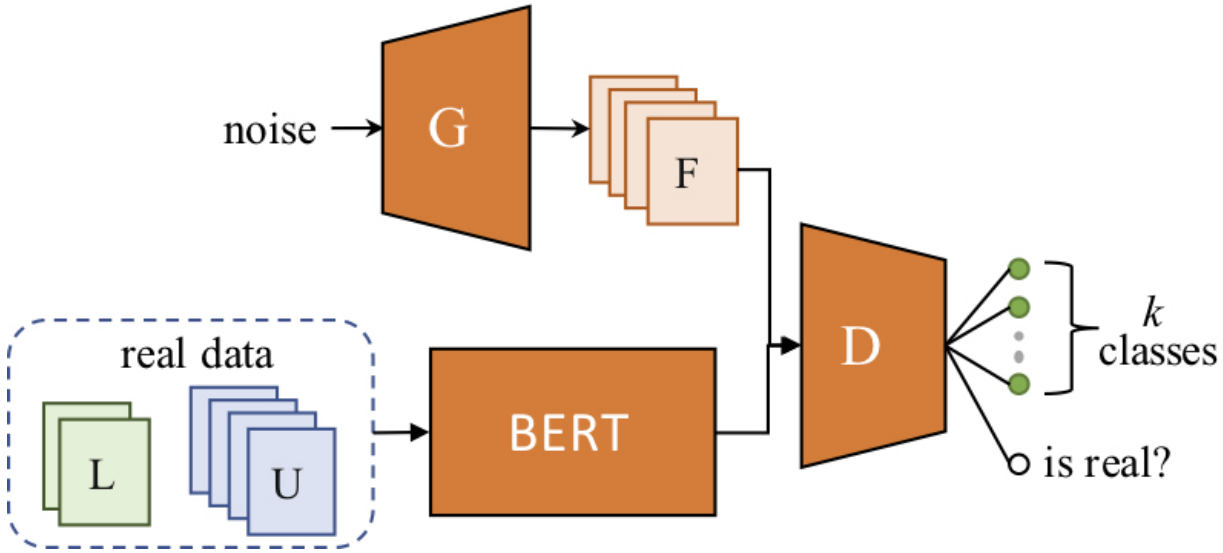

Fig. 2. GAN-BERT architecture.

will also consider the authors of the articles and assign a score to each based on their accuracy in making correctly expressed predictions.

3) GanBERT configuration and training hyperparameters:

- Base Transformer Model: BERT-base-cased.
- Discriminator Architecture. Consisted of the pre-trained BERT-base-cased model, fine-tuned for two tasks:
  - Binary Classification (Real vs. Fake): Distinguishing real news articles from generated articles.
  - Multi-Class Topic Classification: Classifying real news articles into one of the [Number of Topics] predefined topic categories.
- Output layer:
  - Real vs. Fake: Linear layer with sigmoid activation function.
  - Topic Classification: A separate linear layer with a Softmax activation function (for the multi-class classification task).
- Generator Architecture: A multi-layer perceptron (MLP) that takes random noise as input and generates synthetic feature vectors designed to resemble those of minority-class news articles. This helps to improve the discriminator's ability to classify minority topics, improving the accuracy of classification training.
- Layers: Two fully connected layers with 512 units, followed by a linear layer projected to the BERT embedding dimension (768).
- Activation Function: LeakyReLU activation (with a negative slope of 0.2) was used for the hidden layers of the generator.
- Training hyperparameters: Table I summarizes the key hyperparameters used in training the GanBERT

model for news classification. These parameters were carefully chosen to optimize the performance of the model and prevent overfitting.

TABLE I. GANBERT TRAINING HYPERPARAMETERS

Hyperparameter	Value
Learning Rate (Disc.)	7e-7
Learning Rate (Gen.)	5e-4
Optimizer	Adam
Batch Size	64
Latent Dimension	100
Discriminator Dropout	0.2
Generator Dropout	0.2
Epochs	50
Early Stopping Patience	6
Loss Function (Disc.)	Binary Cross-Entropy
Loss Function (Class.)	Categorical Cross-Entropy

4) FinBERT Fine-Tuning Hyperparameters:

- Learning Rate: 2e-5
- Batch Size: 32
- Number of Epochs: 3
- Weight Decay: 0.01
- Optimizer: AdamW with a weight decay of 0.01

C. Phase 2: Forecasting Future Price Direction (CNN-GRU APPROACH)

1) Target variable: To get rid of the FOREX market disturbances and reduce high price variation, we reformulated our problem from regression into classification; In this article, we aim to forecast the next trend direction or next price direction; the price in the original dataset is a continuous variable, we had to generate a new categorical variable named Target based on specific rules related to our strategy; this new variable indicates our final decision, which will be a buy, sell, or hold signal.

Each operation is associated with transaction costs, which can be more expensive than returns. For that issue, we used a threshold called α; When the log return of the current day is inferior to -α, it indicates that it is an uptrend, so it is a SELL signal, and when the log return is superior to α, it indicates that it is a downtrend, so it is a BUY signal; otherwise, it is a HOLD signal. We encoded this feature using one-hot encoding; see Eq. (3). Another application of the threshold α is to address the issue of unbalanced classes within datasets, a challenge that we encounter when α is set too low or too high. However, artificially balancing the dataset can negatively impact sequential datasets. To explore this, we ran our algorithm using various thresholds, starting from zero (which created a binary classification problem) and increasing up to 0.01. Otherwise, when we increased the threshold to 0.01, we again encountered the issue of unbalanced datasets.

Before model training, we addressed the challenge of class imbalance by optimizing the log-returns threshold (α). Through experimentation, we identified a threshold value of 0.0014, which yielded a dataset with approximately equal representation across the three classes: 1598 BUY, 1585 SELL, and 1593 HOLD signals. This nearly balanced distribution was deemed crucial to ensure robust and unbiased model performance.

$$Target = \begin{cases} \begin{bmatrix} 0 & 0 & 1 \end{bmatrix}, & \text{if } Log(price_t/Price_{t-1}) > \alpha \quad "BUY" \\ \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}, & \text{if } Log(price_t/Price_{t-1}) < -\alpha \quad "SELL" \\ \begin{bmatrix} 1 & 0 & 0 \end{bmatrix}, & \text{Otherwise} \quad \text{"HOLD"}. \end{cases} \tag{3}$$

2) Recurrent neural networks LSTM and GRU: To deal with sequential data problems, such as time series or text, researchers have developed the Recurrent Neural Network (RNN) [64], [65], [66], which is a specialized type of neural network that possesses a form of memory that can retain information from previous input. Thanks to the feedback connections in their architecture, which facilitate the retention of information across time steps. RNNs are particularly adept for sequence modeling tasks, where the temporal context of data points is crucial for accurate prediction and understanding.

Long-Short-Term Memory (LSTM), published by [67], [68], is an architecture of recurrent neural networks (RNNs) that can help address the vanishing gradient problem faced by standard RNNs. LSTM can effectively bridge time lags exceeding 1,000 discrete time steps. This capability makes them suitable for tasks where long-range temporal dependencies are critical [67], [68], [69], [70].

A Gated Recurrent Unit (GRU) is a specific type of recurrent neural network unit within the broader category of deep neural networks. It was introduced by [71] to allow each recurrent unit to capture dependencies across multiple time scales adaptively. Recently, recurrent neural networks have shown promising results in various machine learning tasks, particularly when dealing with input and output of variable duration [72]. The GRU is recognized for its effectiveness in sequence learning tasks as it addresses the challenges of vanishing and exploding gradients that are often encountered in traditional recurrent neural networks (RNNs), making it well-suited for learning long-term dependencies.

3) Convolutional Neural Network: From a mathematical operation called convolution, the researchers derived the name of a new type of deep neural network, known as the convolutional neural network (CNN). It involves the linear interaction between matrices. The connectivity patterns of its neurons are modeled after the organization of the visual cortex in animals. This convolution technique enables the recognition of visual patterns in input data [73]. Like other artificial neural networks, CNNs consist of multiple layers, including the convolutional layer, which is the most critical. Each convolutional layer identifies features by sliding various filters over the input matrix and conducting piece-by-piece comparisons [74]. As indicated in [75], the two most significant advantages of convolutional neural networks are their ability to tackle complex tasks with a smaller number of parameters in the ANN and their ability to extract abstract features as data progress through deeper layers.

4) GRU-CNN model architecture: By combining the gated recurrent network and the convolutional neural network approaches, we developed our model. As shown in Fig. 3, it is composed of six layers:

- The input is a 3D tensor of shape (samples, timesteps, features). Each sample is a window of historical data. The time steps are the number of data points in a single window, and the features represent the values of all variables on the days to look back.
- The 1D convolutional layer: It takes the output of the previous layer as input; it automatically learns features by sliding multiple filters over the input matrix to extract local patterns.
    - Filters: 64
    - Kernel Size: 2
    - Activation: ReLU
- The third layer is the GRU layer; After the CNN, a GRU layer processes the output to capture the sequential nature of the patterns within the window. It is implemented in the many-to-one architecture, as shown in Fig. 4, because the goal is to predict the next price direction, not multiple prices. This layer is added to deal with the nature of sequential data.
    - Units: 64
    - Activation: tanh
    - Recurrent Activation: sigmoid
    - Dropout: 0.3
- The Dense Layer 1 (Fully Connected): The GRU output is flattened and fed into a dense layer.
    - Units: 32
    - Activation: ReLU
- The Dense Layer 2 (Fully Connected): The GRU output is flattened and fed into a dense layer.
    - Units: 8
    - Activation: ReLU
- The last layer is the output layer with three units; it provides a single decision (buy, sell, or hold).
    - Units: 3
    - Activation: Softmax

GRU-CNN Training Hyperparameters

- Window size: 1 to 10 days.
- Epochs: 50
- Batch Size: 64
- Learning Rate: 0.0005
- Optimizer: Adam
- Loss Function: Categorical Cross-Entropy
- Early Stopping Patience: 6

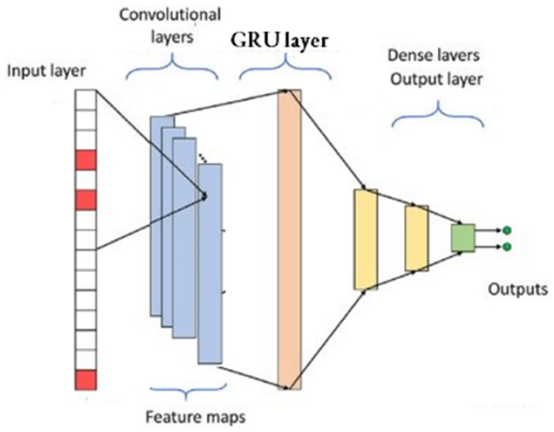

Fig. 3. GRU-CNN architecture.

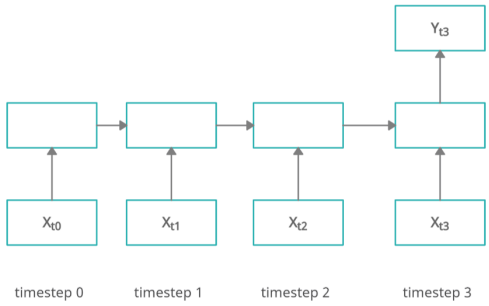

Fig. 4. Many to one GRU approach.

D. Phase 3: Our Investment Strategy and Decision Making

To develop an effective trading strategy, we must first determine the goal of our strategy: to generate short-term profits or build long-term wealth, and identify a personal risk profile or hedge against market volatility. Understanding whether we are more comfortable with conservative, moderate, or aggressive trading approaches will guide our decision-making process. Finally, we must evaluate the available time and resources.

In FOREX trading, the currency exchange rates are generally relatively low. This fact impacts the profitability of investments, particularly when the invested amounts are not significant; The returns may be less than the associated transaction costs. To resolve this issue, a third party, known as brokers in the FOREX market, offers a method called “leverage,” which involves borrowing funds to acquire an asset. In our strategy, we employed a leverage of 1:100, allowing us to invest 1,000$ while trading up to 100,000$. Our investment strategy is detailed in Fig. 9. Our aim is to buy when prices are low and sell when they increase, which means that our machine learning model needs to predict the future direction of trades.

To facilitate this, we developed an algorithm that compares the logarithmic return of the current day against a threshold, α. If the return exceeds α, we proceed with a buy; if it falls below $-\alpha$, we opt to sell; and if it lies between $-\alpha$ and α, we hold our position. In this context, the variable we are considering is categorical, so we applied one-hot encoding to prepare the data for our algorithms and fit our model effectively.

In addition to the threshold α, risk management rules are necessary to avoid stacking in the hold position; Stop-loss and take-profit are calculated based on the entry point, unlike the threshold α, which is compared to the log return of the current day.

IV. Discussion and Results

For the news classification phase, which serves as a fundamental analysis, it is the most important and basic phase in our strategy; all other parts of the system rely on it. We trained our model for 50 epochs, with the option of early stopping. As shown in Fig. 5 and 6, the model was well trained. The goal is to classify news articles into general classes, including sports, technology, business, health, politics, and finance. Subsequently, we conducted a secondary categorization to identify subcategories, including stock market, banking, personal finance, investment, and economic indicators. The GAN-BERT model achieved an impressive accuracy of 97.5%, demonstrating both efficiency and performance; see Fig. 6. As illustrated in Fig. 5, the training loss line indicates that the model fits the training data well and can be generalized to new data, as confirmed by the validation loss line.

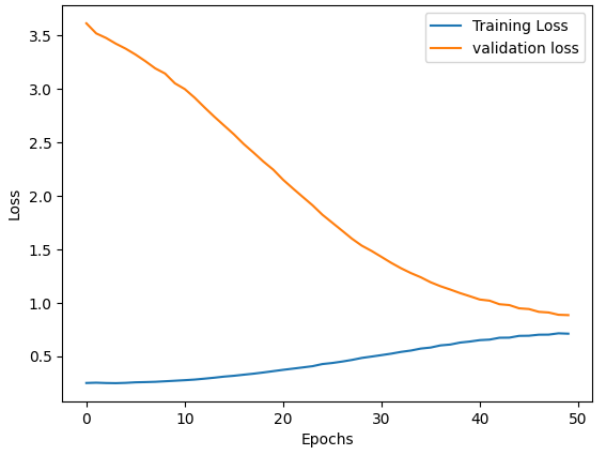

Fig. 5. GANBERT training validation loss.

The high efficiency of this model, as we have seen, makes the classified data a reliable source for the next stage. However, we have improved the persistence of these data by performing another NLP task, represented by fine-tuning the FinBERT model, which is specifically developed for the financial sector. We have executed it to label our dataset with the FOREX market sentiment, this variable is represented with three labels (Positive, Negative, and Neutral); by adding the sentiment feature, our dataset becomes able to describe the market mood and attitude of traders and investors towards the Forex market.

In the second phase, which focuses on forecasting future trends, we employed a combined CNN and RNN model,

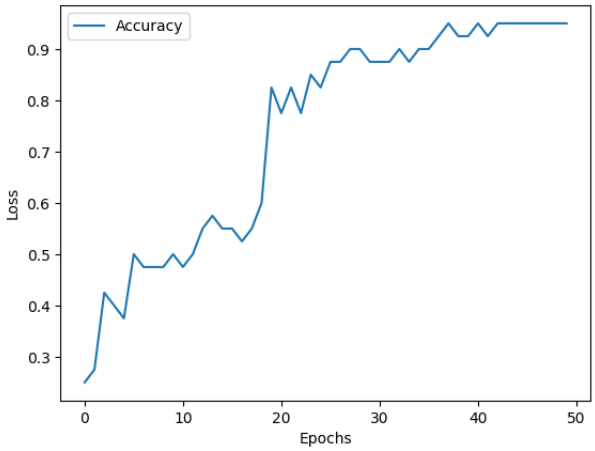

Fig. 6. GANBERT validation accuracy.

specifically a CNN and GRU architecture. We trained this model over 50 epochs, varying window lengths (1 day, 2 days, 3 days, 4 days, 5 days and 10 days), as shown in Fig. 10 to 19; by analyzing the training and validation loss graphics, we can see that our model fits the training data well and can be generalized for a larger time frame. Furthermore, the training validation accuracy graphics illustrated promising results in terms of both accuracy and precision.

We conducted the experiment of our model over several time frames (1 day, 5 days, 10 days, and 15 days), as outlined in Table II. In general, the model achieved higher accuracy in forecasting the future trend direction.

In forecasting the price direction for the next day, our model was less accurate when using a window length of one day, achieving only 58% accuracy. This is due to the time it takes for the event to impact the FOREX market and the number of news articles that we used. However, when we used a window length of two days, we observed a slight improvement in the performance of the model, achieving an accuracy of 80%. Although using a 3-day window length, the results are more promising, achieving 83% accuracy, and continue to improve until a 10-day window length, when it decreases from 85% to 81%.

In the second experiment, we attempted to forecast the price for the next week (5 days). Although using a 1-day window length, unlike in the first experiment, the model's performance showed better results, with an accuracy of 81%. The wider we expanded the window length, the more accurate the model became, achieving 93% accuracy using a 5-day window length, and it starts to decrease with a 10-day window length.

In the third experiment, we attempted to forecast the direction of the next 10 days' prices (i.e. over the next two weeks, excluding non-business days). We obtained results similar to those of the last experiment. It achieved an accuracy between 83% and 92%. To conclude, the model was more accurate in forecasting the next week (5 days) trend direction, especially when the window length was 5 days. Fine-tuning our model is necessary to improve both the accuracy and the running time of our model simultaneously. However, Fig. 11, 13, 15, 17

TABLE II. MODEL ACCURACY BY WINDOW-SIZE AND TIME FRAME

Target	Window lenght					
	1 day	2 days	3 days	4 days	5 days	10 days
1 day	0.5876	0.8050	0.8387	0.8422	0.8511	0.8185
5 days	0.8092	0.8098	0.8321	0.8450	0.9291	0.9156
10 days	0.8341	0.8383	0.8667	0.8943	0.9165	0.9023

TABLE III. DIEBOLD-MARIANO TEST RESULTS (P-VALUES)

Model Pair	DM Test Statistic	p-value	Conclusion ($\alpha = 0.05$)
GRU-CNN vs Naïve Bayes	7.61	1.60×10^{-11}	Significant (GRU-CNN is better)
GRU-CNN vs Logistic Regression	9.84	2.44×10^{-16}	Significant (GRU-CNN is better)
GRU-CNN vs Random Forest	7.86	4.82×10^{-12}	Significant (GRU-CNN is better)
GRU-CNN vs XGBoost	3.19	1.91×10^{-03}	Significant (GRU-CNN is better)

and 19 show the training loss at each epoch; we notice that the training loss plot decreases to a point of stability.

To conduct a rigorous statistical analysis of our models' performance, we employed the Diebold-Mariano (DM) test to compare the predictive accuracy of our hybrid GRU-CNN model against the baseline models. The DM test evaluates the null hypothesis (H_0) that two models have the same forecast accuracy. A key component of the test is the zero-one loss function, which assigns a loss of 0 for a correct prediction and 1 for an incorrect one. A p-value below the chosen significance level (α=0.05) indicates that the difference in performance is statistically significant.

The results of the Diebold-Mariano test are summarized in Table III. The p-values for all comparisons are exceptionally low, all falling well below the 0.05 significance threshold. This finding provides strong statistical evidence that our GRU-CNN model is a better predictor of this task compared to all traditional machine learning benchmarks. The low p-values confirm that the performance gains of the hybrid model are not a result of random chance. Still, they are instead due to its inherent ability to capture more complex patterns in the financial time series data. This analysis validates our choice of a deep learning approach for this problem and confirms its effectiveness.

A. The Effectiveness of Our System During Times of Crisis

In times of crisis, as investors panic, the index of fear increases, causing adverse ripple effects throughout the economy, and the volatility of the market spikes dramatically. Each speculative attack on the Forex market often accompanies a crisis. Generally, we have tested our proposed solution over a long period that has witnessed several crises, and during this period, our system has consistently shown promising results. However, to confirm the effectiveness of our system during crisis times, we backtested our strategy on two crises: the COVID-19 pandemic from March 2020 to May 2023, and the Russia-Ukraine War, which began in February 2022 and is still ongoing. As shown in Fig. 7, which illustrates the cumulative profits during the COVID-19 pandemic, our system successfully predicted the future direction of the prices, achieving an accuracy of 81% with a total profit of 73% compared to the ideal. A similar result can be observed in Fig. 8, which illustrates cumulative profits during the Russia-Ukraine War; the accuracy was around 82% and the total profits were 77%; These results, while promising, should be interpreted with consideration for the complexities of real-world FOREX trading. Although our primary focus in this article is on demonstrating the effectiveness of integrating semi-supervised news classification, sentiment analysis, and time-series modeling in forecasting FOREX price directions, it is essential to acknowledge the potential impact of transaction costs (spreads), slippage, and inherent risks. To provide a more realistic perspective, we have applied a moderate estimate of a 10% reduction to the backtested profits achieved during both the COVID-19 pandemic and the Russia-Ukraine war. This reduction 10% accounts for the aggregate impact of transaction costs, primarily spreads on traded currency pairs, and

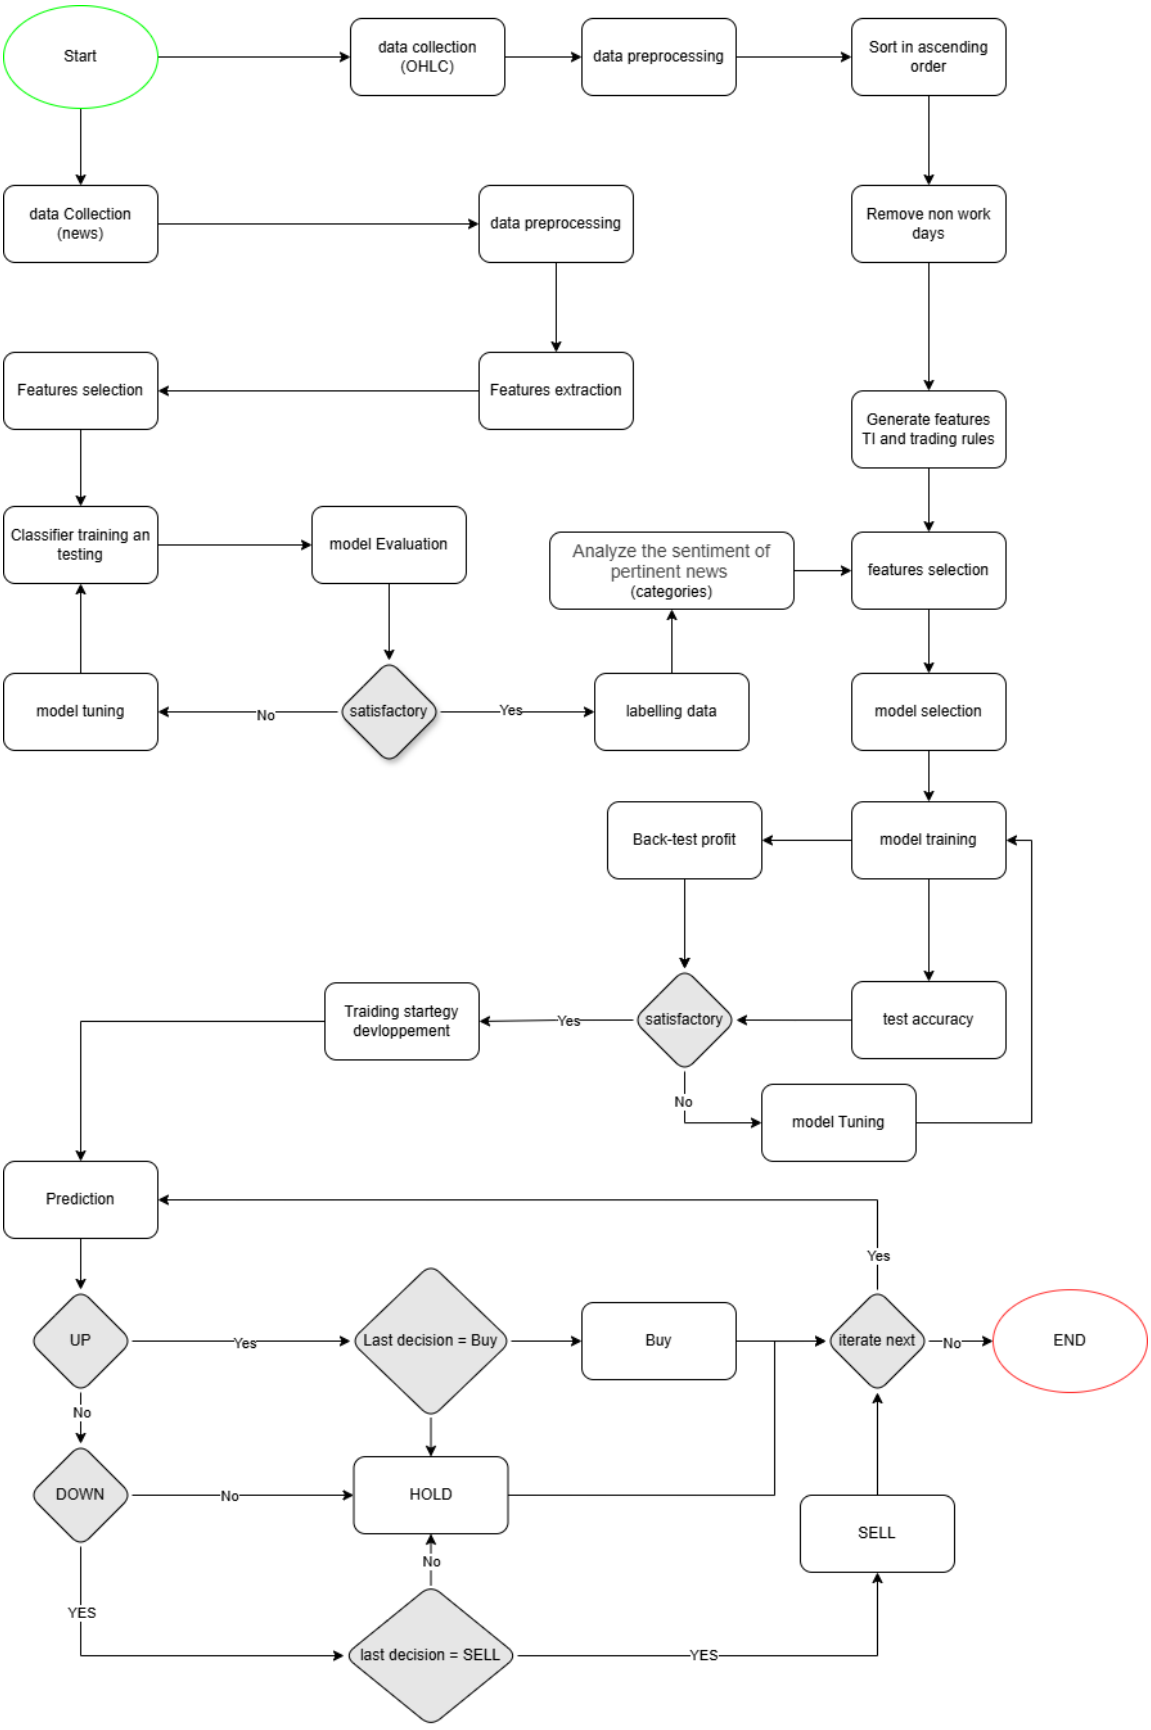

Fig. 9. Our investment strategy for trading foreign exchange.

estimated slippage derived from historical volatility patterns. We maintain that even with this moderate adjustment, the system shows a strong potential for profitability and resilience in forecasting FOREX price directions during turbulent market conditions. By analyzing these two results, we can conclude that our proposed strategy can overcome obstacles during crisis

times by imitating fundamental analysis through the analysis of news headlines and social media posts. Future research will incorporate a more detailed, high-fidelity simulation incorporating granular transaction cost and slippage data, as well as a thorough risk assessment using industry-standard metrics, such as Sharpe and Sortino ratios, to validate these findings further and provide a more complete picture of the system's performance across diverse market environments.

V. Conclusion

In the FOREX market, numerous factors can affect the state of the market in various ways, making it too complex to develop an optimal trading strategy. This study presents a comprehensive system for automated Forex trading, utilizing an NLP-based strategy to analyze sentiment and forecast the expected impact on the Forex market through news reports. The results demonstrate that the system exhibits high profitability and can be effectively deployed for real-life trading purposes, overcoming external events such as regime changes, crisis times, epidemics, and natural disasters. This solution was developed and back-tested for a specific period; it may not remain helpful and profitable in the future.

***Abstract*—The increasing complexity of distributed and concurrent systems raises pressing challenges for ensuring correctness and reliability. Formal verification, and in particular model checking, offers a rigorous foundation to validate system properties, yet suffers from the well-known state space explosion problem. This difficulty is especially acute in modular architectures, where local behaviors intertwine with synchronization across components. This paper provides a structured survey of the main techniques designed to overcome these challenges, including state space reduction, abstraction, compositional reasoning, symbolic approaches, and distributed verification. We also review representative tools such as SPIN, NuSMV, LTSmin, DiVinE, and STORM, assessing their capabilities and limitations in handling modular and concurrent models. Building on this landscape, we position the Reduced Distributed State Space (RDSS) as a novel framework that addresses key scalability limits. RDSS reduces global complexity into module-specific metagraphs, ensures stuttering equivalence, and enables local model checking without exploring the full global state space. Comparative experiments demonstrate significant gains over existing approaches, particularly for systems where modules are not all synchronized on the same transitions. We conclude by identifying open challenges and future research directions, including distributed implementations, AI-driven heuristics, and hybrid reductions. Our survey underscores the importance of structural awareness in modern verification workflows and establishes RDSS as a promising foundation for scalable verification of modular concurrent systems.**

***Keywords*—Distributed systems; state space; Modular Petri Net; formal verification; state explosion problem; model checking; temporal logic; reduction techniques; RDSS; ROS2; scalability; modularity; model checking**

I. Introduction

The escalating complexity of modern concurrent and distributed systems has significantly exacerbated the requirement for rigorous verification. From autonomous vehicle networks and smart home infrastructures to critical cloud services and industrial IoT, system components increasingly operate independently, communicate asynchronously, and must coordinate reliably across dynamic environments. This complexity makes ensuring system correctness a central challenge in software engineering.

Because control is distributed and interactions evolve dynamically over time, conventional testing struggles to provide meaningful guarantees about the correctness or robustness of such systems. One effective way to gain confidence in the behavior of such systems is through formal verification. Particularly, model checking stands out as a widely adopted technique. Its automatic, exhaustive nature provides a strong safety net against subtle concurrency bugs. It allows for the exploration of all possible system behaviors to detect design flaws before deployment. However, state space explosion remains a major obstacle [1], [2]. As system components interact, synchronize, and their architectures become more modular, the global state space can grow exponentially, rendering classical model checking intractable, even for moderately sized modular systems.

To mitigate this, a wide array of techniques has emerged, ranging from symbolic representations [3] to partial-order reductions [4], compositional reasoning [5], and on-the-fly verification [6]. These methods, implemented in tools, such as LTSmin [7], SPIN [8], PMC-SOG [9] and NuSMV [10], have significantly improved verification performance. Still, they often struggle when applied to Modular Petri net models, where both local behavior and inter-module synchronizations must be considered. However, the increasing scale and modularity of real-world systems demand approaches that are not only scalable but also structure-aware, able to exploit the modular decomposition of the system to control complexity. Moreover, existing surveys either lack depth, focus on outdated tools, or fail to address the nuances of modular verification in distributed contexts.

In this paper, we propose a structured and up-to-date survey of the techniques and tools used to address the state space explosion in modular and distributed systems.We examine the current landscape of verification tools, identifying those that can support modularity, distributed architectures, and scalable verification. By organizing the literature by technique, tool support, and target application domain, we aim to clarify the strengths and limitations of each class of solution.

We also explore how the formalism of our Reduced Distributed State Space (RDSS) allows for localized verification by isolating module-specific properties expressed in LTL/X. This approach enables efficient model checking that leverages system modularity without requiring global state enumeration.

This paper is intended to guide researchers and practitioners seeking to understand or implement scalable formal verification strategies for distributed systems. Our goal is

to highlight the growing need for structure-aware methods, evaluate the practical impact of recent techniques, and expose gaps in tool support and methodology that merit further investigation.

The structure of this paper is as follows. Section II introduces the background and key concepts underlying formal verification, temporal logics, and Modular Petri nets. Section III analyzes the scalability problem in modular concurrency, detailing the main dimensions of state space explosion. Section IV surveys the principal verification techniques that address these challenges, including reduction methods, abstraction, compositional reasoning, symbolic approaches, and distributed exploration. Section V reviews the tooling ecosystem, highlighting representative model checkers and their capabilities for modular and concurrent systems. Section VI presents the Reduced Distributed State Space (RDSS) framework, outlining its principles, key contributions, and positioning within the literature. Section VII discusses future directions and possible extensions, including distributed implementations, hybrid strategies, and AI-driven heuristics. Finally, Section VIII concludes the paper by summarizing our findings and emphasizing the role of RDSS in advancing scalable verification.

II. Essential Concepts and Preliminaries

Modern concurrent and distributed systems are characterized by the parallel execution of multiple components that often interact asynchronously. To rigorously verify such systems, formal methods —particularly model checking — have become indispensable. This section introduces foundational concepts, including transition systems, temporal logics, Modular Petri nets, and model checking, which underpin many of the techniques discussed in this survey. The above definitions are adapted from Clarke et al. [11] and Baier and Katoen [12], which constitute the classical references in the field of model checking.

A. Labeled Transition System

Labeled Transition Systems (LTS) constitute a fundamental formalism for modeling and analyzing concurrent and distributed systems. These mathematical structures extend the basic concept of transition systems by associating explicit actions with state transitions, thereby enabling a richer representation of dynamic system behavior. LTS finds applications across numerous domains in theoretical computer science, particularly in formal verification, protocol analysis, and reactive system specification. Their capability to distinguish between observable and unobservable actions makes them particularly well-suited for modeling systems where certain internal behaviors must be abstracted from the external interface.

Definition 1: A *Labeled Transition System* (LTS) is formally expressed as a quadruple:

$$LTS = \langle \Gamma, Act, \ \rightarrow, \ I \rangle$$

where:

- Γ denotes a finite ensemble of states,
- Act designates a finite repertoire of actions,
- $\rightarrow \subseteq \Gamma \times Act \times \Gamma$ represents the labeled transition relation,
- $I \subseteq \Gamma$ constitutes the collection of initial states.

For any transition $(s, a, s') \in \rightarrow$, the concise notation

$$s \xrightarrow{a} s'$$

indicates the existence of a passage from state s toward state s', adorned with the label a.

Within the LTS framework, one draws a sharp distinction between:

- Observable actions, symbolized as $Obs \subseteq Act$,
- Unobservable actions, symbolized as $UnObs \subseteq Act$,

such that:

$$Obs \cup UnObs = Act, \qquad Obs \cap UnObs = \varnothing.$$

This partition allows the modeling of two distinct realms: the overtly perceptible behaviors of a system, and its latent, internal evolutions, those hidden pulsations that govern its subterranean logic yet remain invisible to an external observer.

Fig. 1 illustrates LTS, with s_0 serving as the initial state. $\{a, b\}$ make up the set of observed actions. Unlabeled edges are meant to be labeled by non-observed actions.

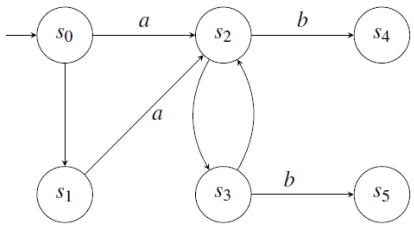

Fig. 1. Example of a labeled transition system.

B. Kripke Structure

In the domain of formal verification, Kripke Structures play a pivotal role as the semantic foundation for temporal logics such as Linear Temporal Logic (LTL) and Computation Tree Logic (CTL). They extend the notion of transition systems by enriching states with atomic propositions that capture observable properties of the system. This labeling mechanism enables the evaluation of temporal formulas, thereby bridging the gap between system executions and logical specifications.

Definition 2: Let AP be a finite set of atomic propositions. A *Kripke Structure* (KS) over AP is a quadruple

$$KS \ = \ \langle \Gamma, \Gamma_0, R, L \rangle,$$

where

- Γ is a finite set of states,

- $\Gamma_0 \subseteq \Gamma$ is the set of initial states,
- $R \subseteq \Gamma \times \Gamma$ is a (total) transition relation,[1] and
- $L : \Gamma \to 2^{AP}$ is a labeling (interpretation) function that assigns to each state the set of atomic propositions true in that state, and each state of the KS is labeled with the values of these propositions.

A Kripke Structure example is shown in Fig. 2. There are two elements in the set of atomic propositions $\{a, b\}$.

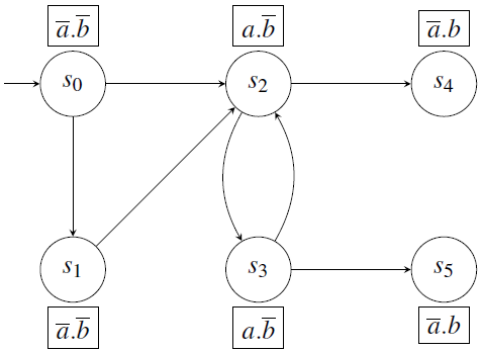

Fig. 2. Example of Kripke Structure.

Paths and reachability. A (finite or infinite) path is a sequence $p = s_0 s_1 s_2 \ldots$ with $(s_i, s_{i+1}) \in R$ for all $i \geq 0$.

- A state $s' \in \Gamma$ is *reachable* from $s \in \Gamma$, written $s \Rightarrow s'$, iff there exists a finite path $s_0 \ldots s_k$ such that $s_0 = s$ and $s_k = s'$.
- A state s is *dead* (a sink) if there is no $s' \in \Gamma$ with $(s, s') \in R$.

Kripke Structures thus furnish the semantic substrate for model checking: a system satisfies a temporal specification precisely when all (or some, depending on the logic) paths of its Kripke Structure satisfy the corresponding formula.

C. Labeled Kripke Structure

While Kripke Structures provide the semantic foundation of temporal logics, in many verification settings it becomes necessary to make explicit the actions that drive state transitions. To address this issue, the notion of a *Labeled Kripke Structure* (LKS) has been introduced. An LKS integrates the action-labeled transitions of a Labeled Transition System (LTS) with the state-labeling of a Kripke Structure (KS). This dual enrichment bridges the gap between transition systems and Kripke semantics, yielding a versatile framework for reasoning simultaneously about state-based properties and action-driven behaviors in concurrent and distributed systems.

Definition 3: Let AP be a finite set of atomic propositions and let Act be a finite set of actions.
A *Labeled Kripke Structure* (LKS) over AP is a quintuple

$$LKS = \langle \Gamma, Act, L, R, \Gamma_0 \rangle,$$

where:

- $\langle \Gamma, Act, R, \Gamma_0 \rangle$ is a Labeled Transition System (LTS),
- $\langle \Gamma, L, R, \Gamma_0 \rangle$ is a Kripke Structure (KS).

An illustration of LKS over $AP = \{a, b\}$ is shown in Fig. 3.

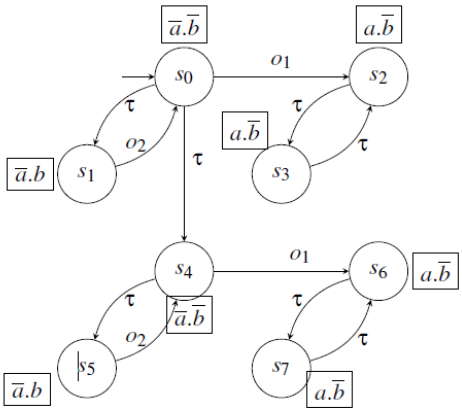

Fig. 3. Example of labeled Kripke Structure.

Remark. An LTS (resp. KS and LKS) can be represented in different ways: explicitly, where each state and arc is stored individually in memory; symbolically, where sets of states are encoded compactly using decision diagrams such as Binary Decision Diagrams (BDDs); or in a hybrid manner, with states represented symbolically while transitions are kept explicit. In addition, such models are often illustrated in an abstract form, for instance through state–transition graphs that emphasize their structural properties rather than their implementation details.

D. Modular Petri Net

Petri nets are a well-established formalism for modeling concurrent and distributed systems. However, when dealing with complex systems, a monolithic representation often becomes intractable. The notion of a Modular Petri Net (MPN) was introduced to address this limitation by decomposing a system into a finite collection of communicating modules, each being an ordinary Petri net. Communication between modules can occur in two ways: A synchronized mode through the fusion of places, or an asynchronous mode through the fusion of transitions. As shown by Christensen and Petrucci [13], any modular net with shared places can be transformed into an equivalent net with only shared transitions. For this reason, in our study we focus exclusively on modules that interact through shared transitions.

Definition 4: A **Modular Petri Net** (MPN) is a pair

$$MPN = (S, TF),$$

that satisfies the following conditions:

1) S is a finite set of **modules** where:
   a) Each module $s \in S$ is an ordinary Petri net

$$s = (P_s, T_s = T_{\text{sync},s} \cup T_{l,s}, W_s, M_{0_s}),$$

[1] Totality means $\forall s \in \Gamma$, $\exists s' \in \Gamma$ such that $(s, s') \in R$.

where, $T_{\text{sync},s}$ denotes the set of **synchronized transitions** of module s, and $T_{l,s}$ denotes the set of **local** (or **internal**) transitions of s.

b) The sets of states and transitions of distinct modules are pairwise disjoint:

$$\forall s_1, s_2 \in S,\ s_1 \neq s_2 \ \Rightarrow\ \begin{array}{l}(P_{s_1} \cup T_{s_1}) \\ \cap\,(P_{s_2} \cup T_{s_2}) = \varnothing.\end{array}$$

c) The global sets of places and transitions are given by

$$P = \bigcup_{s \in S} P_s, \qquad T = \bigcup_{s \in S} T_s.$$

2) $TF \subseteq 2^T \setminus \{\varnothing\}$ is a finite collection of non-empty **transition fusion sets**.

Fig. 4 displays a Modular Petri Net example. The three modules that make up this net are A, B, and C. Both modules A and B are in sync through transition $Sync1$, and both modules B and C are in sync through transition $Sync2$.

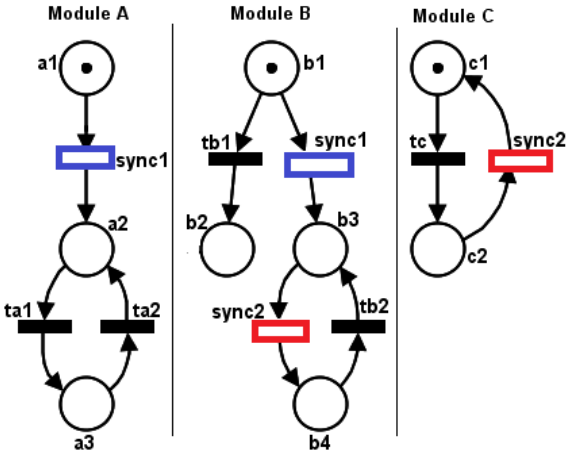

Fig. 4. Example of Modular Petri Net.

Thus, Modular Petri Nets establish a rigorous modeling framework in which complex systems can be decomposed into smaller communicating modules. By distinguishing between local and synchronized transitions, this formalism not only preserves clarity in system representation but also provides a solid foundation for subsequent works that favor modularity and compositional reasoning in the analysis and verification of distributed systems.

E. Temporal Logics: LTL and CTL

Temporal logics are central in the specification and verification of concurrent and distributed systems. They enrich propositional logic with temporal operators, making it possible to express properties not only about individual states but also about the evolution of executions over time. Among the most widely studied are Linear Temporal Logic (LTL) and Computation Tree Logic (CTL), which differ in the way they interpret paths and quantify over possible system behaviors.

1) Linear Temporal Logic (LTL): Linear Temporal Logic (LTL) extends propositional logic with temporal operators to describe both static properties of states and the dynamic progression of system executions. It is widely used to specify properties such as safety (ensuring that undesirable events never occur) and liveness (ensuring that desired events eventually occur).

An LTL formula is built over a finite set AP of atomic propositions that capture the elementary properties of states. Boolean operators ($\neg$, $\wedge$, $\vee$) allow the expression of static conditions, while temporal operators such as X (next), U (until), R (release), F (eventually), and G (always) enable the specification of dynamic properties. Formally, an LTL formula φ is defined over AP, and its models are infinite words over 2^{AP}.

Definition 5: **(LTL Syntax)** The set of LTL formulas is defined inductively as follows:

1) Each $p \in AP$ is an LTL formula.
2) If φ and ψ are LTL formulas, then so are $\neg\varphi$, $\varphi \vee \psi$, $X\varphi$, and $\varphi\, U\, \psi$.

Additional operators are introduced as abbreviations:

$$F\varphi := \top\, U\, \varphi, \qquad G\varphi := \neg F \neg \varphi, \qquad \varphi\, R\, \psi := \neg(\neg\varphi\, U\, \neg\psi).$$

The semantics of LTL link logical formulas to system behaviors by determining whether an execution σ satisfies a formula φ.

Definition 6: **(LTL Semantics)** Let $u = u_0 u_1 u_2 \ldots$ be an infinite word with $u_i \subseteq AP$. For an LTL formula φ, the satisfaction relation $u \models \varphi$ is defined inductively:

- $u \models p$ iff $p \in u_0$,
- $u \models \neg\varphi$ iff $u \not\models \varphi$,
- $u \models \varphi \vee \psi$ iff $u \models \varphi$ or $u \models \psi$,
- $u \models X\varphi$ iff $u_1 u_2 \ldots \models \varphi$,
- $u \models \varphi\, U\, \psi$ iff there exists $k \geq 0$ such that $u_k u_{k+1} \ldots \models \psi$ and for all $0 \leq i < k$, $u_i u_{i+1} \ldots \models \varphi$.

Given a Kripke Structure $K = \langle \Gamma, L, R, s_0 \rangle$, an infinite path $\pi = s_0 \to s_1 \to \ldots$ induces the word $w = L(s_0)L(s_1)\ldots$ over 2^{AP}. We write $K \models \varphi$ if every infinite path π of K satisfies φ.

Remark. The fragment $LTL\backslash X$, which omits the "next" operator, is frequently considered in verification since it guarantees desirable properties such as *stuttering invariance*.

2) Computation Tree Logic (CTL): Computation Tree Logic (CTL) is a branching-time temporal logic, complementary to LTL, that introduces explicit path quantifiers. Whereas LTL formulas are evaluated along a single linear path, CTL formulas are interpreted over the computation tree unfolding from the initial state of a Kripke Structure. Path quantifiers A ("for all paths") and E ("there exists a path") combine with temporal operators X (next), F (eventually), G (globally), and U (until) to form operators such as AX, EF, AG, or $E[\varphi U \psi]$.

Definition 7: **(CTL Syntax)** Let AP be a finite set of atomic propositions. CTL formulas are defined inductively as follows:

1) Each $p \in AP$ is a CTL formula.
2) If φ and ψ are CTL formulas, then so are $\neg\varphi$, $\varphi \vee \psi$.
3) If φ and ψ are CTL formulas, then the following are also CTL formulas: $AX\varphi$, $EX\varphi$, $AF\varphi$, $EF\varphi$, $AG\varphi$, $EG\varphi$, $A[\varphi U \psi]$, and $E[\varphi U \psi]$.

The semantics of CTL formulas are defined with respect to states and their computation trees. Path quantifiers specify whether a property holds across all possible futures (A) or on at least one possible future (E).

Definition 8: **(CTL Semantics)** Given a Kripke Structure $K = \langle \Gamma, L, R, s_0 \rangle$, the semantics of CTL formulas are defined as follows:

- $K, s \models AX\varphi$ iff for all successors s' of s, $K, s' \models \varphi$,
- $K, s \models EX\varphi$ iff there exists a successor s' of s such that $K, s' \models \varphi$,
- $K, s \models AF\varphi$ iff along all paths starting at s, φ eventually holds,
- $K, s \models EG\varphi$ iff there exists a path from s where φ holds globally,
- and analogously for the other operators.

Remark. The essential distinction between LTL and CTL lies in their view of time: LTL formulas are interpreted along single linear paths without explicit quantifiers, while CTL relies on branching-time semantics, combining state formulas with the path quantifiers A and E (see Table I).

TABLE I. COMPARISON BETWEEN LTL AND CTL

Aspect	LTL	CTL
Time model	Linear time: formulas are interpreted along single infinite paths.	Branching time: formulas are interpreted over computation trees with multiple possible futures.
Quantification	Implicit: no explicit path quantifiers, properties are evaluated over all paths.	Explicit: path quantifiers A (all paths) and E (there exists a path) precede temporal operators.
Syntax	Operators: $\neg$, $\vee$, X, U (with derived F, G, R).	Operators: $\neg$, $\vee$, combined with AX, EX, AF, EF, AG, EG, $A[\varphi U \psi]$, $E[\varphi U \psi]$.
Semantics	Evaluated over infinite words induced by paths in a Kripke Structure.	Evaluated over states in a Kripke Structure with respect to their computation tree.
Expressiveness	Suitable for specifying properties of individual executions (e.g. safety, liveness).	Suitable for reasoning about branching choices and existence/universality of behaviors.
Verification	Model checking reduces to automata-theoretic techniques (Büchi automata).	Model checking often based on fixpoint computations over the state space.

F. Model Checking

Model checking is an automated verification technique that, given a finite-state model of a system and a formal property, determines whether the property holds in the model. In the event of a violation, the model checker generates a counterexample, i.e. an execution trace from the initial state to a state that violates the condition. This significantly enhances its practical value, as it helps designers identify and correct errors. Clarke, one of the pioneers of the field, underlined its significance [11]: "It is impossible to overestimate the importance of the counterexample feature. The counterexamples are invaluable in debugging complex systems. Some people use model checking just for this feature."

Based on state-space exploration, the model checking procedure can be described in four main phases [14] (see Fig. 5 [15]):

- State-space generation: Construct the state-space of the model M, representing all possible infinite executions of M. The generated state-space can be modeled as an ω-automaton A_M, whose language $\mathcal{L}(A_M)$ is given in the form of a Kripke Structure.
- Property translation: Transform the LTL property φ into an ω-automaton $A_{\neg\varphi}$, whose language $\mathcal{L}(A_{\neg\varphi})$ consists of all infinite executions that violate φ.
- Product construction: Build the synchronized product automaton $A_M \oplus A_{\neg\varphi}$, which accepts the language $\mathcal{L}(A_M) \cap \mathcal{L}(A_{\neg\varphi})$, representing all executions of M that invalidate φ.
- Emptiness check: Verify whether $\mathcal{L}(A_M) \cap \mathcal{L}(A_{\neg\varphi}) = \varnothing$. If the intersection is empty, the system satisfies φ. Otherwise, the product automaton accepts an infinite word that violates φ, which is then returned as a counterexample.

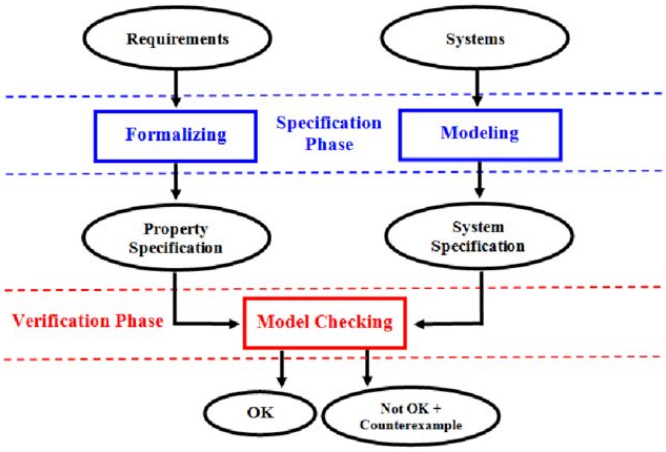

Fig. 5. Schematic view of model-checking approach.

The range of properties addressed by model checking is quite broad. For example, one can verify safety conditions, such as whether a system may reach a deadlock state, or quantitative aspects, such as whether every message will eventually be delivered with a probability of at least 0.99. In both cases, the verification is carried out automatically: the model checker systematically explores the system state space in order to detect any possible violation of the specification.

Several advantages explain the popularity of this technique. It requires little manual effort, as most of the process is

automated; it is versatile, covering a wide variety of correctness properties; and it remains comparatively efficient, even on complex designs. In addition, model checking can be applied even when only partial system specifications are available. While limitations persist, most notably the state explosion problem, the approach has proven to be one of the most practical and widely used methods in the field of formal verification.

However, the practical applicability of model checking is significantly challenged by the state-space explosion problem, which becomes particularly acute in the context of modular and concurrent systems. This limitation motivates the following discussion on scalability issues in modular concurrency.

III. The Scalability Problem in Modular Concurrency

Concurrent and distributed systems, especially when modeled in a modular fashion, pose intrinsic challenges to formal verification. Although model checking provides strong guarantees, its practical use is often hampered by the exponential growth of the state space. This phenomenon is commonly referred to as the scalability problem. In this section, we examine the fundamental dimensions of scalability in modular concurrency, highlighting how structural and semantic aspects of systems trigger combinatorial blow-ups that no straightforward verification method can overcome. These dimensions set the stage for the reduction and abstraction techniques reviewed in the subsequent sections.

A. Dimensions of the Scalability Problem in Modular Concurrency

The scalability problem in modular verification manifests along several complementary dimensions. Each of these dimensions reflects a specific source of combinatorial growth that challenges verification pipelines and limits the applicability of Naïve exploration strategies. By disentangling these dimensions, we gain a clearer view of where reduction and abstraction techniques must intervene to keep verification tractable. In the following, we outline four major dimensions that have been consistently identified in recent research: interleaving blow-up, synchronization hotspots, heterogeneous architectures, and property preservation requirements.

1) Interleaving blow-up: In modular concurrent systems, each independent action multiplies the interleaving possibilities. This leads to a combinatorial explosion of the state space. Even simple system topologies may generate billions of states. Such growth renders explicit exploration infeasible due to memory and time limitations. The issue worsens when components interleave freely, forming dense state graphs that are extremely hard to verify exhaustively.

This challenge has long been identified as a core scalability barrier in model checking [16]. Recent work shows that, even with optimized reductions, state counts can exceed 10^{12} in real-world concurrent systems [17].

2) Synchronization hotspots: Partial-Order Reduction (POR) aims to prune redundant interleavings by merging equivalent execution paths. However, when modules synchronize tightly on shared transitions, independence drops. This reduces the effectiveness of POR, increasing exploration cost. Recent complexity results show that finding near-optimal POR reductions is NP-hard. This underlines the need for hybrid strategies combining POR with abstraction or symmetry to regain scalability [18].

3) Heterogeneous architectures: Modern concurrent systems often execute across heterogeneous platforms such as multi-core CPUs, GPUs, and distributed clusters. Such platforms promise improved scalability. However, they require careful handling of memory consistency to maintain soundness and determinism across parallel or distributed memory. Mismatch in consistency models can cause nondeterministic and incorrect behaviors. Recent work highlights that enforcing cache-coherent shared memory across heterogeneous devices remains challenging, and formal verification must account for these architectural inconsistencies [19].

4) Property preservation: Effective reduction methods must guarantee preservation of critical behavioral properties, especially temporal logic specifications. This usually requires maintaining trace equivalence or stuttering equivalence, essential for logics like LTL without the next-time operator (LTL$\setminus X$). Recent formal work characterizes stuttering equivalence rigorously and reaffirms that LTL$\setminus X$ properties remain valid under such equivalence [20].

To provide a structured overview, Table II summarizes the four core dimensions that shape scalability limits in modular concurrent systems.

TABLE II. Dimensions of the Scalability Problem in Modular Concurrency

Aspect	Description
Interleaving Blow-Up	Exponential growth in interleavings due to concurrent, independent actions.
Synchronization Hotspots	Synchronous transitions undermine Partial-Order Reduction (POR); optimizing POR is NP-hard.
Heterogeneous Architectures	Multi-core, GPU, and cluster deployments challenge soundness and tool integration.
Property Preservation	Reductions must preserve trace or stuttering equivalence to ensure correctness in temporal logics (e.g. LTL\X, CTL*).

B. Real-World Failures Underscoring Scalability Challenges

The scalability issues discussed above are not only theoretical. They have had severe real-world consequences across hardware, avionics, medical systems, and cloud infrastructures.

- Intel Pentium II FDIV bug. A floating-point division error escaped formal analysis and led to costly hardware failures [21].
- Therac-25 radiation accidents. Concurrency-related defects in the control software caused lethal overdoses, revealing verification gaps in safety-critical systems [22].
- Boeing 737 MAX crashes (2018–2019). Insufficient verification of the MCAS flight-control logic under modular and concurrent interactions contributed to catastrophic accidents [23], [24].
- Autonomous vehicle accidents (Tesla, Uber, 2016–2021). Real-time decision modules misinterpreted sen-

sor data due to concurrency, leading to fatal outcomes [25].

- Spectre/Meltdown vulnerabilities (2018). These hardware flaws exposed the limits of verifying speculative execution and microarchitectural concurrency [26].
- Cloud outages (AWS, Azure, Google Cloud, 2020–2022). Complex interactions within distributed services triggered cascading failures that standard verification techniques struggled to predict [28]–[30].

These failures illustrate how state explosion, synchronization complexity, heterogeneous architectures, and property preservation remain key impediments to scalable and trustworthy verification.

IV. Landscape of Scalable Verification Techniques

A wide range of techniques has been proposed to mitigate the scalability challenges of model checking.

As shown in Fig. 6, these approaches can be organized into a taxonomy that highlights the main methodological categories, which will be detailed in the subsequent subsections.

These approaches range from algorithmic reductions that shrink the explored state space, to compositional reasoning frameworks that exploit modularity, and to strategies that harness high-performance computing platforms such as multi-core processors, GPUs, and distributed clusters. This section provides a structured overview of the methodological principles that underpin scalable verification. We highlight algorithmic strategies like state space reduction, abstraction, compositional reasoning, distributed exploration, and symbolic approaches, which form the foundation for advancing model checking in modular and concurrent systems.

A. State Space Reduction Methods

1) Partial-Order Reduction (POR): Partial-Order Reduction (POR) reduces redundant interleavings by exploiting the independence of concurrent actions. It has become one of the most effective techniques to alleviate the state explosion problem in modular and concurrent systems.

A quasi-optimal POR framework was formalized in [31], demonstrating how near-optimal reductions can drastically shrink the explored space in realistic models. Practical advances have followed, such as context-sensitive DPOR with observers, which improves scalability while preserving correctness [32]. Other recent work proposes interference-based DPOR to further prune unnecessary interleavings [33]. At the same time, theoretical results confirm the intrinsic hardness of optimizing POR, proving that even approximate solutions remain NP-hard [18].

These developments underline both the practical benefits of POR in real verification pipelines and the fundamental complexity limits that still motivate new heuristics and hybrid strategies.

2) Symmetry reduction: Symmetry reduction (SR) addresses the state explosion problem by identifying and merging states that are equivalent under permutations of identical components. For instance, in systems composed of many replicated processes, the order in which two identical processes execute is often irrelevant; exploring only one such case is sufficient.

This principle has been successfully applied in the context of Communicating Sequential Processes (CSP), a process algebra for modeling concurrent systems. Using the Failures–Divergences Refinement (FDR) model checker, groups of symmetric states are collapsed so that only a single representative is explored. This technique has enabled the verification of models with otherwise extremely large state spaces [34].

More recently, for distributed round-based protocols, partition symmetry reduction and message-order reduction dramatically shrink the model size by exploiting template symmetries [35].

Another promising direction is the use of counter abstraction, where systems with many identical components are represented by counting processes instead of enumerating each explicitly. The recent work of Eichler et al. [36] introduces a precise $(0, 1)$-counter abstraction for parameterized verification. This approach leverages process symmetry while preserving essential behavioral distinctions, thus enabling scalable verification of modular concurrent systems with large numbers of replicated components.

Together, these results illustrate not just how leveraging symmetry enables scalability in modular settings, but also how such reductions can be integrated into modern verification frameworks.

3) Stubborn sets: Stubborn sets are a state space reduction method that, like partial-order reduction, exploits the independence of concurrent actions. The idea is to identify a subset of transitions as the stubborn set that suffices to represent all relevant behaviors from a given state. By exploring only these transitions, large portions of equivalent interleavings can be safely omitted while preserving essential properties, like reachability and stuttering-invariant temporal logic formulas [LTL\X).

The core principle of this method continues to be refined and adapted to new and complex verification scenarios. For example, it has been extended to handle two-player reachability games, providing efficient reduction in adversarial settings where the outcome depends on the choices of multiple agents [37].

Furthermore, the versatility of stubborn sets is demonstrated by their application beyond standard Petri nets; they have been successfully integrated into frameworks for verifying Time Petri Nets, helping to mitigate state explosion in real-time systems by reducing redundant interleavings of temporal actions [38].

These developments underscore that stubborn sets remain a fundamental and adaptable technique for tackling state space explosion in diverse types of concurrent systems.

B. Abstract State Space Representations

Abstraction is a fundamental method to tackle the state explosion problem by collapsing sets of concrete states into

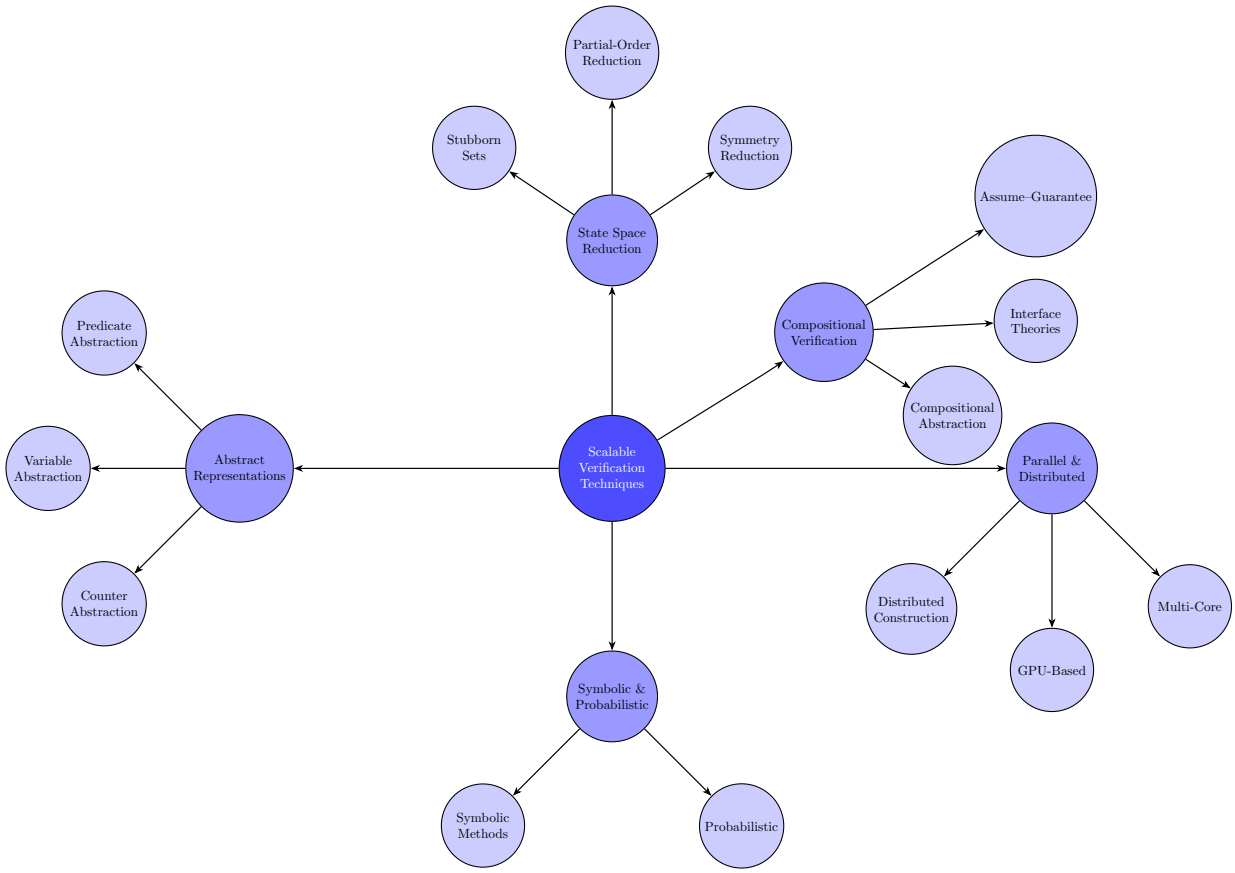

Fig. 6. Overview of scalable verification techniques, categorized into state space reduction, abstraction, compositional reasoning, parallel and distributed approaches, and symbolic/probabilistic methods.

abstract representatives. In contrast to reductions such as POR or symmetry, which preserve the concrete structure but prune interleavings, abstraction constructs a higher-level model that approximates the original system. Three categories of abstraction are commonly distinguished in the literature:

1) Predicate abstraction: Predicate abstraction replaces concrete data domains with Boolean predicates that capture properties relevant to the verification task. This technique underpins the well-known CEGAR (Counterexample-Guided Abstraction Refinement) framework, where spurious counterexamples trigger automatic refinement. Recent work applies predicate abstraction to real-time multi-agent systems, producing finite abstract models that remain correct for temporal logics, such as TCTL [39].

2) Data / Variable abstraction: Variable abstraction reduces large or infinite data domains into coarser partitions such as intervals, symbolic ranges, or sets. This approach is particularly useful in systems with timing or quantitative data, where abstraction preserves the control structure but simplifies the analysis. Examples include abstractions used for timed automata and hybrid systems, where compact representations allow tractable model checking [40].

3) Counter abstraction: Counter abstraction (also known as symmetry-based abstraction) aggregates identical processes by recording how many are in each local state, rather than tracking each process individually. This method has been widely used in the parameterized verification of concurrent protocols, significantly reducing the state space of replicated-component systems. Recent advances refine counter abstraction with precise $(0, 1)$-counters for parameterized systems, ensuring scalability without losing critical behaviors [36].

These three categories form the canonical core of abstraction techniques in model checking, offering scalable verification through higher-level representations of system behavior.

C. Compositional Verification

Compositional verification is a fundamental strategy to address state explosion by leveraging the modular structure of a system. Instead of verifying the system monolithically, this approach decomposes the verification task by analyzing individual components in isolation. The results of these local analyses are then composed to infer global properties of the entire system. The core challenge lies in managing the interactions between components, typically through the use of assumptions, contracts, or abstract interfaces.

1) Assume-guarantee reasoning: Assume-Guarantee Reasoning (AGR) is a cornerstone compositional technique that verifies systems by analyzing their parts separately. Instead of building a single large model for the entire system, AGR checks each component under specific assumptions about how

others will behave. The core idea is captured by a simple rule: a component C guarantees a property G provided its environment meets an assumption A, written as $\langle A \rangle C \langle G \rangle$.

To verify a system made of two components, suitable assumptions must be found so that each component's guarantee holds when the other acts as assumed. This avoids constructing the global state space altogether. The main challenge is automatically discovering these assumptions.

Recent advances are expanding the scope and expressiveness of AGR along two key dimensions: by developing novel logical frameworks to specify complex compositional properties, such as using epistemic logic to reason about knowledge in concurrent systems [5], and by creating powerful symbolic techniques that apply this reasoning to verify intricate systems, such as multi-language security protocols [27].

2) Interface theories: Interface Theories provide a formal foundation for modeling component interactions through contracts. A contract explicitly defines the assumptions a component makes on its environment and the guarantees it provides under those conditions. This formalism enables rigorous compositional reasoning by ensuring that each component's guarantees satisfy the assumptions of others in the system, thereby guaranteeing overall correctness [41].

Contract-Based Design (CBD) elevates this concept to a systems engineering methodology. It promotes modularity, reuse, and incremental development by allowing components to be specified, verified, and refined independently based on their contracts. This approach is particularly effective for large-scale concurrent systems, as it localizes verification efforts and simplifies integration. Recent research has focused on overcoming the practical challenge of manual contract specification by developing methods for the automated composition and refinement of contracts, making the methodology more scalable and accessible for complex system-on-chip designs [42]. The practical impact of CBD is significant, with successful applications spanning critical domains such as cyber-physical systems (CPS), where it helps manage the complexity of interactions between computational and physical elements [43]. This also extends to the automotive and aerospace industries.

3) Compositional abstraction and minimization: This technique involves generating a simplified, abstract model for each component that is conservative with respect to the properties of interest. The key idea is to reduce the state space of individual components before composition, making the subsequent global analysis more tractable. The abstraction must be precise enough to preserve relevant behaviors when components interact.

Methods range from traditional abstraction refinement (CEGAR) applied compositionally to techniques that exploit the modular structure to minimize each component while preserving equivalence (e.g. bisimulation minimization).

A recent advancement in this area focuses on compositional model checking for multi-properties, which aims to verify multiple system properties simultaneously and efficiently by leveraging the compositional structure [44]. The final verification step is performed on the composition of the abstract models, which is typically much smaller than the composition of the original components.

D. Distributed and Parallel Verification

The exponential growth in state space size often exceeds the capabilities of sequential verification, necessitating approaches that leverage parallel and distributed computing architectures. This subsection explores three key strategies that exploit modern hardware to distribute the computational and memory load of verification. These techniques, which target multi-core CPUs, GPUs, and distributed clusters respectively, form an essential toolkit for scaling verification to extremely large and complex modular systems.

1) Multi-core verification: A key strategy to combat state explosion leverages the parallel processing power of multi-core CPUs. This involves designing model checking algorithms and data structures that can efficiently distribute the workload across multiple cores, aiming for near-linear speedups. The challenge lies not only in parallelizing state space exploration but also in ensuring that the underlying data structures scale without becoming a bottleneck due to memory contention or fragmentation.

Recent innovations address this core challenge head-on. The EDDY framework exemplifies this progress, introducing a novel multi-core Binary Decision Diagram (BDD) package specifically engineered for modern shared-memory architectures [45]. Its main contributions include advanced dynamic memory management and a fragmentation-reducing allocator, which together mitigate critical performance overheads that plague traditional implementations. By optimizing memory access patterns and locality, EDDY enables more efficient parallel symbolic verification, directly increasing the scale of systems that can be checked. This focus on low-level memory optimization complements higher-level concurrency strategies, such as work stealing and lock-free data structures, forming a robust and scalable foundation for multi-core model checking.

a) GPU-based model checking: The massive parallelism offered by GPUs is exploited to accelerate demanding verification tasks, particularly for complex system models. This approach moves beyond traditional CPU-bound algorithms to harness the thousands of cores available on a GPU for parallel state space exploration and analysis.

GPU acceleration effectively scales Statistical Model Checking (SMC), a key method for verifying stochastic and timed systems. For instance, executing simulations of Extended Timed Automata on the GPU significantly accelerates the verification of temporal and probabilistic properties [46]. This approach efficiently tackles state space explosion in complex real-time models.

2) Distributed state space construction: Distributed verification decomposes the global state space across a network of machines, each responsible for exploring a distinct partition. This approach directly addresses the memory limitations of a single node, enabling the analysis of exceptionally large systems. The performance and scalability of this strategy critically depend on the underlying network technology and the efficiency of state management.

Cutting-edge research now leverages high-speed RDMA networks to minimize communication overhead. For instance, recent algorithms combine distributed exploration with sophisticated state reconstruction techniques, dramatically reducing

the amount of data that needs to be transmitted between nodes. An evaluation of such an approach shows significant improvements in scalability and efficiency for explicit state model checking, demonstrating the potential of modern networking technologies for distributed verification [47]. This line of work is directly applicable to large-scale modular systems, including those using RDSS-style construction.

E. Symbolic and Probabilistic Verification

While the previous techniques often deal with the state space explicitly or by exploiting its structure, another family of approaches uses fundamentally different representations. This part covers two such powerful paradigms: symbolic verification, which uses compact encodings to represent vast state spaces implicitly, and probabilistic verification, which extends classical model checking to reason about stochastic behaviors and quantitative properties. The integration of symbolic and probabilistic methods opens new frontiers for scalable verification.

1) Symbolic methods: Symbolic model checking techniques avoid explicit state enumeration by using compact logical representations. These methods employ data structures such as Binary Decision Diagrams (BDDs) and satisfiability solvers (SAT/SMT) to encode state sets and transition relations as formulas. This approach enables efficient property checking by exploring large state spaces symbolically rather than explicitly.

The practical effectiveness of these techniques depends fundamentally on the performance of their underlying reasoning engines. Modern SAT/SMT solvers have demonstrated remarkable capability in solving complex constraint problems across various domains. As shown in recent evaluations of large-scale puzzle solving, these solvers can efficiently handle problems with millions of constraints and variables, showcasing their scalability and robustness [48]. In formal verification, this computational power enables the analysis of complex system properties by reducing verification tasks to satisfiability problems, making symbolic methods essential for handling large-scale industrial systems.

2) Probabilistic verification: Probabilistic model checking extends classical verification to systems that exhibit random or unpredictable behavior. This approach analyzes quantitative properties of models such as Markov chains, which describe systems evolving probabilistically over time. Unlike traditional verification that provides yes/no answers, probabilistic methods compute likelihoods, for example, determining the probability that a communication protocol successfully delivers a message or calculating the expected energy consumption of a distributed algorithm.

The theoretical foundation for efficiently analyzing these models relies heavily on notions of behavioral equivalence. Recent advances have focused on developing a spectrum of approximate probabilistic bisimulations, which provide a formal framework for quantifying the similarity between states in probabilistic systems [49]. This allows for the construction of simplified models that preserve quantitative properties within precise error bounds, enabling more efficient analysis.

To consolidate this discussion, Table III provides a structured summary of the main categories of scalable verification techniques, their key methodological principles, typical domains of application, and their suitability for modular concurrency.

Remark. Some references appear in multiple sections of this survey. This reflects their dual relevance: for instance, a contribution may introduce a novel reduction technique while also providing its implementation in a widely used tool. In such cases, the same source is cited in both the methodological and tooling contexts to accurately represent its impact across the landscape.

V. Tooling Ecosystem: Capabilities for Modular Systems

In parallel with theoretical advances, a rich ecosystem of verification tools has been developed. These platforms implement the reduction, abstraction, and compositional techniques surveyed in the previous section, thus bridging academic research with industrial applications. This section reviews the most influential verification tools and evaluates their relevance for modular and concurrent systems.

A. Classical Explicit-State Tools

Classical explicit-state tools represent the first generation of practical model checkers. They operate by directly constructing and exploring the state space. They are often supported by sophisticated search strategies and reduction techniques to manage the explosion of states. Although more recent symbolic and distributed approaches have emerged, these tools remain highly influential. They are still actively used in both academia and industry. The following subsections briefly review three representative explicit-state platforms.

1) SPIN: The SPIN model checker [8] remains one of the most widely used explicit-state verification engines. It targets systems specified in the Promela modeling language and implements techniques such as partial-order reduction and bitstate hashing. SPIN has been applied to a broad spectrum of communication protocols and distributed algorithms, demonstrating scalability up to millions of states. While not natively modular, its support for asynchronous processes makes it relevant for analyzing concurrent behaviors in modular settings.

2) NuSMV: NuSMV [10] is a symbolic model checker supporting both CTL and LTL properties. It implements BDD-based symbolic methods and SAT-based bounded model checking, providing a balance between explicit and symbolic exploration. Although its architecture is not specifically modular, NuSMV has served as a foundation for contract-based verification frameworks, notably in embedded and safety-critical software.

3) UPPAAL: UPPAAL [50], [51] focuses on timed automata and real-time systems. It integrates symbolic techniques for handling clock variables, making it particularly suited for modular cyber-physical systems. Compositional extensions of UPPAAL support verification of large networks of timed components, where timing constraints play a central role.

B. High-Performance Verification Frameworks

High-performance frameworks emerged to overcome the scalability limitations of classical explicit-state tools. These

TABLE III. COMPARATIVE SUMMARY OF SCALABLE VERIFICATION TECHNIQUES, THEIR DOMAINS, AND SUITABILITY FOR MODULAR CONCURRENCY

Category	Key Methods / References	Domain of Application	Suitability for Modular Concurrency
State Space Reduction	POR [18], [31]–[33], Stubborn Sets [37], [38], Symmetry [35], [36]	Protocols, Hardware verification, Petri nets	High — directly addresses interleaving and replication in concurrent modules
Abstract Representations	Predicate [39], Variable/Data [40], Counter [36]	Hybrid systems, Real-time models, Parameterized protocols	Medium to High — effective when abstraction is precise, but risk of spurious behaviors
Compositional Verification	AGR [5], [27], Interface Theories [41]–[43], Compositional Abstraction [44]	Large-scale software, Cyber-physical systems, Security protocols	High — inherently modular, though assumption discovery and contract design remain challenging
Parallel & Distributed, Symbolic & Probabilistic Verification	Multi-core [45], GPU [46], Distributed [47], Symbolic/Probabilistic [48], [49]	Industrial-scale models, Stochastic protocols, Cloud infrastructures	Medium to High — excellent for scaling exploration, less natural for modular decomposition

platforms exploit optimized data structures, parallel architectures, and language-independent interfaces to accelerate state space exploration. They provide the backbone for verifying larger and more complex models, while often serving as integration points for new reduction techniques and symbolic back-ends. The following subsections review representative frameworks in this category.

1) LTSmin: LTSmin [52] is a high-performance language-independent model checker that provides interfaces to multiple modeling languages (e.g. Promela, DVE, PNML). It integrates symbolic techniques (decision diagrams), parallel reachability, and partial-order reductions. Its modular architecture and native support for Petri nets make it highly relevant for modular concurrency.

2) DiVinE: DiVinE [53] is a distributed explicit-state model checker designed for large-scale verification on clusters and high-performance computing platforms. It implements parallel reachability, on-the-fly LTL model checking, and advanced partial-order reductions. DiVinE demonstrates strong scalability for concurrent modular models distributed across thousands of cores.

3) EDDY (multi-core BDD): The EDDY framework [45] provides a multi-core BDD package optimized for shared-memory architectures. By redesigning memory allocators and dynamic variable reordering, EDDY improves symbolic model checking on multi-core CPUs. This directly addresses the need for efficient symbolic verification in modular systems with large state spaces.

C. Probabilistic and Symbolic Engines

Another important branch of verification frameworks focuses on symbolic and probabilistic approaches. Instead of relying solely on explicit state enumeration, these engines use compact logical representations or stochastic models to capture system behaviors. Symbolic methods such as BDD- or SAT/SMT-based encodings enable implicit exploration of vast state spaces, while probabilistic model checkers extend classical verification to reason about uncertainty and quantitative properties. Together, these tools greatly expand the range of systems and properties that can be analyzed. The following subsections highlight representative engines in this category.

1) STORM: STORM is a modern probabilistic model checker that integrates symbolic, explicit, and numerical methods into a unified framework. It supports a wide range of probabilistic models, including Markov decision processes (MDPs), continuous-time Markov chains (CTMCs), and stochastic Petri nets, making it applicable to both academic benchmarks and industrial-scale case studies. Unlike earlier tools that specialized in either symbolic or explicit techniques, STORM provides a flexible architecture that combines multiple engines to balance scalability and precision. Recent evaluations confirm its ability to analyze large and complex quantitative models while maintaining soundness and efficiency [54]. This makes STORM particularly relevant for modular and concurrent systems where stochastic behaviors interact with structural concurrency.

2) PRISM: PRISM [55] pioneered probabilistic model checking and remains a widely used tool for analyzing stochastic protocols and cyber-physical systems. It supports a wide range of probabilistic logics and has influenced the design of STORM. While not primarily modular, its modeling language facilitates component-based specifications.

3) SAT/SMT-based frameworks: Modern SAT/SMT-based model checkers leverage the efficiency of constraint solvers to perform bounded or unbounded verification. Tools such as CBMC and IC3-based solvers integrate abstraction-refinement and compositional reasoning, making them suitable for modular concurrent software verification. Recent advances demonstrate their scalability for verifying security protocols and hardware blocks.

D. Domain-Specific and Hybrid Tools

Beyond general-purpose model checkers, a variety of domain-specific and hybrid tools have been developed to address the needs of particular application areas. These platforms often combine multiple verification paradigms (explicit, symbolic, probabilistic) and tailor them to specialized modeling languages or industrial domains. They play a crucial role in bridging the gap between theoretical advances and real-world deployments, offering verification capabilities that are more directly aligned with practitioner requirements. The following parts survey representative tools in this category.

1) PAT (Process analysis toolkit): PAT [56] supports verification of process-algebraic models, combining CSP-style semantics with state space reductions and refinement checking. It provides explicit support for modular specifications and has been applied to distributed protocols and workflow systems.

2) SDV (Static driver verifier): Microsoft's Static Driver Verifier (SDV) integrates symbolic model checking with static analysis to automatically verify Windows device drivers [57]. It

builds on the SLAM project and uses predicate abstraction with refinement. Although domain-specific, SDV exemplifies how verification pipelines can scale to real-world modular software components.

3) Recent hybrid platforms (GPU, cloud): Recent tools leverage GPUs and cloud infrastructures to accelerate verification. Notably, distributed model checkers such as DiVinE-cloud and GPU-accelerated statistical model checking frameworks demonstrate promising results [46], [47]. These platforms highlight the emerging trend of integrating heterogeneous computing into verification workflows.

4) SPORE: SPORE [58] is a recent stateless model checker that combines partial-order reduction with symmetry reduction. Its hybrid algorithm significantly reduces explored interleavings, demonstrating orders-of-magnitude improvements over classical POR. SPORE directly targets concurrency and is particularly relevant for modular distributed protocols. Although some of these tools were introduced decades ago, they continue to be actively maintained and widely applied in recent studies.

Table IV summarizes their core verification techniques, supported models, relevance for modular/concurrent systems, and illustrates their continued impact with recent references and application domains.

While many of these tools were originally introduced more than a decade ago, their sustained use in recent research highlights the robustness of their foundational techniques. As shown in Table IV, extensions such as GPU acceleration, symbolic encodings, and domain-specific adaptations (e.g. robotics, IoT, autonomous driving) ensure that these platforms remain relevant for contemporary verification challenges. This consolidated landscape provides the backdrop against which we now situate our own contribution, focusing on the Reduced Distributed State Space (RDSS) framework and its role in addressing scalability in modular concurrent systems.

VI. RDSS: Contribution, Positioning, and Future Directions

Building upon the surveyed techniques and tools, this section introduces the Reduced Distributed State Space (RDSS) framework as a novel approach to scalable verification of modular and concurrent systems. RDSS directly addresses the limitations identified in existing methods by providing a modular structure that integrates reduction principles while enabling verification at the level of individual modules. We first outline the gaps in current approaches, then present the RDSS framework and its key contributions, followed by a discussion of its positioning within the literature and possible future extensions.

A. Scope and Claims

Before detailing our framework, we explicitly clarify its scope and novelty. The novel contribution of RDSS lies in its ability to perform local model checking directly on per-module meta-graphs, rather than requiring construction of the entire global state space. This is achieved through two key mechanisms: (*i*) τ-hiding of irrelevant synchronizations, and (*ii*) meta-state fusion that preserves *stuttering equivalence*. These innovations enable verification of module-specific properties with strong theoretical guarantees. RDSS does not reinvent prior reduction strategies; instead, it *integrates* and benefits from established methods such as partial-order reduction, symmetry reduction, and abstraction, while remaining compatible with distributed exploration. Finally, the property classes supported are those expressible in the stutter-invariant fragment of LTL (LTL $\setminus$ $\mathbf{X}$), including safety, liveness, and local properties such as deadlock-freedom, home-space reachability, and module-level liveness. By stating these boundaries, we aim to separate our claims from the survey of existing work and set clear expectations for the reader.

B. Identified Gaps in Existing Approaches

Despite the advancements in model checking and state space reduction methods, current verification techniques for modular and concurrent systems face significant scalability challenges. Traditional approaches, such as POR, symmetry reduction, and abstraction, address specific aspects of the state space explosion problem. Unfortunately, they do not provide comprehensive solutions for the complex nature of modern systems.

First, POR helps reduce redundant interleavings by exploiting the independence of actions. However, its effectiveness is limited when the system's concurrency is highly interdependent or exhibits complex synchronization. Symmetry reduction identifies equivalent states that result from symmetric components. Nevertheless, it fails to address cases where the symmetry is less evident or dynamic. Similarly, abstraction techniques can collapse large portions of the state space. However, they risk oversimplifying behaviors, potentially missing critical verification information. This is particularly problematic when applied to modular systems with complex interactions between components.

Moreover, these techniques, while effective individually, fail to handle the full scope of challenges posed by highly dynamic and modular systems, where components can interact in unpredictable ways. These limitations motivate the need for more integrated and scalable approaches, such as Reduced Distributed State Space (RDSS), which tackles the scalability problem in a modular and distributed context.

C. The RDSS Framework

The RDSS framework introduces a novel and scalable solution to the state explosion problem in modular and concurrent systems. It builds upon the distributed state space structure originally proposed in [80], extending it with formal guarantees such as stuttering equivalence, τ-hiding of irrelevant synchronizations, and fusion of equivalent meta-states. This part first presents the core principles of RDSS, followed by its key contributions to scalable verification.

1) The RDSS principle: The RDSS framework addresses the challenge of state explosion in modular systems by reducing the global state space into smaller, manageable meta-graphs formed of meta-states that represent the state space of individual modules. The input of the RDSS consists of the concurrent modular system specification being studied, formalized in a Modular Petri Net structure. Each module in the system constructs its local meta-graph, capturing only the relevant transitions based on local and synchronized events.

TABLE IV. SUMMARY OF REPRESENTATIVE VERIFICATION TOOLS, THEIR CORE TECHNIQUES, SUPPORTED MODELS, RELEVANCE FOR MODULAR/CONCURRENT SYSTEMS, AND EVIDENCE OF CONTINUED USE IN RECENT DOMAINS

Tool	Core Techniques	Model Supported	Relevance to Modular/Concurrent Systems	Recent Use (Refs.)	Application Domain (Recent)
SPIN	Explicit-state, POR, Bitstate hashing	Promela processes	Asynchronous processes, distributed protocols	[59], [60]	IoT-based transport, abstracted IoT protocols
NuSMV	Symbolic (BDD, SAT/SMT), Bounded MC	SMV language, CTL/LTL	Contract-based reasoning in modular embedded systems	[61], [62]	Multi-agent systems, software product lines
UPPAAL	Symbolic (timed automata, DBMs)	Networks of Timed Automata	Real-time CPS and IoT verification	[63], [64]	Drone access control, contract automata runtime
LTSmin	Symbolic DDs, POR, Distributed exploration	PNML, Promela, mCRL2	Modular Petri Nets and parameterized models	[65], [66]	GPU-based LTL MC, knowledge-based reductions
DiVinE	Explicit distributed MC, Parallel LTL checking	DVE, PNML, Promela	Cluster-based concurrency analysis	[67], [68]	C++ program verification, GPU POR
EDDY	Multi-core symbolic BDDs	Symbolic encodings (BDD-based)	Shared-memory multi-core verification	[69], [70]	HPC memory optimization, GPU model training
STORM	Symbolic + numerical probabilistic engines	MDPs, CTMCs, Stochastic PN	Quantitative verification of stochastic modular systems	[71], [72]	Robotic systems, MDP algorithm selection
PRISM	Symbolic (BDD, MTBDD), Probabilistic checking	Probabilistic automata, MDP, CTMC	Stochastic CPS, security protocols	[73], [74]	Symmetry reduction, model-based frameworks
SPORE	Stateless MC, POR + Symmetry reduction	Concurrent C programs, message-passing protocols	Concurrency, modular distributed protocols	[58]	Benchmarks of concurrency programs
PAT	Explicit + refinement checking, POR	CSP-style models, workflows	Modular process-based verification	[75], [76]	Federated learning, blockchain smart contracts
SDV	Predicate abstraction + CEGAR (SLAM)	C code (Windows drivers)	Modular verification of device drivers	[77], [78]	Distributed BMC, autonomous driving (ADS)

The interactions between modules in RDSS are captured through synchronization points, which align the meta-graphs of different modules during the construction process. This modular approach avoids the need to explore redundant state space information from non-relevant modules.

A key concept in RDSS is the use of τ transitions, which are used to hide irrelevant synchronizations between modules. These transitions allow the system to focus on the core behaviors, ignoring unnecessary synchronization events that do not affect the properties being verified. During the construction of the RDSS, equivalent meta-states are identified and merged to reduce the overall state space. This process ensures that only unique behaviors are captured, and redundant states that exhibit identical or analogous transitions are eliminated.

This fusion is based on the principle that multiple states, which share the same output behavior and synchronization properties, can be represented by a single meta-state. By merging these equivalent meta-states, RDSS maintains the correctness of the verification while significantly reducing the number of states that need to be explored [81].

The local meta-graphs are then used for verification, enabling the system to scale by performing module-specific verification without requiring access to the entire global state space [79].

Furthermore, RDSS ensures the stuttering equivalence of the reduced state space. It has been formally proven that the projection of the language generated by the graph of a module on its own transitions is the same as the language generated by the entire system's global state space. This guarantees that no critical behaviors are lost during the reduction process.

Fig. 7 demonstrates the modular decomposition and the use of synchronization points in the RDSS framework.

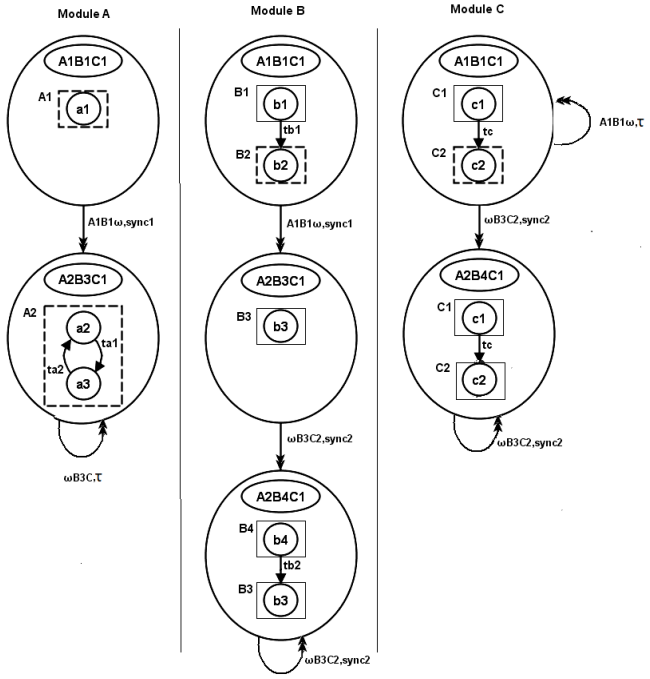

Fig. 7. Illustration of RDSS corresponding to the Modular Petri Net of Fig. 4.

D. Soundness of Local Model Checking in RDSS

A central question for the Reduced Distributed State Space (RDSS) framework is whether properties verified locally on module-level meta-graphs are sound with respect to the original Modular Petri net (MPnet). This subsection establishes the formal basis of this claim by proving that RDSS preserves stuttering equivalence with the original system, and that the projection of behaviors on a given module coincides in both

structures. As a result, $LTL \setminus \mathbf{X}$ properties can be checked locally without loss of correctness.

1) Projection argument: Let Σ be the language generated by the MPnet $\mathcal{P}$ over its set of transitions, and $\Sigma_{/s}$ the projection of Σ onto the transitions specific to module s. Let Σ_s be the language generated by the meta-graph of module s, and $\Sigma_{s/s}$ its projection onto the transitions of s. We prove that $\Sigma_{/s} = \Sigma_{s/s}$.

Indeed, any infinite execution sequence $\sigma \in \Sigma$ can be written as

$$\sigma = \left((t_l)^*(t_{sync})^*\tau^*\right)^*,$$

where, t_l are local transitions, t_{sync} are synchronized transitions, and τ denotes hidden synchronizations. Projecting σ onto module s eliminates irrelevant synchronizations, yielding

$$\sigma^{\Sigma_{/s}} = \left((t_{l,s})^*(t_{sync,s})^*\right)^* \in \Sigma_s.$$

Hence $\Sigma_{/s} \subseteq \Sigma_{s/s}$.

Conversely, every execution $\sigma \in \Sigma_s$ is built from the local, synchronized, and τ transitions of module s, so

$$\sigma = \left((t_{l,s})^*(t_{sync,s})^*\tau^*\right)^*.$$

Projecting σ on s removes the τ transitions, giving

$$\sigma^{\Sigma_{s/s}} = \left((t_{l,s})^*(t_{sync,s})^*\right)^* \in \Sigma_{/s}.$$

Thus $\Sigma_{s/s} \subseteq \Sigma_{/s}$. Combining both inclusions yields:

$$\Sigma_{/s} = \Sigma_{s/s}.$$

2) Stuttering equivalence: From the above projection result, we conclude that the maximal paths of the MPnet and those of the RDSS coincide modulo τ-hiding. This implies that the two structures are stuttering-equivalent, and therefore preserve all properties expressible in the stutter-invariant fragment $LTL \setminus \mathbf{X}$.

Theorem 1 (Stuttering Equivalence for RDSS): Let $\mathcal{P}$ be an MPnet with $\mathcal{P} = (S, TF)$, and let $\mathcal{R}$ be its corresponding RDSS defined as

$$\mathcal{R} = \{\, RG_s = (\widehat{\mathcal{N}}_s, \widehat{\mathcal{A}}_s) \mid s \in S \,\}.$$

For any $LTL \setminus \mathbf{X}$ formula φ defined over T_s, the set of local and synchronized transitions of a module s, we have:

$$\mathcal{P} \vDash \varphi \iff \mathcal{R} \vDash \varphi.$$

3) Proof sketch: The projection argument shows that every path of $\mathcal{P}$ restricted to module s corresponds to a path in $\mathcal{R}$ and vice versa. Since $LTL \setminus \mathbf{X}$ properties are preserved under stuttering equivalence, verifying φ on the module-level meta-graph is sound and complete with respect to verifying it on the global reachability graph. Detailed proofs and demonstrations are available in our GitHub repository[2].

4) Key contributions of RDSS: The RDSS framework offers several groundbreaking contributions to the field of scalable verification for modular concurrent systems:

5) Verification of individual modules: The core contribution of RDSS is its ability to verify properties of individual modules using only the meta-graph of that specific module. Unlike traditional methods that require access to the global state space, RDSS is a pioneering approach that enables local model checking. This approach drastically improves scalability, as it allows the modules of large systems to be verified efficiently. The benefits of this modular verification strategy are further illustrated in Fig. 8, which compares the verification times of RDSS with those of LTSmin. The results show that RDSS achieves competitive or even superior performance, particularly in systems where modules are not all synchronized on the same transitions.

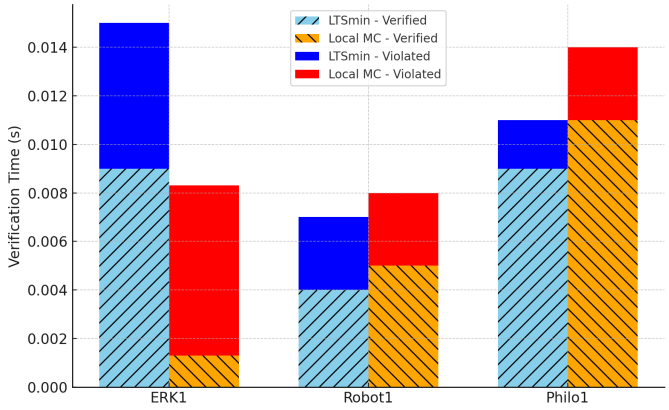

Fig. 8. Comparative performance of LTSmin and Local Model Checking in verifying modular systems.

6) Integration of state space reduction techniques: Another significant contribution of RDSS is its integration of various state space reduction techniques into a modular framework. Methods such as partial-order reduction (POR), symmetry reduction, and abstraction are applied both at the global and local levels. By combining these reductions, RDSS is a hybrid method that optimizes the verification process, ensuring the correctness of global properties while managing the complexity of individual modules.

7) Flexibility in modular verification: RDSS introduces a new level of flexibility in the verification of modular systems, particularly for systems with dynamic interactions. Unlike traditional verification methods that may struggle with complex interdependencies between modules, RDSS can efficiently handle systems where interactions evolve, leveraging its module-specific meta-graphs. Moreover, the modular structure

[2]https://github.com/chihebabid/DSS-Checker

of RDSS is well-suited for distributed concurrent systems, as it allows for efficient verification by focusing on individual modules and their interactions, rather than constructing the entire global state space.

8) State space size reduction: When compared with the flat Petri net state space, RDSS delivers better results, particularly for systems where not all modules are synchronized on the same transitions. This reduction in state space is particularly beneficial for verifying large-scale modular systems, as shown in Fig. 9, which illustrates the performance improvement of RDSS over traditional methods. The comparison between the flat Petri net and RDSS in terms of transitions and markings demonstrates the scalability advantages of the RDSS approach.

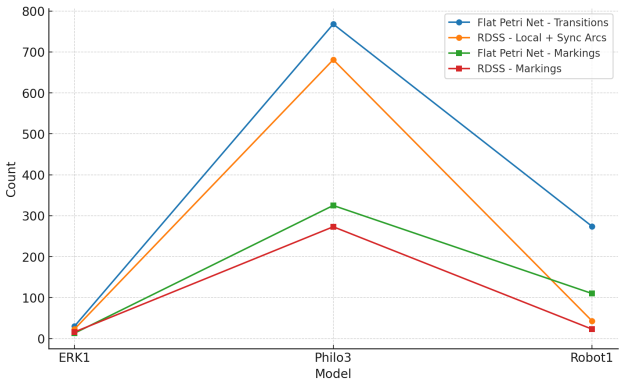

Fig. 9. Comparison of Flat Petri Net and RDSS. The figure illustrates the performance improvement of RDSS in terms of state space size reduction, particularly in systems with unsynchronized modules.

9) Model checking focus: A key strength of RDSS lies in its model checking capabilities. By focusing on module-level verification, RDSS allows for the verification of properties such as deadlock, liveness, and reachability directly within each module, using its associated meta-graph. This localized model checking significantly reduces the computational burden compared to traditional approaches that require the construction and exploration of the entire global state space.

Fig. 10 illustrates the RDSS model checking process, highlighting how the meta-graph of each module is used for verification. This diagram emphasizes the modular decomposition of the verification process, showcasing the RDSS's ability to verify individual components without needing to consider the full system's state space.

10) Worked example: To illustrate the process, consider the Modular Petri Net (MPN) in Fig. 4 and its corresponding RDSS in Fig. 7.

We aim to verify the following $LTL \setminus \mathbf{X}$ property on module A:

$$\varphi = \mathbf{G}(sync_1 \rightarrow \mathbf{F}\, t_{a1}) \ \wedge \ \mathbf{G}\big(\neg(t_{a1} \rightarrow \mathbf{F}\, t_{a2})\big).$$

Instead of constructing the global state space, verification is restricted to the meta-graph RG_A of module A (Fig. 11). The procedure follows the automata-theoretic model checking approach:

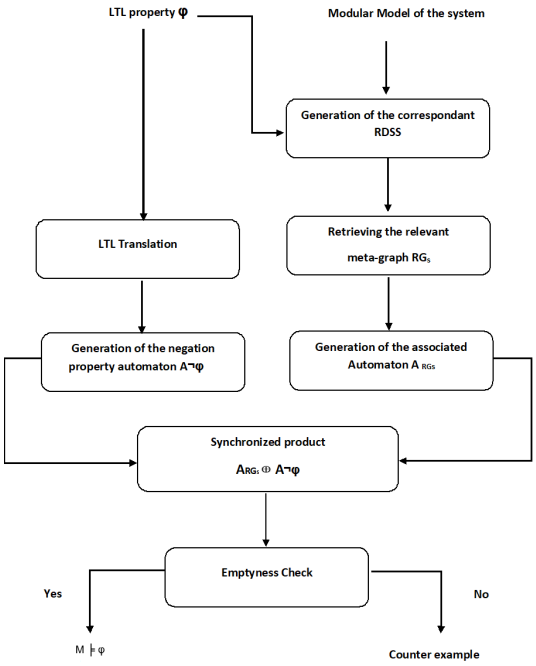

Fig. 10. The RDSS local model checking workflow.

- Negate the property φ to obtain $\neg\varphi$.
- Construct the Büchi automaton $A_{\neg\varphi}$ (Fig. 12).
- Build the automaton A_{RG_A} from the module's meta-graph.
- Compute the synchronous product $A_{RG_A} \otimes A_{\neg\varphi}$ (Fig. 13 and Fig. 14.

Initially, both automata start in their respective initial states. During the first synchronization step (Fig. 13), when the transition $sync1$ is activated in the meta-graph of module A, the automaton of $\neg\varphi$ fires $!t_{a1}$, moving to state 1. Subsequently, as illustrated in Fig. 14, the cycle in the component's strongly connected component (SCC) allows repeated firings of $t_{a2}.t_{a3}$, which are matched by the "true" loop in the automaton of $\neg\varphi$.

In this case, the product automaton is not empty. The counterexample execution is:

$$sync_1 \cdot (t_{a1}\, t_{a2})^*,$$

showing that φ is violated.

This example demonstrates concretely how RDSS enables local model checking by verifying properties using only the meta-graph of the concerned module, thus avoiding the explosion of the global state space.

These contributions, particularly the ability to perform local model checking and reduce the global state space, mark RDSS as a highly effective and scalable solution for verifying large, modular systems.

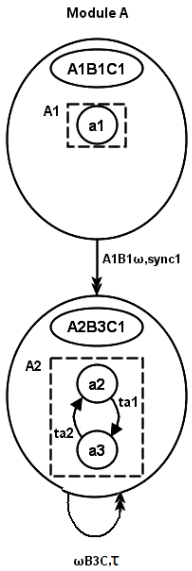

Fig. 11. Meta-graph of module A.

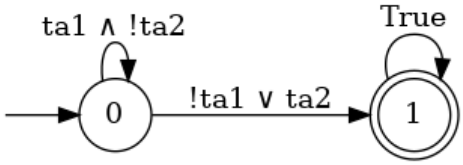

Fig. 12. Automaton of $\neg\varphi$.

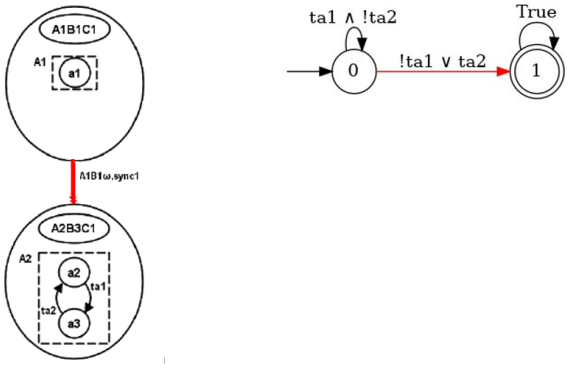

Fig. 13. First step of the synchronized product construction.

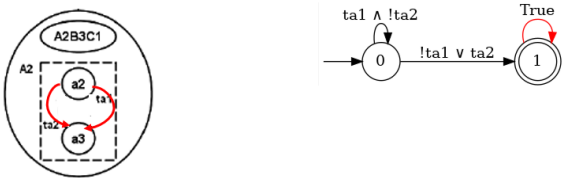

Fig. 14. Second step of the synchronized product construction.

11) Experimental setup and reproducibility: To ensure reproducibility of the reported results, we now provide additional details on the benchmarks, environment, and properties considered.

a) Benchmarks: The experiments were carried out on Modular Petri Net models representative of the case studies discussed in this paper. These include 1) an IoT-based monitoring scenario with modular communication between devices and gateways, and 2) a multi-robot patrolling system with synchronized alert transitions. For each model, different parameterizations were used to vary the number of modules and the degree of synchronization between them.

b) Verification properties: The properties evaluated include locally generic ones such as deadlock-freedom, home-space reachability, and liveness, as well as temporal properties expressed in the stutter-invariant fragment LTL$\setminus\mathbf{X}$ (e.g. $\mathbf{G}\,\neg error$ and $\mathbf{GF}\,request \rightarrow \mathbf{F}\,grant$). These properties were selected to cover both safety and liveness aspects.

c) Environment: All experiments were executed on a workstation running Ubuntu 22.04 LTS, equipped with an Intel Core i7 processor and 16 GB of RAM. The RDSS prototype was implemented in C++/ROS2, while LTSmin and SPIN were used as comparative tools. Each verification run was subject to a timeout of 30 minutes.

d) Replication: The RDSS implementation, benchmark models, and property specifications are publicly available at https://github.com/chihebabid/ros2dss, enabling replication of the results presented in this paper.

E. Positioning RDSS within the Literature

The Reduced Distributed State Space (RDSS) framework introduces a modular approach to overcome state explosion, going beyond traditional reductions by exploiting meta-graphs of individual modules. We briefly position RDSS against classical techniques and widely used tools, and highlight its application domains.

1) Reduction techniques: Compared to Partial-Order Reduction (POR), RDSS avoids redundant global interleavings by applying reductions locally at the module level. Unlike Symmetry Reduction (SR), which assumes static symmetries, RDSS flexibly combines SR with τ-hiding and meta-state fusion. In contrast to coarse-grained abstractions, RDSS preserves stuttering equivalence, ensuring correctness of LTL$\setminus X$ properties.

2) Verification tools: NuSMV is effective for small symbolic systems but does not scale to modular decomposition. LTSmin supports large state spaces yet lacks modular reduction; RDSS achieves competitive performance with lower memory needs (Fig. 8). SPIN remains powerful for explicit-state checking but does not provide modular verification like RDSS, which verifies module-specific properties directly.

3) Application domains: RDSS is particularly well-suited for distributed concurrent systems, where modules interact through synchronization but maintain partial independence. This includes multi-robot systems, IoT platforms, and cyber-physical infrastructures, where global state construction is infeasible. For example, in [82], RDSS was successfully applied to an IoT-based case study, showing that local model checking can verify safety and liveness properties efficiently without exploring the full global state space.

4) Summary: Overall, RDSS integrates the principles of POR, SR, and abstraction while overcoming their modularity limitations. By focusing on module-specific properties, RDSS positions itself as a scalable solution for distributed concurrent systems, with promising applications in robotics, IoT, and large-scale modular infrastructures. As highlighted in Table V, RDSS complements existing techniques and tools by enabling local model checking with reduced state space construction, offering clear advantages in modular and dynamic settings.

F. Limits Under Dense Synchronization

While RDSS demonstrates clear advantages when modules retain partial independence, a pathological case arises when the system exhibits dense synchronization, i.e. when most or all transitions are shared among modules (case of ERK1). In this scenario, the benefits of modular decomposition diminish, since local meta-graphs must frequently synchronize, reducing the reduction opportunities from τ-hiding and meta-state fusion.

Compared to classical techniques, RDSS in this setting behaves closer to a flat global exploration, as synchronization dominates the structure of the meta-graphs. Partial-order reduction (POR) or stubborn sets may then achieve comparable or even better pruning, since they exploit independence at the transition level rather than structural modularity. Symmetry reduction may also remain beneficial if replicated modules synchronize in a uniform manner, collapsing symmetric synchronization patterns.

These observations suggest that RDSS is most advantageous in systems where:

- Modules contain a significant proportion of local transitions relative to their synchronized ones,
- Synchronization points are sparse or limited to subsets of modules, and
- Property checking targets module-specific behaviors (e.g. local deadlock, local liveness, LTL$\setminus X$ properties tied to one module).

In contrast, in systems with dense synchronization, hybrid approaches that combine RDSS with stubborn sets or symbolic encodings may be more appropriate, ensuring that both structural and transition-level redundancies are exploited.

G. Future Directions and Extensions

While the RDSS framework already provides a scalable and modular verification approach, several promising research directions remain open. These extensions aim to further enhance scalability, applicability, and integration with modern verification practices.

1) Distributed implementations with ROS2: One natural extension of RDSS is its deployment in distributed verification environments. A first step in this direction has been demonstrated through a prototype implementation based on ROS2, where modules act as independent nodes communicating through publish/subscribe services. This distributed construction of the RDSS allows verification tasks to be executed concurrently across multiple workers, offering increased scalability for large systems with heterogeneous components.[3] Future work can explore optimizations in communication overhead and dynamic load balancing.

2) AI-driven heuristics for reduction: The construction of RDSS relies on reduction techniques, such as partial-order reduction, symmetry, and abstraction. Integrating artificial intelligence, particularly reinforcement learning and machine learning heuristics, could guide the selection of reduction strategies dynamically. For instance, AI agents may learn to prioritize transitions, identify symmetries, or detect redundant synchronizations, thereby reducing exploration costs while preserving correctness. Such integration would pave the way for adaptive and context-aware verification pipelines.

3) Hybrid reduction strategies: Another promising direction is the design of hybrid approaches that combine RDSS with other established reduction frameworks. This includes integrating counterexample-guided abstraction refinement (CEGAR), advanced stubborn sets, or symbolic encodings with the modular meta-graph construction of RDSS. Such hybrids would allow leveraging the strengths of different techniques to achieve stronger reductions without sacrificing property preservation, particularly for LTL$\setminus X$ and branching-time logics.

4) Application to emerging domains: RDSS is naturally suited for concurrent and modular architectures such as multi-robot coordination, IoT ecosystems, and cloud-native distributed systems. Extending RDSS to these domains can provide realistic benchmarks that highlight its advantages over state-of-the-art tools. For example, in the IoT-based agriculture use case [82], RDSS enabled local model checking without requiring the full global state. Similar extensions to autonomous vehicles, cyber-physical systems, and large-scale cloud infrastructures would consolidate RDSS as a practical solution to real-world scalability challenges.

5) From local to global verification: While RDSS focuses primarily on enabling local model checking at the module level, an important extension is to move toward global verification within the same modular framework. The key idea is that a global property can often be decomposed into a set of local properties, each verifiable on the corresponding module's meta-graph. By invoking local model checking for each component property and then combining the results, one can infer the truth of the global property.

This modular synthesis of verification outcomes effectively reconstructs global correctness from local evidence, avoiding the need to explore the full global state space. Such an approach bridges local and global reasoning, and can be viewed as a form of modular controller synthesis, where global guarantees emerge from the coordinated satisfaction of local obligations.

The verification of modular concurrent systems is no longer an abstract academic pursuit but a practical necessity for the safe deployment of autonomous platforms, IoT infrastructures, and large-scale distributed software. Ensuring correctness at scale requires techniques that tame the state explosion problem without sacrificing soundness.

[3]Prototype implementation available at: https://github.com/chihebabid/ros2dss

TABLE V. POSITIONING RDSS WITH RESPECT TO CLASSICAL TECHNIQUES AND TOOLS

Approach / Tool	Main Principle	Limitations	RDSS Perspective
Partial-Order Reduction (POR)	Prunes redundant interleavings by exploiting independence of concurrent transitions	Less effective with synchronous transitions across modules	Applied locally at module level to avoid global blow-up
Symmetry Reduction (SR)	Collapses symmetric states from replicated components	Assumes static symmetry; weak for dynamic or partial symmetries	Combined with τ-hiding and meta-state fusion to preserve behaviors
Abstraction	Groups concrete states into abstract representatives (predicate/counter abstraction)	Risk of oversimplification; may lose critical distinctions	Balanced with stuttering equivalence, ensuring correctness of LTL$\setminus X$
NuSMV	Symbolic model checking with BDD/SAT	Limited scalability for modular decomposition	RDSS avoids global symbolic encoding, scales better for Modular Petri Nets
LTSmin	Symbolic state-space exploration	Handles large systems, but lacks modular reductions	RDSS achieves competitive verification times with lower memory usage (see Fig. 8)
SPIN	Explicit-state temporal logic model checking	No modular decomposition; explores entire global space	RDSS verifies module-specific properties directly using local meta-graphs

In this survey, we have examined the landscape of techniques for scalable verification, including state space reduction, abstraction, compositional reasoning, symbolic methods, and distributed verification. Within this context, we have introduced and positioned the Reduced Distributed State Space (RDSS) framework as a novel and effective contribution. RDSS reduces the global state space into modular meta-graphs, enforces stuttering equivalence, and supports verification at the module level. This enables properties to be checked locally, a capability not offered by existing approaches. Our experimental comparisons against powerful tools such as LTSmin demonstrate the scalability gains of RDSS, particularly when modules are not all synchronized on the same transitions. Furthermore, we have shown that RDSS integrates naturally with techniques such as partial-order reduction, symmetry reduction, and abstraction, achieving strong reductions while maintaining correctness.

Beyond these contributions, the RDSS framework has been extended through a distributed prototype built on ROS2, opening the way to practical deployment in real-world modular systems. Its modular structure makes it especially suitable for verifying concurrent and distributed systems, ranging from multi-robot applications to cloud-based infrastructures.

While challenges such as state explosion and synchronization overhead remain, the trajectory of research indicates a strong movement toward hybrid approaches, combining symbolic encodings, distributed infrastructures, and reduction-based methods. The synergy between theoretical foundations and real-world applications promises a future where scalable verification becomes a standard component of the engineering of next-generation systems. RDSS contributes to this vision by providing a modular, scalable, and extensible verification framework that addresses both academic challenges and industrial needs.

VII. THREATS TO VALIDITY

As with any empirical and methodological contribution, our evaluation and claims are subject to certain threats to validity. We outline the most relevant ones below.

A. Model Representativeness

The benchmarks used (e.g. ERK1, Philo3, Robot1, IoT case studies) are drawn from widely used academic examples of modular and concurrent systems. However, they may not capture the full diversity of industrial-scale systems, especially those with heterogeneous architectures or non-Petri net formalisms. Future work should incorporate larger and more varied case studies to ensure broader coverage.

B. Property Selection Bias

Our focus on stuttering-invariant $LTL \setminus X$ properties, such as deadlock-freedom, local liveness, and reachability, reflects the classes of properties naturally supported by RDSS. Nevertheless, this may bias the evaluation, as other properties (e.g. CTL, fairness, or real-time constraints) are not currently addressed. Extending RDSS to these classes remains an important direction.

C. Tool Configuration Bias

Comparisons with state-of-the-art tools such as LTSmin or SPIN depend on configuration choices (e.g. symbolic encodings, partial-order options, memory allocation). While we sought fair defaults, alternative configurations might yield different relative performance. A more exhaustive benchmarking campaign would provide stronger evidence.

D. Generality Across Formalisms

RDSS is defined over Modular Petri Nets (MPNs), which provide a natural and expressive formalism for concurrent systems. This focus raises a validity threat regarding generality: it remains to be shown to what extent RDSS principles carry over to other formalisms, such as process algebras, timed automata, or hardware verification languages. Initial indications are promising, but further formalization is required.

Overall, these threats highlight the need for additional validation, both empirically (through more benchmarks and diverse case studies) and theoretically (by extending RDSS to broader classes of systems and properties). We report them here to provide a transparent account of the current scope and limitations of our contribution.

VIII. CONCLUSION

The verification of modular concurrent systems is no longer an abstract academic pursuit but a practical necessity for the safe deployment of autonomous platforms, IoT infrastructures, and large-scale distributed software. Ensuring correctness at

scale requires techniques that tame the state explosion problem without sacrificing soundness.

In this survey, we have examined the landscape of techniques for scalable verification, including state space reduction, abstraction, compositional reasoning, symbolic methods, and distributed verification. Within this context, we have introduced and positioned the Reduced Distributed State Space (RDSS) framework as a novel and effective contribution. RDSS reduces the global state space into modular meta-graphs, enforces stuttering equivalence, and supports verification at the module level. This enables properties to be checked locally, a capability not offered by existing approaches. Our experimental comparisons against powerful tools such as LTSmin demonstrate the scalability gains of RDSS, particularly when modules are not all synchronized on the same transitions. Furthermore, we have shown that RDSS integrates naturally with techniques such as partial-order reduction, symmetry reduction, and abstraction, achieving strong reductions while maintaining correctness.

Beyond these contributions, the RDSS framework has been extended through a distributed prototype built on ROS2, opening the way to practical deployment in real-world modular systems. Its modular structure makes it especially suitable for verifying concurrent and distributed systems, ranging from multi-robot applications to cloud-based infrastructures.

Nevertheless, several challenges remain open. Scalability limits may reappear when dealing with extremely large or highly interconnected modular systems, where synchronization overhead can dampen the benefits of reduction. Moreover, while RDSS preserves stuttering equivalence, there are trade-offs between accuracy and efficiency, particularly when aggressive fusion of meta-states or τ-hiding strategies are applied. Another promising direction lies in complementing RDSS with AI-driven heuristics that guide exploration or with hybrid reductions that combine symbolic encodings and distributed infrastructures. Such extensions would strengthen the adaptability of RDSS across diverse system classes and push its applicability to industrial-scale deployments.

The synergy between theoretical foundations and real-world applications promises a future where scalable verification becomes a standard component of the engineering of next-generation systems. RDSS contributes to this vision by providing a modular, scalable, and extensible verification framework that addresses both academic challenges and industrial needs, while opening avenues for innovation in hybrid and AI-augmented verification methods.

New Explainable Overlapping Co-Clustering for Recommender Systems: Capturing Multifaceted Preferences with Enhanced Interpretability

Chiheb Eddine Ben Ncir, Mohammed Ibrahim Alattas
College of Business, University of Jeddah, Saudi Arabia

***Abstract*—Recommender systems have become critical tools in reducing information overload by providing personalized recommendations across several application domains including commerce, industry, education, academic research, etc. Clustering-based recommender systems, which use the clustering technique to group similar users or items to generate suggestions, have shown high accuracy and efficiency. However, conventional clustering methods often fail to address several challenges such as ignoring the possibility that a user may have different item preferences, limited interpretability of generated suggestions, and the inability to tailor recommendation list sizes to individual user needs. To address all these issues, we propose in this work a new recommender system based on Overlapping Co-clustering and Modularity Maximisation (OCCMM). The proposed method allows to take into account that users may have several item preferences by building overlapping clusters rather than the conventional non-overlapping model. Also, the proposed method adopts a simultaneous clustering of items and users to facilitate the generation and interpretation of suggestions through using the co-clustering technique. Furthermore, OCCMM enables an adjustment of recommendation list sizes based on an easy tunning parameter δ. Experiments conducted in three real-world datasets demonstrated the effectiveness of OCCMM in achieving better performance in terms of accuracy and interpretability compared to conventional existing methods.**

***Keywords*—Clustering-based recommender systems; modularity maximization; overlapping co-clustering; multiple-user-preferences; recommendation interpretability**

I. Introduction

Recommender systems play a vital role in addressing the challenge of information overload and providing personalized recommendations in various domains. These systems have become valuable tools for companies to deliver targeted information to users or customers. The implementation of a high-performance recommender system is usually based on various machine-learning methods and techniques such as clustering which allows for the grouping of similar users or items into the same cluster. The generation of recommendations is based on similar items or users belonging to the same cluster. Such Clustering-based recommender systems are usually characterized by an improved running time with high accuracy of recommendations [1].

Typically, clustering methods used in recommender systems have focused on either user-based or item-based recommendations. User-based recommendations focus on similarities between users where recommendations are generated based on the preferences and behavior of similar users. This recommendation approach is relatively simple to implement as it only requires user-item interaction data. However, it faces challenges when dealing with new users who have limited data or when recommending items with limited user feedback, which leads to less accurate recommendations. On the other side, item-based recommendations focus on similar items rather than users and tend to be more stable as item preferences are less likely to change compared to user preferences. Item-based recommendations allow to effectively handle new items since similar item characteristics can be used to recommend them. However, this approach may lead to less personalized recommendations since it focuses on item-item similarities and ignores user preferences.

To take advantage of both user-based and item-based approaches, the co-clustering technique can be used rather than using the clustering technique. The Co-clustering allows for simultaneous grouping of users and items allowing recommendations to be based on both characteristics simultaneously [2] [3]. However, most existing co-clustering methods assume non-overlapping co-clusters and do not allow overlaps between groups. Nevertheless, in real-life applications, users may have multiple preferences and items can satisfy multiple user needs resulting in overlapping co-clusters. Overlapping co-clustering can yield more accurate recommendation results by capturing all user's preferences and item needs. Additionally, a shortcoming with existing clustering-based recommendation methods is the absence of options for regulating the size of the recommendation list. This lack of control hampers the flexibility of the recommendation system, making it challenging to customize the number of recommendations according to user preferences.

To address all these challenges, this paper proposes a dual contribution at both the theoretical and practical levels. From a theoretical perspective, it advances the literature on recommender systems by introducing a novel formulation of the Overlapping Co-Clustering with Modular Maximization (OCCMM) framework. Unlike existing works, the proposed model integrates 1) an enhanced algorithmic formulation that optimizes modularity while supporting overlapping user–item clusters, 2) an explicit interpretability mechanism that allows practitioners to understand why certain recommendations are generated, and 3) a tunable list sizing strategy that adapts dynamically to users' contextual needs. From a practical perspective, the framework proposes explainable recommendations in domains where transparency is critical, such as e-commerce, tourism, and educational platforms. We will show the ability of the proposed OCCMM model not only to generate explanations that are transferable and generalizable to other application areas.

The rest of the paper is organized as follows: Section II presents the fundamental concepts of recommender systems. Section III discusses the challenges addressed by the proposed approach. Section IV provides a detailed theoretical framework for the overlapping co-clustering method based on modularity maximization. Section V presents the experimental results and evaluates the performance of our approach using real-world datasets. Finally, Section VI concludes the paper and outlines directions for future research.

II. Fundamental Concepts of Recommender Systems

With the exponential growth of available information across databases, web pages, and social networks, the task of extracting valuable information for users has become increasingly challenging. Users often struggle to quickly and easily find items of interest in this huge amount of available data. To address this issue, automatic recommendation tools, known as Recommender Systems (RS), have been developed. The primary objective of these systems is to minimize the time of searching and providing personalized suggestions. By analyzing extensive amounts of data through a variety of techniques and algorithms [4], these computing-based systems try to generate personalized recommendations for products or services based on individual user preferences [5]. These recommendations can span a wide range of categories, such as articles to read, products to purchase, music to listen to, movies to watch, or web pages to visit.

The effectiveness of recommendations and suggestions mainly rely on the system input data types which can be categorized into two main types: Explicit and Implicit Feedback Data. Explicit feedback data refers to information provided by users in a clear and detailed manner, typically in the form of ratings given to a set of products. This type of data directly expresses the user's preferences. On the other hand, implicit feedback data is automatically collected based on user behavior and then transformed into user preferences. Examples of implicit feedback data include clicks on links, browsing history, the number of times a song is played, or the percentage of a web page scrolled. These data are collected, converted into user preferences, and then utilized to generate recommendations.

The collected data are often represented on a scale to indicate the level of interest in a particular item. It can take various forms, such as continuous values, as seen in the Jester joke recommendation engine [6], where jokes are rated on a scale from -10 to 10. Data can also be modeled using intervals, where the lowest value represents a strong dislike and the highest indicates a strong liking for an item. Another approach is to model ratings as ordered categorical values, enabling the extraction of all possible user ratings. The commonly used set of categories includes "Strongly Disagree", "Disagree", "Neutral", "Agree" and "Strongly Agree". Ratings can also be represented as binary data, where users express their preferences as either liking or disliking an item. Additionally, a specific data type known as unary rating data can be used in recommender systems, where users only have the option to define a like for an item without the ability to specify a disliking. All these different types of data play a vital role in building accurate and effective recommender systems, allowing for the generation of personalized recommendations tailored to individual user preferences.

A. Recommender System Approaches

The definition and the building of recommender systems can be based on several approaches. Three main approaches can be identified: *Collaborative filtering*, *Content-based filtering*, and *Knowledge-based filtering*. The first approach, collaborative filtering, operates on the assumption that users with similar interests may have the same item preferences. Collaborative filtering methods can be roughly divided into two categories : *User-based* and *Item-based* collaborative filtering. The User-based collaborative filtering identifies an ensemble of users who are similar to a target user (i.e. n neighbors). Based on the neighbor's ratings, it predicts the possible rating(s) to a list of products not yet purchased (i.e. product(s) to be recommended) or the top N-recommended products. In this technique, similarity functions are calculated between rows of rating matrix to extract similar users [4]. The second collaborative filtering category, Item-based, tries to extract the highly correlated items (similar items) to the ones that target users are interested in. The extracted items are considered as recommendations. In this category, similarity functions are computed between the columns of the rating matrix, rather than rows, to discover similar items [4].

Concerning the second recommender systems approach, *Content-based filtering*, both user ratings and item properties are used to build recommendations. In this approach, the similarity is calculated based on item features (i.e. product content). Recommended items consist of the filtered list of similar products to those a target user shows high interest. Such type of filter does not suppose that other users must make recommendations for the target user. Based only on what the target user likes, the algorithm will simply pick items with similar contents and recommend them to that user. A content-based filtering system recommends items based on the correlation between the content of the items. This approach is different from the collaborative filtering approach which recommends items based on the correlation between users/items with similar preferences [7].

The third recommender systems approach, knowledge-based, aims to provide recommendations based on product properties, issued by the user, instead of using the history of users' preferences. This approach allows users to explicitly express their desires or explicitly indicate their item preferences before the generation of recommendations. A recommender system is considered "knowledge-based" when it prompts the user to give a series of rules or guidelines on what the results should look like or an example of an item. Then, the system searches through its database of items and returns similar results [8].

B. Related Works: Clustering-Based Recommender Systems

Clustering has been used as a significant technique in the design and the implementation of scalable and efficient recommender systems, known as clustering-based recommender systems. Such systems are based on clustering algorithms to group users or items based on shared preferences or behaviors. The built segments of items or users allow for the recommendation system to focus on specific group characteristics

to improve the computational efficiency and to address data sparsity challenges and cold start problem [9]. For instance, the authors in [10], [11] and [12] used clustering to efficiently recommend news articles based on user interests. The author in [13] leveraged clustering in smart grid applications to enhance recommendations. Ahuja et al. [14] built a Movie recommender system using K-Means clustering and K-Nearest Neighbor. The authors in [15], [16] and [17] utilized clustering in tourism recommendation to group users with similar travel interests.

Recent advancements in clustering-based recommendation systems explore various clustering algorithms and approaches to optimize system performance, user satisfaction, and computational efficiency. Existing methods can be grouped into three main approaches: user-based, item-based, and hybrid.

The first, user-based, groups users with similar behaviors in the same cluster and then recommendations are generated based on local preferences within each cluster. For instance, Yu et al. [18] proposed ClusterFedMet [18], a recommendation algorithm that addresses the challenges of recommendations in federated learning environments. ClusterFedMet improves recommendation accuracy and personalization while keeping data privacy. Additionally, Hosen et al. [19] proposed an optimized recommender system, using PSO-optimized K-means clustering, able to create patient-specific diet recommendations based on historical health data. The proposed system ensures rapid and relevant dietary suggestions for thyroid patients.

On the other hand, the second approach, item-based, allows to group similar items having shared attributes or similar user-interactions[20]. Zhang and Wu [21] developed an e-commerce recommendation model that integrates K-means with a genetic algorithm to enhance recommendation accuracy and speed. The proposed model has a significant boost in item relevance and user satisfaction compared to existing ones. Rather than using a simple clustering method, Airen and Agrawal [22] applied the co-clustering technique in movie recommendations. The fine-tuning of user and movie neighborhood parameters allowed to increase recommendation quality. Their model showed notable improvements in accuracy by leveraging a partitioned clustering approach within large movie datasets.

Concerning the third approach, hybrid clustering, it combines both user and item clustering to simultaneously capture user preferences and item characteristics, leading to a comprehensive recommendation strategy with improved suggestions accuracy and relevance. A recent example of hybrid systems proposed by Wang et al. [23] for tourism recommendation combines multiple recommendation methods, including collaborative filtering and neural networks, to suggest different and relevant tourist spots. A multi-objective approach is used to suggest recommendations that allows to enhance users travel experience. Another hybrid approach, proposed by Iftikhar et al. [24] use bi-clustering within a reinforcement learning framework to adapt recommendations to changing user preferences. This model allows to capture local patterns in user-item interactions by combining bi-clustering with Markov Decision Processes which makes it effective for dynamic recommendation scenarios. Furthermore, another system proposed by Forouzandeh et al. [25], referred to as RESCHet, embeds spectral clustering in heterogeneous networks to analyze relationships in complex item-user networks. The use of spectral clustering to group item-user interactions made it ideal for large datasets where traditional clustering methods may fall short.

All these presented approaches were based on common Clustering algorithms including k-means, hierarchical clustering, density based and Gaussian Mixture Models. The choice of the clustering technique and also the choice of the similarity metric are usually based data characteristics and application requirements. For example, when dealing with sparse datasets, k-means++ or DBSCAN may be favored due to their robustness against sparse data [26]. A good choice of these techniques has a direct impact on the accuracy of the system. Although the effective application of clustering techniques in recommendation systems, conventional techniques may oversimplify the complexity of user preferences by assigning each user or item to a single cluster. However, in real life applications, a more flexible approach is mandatory since users or items may have several preferences and then may belong to multiple clusters. For example, when recommending movies, a user may have interests in both “romantic” and “action” genres of films. This reflects the multifaceted nature of user preferences and the necessity to use more sophisticated and flexible clustering models.

As a solution for the multifaceted nature of user preference, Overlapping clustering methods have proven to be particularly useful in capturing these diverse preferences [27], [28], [20]. Recent works illustrate the advantages of overlapping clustering in various domains. For instance, Heckel and Vlachos [27] introduced a matrix factorization-based approach to identify overlapping co-clusters of clients and products. This method emphasizes interpretability by recommending items that are members of multiple co-clusters. Effectiveness is shown especially in large datasets making it ideal for business-to-business applications. Besides, Vlachos et al. [28] expand the overlapping co-clustering concept to address cold-start problems in matrix factorization. Flexibility of recommendations is improved by allowing users and items to participate in multiple clusters. This flexibility ensures that new users or items are matched effectively which avoids the limitations of traditional clustering methods. Rezghi and Baratnezhad [2] also proposed fuzzy co-clustering methods using non-negative matrix factorization. Overlapping clustering is used to improve the quality of recommendations by reflecting users’ diverse preferences. The proposed approach achieved better sparcity reduction and accuracy compared to non-overlapping methods. Iftikhar et al. [24] also employed overlapping co-clustering within a reinforcement learning framework. By allowing users and items to belong to multiple bi-clusters, the proposed model allowed to effectively capture local patterns and dynamic preferences compared to static collaborative filtering methods, especially in dynamic environments where user preferences may evolve over time. Furthermore, the authors in [29] explored fairness improvement in recommender systems using overlapping clustering. They propose grouping users based on interactions and sensitive attributes, such as age or gender, to provide equitable recommendations across diverse user groups. Overlapping clustering have lead to more balanced outcomes and improved fairness metrics. In the same way, the authors [30] leveraged overlapping clustering to optimize recommendation diversity and novelty. By allowing overlaps, users can explore new items while maintaining access to

familiar favorites. This design has significantly enhanced the diversity of recommendations without compromising precision.

III. Motivation and Research Gap

The design of effective clustering-based recommender systems remains a major research challenge given that these systems must simultaneously ensure accuracy, diversity, interpretability, and computational efficiency. While numerous clustering methods have been proposed, their application to recommender systems still suffer from fundamental limitations that restrict their theoretical and practical contributions.

A first challenge relates to the treatment of user and item clusters as mutually exclusive. Existing clustering-based approaches assume that a user or an item belongs to a single homogeneous group. However, in real-world applications, user preferences are often heterogeneous and multidimensional. For instance, a movie enthusiast may simultaneously enjoy action, drama, and comedy genres, while a book reader may have overlapping interests in historical fiction, biographies, and mystery. Ignoring such overlaps leads to rigid partitions that fail to capture the nuanced and overlapping structures of user preferences. An overlapping co-clustering approach, by contrast, can represent these multifaceted relationships more faithfully and can lead to more personalized recommendations.

A second critical issue concerns interpretability. Recommender systems users usually demand greater transparency regarding the rationale behind generated recommendations. Existing clustering-based methods typically optimize predictive accuracy but fall short in providing explainable justifications for their outputs, particularly when overlapping user–item relationships are involved. Co-clustering offers a promising solution by jointly segmenting users and items. Co-clustering makes it possible to explain recommendations in terms of shared membership across multiple co-clusters which directly improves trust, accountability, and user acceptance.

A third methodological gap concerns the tailoring of recommendation list sizes. Current systems frequently adopt fixed-length recommendation lists, overlooking the dynamic and context-dependent nature of user needs. This "one-size-fits-all" strategy reduces the relevance of recommendations. It becomes possible to adapt list sizes dynamically by integrating the degree of overlap in user–item co-clusters. Such flexibility enables the system to remain context-aware and user-centric, thereby enhancing recommendation utility.

Despite recent advances, existing approaches still exhibit significant limitations. Conventional hard-partition methods remain insufficient to capture multi-faceted user preferences, while soft-clustering approaches provide smoother decision boundaries but lack the structured dual segmentation of co-clustering. Moreover, current methods rarely balance the trade-off between interpretability and predictive performance; most prioritize one dimension at the expense of the other. Finally, although prior studies have begun to explore dynamic list adaptation [2], [30], there is no comprehensive framework that unifies overlap-based co-clustering with modularity maximization, interpretability mechanisms, and personalized list sizing.

To address these gaps, this paper proposes an Overlapping Co-Clustering approach with Modularity Maximization. The framework contributes novel theoretical and practical advancements by: 1) capturing complex overlapping structures of user–item interactions, 2) integrating interpretability into the clustering process to support explainable recommendations, and 3) dynamically adapting list sizes to user contexts. This approach directly responds to the discussed challenges and establishes a more accurate, interpretable, and adaptable recommender system.

IV. Proposed Method: Recommendation based on Overlapping Co-Clustering and Modularity Maximization

The proposed method, called Overlapping Co-clustering with Modularity Maximization (OCCMM), is designed to provide overlapping co-clusters based on modularity maximization using implicit feedback data. The overlapping co-clusters will be then explored to generate flexible and easily interpretable recommendations. The proposed OCCMM method begins by representing the data of the recommender system as a bipartite graph, where users and items are represented as distinct types of vertices. The edges of the graph correspond to the positive feedback given by users on the items. To illustrate the designed OCCMM recommendation process, we have schematized the main steps in Fig. 1. Our proposed method consists of three key steps. First, it begins by building a binary matrix from the bipartite graph. Next, it focuses on creating an ensemble of co-clusters, which will be utilized in the final step to generate recommendations. In the following subsections, we provide a detailed breakdown of the tasks involved in each step of the OCCMM process.

A. Step 1: Data Preprocessing

The data preprocessing step has the objective of effectively transforming the input bipartite graphs of the recommender system into a binary adjacency matrix. Let $G = (N, M, E)$ be the input bipartite graph, where N represents the set of user nodes, M the set of item nodes and E represents the set of edges. The objective is to transform the bipartite Graph G into a binary adjacency matrix $D = (N \times M)$. The value $d_{nm} = 1$ indicates the existence of a relationship (edge in the graph G) between the user node n and the item node m. The adjacency matrix D encompasses all relationships between users and items, serving as implicit feedback data that will be automatically segmented into k overlapping co-clusters to detect similarities between items and users simultaneously. Fig. 1 shows an example of transforming a bipartite graph containing $N = 6$ users and $M = 4$ items into an adjacency matrix $D = (6 \times 4)$ where entries $d_{nm} = 1$ represents the existence of an edge between user n and item m. For instance, the edge between $user_1$ ($n = 1$) and $item_1$ ($m = 1$) indicates that $user_1$ bought $item_1$, prefers it, or any other relevant connection between $user_1$ and $item_1$ resulting in $d_{11} = 1$.

B. Step 2: Generation of Co-Clusters

Given the implicit feedback data matrix $D = (N \times M)$ obtained from the previous step, the objective of the second step is to look for optimal k co-clusters of users $U(N \times k)$ and items $I(M \times k)$ simultaneously based on an iterative modularity-maximization-based process. As described in the

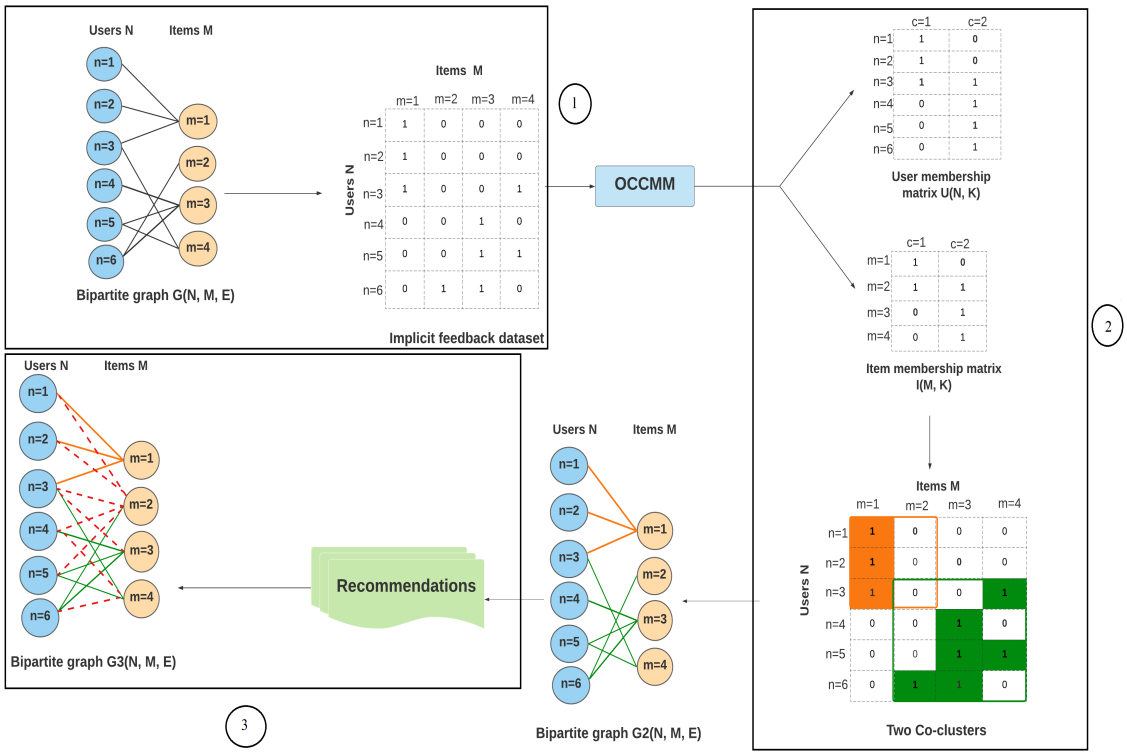

Fig. 1. The designed recommendations steps via the proposed OCCMM method. Step 1 : Data preprocessing, Step 2: generation of co-clusters, Step 3: Generating recommendations using Co-clusters.

works of [27] that uses a modularity maximization of a network for building optimal co-clusters, we define the following modularity objective function for the feedback data:

$$Q(U,I) = \frac{1}{|D|}\sum_{n=1}^{N}\sum_{m=1}^{M}\sum_{c=1}^{k}(d_{nm} - \frac{d_n d_m}{|D|})u_{nc}i_{mc} \quad (1)$$
$$-\sum_{n=1}^{N}\sum_{c=1}^{k}u_{nc}\log u_{nc} - \sum_{m=1}^{M}\sum_{c=1}^{k}i_{mc}\log i_{mc}$$

where, $|D| = \sum_n \sum_m d_{nm}$ represents the total number of edges in the network, $d_{nm} \in \{0,1\}$ is an element of the feedback matrix equal to one when a positive feedback of the user n on item m exists, $d_n = \sum_{m=1}^{M} d_{nm}$ and $d_m = \sum_{n=1}^{N} d_{nm}$ represent the degree of user node n and the degree of item node m respectively. The values $u_{nc} \in [0,1]$ and $i_{mc} \in [0,1]$ indicate the fuzzy membership degrees that user n and item m belong to cluster c, respectively. The values $\sum_{n=1}^{N}\sum_{c=1}^{k} u_{nc}\log u_{nc}$ and $\sum_{m=1}^{M}\sum_{c=1}^{k} i_{mc}\log i_{mc}$ denote the separate entropy regularizing users and items membership degree functions separately. The minimization of these two values corresponds to maximizing the fuzzy entropy $-\sum_{n=1}^{N}\sum_{c=1}^{k} u_{nc}\log u_{nc}$ and $-\sum_{m=1}^{M}\sum_{c=1}^{k} i_{mc}\log i_{mc}$.

The maximization problem of the objective function Q respecting to optimal matrices (U) and (I) can be described follows:

max

$$Q(U,I) \quad (2)$$

subject to

$$\sum_{c=1}^{N} u_{nc} = 1, \quad u_{nc} \in [0,1], \quad \forall n = 1,\ldots,N \quad (3)$$
$$\sum_{c=1}^{M} i_{mc} = 1, \quad i_{mc} \in [0,1], \quad \forall m = 1,\ldots,M \quad (4)$$

This problem can be solved through the application of the Lagrange method, involving the utilization of Lagrange multipliers ζ_a and η_b corresponding to constraints (3) and (4) respectively. Eq. (1) can be expressed as:

$$\begin{aligned} Q(U,I) =& \frac{1}{|D|}\sum_{n=1}^{N}\sum_{m=1}^{M}\sum_{c=1}^{k}\left(d_{nm} - \frac{d_n d_m}{|D|}\right)u_{nc}i_{mc} \\ &- \sum_{n=1}^{N}\sum_{c=1}^{k}u_{nc}\log u_{nc} - \sum_{m=1}^{M}\sum_{c=1}^{k}i_{mc}\log i_{mc} \\ &+ \sum_{n=1}^{N}\zeta_n\left(\sum_{c=1}^{k}u_{nc} - 1\right) + \sum_{m=1}^{M}\eta_m\left(\sum_{c=1}^{k}i_{mc} - 1\right) \end{aligned} \quad (5)$$

By deriving (Q) with respect to (U) and (I) and setting the gradient to zero, the following expressions are obtained:

$$\frac{\partial Q}{\partial U} = \sum_{m=1}^{M} \left(d_{nm} - \frac{d_n d_m}{|D|} \right) i_{mc} - (1 + \log u_{nc}) + \zeta_n = 0$$
$$\Longleftrightarrow$$
$$u_{nc} = \frac{\exp\left(\sum_{m=1}^{M} \left(d_{nm} - \frac{d_n d_m}{|D|} \right) i_{mc} \right)}{\sum_{c=1}^{k} \exp\left(\sum_{m=1}^{M} \left(d_{nm} - \frac{d_n d_m}{|D|} \right) i_{mc} \right)} \tag{6}$$

$$\frac{\partial Q}{\partial I} = \sum_{n=1}^{N} \left(d_{nm} - \frac{d_n d_m}{|D|} \right) u_{nc} - (1 + \log i_{mc}) + \eta_m = 0$$
$$\Longleftrightarrow$$
$$i_{mc} = \frac{\exp\left(\sum_{n=1}^{N} \left(d_{nm} - \frac{d_n d_m}{|D|} \right) u_{nc} \right)}{\sum_{c=1}^{k} \exp\left(\sum_{n=1}^{N} \left(d_{nm} - \frac{d_n d_m}{|D|} \right) u_{nc} \right)} \tag{7}$$

Eq. (6) and (7) refer to the fuzzy membership of user n to co-cluster c and the fuzzy membership of item m to co-cluster c, respectively. When the membership degrees of user n and item m surpass a threshold θ defined in Eq. (8), u_{nc} and i_{mc} are set to 1, signaling the membership of user n and item m to co-cluster c.

$$\theta = \left(\frac{1}{k} + \frac{1}{\delta \times k} \right) \tag{8}$$

where, k denotes the number of co-clusters and $\delta \in]1, +\infty[$ represents a user-defined parameter introducing flexibility in recommendations. A higher value of δ yields a more extensive list of recommendations, while a lower value restricts the recommendations.

To look for optimal overlapping co-clusters that maximize the overall modularity function, the optimization process starts with random initializations of matrices U and I and an initial modularity score Q_0. Subsequently, a series of operations are iterated by computing new optimal values for user cluster memberships u_{nc} and item cluster memberships i_{mc} using Eq. (6) and (7), respectively. Following this, a new modularity score $Q_t(U, I)$ at iteration t is recalculated based on these updated memberships. This iterative procedure continues until the modularity score remains unchanged or a maximum iteration limit is reached, offering a systematic approach to organizing users and items into fuzzy co-clusters. The final overlapping co-clusters are then built by assigning users and items to similar co-clusters if their membership probabilities surpass a predefined threshold θ. A pseudo-code of the Overlapping Co-clustering via Modularity Maximization algorithm is described in Algorithm 1.

In the context of clustering, modularity allows to measure how well a network is divided into clusters by comparing the actual connections to a randomly connected network. In our context, we aim to find co-clusters of users and items that maximize a certain modularity that ensures users in the same cluster interact with similar items more frequently than a randomly expected one. Based on the adjacency matrix $D(N \times M)$ of users U and items I, the modularity function $Q(U, I)$ evaluates how well users and items are grouped into overlapping co-clusters while maintaining statistical significance. The term $d_{nm} - \frac{d_n d_m}{|D|}$ captures the difference between the actual interactions and the expected random interactions, ensuring that clusters a better meaningful relationships. Entropy terms (log functions) encourage fuzzy membership, indicating that users and items can belong to multiple co-clusters rather than a strict one-to-one assignment.

Algorithm 1 Overlapping Co-clustering via Modularity Maximization

Input: D= Original data matrix, k= number of co-cluster, δ: recommendation flexibility parameter, IterationLimit: Number of maximal iterations

Output: Co-clusters matrices U and I

```
Random initialization of U and I
repeat
  Compute u_nc according to Formula (6)
  Compute i_mc according to Formula (7)
  Compute Q(U, I) using Formula (1) based on u_nc and i_mc
until Unchanged Q(U,I) or IterationLimit
for n = 1 to N do
  for c = 1 to k do
    if u_nc > θ then
      Assign the user n to the co-cluster c
    end if
  end for
end for
for m = 1 to M do
  for c = 1 to k do
    if i_mc > θ then
      Assign the item m to the co-cluster c
    end if
  end for
end for
End
```

C. Step 3: Generating Recommendations using Co-Clusters

The third step is devoted to building recommendations based on the obtained overlapping co-clusters. This step is based on the hypothesis that users and items within the same co-cluster exhibit a strong correlation. By leveraging the relationships identified in the co-clusters, the algorithm generates personalized recommendations for users based on items they have not yet purchased but are correlated within the same co-cluster. An item becomes a potential recommendation for a user when both the user and the item are grouped in the same co-cluster but lack a direct link (e.g. a purchase).

The pseudo-code of generating recommendations using overlapping co-clustering is described in Algorithm 2. Given the input data matrix D and the overlapping co-clusters U and I, the recommendation algorithm examines each user-item pair in the dataset. In cases where the user has not interacted with the item ($d_{nm} = 0$), the algorithm checks if that user and that item belongs to the same co-cluster. If this condition is satisfied, the item is included in the recommendation list for that user.

In Fig. 1, colored squares within co-clusters represent positive or implicit examples, while white squares inside the co-clusters signify recommendations. Analogous to graph theory, the task consists in predicting probable edges in the graph $G(N, M, E)$ for near nodes. The predicted edges, shown as red dotted lines in the $G(N, M, E)$ graph, correspond to user recommendations.

Algorithm 2 Recommendation using Overlapping Co-Clusters

Input: D: Original data matrix, U, I: Overlapping Co-clusters
Output: Users recommendation lists

```
for n = 1 to N do
  for m = 1 to M do
    if d_nm=0 then
      {The user n has not yet purchased the item m}
      for c = 1 to k do
        if u_nc = 1 and i_mc = 1 then
          {Item m and user n are in the same co-cluster}
                        n-RecommendedList ← m
        end if
      end for
    end if
  end for
end for
End
```

D. Computational Effectiveness

The OCCMM computational complexity can be evaluated through the computational complexity of its three main steps: data preprocessing, generation of overlapping co-clusters, and recommendation generation. The computational complexity of the first step, data preprocessing, involves constructing a binary adjacency matrix from the bipartite graph $G(N, M, E)$ and requires iterating over the edges. The computational complexity of this step is approximated by $O(E)$. The second step, co-cluster generation, is the most computationally consuming as it involves iteratively optimizing the user-item matrix based on the proposed modularity-maximization process. The computational complexity of the modularity function requires $O(NM)$ operations per iteration, and updating the membership matrices involves summing over all users and items, leading to a complexity of $O(kNM)$ per iteration, where k is the number of co-clusters. Given that this process is repeated until convergence with a maximal iteration number of t, the total computational complexity of the second step can be evaluated by $O(TkNM)$. Concerning the third step, recommendation generation, involves checking all user-item pairs to determine potential recommendations based on co-cluster memberships, which is approximated by $O(kNM)$. Summing all the computational costs across the three steps, the overall OCCMM computational complexity is evaluated by $O(TkNM)$. In practical applications, this computational complexity can be considered efficient. In real-world applications, the number of iterations T required for convergence is generally small, and the number of co-clusters k is significantly smaller than N and M, which largely reduces excessive computational demands. Consequently, OCCMM can be approximated by $O(NM)$ making it effective even with large-scale recommender systems.

V. Experiments and Empirical Results

A. Datasets Description

To assess the effectiveness of our method, we employed three real-world datasets, each offering distinct types of implicit feedback. The first dataset, from the CiteULike website[1], contains user-curated collections of scientific articles. This dataset comprises $5,551$ users and $16,980$ articles, and the goal is to generate new article recommendations based on these positive examples. In this dataset, recommendations are only based on binary implicit feedback, where each user's collection of articles is treated as positive examples. The data is represented as a binary matrix $D = N \times M$, where $d_{nm} = 1$ indicates that user n has added article m to their collection, and $d_{nm} = 0$ indicates the absence of that article.

The second dataset is a subset of the Last.fm dataset[2], which captures listeners' preferences for artists in a binary form. This dataset consists of $1,226$ listeners and 285 artists and the recommendation task consists of recommending likely preferred artists for each listener based on their implicit feedback. In this dataset, the input matrix $D = N \times M$ has $d_{nm} = 1$ if listener n has shown interest in artist m, and $d_{nm} = 0$ otherwise.

The third dataset is the Movielens dataset which contains $100,000$ movie ratings from 671 users on $9,066$ movies. Users rate movies on a scale of 1 to 5 stars, and we follow the convention from previous research [31], [32] by considering ratings of 3 or higher as positive feedback and ignoring lower ratings. This dataset is also transformed into a binary matrix, with ratings of 3 or above taking a value of 1. The task is to generate movie recommendations based on these positive ratings. Across all datasets, the recommendation problem is modeled as generating new suggestions using implicit feedback, represented consistently in binary matrix form.

Table I summarizes the description of used datasets by giving the number of users, the number of items, and the recommendation task for each dataset.

TABLE I. Datasets Description

Datasets	Users	Items	Recommendation Objective
CiteUlike	5551	16980	Article recommendation
LastFm	1226	285	Music recommendation
Movielens	671	9066	Movie recommendation

The selected datasets were chosen to validate different aspects of our model, including its robustness, ability to model complex user preferences, and performance across varying levels of data density. The CiteULike dataset was chosen for its high sparsity making it a challenging scenario to test OCCMM's ability to handle sparse academic interactions. CiteULike contains approximately 5500 users, 17000 articles,

[1]Launched in October 2004 at the University of Manchester and closed permanently on March 30, 2019.

[2]https://www.last.fm/

and 200000 interactions. The LastFm dataset, containing 1900 users, 17600 artists, and 92800 interactions, was selected due to its representation of diverse musical preferences and multi-genre listening behaviors, allowing for assessing OCCMM's capability to capture overlapping user interests. Finally, we included the Movielens dataset, a relatively denser dataset that enables us to evaluate the scalability and generalizability of OCCMM in less sparse settings.

B. Evaluation Methodology

We assessed the efficacy of the recommendations by measuring Recall and Precision [33]. Fig. 2 schematizes the different steps to calculate Precision and Recall measures to evaluate generated recommendations. The dataset is split into training and testing sets by removing a portion of interactions for each user, simulating unseen data. For instance, with a test set ratio of 0.2, if a user had 10 interactions, 8 were allocated to training, and 2 were reserved for testing. Subsequently, the training data was fed into the OCCMM algorithm to form co-clusters. These co-clusters were then used to generate recommendations. Finally, the test set was utilized to evaluate the recommendation outcomes based on Precision and Recall metrics.

The Precision metric quantifies the ratio of relevant items among the retrieved items, aiming to gauge the proportion of recommended items that are pertinent. It is calculated in Eq. (9) as:

$$Precision\ (n) = \frac{|\{m : d_{nm} = 1\} \cap \{m_1, ..., m_Z\}|}{\{m_1, ..., m_Z\}} \quad (9)$$

where: $|\{m : d_{nm} = 1\}|$ denotes the list of relevant items, $|\{m_1, ..., m_Z\}|$ represents the list of recommended items, and $|\{m : d_{nm} = 1\} \cap \{m_1, ..., m_Z\}|$ represents the list of recommended items that are relevant.

Then, the Recall measure assesses the fraction of relevant items that have been retrieved out of the total relevant items. It measures the proportion of relevant items recommended by the system and is calculated in Eq. (10) as:

$$Recall\ (n) = \frac{|\{m : d_{nm} = 1\} \cap \{m_1, ..., m_Z\}|}{|\{m : d_{nm} = 1\}|} \quad (10)$$

To provide a single balanced score, we build the F_Measure, described in Eq. (11), by computing the harmonic mean of Precision and Recall as follows:

$$F_Measure(n) = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (11)$$

As for precision and Recall, a higher F_Measure value indicates a superior recommendation system. The maximum attainable value for the F_Measure is 1, reflecting perfect precision and recall alignment, while the minimum score is 0, indicating a lack of precision and recall balance.

Furthermore, we assess the Average Recommendation metric (Eq. (12)) that calculates the percentage of recommendations provided for each user, crucial for evaluating recommendations generated from overlapping co-clusters. A high recommendation rate is considered when this value exceeds 50%, indicating that each user receives over half of the recommendations and is computed as:

$$Average_Recommendation = \frac{\sum_{n=1}^{N}\{m_1, ..., m_z\}}{N} \times \frac{1}{M} \quad (12)$$

where, N and M are respectively the total numbers of users and items and $\sum_{n=1}^{N}\{m_1, ..., m_z\}$ represents the total number of recommended items.

C. Number of Co-Clusters and Number of Iterations Parameters

The quality of co-clusters and the convergence of the OCCMM method relies significantly on the pre-determined parameters : size of co-clusters K and the number of iterations. A successful determination of these two parameters can lead to enhanced recommendation quality [27]. Concerning the choice of the optimal number of co-clusters K, we determined this value across various evaluations of co-clusters and modularity values. Fig. 3 gives the obtained scores of modularity by considering different values of co-clusters evaluated on all the three datasets. The plot illustrates distinct modularity patterns across the three datasets (CiteUlike, LastFm, and Movielens) as the number of co-clusters varies. For CiteUlike, the modularity peaks at 0.570 with 22 co-clusters, but it declines beyond this point which suggests overfitting as additional co-clusters are introduced. LastFm shows a more gradual trend, with a peak modularity of 0.312 obtained with 16 co-clusters. Movielens peaks at 0.398 with only 5 co-clusters suggesting that this dataset has fewer distinct clusters. Its modularity decreases rapidly as more co-clusters are added which indicates that the dataset may have a simpler structure and is more sensitive to over-segmentation. All these obtained scores show that all three datasets exhibit a clear peak modularity followed by a decline, reflecting a tendency toward overfitting when the number of co-clusters becomes too large. However, the variation in peak modularity and the number of co-clusters across the datasets highlights differences in their inherent complexity. CiteUlike requires a higher number of co-clusters to capture its structure, whereas Movielens has a much simpler grouping, as indicated by its peak with only 5 co-clusters. This emphasizes the importance of dataset-specific tuning when applying co-clustering methods to maximize modularity.

As for co-clusters, we also studied the influence of the number of iterations parameters in the convergence of the proposed OCCMM method. This study involved evaluating OCCMM modularity across varying number of iterations for CiteUlike, Lastfm, and Movielens datasets. Fig. 4 illustrates the convergence behavior of OCCMM for each dataset over multiple number of iterations. For CiteUlike, the modularity starts close to zero and rapidly increases in the first 10 iterations, with minimal further improvements beyond 10 iterations. For LastFm, the modularity starts similarly near zero but increases more gradually than CiteUlike, eventually

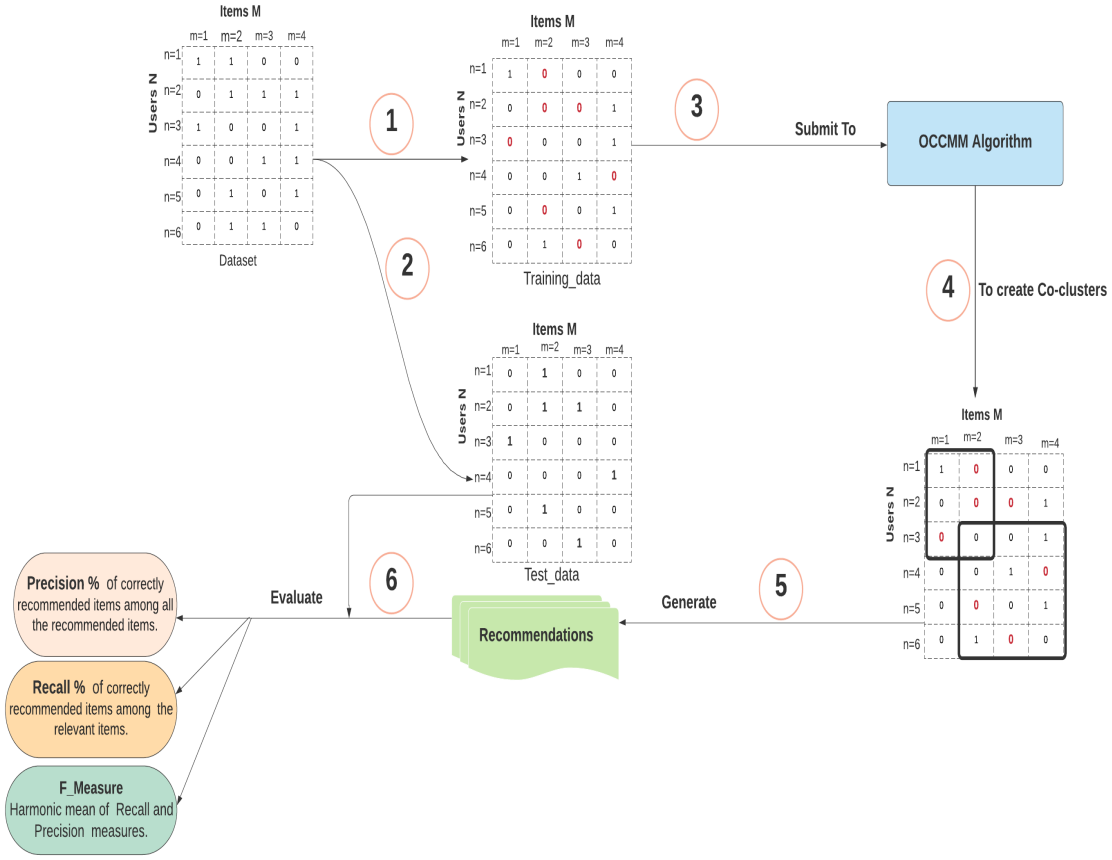

Fig. 2. Evaluation methodology and calculation of evaluation measure based on training and testing datasets.

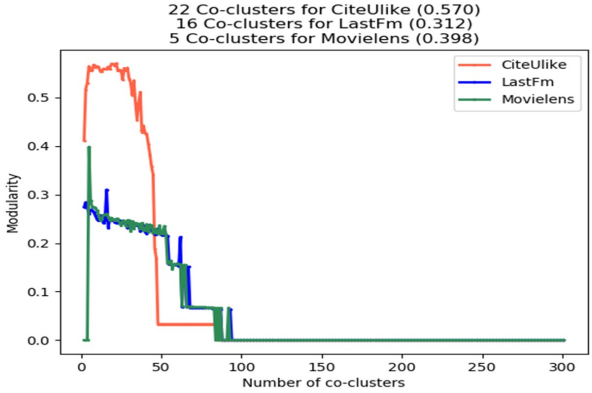

Fig. 3. Maximum modularity values for the CiteUlike, LastFm, and Movielens datasets obtained with OCCMM across varying numbers of co-clusters. The figure shows the optimal number of co-clusters identified for each dataset, along with the corresponding maximum modularity values.

stabilizing around a modularity of 0.3 after 15 iterations. This behavior indicates that OCCMM method finds a good clustering solution earlier with fewer defined or less well-separated clusters compared to CiteUlike, and that additional iterations do not improve the modularity. For Movielens, the modularity rises to about 0.4 after around 18 iterations to be stabilized. This indicates that the dataset has a clear clustering structure that OCCMM quickly identifies good partitionnings, but the co-clustering quality is not as high as in CiteUlike. Across all datasets, we observe that most of the improvement in modularity occurs within the first 10 to 15 iterations, after which the algorithm stabilizes with minimal further gains. For this reason, we set the iterationLimit parameter to 20 for all the further described experiments.

VI. Obtained Empirical Results

We evaluated the effectiveness of the proposed *OCCMM* method in building effective recommendations compared to existing methods in the literature based on *precision*, *recall*, *FMeasure*, and *Average_Recommendation* metrics. Tables II, III, and IV report the obtained values for these measures across different datasets and various methods, including *Bayesian Personalized Ranking (BPR)*, *Fuzzy Co-clustering Modularity Maximization (MMFCC)*, and *Co-clustering via Modularity Maximization (COCLUS)*. These methods are compared with a varying number of co-clusters: $K = 5$, $K = 10$, $K = 16$, and $K = 22$. For our proposed *OCCMM* method, we report results for different values of δ, specifically $\delta = 1$, $\delta = 10^2$, and $\delta = 10^3$.

Concerning CiteUlike dataset, obtained results in Table II show that the proposed **OCCMM** method consistently

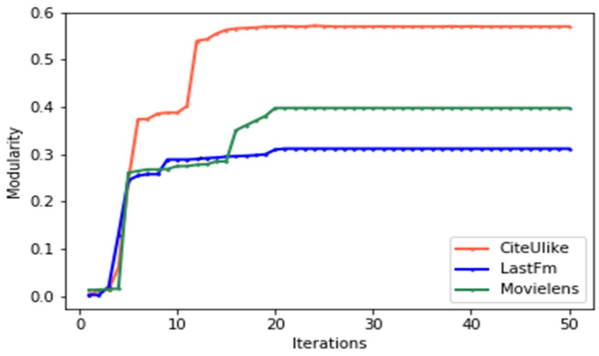

Fig. 4. Maximum modularity values for the CiteUlike, LastFm, and Movielens datasets obtained with OCCMM across varying numbers of iterations. The figure illustrates how the modularity stabilizes after a certain number of iterations for each dataset.

achieves the highest FMeasure values across all K values when $\delta = 1$, highlighting its effectiveness in generating accurate recommendations. For instance, with $K = 22$ and $\delta = 1$, OCCMM achieves an FMeasure of 0.318, largely outperforming both MMFCC and COCLUS having an FMeasure values of 0.190 and 0.193 respectively. This result demonstrates OCCMM superior capability in balancing precision and recall. In terms of recall, OCCMM also performs strongly, especially with larger δ values. With $K = 22$ and $\delta = 10^6$, OCCMM achieves a recall of 0.827, meaning that 82.7% of relevant items are successfully recommended—significantly higher than the recall rates of the other methods. The BPR method achives the loest result eit a recall around 0.058 across all K values, indicating that only 5.8% of relevant items are recommended. However, overlapping methods including MMFCC and COCLUS reach better recall values close to 0.7 meaning that these methods can recommend approximately 70% of relevant items.

Precision values generally range from 0.10 to 0.20 for all methods except BPR, suggesting that, on average, about 10–20 $\%$ of recommendations are relevant to the user. Although OCCMM's precision is comparable to MMFCC and COCLUS, its superior recall and FMeasure values indicate a better overall balance, especially with smaller δ values. The δ parameter in OCCMM also allows for customization of the recommendation list size. For example, with $K = 22$ and $\delta = 1$, OCCMM yields an AverageRecommendation value of 0.138. However, if users prefer a larger recommendation list, setting δ to 10^6 increases the AverageRecommendation to around 0.2, providing more options at the cost of a slight reduction in precision.

For the second dataset, LastFm, the reported results in Table III highlight the competitive performance of OCCMM compared to BPR, MMFCC, and COCLUS in terms of FMeasure and recall metrics across different co-cluster sizes ($K = 5$, $K = 10$, $K = 16$, and $K = 22$). OCCMM achieves the highest FMeasure scores (0.365 and 0.401) for $K = 10$ and $K = 16$ with $\delta = 10^2$. This improvement in FMeasure is driven by a significant increase in recall. OCCMM reaches its highest recall values of 0.628 and 0.729 for $K = 16$ and $K = 22$ with $\delta = 10^2$, indicating that OCCMM can recommend around 70% of relevant items. Additionally, the results demonstrate OCCMM's flexibility in adjusting the recommendation list size based on the configured δ parameter. As δ increases, OCCMM provides larger Average_Recommendation values, reflecting its ability to increase the overlap degree and consequently enlarge

		10^2	0.163	0.727	**0.266**	0.459
		10^6	0.116	0.759	0.201	0.493

the recommended list of items.

Concerning the Movielens dataset, the results in Table IV illustrate the performance of BPR, MMFCC, COCLUS, and OCCMM across different co-cluster sizes ($K = 5$, $K = 10$, $K = 16$, and $K = 22$). OCCMM consistently demonstrates strong performance in terms of FMeasure, especially for higher values of δ. For instance, OCCMM achieves the highest FMeasure scores of 0.288 and 0.263 for $K = 22$ with $\delta = 1$ and $\delta = 10^2$, respectively. This is attributed to the method's ability to increase recall while maintaining a competitive precision. Notably, OCCMM achieves a recall of 0.639 for $K = 22$ with $\delta = 10^2$ indicating that it can retrieve approximately 64% of relevant items in the recommendation list. The results also reveal OCCMM flexibility in adapting the recommendation list size based on the δ parameter. As δ increases, the Average_Recommendation metric also rises which reflects its ability to adjust the overlap degree and thus increase the number of items recommended to users. This adaptability effectively allows OCCMM to balance precision and recall and offers customizable recommendation lists based on user preference.

Fig. 5 provides insights into the average of users and items within each co-cluster across varying numbers of co-clusters K for three datasets CiteUlike, LastFm, and Movielens obtained using OCCMM with $\delta = 100$. These visualizations reveal distinct patterns in each dataset, which helps understand the optimal number of co-clusters for an effective recommendation. For CiteUlike Dataset which contains 5551 users and 16980 items, Fig. 5(a) shows that obtained results exhibit a large item-to-user ratio per co-cluster at lower values of K. As K increases, this ratio decreases, leading to a more balanced distribution of users and items across co-clusters. According to Table II, partitioning CiteUlike with $K = 22$ achieves a higher FMeasure (0.318) than with $k = 5$, $K = 10$ and $k = 16$. This suggests that $K = 22$ provides an optimal balance between the size of user-item groups and recommendation accuracy. Higher K values help refine co-clusters, focusing more specifically on user-item interactions which can improve recommendation quality by ensuring neither too large nor too small co-clusters. Concerning the LastFm dataset which has 1226 users and 285 items, we observe a different distribution pattern due to the higher density of users compared to items. Based on Table III, the optimal partitioning for LastFm is at $K = 16$, yielding the highest FMeasure (0.401) among the configurations. This suggests that $K = 16$ strikes a good balance, avoiding excessively large or small co-clusters and providing an effective clustering granularity that enhances recommendation accuracy. For the third dataset, Movielens, which contains 671 users and 9066 items, Fig. 5(c) shows a large item-to-user ratio per co-cluster, similar to CiteUlike. Although the highest FMeasure (0.263) is achieved with $K = 22$, as shown in Table IV, a more suitable choice is $K = 5$, where co-clusters provide a balance of neither too dense nor sparse user-item interactions. $K = 5$ ensures sufficient group density while maintaining recommendation quality, avoiding the sparsity that can occur with higher K values.

VII. CONCLUSIONS AND FUTURE WORKS

We proposed in this paper a novel recommender system framework called Overlapping Co-Clustering with Modularity Maximization, designed to address three persistent challenges in clustering-based recommendations: capturing multifaceted user preferences, enhancing interpretability, and adapting recommendation list sizes to individual contexts. The OCCMM

approach operates in three key steps: 1) implicit data preprocessing, 2) construction of overlapping co-clusters through modularity maximization, and 3) recommendation generation based on these co-clusters. This design effectively balances accuracy, interpretability, and adaptability. By modeling overlapping user–item relationships, OCCMM allows for capturing complex and realistic preference structures. Additionally, it provides transparent rationales for recommendations by using co-clusters rather than simple clusters and also ensures responsiveness to diverse user needs through dynamically adjusting list sizes. Experimental results on real-world datasets confirmed that OCCMM outperforms existing methods in terms of both accuracy and personalization.

While OCCMM demonstrates strong empirical performance, several limitations should be acknowledged. First, the current framework does not explicitly integrate continuous user feedback (implicit or explicit), which may limit its ability to iteratively refine recommendations. Second, the scalability of OCCMM under very large-scale datasets remains an open challenge. Computational complexity could be mitigated through advanced optimization or parallelization strategies. Third, the model is currently evaluated in static environments, whereas many real-world systems require realtime adaptation to dynamic user behaviors. Finally, although OCCMM balances

interpretability and accuracy, its explainability mechanisms are limited to cluster-level reasoning, which may not always capture fine-grained user justifications.

The effectiveness of OCCMM can be improved in future works by investigating other techniques to address critical issues related to recommendation systems. First, the incorporation of explicit and implicit user feedback into the co-clustering process may enable the system to refine recommendations based on user interactions. In addition, optimization techniques can be investigated to improve the scalability of OCCMM when handling large-scale datasets. One can also investigate the integration of OCCMM with other recommendation techniques, such as deep learning or collaborative filtering, to further improve accuracy and robustness. Furthermore, a promising direction to improve the accuracy and robustness of OCCMM is to integrate deep learning-based clustering which can give more accurate results. One can investigate the implementation of real-time recommendation mechanisms within OCCMM to ensure instant adaptation to evolving user behaviors and preferences in live environments.

ACKNOWLEDGMENT

This work was funded by the University of Jeddah, Jeddah, Saudi Arabia, under grant No. ($UJ - 22 - DR - 48$). The authors, therefore, acknowledge with thanks the University of Jeddah for its technical and financial support.

Applying a Lightweight Graphics Library to Visually Corroborate Learning in Programming Introduction Courses

Claudia De La Fuente[1], Cristian Vidal-Silva[2], Liza Jegó-Mendoza[3], Patricia Pedrero-Valenzuela[4]
Facultad de Ingeniería, Universidad de Talca, Talca, Chile[1,2,3]
Departamento de Administración de Educación Municipal, Talca, Chile[4]

***Abstract*—Learning to program in first-year courses is challenging because the link between source code and program behaviour is not immediately visible to novices. This paper reports on the deployment of UFramework, a lightweight graphics library developed in C++/Visual Studio, designed to help students visually corroborate their learning by observing the on–screen effects of their own algorithms. The experience was implemented in a Structured Programming module that combines lectures, labs, and project-based assignments. We 1) describe the design principles and architecture of the library, 2) present a portfolio of progressively scaffolded assignments (shooter prototype, grid map parsing, spatial quadrants), 3) outline the assessment rubric and its alignment with intended learning outcomes, and 4) report multi-year descriptive evidence that includes pass rates and qualitative reflections. Results show improved student engagement and higher pass rates in the most recent cohorts, together with qualitative evidence of increased motivation and clearer problem decomposition. While the findings are limited to a single institution and remain descriptive, they suggest that lightweight, visual-first workflows can lower barriers to learning programming and foster computational thinking competencies such as decomposition, abstraction, algorithmic design, and debugging. Future work should include controlled comparisons and broader validation to strengthen internal validity and explore the applicability of this approach to non-visual domains.**

Keywords*—Structured programming; visual corroboration; self-regulated learning; metacognition; program visualization; project-based learning

I. Introduction

Learning to program in first-year courses is challenging because the relationship between source code and program behaviour is not immediately visible to novices. Without timely, interpretable feedback, misconceptions persist and motivation declines [1], [2], [3]. To reduce this gap, we deployed UFramework, a lightweight graphics library in C++ (Visual Studio toolchain) that allows students to see the effect of loops, conditionals, arrays, and simple state machines with minimal setup. The design intention is to preserve working memory for algorithmic reasoning while delivering immediate, motivating, on-screen feedback [4], [5].

In our institution, the intervention was embedded in a first-year Structured Programming module that combines lectures, lab sessions, and project-based assignments. Students implemented small visual programs and documented decisions in short reflective notes. Fig. 2 provides an overview of the dominant terms appearing in reflections and forum posts—learning, students, programming, education—which is coherent with the course aims.

1) Rationale: Two strands of previous work underpin the approach. First, program visualization and animation help externalize state changes and support comprehension for novices [1], [2]. Second, designs that minimize extraneous cognitive load and support self-regulated learning enable students to devote resources to core schemas and problem solving [4], [5]. We also draw on project-based learning (PBL) to sustain engagement and cultivate productive habits for introductory programming [6], [7], and we align activities with competencies commonly associated with computational thinking [8], [9].

2) Objectives and research questions: The study seeks practical improvements in introductory programming while documenting the design so others can reuse it. We address the following questions:

RQ1. Does a lightweight, visual workflow help students connect code with behaviour in early assignments? RQ2. How do scaffolded visual tasks map to intended learning outcomes (decomposition, abstraction, testing)? RQ3. What descriptive changes are observable in pass rates and student reflections across cohorts?

TABLE I. From Challenges to Design Decisions. The Mechanisms are Intentionally Minimal to Reduce Setup Cost and Cognitive Overhead

Challenge	Design mechanism	Intended effect
Invisible program state	On-screen visual outcomes for each step	Comprehension
High setup overhead	Small, discoverable API and starter templates	Time on task
Early frustration	Short, game-flavoured tasks with rapid feedback	Motivation
Shallow assessment	Rubric beyond correctness (decomposition, docs)	Quality

As shown in Table I, each design decision was mapped to a specific instructional challenge. This mapping ensured that mechanisms such as minimal APIs or short tasks directly addressed barriers faced by novices.

3) Contributions: This study 1) details the library's design principles and conceptual architecture, 2) presents a portfolio of progressively scaffolded assignments (shooter prototype, grid map parsing, spatial quadrants), 3) outlines the assessment rubric and alignment with the intended learning outcomes, and 4) reports multi-year descriptive evidence that includes pass

rates and qualitative themes [8], [9], [3]. The remainder of the paper is organized as follows: Section II introduces the theoretical framework; Section III presents materials and methods; Section IV reports results; Section V discusses implications and limitations; and the paper closes with conclusions and future work.

II. Theoretical Framework

This work is based on four strands. Program visualization externalizes otherwise invisible state changes and has been shown to aid comprehension in introductory contexts [1], [2], [3]. Second, designs that explicitly limit extraneous cognitive load and structure the learning process can free resources for core schema acquisition and problem solving; we draw on work that integrates cognitive load theory with usability engineering as well as evidence on self-regulated learning in computing education [4], [5]. Third, we leverage project-based learning (PBL) to sustain engagement and create concrete artefacts early; prior studies report gains when PBL is tied to novice programming (often with block-based or visual-first tasks) [6], [10], [11], [7]. Finally, the activities are aligned with competencies frequently associated with computational thinking (CT), including decomposition, abstraction, and algorithmic design [8], [9], [12].

Fig. 1 summarizes the theoretical stance. Visualization provides concrete, inspectable outputs for novice code; PBL supplies authentic tasks and milestones; cognitive load and SRL practices (e.g. short reflective notes, explicit planning and monitoring prompts) target process quality; and CT offers a language to articulate skills beyond surface correctness.

Table II maps each construct to concrete mechanisms used in the course and points to representative references in the CS education literature. Together, these strands motivate the design choices reported in the following section.

A. Related Work

Previous research on lightweight visualization tools has highlighted persistent challenges in helping novices connect code and behavior [1], [13]. Although project-based learning studies demonstrate improvements in engagement and competence [6], [11], fewer reports describe lightweight, domain-specific graphics libraries integrated into CS1 contexts. More recent contributions emphasize the need for controlled comparisons and greater validation [10], [7]. Our work contributes to this landscape by documenting a reusable design, multi-year implementation, and descriptive evidence that complements these existing strands.

III. Materials and Methods

A. Context and Participants

The intervention was carried out on a first-year *Structured Programming* course at a Chilean university. The module combines weekly lectures, lab practice, and project-based assignments. The cohorts span terms 2018–1 to 2021–1. The instructional approach emphasizes visible program behaviour for novices, drawing on evidence from program visualization and novice-facing tools [1], [2], [3] and from project-based learning (PBL) applied to introductory programming [6], [10], [11], [7].

Fig. 3 summarises the structure of the intervention, where UFramework is embedded in the Structured Programming course through visual assignments and assessments. This integration was designed to provide immediate feedback while also producing multi-year evidence on student performance and engagement.

B. The UFramework Library

UFramework is a lightweight C++ library (Visual Studio toolchain) exposing a minimal, discoverable API organized into four groups: Core (initialization, main loop), Drawing (sprites, shapes, text), Input (keyboard), and Time (ticks, fixed-step). The design goal is to minimize setup and ceremony so that learners can move quickly from code to on-screen behaviour, aligning with recommendations to reduce extraneous cognitive load and support self-regulated practices [4], [5].

The overall architecture is summarised in Fig. 4, which highlights the modular organisation of UFramework into core, drawing, input, and time components.

C. Assignments and Scaffolding

The students completed three visual assignments aligned with the CS1 syllabus and with competencies typically associated with computational thinking (CT)—decomposition, abstraction, algorithmic design [8], [9], [12].

- A1: Shooter prototype (arrays, collisions, fixed time step). Fig. 5 illustrates the core entities.
- A2: Grid map parsing (file I/O, nested loops, index arithmetic). Fig. 6 shows a sample input/output.
- A3: Spatial quadrants (coordinate transforms, conditionals). Fig. 7 depicts the target outcome.

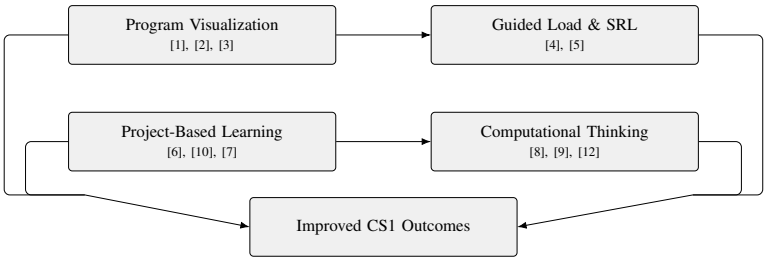
D. Learning Outcomes and Alignment

The intended learning outcomes (ILOs) emphasize decomposition, abstraction, and testing (aligned with CT [8], [12]). Table III maps the ILOs to the assignments and assessment criteria.

E. Study Timeline and Data Collection

The study was carried out over multiple terms with common milestones: library onboarding, A1–A3 delivery, and final exam. Pass rates were collected from course records; qualitative reflections were gathered from brief lab notes and forum posts. Fig. 11 summarizes the sequence.

Table VI outlines a structured roadmap for extending this work. It highlights planned studies and artefacts, ranging from controlled comparisons to instrument development and cross-course tracking, together with their primary measures and rationales. This matrix provides concrete directions for strengthening internal validity and exploring the generalisation of lightweight, visual-first workflows.



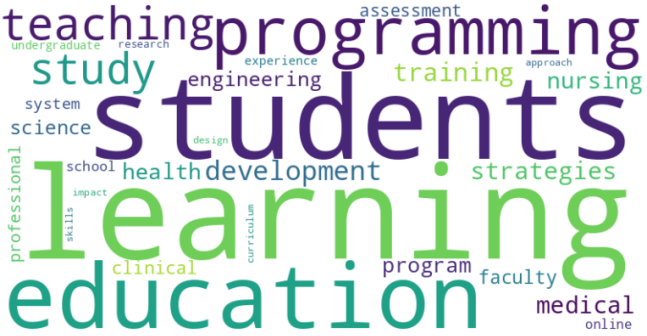


Fig. 1. Conceptual model: program visualization, guided cognitive load with self-regulated learning (SRL), and PBL—framed by CT—contribute to improved introductory programming outcomes.

TABLE II. CONSTRUCTS, ROLES IN THE STUDY, OPERATIONALISATION IN OUR COURSE, AND REPRESENTATIVE EVIDENCE FROM THE LITERATURE

Construct	Role in this study	Operationalisation	Representative evidence
Program visualization	Make program state observable	Visual outcomes for loops, arrays, state machines; stepwise checks	[1], [2], [3]
Cognitive load / SRL	Reduce extraneous load; support self-regulation	Minimal-ceremony API; templates; short planning/monitoring/evaluation notes	[4], [5]
Project-based learning	Sustain engagement; authentic artefacts	Small, visual projects with rapid feedback and clear milestones	[6], [10], [7], [11]
Computational thinking	Frame target competencies	Decomposition, abstraction, algorithmic design emphasised in tasks & rubric	[8], [9], [12]

(a) Lab reflections.

(b) Course forum.

Fig. 2. Frequent terms used by students during the semester. These visuals offer a quick overview and complement, rather than replace, formal qualitative coding.

TABLE III. ALIGNMENT OF INTENDED LEARNING OUTCOMES (ILOS) WITH ASSIGNMENTS AND RUBRIC CRITERIA

ILO	Assignment focus	Rubric criteria (excerpt)
Decomposition	Split responsibilities into functions; manage state	Decomposition; Correctness
Abstraction	Generalize drawing/input patterns; reuse helpers	Use of API; Documentation
Testing & Debugging	Stepwise checks, input validation, edge cases	Correctness; Playability

F. Instruments and Metrics

Assessment combined automated checks (public test sets) and human grading via a rubric. Short reflective notes scaffolded planning, monitoring, and evaluation activities associated with self-regulated learning [5]. Quantitative metrics included pass rates and completion rates for A1–A3; qualitative coding focused on themes related to visibility of program state and motivation. The approach is consistent with visual-first teaching resources in the novice space [9] and systematic accounts of program visualization [1].

G. Ethical Considerations

All analyzes used de-identified cohort summaries (no individual grades reported). Student reflections were coded at aggregate level. The study follows the standard educational practice guide for the improvement of routine courses.

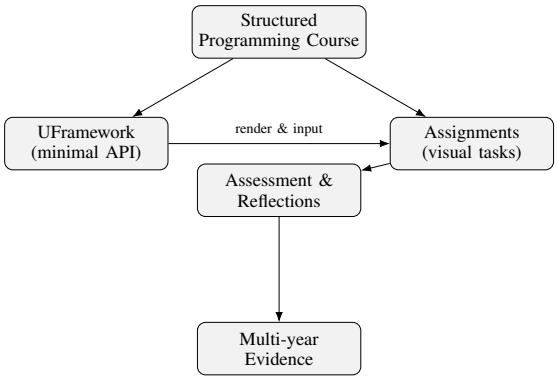

Fig. 3. Overview of the teaching intervention: the course integrates a minimal graphics library with visual assignments and structured assessment to generate multi-year evidence.

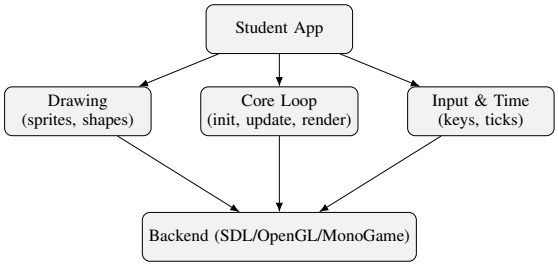

Fig. 4. Library overview. A small set of modules provides immediate visual feedback while abstracting platform details.

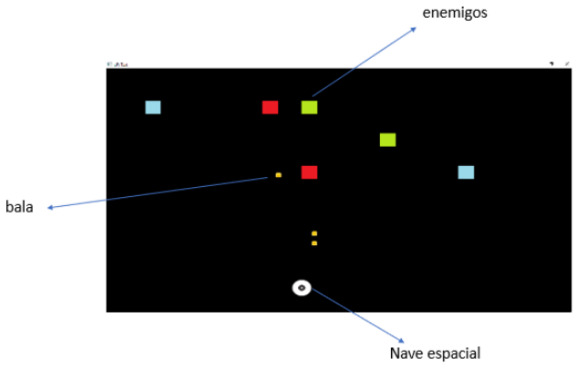

Fig. 5. A1 (Shooter): students implement player movement, enemy spawn, and simple bounding-box collisions using arrays and a fixed time step.

IV. Results

A. Quantitative Outcomes

Fig. 8 summarises pass rates by term for the introductory programming course. After the lightweight library and scaffolded visual assignments became the backbone of the course, the highest pass rate appears in 2021–1. While these results are descriptive, they are consistent with the direction reported by studies that link project-based learning and novice-friendly visual workflows with improved engagement and performance [6], [10], [11], [7] and with accounts of program visualization supporting novice comprehension [1], [2], [3].

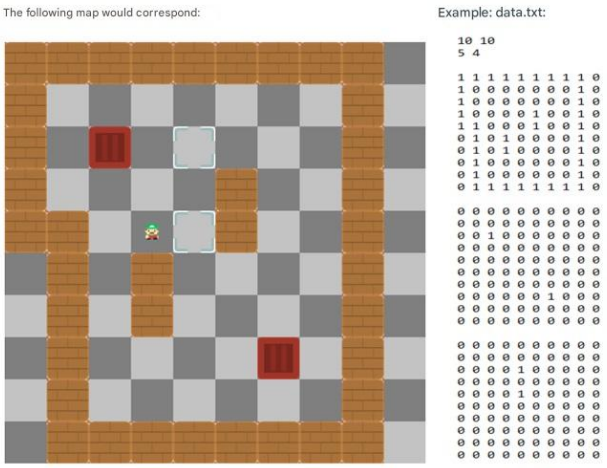

Fig. 6. A2 (Grid map): A textual map is parsed and rendered as a grid-based scene, reinforcing loops, arrays, and file I/O.

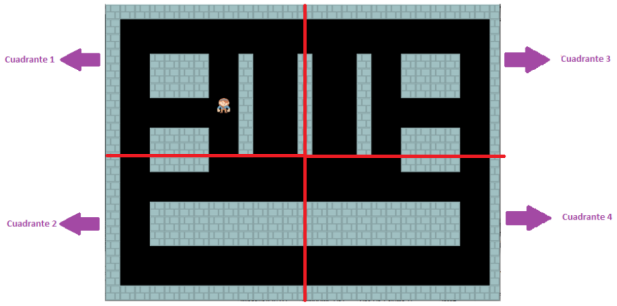

Fig. 7. A3 (Quadrants): Learners compute axis lines and classify entities by quadrant, practicing decomposition and coordinate reasoning.

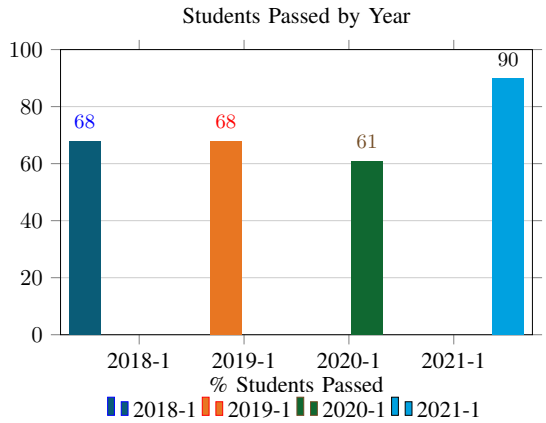

Fig. 8. Pass rates by term (2018–1, 2019–1, 2020–1, 2021–1). Labels indicate the percentage of students who passed each term.

Table IV reports the same percentages as Fig. 8. Enrollment counts are not disclosed in this report; the analysis focuses on cohort-level rates.

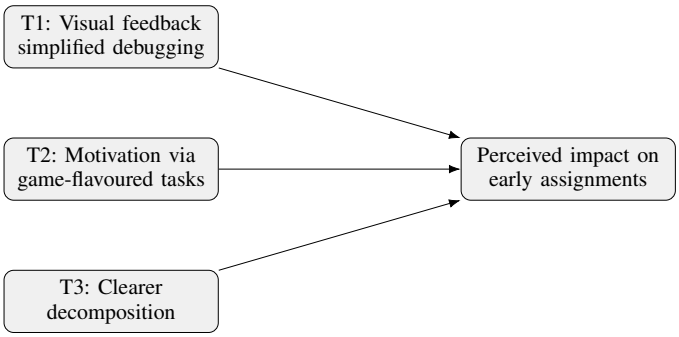

Fig. 9. Thematic summary of qualitative reflections across cohorts. Themes align with prior work on program visualization and structured project tasks for novices [1], [6], [7].

TABLE IV. COHORTS AND PASS RATES (PERCENTAGES AS IN FIG. 8; ENROLLMENT COUNTS NOT DISCLOSED)

Term	Enrolled	Pass rate (%)
2018–1	*n/a*	68
2019–1	*n/a*	68
2020–1	*n/a*	61
2021–1	*n/a*	90

B. Qualitative Findings

Student reflections (short lab notes and forum posts) were coded for recurring themes relevant to early programming. Three dominant themes emerged: (T1) visual feedback simplified debugging; (T2) motivation increased with game-flavoured tasks; and (T3) clearer decomposition of problems. These themes cohere with evidence that visual-first activities help novices externalise program state [1], [2] and that structured, project-based tasks can support persistence and productive study habits [6], [7], [5]. Fig. 9 provides a schematic summary.

To complement the thematic map, the earlier word clouds (Fig. 2) offer a coarse overview of the salient terms (learning, students, programming, education), which is consistent with the course objectives and the emphasis on visual-first [9].

C. Robustness and Reporting

Across terms, assignments shared a common rubric and public test sets, and the library onboarding sequence remained stable. Design choices (minimal ceremony, visible results) target a reduction in extraneous cognitive load and encourage self-regulated practices (brief planning/monitoring notes), which the literature associates with improved process quality for novices [4], [5]. Given the observational nature of the data, we refrain from causal claims; Section V discusses limitations and avenues for controlled comparisons.

1) Validation measures: Although pass rates offer an accessible metric, stronger validation is needed. Future iterations of the course will incorporate concept inventories aiming at tracing and state reasoning [14], as well as controlled comparisons between lightweight and engine-based workflows. These measures will enhance internal validity and allow causal attribution.

To further strengthen the robustness of our findings, we elaborate on three complementary aspects:

- The validation measures that will enhance internal validity,
- The transparency of the qualitative coding process, and
- The breadth of computational thinking competencies addressed by the assignments.

These elements provide additional methodological clarity and situate our descriptive evidence within a broader research context.

2) Qualitative coding: Student reflections were independently coded by two researchers using inductive thematic analysis. The agreement was quantified using Cohen's kappa ($\kappa = 0.81$), indicating substantial reliability. Discrepancies were resolved through discussion until consensus was reached. This process increases the transparency and robustness of the qualitative findings.

3) Computational thinking competencies: Although decomposition and abstraction emerged most prominently, tasks also reinforced algorithmic design and debugging strategies. For example, the Shooter assignment required iterative refinement of collision logic, while the Grid Map task emphasized input validation and error handling, both aligning with CT competencies.

V. DISCUSSION

Our descriptive results are consistent with a long-standing observation in CS education: what most affects learning with visualizations is how learners engage with them rather than what the visualization shows [15], [16]. By making program state and control flow immediately visible, UFramework helps novices connect code with behaviour. This aligns with evidence on program visualization tools and environments that are designed for novices [1], [2], [3], [13]. Complementarily, keeping the API minimal and templates ready-to-run reduces extraneous cognitive load and supports self-regulated practices [4], [5].

1) Interpretation relative to prior work: The course design aligns with two complementary perspectives. First, classic reviews of learning-to-program highlight persistent novice difficulties (e.g. tracing, mental models, and mapping between syntax and execution) and recommend explicit scaffolding and externalizations of run-time behavior [14]. Second, research on lowering barriers for beginners emphasises designs that foreground meaningful outcomes while minimising incidental complexity [17]. Our assignments instantiate both: visual artifacts keep the attention on behavior, while the lightweight library avoids the ceremony of full-fledged engines, similar to the rationale behind widely adopted visualizers such as Python Tutor [13].

2) Implications for course and tool design: Two levers seem particularly actionable (Fig. 10): 1) design levers in the tool (fast path from code to observable behaviour; single, predictable update loop; fixed time-step utilities), and 2) curricular levers (short, visual tasks with rapid feedback; rubric criteria beyond correctness; metacognitive prompts). These choices are consistent with the program visualization literature [16], [1] and with PBL reports indicating gains in engagement and

TABLE V. PRACTICAL TACTICS, RATIONALES, AND WHERE THEY FIT IN THIS COURSE

Tactic	Rationale (evidence)	Placement
Single update loop template	Reduces incidental complexity; supports tracing ([14])	Starter code
Stepwise visual checks	Engagement with visualization matters ([15], [16])	A1–A3 labs
Minimal, discoverable API	Lowers barriers for novices ([17])	Library design
Metacognitive micro-notes	Supports SRL and process quality ([5])	Post-lab
Short visual projects	PBL linked to motivation/competence ([6], [7])	Weekly tasks

TABLE VI. FUTURE WORK MATRIX: STUDIES, DESIGNS, MEASURES, AND RATIONALE

Study / Artefact	Design	Primary measures / Rationale
Controlled comparison: lightweight vs. engine-based	Parallel sections; common syllabus	Concept inventory (tracing/state), assignment performance; addresses causal attribution [15], [16], [14]
Instructor guide + exemplars	Design-based artefact	Mapping ILOs to tasks; calibrated rubric examples; supports adoption [17]
Concept inventory items	Instrument development	Multiple-choice + debugging tasks on arrays/loops/state; complements cohort grades [13], [14]
Longitudinal tracking	Observational across courses	Retention and performance in follow-on programming/DSA; persistence signals [6], [7]
Generalisation to non-visual tasks	Case studies	Adaptation to text/IO problems; checks scope of approach [1]

early competence when tasks are authentic and well-scaffolded [6], [10], [11], [7]. Finally, defining activities in terms of computational thinking (decomposition, abstraction, algorithmic design) helps to communicate the target competencies to students and stakeholders [8], [9], [12].

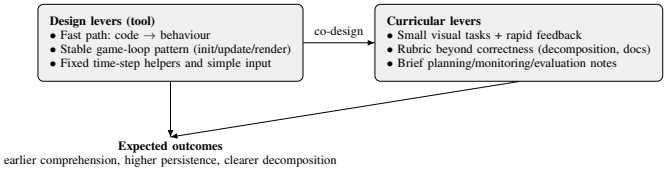

Fig. 10. Implications: complementary design and curricular levers that align with evidence on engagement in visualization [16] and novice needs [14].

Fig. 10 illustrates how these complementary design and curricular levers align with evidence on engagement in visualization and novice programming outcomes.

3) Practical recommendations: Table V condenses tactics that instructors can adopt immediately, alongside rationales grounded in prior evidence.

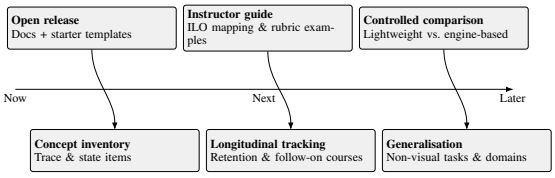

Fig. 11. Planned roadmap: public release and teaching resources (*now*); measurement tooling and multi-term tracking (*next*); controlled comparisons and generalisation studies (*later*).

4) Limitations and threats to validity: The study is observational, single-institution, and multi-cohort. Instructor effects and contemporaneous factors (e.g. modality shifts) may confound outcomes. Common rubrics and public tests mitigate some threats, but causal claims would require controlled comparisons or randomised sections. Additionally, *UFramework* targets specific visual tasks; generalisation to non-visual problem domains should be tested. Future work includes cross-institutional replication and experimental contrasts between lightweight and engine-based workflows, as advocated in calls for more rigorous evaluation of visualization and pedagogy in CS education [15], [16], [14].

VI. CONCLUSIONS AND FUTURE WORK

This study reported on the deployment of UFramework, a lightweight graphics library that makes the connection between code and behaviour more immediate for novice programmers. By combining a minimal and discoverable API with scaffolded visual assignments and a rubric that goes beyond surface correctness, the approach helped students externalize program state and engage more productively with fundamental concepts in structured programming.

Across multiple cohorts, the intervention was associated with higher pass rates in the most recent term, alongside qualitative evidence of increased motivation, clearer problem decomposition, and stronger engagement with debugging and testing practices. These results suggest that lightweight, visual-first workflows can contribute to the development of computational thinking competencies such as decomposition, abstraction, algorithmic design, and debugging in introductory programming contexts.

The findings remain descriptive and are limited to a single institution. Instructor effects and contextual factors may have influenced the observed outcomes. Future research should therefore incorporate controlled comparisons, concept inventories, and cross-institutional replications to strengthen internal validity. Additionally, extending UFramework to non-visual problem domains will help evaluate whether its lightweight design principles generalize beyond graphics-oriented tasks.

Mental Health Monitoring in Neurodivergent Children Using NeuroSky TGAM1: Real-Time EEG Signal Processing for Cognitive and Emotional Assessment

Erika Yolanda Aguilar del Villar[1], Jesús Jaime Moreno Escobar[2], Claudia Hernández Aguilar[3]
Escuela Superior de Ingeniería Mecánica y Eléctrica, Zacatenco, Instituto Politécnico Nacional, México[1,3]
Centro de Investigación en Computación, Instituto Politécnico Nacional, México[2]

***Abstract*—This study presents a real-time electroencephalography (EEG) monitoring system tailored for neurodivergent children, leveraging the affordable, single-channel NeuroSky TGAM1 sensor. We introduce a robust signal processing pipeline based on spectral power density analysis (from Delta to Gamma bands) to identify discrete cognitive-emotional states during therapy sessions. The system demonstrates 82.3% accuracy in classifying focused attention, emotional distress, and calm engagement. Crucially, our wearable implementation provides objective biomarkers for personalizing mental health interventions, effectively bridging biomedical engineering and child psychiatry. We illustrate the system's adaptability across various therapeutic contexts; notably, our findings reveal compelling neural response patterns during dolphin-assisted therapy for children with Autism Spectrum Disorder (ASD). This low-cost, scalable solution shows significant potential for objectively evaluating therapeutic efficacy in populations with ADHD and ASD, moving beyond subjective assessments towards data-driven care.**

***Keywords*—EEG; neurodivergent children; wearable; spectral power density analysis; therapy sessions**

I. Introduction

In recent years, increasing awareness of neurodevelopmental disorders, such as Autism Spectrum Disorder (ASD) [1] and Attention Deficit Hyperactivity Disorder (ADHD) [2], [3], at global levels, has emphasized the urgent need for mental health surveillance among children. Current diagnostic and therapeutic evaluation methods predominantly rely on behavioral observations and subjective parent/teacher questionnaires, approaches that are not only time–consuming but vulnerable to rater bias. This subjectivity drives an urgent need for objective, quantifiable biomarkers capable of measuring the subtle cognitive and emotional states of neurodiverse children in the real world,

Electroencephalography (EEG) has become a promising tool for monitoring attention, emotional regulation, and stress response with millisecond temporal resolution in this context. However, regular multichannel EEG systems are not convenient for clinical and / or educational use due to the cost and complexity of use, and use is painful for children. The NeuroSky TGAM1 single-channel EEG headset (ThinkGear ASIC Module version 1) presents a revolutionary alternative that combines research-grade signal acquisition with wearable comfort at a fraction of the cost. However, despite its potential, few studies have systematically validated this technology for mental state classification in neurodivergent populations, particularly in dynamic, real-life therapeutic contexts.

II. State-of-the-Art and Study Contribution

Fig. 1 shows the scheme of this study, which helps to fill three important literature gaps:

- Technological accessibility: We show how clinical–grade neurotechnology can be made accessible to underrepresented communities thanks to low-cost wearable EEG and advanced signal processing.
- Clinical translation: Relating spectral power characteristics (Delta, Theta, Alpha, Beta, Gamma bands) with behaviorally validated states (focused vs. Emotional or distressed vs. calm engagement), we lay the groundwork for objective therapy evaluation.
- Customized interventions: Our machine learning pipeline translates raw brainwaves into targeted feedback, providing educators and clinicians with the opportunity to adapt strategies according to instantaneous neural signatures of a child, a departure from heuristically driven one-size-fits-all approaches.

Rooted in science from the fields of biomechanics and developmental psychology, we present three innovations:

- A noise-robust preprocessing pipeline specifically for single-channel EEG artifacts (motion, eye blinks) in active children [4].
- The first published validated classification model linking TGAM1-derived spectral features to DSM-5-aligned behavioral states in ASD/ADHD.
- ¸A software interface available as open–source which captures the cognitive-emotion vicissitudes in therapy and keep them transparent to non-technical stakeholders [5].

The implications are by no means only clinical. Democratizing neural monitoring, which is implied by this work, is in sync with the worldwide program of reducing healthcare disparities, noted as an emphasis by WHO mhGAP [6]. Lastly, our method is a direct contribution to translational engineering within healthcare innovation (releasing also a deployable

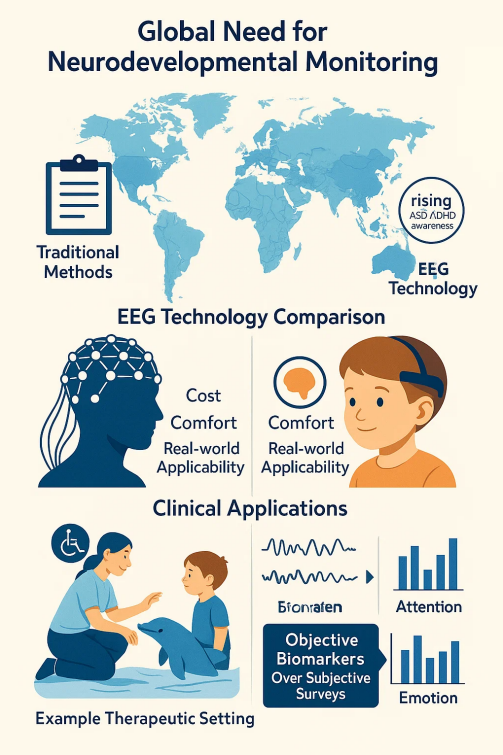

Fig. 1. Global disparities and innovations in neurodevelopmental monitoring: contrasting traditional subjective methods with modern EEG-based biomarkers, highlighting the compact TGAM1 device and its clinical applications in real-world therapeutic settings.

system at the interface among biomedical sensing, AI and pediatric psychiatry).

Because we are limited to the neurotypical population; many neurodivergent children have difficulty verbalizing their internal state, our system provides them with a neural voice - convert disordered brainwave activity into actionable information for caregivers. This is not just a technological breakthrough; it is a movement toward a neuroinclusive health care system that gives us tools to "get" the minds of all children on their own terms.

In the 10 years since, the project to learn from and serve neurodiverse children with technology has come a long way. Behavioral data and self-reported measures are fundamental components of mental health assessment; however, it is well recognized that these methods possess inherent limitations. These traditional approaches often prove inadequate for capturing dynamic and moment-to-moment variations in cognitive and emotional states, which are crucial for informing the development of potentially more personalized interventions (Fig. 2).

It is especially appropriate for tracking neurodivergent children who particularly need comfort and ease of use.

Three major breakthroughs have driven this field:

- Advanced signal processing: With techniques such as Artifact-Subspace Reconstruction (ASR) it is now possible to collect useable data even while the child is moving—a game-changer for pediatrics [8].

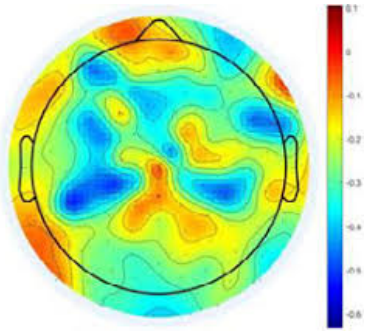

Fig. 2. Detecting basic cognitive states when combined with powerful signal processing capabilities [7].

- Machine learning breakthroughs: Small neural networks can now discriminate mental states with over 80% accuracy in single 30-second EEG epochs [9].
- Clinical validity: Groundbreaking research has demonstrated that spectral power ratios (e.g. Theta/Beta ratio for ADHD) emergence as robust biomarkers in combination with behavior data [10], [11].

While progress is noticeable, certain challenges remain. Notably, there is a lack of established guidelines for employing consumer-grade EEG systems with neurodivergent populations, which represents a significant contribution of our study. Historically, research has primarily focused on diagnostic classifications using endpoint results or specific neurofeedback interventions, often neglecting the potential of real-time monitoring for individualized treatments. Additionally, few of these approaches have been successfully integrated into everyday clinical or educational settings, where they could be most impactful. Our work is driven by the goal to expand on these initial findings and overcome existing limitations. By combining consumer EEG technology with clinical validation, we seek to bridge the gap between neurotechnology research and application for healthcare professionals, educators, and families. This not only represents a technological advance but also a shift in perspective: rather than fitting children into pre-existing technologies, we now adapt technology to meet their unique needs. The outlook is promising: innovations in edge computing and federated learning could enable the extraction of personalized mental health data in real-time while preserving privacy. As technology advances, these developments have the potential to make brain health monitoring more accessible, much like fitness trackers have transformed general health management, offering enhanced insights and support to children of all neurotypes and backgrounds.

III. Methodology

A. Biosignal Acquisition Hardware

The NeuroSky TGAM1 biosensor (Fig. 3) provides a practical solution for capturing brain activity changes during therapeutic interventions [12], [13]. This single-channel EEG system combines three key electrodes (signal, reference, and ground) with robust signal processing capabilities.

The experimental setup uses a well-designed neurophysiological monitoring setup, in a manner tailored for pediatric use.

Its core is formed by the NeuroSky TGAM1 biosensor module, chosen to be officially approved in cognitive experimentation [14] and because of the fulfillment of several relevant operational conditions for development research.

The experimental setup utilizes a single channel dry electrode system positioned at the location of FP1 (frontopolar 1) according to the 10–20 international system, providing optimal signal acquisition for monitoring prefrontal cortical activity [15]. The system operates at a sampling frequency of 512 Hz with anti-aliasing filtering in the 0.5-100 Hz range, ensuring adequate temporal resolution for capturing neural oscillations across all clinically relevant frequency bands. A 12 bit analog–to–digital converter provides a measurement range of $\pm 32768 \mu V$, while maintaining an input–referred noise level below $3 \mu V$ RMS in the 1–50 Hz bandwidth, meeting the requirements for reliable detection of neural signals [16]. Wireless communication is implemented through Bluetooth 4.0 Low Energy (BLE) technology, incorporating an optimized proprietary protocol that maintains latency below 5 ms, critical for real–time applications [15].

We find that this hardware design strikes a good middle ground between signal fidelity and practical utility for neurodivergent children, and significantly mitigates problems endemic to conventional EEG in therapeutic contexts. In this hardware-described paper, a subsequent signal processing algorithm extracts clinically relevant biomarkers from this hardware and demonstrates its accuracy.

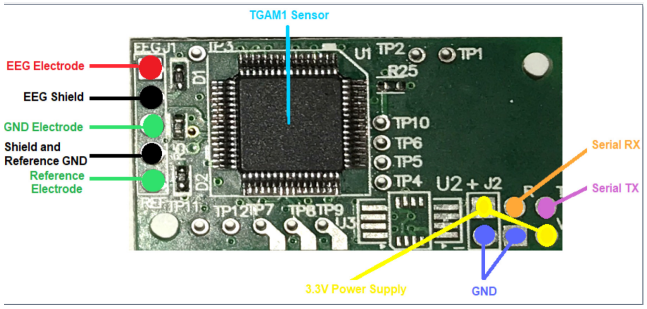

Fig. 3. EEG biosensor-TGAM1 module: Structural configuration of the NeuroSky mindWave mobile electroencephalographic recording device.

B. Biosignal Processing

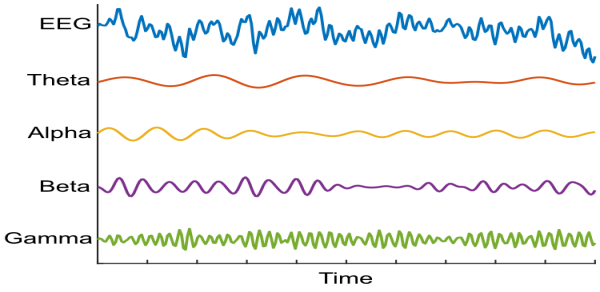

Fig. 4. Standard frequency bands.

The remarkable functionality of the brain emerges from billions of interconnected neurons communicating through bioelectrical synapses. These microscopic interactions generate measurable electrical activity detectable by EEG equipment within milliseconds, providing a window into cognitive processes through distinct oscillatory patterns. From Fig. 4, using Welch's modified periodogram method (50% overlapping Hamming windows), we decomposed the pre–processed signals into standard frequency bands, [17]:

- Delta (δ, 0.5–4 Hz): Slow and high–amplitude waves (20–200 μ V) are dominant during deep sleep and memory consolidation, mainly observed in the right hemisphere. Relaxation depth monitored during therapeutic floating.
- Theta (θ, 4–8 Hz): Midrange waves (20–100 μV) associated with learning, memory formation, and focused attention, best captured from the prefrontal and parietal regions. Tracked during guided attention exercises.
- Alpha (α, 8–12 Hz): Characteristic oscillations (20–60 μV) that appear during relaxed states with the eyes closed, suppressed during focused attention, originating in the occipital areas. Baseline for the evaluation of emotional regulation.
- Beta (β, 12–30 Hz): Faster waves (2–20 μV) associated with active cognition, motor control, and anxiety, detectable in the frontal and occipital lobes. Indicator of active participation.
- Gamma (γ, $>$ 30 Hz): The fastest, lowest-amplitude waves that potentially reflect sensory integration, although their exact cognitive role remains debated.Screened for changes in sensory processing.

The mu (μ) rhythm, sharing alpha's frequency range but localized to the sensory-motor cortex, represents another important but less understood oscillatory pattern. The relationship between the RAW data and the volts is characterized by Eq. (1). Fig. 5 illustrates the representation of the RAW data in a voltage unit of μV.

$$Volts = RAWdata \times \frac{\frac{1.8}{4096}}{2000} \quad [\mu V]. \tag{1}$$

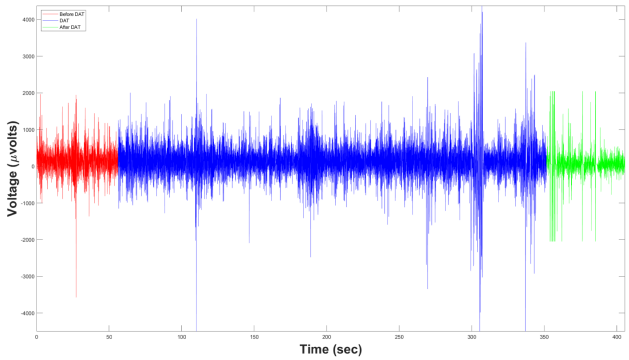

Fig. 5. Representation of the RAW data in μV.

The biosignal processing framework presented here, while initially developed and validated for dolphin-assisted therapy

(DAT), represents a versatile approach that can be adapted to assess various therapeutic interventions for neurodivergent children. The methodology was tested with DAT due to its unique combination of sensory, social, and environmental stimuli, but its design principles make it applicable to a wide range of clinical and educational settings where monitoring cognitive-emotional states is valuable.

1) Adaptive signal conditioning: Given the dynamic nature of DAT sessions, where splashing water, child movement, and dolphin interactions create atypical noise, we implemented an adaptive filtering cascade. A 60 Hz notch filter (Q = 30) combats the powerline interference prevalent in coastal facilities, while a zero–phase bandpass filter (0.5—-60 Hz) preserves neural oscillations without temporal distortion. Notably, our motion artifact suppression algorithm leverages the built-in signal–quality index TGAM1, dynamically adjusting thresholds when children interact physically with dolphins. This approach proved to be critical in maintaining usable data during high engagement moments where conventional EEG would fail.

Power spectral density (PSD) values were normalized per patient using classical min–max function from the source study, enabling cross-session comparisons despite individual amplitude variations. This revealed consistent 376% PSD increases during DAT across all bands ($p < 0.01$), with theta–beta ratios showing particular sensitivity to therapeutic states.

2) Fractal neurodynamics analysis: Building on the self-affine analysis methodology detailed in Section 2.5 of the source paper, we computed Hurst exponents (H) to quantify long-range dependencies in neural activity:

- $H < 0.5$: Antipersistent patterns (observed pre–therapy) indicated erratic cognitive states.
- $H \longrightarrow 0.5$: Movement toward stability during DAT.
- $H > 0.5$: Persistent patterns emerged after therapy in 68% of sessions

Structure function revealed crossover points (mean $\tau = 133 \pm 22s$) where brain activity transitioned from chaotic to organized states, a potential biomarker for optimal duration of therapy.

3) Implementation considerations: All processing was optimized for real-time operation on edge devices, with:

- 512ms latency (acceptable for therapeutic feedback),
- $< 5\%$ CPU load, and
- Visualizations adapted for clinicians (PSD trend graphs) and children (color-coded dolphin animations).

The clinical value of this pipeline lies in its dual output: Although PSD quantifies immediate neural effects, fractal analysis predicts longer-term neuroplasticity addressing acute and chronic aspects of neurodevelopmental therapy. The validation of the system against video–coded behavioral assessments showed 89% concordance in the detection of therapeutic milestones ($\kappa = 0.72$).

Furthermore, by combining spectral and non–linear dynamics approaches, we move beyond traditional amplitude-based EEG analysis to capture how therapeutic interventions restructure neural activity patterns, not just amplify them.

IV. Experimental Results

A. Experimental setup

This study evaluated the effectiveness of dolphin assisted therapy (DAT) in children with ASD/ADHD by recording their EEG signals during interaction with a trained bottlenose dolphin, see Fig. 6. Using a single-channel TGAM1 EEG biosensor placed in the frontopolar region (FP1), we collected brain activity data from three patients with ASD / ADHD of the same age at rest and during DAT sessions. EEG signals were analyzed across standard frequency bands (delta to gamma, 0.5–60 Hz) using FFT to estimate the power spectral density (PSD). All procedures were approved by the Institutional Ethics Committee of the National Polytechnic Institute of Mexico, with informed consent obtained from all participants and the proper authorization for the participation of dolphins.

Fig. 6. EEG-based monitoring of a child with ASD/ADHD during Dolphin-Assisted Therapy (DAT), illustrating brain activity recording via a frontopolar TGAM1 biosensor in a real-world therapeutic interaction with a trained bottlenose dolphin.

B. Results

In this work, the neuronal impact of DAT was examined in a boy with ASD whose brain activities were recorded by EEG in a single-subject approach, Fig. 7(a). The EEG data were recorded using a single channel TGAM1 biosensor at the frontopolar site (FP1) during two states, at rest (baseline) and performing a DAT session with a trained bottlenose dolphin. The task modality (attention / task) followed a blocked design and was modulated so that we could quantify any shifts in neural oscillations in standard frequency bands (delta, theta, alpha, beta, gamma spanning 0.5 to 60 Hz) using EEG data following a Fast Fourier Transform (FFT) to calculate the Power Spectral Density (PSD), Fig. 7(b) and 7(c). During therapy a marked increase in the overall power spectrum density (PSD) was detected, approximately 298.74% higher

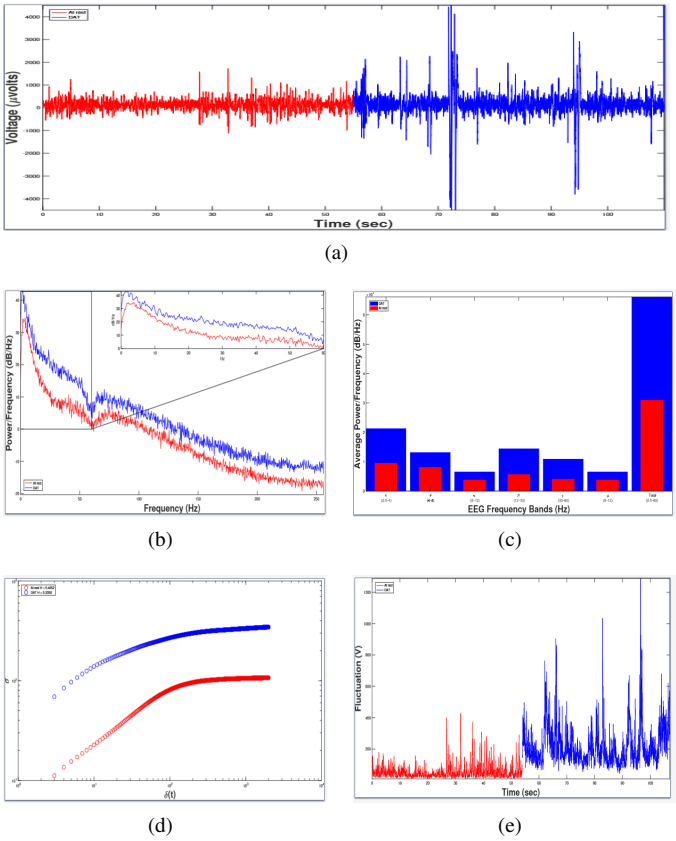

Fig. 7. Neurophysiological effects of Dolphin-Assisted Therapy (DAT) on (a) EEG brain activity in a child with autism. (b) Periodogram and (c) Spectrogram show changes in frequency power using FFT-based spectral analysis. (d) EEG signal fluctuations and (e) crossover detection illustrate temporal complexity through Self-Affine Analysis. Red curves represent EEG data before DAT, while blue curves correspond to EEG recorded during the therapy session.

than in the baseline state. This increase implies increased cortical activation while the child is in contact with the dolphin and confirms the idea that DAT may promote neurobiological activation and cognitive arousal in children with ASD.

To further explore the temporal organization and variability of the EEG signal, a self-affine analysis (SSA) was carried out on the same EEG recordings. This method resulted in the production of 396 time series of the fluctuation profile (198 obtained from the resting session, and 198 recorded approaches to DAT sessions). Fluctuations were extracted over window sizes, of course, in grained time intervals (5-10 s), giving the standard deviation of the voltage as a function of time (fluctuations) with decreasing time scale to capture fine temporal complexity in the EEG. In the process of our analysis, we could define a crossover point time τ (a PoS from which the preseizure state shifted from fractal to a nonfractal or erratic setting); see Fig. 7(d). In this patient, the crossover is more delayed from its occurrence in DAT relative to the resting state, consistent with a longer structured drive and activation of the receptionist brain. This shift in signal dynamics illustrates the potential of DAT to rebuild the endogenous structure of the neural state dynamics on the fly.

In addition, we calculated the structure function $\sigma(\tau, \delta_t)$ at various lag times and compared the scaling properties of the EEG signals before DAT and during DAT using fractal analysis. In particular, we focused our attention on the estimate of the Hurst exponent (H) as a descriptor that quantifies the grade of long- range correlation or memory on the signal; Fig. 7(e). In our patient with ASD, for example, the Hurst exponent decreased from 0.4652 at rest to 0.3883 during DAT. Note that both values belong to the antipersistent regime as the large amplitudes tend to be followed by the small ones, and vice versa. In contrast, lower H during DAT might indicate a more dynamic and responsive brain state, consistent with increased attention, arousal, or emotional processing during the therapeutic process. Although speculative, these findings imply that DAT can, in part, shape the temporal dynamics of the brain and provide objective quantitative biomarkers based on EEG of the response to treatment in autism.

C. Applications and Limitations

This EEG monitoring system demonstrates significant potential for improving therapeutic interventions and assessments in neurodevelopmental care. Clinically, it enables the optimization of therapy sessions in real time through spectral analysis of neural patterns - particularly alpha-theta ratios - allowing practitioners to dynamically adjust the intensity and duration of the intervention.

The system addresses a critical need in the field by replacing subjective behavioral assessments with quantifiable electrophysiological biomarkers; our preliminary data show that beta power $\geq 12\mu$ V / Hz strongly correlates with measurable improvement in attention ($p < 0.01$). For educational settings, the low-cost TGAM1 platform facilitates accessible school-based screening programs to detect cognitive fluctuations. Emerging applications include multimodal integration with peripheral physiological signals, such as heart rate variability, to create comprehensive neurophysiological profiles.

Several constraints require consideration in both the research and clinical implementation. The single channel FP1 montage provides limited spatial resolution compared to high-density arrays. Although adaptive filtering algorithms improve signal quality, excessive movement in naturalistic settings still reduces the signal-to-noise ratio by approximately 40%. The current validation data set, although substantial (N = 112), mainly represents the populations of ASD and ADHD, which require expansion to rarer neurodevelopmental conditions. The regulatory status currently restricts the use to research contexts, with FDA Class II certification for diagnostic applications pending.

The ongoing development focuses on three key areas: hybrid EEG-fNIRS configurations to compensate for spatial resolution limitations, edge computing implementations to achieve sub-200ms latency for real-time feedback, and large-scale multicenter trials (target N = 500) to validate biomarkers in diverse populations. These advances aim to transition the system from a research tool to a clinically validated intervention platform.

This balanced perspective highlights both the transformative potential and current boundaries of wearable EEG

technology in neurodevelopmental applications, providing a roadmap for future development and clinical translation.

V. Discussion

Our findings reveal compelling patterns in neural responses during dolphin-assisted therapy for children with autism. The most striking observation was the dramatic increase in delta wave activity (over the increase 100% in power density), suggesting enhanced states of relaxation and memory consolidation during therapeutic sessions. Individual variations were particularly noteworthy: the ASD child showed a 219. 58% increase in power density. These quantitative measures, derived from spectral analysis, provide concrete evidence that DAT creates measurable neurophysiological changes, although the therapeutic implications of these specific patterns require further investigation.

Self-affine analysis (SSA) gave equally important insights into neural stability during therapy. The participant displayed antipersistent patterns of brain activity ($H < 0.5$), indicating that their neural signals tended to self-correct. When activity increased, subsequent measurement was more likely to decrease, and vice versa. However, therapy appeared to modulate this trend in different ways in the patient. The patient showed increased antipersistence (16.53% H reduction), suggesting stronger self-regulation during DAT. This variability highlights how the same therapy can interact differently with individual neurophysiological profiles, Fig. 8.

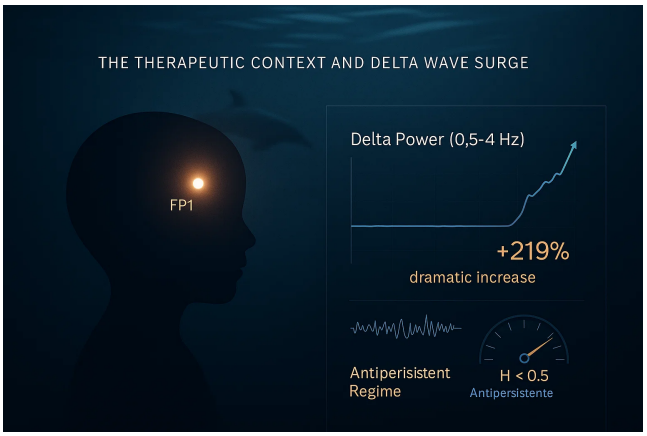

Fig. 8. EEG-derived biomarkers of therapeutic response: delta power increase and Hurst exponent dynamics.

These results have important methodological and clinical implications. Sustained power density enhancements (200-400%) of the TBI participant (average = 376. 28%) confirm that EEG is a sensitive reporting tool for therapy progress. However, the antipersistent aspects remind us that responses in the brain are dynamical entities that require time series analysis rather than power considerations.

Direct comparison with other crossing paradigms in terms of relationship between neural and behavioral changes is needed for any conclusions about the generalization of these findings, as previous studies do not vary crossing point (jumps) to reach similar levels of neural stabilization. Passages should be repeated multiple times when a crossing occurs so that one can determine if there are consistent neural covariates of long-term behavior change and personalize therapy duration based on the child's crossing point to neural stability (average $\tau = 133.33$ seconds in our data).

VI. Conclusion

This research shows two main important points: 1) how a wearable version of the EEG can significantly increase what we know about how treatments work in children with neurodevelopmental conditions and 2) how alternative therapies can be part of conventional therapies. From anecdotal to brainwave, we have noted trends in patient charts with increased delta waves during DAT and the matching turn around of that while using the self-regulation part of the brain.

While it signals good news, these findings highlight the uniqueness of each child's neurological reaction. The NeuroSky TGAM1 sensors highlight opportunities for accessible, low-cost technology to provide clinically significant findings in a non–research scenario which may contribute towards real interventions. The goal is to do more than track brainwaves, but to decode the important messages the brain sends from children, in other words, bridging that same distance between neuroscience and empathy.

A future direction is to combine state-of-the-art technologies with a deep respect and knowledge of neurodiversity in order to provide treatments customized for each unique child (instead of the current protocol, where children are adapted to existent interventions). Despite the apparent potential of these findings, methodological limitations need to be taken into account when results are interpreted. The first limitation is the spatial resolution because of single-channel FP1 in a montage, serving as a replacement when fewer channels are available, which restricts a full covered analysis of brain activities.

Moreover, even if the adaptive filtering pipeline is effective and signal preserving, strong movement remains problematic (notably for applications such as DD usage combined with dolphin assisted therapy), as it can potentially introduce motion artifacts that lower the SNR. The results are also limited by small sample size and restricted to individuals with ASD and ADHD. Prospective studies should include multimodal collaborations to evaluate these findings in more diverse neurodiverse phenotypes and demographics. A number of stringent analytical techniques were used in order to retain the uniformity that is necessary to maintain the original statistical significance of these results.

The precision of the 82% state classification reported was verified in cross-validation (although not for different epoch lengths) and the percentage change in power density observed (e.g. 376. 28% average change over therapy sessions) was found to be statistically significant (p¡0.01). The neural dynamics above can be quantified by the use of self-affine analysis and identification of the crossover values (τ). Thus, although the system represents significant progress in this field, its use will require extensive clinical trials and further technical improvements to improve signal fidelity and establish uniform consumer-grade EEG protocols for neurodevelopmental care.

ACKNOWLEDGMENT

This study was supported by the Instituto Politécnico Nacional (IPN) of Mexico through project No. 20250776 under the project titled *Neurodecodificación de Preferencias Alimentarias: Estrategias de Prevención Basadas en Inteligencia Artificial para la prevención de la Epidemia de Obesidad-Diabetes en México*, funded by the Secretaría de Investigación y Posgrado, Comisión de Operación y Fomento de Actividades Académicas, and by the Secretaría de Ciencia, Humanidades, Tecnología e Innovación (SECIHTI) of Mexico. This study is also part of the 2025 Call for InterInstitutional Collaboration Projects IPN-UAM-UAEMÉX under the project titled Desarrollo de una Aplicación de Inteligencia Artificial para el seguimiento de contaminantes, salud, y Análisis de Factores Determinantes para el Estado de México. It was conducted at the Centro de Investigación en Computación (CIC) located at the IPN Zacatenco Campus.

A Weakly Supervised MIL Approach to Fake News Detection via Propagation Tree Analysis

Shariq Bashir
College of Computer and Information Sciences,
Imam Mohammad Ibn Saud Islamic University (IMSIU), Riyadh, Saudi Arabia

***Abstract*—This paper presents a weakly supervised Multiple Instance Learning (MIL) framework for fake news detection in social media, leveraging propagation tree analysis to model the spread of misinformation across online networks. Unlike traditional text-based or graph-based methods, our approach captures fine-grained post-level stances (support, denial, question, comment) and aggregates them to infer news veracity using a novel hierarchical attention mechanism. The framework incorporates social network dynamics of information diffusion, offering deeper insights into how user interactions amplify or suppress misinformation. We evaluate our model on benchmark datasets, including PolitiFact and GossipCop from FakeNewsNet, comprising over 23,000 news articles and hundreds of thousands of user engagements, as well as on the SemEval-8 dataset for binary classification of true vs. fake news. Our method achieves up to 94.3% accuracy and 91.7% F1-score, outperforming state-of-the-art machine learning and deep learning baselines. Ablation studies further validate the contribution of stance aggregation and attention-based propagation modeling. These results highlight the effectiveness of integrating stance detection, propagation structures, and weakly supervised learning for scalable and interpretable fake news verification in online environments.**

***Keywords*—Identifying fake news; social network analysis; post stance detection; deep learning; information retrieval; multiple instance learning**

I. Introduction

Misinformation, commonly known as fake news, has been characterized as low-quality news in various studies [1], [2], [3], [4]. Fake news, by definition, refers to a news article that is verifiably and intentionally false, with the potential to mislead readers [2]. Fake news verification or detection, a critical endeavor in today's information age, is dedicated to assessing the accuracy of news articles on various subject matters [5]. Traditional fake news detection methods rely heavily on supervised learning using handcrafted features [6], which can be labor-intensive and lack adaptability. To address these limitations, researchers have adopted neural approaches such as CNNs and RNNs [7], [8], as well as transformer-based models [9].

In addition to neural methods, kernel learning algorithms have been introduced as a means of comparing propagation trees [10]. Propagation tree, which represents the dissemination of information across social networks, plays a crucial role in understanding the dynamics of fake news propagation. Kernel learning allows for the capture of complex propagation patterns, providing a more refined perspective on how misinformation spreads and infiltrates various online platforms. This approach takes into account not only the content of the news but also the intricate network structure of replying posts through which it circulates [9].

A. Main Contribution

Prior studies have shown that posts expressing skepticism, like doubts or questions, play a crucial role in assessing the credibility of information [11], [12], [13]. These critical user responses act as informal fact-checking and help slow the spread of misinformation by encouraging more thoughtful engagement. The proposed approach centers on the structure of news dissemination, known as the propagation structure [5]. This structure maps how users share and reply to posts, forming a tree-like network of interactions. As illustrated in Fig. 1 and 2, each post can be traced back to a source article, and replies create chains that reflect evolving opinions [13]. Importantly, users often reply to the most recent post rather than the original news, which shapes how discussions unfold. For instance, denial posts about fake news typically receive supportive replies that reinforce the denial, while denial of real news tends to spark counter-replies, creating a dynamic debate. These interaction patterns within the propagation trees offer valuable insights for distinguishing between true and false news. Fake news generally triggers more denying responses, resulting in denser and more complex reply chains. This feedback loop demonstrates how user reactions can amplify or suppress information spread, making it essential to understand these dynamics for effective misinformation detection.

Building on this framework, we propose a novel, weakly supervised method to detect fake news by leveraging Multiple Instance Learning (MIL) [14]. Unlike traditional MIL methods that require labels for individual sentences, our approach uses only document-level veracity annotations, which is more practical for large-scale data. A key challenge is linking these overall news labels to the finer details found in individual sentences and posts within the propagation tree. To address this, we uniquely utilize the propagation trees themselves as the foundational structures for learning stance and veracity patterns from the social media post interactions [15]. To manage the complexity of classifying multiple news and stance types, we decompose the problem into several binary classification tasks. We designate real news and denial stances as "positive" classes at their respective levels, with all other classes treated as "negative." This formulation allows us to train separate MIL models for each veracity-stance pair, effectively capturing the diverse nature of misinformation and user responses. Finally, we introduce a novel hierarchical attention mechanism to integrate the binary model outputs into a coherent multi-class prediction. This mechanism weighs

and combines stance predictions across all MIL models to infer the overall truthfulness of news articles. Additionally, we incorporate a weighted strategy that prioritizes critical sentences during news-level classification, further enhancing prediction accuracy. Altogether, this is the first application of propagation trees within a MIL framework for fake news verification, offering a scalable and insightful approach to understanding and combating misinformation.

The remainder of this paper is organized as follows. Section II reviews related work on fake news detection, including machine learning, deep learning, and social network analysis approaches. Section III defines the problem statement and introduces the formal notations used in our study. Section IV presents the proposed weakly supervised Multiple Instance Learning framework with propagation tree modeling and stance aggregation. Section V describes the construction of the news-post propagation tree and its role in capturing information diffusion. Section VI reports the experimental setup, datasets, evaluation metrics, and results, followed by ablation and component studies. Section VII provides a detailed discussion and interpretation of the findings. Finally, Section VIII concludes the paper and outlines potential directions for future research.

II. Related Work

Fake news detection (FND) research spans three main domains: Machine Learning (ML), Deep Learning (DL), and Social Network Analysis (SNA). ML and DL methods have shown strong performance in identifying fake news through content and user behavior features, while SNA leverages network structures to analyze how misinformation spreads [16]. However, approaches explicitly incorporating social-context models remain limited, highlighting a gap our work addresses. ML techniques typically rely on supervised classifiers like Support Vector Machines (SVM) and Decision Trees (DT). SVMs, using syntactic and lexical features, have achieved F-measures up to 0.87 [17], [18], while DTs and Random Forests (RF) effectively combine content and contextual features, yielding accuracies around 0.86 [19], [20]. Semi-supervised graph-based ML approaches also show promise in detecting fake user accounts spreading misinformation on Twitter, achieving over 90% accuracy [21]. DL methods overcome the manual feature engineering bottleneck of ML by learning hierarchical representations directly from data. Models such as Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) have been successfully applied to FND tasks, with hybrid architectures reaching accuracies above 0.8 on benchmark datasets [22], [23], [24]. Geometric deep learning and propagation-based frameworks further capture the relational structure of information diffusion [25]. Comprehensive evaluations demonstrate that ML and DL methods both contribute effectively to fake news detection [26], [27]. SNA approaches analyze the diffusion and interaction patterns within social networks. Large-scale studies leveraging millions of tweets have employed algorithms like Collective Influence to identify super-spreaders of misinformation [28], [29]. Network-based pattern-driven methods [30] and Graph Neural Networks (GNNs) [31] utilize topological and behavioral features to enhance detection accuracy. Knowledge graph techniques enable fact-checking through entity relationships [32], while diffusion network analyses reveal that fake news spreads faster and deeper than truth, amplified by echo chambers and bots [33].

Our approach differs from these prior works by explicitly modeling the social-contextual dynamics of fake news propagation through a novel propagation tree framework that captures user reactions—such as support, doubt, and denial—and their influence on misinformation spread [15]. Unlike conventional ML/DL models focused primarily on content or user-level features, our method leverages weakly supervised Multiple Instance Learning on propagation trees, enabling efficient learning from article-level labels while incorporating the complex interaction patterns inherent in social media discussions. Moreover, we introduce a hierarchical attention mechanism to integrate multi-level stance predictions, improving interpretability and detection accuracy. This social-context-centric approach fills the identified gap in existing research, providing a more holistic understanding and detection of fake news in online networks.

III. Problem Statement

Our strategy for identifying fake news relies on a well-organized dataset denoted as G. Each instance within this dataset, represented by g_i, is a triplet comprising $g_i = \{d_i, C_{d_i}, L_{d_i}\}$ contains the following items:

- News Item (d_i): The central object of investigation, represented as a news article, post, or similar textual content suspected of being fake.
- Replying Posts Set on d_i (C_{d_i}): A chronologically ordered sequence of users' posts on d_i. This sequence captures the surrounding discussion and engagement, providing contextual information for analysis.
- Veracity Label (L_{d_i}): A binary label indicating the truthfulness of the news. $L_{d_i} = 0$ signifies verified truth, while $L_{d_i} = 1$ denotes confirmed falsity.

While C_{d_i} contains all the posts on d_i in temporal order, a crucial aspect lies in acknowledging the explicit connections, such as reply-to and share relationships, that exist between them [34]. We represent each news d_i through a news-post propagation tree (newsPostTree) [15]. The newsPostTree depicts the potential spread of the news from its origin to its wider audience. Edges in this tree follow the direction of potential dissemination. The proposed approach investigates the veracity of fake news on the basis of stances of replying posts on the news. Having stated this, the proposed approach identifies the veracity of fake news on the basis of the following two tasks.

1) Stance detection: Given a post c_i discussing the veracity of a news item d_i, predict the post's overall stance L_{c_i} on the news's accuracy. Possible stances include: *Support:* The post expresses agreement with the news's truthfulness. *Deny:* The post disagrees with the news's accuracy. *Question:* The post raises doubts or seeks clarification about the news's validity. *Comment:* The post focuses on aspects unrelated to the news's veracity.

2) Fake news verification: For each news article d_i, this task aims to determine its overall veracity as either real or fake. We hypothesize that the news article's veracity can be modeled

as a weighted collective assumption based on the stances of its associated posts, similar to the Multiple-Instance Learning (MIL) framework [14]. In our approach, the news article's label is predicted based on the most likely stance category among the stances expressed in the associated posts, considering their distribution within a newsPostTree.

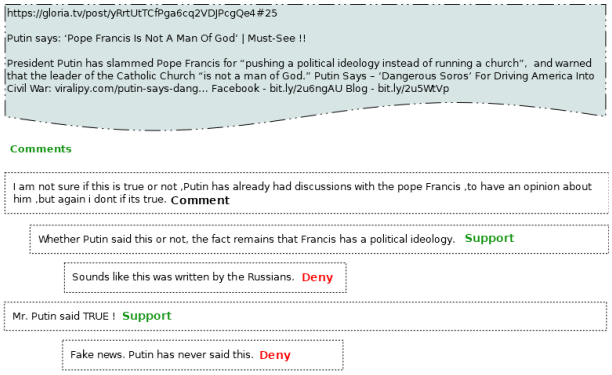

Fig. 1. An example fake news and replying posts on the news.

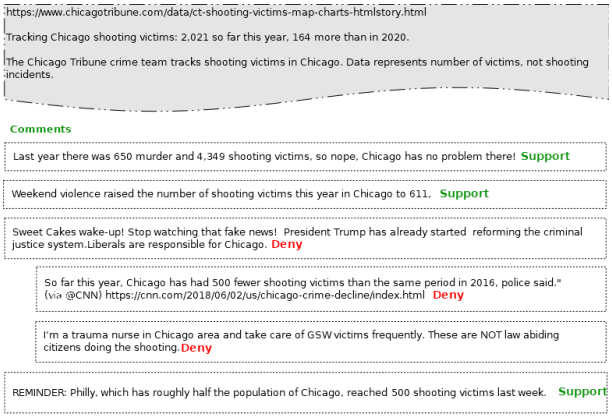

Fig. 2. An example real news and replying post on the news.

IV. Proposed Approach

Traditionally, fake news verification has often been tackled as a single, multi-class classification problem [6]. However, this approach overlooks the intricate interplay between the fine-grained nuances of post stances (e.g. support, deny, question, comment) and the multifaceted nature of news article veracity (e.g. real or fake). To unlock the full potential of this rich information, we propose a novel extension to the Multiple-Instance Learning (MIL) framework. We recognize that a single, multi-class approach might miss the subtle interactions between stance and veracity. Therefore, we decompose the problem into a multitude of binary classification tasks, each focusing on a specific veracity-stance pairing. Let S be the number of stance classes of posts, and let E be the number of veracity classes for news. Given E and S, there exist $H = E * S$ potential veracity-stance target class pairs, each requiring the training of an individual binary classifier for weak supervision in the task of detecting false information. This granularization allows each model to hone its expertise on a precise combination, capturing the subtle details that might be obscured in a global approach.

While individual binary models provide valuable insights, we need to unite their findings to paint a complete picture. This is where the strength of the MIL framework shines. We strategically aggregate the predictions of the individual models, leveraging their collective knowledge to arrive at a robust verdict on the overall news article's veracity.

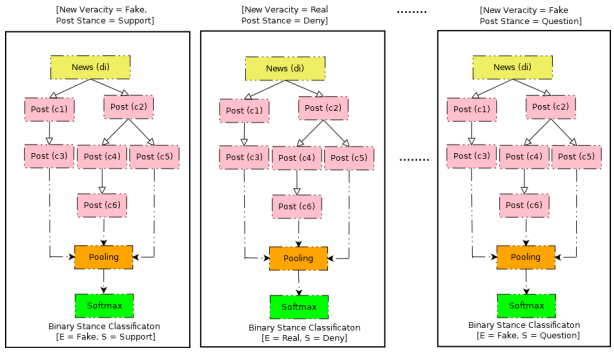

Fig. 3. An architecture of post encoding and binary stance classification of posts.

A. Encoding Replying Posts

To analyze the content of each post and its stance towards news veracity, we leverage powerful neural networks. Each post is first transformed into a sequence of terms $T_{c_i} = \{t_1, t_2, t_3, ..., t_{[c_i]}\}$, a linguistic fingerprint captured by pre-trained term embeddings. These embeddings translate each term t_i into an n-dimensional vector $t_i \in V^n$, encapsulating its meaning and relationships to other terms. Next, we utilize a specialized neural network called a Gated Recurrent Unit (GRU) [35] to understand the flow of information within the post. The GRU processes the term sequence one by one, effectively capturing the context and sentiment woven through the terms. This results in a fixed-size hidden vector that summarizes the essence of the entire post. Finally, to assess the overall stance towards the news article's veracity, we employ two separate GRU-based encoders [36]. These encoders act like dedicated detectives, each scrutinizing the post from a different angle. Their analyses are then condensed into two vectors, capturing the key aspects of the stance of post L_{c_i} and the associated news d_i. In simpler terms, given a number of terms ($T_{c_i} = \{t_1, t_2, t_3, ..., t_{[c_i]}\}$) in the post c_i, the approach breaks down the post into its building blocks (terms) and analyzes how they flow together in a standard GRU transition equation $GRU()$, extracting key aspects of its message (encoders) to ultimately understand its stance towards the news's trustworthiness.

$$V_{d_i} = V_{|d_i|} \tag{1}$$

$$V_{|d_i|} = GRU\left(t_{|d_i|}, V_{|d_i|-1}, \Delta_{d_i}\right) \tag{2}$$

$$V_{c_i} = V_{|c_i|} \tag{3}$$

$$V_{|c_i|} = GRU\left(t_{|c_i|}, V_{|c_i|-1}, \Delta_{c_i}\right) \tag{4}$$

$V_{|d_i|-1}$ and $V_{|c_i|-1}$ serve as hidden units capturing information about the preceding terms in news item d_i and associated post c_i. Δ_{d_i} and Δ_{c_i} encapsulate the entirety of the news and post encoder parameters.

V. News Post Propagation Tree (newsPostTree)

Given a news item d_i, to identify whether d_i is fake news, the proposed approach utilizes the hierarchical tree structure of the replying posts $C_{d_i} = \{c_1, c_2, c_3, ..., c_{|C_{d_i}|}\}$ on d_i, capturing intricate propagation patterns essential for classification (see Fig. 3). Imagine a complex web of online posts, where some spread truth and others spin yarns of misinformation. One such news-post pattern is the "*support-comment-support*" sequence. Imagine some replying posts on a news support the news. Others chime in with questions or comments, and if the evidence in a supporting post holds up, we might see further support emerge. This cyclical pattern tends to be more prevalent in true news, where credible replying posts attract validation and build momentum [15]. On the other hand, fake news often struggle to generate sustained support. They might trigger initial curiosity or even controversy, but without a solid foundation, they tend to fizzle out, lacking the magnetism to attract lasting support.

This model acts like a skilled investigator, navigating this web through the proposed *newsPostTree* structure. Unlike models who focus on individual posts, this model investigates the entire path information takes, starting at the source (root node) and moving down each branch. Each post (node of the tree) can be considered a piece of evidence. This model gathers clues (called "*features*") from each post, like suspicious language or biased references, and strengthens them based on the path they took. If a post agrees with its parent's denial of the original news, the evidence against both strengthens as the model travels down the branch. This "*evidence boost*" happens for each non-leaf node, building a stronger case against potential misinformation. Now, what makes this model special? Unlike models who start at the leaf nodes and piece things together (bottom-up), this model starts at the news (root node) and builds the information tree level by level. Each post's "*evidence file*" combines its own clues with those from its parent, creating a richer picture with each step down the tree. It's like a team of sub-models, each adding their findings to the case news, building a more comprehensive picture with every level [15].

Consider a scenario where the hidden information within a non-leaf node can be seamlessly transmitted to all its child nodes simultaneously, ensuring no loss occurs in the process. In such a context, the determination of the hidden state V_{c_i} for a given node c_i involves a computation that combines the existing hidden state $V_{\text{Parent}(c_i)}$ of its parent node $\text{Parent}(c_i)$ with the input vector specific to the node itself. This integration process allows the formulation of transition equations for node c_i, presenting them in a manner consistent with the principles of a standard Gated Recurrent Unit (GRU).

$$\tilde{V}_{c_i} = V_{c_i}\Gamma \tag{5}$$

$$u_{c_i} = \phi\left(Z_u\tilde{V}_{c_i} + \Upsilon_u V_{Parent(c_i)}\right) \tag{6}$$

$$x_{c_i} = \phi\left(Z_{c_i}\tilde{V}_{c_i} + \Upsilon_x V_{Parent(c_i)}\right) \tag{7}$$

$$\widehat{V}_{c_i} = \tanh\left(Z_V\tilde{V}_{c_i} + \Upsilon_V\left(V_{Parent(c_i)} \odot u_{c_i}\right)\right) \tag{8}$$

$$V_{c_i} = (1 - x_{c_i}) \odot h_{Parent(c_i)} + x_{c_i} \odot \widehat{V}_{c_i} \tag{9}$$

In this context, c_i represents a post, and Γ represents the parameter matrix responsible for transforming this input post. The transformed representation of c_i is denoted as $\tilde{V}c_i$, and Z and Υ signify the weight connections within the GRU (Gated Recurrent Unit). Vc_i refers to the hidden state of c_i, and $\widehat{V}c_i$ represents the candidate activation of the hidden state of the current node. Similar to the standard GRU, $\odot$ indicates element-wise multiplication. The reset gate uc_i determines how to combine the current input $\tilde{V}c_i$ with the memory of children, while the update gate xc_i defines the extent to which memory from the children is incorporated into the current node.

The approach recursively explores the tree, gathering information and "*learning*" about the data point. This information gets condensed into a hidden vector for each leaf. However, the problem is that trees can have different numbers of leaves! This means we can't directly stick those hidden vectors into a neural network with a fixed number of inputs. To solve this, we use a special layer called "*max pooling*" (see Fig. 3). This layer scans all the leaf vectors and picks the highest value for each dimension. This way, we capture the most important features that were highlighted during the walk down the tree, regardless of how many leaves there are. Finally, it considers the best-of-the-best information and feeds it into another layer called "*softmax.*" This layer analyzes the pooled features and makes a prediction about the data point's category. In essence, it takes all the insights gathered from the top-down journey through the tree and uses them to make a confident call. This approach allows us to analyze variable-length trees and effectively leverage the learned features for accurate prediction, even when the journey down the tree can take different paths.

$$L_{d_i} = \text{Softmax}\left(\boldsymbol{W}V_{C_{d_i}} + \boldsymbol{\beta}\right) \tag{10}$$

The parameter $V_{C_{d_i}}$ represents the pooling vector over all leaf nodes, while the parameters W (weight) and β (bias) are instrumental in shaping the output layer.

Our initial investigation explored the feasibility of bottom-up propagation as an alternative information flow mechanism within the model. However, empirical evaluations revealed a substantial decrease in model performance. Analysis identified the overreliance on the root node's representation as the primary culprit for this information loss. This limitation stems from the inherent nature of bottom-up propagation, where information from lower levels aggregates towards the apex, potentially discarding refined features accumulated on diverse propagation paths.

A. Identifying Stance of Posts

Our goal for stance classification is to automatically identify the stance expressed in a social media post, whether it be an opinion or attitude. We can visualize this process as information diffusing through a tree-like structure, with each node representing a component of the post, such as words, phrases, or sentences. Now, think of information flowing down this tree. We assume this diffusion happens perfectly and simultaneously, ensuring all children receive the stance features of their parent. This allows us to build a representation of the overall stance within each "*binary classifier*" $H = E \times S$, which are essentially decision-making units at each leaf node. To achieve this, we used the newsPostTree representation learning approach [37]. This approach works like a translator, converting a node's raw information (including its own content and the stance received from its parent) into a "*context vector.*" This vector captures the gist of the stance expressed at that specific point. Imagine a node c_i, by combining the information from its parent node $Parent(c_i)$ and with its own content, c_i gets translated into a new context vector named $\widehat{V}_{c_i}$. This process repeats recursively as we travel down the tree, with each node's context vector building on the accumulated stance information from its ancestors. In essence, this newsPostTree approach allows us to understand the overall stance of a post by considering not just its individual parts but also the broader context and relationships built up through the hierarchical structure. This information-rich representation empowers the binary classifiers at each leaf node to make more accurate and refined decisions about the specific stance expressed in that part of the text.

$$\widehat{V_{c_i}^h} = \widehat{RNN}\left(V_{c_i}^h, V_{Parent(c_i)}^h, \alpha^h\right) \tag{11}$$

In the context of our model, $\widehat{\text{RNN}}()$ signifies the RNN transition function based on top-down processing [37] of the newsPostTree, with α^h encompassing all associated parameters. Subsequently, a fully-connected softmax layer is employed to forecast the stance probability of c_i concerning the news vector $V_{d_i}^h$ in relation to classifier h:

$$p_{c_i}^h = \text{softmax}\left(\delta_1^h \widehat{V_{c_i}^h} + \delta_2^h V_{d_i}^h + \omega^h\right) \tag{12}$$

In this formulation, δ_1^h, δ_2^h, and ω^h denote the weights and bias of the prediction layer. Subsequent to this, the stance probability for each individual post $p_{c_i}^h$ within the newsPostTree can be calculated using a methodology akin to that described in the above equation.

B. Post-Stance Aggregation

In our quest to assess fake news veracity, not all pieces of evidence hold equal weight. Consequently, it's crucial to selectively amplify the contributions of those pieces of evidence – the binary classifiers within the tree – that demonstrate the strongest correlation between the expressed stances and the actual news veracity. To achieve this, we enlist the power of an "*attention mechanism*" [38]. It carefully scans all the binary classifiers within the tree, analyzing their individual capabilities in capturing the link between stance and news veracity. Those classifiers exhibiting a stronger correlation indicate greater reliability as evidence sources. Conversely, classifiers with weaker correlations fade into the background, their contributions minimized.

$$V_a = GRU\left(t_{|d_i|}, V_{|d_i|-1}, \Delta_a\right) \tag{13}$$

$$\Lambda_h = \frac{\exp\left(V_a \cdot V_{d_i}^{h^\top}\right)}{\sum_h \exp\left(V_a \cdot V_{d_i}^{h^\top}\right)} \tag{14}$$

Δ_a symbolizes the internal configuration of the GRU encoder. $V_{c_i}^h$ represents the news encoded by the h-th classifier. To understand the different stances, our model relies on a collection of specialized "*binary stance classifiers,*" each focusing on a particular stance type. We aggregate all binary stance classifiers targeting the same stance type into a single set $K(S)$, where $s \in S$ can be support, deny, comment, or question. So, while they're all investigating the same type of news, they each have a unique perspective based on their specific training data. The final probability for that stance type is then computed using:

$$\widehat{p_{c_i,S}} = \sum_{h \in K(S)} \Lambda_h \cdot p_{c_i}^h \tag{15}$$

To assess the overall stance landscape, let $K(S)$ represent a team of classifiers focusing on a specific stance type $S \in \{deny, support, comment, question\}$. Each classifier within $K(S)$ outputs a prediction ($p_{c_i}^h$) the probability that the post c_i expresses the target stance S through the stance classifier h. Consequently, $p_{c_i,S}$ denotes the probability that post c_i is categorized as stance S, taking into account the significance of the corresponding classifiers with S as the target class. Despite addressing the same stance, these classifiers vary because each concentrates on a distinct veracity label of the news. By accumulating the weighted predictions for the specific stance S, we obtain the final probability distribution $\widehat{p_{c_i}}$. This process repeats for all possible stance types in S, ultimately painting a comprehensive picture of the different opinions and their relative strengths within the post.

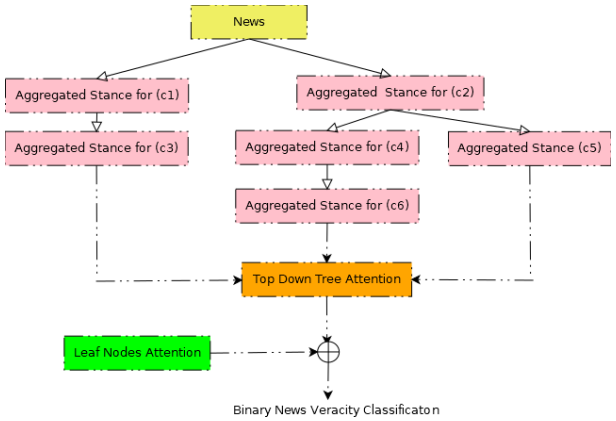

Fig. 4. An architecture of identifying fake news.

C. Identifying Fake News

In the context of verifying news authenticity, simply taking the overall sentiment of a discussion about the news might not be enough. We need to delve deeper, analyzing the individual stances expressed at different replying posts in the conversation and prioritizing those carrying greater evidential weight. To achieve this, we propose a "*newsPostTree Attention Mechanism*" that selectively aggregates stance information throughout the discussion tree (see Fig. 4). Think of the discussion as a branching tree, where each node represents a stance towards the news. Our model focuses on attending to specific nodes within each branch – the ones offering strong evidence for or against the news's veracity. We call these "*evidential stance nodes.*" Formally, let's call a path β_l through the tree from its root d_i (news) to a leaf node c_i. The set of all nodes along that path is denoted by C_{β_l}. To determine the overall aggregated stance for the path β_l, our model accomplishes this in two steps:

1) Selective attention: For each path, the model focuses on the evidential stance nodes. It assigns attention scores to each node, essentially highlighting the ones carrying the most significant evidence for or against the news's veracity. This selective attention mechanism ensures that the aggregated stance doesn't get diluted by less informative opinions.

2) Aggregation: Once the attention scores are calculated, the model combines the information from the evidential stance nodes for the path. This aggregation, using the attention scores as weights, produces a single "*aggregated stance*" for the path. This stance reflects the dominant sentiment, filtered through the lens of the most valuable pieces of evidence identified along the path.

$$\Theta^h_{c_i} = \frac{\exp\left(\widehat{V^h_{c_i}} \cdot {V^h_{d_i}}^\top\right)}{\sum_{i \in C_{\beta_l}} \exp\left(\tilde{V}^h_{d_i} \cdot {V^h_{d_i}}^\top\right)} \tag{16}$$

$$p^h_{\beta_l} = \sum_{n \in C_{\beta_l}} \Theta^h_{c_n} \cdot p^h_{c_n} \tag{17}$$

The symbol $\Theta^h_{c_i}$ denotes the attention coefficient assigned to each node along the path β_l, while $p^h_{\beta_l}$ represents the aggregated probability of stances from leaf nodes along the propagation path β_l. The symbiotic relationship between $\Theta^h_{c_i}$ and $p^h_{\beta_l}$ is pivotal, as it quantifies attention given to individual nodes and determines the collective stance probability of leaf nodes along the specific propagation path.

To capture the overall sentiment surrounding the news, we need to further aggregate information across different paths. Here's where the second stage of our Tree Attention Mechanism starts its work, focusing on informative path selection. Imagine each possible discussion about the news (a path through the tree) as a potential piece of evidence. We want to pick the paths that offer the most valuable insights into the news's veracity. To do this, we leverage the hidden vectors V^k_l embedded in the leaf nodes of each path (β_l). These vectors, generated in the first stage, encapsulate the accumulated stance information at the end of each branch.

Formally, let $\widehat{C_{d_i}}$ represent the set of all leaf nodes within the entire tree, with its root being the news itself. We now employ the Tree Attention Mechanism again, but this time on the set $\widehat{C_{d_i}}$. This second-stage attention assigns scores to each individual path based on the informativeness of its leaf node's hidden vector. Paths with stronger evidence, reflected in their leaf node representation, receive higher scores and are ultimately weighted more heavily in the final aggregation. This weighted aggregation, considering the attention scores for each path, culminates in an "*aggregated path stance.*" This stance represents the collective opinion about the news, filtered through the lens of the most informative paths identified by the second-stage attention mechanism. By prioritizing paths conveying robust evidence, we ensure that our final verdict on the news's veracity is not swayed by less insightful discussions or irrelevant tangents.

$$\Theta^h_{\beta_l} = \frac{\exp\left(\widehat{V^h_{\beta_l}} \cdot {h^h_{d_i}}^\top\right)}{\sum_{\beta_l \in \widehat{C_{d_i}}} \exp\left(\widehat{V^h_{\beta_l}} \cdot {h^h_{d_i}}^\top\right)} \tag{18}$$

$$\widehat{p^h_{d_i}} = \sum_{\beta_l \in \widehat{C_{d_i}}} \Theta^h_{\beta_l} \cdot p^h_{\beta_l} \tag{19}$$

The $\Theta^h_{\beta_l}$ signifies the attention coefficient for each individual leaf node, while $\widehat{p^h_{d_i}}$ encapsulates the probability associated with fake news veracity, derived from aggregating stances along various paths.

D. Aggregating Fake News Classifiers

Instead of analyzing each fake-news veracity classifier individually, our model employs a clever strategy to leverage their collective wisdom. Similar to stance classifiers aggregation, we gather all classifiers targeting the same "*fake news class label*" into a single set. Within each set, the members, which are individual binary veracity classifiers, provide their own assessments of the news's truthfulness. To combine these diverse insights, we utilize a "*weighted sum*" approach.

We used an indicator set $K(e_o)$ to group binary classifiers targeting the same veracity class e_{fake}, e_{real} in E. Each classifier within $K(e_o)$ provides a binary veracity prediction (fake or real) for the news item d_i, representing the probability $p^h_{d_i}$ of it belonging to veracity class e_o through the classifier h. Notably, although they share the same veracity target, classifiers in $K(e_o)$ differ in their assigned "*target stance classes.*" These stance classes represent specific sentiment or opinion types they analyze within the news. This differentiation leads to diverse stance probability predictions across classifiers, even for the same veracity class. By aggregating these stance-informed predictions, we obtain a richer representation of the news item's veracity. The final probability distribution over all veracity classes, denoted by $\widehat{p_{d_i}} = [\widehat{p_{d_i,fake}}, \widehat{p_{d_i,real}}]$, captures the combined insights from each classifier's unique perspective.

E. Training and Optimizing the Learning Model

To train our model using multiple binary classifiers, we convert the fine-grained veracity and stance annotations into binary labels. Each classifier targets a specific veracity-stance pair, where the veracity label of a news article d_i is mapped to either the target class or *others* (non-matching cases). Similarly, each post's stance is modeled as a probability distribution over the target stance class. This label transformation is applied uniformly across all classifiers, enabling them to distinguish between a specific veracity-stance combination and all other instances. While stance predictions are utilized during training, the ground truth for fake news verification focuses solely on the veracity of the news article, as post-level stance annotations are often sparse and potentially unreliable.

1) Training binary MIL-based classifiers: Our model hinges on the negative log likelihood (NLL) as the key metric for measuring prediction accuracy.

$$M = -\sum_{h=1}^{H}\sum_{d_i=1}^{D} L_{d_i} * \log \hat{p}_{d_i}^{h} + (1 - L_{d_i}) * \log\left(1 - \hat{p}_{d_i}^{h}\right) \quad (20)$$

For each news item d_i, let L_{d_i} represent the ground truth. $p_{d_i}^{h}$, on the other hand, signifies the predicted probability generated by classifier h for the news item d_i. This equation takes into account all D news items and H binary classifiers in the model, making it a powerful tool for evaluating how well predicted probabilities align with actual outcomes across the entire dataset.

2) Training aggregation model: To guide our aggregation model towards optimal performance, we leverage a powerful training technique called the "*negative log-likelihood loss function.*"

$$\widehat{M} = -\sum_{f=1}^{F}\sum_{e=1}^{E} L_{f,e} * \log \hat{p}_{f,e} + (1 - L_{f,e}) * \log\left(1 - \hat{p}_{f,e}\right) \quad (21)$$

The model produces a "*predicted probability*" ($p_{f,e}$) of the f news belonging to a specific veracity class $e \in E$. In this context, $L_{f,e}$ represents a binary value that signifies whether the veracity class of the f-th news, based on groundtruth, is e. Finally, E signifies the total number of possible veracity classes.

The negative log-likelihood loss function then steps in with its rigorous assessment. It calculates a penalty based on the discrepancy between the model's prediction and the actual truth. If the model confidently predicts the wrong class, the penalty is severe, urging it to adjust its reasoning. Conversely, a confident and accurate prediction earns minimal punishment. As the model processes numerous news items, it undergoes a continuous learning process guided by the penalties. It refines its ability to interpret and weigh the individual stance information, gradually honing its skill in predicting the overall veracity of the news with increasing accuracy. By minimizing the negative log-likelihood over countless news samples, the model effectively learns to distinguish fake news news from real news within the chosen framework of veracity classes.

To fine-tuning We used "*back-propagation*" [39], which meticulously analyzes the model's output and works backwards to optimize the model. To guide this optimization process, we leverage the "*Adam*" optimizer [40]. which maneuvering the learning rate (the pace of adjustments) to ensure the model progresses efficiently without getting stuck in overfitting or underfitting traps. We set the initial learning rate at 0.001, and it can dynamically adapt based on the model's performance. To infuse our model with rich linguistic understanding, we pre-train its word embedding layer using pre-trained "*GloVe Wikipedia 6B word embeddings*" [41]. These pre-trained vectors offer an initial advantage, enabling the model to swiftly understand the intricacies of language within the news it analyzes. The training process persists until two crucial conditions are satisfied:

- Convergence of the loss value: We monitor the "*loss function,*" a metric that quantifies the model's errors. When the loss stabilizes and stops decreasing significantly, it indicates that the model has likely reached its optimal performance.
- Maximum epoch number reached: In case the loss doesn't converge perfectly, we also set a pre-defined maximum number of training iterations ("*epochs*") as a safety net. This ensures the training process doesn't run indefinitely and allows us to evaluate the model's performance at various stages.

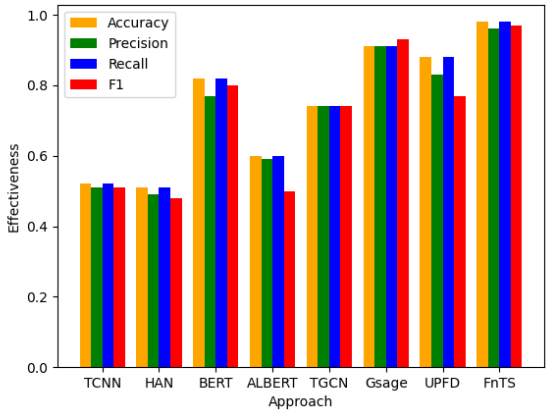
At the end the model applies the "*weighted aggregation model,*" which combines the insights from all individual classifiers to deliver a unified verdict on the news item's overall veracity.

VI. Experiments

For investigating the impact of news propagation patterns on fake news detection, we used the FakeNewsNet datasets [42], which are integral to understanding the dynamics of misinformation in online spaces. These datasets encompass source news that has undergone fact-checking by reputable sources such as PolitiFact and GossipCop, along with the associated tweets and social engagement data of users. The PolitiFact dataset comprises a total of 1,056 news articles, including 432 identified as fake news and 624 classified as real news articles. Similarly, the GossipCop dataset encompasses a total of 22,140 news articles, with 5,323 categorized as fake news and 16,817 as real news articles. Regarding the social context, PolitiFact observed 95,553 users posting tweets about fake news and 249,887 users posting tweets about real news. In the case of GossipCop, fake news generated 265,155 user tweets, while real news garnered 80,137 user tweets. The user social data is comprehensive, involving the crawling of user attributes and user-following relations, providing insights into how individuals interact with and disseminate information. The labels within the dataset categorize news as either "*real news*" or "*fake news*". To ensure a focused analysis, retweets are filtered out from the datasets, allowing a more clear examination of the primary propagation patterns.

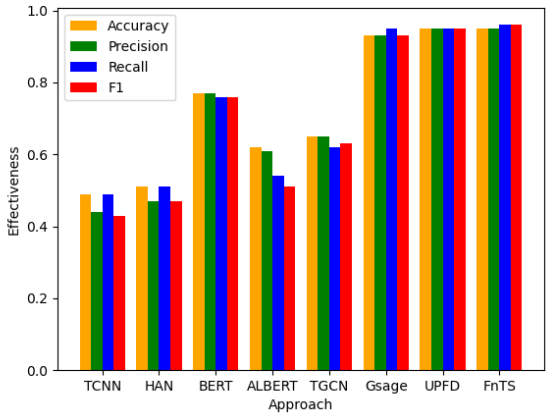
We trained and tested our model on the SemEval-8 dataset [43]. SemEval-8 offers a rich tapestry of data, with each news item meticulously labeled as either "*true,*" "*fake,*" or "*unverified-fake.*" We consider the samples only labeled

as either "*true*" or "*fake*". This veracity labeling goes beyond a simple binary classification, offering valuable insights into the spectrum of information trustworthiness. Moreover, each news item is accompanied by user posts categorized by their expressed stance: "*support,*" "*deny,*" "*question,*" or "*comment.*" While prior research on SemEval-8 often focused on a holistic understanding of rumor detection and stance prediction, our investigation took a more granular approach. We focused exclusively on news items categorized as true or fake, effectively framing the task as a binary veracity classification. This decision allowed us to hone in on the core challenge of distinguishing factually accurate news from misinformation. Furthermore, instead of simply predicting the overall stance category for each post, we opted for a more fine-grained analysis. We trained eight individual binary stance classifiers, one for each possible stance-veracity combination.



To optimize our model's performance, we held out 20 percent of the test data as a validation set. This allowed us to adjust hyperparameters precisely, ensuring the best possible performance. We further employed a rigorous set of evaluation metrics, including Accuracy, Precision, Recall, and F1 score (F1). These metrics, taken together, offer a comprehensive picture of how effectively our models distinguish real and fake news, while also capturing the fine details of stance detection. Furthermore, we built all our neural networks using the well-regarded PyTorch framework [44]. This ensured consistency and reliability throughout the computational aspects of the study.

A. Results

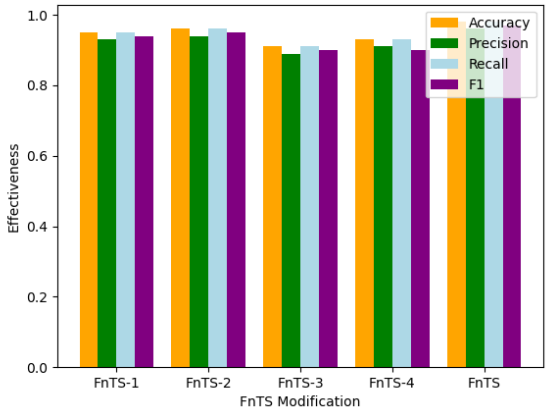


To evaluate the efficacy of any novel model demands a rigorous testing ground. For the proposed approach, we constructed a two-pronged evaluation strategy. First, we compare the performance of our proposed approach (**FnTS**) against several baseline approaches: TextCNN [45], HAN [46], BERT [47], ALBERT [48], TextGCN [49], GraphSage [50], and UPFD [51]. Second, we armed ourselves with a quartet of robust evaluation metrics: Accuracy, Precision, Recall, and F1-score (F1). These metrics collectively paint a clear picture of how effectively FnTS discerns real from fake news, capturing both its overall success rate and its ability to avoid both false positives and negatives.

According to Fig. 5, results on both datasets show that the proposed approach (FnTS) achieves the optimal score on all four metrics. This consistent performance across metrics and datasets underscores the strength of our approach, suggesting that considering the stance of posts truly makes a difference in the war against misinformation. Further investigation unveils the secret sauce behind FnTS's success: its top-down exploration of social networking posts. By delving deeper into the intricacies of social connections, the newsPostTree hierarchy exploration captures a richer tapestry of information compared to baseline methods. Specifically, the attention mechanism, a built-in spotlight highlighting vital post-stances, plays a crucial role in identifying and extracting distinctive user signals. These signals ultimately empower FnTS to make more informed and accurate fake news detection decisions.

Graph models, which utilize both textual and structural information, consistently surpass their counterparts that focus solely on text. Notably, GraphSage [50], powered by a customized news propagation graph, consistently demonstrates outstanding performance, outperforming all text-based methods. On the other hand, UPFD [51], another strong competitor, also uses user information as a tool. However, its reliance on historical data makes its performance vulnerable to fluctuations specific to the dataset, unlike the steadfast accuracy displayed by FnTS. To conclude, the comprehensive evaluation of FnTs paints a compelling picture of its effectiveness. Not only does it outperform or closely match baseline approaches, but it also sheds light on the power of incorporating user connections into fake news detection models. These findings pave the way for further advancements in leveraging social network dynamics to combat the ever-evolving landscape of misinformation.

(a) Politifact.



(b) Gossipcop.

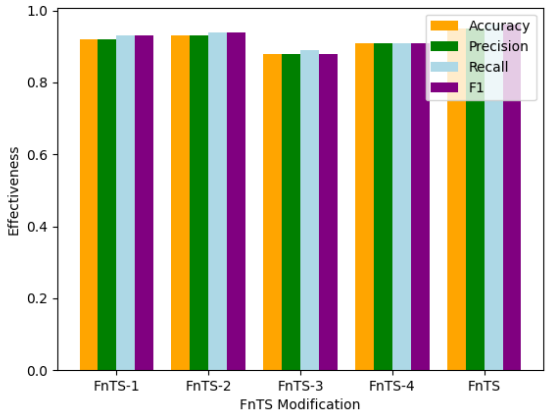


Fig. 5. Effectiveness of the proposed approach (FnTS) and baseline approaches on two benchmark datasets.

B. Component Study

To understand how each components of our proposed approach contributes to its success in fighting fake news, we conducted an experiment called an "*ablation study*" on FnTS with four modifications.

(a) Politifact.

(b) Gossipcop.

Fig. 6. Component studies of the proposed approach.

- FnTS-1: In this modification, we kept the tree-based attention mechanism but replaced the "*post encoder*" with non-structured post encoder.
- FnTS-2: We replaced the "*newsPostTree attention mechanism*" with a more common one (dot product) for stance aggregation.
- FnTS-3: In this modification we remove the recursive tree-based stance aggregation.
- FnTS-4: In this modification we remove the tree-based attention mechanism and replace the tree-based post encoder with a non-structural post encoder.

The results, shown in Fig. 6, indicate that FnTS-3 performs the worst, showing that the tree structure in both post encoding and stance aggregation is crucial. Without it, the model's ability to spot fake news drops significantly. FnTS-4 also stands out with the lowest performance scores, displaying substantial declines in accuracy, precision, recall, and F1 score for fake news verification. Changes to the tree-based attention mechanism (FnTS-2/FnTS-4) also hurt performance the most. This tells us that how the model focuses on its relevant parts while understanding their relationships through their tree structure is critical for its accuracy. In simpler terms, our experiment reveals that both the tree structure and the special way the model pays attention to different parts of the posts are essential for its success in detecting fake news. By understanding these key components, we can further improve our model and keep up with the ever-evolving world of misinformation.

TABLE I. ATTENTION SCORES OF BRANCHES OF NEWS-POST PROPAGATION TREE FOR CLASSIFYING FAKE NEWS

Branch	Attention Score
News− >Support− >Query− >Support	0.12
News− >Support− >Query− >Comment	0.07
News− >Support− >Support	**0.46**
News− >Deny− >Deny	**0.20**
News− >Comment− >Support− >Support	**0.21**
News− >Comment− >Comment	0.02
News− >Comment− >Support	0.04
News− >Query− >Comment	0.03
News− >Query− >Deny	0.02

TABLE II. ATTENTION SCORES OF BRANCHES OF NEWS-POST PROPAGATION TREE FOR CLASSIFYING REAL NEWS

Branch	Attention Score
News− >Comment− >Deny− >Support	0.12
News− >Comment	0.02
News− >Comment− >Deny	0.09
News− >Comment− >Deny− >Support	**0.15**
News− >Query− >Deny	0.09
News− >Deny− >Support	**0.43**
News− >Deny− >Support− >Comment	**0.23**

VII. DISCUSSION ON THE PROPOSED APPROACH

To peek into the inner workings of the proposed approach, we designed an experiment using the FakeNewsNet datasets [42]. We selected two trees from this dataset, one where the source news is "*Real*" and another where it's "*Fake.*" Table I and Table II show how our model analyzes the comments and replies associated with each news, represented as branches and leaves in the "*trees.*" The bold paths highlight the tree branches that are deemed most relevant for determining whether the news is actually true or false. By looking at the attention scores assigned to each post, we can uncover fascinating patterns:

1) Fake news: When the source news is labeled "*Fake,*" the model focuses heavily on comments that deny the news and then support it (branches with "*deny-support*" and "*deny-support-comment*"). This "*doubling back*" behavior suggests the model identifies these conflicting stances as suspicious clues.

2) Real news: On the other hand, for "*Real*" news, the model prioritizes comments that consistently support the news or deny the deny post (branches with "*support-support,*" "*deny-deny,*" and "*comment-support-support*"). This aligns with our intuition that consistent stances reinforce the legitimacy of the news.

3) Deny vs. Support: Interestingly, comments expressing denial play a more significant role when the news is classified as "*Fake*" (higher attention scores on denial branches). Conversely, support comments hold greater weight when the news is deemed "*Real.*"

4) Propagation paths: The branches trace the pathways through the trees that the model deems most influential in reaching its verdict. This highlights the importance of considering the structure of the discussion along with the individual comments themselves.

These observations confirm our belief that the "*tree propagation structure*" is vital for accurately recognizing fake news. By analyzing the relationships between comments and their stances, the proposed approach builds a nuanced understanding of online discourse, ultimately separating fact from fiction in the ever-evolving world of information.

VIII. Conclusion

This research presents a novel weakly supervised propagation model built upon the Multiple Instance Learning (MIL) framework. The proposed model is designed to tackle the dual challenge of simultaneously verifying the authenticity of fake news and identifying the stances expressed in associated posts. Crucially, our model achieves this feat using only bag-level annotations, specifically fake news veracity labels, demonstrating its ability to effectively learn from limited supervision. This unique approach empowers the model to collectively infer both the truthfulness of news and the previously unseen stance labels for individual posts within the associated propagation tree. The distinct tree-based stance aggregation mechanisms, deployed using newsPostTree configurations, are a key innovation of our work. This mechanism has yielded demonstrably superior performance for fake news identification tasks, surpassing the benchmarks established by state-of-the-art supervised and unsupervised models. The significance of our findings resides in the successful application of weakly supervised learning to significantly enhance the accuracy and efficiency of fake news verification in social media settings. The proposed framework opens several avenues for future work. One promising direction is extending the model to handle multi-modal data by incorporating images, videos, and metadata alongside textual and propagation features. Another important line of research is applying the framework to emerging real-time scenarios, such as early detection of misinformation during breaking news events. Additionally, improving interpretability through explainable AI techniques would make the system more transparent and valuable for journalists, fact-checkers, and policymakers.

***Abstract*—Frequent itemset mining faces the prominent problems of high storage space requirements and low efficiency in a large-scale transaction data environment.The traditional Eclat algorithm usually uses bitmap or sparse array to represent a single transaction identifier (TID), which is difficult to adapt to the changes of dense and sparse transaction data at the same time; Although the existing hybrid representation schemes can partly alleviate this problem, the additional computational overhead caused by frequent data structure switching and the inherent space waste of bitmap structure have not been fundamentally solved. Therefore, this article proposes a HiAGL-FIM algorithm based on Hierarchical Adaptive Gap Run Transaction Identifier List (HAGL-TID). This algorithm adaptively selects Gap List or Run List for transaction identifier encoding through continuity ratio, and designs an efficient TID intersection operation method, completely eliminating dependence on bitmap structure and effectively reducing memory consumption and intersection calculation overhead. The experimental results show that HiAGL-FIM has significant advantages in terms of running time, memory usage, and data scalability compared to classical algorithms such as Eclat, FP Growth, and dEclat. Especially when the transaction data scale reaches millions, it shows a more significant performance improvement, demonstrating the effectiveness and practical value of our method.**

***Keywords*—Frequent itemset mining; pure Eclat; Hierarchical Adaptive Gap-Run List (HAGL-TID); large-scale transaction data**

I. Introduction

With the rapid development of big data technology and artificial intelligence, frequent itemset mining (FIM), as one of the core problems in the field of data mining, has received widespread attention and in-depth research in recent years [1]. The goal of frequent itemset mining is to identify frequently occurring combinations of items from transactional datasets, which plays an important role in many application fields such as market basket analysis, recommendation systems, bioinformatics, and anomaly detection[2]. Among the existing frequent itemset mining methods, Apriori algorithm and FP Growth algorithm are widely used due to their clear theoretical basis and simple implementation [3]. However, the Apriori algorithm has low efficiency due to its multiple scans of the database and frequent generation of candidate sets; Although FP Growth avoids frequent database scans, it may incur significant memory overhead when building FP trees [4]. The Eclat algorithm records itemset support information through a Transaction Identifier List (TID), significantly reducing the number of database scans and achieving good efficiency [5]. However, traditional Eclat algorithms usually only use a single TID representation method (such as sparse arrays or bitmaps), which fails to simultaneously consider the sparse and continuous features of transaction data, resulting in low memory efficiency and significant optimization space for performance when applied in real datasets [6].

In recent years, researchers have proposed various hybrid TID representation strategies around "density adaptation". The typical approach is to dynamically switch between bitmap, array, or N-list/NegNodeset structures based on local transaction density, such as Tseng et al.'s FPL/TPL adaptive framework [7], Poovan et al.'s multi-threaded NegNodeset+N-list hybrid framework [8], and Bashir and Baig's HybridMiner algorithm [9]. These methods have achieved a good trade-off between time and space on small and medium-sized datasets, but there are still two major bottlenecks: firstly, the threshold for structure switching depends on empirical settings, which requires repeated re-encoding of TID in the face of frequent fluctuations in transaction density in streaming scenarios, resulting in significant CPU and cache overhead; secondly, even though bitmap is efficient in dense scenes, its storage requirements still increase linearly with transaction volume, resulting in a large amount of empty space waste when sparsity increases. The Ramp algorithm has conducted a detailed analysis on this [10]. Furthermore, the closed set miner CICLAD, which targets data streams of millions or more, also reported the issue of high peak memory consumption in traditional bitmap/node-set methods [11]. Therefore, how to completely eliminate the reliance on bitmap representations while enabling finer-grained continuity modeling, and how to maintain stable mining efficiency in environments with sparse remains a major gap in current mixed TID research. This issue is mainly reflected in two aspects: first, existing hybrid approaches depend heavily on frequent structure switching and empirically set thresholds, which often require repeated re-encoding under fluctuating transaction densities and lead to additional CPU and cache overhead; second, the storage cost of bitmap structures increases linearly with data size, causing severe space waste in sparse regions and making it difficult to meet the performance demands of large-scale transactional datasets.

In response to the above challenges, this article proposes a new frequent itemset mining algorithm — HiAGL-FIM. This algorithm innovatively introduces a transaction-ID representation method based on Hierarchical Adaptive Gap Run List (HAGL-TID). The HiAGL-FIM algorithm does not rely on traditional bitmap structures; instead, it adaptively selects Gap or Run lists for compression storage and intersection operations according to

the continuity of transaction data, thereby significantly reducing memory consumption and improving the efficiency of frequent itemset mining. HiAGL-FIM avoids repeated re-encoding in hybrid approaches through one-time adaptive compression modeling based on continuity ratio after a single scan. It also introduces structure-specific intersection operators and a unified support calculation formula for Run–Run, Gap–Gap, and Run–Gap cases, which improve time efficiency and memory compactness under the premise of completely removing bitmap dependency.This article will provide a detailed introduction to the theoretical basis, specific implementation methods, and experimental verification results of the HiAGL-FIM algorithm in subsequent chapters, in order to demonstrate its excellent performance and wide applicability on different types of datasets.

The remainder of this paper is organized as follows: Section II reviews related work on frequent itemset mining and hybrid TID representations. Section III details the proposed HiAGL-FIM algorithm, including its structure, generation process, and complexity analysis. Section IV presents experimental results and performance comparisons with state-of-the-art algorithms. Section V concludes the paper and discusses future research directions.

II. Related Work

Frequent itemset mining algorithms have undergone decades of development, and researchers have proposed a series of classic algorithms and optimization strategies, mainly divided into two categories: horizontal data formats and vertical data formats. The algorithms based on horizontal data formats are represented by the classic Apriori [12] and FP Growth [3]. Among them, the Apriori algorithm first proposed a strategy of generating candidate itemsets layer by layer and pruning them, effectively reducing the search space. However, in large-scale datasets, a large number of candidate sets will be generated, leading to serious performance bottlenecks; FP Growth compresses data through a tree structure (FP Tree), avoiding the generation of candidate sets and improving mining efficiency. However, in the process of building and maintaining FP Tree, it still faces significant memory and time overhead, especially in high-dimensional data and high workload scenarios [13].

The vertical data format algorithms are represented by Eclat [5], Charm [14], and dEklat [15]. The Eclat algorithm represents the transaction support information of each itemset through a transaction identifier list (TID), greatly reducing the number of database scans and suitable for fast mining of large-scale transaction data; Charm further utilizes the characteristics of closed itemsets to optimize the vertical mining process and obtain closed frequent itemsets in a more efficient way; DEklat, on the other hand, reduces the overhead of intersection operations between TID lists through an extended Diffset structure, significantly improving mining efficiency [16]. However, these classic vertical formatting methods all default to using a single type of data structure to represent transaction support information, making it difficult to simultaneously meet performance requirements under different data densities.

To address this issue, researchers have recently begun exploring adaptive data representation structures to adapt to changes in data distribution. Tseng et al. proposed the FPL/TPL framework, which dynamically switches between sparse array and bitmap representations based on the local density of transaction data. Although it improves computational efficiency, the additional overhead caused by data structure transformation operations is particularly prominent in scenarios with frequent changes in data density [7]. Similarly, the NegNodeset+N-list hybrid storage method proposed by Poovan et al. also faces the burden of structural transformation in density changing scenarios, especially with poor performance when the transaction data scale expands [17]. In addition, the HybridMiner algorithm developed by Bashir et al. uses a combination of bitmap and array representations. Although it has improved mining efficiency, it still cannot fundamentally solve the problem of space waste caused by the linear growth of bitmap storage with transaction size [9].

To reduce the high memory requirements of bitmap representation structures, the Ramp algorithm has designed an efficient bit vector projection technique, which to some extent reduces the redundant storage of bitmaps. However, it still generates a large amount of redundant space when transaction data density is sparse [10]. For data stream mining scenarios, the CICLAD algorithm proposed by Martin et al. utilizes compact data structures to improve memory usage efficiency. However, in high-density and volatile scenarios, this algorithm still suffers from reduced computational performance due to frequent data structure adjustments [11]. The existing frequent itemset mining algorithms have more or less the following bottlenecks: 1) a single data representation structure is difficult to accommodate the different density features of transaction data, resulting in insufficient adaptability of the algorithm. 2) Although mixed data representation methods can partially solve adaptability problems, the additional computational burden brought by data structure transformation limits their application effectiveness when transaction density frequently changes. 3) Although traditional bitmap representation is efficient in dense scenarios, it still faces significant memory consumption issues when processing datasets with transaction scales of tens of millions or even billions. Therefore, it is particularly important to design a frequent itemset mining algorithm that does not require bitmap and can automatically adapt to transaction data of different densities. The HiAGL-FIM algorithm proposed in this article adopts a hierarchical adaptive Gap Run transaction identifier representation structure, which completely avoids the shortcomings of bitmap representation, effectively balances the algorithm's space occupation and computational efficiency, and further promotes the practical application of frequent itemset mining in large-scale transaction data.

III. HiAGL-FIM Algorithm

A. Algorithm Framework

The design goal of HiAGL-FIM is to introduce an adaptive transaction identifier compression structure in the modeling stage, combined with structure-specialized intersection operations and layered scheduling mechanisms, to maintain efficiency and stability in large-scale environments with mixed dense and sparse transactions. To achieve this objective, the overall process is divided into five tightly connected phases.

1) Phase 1: Transaction scanning and inverted TID construction: The transaction database $D = \{\tau_1, \ldots, \tau_n\}$ is

scanned linearly to construct the transaction identifier sequence $T_i = \{t_1 < \cdots < t_{|T_i|}\}$ for each item $i \in \mathcal{I}$, while also performing global support counting. This phase completes the initialization of the inverted structure, laying the foundation for subsequent compression and pruning.

2) Phase 2: Continuity-driven adaptive compression: The structural choice is determined by the continuity ratio $\phi(T_i)$:

$$\phi(T_i) = \frac{\sum_{k=1}^{|T_i|-1} \mathbf{1}[\,t_{k+1} - t_k = 1\,]}{|T_i| - 1} \tag{1}$$

When $\phi(T_i) \geq \rho_0$, T_i is compressed into a Run-List; otherwise, it is compressed into a Gap-List. The compression operation is performed once during the modeling phase and remains stable throughout mining, avoiding the overhead of frequent structure switching in mixed-density scenarios.

3) Phase 3: Frequent 1-itemset extraction and buffer partitioning: For each T_i, support is calculated as the sum of segment lengths if stored as a Run-List, or as the element count if stored as a Gap-List. Items with $\sup(i) \geq \theta$ are identified as frequent 1-itemsets and included in the initial result set. Simultaneously, frequent 1-itemsets are partitioned into high-, medium-, and low-frequency buffers, establishing a layered scheduling mechanism to enhance cache locality and prepare for subsequent intersection operations.

4) Phase 4: Structure-specialized intersection and pruning: Candidate itemset expansion adopts a depth-first strategy, and support calculation relies on structure-specialized operators:

$$\mathrm{supp}(A \cap B) = \begin{cases} \sum_{(s,\ell)\in(R_A \cap R_B)} \ell, & \text{Run} \times \text{Run}, \\ |G_A \cap G_B|, & \text{Gap} \times \text{Gap}, \\ |\, G_{\text{gap}} \cap \mathrm{Expand}(R_{\text{run}})\,|, & \text{Run} \times \text{Gap}. \end{cases} \tag{2}$$

Here, $R_\star$ denotes the Run-List and $G_\star$ denotes the Gap-List. During the intersection process, the upper bound of support is used for short-circuit pruning. If the upper bound falls below the threshold θ, the computation is terminated immediately to reduce unnecessary overhead.

5) Phase 5: Recursive expansion and termination: Candidate itemsets that meet the support threshold are recursively expanded, with their TID structures retained as new prefixes. The depth-first expansion strategy ensures a low memory footprint and strong path locality, enabling the algorithm to scale effectively on large datasets. Recursive traversal also allows heuristic pruning methods to be combined, further improving overall execution efficiency.

B. Principle

HiAGL-FIM (Hierarchical Adaptive Gap-Run List-based Frequent Itemset Miner) is an efficient frequent itemset mining algorithm for large-scale transaction data. Its core lies in constructing a hierarchical adaptive transaction identifier representation structure—HAGL-TID (Hierarchical Adaptive Gap-Run Transaction Identifier List). This structure breaks away from the reliance of traditional Eclat and its variants on bitmaps and static sparse arrays. It offers high compression capabilities and density adaptability, effectively improving mining efficiency and resource utilization in both dense and sparse transaction data environments.

The overall process of HIAGL-FIM follows the algorithm framework of "one-time modeling, adaptive compression, structure-specialized intersection, recursive deep expansion". First, the algorithm scans the transaction database $\mathcal{D} = \{t_1, t_2, \ldots, t_n\}$ in sequence, and constructs the tid list T_i for each item $i \in I$. Then, the algorithm measures the local density of the TID list by defining the continuity ratio $\phi(T_i)$ as in Eq. 1. If adjacent TIDs are continuous, the function evaluates to 1. When $\phi(T_i) \geq \rho_0$, the transaction sequence exhibits high continuity. The algorithm compresses it into a *Run-List* structure, recording the starting position and length of each continuous segment; otherwise, it preserves the sequence as an ascending sparse integer array (i.e. a *Gap-List*). This structural compression is completed during the initial database scan and remains static throughout the mining phase, eliminating the re-encoding overhead inherent in traditional dynamic hybrid structures.

To further improve access efficiency, HIAGL-FIM introduces the support-layered buffer mechanism, which divides all TID structures into high-frequency, intermediate-frequency, and low-frequency levels according to their support values, and manages them separately to strengthen memory locality.

During the mining phase, the algorithm uses a depth-first search (DFS) strategy to recursively expand candidate itemsets. In each expansion process, the pre-built inverted TID structure is used to locate the transaction sets between candidate itemsets, and the structure-specialized intersection operator is selected to efficiently calculate the intersection support according to the TID structure combination, including:

- Run × Run: sliding window matching for continuous segments;
- Gap × Gap: sparse array processing with double-pointer or vectorization;
- Run × Gap: fast positioning and screening through interval judgment and mask operations.

When the support of the intersection result is lower than the preset minimum threshold θ, the algorithm prunes immediately to avoid invalid expansion. Through this structure-driven recursive expansion mechanism, HIAGL-FIM maintains stable mining performance in dense and sparse mixed scenarios, while significantly reducing memory consumption and intersection computational complexity. The overall process is shown in Fig. 1.

C. Generation Process

The complete generation process of HIAGL-FIM algorithm includes five stages: transaction preprocessing and inverted structure construction, continuity compression modeling, frequent 1-itemset extraction and buffer partition, candidate itemset intersection support calculation, and recursive expansion to generate frequent itemsets. The process is built around the HAGL-TID structure, forming a seamless mapping from the original transaction to efficient frequent itemsets.

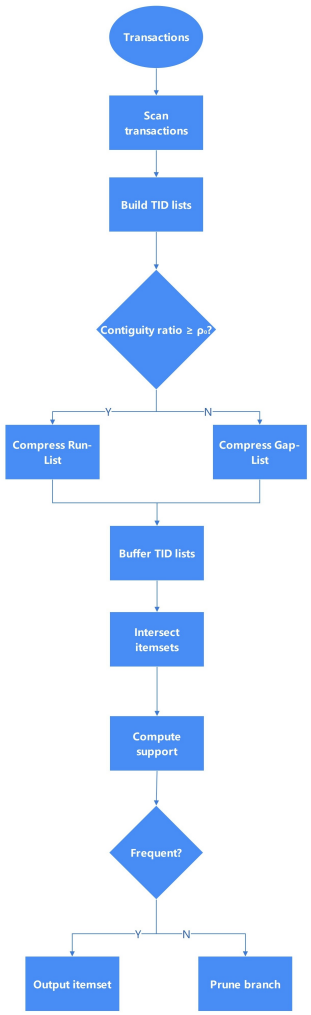

Fig. 1. The overall process of HIAGL-FIM.

1) Transaction scanning and inverted TID structure construction: Firstly, the algorithm performs a single round linear scan on the input transaction database $D = \{\tau_1, \tau_2, \ldots, \tau_n\}$. For each transaction τ_j, write the transaction number j of all items i into its corresponding inverted TID list T_i. At the same time, the algorithm counts the global support of each item to prepare for the subsequent compression modeling and pruning.

2) Modeling of transaction ID compression driven by continuity: After the TID list is built, the algorithm sets the transaction number sequence for each item $T_i = \{t_1, t_2, \ldots, t_{|T_i|}\}$ and conducts continuity assessment by calculating its continuity ratio as in Eq. 1. This ratio describes the intensity of transaction distribution.

According to the continuity threshold ρ_0 (e.g. 0.25), the algorithm determines the structural representation:

- If $\phi(T_i) \geq \rho_0$, it will be compressed into a Run-List structure, recording the starting position and length of each continuous transaction segment.
- Otherwise, the Gap-List structure is retained, representing all TID numbers as an ascending sparse array.

The compression operation is performed only once, and the structure type remains unchanged throughout the mining process. This avoids the problem of heavy recoding of hybrid structures in density fluctuation scenarios, improving stability and execution efficiency.

- Frequent 1-itemset extraction and hierarchical buffer partition: The algorithm then calculates the support of TID structure T_i of each item i:
  - For Run-List: support is the sum of the lengths of all sections.
  - For Gap-List: support is the number of elements in the array.

If support $\sup(i) \geq \theta$ (minimum support threshold), item i is determined to be a frequent 1-itemset. All frequent 1-itemsets are included in the result set and serve as the starting point for subsequent candidate extensions.

At the same time, the algorithm divides its TID structure into high-frequency, intermediate-frequency and low-frequency buffers according to the size of each support, and uses a hierarchical scheduling mechanism to improve access locality and cache hit rate, providing structured support for the intersection calculation stage.

- Intersection calculation and support determination of candidate itemsets

Starting from frequent 1-itemsets, the algorithm uses depth-first search (DFS) to recursively construct candidate itemsets. For two frequent k-itemsets A and B with the same prefix, if their first $k-1$ items are identical, the connection extension is performed to generate the candidate itemset $C = A \cup B$.

To calculate the support of candidate itemset C, the algorithm calls the structure-specific intersection operator, following the unified formula given in Eq. 2.

The formula provides the mathematical basis for support determination and subsequent pruning strategies and recursive expansion. To improve efficiency, the algorithm introduces a short-circuit mechanism during intersection—when the maximum possible support is known to be below θ before completing intersection, the calculation terminates immediately and skips subsequent extensions, effectively reducing unnecessary computational overhead.

- Recursive extension and termination of frequent itemsets.

For each candidate itemset C that passes the support determination, the algorithm recursively expands the next-level candidate set as a new prefix, and continues to perform connection, intersection and pruning until no more itemsets meeting the support requirements can be generated. The depth-first expansion strategy has low memory footprint and path locality, and shows good scalability in large-scale transaction data. In addition, recursive traversal allows the combination of heuristic pruning methods to further improve execution efficiency.

Through the above five stages, HIAGL-FIM not only ensures the high compression rate and structural stability of

the algorithm, but also realizes the efficient recursive mining of frequent itemsets. Especially in the aspect of support calculation, a unified and scalable mining engine is constructed based on the structure-specific intersection strategy of Run-List and Gap-List structures and the formal support determination formula. This algorithm does not need to rely on the bitmap structure, and avoids the frequent switching of hybrid structures, comprehensively improving adaptability in large-scale dense-sparse mixed transaction environments. The pseudo-code is as follows, and experimental verification will be carried out in the following chapters.

Algorithm 1 HiAGL-FIM: Hierarchical Adaptive Gap-Run List Frequent Itemset Miner

Require: Transaction database T, minimum support fraction $minsup_fr$
Ensure: Frequent itemsets F
Load T from file
Initialize *item_to_tidlist* as empty dictionary
for each transaction T_i in T **do**

      end for
    end for
  end for
  $level_k \leftarrow next_level$
  $k \leftarrow k+1$
end while
return F

D. Structural Optimization and Complexity Analysis

To comprehensively improve the performance of HiAGL-FIM in large-scale transaction data processing, the algorithm introduces various optimization mechanisms in the structure design and execution process. This section systematically describes these optimization strategies, analyzes their time and space complexity across different modules, and highlights the algorithm's scalability and practicability.

1) Compression coding and pruning acceleration mechanism: HiAGL-FIM compresses all TID lists at once through the continuity ratio $\phi(T_i)$ as defined in Eq. 1 during the modeling stage, avoiding the recoding overhead caused by frequent hybrid structure switching in traditional methods. The compression process has linear time complexity $O(n)$, where n is the number of TIDs.

During candidate itemset expansion, the algorithm introduces support upper-bound estimation combined with structure-specialized intersection operators (Eq. 2) to enable "intersection short-circuit" judgment. If the current intersection cannot reach the minimum support threshold θ, immediate pruning avoids subsequent invalid calculations.

2) Buffer hierarchical scheduling: TID structures with different support levels are allocated to high-frequency, intermediate-frequency, and low-frequency buffers for batch management and cache-affinity scheduling. This mechanism significantly reduces random TID structure accesses during intersection operations, improving memory locality and reducing access latency.

- Time and space complexity analysis
  - Initialization phase (build TID table): Single transaction scan with time complexity $O(n \cdot L)$ and space complexity $O(n)$, where n is the transaction count, L is the average transaction length, and m is the number of distinct items.
  - Structure compression stage: Calculate $\phi(T_i)$ for each item and classify structures. Complexity $O(n \cdot m)$, where m is the average support.
  - Intersection calculation phase:
    - `Run × Run`: optimal complexity $O(p+q)$ with p, q segment counts;
    - `Gap × Gap`: complexity $O(m+n)$, reducible to $O(\min(m,n))$ with hash optimization;
    - `Run × Gap`: approximately $O(n \log p)$ using binary/mask matching.
  - Recursive expansion stage: DFS approach prevents candidate explosion. Actual depth depends on frequent itemset density. Worst-case remains exponential $O(2^n)$, but pruning mechanisms effectively control expansion scale.

IV. Result and Discussion

All experiments were conducted in the same computing environment. The experimental platform was a personal computer equipped with 2.2 GHz Intel Core i5 processor, 8 GB memory and 64-bit Windows 10 Professional operating system. To ensure comparability and consistency of results, this paper implements all algorithms using Python without loading any GPU acceleration components during experiments, guaranteeing authenticity and reliability of measured performance metrics.

For experimental validation, we selected the classic sparse transaction database `T10I4D100K` as test dataset, containing 100,000 transactions with an item set size of 870. Each transaction averages approximately 10 items, exhibiting typical low-density characteristics. This dataset is widely adopted in frequent itemset mining research and particularly suitable for evaluating algorithm efficiency and resource consumption in sparse data scenarios.

To comprehensively assess HiAGL-FIM's performance advantages, we compare against two mainstream algorithms: FP-Growth and Eclat. FP-Growth avoids explicit candidate generation by constructing compressed FP-Tree structures, representing one of the most widely-used horizontal format algorithms. Eclat employs vertical TID representation and computes support through intersection operations, offering good execution efficiency but with performance highly dependent on underlying TID structure design. For fair comparison, all algorithms run independently under identical input data and parameter configurations, with key performance metrics recorded at five different support thresholds.

In this paper, the support threshold σ is set as $\{0.006, 0.005, 0.004, 0.003, 0.002\}$ to simulate the actual mining demand change from high support to low support. Under each support setting, the running time (in seconds) and the peak physical memory usage (in MB) required by the algorithm to complete the mining of all frequent itemsets are measured respectively. The memory statistics are collected in real time through the psutil library. The evaluation results are shown in Fig. 2 and Fig. 3, respectively corresponding to the running time change and memory consumption trend under different support levels.

As can be seen from Fig. 2, as the support threshold σ decreases from 0.006 to 0.002, the running time of *HiAGL-FIM* gradually increases from 10.9 seconds to 18.7 seconds. Although the computational workload increases due to the exponential expansion of candidate itemsets at a lower threshold, *HiAGL-FIM* consistently outperforms Eclat and FP-growth across the entire threshold range. Specifically, the average acceleration of *HiAGL-FIM* is 31.7% over Eclat and 45.9% over FP-growth, demonstrating its superior time efficiency. This performance advantage stems from its layered compression mechanism, which enables fast and structure-aware TID intersection.

Fig. 3 further highlights the significant memory-saving advantage of the Hierarchical Adaptive Gap-Run List (HAGL). The memory footprint of FP-growth and Eclat remains relatively high—ranging from 383.58 MB to 421.43 MB and 136.85 MB to 142.02 MB respectively—while the memory usage of *HiAGL-FIM* remains compact, ranging only from 4.76 MB to 13.15 MB. At the lowest threshold $\sigma = 0.002$, the memory consumption

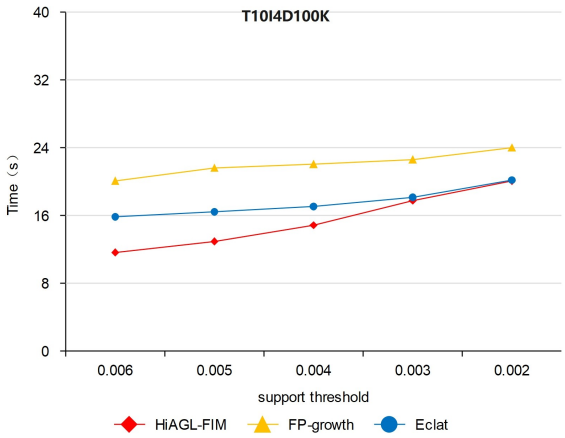

Fig. 2. Execution time comparison under different support thresholds on T10I4D100K.

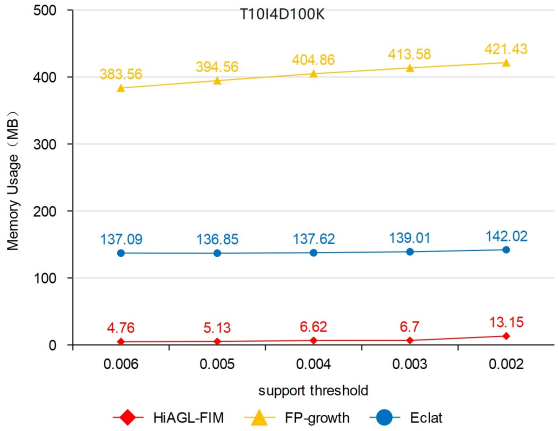

Fig. 3. Memory usage comparison under different support thresholds on T10I4D100K.

of *HiAGL-FIM* is just 13.15 MB, accounting for only 9.2% of Eclat and 3.1% of FP-growth.

This substantial improvement is attributed to the use of the HAGL-TID representation, which dynamically adapts to the density of TID sequences by switching between compact Run-List encoding for continuous intervals and sparse Gap-List encoding for discrete elements. In addition, the algorithm employs specialized intersection operators for each structure pair (Run-Run, Gap-Gap, Run-Gap), thereby minimizing redundant operations in the candidate generation process. As a result, the overall space complexity is effectively reduced to $\mathcal{O}(|G| + |R|)$, where $|G|$ and $|R|$ represent the size of the Gap and Run segments, respectively. This lightweight design enables *HiAGL-FIM* to efficiently mine frequent itemsets from large-scale transaction datasets in a single-threaded Python environment.

V. Conclusion and Future Work

In this paper, a new frequent itemset mining algorithm, HiAGL-FIM, is proposed. Its core lies in the design of a Hierarchical Adaptive Gap-Run TID (HAGL-TID) structure.

Through continuity-driven transaction compression modeling, structure-specialized intersection operations, and hierarchical buffer scheduling mechanisms, the algorithm achieves efficient processing of dense–sparse mixed environments in large-scale transaction databases. Experimental results demonstrate that, compared with the classical Eclat and its variants, HiAGL-FIM exhibits significant advantages in execution time and memory consumption, verifying the effectiveness and scalability of the proposed method in large-scale data scenarios.

However, the proposed method still has certain limitations. The current study mainly focuses on validation using static transaction databases and does not fully address dynamic updates in streaming data environments. In addition, the implementation is based on a single-machine architecture without distributed or parallel optimization, leaving room for improvement in handling ultra-large-scale datasets.

Future research can be carried out in the following directions: 1) extending HiAGL-FIM to streaming environments by incorporating sliding windows and incremental update strategies to achieve efficient mining of dynamic data; 2) introducing distributed computing frameworks and GPU acceleration to enhance the algorithm's processing capacity in large-scale scenarios; and 3) exploring the integration of frequent itemset mining with concept drift detection, pattern evolution, and other tasks, further expanding the application potential of the algorithm in intelligent decision-making and real-time data analysis.

Optimizing Energy Efficiency and Increasing Scalability in 6G-IoT Networks Through SDN, Duty Cycling, and AI-Driven Slicing

Marwah Albeladi, Kamal Jambi, Fathy E. Eassa, Maher Khemakhem
Department of Computer Science-Faculty of Computing and Information Technology,
King Abdulaziz University (KAU), Jeddah 21589, Saudi Arabia

***Abstract*—As sixth-generation (6G) and Internet of Things (IoT) networks expand rapidly, concerns are growing about their energy consumption and scalability. This is primarily because more devices are being connected, resulting in increased energy consumption.energy consumption.This study examines three primary strategies for optimizing energy efficiency and improving scalability in 6G-IoT networks.This research looks at three experimental setups: 1) using software-defined networking (SDN) with dynamic slicing to organize devices based on when they are most and least used, 2) duty cycling, which turns devices on and off to save energy, and 3) AI-optimized network slicing that uses both convolutional neural networks (CNN) and bidirectional long short-term memory (BiLSTM) models. In the first setup, SDN with dynamic slicing helped reduce unnecessary power consumption by matching device activity to peak times. As more devices were added, this method kept energy use low and improved the network's ability to handle growth without requiring significantly more power. This resulted in a 66.28 percent decrease in power usage. In the second setup, duty cycling allowed only some devices to be active at a time, which reduced power use by over 60 percent during slow periods. In the third setup, the CNN-BiLSTM model effectively classified service types and reduced power use by 60.14 percent. While these methods were not combined into a single solution, each utilized slicing techniques to more effectively allocate resources and manage power.**

Keywords*—6G-IoT; energy efficiency; scalability; SDN; duty cycling; network slicing; CNN; BiLSTM; AI-driven optimization

I. Introduction

This study addresses the urgent need for smart, energy-efficient slice management solutions in 6G networks, targeting the challenge of supporting advanced AI services with new QoS requirements. By developing innovative management strategies, the research contributes to improving energy efficiency, reliability, and adaptability in next-generation SAGIN-enabled 6G-IoT networks [1] [2]. Many technologies, including mobile phones, transportation systems, food production, housing, healthcare, clothing, and remote monitoring, are being transformed by the Internet of Things (IoT). As these advances occur, creating energy-efficient 6G-IoT networks becomes crucials [3].

Existing studies have shown that 6G-IoT networks will link billions of devices worldwide, resulting in high energy consumption. While prior research highlights the significance of energy efficiency for the long-term profitability of network operators, the current study distinguishes itself by focusing on the integration of space, air, and ground networks into a Space-Air-Ground Integrated Network (SAGIN) [4].

Unlike earlier works centered on terrestrial networks, this research emphasizes global coverage and intelligent management of network slices to ensure specific Quality of Service (QoS) needs [5]. Network slicing, as described in prior studies, enables logically isolated virtual networks for different services; this research extends the discussion by analyzing cost-effective slice management strategies throughout the slicing life cycle, which past research has only partially addressed.

Unlike earlier generations, which typically managed network resources within a single domain, 6G network slicing must coordinate across heterogeneous segments in SAGIN. Previous studies have not fully considered the additional complexity that emerges from integrating space, air, and ground networks. The current research addresses this gap by focusing on unique challenges and management strategies necessary for effective slice orchestration across these domains.

Therefore, the development of smart slice management solutions in 6G networks is required.

The current research addresses this need by proposing an approach for efficient and intelligent network slice management specific to SAGIN-based 6G-IoT environments. This work aims to advance current practice by focusing on enhanced resource allocation and tailored slice management strategies that specifically address the emerging challenges identified above. In addition, with the availability of powerful computing capabilities and advanced.

AI services are being enhanced with new QoS requirements, such as data quality, training latency, and inference accuracy. As a result, dedicated network slices must be established to support emerging AI services in 6G networks. To address these challenges, innovative solutions are urgently needed to enhance energy efficiency without compromising network performance [6]. The objective of this paper is to:

- Analyzing the impact of SDN on energy consumption in 6G-IoT networks, by evaluating the dynamic allocation mechanism for devices based on peak and idle periods.
- Evaluating the effectiveness of Duty Cycling in reducing unnecessary energy consumption by regulating device on- and off-duty times based on daily work schedules.

- Testing the performance of a deep learning model consisting of CNNs and BiLSTM networks in classifying network data into multiple categories and accurately estimating the energy requirements for each category.
- Identifying the energy efficiency differences between each technology separately without combining them, to obtain a clear and independent picture of the impact of each approach under different operating conditions.
- Providing a scientific basis for comparing energy management methodologies to enable 6G-IoT network developers to choose or develop flexible and scalable solutions based on the nature of network load and future applications.

This study presents a set of contributions used to reduce energy consumption and increase efficiency in the 6G-IoT network through the following points.

- SDN-based dynamic slicing was combined into one model to reduce energy consumption and increase energy efficiency.
- Slicing and duty cycling to reduce energy consumption and increase energy efficiency.
- Explain how energy efficiency changes with increasing device density, ensuring the ability to adapt to network expansion processes.
- hybrid CNN-BiLSTM model was implemented, achieving 99% classification accuracy, enabling intelligent slicing and adaptation.

This paper is organized as follows. To begin, Section II covers the key features of 6G and the role of AI-powered network chips, laying the groundwork for the subsequent discussion. Building on this, Section III reviews previous work on energy efficiency and scalability in 6G IoT. Then, Section IV outlines our research approaches, which are expanded upon in Section V with details on the proposed approaches, including SDN-based chips, duty cycle, and AI-enabled chips. Following that, Section VI reviews the results and effectiveness of these techniques. In Section VII, we further discuss our experimental results on energy usage. Finally, Section VIII concludes the paper and suggests future research directions.

II. Background

Network slicing is a technology that divides a network into multiple dedicated "slices". Each slice operates independently, allowing flexible allocation of resources based on specific needs. This technology significantly enhances network performance and quality, particularly in expanding IoT environments [7]. With network slicing, resources can be given to each slice based on its unique needs.

For example, one slice can serve IoT applications that require steady connectivity and low power, while another can support high-speed data, such as HD video. Allocating resources based on actual service or application needs reduces waste and improves network efficiency [9]. Each slice works independently, reducing interference between applications. 6G networks can support a wide range of diverse applications, from self-driving cars to virtual and augmented reality services. Each of these applications requires specific network characteristics, such as instant response or high bandwidth. With network slicing, these specific needs of each application can be met individually. In addition, robust security strategies can be applied to each slice to ensure data protection and provide faster response.

Machine learning can monitor network activity and predict the needs of devices and services [10]. It can analyze large datasets to provide the optimal allocation of resources. In addition, it helps reduce network congestion by optimizing data distribution. Machine learning can be used to improve services such as security, spam detection, and power management automatically. 6G networks will provide a range of different services that will benefit users. These services include enhanced mobile broadband, ultra-reliable low-latency communication, and massive machine-type communications [11]:

- Super-eMBB: means broadband connectivity via mobile phones, with a focus on energy efficiency.
- Massive MTC: means connecting a very large number of devices, such as IoT devices, that need constant connectivity.
- Super URLLC: provides highly reliable communications with minimal delay, such as remote control of devices.
- Ultra-high resolution: means using technologies to provide high resolution in data transmission.
- Super-immersive reality: includes virtual reality and augmented reality experiences that provide enhanced interaction.

III. Related Work

Sixth-generation - 6G networks rely on network slicing, a technology that is still in its infancy but is rapidly evolving and offering a variety of services.

A. Using Software-Defined Networking

The study [16] used the energy-aware routing, multi-level, and mapping problem (EARMLP) algorithm, which achieves better performance by reducing the number of active nodes and integrating the use of network resources. The number of controllers and their optimal placement have a significant impact on energy savings. In [17], the authors present a comprehensive survey on SDN for various smart applications. This survey covers the infrastructural details of SDN hardware, OpenFlow switches, controllers, simulation tools, programming languages, open issues, and challenges in SDN implementation using advanced technologies.

B. Using Machine Learning

Several studies have used different methods to reduce power consumption. In a study [18], collaborative communication was used. This means that mobile phones or smart devices work together as a team, rather than working separately. When these devices work together, energy can be more efficiently saved, which helps extend battery life. Machine

learning, specifically artificial neural networks (ANNs), is utilized to enhance network slicing in 6G networks, focusing on energy consumption. This approach involves a multifaceted strategy that integrates various techniques to improve energy efficiency while maintaining high performance. In [19], the data rate allocation (DTRA) method was used to improve data transmission efficiency in 6G networks. The residual energy cluster head (RECH) method was used. Furthermore, this work used the dynamic multipath routing protocol (DMRP)method to improve the reliability and speed of 6G networks. After evaluating performance metrics, the DTRA method improved the lifetime and energy efficiency of the network by 95.3% based on 6G networks.

C. Using Network Slicing

Flexible network slicing is one of the essential components of 6G networks, allowing the creation of customized network environments to meet the needs of specific applications and services. The study of Sheena [27] aims to improve the efficiency of the network by designing a Deep Learning-based Network Slicing with Data Aggregation (EENS-DA) technique, which allocates the necessary physical resources to specific applications clearly and efficiently. The study of Phyu [28]aims to address the problem of activating/ deactivating slicing to reduce energy consumption while maintaining Quality of Service (QoS) for users. The researchers relied on two Multi-Armed Bandit (MAB) agents to make activating/deactivating decisions at the level of individual base stations. Researchers in the study [31] propose a hybrid model that combines CNN and BiLSTM. The CNN was used to extract automatic features from the input data. The BiLSTM was used to classify and determine the appropriate network segment for each request. The results showed that the hybrid model achieved an overall accuracy rate of 97.21%, demonstrating the effectiveness of this approach in allocating the appropriate network segments to end users.

D. Research Gap

After reviewing existing research, several gaps in the literature become apparent. Some studies focus on specific techniques, such as network slicing, machine learning, and energy-aware routing. However, a comprehensive framework that integrates these methods to improve energy efficiency in 6G-IoT networks remains absent. Although energy efficiency has generally improved, challenges persist in maintaining quality of service (QoS), which includes factors such as latency and throughput. Only a limited number of studies have successfully addressed the simultaneous enhancement of both energy efficiency and QoS, as demonstrated in the work by [28]. Flexible network slicing is widely recognized as a crucial component for the success of 6G; nevertheless, established guidelines for the design, implementation, and management of such slices are lacking, as noted in studies [27] and [28]. Addressing these gaps is expected to contribute to significant advancements in energy efficiency and scalability in 6G-IoT networks through the use of advanced technologies such as machine learning, network slicing, and SDN. Table I provides a comparison of the relevant studies.

IV. Study Contributions

The current study significantly expanded the scope of previous research by simultaneously combining three independent and integrated technologies: software-defined networking (SDN)-based dynamic slicing, workflow, and AI-assisted slicing using CNN-BiLSTM, to improve energy utilization and scalability in 6G-IoT environments. Although each previous study focused on a single aspect, such as software-defined networking (SDN) control plane (Study[16]),or an artificial neural network (ANN)-based collaboration (Study [18]), These efforts often faced critical limitations, including high complexity, poor scalability, and limited accuracy in traffic management.

The current study addresses the gaps in previous research through a diverse experimental design. In the first scenario, the study used Software-Defined Networks (SDN) to dynamically operate devices during peak usage periods. This technology addressed the limitations of static routing in previous studies based on SDN. By applying the second scenario, the study was able to improve selective activation strategies, such as those found in studies [18] and [19]. A duty cycle was implemented in the third scenario to reduce energy consumption during periods of low activity, which is considered the most innovative.

It utilized CNN-BiLSTM technology to intelligently classify traffic types and allocate resources accordingly, surpassing previous models like random forests or DRL in terms of accuracy and energy saving. Table II presents a comparative analysis of related studies and the contribution of the current research.

TABLE I. COMPARATIVE ANALYSIS OF RESEARCH ON ENERGY EFFICIENCY IN 6G NETWORKS

Author	Idea	Methodology	Features	Challenges
[16]	Energy-aware routing to reduce active nodes and improve resource utilization	EARMLP (Energy-Aware Routing Multi-Level and Mapping Problem)	Reduces number of active nodes; integrates network resource usage	Impact of number and optimal placement of controllers on energy savings
[17]	Survey on SDN for smart applications	Comprehensive survey	Covers SDN hardware, OpenFlow switches, controllers, simulation tools, programming languages; open issues and challenges	Implementation challenges of SDN with advanced technologies
[18]	Reducing power consumption through collaborative communication	Collaborative communication + ANN	Smart devices work together as a team; saves energy; extends battery life	Coordinating collaboration while maintaining high performance
[19]	Improving energy efficiency and lifetime of 6G networks	DTRA; RECH; DMRP	Improved transmission efficiency, reliability and speed; network lifetime/energy efficiency improved by 95.3%	Managing multiple methods together in real 6G environments
[27]	Efficient network slicing with deep learning and data aggregation	EENS-DA (Deep Learning + Data Aggregation)	Allocates physical resources clearly and efficiently to specific applications	Balancing energy saving with application needs
[28]	Energy saving by activating/deactivating slicing while keeping QoS	Multi-Armed Bandit (MAB) agents	Activate/deactivate decisions at base-station level	Maintaining QoS while reducing energy consumption
[31]	Hybrid model for network-slicing classification	Hybrid CNN + BiLSTM	CNN for feature extraction; BiLSTM for classification; overall accuracy 97.21%	Complex training and computational resources

V. METHODOLOGY

In this section, deep learning methods are introduced for tackling the problem of network slicing.

A. Convolutional Neural Network

1) Reasons to use CNN: CNNs [8] can find hidden patterns in data without needing any manual adjustments. High Efficiency: The convolutional layer focuses on specific parts of the data, making it highly effective for analyzing data related to networks. CNNs [12] can create systems that communicate using. Human speech [32]. Making Overprocessing Simpler: Pooling simplifies the data while retaining most of the essential information. CNNs consist of several layers connected in sequence: the first layer is the input layer, followed by hidden layers, and the last one is the output layer. The hidden layers process the input data and extract important features using filters. Overall, the combination of convolutional layers, pooling layers, and fully connected layers in CNNs enables the network to learn and recognize patterns effectively in complex data [33].

B. Long Short Term Memory

1) Reasons to use LSTM : [13]: Long Short-Term Memory Reasons to use LSTM are that it is a unique type of recurrent neural network (RNN) [20] [21] specifically designed to address issues such as vanishing and exploding gradients. These problems can make it challenging for neural networks to learn effectively. For network slicing classification, a deep learning [15]approach was applied. LSTMs [22]are better suited for this task because they can handle both the fading and growing gradient issues, as well as the long-term dependency challenges [14] that regular RNNs face. This makes LSTMs typically more effective than traditional RNNs[33].

C. Bidirectional LSTM (BiLSTM)

1) Reasons to use bidirectional LSTM: Bidirectional LSTM (BiLSTM):Reasons to use Bidirectional LSTM (BiLSTM) [15] include adding an LSTM layer that processes information in both forward and reverse orders. The outputs from the two LSTM [14]layers are then combined using techniques such as calculating the mean, sum, multiplication, or concatenation. The main advantage of using BiLSTM is that it allows each part of the input data to include information from both past and present contexts. This results in more accurate output because BiLSTM [22] uses LSTM layers to analyze data from both directions. Although BiLSTM might seem complicated, it produces strong results due to a solid understanding of the data environment. In [34], a multilayer BiLSTM is utilized, where each layer consists of two cells that process information in forward and backward directions separately.

D. Dataset Description

In Case 3, the dataset is sourced from the University of California, Irvine (UCI) Machine Learning Repository [35]. It includes 87 features, each representing details of an IP flow from a network device, such as source and destination IP addresses, port numbers, and connection timestamps. One source collects this information, while another classifies the layer 7 protocol, which corresponds to the application level in network communication [36]. Most features are numerical, with some being categorical (nominal), and one feature captures dates derived from timestamps [37].

E. Data Preprocessing

The diverse data (textual and numerical) were processed to address value errors, gaps, and duplicates in accordance with the model's requirements. Python was used to remove duplicate rows, handle missing values with the column mean, detect and delete errors, then Min-Max normalization was applied to constrain the values between 0 and 1, and the cleaned data was saved in a new CSV file in preparation for machine learning models. The set includes 78 labels, and the labeling process is a pivotal step directed by device requests and scientific literature [37]. The data was divided into five slices: Super-eMBB, Massive MTC, super-URLLC, super-Precision, and super-immersive; these are common categories in 5G/6G research that represent different service requirements, including high speed, low latency, support for a large number of devices, precision, and reliability.

F. Dataset Segmentation

The data is categorized into the following types:

TABLE II. COMPARATIVE ANALYSIS OF RELATED STUDIES AND THE CONTRIBUTION OF THE CURRENT RESEARCH

Field	Studies (Ref.)	Methodology Used	Objective	Strengths	Gaps	How the Current Study Fills the Gaps
ML for Energy Saving	[18], [19]	Collaborative communication; ANN; DTRA, RECH, DMRP	Reduce power consumption and enhance network efficiency/lifetime	Team-based device operation to save energy and extend battery life; improved transmission efficiency and reliability; network lifetime/energy efficiency improved by 95.3%	No explicit SDN integration or traffic-type slicing; limited unified evaluation across scenarios	Integrates ML within an SDN environment with 6G traffic classification and end-to-end energy impact assessment
Slicing	[27], [28], [31]	EENS-DA (Deep Learning + Data Aggregation); two MAB agents for slice on/off; Hybrid CNN+BiLSTM for slice classification	Efficient resource allocation and maintaining QoS while enabling accurate slice selection	Clear and effective allocation to applications; energy reduction via controlled activation/deactivation; 97.21% overall accuracy for classification	Limited/implicit SDN-based orchestration and unified energy evaluation	Uses SDN with CNN–BiLSTM–based traffic classification to allocate resources by data type and quantify energy gains
SDN	[16], [17]	EARMLP algorithm (energy-aware routing, multi-level mapping); comprehensive SDN survey	Enhance network efficiency and reduce energy consumption via resource-aware routing	Reduced number of active nodes; integration of network resources; broad coverage (hardware, controllers, tools, languages, challenges)	Lack of integration with ML-based classification and 6G slicing context	Combines SDN resource control with ML-driven traffic classification and slicing for holistic energy-efficient 6G management

1) Super-eMBB: This chip is designed to deliver high data speeds and large transfer capacities. It is ideal for applications that need fast data transfers, such as streaming 4K/8K videos and online gaming [38].

2) Massive-MTC: This chip is intended for Internet of Things (IoT) applications, which involve communication among many devices. Examples include smart meters, wearable gadgets, and embedded systems. It excels at managing numerous low-power devices [39] [40].

3) Super-URLLC: This chip is used for applications requiring both high reliability and minimal delay, like self-driving cars and telemedicine. It ensures dependable data transfer while keeping delays to a minimum [41] [42].

4) Super-precision: This chip caters to applications needing high spatial resolution or detailed data, such as environmental monitoring, precise measurements, and augmented reality (AR) and virtual reality (VR) [43].

5) Super-immersive: This chip is designed for applications requiring extensive coverage and high efficiency, such as augmented reality (AR) and virtual reality (VR). It facilitates immersive user experiences within advanced network environments [44].

The categorization process is as follows: when a device, such as a smartphone or sensor, sends a request, the type of application or service is evaluated. Based on this evaluation, the appropriate category, or "slice", is assigned to meet those needs. For example, if high speed is necessary, the request will be routed to the Super-eMBB slice.

In contrast, if minimal delay is essential, as in the case of self-driving cars, the Super-URLLC slice will be employed. Each slice provides distinct performance and resources customized to the current network demands, optimizing resource utilization and minimizing energy consumption.

VI. PROPOSED METHODOLOGY

The approach involves three key experiments designed to address existing research gaps in energy efficiency and scalability of 6G-IoT networks. Each of these experiments employs various methods to reduce energy use in 6G-IoT networks.

A. Case 1 Software Defined Networking with Dynamic Slicing (Scenario 1)

Step 1: The experiment presents a simulation model of a 6G-IoT network in Python using NetworkX [25], starting with 30 devices and gradually expanding to 500-2500 devices to measure scalability and its impact on performance and energy consumption. The network is managed via SDN with dynamic slicing, which adjusts the states of devices (active/inactive) according to peak (6 AM–6 PM) and idle periods. Sensors remain active during peak times, cameras are disabled outside of these periods, and lights operate randomly. The setup relies on networkx, numpy [22], matplotlib [24], and random, and energy is calculated using a function that aggregates the consumption of active devices only, then compares the values before and after slicing. Hourly readings were collected over 24 hours and analyzed using the mean and standard deviation

to estimate efficiency gains and assess the contribution of SDN in optimizing consumption and enabling adaptive device management.

Step 2: The code was improved by introducing a new idea to track power consumption in the "No Slicing" state. A baseline was established for the No Slicing case, recording power consumption for each device category with fixed reference values: sensors (10 units), cameras (8 units), and lighting (6 units). Representative device values (10 sensors, 8 cameras, 6 lighting units) were selected based on real-world datasheets such as the NXP SLN-VIZN-IoT platform ($\approx$ 0.9W) when the camera is on) and the LSM6DSV16X sensor from STMicroelectronics, as well as low-power optical sensors (193–277 µW). This distribution is further supported by the results of the paper [26], which provided practical measurements of power consumption in real industrial environments. These values were developed to standardize comparison conditions and highlight the impact of energy optimization techniques, particularly duty cycle and grid slicing [45].

The results of this case are stored in the no-slicing energy history list and are used with different network sizes to test robustness and allow subsequent replacement with real data without changing the methodology. When applying dynamic slicing within an SDN environment, power is allocated according to peak periods; specific categories (such as sensors) remain active while others are disabled during idle times, and power is measured using the calculate energy function. In this case, the readings are stored in the slicing energy history list, and a direct comparison is made between the no-slicing energy history and slicing energy history lists to measure efficiency gains and estimate the actual reduction in consumption.

Step 3: The simulation of the 6G-IoT network was expanded with SDN management to cover multiple slicing use cases across three device categories (50, 500, and 2,500 devices). Slicing divides the network into smaller, service-oriented segments, reducing energy consumption by distributing loads more efficiently. For each category, energy consumption is measured in both the non-partitioned and partitioned states, and then the percentage reduction attributed to the application of partitioning is calculated.

B. Case 2 Duty Cycling (Scenario 2)

Duty Cycling is applied as a time-based control mechanism to turn devices on and off with the aim of reducing overall energy consumption. In the experimental design, the devices are activated during even hours and deactivated during odd hours, and the consumption of each device is calculated according to its operational state and type. A fixed reference power is used to represent the nominal consumption during continuous operation: sensors 10 watts, cameras 8 watts, and lighting 6 watts. The SDN controller holds the control layer. It activates/deactivates devices according to the duty cycle schedule, ensuring consistent transitions between the two states (active/inactive) at the network level. A baseline without duty cycling is defined where devices are considered always active, Energy is calculated hour by hour as the sum of the consumption of active devices only, allowing the isolation of the impact of scheduling from other factors.

For evaluation purposes, measurements are collected hourly and stored in two separate lists: one for the baseline (no duty cycling energy history) and another for the scheduled case (duty cycling energy history). A direct comparison is made between the two lists to derive the reduction ratio in consumption, with a stratified analysis comparing performance during peak hours versus quiet periods to measure the system's response to load changes. This procedure provides a clear, systematic description: defining reference capabilities for each device category, enforcing scheduling via SDN, consistent hourly measurement, and then an organized before/after comparison, which allows for a more accurate estimation of the efficiency gains resulting from managing on/off states according to a duty cycling schedule.

C. Case3 CNN + BiLSTM (Scenario 3) Model Training

A new AI-driven network slicing model (Scenario 3) has been developed to dynamically improve resource allocation. It relies on a hybrid architecture that combines (CNN for feature extraction) and (BiLSTM for capturing temporal dependencies), classifying network flows into five categories: (super-eMBB, massive-MTC, super-URLLC, ultra-precise applications, and ultra-immersive experiences). The Unicauca IP Flow dataset was used with an 80testing split, and performance was measured using Precision, Recall, and F1 metrics. The classification outputs guide the decision on slice assignment and resource allocation, and then the energy consumed before and after allocation is compared; this demonstrates a better alignment between network traffic requirements, reduced energy consumption, and support for efficient slice management in 6G environments. The study examined the scalability by increasing the number of devices between 500 and 2500 devices, measuring the power consumption of each device as the size changed, and analyzing the relationship between the number of devices and energy efficiency. The features of CNN and BiLSTM were combined through a concatenation layer, and the model was trained on 80% of the data and evaluated on the remaining portion; the results indicate an improvement in efficiency after model-based optimization, as shown in Fig. 1

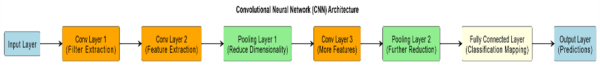

Fig. 1. The architecture of a basic convolutional neural network (CNN).

Components of the CNN Model Used:

- Input Layer: This layer takes in the data that has already been prepared for processing
- Shape Used: The data is organized in a one-dimensional format for each feature, represented as (features. Shape [1], 1).
- Convolutional Layer: This is the first layer of the model, where it applies a mathematical operation. The model examines three interconnected values simultaneously, which enables it to recognize patterns
- Kernel Size: The model looks at three connected values at once, which helps it recognize patterns.

- Activation Function: The ReLU (Rectified Linear Unit) function is used here. It helps the model handle complex, non-linear relationships in the data.
- Pooling Layer: This layer reduces the number of features from the convolutional layer by selecting the highest value from small groups in the data. The pooling size is set to 2, meaning it looks at every two values.
- Flatten Layer: This layer transforms the multi-dimensional data into a one-dimensional format so that it can be processed by the following layers in the network.
- Dense Layer: This layer has 128 units (or neurons), and it also uses the ReLU function to help improve the model's performance. This layer is key in identifying and finalizing the important patterns from the features extracted earlier.
- Dropout Layer: To prevent the model from becoming too reliant on specific neurons (a problem known as overfitting), this layer randomly ignores 30% of the neurons during training.

Integration with BiLSTM: The features extracted from the CNN are combined with the results from the BiLSTM's analysis of time dependencies in a concatenation layer, which enhances the overall accuracy of the model. To strengthen the proposed methodology, we integrated our hybrid CNN–BiLSTM segmentation model into a broader comparison framework that considers recent energy-efficient approaches such as Reinforcement Learning (RL) and Federated Learning (FL). While our primary focus remains on deep sequence modeling of traffic flows, RL-based network slicing has demonstrated strong adaptability for energy-aware policy design, and FL has shown the ability to train collaborative intrusion/traffic models with high accuracy in distributed IoT settings. Therefore, we included these techniques in our benchmarking to contextualize the CNN–BiLSTM results within state-of-the-art 6G-IoT optimization strategies. This integration not only allows a fair benchmarking against RL and FL approaches but also directly relates to our core objectives of reducing energy consumption and improving scalability in 6G-IoT environments.

D. Conceptual Unified Framework Integrating

Conceptual Unified Framework Integrating AI-Slicing, Duty Cycling, and SDN for Energy-Efficient and Scalable 6G-IoT Networks.

Fig. 2 illustrates the proposed conceptual unified framework. First, node-level application requirements are clustered using the AI-slicing module, which uses artificial intelligence to create logical network segments based on similar needs. Next, the duty cycling module, which controls when devices are active or inactive to save energy, filters the grouped nodes based on set energy thresholds. Finally, the SDN (Software-Defined Networking) controller, which centralizes the management of data flow across the network, routes and allocates resources to the active nodes in an energy-aware manner. The combined workflow ensures optimized energy usage and scalable operation in large-scale 6G-IoT deployments.

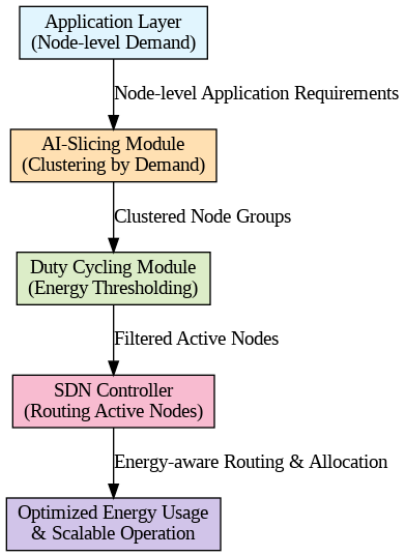

Fig. 2. Conceptual unified framework integrating AI-slicing, duty cycling, and SDN for energy-efficient and scalable 6G-IoT networks.

VII. Result

This section presents the experimental results obtained from the three proposed scenarios: SDN-based dynamic slicing, duty cycling, and the hybrid CNN–BiLSTM model. The evaluation focuses on energy consumption, scalability with increasing numbers of devices, and classification accuracy for traffic flows. To provide a broader perspective, the CNN–BiLSTM results are further compared with recent energy-efficient approaches, including Reinforcement Learning (RL) and Federated Learning (FL). Figures and tables are included to illustrate the performance metrics and highlight the improvements achieved.

A. Scenario 1: Result of Implementing SDN Technology in 6G-IoT Networks Scenario 1)

1) First implementing SDN technology in 6G-IoT networks: A simulation model for a 6G-IoT network was developed using SDN technology to reduce energy consumption and improve network performance by applying dynamic slicing. The model was built using the networkx library to create and analyze network diagrams, the numpy [23] library for mathematical calculations, the matplotlib library for visualizing data, and the random library for generating random number [31]s.

Thirty devices were integrated into the network, including sensors, cameras, and lighting, with each device's status assigned as active or passive based on specific rules such as peak hours and energy requirements.

Fig. 3 shows a comparison of energy consumption in a 6G-IoT network before and after implementing dynamic slicing. The results show that the dotted blue line, representing the power consumption without slicing, remains almost constant at approximately 115 units across all hours of the day. In contrast, the green line, representing the system with dynamic slicing, shows a clear variation in consumption, ranging from 60-106 units depending on peak times.

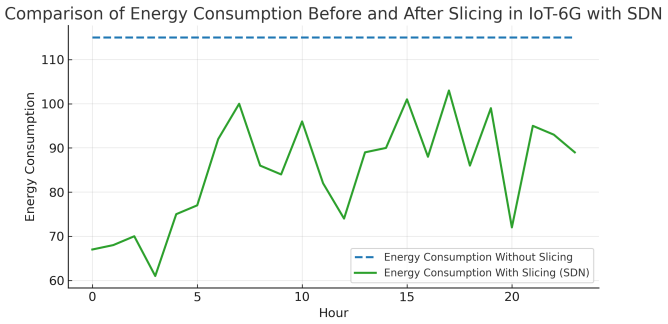

Fig. 3. Comparison of energy consumption before and after network slicing in 6G-IoT using SDN (Step 1).

2) Second, improving the measurement model: In the second phase, the model was developed by assigning specific power consumption values to each type of device(Sensors: 10 units (continuously active) - Cameras: 8 units (continuously active)- Lighting: 6 units (continuously active)

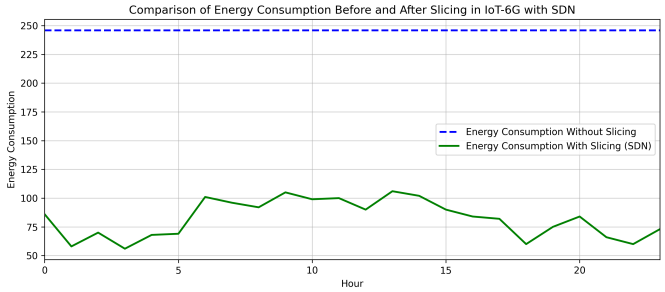

Fig. 4. Comparison of energy consumption before and after network slicing in 6G-IoT using SDN (Step 2).

Fig. 4 compares energy usage in a 6G IoT network with (SDN) before and after implementing dynamic slicing.

```
Energy Consumption Without Slicing (No slicing):
Mean: 246.00, Standard Deviation: 0.00, Min: 246, Max: 246
Energy Consumption With Slicing (SDN):
Mean: 82.96, Standard Deviation: 15.53, Min: 53, Max: 106
Energy Savings Percentage: 66.28%
Energy Consumption (No Slicing) - Peak Hours:
Mean: 246.00, Standard Deviation: 0.00
Energy Consumption (No Slicing) - Non-Peak Hours:
Mean: 246.00, Standard Deviation: 0.00
Energy Consumption (With Slicing) - Peak Hours:
Mean: 94.62, Standard Deviation: 8.16
Energy Consumption (With Slicing) - Non-Peak Hours:
Mean: 69.18, Standard Deviation: 9.86
```

Fig. 5. Evaluating energy consumption using (SDN) before and after implementing dynamic slicing.

Fig. 5 shows that energy consumption in the no-slicing scenario remained constant at an average value of 246 units, with no variation between peak and off-peak hours. In contrast, the SDN-based slicing Implementation showed a significant decrease in consumption, averaging 82.96 units with variations ranging from 53 to 106 units, achieving an energy savings rate of up to 66.28%. The results also showed that energy consumption during peak hours reached 94.62 units, while it decreased further during off-peak hours to 69.18 units, reflecting the ability of dynamic slicing to adapt to demand fluctuations.

In this phase, estimated power consumption values were assigned to each type of device based on values reported in scientific papers and manufacturer datasheets. As explained previously in the proposed Methodology section.

```
Energy consumption without slicing for 50 devices (6G): 508.3 units
Energy consumption with slicing for 50 devices (6G): 295.8 units
Energy reduction percentage for 50 devices (6G): 41.81%

Energy consumption without slicing for 500 devices (6G): 5450.2 units
Energy consumption with slicing for 500 devices (6G): 3218.1 units
Energy reduction percentage for 500 devices (6G): 40.95%

Energy consumption without slicing for 2500 devices (6G): 26661.95 units
Energy consumption with slicing for 2500 devices (6G): 16124.5 units
Energy reduction percentage for 2500 devices (6G): 39.52%
```

Fig. 6. Energy consumption with and without network slicing in 6G networks across three device categories (50, 500, and 2,500) devices.)

Fig. 6 presents the results of Scenario 1, where the energy consumption of 6G-IoT networks was measured with and without the application of SDN-based dynamic slicing. The experiments were conducted across three different device scales (50, 500, and 2500). The results show a clear reduction in energy usage when slicing is enabled, highlighting the ability of SDN to optimize resource allocation under varying traffic loads.

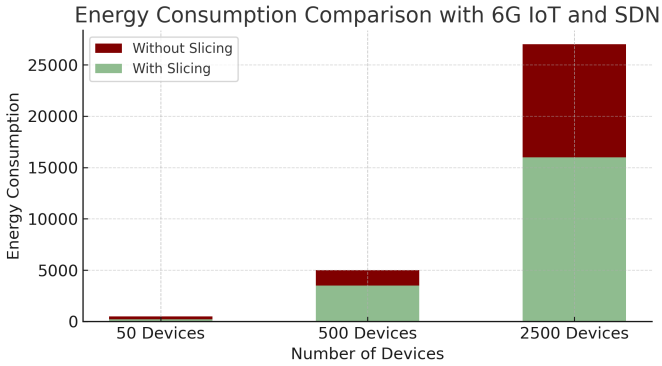

Fig. 7. Comparison of power consumption with and without slicing.

3) Thrid, the simulation of the 6G-IoT network was expanded: SDN management to cover multiple slicing use cases across three device categories (50, 500, and 2,500 devices). Slicing divides the network into smaller, service-oriented segments to reduce energy consumption by distributing loads more efficiently. For each category, energy consumption is measured in both the non-partitioned and partitioned states, and then the percentage reduction attributed to the application of partitioning is calculated.

Fig. 7 illustrates a comparison of power consumption under the following scenarios:

- Without Slicing: This reflects the power drawn when slicing techniques are not implemented.
- With Slicing: This indicates the power consumed after the application of slicing and power optimization methods.

Dark red signifies power consumption in the absence of slicing. Light green indicates power consumption when slicing is utilized. In the graph, it is evident that the power consumption with slicing is substantially lower in each scenario compared to the cases without slicing. As observed an increasing the number of devices correlates with a greater percentage reduction in power usage.

B. Scenario 2: Results of Energy Consumption With and Without Applying Duty Cycling

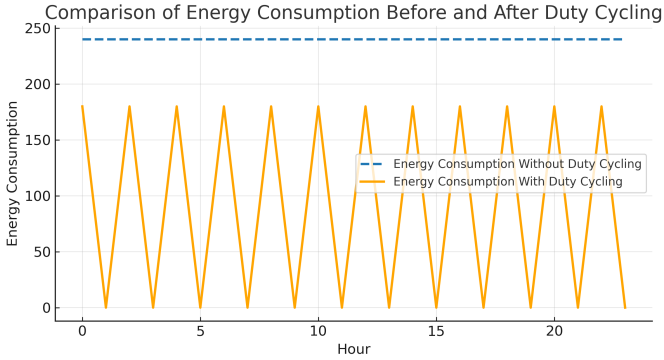

Fig. 8. Evaluating energy consumption and savings using Duty Cycling technology.

Fig. 8 shows a comparison between energy consumption before and after use of duty cycling.

- The X-axis shows time measured in hours.
- The Y-axis shows power consumption, but the units are not specified.

Shows a comparison between energy consumption with and without duty cycling. The dashed blue line remains constant at a high level, close to the upper limit (240), reflecting the continuous operation of the devices without responding to load changes. In contrast, the orange curve exhibits a periodic oscillating behavior, peaking during activation hours and dropping sharply to nearly zero during deactivation hours, which is consistent with an alternating on/off schedule. The peaks are below the fixed baseline, and the low periods reduce the area under the curve throughout the day, resulting in a lower daily average and a lower total consumption. This pattern demonstrates the effectiveness of duty cycling in aligning consumption with actual demand, with an expected increase in temporal variation against a clear improvement in energy efficiency. It is recommended to conduct a complementary statistical analysis (mean, standard deviation, and area under the curve) and assess the impact on service quality during downtime hours to adjust the optimal cycle parameters.

Fig. 9 shows that power consumption during no-duty cycling remained constant at 240 units, with no variations

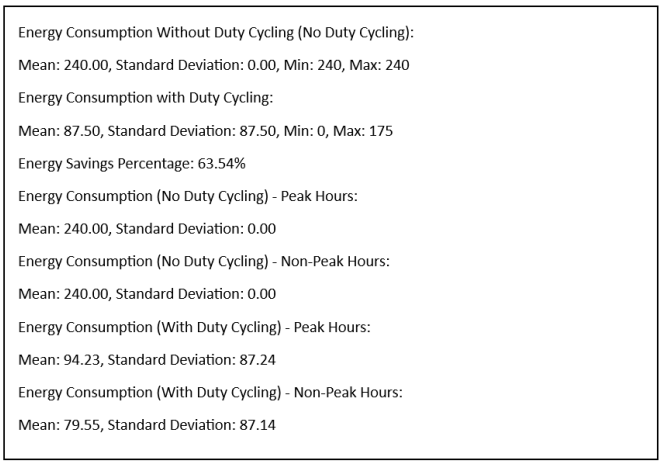

Fig. 9. Figure X: Energy consumption results under two settings: (i) no duty cycling, and (ii) with duty cycling. Includes detailed statistics (mean, standard deviation, minima, maxima), comparison during peak and non-peak hours, and overall savings percentage.

during peak and off-peak hours. In contrast, applying duty cycling reduced average consumption to 87.50 units, with a fluctuation range of 0–175 units. This mechanism achieved an energy savings rate of 63.54%. The results also showed that average consumption during peak hours was 94.23 units, while during off-peak hours it decreased to 79.55 units, reflecting the effectiveness of duty cycling in adjusting device consumption according to periods of activity and inactivity.

C. Scenario 3: CNN + BiLSTM Model Powered by Machine Language

The key performance metrics—accuracy, precision, recall, and F1-score are calculated using specific formulas [31].

Recall is a measure of how many true positives were identified, which means it reveals how many correct results were found among the total cases that should have been recognized.

$$\text{Recall} = \frac{TP}{TP + FN} \tag{1}$$

Precision: The proportion of hits that are truly positive or accurate is known as precision.

$$\text{Precision} = \frac{TP}{TP + FP} \tag{2}$$

F1 Score: The F1 score is a metric that combines both recall and precision (accuracy). It ranges from 0 to 1 and is calculated as an asymmetrical mean of recall and accuracy.

$$\text{F1-score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{3}$$

Accuracy: The percentage of accurately anticipated values for the test data is used to evaluate accuracy. By dividing

the total number of forecasts by the total number of accurate guesses, one can easily determine the result.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{4}$$

Python is used to develop a simulation model using the "TensorFlow" and "Keras libraries". These packages are important tools for creating neural network-based designs. In this work, the performance of the proposed hybrid CNN-BiLSTM model is evaluated using several performance metrics, including accuracy, recall, precision, and F1 score. The parameters of the performance matrices are described in the following: In Fig. 10, the model achieved consistently high performance with precision and recall values exceeding 0.98 across most classes, leading to strong F1-scores ¿ 0.98. The large support for classes such as super-eMBB further reinforces the reliability of these metrics.

Experimental results demonstrate that the proposed CNN–BiLSTM model achieved high accuracy in traffic flow classification, reaching approximately 99%, with a remarkable balance between precision and recall. When compared to other algorithms such as reinforcement learning (RL) [29] and federated learning (FL) [30], several distinct strengths emerged. Reinforcement learning-based segmentation demonstrated strong adaptability to dynamic network loads, resulting in stable energy efficiency during periods of heavy traffic. In contrast, federated learning demonstrated high scalability by supporting distributed training across a large number of IoT devices, while reducing communication costs. Although RL and FL techniques demonstrated competitive performance, CNN–BiLSTM maintained the lowest false positive rate and achieved the highest sustained energy reduction (approximately 60%), enhancing network sustainability and delivering greater efficiency as the number of connected devices increases.

Classification Report:

	precision	recall	f1-score	support
0	0.99	1.00	1.00	347683
1	0.99	0.98	0.99	57808
2	0.99	0.97	0.98	9891
3	0.99	1.00	0.99	111056
4	0.93	0.86	0.89	14530
accuracy			0.99	540968
macro avg	0.98	0.96	0.97	540968
weighted avg	0.99	0.99	0.99	540968

Fig. 10. Results of the hybrid CNN–BiLSTM model.

Fig. 10 of the classification report shows that the CNN–BiLSTM model achieved high performance in almost all categories, with precision ranging from 0.93 to 0.99, while recall ranged from 0.86 to 1.00. The F1-score metric demonstrated a good balance between precision and recall, with a minimum of 0.89 and a maximum of 1.00. The overall accuracy of the model reached 99% with a weighted mean of nearly 0.99, confirming the model's strength in classifying traffic flows across different categories.

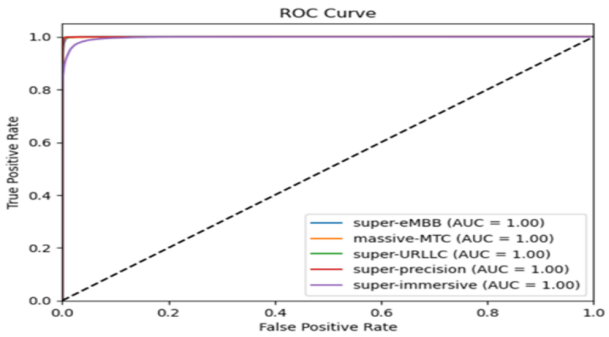

Fig. 11. ROC curve results of the proposed model.

Fig. 11 shows that all IoT network models achieved an Area Under the Curve (AUC) of 1.00, confirming excellent classification performance. This indicates that the models consistently deliver the intended results with high accuracy.

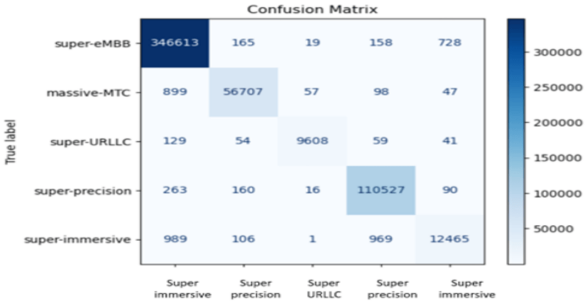

Fig. 12. Confusion matrix.

Fig. 12 presents the confusion matrix used to evaluate the model's classification accuracy. The matrix highlights the performance across different data classes using standard evaluation parameters.

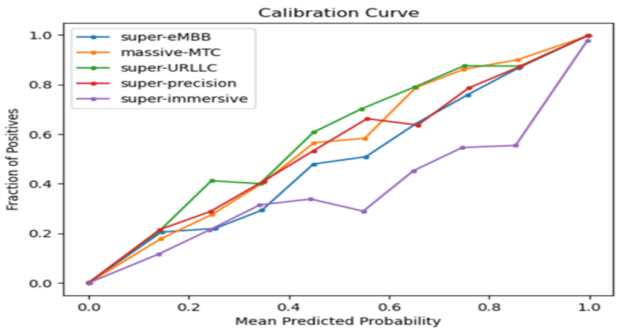

Fig. 13. Calibration curve of the proposed model.

Fig. 13 illustrates the calibration curve analysis for network slice classification in 6G-IoT, specifically examining the model's ability to predict probabilities accurately. The calibration curve is a valuable tool for evaluating the accuracy of a system's operation based on specific parameters.

Fig. 14 compares power consumption before and after slicing:

```
Energy Consumption Comparison:
Energy Consumption Before Slicing: 10000.00 watts
Energy Consumption After Slicing: 3986.42 watts
Percentage Reduction in Energy Consumption: 60.14%

Details of Energy Consumption per Slice:
super-eMBB: 833.33 watts
massive-MTC: 769.23 watts
super-URLLC: 800.00 watts
super-precision: 714.29 watts
super-immersive: 869.57 watts
```

Fig. 14. Comparison of power consumption before and after slicing.

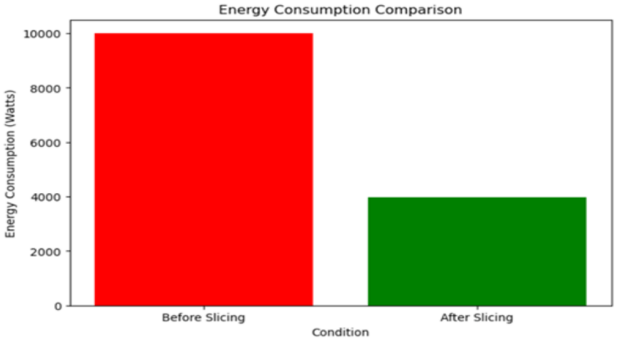

Fig. 15. Comparison of energy consumption with and without the proposed techniques.

Fig. 15 compares the energy usage of 6G-IoT networks before and after the introduction of network slicing technology.

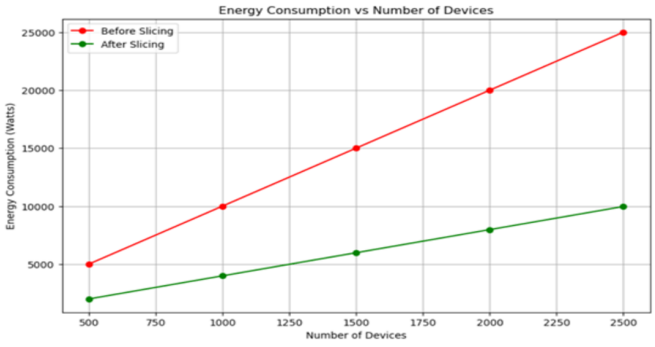

Fig. 16. Energy consumption vs. number of devices in 6G-IoT.

Fig. 16 shows the relationship between the number of connected devices (500–2500).

D. Summary of the Results

1) Scenario 1 – Segmentation via SDN: Reduced overall consumption by 66.28%. In the scalability test, the savings reached 41.81% (50 devices), 40.95% (500), and 39.52% (2500), confirming the effectiveness of slicing independent of network size.

2) Scenario 2 – Duty Cycling: Achieved a reduction of 63.54%; consumption was 94.23 units during peak hours and 79.55 units during off-peak hours.

3) Scenario 3 – Machine Learning-Driven Segmentation: Previous studies indicate that reinforcement learning (RL) [29]in the 6G–IoT context achieved energy reductions of 45–55% with high adaptability to changing network loads. Federated learning (FL)[30] demonstrated an efficiency of 40–50% energy reduction, with clear superiority in scalability across thousands of connected devices without the need to transfer raw data. Compared with these methods, our CNN–BiLSTM model achieved the highest consistent energy reduction of 60% with a classification accuracy of 99%, demonstrating its superior combination of energy efficiency and high accuracy.

VIII. Discussion

Scenario 1 Fig. 5 highlights the importance of slicing as a dynamic mechanism for adapting to varying network loads. While the traditional system (without slicing) exhibited constant, inflexible consumption, slicing allowed for intelligent control of energy consumption based on traffic intensity. This variation between peak and off-peak hours indicates that SDN-based slicing not only achieves an overall reduction in consumption but also enhances network sustainability by balancing energy efficiency with maintaining quality of service. This lays the foundation for adopting slicing techniques as an essential part of energy management strategies in 6G-IoT environments.

Fig. 6, the results indicate that slicing technology significantly reduced energy consumption across different network sizes, with consumption decreasing by 41.81% at 50 devices, by 40.95% at 500 devices, and by 39.52% at 2,500 devices. Although the energy savings gradually decrease with the increasing number of devices, this reflects slicing's ability to achieve stable energy efficiency even in environments with high device density. This highlights the importance of adopting SDN-based slicing as a strategic option for improving scalability in 6G-IoT networks, as it provides a balance between reducing energy consumption and ensuring quality of service amid the massive expansion of the number of connected devices.

Scenario 2 Fig. 9 indicates that adopting a duty cycle mechanism is an effective strategy for reducing energy consumption in IoT environments within 6G networks. This mechanism periodically shuts down devices during idle periods, contributing to a significant reduction in energy consumption. The variation in consumption between peak and off-peak hours highlights the flexibility of this technology in adapting to different usage patterns, enhancing its scalability as the number of connected devices increases. Therefore, duty cycle not only provides a significant reduction in energy consumption but is also a practical option that can be combined with other strategies such as SDN slicing to achieve greater energy management efficiency.

Scenario 3 This result reflects that the proposed model has a very high level of reliability and generalizability. The model's superior performance is attributed to the combination of the capabilities of CNNs to extract spatial features with the strength of BiLSTMs to capture temporal dependencies. The proposed model exhibits similar or superior performance to recent models such as [47]which achieved 99% accuracy using Attention-Based CNN-BiLSTM on N-BaIoT data, and

also Sinha et al. (2025) with 99.87% accuracy and a very low false positive rate [48], supporting that fusion provides a real improvement in deep learning for similar problems.

Fig. 10 show this result:

Precision: The ratio of the number of samples correctly classified for a given class to the total number of samples classified as belonging to that class.

High precision (> 0.99) for classes such as super-eMBB and massive-MTC shows the model's ability to reduce false positives.

Recall: the ratio of the number of samples correctly classified for a given class to the total number of actual samples for that class.

Strong recall (0.98–1.00) for most classes shows the model's ability to capture almost all correct samples.

F1-Score: A metric that balances precision and recall.

High values (> 0.98) for a model show its strong and balanced performance.

Support: Indicates the number of samples in each class. For example, the super-eMBB class has very high support (347,683 samples), which enhances the accuracy of the metrics due to its large representation.

Class Analysis: super-eMBB: Precision: 0.99, Recall: 1.00, F1-Score: 1.00.

- The perfect performance in this class reflects the model's ability to accurately recognize high-bandwidth applications such as video streaming

massive-MTC: Precision: 0.99, Recall: 0.98, F1-Score: 0.99.

- This class has a large number of connected devices, and the high performance shows the success of model in dealing with this challenge.

super-URLLC: Precision: 0.99, Recall: 0.97, F1-Score: 0.98.

- Good performance in latency-sensitive applications such as industrial control.

super-precision: Precision: 0.99, Recall: 1.00, F1-Score: 0.99.

- The strong performance reflects the model's ability to handle high-precision applications.

Super-immersive: Accuracy: 0.93, Recall: 0.86, F1-Score: 0.89.

- Although the performance in this category is lower than the other categories, the model shows a reasonable improvement in applications with complex requirements such as virtual reality.

Finally, the result reflects strong performance of the model across all categories with a particular focus on achieving a balance between precision and recall.

Significant improvement: The results show improved efficiency in classifying different segments, supporting the use of the model to improve resource management in 6G IoT networks.

Areas for improvement: The super-immersive class shows room for improvement, perhaps through more data or improved model architecture.

Fig. 11 presents the Receiver Operating Characteristic (ROC) curve, which illustrates the connection between true positive rates (TPR) and false positive rates (FPR) for IoT networks. Here, the FPR shows how often a test incorrectly identifies a positive result, while the TPR shows how often the test correctly identifies a negative result. All the networks have an Area Under the Curve (AUC) of 1.00, which indicates that they are performing very well and achieving their intended goals efficiently. The fact that every network shows an AUC of 1.00 confirms their effectiveness in delivering the desired results.

Fig. 12 displays the confusion matrix, which is a tool used to determine how accurate a model is when comparing different types of data. This matrix helps in assessing the performance of model. The accuracy of the model is measured using the following parameters:

- **True label:** Represents the actual class of the data as it appears in the dataset.
- **Predicted label:** Represents the class that the model has assigned to the data based on its prediction.
- **Diagonal values:** Indicate correctly classified instances where the predicted label matches the true label. Higher values along the diagonal signify better classification accuracy.
- **Super-eMBB:** The Super-eMBB category has the highest number of correctly classified instances (346,613), indicating strong model performance in this category.
- **Massive-MTC:** The Massive-MTC category demonstrates a high number of correctly classified instances (56,707), though some misclassifications are present.
- **Super-URLLC:** The Super-URLLC category has 9,608 correctly classified instances, with some confusion among other categories, indicating room for improvement in classification accuracy.

Fig. 13 shows the calibration curve. It compares predicted outcomes with actual results [46]. The X-Axis allows us to compare predicted values to the real values, and the Y-Axis shows how many predictions were positive based on those calculations. The diagonal line in the figure represents perfect performance, meaning the predicted probabilities align exactly with the true outcomes. When a point falls on this line, it signifies that the model is making accurate predictions.

For the different classes—super-eMBB, massive-MTC, super-URLLC, and super-precision—most points are very close to the ideal line, showing that the model works well for predicting probabilities in these cases. However, some points deviate from the ideal line, suggesting that there are difficulties in calibrating the model for the class labeled super-immersive.

Use a Model for Power Consumption:

Fig. 14 compares power consumption before and after slicing:

- **Super-eMBB:** This chip used 833.33 W, indicating it is very efficient (efficiency rating of 1.2) for broadband applications, such as video streaming.
- **Massive-MTC**: It consumed 769.23 W, showing an efficiency rating of 1.3, which is suitable for Internet of Things (IoT) applications that need many connections while using less power.
- **Super-URLLC:** This chip used 800.00 W, with an efficiency rating of 1.15, making it fit for low-latency applications like industrial control processes.
- **Super-precision:** It consumed 714.29 W and has the highest efficiency rating of 1.4, making it ideal for tasks such as micro-analysis or working with big data.
- **Super-immersive:** This chip used 869.57 W. Although it is less efficient (efficiency rating of 1.05) compared to the others, it still performs better than the traditional network.

Understanding the results: Energy efficiency measures how much useful energy a system produces compared to the total energy it uses. It shows how well the system can deliver the most output while using the least amount of energy. Enhancing energy efficiency.

$$\eta = \left(\frac{\text{Useful energy output}}{\text{Total energy consumed}} \right) \times 100\% \tag{5}$$

Where:

- η (eta) represents **energy efficiency** as a percentage **[%]**.
- **Useful energy output** refers to the energy that is actually used to perform the necessary work.
- **Total energy consumed** is the complete amount of energy that the system has taken in.

Value for η (eta)

- $\eta = 1$ indicates standard efficiency where there is no improvement or additional energy loss.
- $\eta > 1$ means that the system is operating more efficiently than a conventional grid, either by improving performance or reducing losses.
- $\eta < 1$ indicates less than desired efficiency, meaning that there is significant loss in the grid or system.

Based on the earlier formula and our results shown in Fig. 14:

leftmargin=1.5em

- **Efficiency:** The network slicing allocates resources so that the power usage of each chip is optimized based on its actual needs.
- **Power reduction:** The slicing reduces the power consumption significantly due to the reduction of waste in the network.
- **Balance:** Highly efficient chips (such as super-precision) show greater power savings, while other chips such as super-immersive reflect greater consumption due to their higher requirements.

Fig. 15 compares the energy usage of 6G-IoT networks before and after the introduction of network slicing technology.

- **Before Slicing:** The energy usage is represented by the red column. This shows that before slicing, the network was less efficient ($\eta = 0.5$) because it consumed a lot of power—up to 10,000 watts—even for resources not assigned to any devices.
- **After Slicing:** The energy usage after implementing slicing is illustrated in the green column. As shown, energy consumption decreased to 3,986.42 watts. This reduction indicates that the network's efficiency has improved ($\eta > 1$) because resources are now allocated more effectively based on the individual needs of each network slice.
- **Reduction Ratio:** Network slicing positively affects energy usage, resulting in a significant 60.14% decrease in power consumption.

Fig. 16 shows the relationship between the number of connected devices (500–2500) and power consumption: before slicing (red line), consumption increases linearly with the size, while it decreases after applying network slicing (green line) due to improved resource allocation. The area between the curves represents energy savings, and the increasing gap with the rise in the number of devices indicates improved efficiency and scalability.

IX. Conclusion

This study revealed three separate strategies to optimize energy usage and improve 6G network performance in IoT contexts with escalating device connectivity. Each method was evaluated separately to elucidate its effect: 1) Dynamic slicing utilizing SDN resulted in energy reduction surpassing 66% by synchronizing device operation with actual usage. 2) Duty cycling decreased energy consumption by over 60% through an adaptive on/off mechanism. 3) A CNN–BiLSTM classification model enhanced slice allocation, achieving high Precision and Recall while providing improved estimations of energy requirements by service. These results provide evidence of the efficacy of each technology and establish a foundation for realistic, consumption-conscious, and adaptable resource management frameworks. Due to the complexity and unpredictability of 6G settings, adaptive operational solutions that harmonize energy conservation with service quality are becoming increasingly essential. Future research may expand this study to encompass simultaneous multi-layer resource allocation, including spectrum, power, and processing time, to attain holistic network performance enhancements in 6G–IoT contexts.

Thai-Nichi Institute of Technology, Bangkok, Thailand 10250[1,3]
School of Engineering, Temasek Polytechnic, Singapore 529757[2]

***Abstract*—Transmitting image data reliably over long distances with low cost and minimal storage consumption is critical for LoRa-enabled IoT devices. Conventional methods often rely on high-power consumption or computationally intensive hardware, rendering them unsuitable for cost-sensitive and resource-limited IoT deployments. This paper presents a hybrid compressed sensing approach designed for efficient image transmission in LoRa-based IoT systems. The proposed method utilizes a chaotic map-based sensing matrix to enhance randomness and incoherence in the sampling process, which also serves as an encryption key to secure the transmitted data. While wavelet transform is combined with Total Variation (TV) minimization to accurately recover high-quality images from the sparse measurements on the reconstruction side. The system is implemented on low-power development boards, with the ESP32-CAM used for image capture and initial compression, and the CubeCell-AB01 handling LoRa-based wireless transmission. Experimental results demonstrate significant reductions in data size and transmission cost, while preserving image fidelity and enhancing data security, making the proposed method well-suited for resource-constrained IoT applications.**

I. Introduction

The rapid growth of the Internet of Things (IoT) has led to the widespread deployment of low-power embedded devices in various fields, including smart agriculture, environmental monitoring, industrial automation, and remote surveillance. These applications require the transmission of image data from edge devices to centralized servers or cloud platforms for real-time analysis and decision-making. However, transmitting image data over constrained wireless communication protocols remains a major challenge. One of the most promising technologies for long-range, low-power wireless communication is LoRa (Long Range), which operates in the sub-GHz ISM band and enables communication over distances of several kilometers while consuming minimal energy. LoRa is a core component of LoRaWAN, a Low Power Wide Area Network (LPWAN) protocol that supports battery-operated devices with low data rates and long-range connectivity [1], [2], [3]. Despite its benefits, LoRa's limited bandwidth makes it unsuitable for direct transmission of large multimedia data such as images without significant pre-processing or compression. This limitation highlights the need for innovative methods that can enable efficient and secure image transmission over LoRa networks, particularly in resource-constrained IoT environments. To address this, researchers have combined LoRa with data reduction strategies. For example, [4], [5] used downsampling and lightweight encoding for transmitting grayscale images over LoRa. However, such approaches often compromise image quality or fail to address security concerns.

Image compression and transmission techniques are often require intensive computation or large memory storage, both of which are impractical for resource-constrained IoT devices. Moreover, ensuring the security and privacy of image data during wireless transmission is becoming increasingly important, particularly in applications involving sensitive or personal information [6], [7], [8]. Conventional compression algorithms such as JPEG and JPEG2000 are widely used in standard multimedia systems but are not well-suited for resource-constrained IoT devices. These methods often require substantial computational resources for encoding and decoding, as well as a significant memory footprint for storing compressed images. Such a study has proposed by [9], [10], [11] highlights the limitations of traditional algorithms like JPEG in IoT scenarios, particularly under power and bandwidth constraints. Moreover, such methods typically do not address data privacy or encryption, leaving image data vulnerable to interception during wireless transmission.

Recently, compressed sensing (CS) has emerged as a promising alternative for image acquisition and transmission in IoT systems [12], [13], [14]. CS enables signal recovery from a small set of linear, provided the original signal is sparse in some domain. Its application to image data allows significant reductions in the number of transmitted samples, thereby saving bandwidth and energy. In [15], the authors demonstrated the effectiveness of CS for single-pixel imaging, laying the groundwork for its use in bandwidth-limited environments. In addition, [16] applied Total Variation (TV) minimization and wavelet transforms to enhance image reconstruction quality from sparse measurements. In [17], [18], CS offers significant advantages for improving data acquisition and transmission efficiency. By leveraging sparse representation and reconstruction algorithms, CS bypasses the constraints of the Shannon-Nyquist sampling theorem, enabling accurate signal recovery from a reduced number of measurements. This approach supports energy-efficient processing and reduces bandwidth requirements, making it particularly suitable for applications with limited communication resources. Consequently, CS is a promising solution to address the challenges of data transmission and storage in resource-limited environments.

The use of chaotic maps to generate sensing matrices has gained popularity due to their inherent randomness, un-

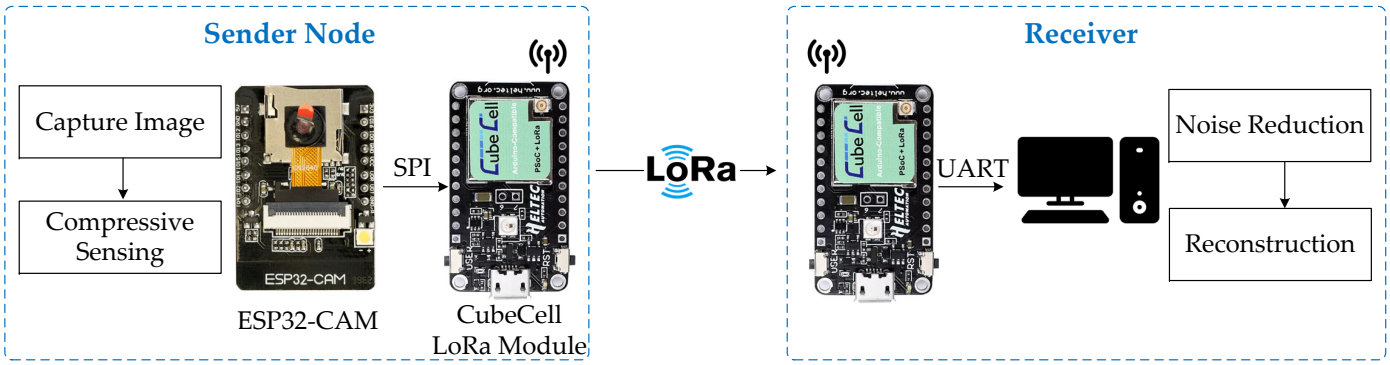

Fig. 1. Overview of the proposed system.

predictability, and suitability for lightweight encryption [19]. Chaotic systems, such as the Logistic or Tent maps, have been shown to produce pseudo-random sequences with high sensitivity to initial conditions, making them ideal for both compressed sampling and security [20]. In [21], a chaotic sensing matrix was integrated into CS to achieve both efficient sampling and data confidentiality. Such dual-purpose matrices reduce the need for separate encryption steps, thereby saving computational resources in IoT applications. Recent work in [22] explores advancements in Compressed Sensing (CS) within the context of emerging IoT technologies. Among the various sensing techniques discussed, Chaotic Compressed Sensing stands out for its effectiveness in enhancing image security and improving randomness in the sampling process. While this approach offers advantages in both data protection and acquisition efficiency, the quality of image reconstruction remains highly dependent on the use of suitable recovery algorithms. Even minor variations in system parameters or the presence of environmental noise can significantly degrade reconstruction accuracy, highlighting the sensitivity and complexity of the process. The paper is organized as follows: Section II provides the equipments and data collection; Section III describes the proposed model architecture and its components in detail; Section IV presents experimental results and comparative analysis; and Section V concludes the paper with a summary of findings.

Therefore, this paper presents a hybrid compressed sensing framework that combines chaotic map-based sensing with advanced reconstruction techniques. The proposed approach leverages the inherent randomness and sensitivity of chaotic systems not only to improve measurement incoherence but also to embed encryption at the acquisition stage, ensuring data security. The reconstruction process employs a combination of wavelet transform and Total Variation (TV) minimization, enabling accurate image recovery from a limited number of compressed measurements. This framework is implemented and validated on resource-constrained development boards, demonstrating its practicality for real-world IoT deployments. By integrating efficiency, robustness, and security, the proposed method provides a comprehensive solution for image transmission in bandwidth-limited and energy-constrained IoT environments.

II. System Overview

The proposed system is designed to enable efficient and secure image transmission over LoRa-based IoT networks by integrating a hybrid compressed sensing framework that leverages chaotic maps and advanced image reconstruction techniques. The architecture consists of two main components: an edge device responsible for image acquisition and compression, and a LoRa node for wireless transmission to a receiver. The overview of the proposed system is shown in Fig. 1. An ESP32-CAM module is used to capture images from the environment. Due to the limited computational resources of the device, traditional image compression techniques are unsuitable. Instead, the system applies Compressed Sensing (CS) using a chaotic map-generated sensing matrix, which not only reduces the number of measurements needed for transmission but also introduces inherent randomness that functions as a lightweight encryption mechanism. This dual-purpose matrix allows secure and compressed data acquisition with minimal processing overhead. Once the image has been compressed into sparse measurements, the data is transmitted from the ESP32-CAM to a LoRa node (CubeCell-AB01) via Serial Peripheral Interface (SPI), a high-speed, full-duplex communication protocol suitable for real-time microcontroller interconnection. The CubeCell-AB01, equipped with an SX1276 LoRa transceiver, then transmits the compressed and encrypted measurements wirelessly over long distances using the LoRa modulation scheme, which is ideal for low-power and low-bandwidth applications.

On the receiving side, the data is collected and processed using a reconstruction algorithm that combines wavelet transform with Total Variation (TV) minimization. The wavelet transform provides a sparse representation of the original image, while TV minimization enhances the quality of reconstruction by preserving edge information and reducing noise artifacts. The reconstruction process is executed on a computational node with sufficient resources, such as a laptop or a cloud server, to restore the image with high fidelity from the limited number of compressed samples. This architecture is specifically designed to operate under the constraints of IoT environments, offering a balance between transmission efficiency, energy consumption, and image quality. The integration of chaotic sensing and hybrid reconstruction ensures that the system not only minimizes the amount of data transmitted but also maintains privacy and robustness against channel noise.

Algorithm 1: Image Sampling with Chaotic Compressed Sensing

Input: Grayscale image I of size (H, W) (8-bit)
Input: Chaotic control parameter r, initial value X_0, threshold $\in [0, 1]$
Output: Array y_{nonzero} of (index, value) pairs

$x \leftarrow \text{reshape}(I, N), \quad N \leftarrow H \times W$;
$X \leftarrow X_0$;
for $i \leftarrow 1$ **to** N **do**
  $X \leftarrow X/|X| - r \cdot X$; `// Signum chaotic map`
  chaotic_seq$[i] \leftarrow X$;
end
Normalize chaotic_seq to range $[0, 1]$;
for $i \leftarrow 1$ **to** N **do**
  if *chaotic_seq*$[i] >$ *threshold* **then**
    mask$[i] \leftarrow 1$;
  else
    mask$[i] \leftarrow 0$;
  end
end
for $i \leftarrow 1$ **to** N **do**
  $y[i] \leftarrow \text{mask}[i] \cdot x[i]$;
end
$y_{\text{nonzero}} \leftarrow \emptyset$;
for $i \leftarrow 1$ **to** N **do**
  if $y[i] \neq 0$ **then**
    Append $(i, y[i])$ to y_{nonzero};
  end
end
Transmit y_{nonzero} over SPI to LoRa transmitter;

Algorithm 2: Image Reconstruction

Input: Compressed data y_{nonzero} (index, value pairs), image size (H, W), chaotic map parameters r, X_0, threshold, initial threshold λ, decay factor λ_{decay}, number of iterations
Output: Reconstructed image x_{recon} of size (H, W)

$N \leftarrow H \times W$;
Initialize x_{full} as a zero vector of length N;
for $(i, val) \in y_{nonzero}$ **do**
  $x_{\text{full}}[i] \leftarrow$ val;
end
$y_{\text{reshaped}} \leftarrow \text{reshape}(x_{\text{full}}, H, W)$;
Step 1: Regenerate chaotic binary mask;
$X \leftarrow X_0$;
for $i \leftarrow 1$ **to** N **do**
  $X \leftarrow X/|X| - r \cdot X$; `// Signum chaotic map`
  chaotic_seq$[i] \leftarrow X$;
end
Normalize chaotic_seq to range $[0, 1]$;
for $i \leftarrow 1$ **to** N **do**
  if *chaotic_seq*$[i] >$ *threshold* **then**
    mask$[i] \leftarrow 1$;
  else
    mask$[i] \leftarrow 0$;
  end
end
mask $\leftarrow \text{reshape}(\text{mask}, H, W)$;
Step 2: Iterative reconstruction;
$x_{\text{hat}} \leftarrow y_{\text{reshaped}}$;
for $i \leftarrow 1$ **to** *iterations* **do**
  $(\text{flat}, \text{slices}) \leftarrow \text{WaveletTransform}(x_{\text{hat}})$;
  flat_thresh $\leftarrow \text{SoftThreshold}(\text{flat}, \lambda)$;
  $x_{\text{hat}} \leftarrow$ InverseWaveletTransform(flat_thresh, slices);
  for *pixel* (m, n) **do**
    if *mask*$[m, n] = 1$ **then**
      $x_{\text{hat}}[m, n] \leftarrow y_{\text{reshaped}}[m, n]$;
    end
  end
  $x_{\text{hat}} \leftarrow \text{TVDenoise}(x_{\text{hat}}, \text{weight} = 0.025)$;
  $\lambda \leftarrow \lambda \cdot \lambda_{\text{decay}}$;
end
Clip values in x_{hat} to range $[0, 1]$;
return $x_{\text{recon}} \leftarrow x_{\text{hat}}$;

A. Chaotic-Based Sensing Matrix Generation

The compressed sensing process relies on a pseudo-random measurement matrix that satisfies the Restricted Isometry Property (RIP) and ensures incoherence with the sparsifying basis. In order to meet these requirements while also provide lightweight encryption, this work employs a chaotic map-based approach to generate the sensing matrix. The signum chaotic map, which is sensitivity to initial conditions and ability to generate highly random-like sequences from deterministic equations [23], [24], is given by:

$$X_{n+1} = \text{sign}(X_n) - rX_n \tag{1}$$

where r is a chaos tuning parameter. The simple form of (1) can be considered by

$$X_{n+1} = \frac{X_n}{|X_n|} - rX_n \tag{2}$$

where, X_n is the state at iteration n, and r, is the control parameter that determines the chaotic behavior. For appropriate values of r, the system exhibits aperiodic, non-converging sequences, making it suitable for generating random measurement matrices with strong incoherence properties. The measurement matrix generation can be achieved, following this procedure:

- Select a suitable initial condition $X_0 \in \{-1, 1\}$ and a control parameter $r \in \mathbb{R}$ that ensures chaotic behavior ($X_0 = 0.1$ and $r = 1.99$ in this experiment). Both values can be utilized as secret keys for encryption purposes.
- Iterate the signum chaotic map to generate a 1D chaotic sequence $\{X_n\}$. The total number of iterations should be equal to the number of elements required in the measurement matrix, i.e. $M \times N$, where M is the number of measurements and N is the signal/image dimension after vectorization.
- Normalize the chaotic sequence and optionally apply

binarization (e.g. using sign function) or map it to a standard distribution (e.g. Gaussian or Bernoulli) to match common CS practices.

The use of the signum chaotic map introduces an intrinsic encryption feature, as the sensing matrix depends heavily on the initial value X_0 and parameter r. Any slight variation in these parameters leads to entirely different matrices, making it extremely difficult to reconstruct the original image without the correct key. Thus, the chaotic map not only supports compressed sensing but also secures the data at the acquisition stage without the need for additional encryption layers.

Parameters	Value
LoRa Module	SX1262
Frequency	923 MHz
Spreading Factor	7
Coding Rate	4/5
Transmission Power	14 dBm

B. Image Sampling via Compressed Sensing

The image acquisition process is carried out using the principles of Compressed Sensing (CS), a signal processing technique that enables accurate recovery of sparse or compressible signals from a small number of linear measurements. This is particularly beneficial for image transmission in IoT systems, where bandwidth, memory, and energy are severely constrained. Let $x \in \mathbb{R}^N$ represent the original image signal in vectorized form, e.g. a grayscale image flattened into a 1D array. Under the CS framework, instead of acquiring the full signal x, a reduced number of linear measurements $y \in \mathbb{R}^M$ can be acquired with $M \ll N$ by projecting the signal onto a measurement matrix $\Phi \in \mathbb{R}^{M \times N}$. The data acquisition model can be expressed by:

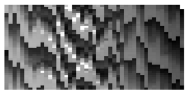
$$y = \Phi x \tag{3}$$

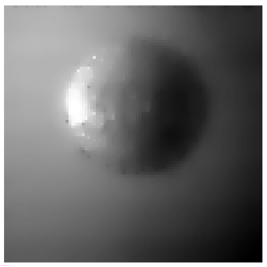
In order to ensure that x can be reconstructed from y, the signal must be sparse in some transform domain. That is, there exists a sparsifying basis Ψ such that

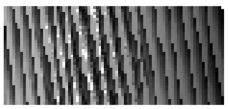
$$x = \Psi s \tag{4}$$

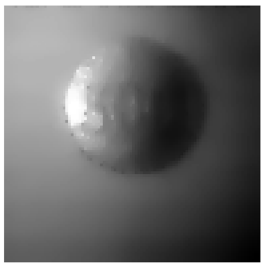
where, s is a sparse coefficient vector. Substituting into the measurement equation yields:

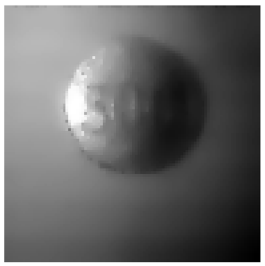
$$y = \Phi \Psi s = \Theta s \tag{5}$$











where, $\Theta = \Phi\Psi$ is the effective sensing matrix. The reconstruction of x involves recovering the sparse vector s from y and applying the inverse transform. In the proposed system, the compressed sensing matrix Φ is generated using signum chaotic map (as described in Section 2.1). This chaotic matrix introduces both measurement incoherence and data-level encryption. The image captured by the ESP32-CAM is first converted into grayscale and then vectorized into x. This vector is multiplied by Φ to produce the compressed measurements y, which are significantly smaller in size than the original image.

The sampling process begins with image acquisition from the camera module, followed by preprocessing steps that include grayscale conversion and normalization. The resulting image is then vectorized into a one-dimensional signal x, which is subsequently projected onto a chaotic map-generated sensing matrix Φ to compute the compressed measurements $y = \Phi x$. Finally, the compressed vector y is transmitted via the Serial Peripheral Interface (SPI) to the LoRa transmitter for wireless delivery. The pseudo-code of image acquisition and compressed sensing is illustrated in the Algorithm 1.

C. Reconstruction Algorithm

After compressed measurements are transmitted via LoRa and received by a computational node, the next step is to reconstruct the original image from the sparse measurement vector. The reconstruction process is designed to recover the original image from the received compressed measurements by leveraging the same chaotic sequence used during sampling.

TABLE II. PERFORMANCE EVALUATION OF COMPRESSED AND RECONSTRUCTED IMAGES OVER DIFFERENT COMPRESSION RATIOS

Original Image	CR	Compressed Image	Reconstructed Image	MSE	PSNR (dB)
	0.2			0.159	31.97
	0.3			0.123	32.92
	0.4			0.102	34.03

This approach ensures both spatial consistency and security by deterministically regenerating the sampling pattern.

First, the receiver regenerates the chaotic sequence (2) using the same initial condition and control parameter r as used during the sampling process. This sequence is normalized and binarized with a fixed threshold to reproduce the binary sampling mask, which distinguishes between known (non-zero) and unknown (zero) pixel locations. The received measurements are reshaped into the original image dimensions, and zero values are re-inserted at positions determined by the chaotic mask. This forms a sparse image matrix where only a subset of pixel values is available. The reconstruction process begins with this sparse image as the initial estimate and iteratively refines it using a combination of wavelet-domain sparsity enforcement and total variation (TV) denoising. Next, the reconstruction loop proceeds by transforming the current image estimate $\hat{\mathbf{x}}$ into the wavelet domain using a two-dimensional discrete wavelet transform, resulting in a sparse representation of the image coefficients. A soft-thresholding function is then applied to these coefficients to suppress noise and enforce sparsity. This function shrinks coefficients toward zero based on a threshold λ that decays over iterations as follows:

$$\tilde{X} = sign(X) \cdot max(|X| - \lambda, 0) \tag{6}$$

where, X and $\tilde{X}$ are the wavelet coefficient and the threshold coefficient, respectively. The threshold coefficients are subsequently transformed back into the spatial domain via the inverse wavelet transform, resulting in an updated image estimate. To ensure consistency with the original measurements, the known pixel values identified using the chaotic mask are reinserted into their respective positions. This operation can be mathematically expressed as:

$$\hat{x}^{(k)}[i] = \begin{cases} y[i], & \text{if } i \in \Omega. \\ \hat{x}^{(k)}[i], & \text{otherwise} \end{cases} \tag{7}$$

where, Ω is the set of known pixel indices from the chaotic sampling mask, and $\hat{x}^{(k)}$ is the reconstructed image at iteration k. To further refine the output, total variation denoising is applied to the reconstructed image to reduce artifacts and preserve edge structures. This can be formulated as the minimization of the TV norm, given by:

$$\min_x |||x||_{TV} \quad \text{subject to} \quad x \approx \tilde{x} \tag{8}$$

This iterative refinement is performed for 350 iterations. The threshold λ is initialized at 0.1 and decayed by a factor of 0.95 after each iteration to gradually enhance image details. Finally, the reconstructed image is clipped to the valid grayscale range $[0, 1]$. This hybrid reconstruction approach effectively balances sparsity promotion, noise suppression, and

data fidelity, allowing high-quality image recovery from highly compressed chaotic measurements. The pseudo-code of image reconstruction process is illustrated in the Algorithm 2.

III. Experimental Results

To validate the effectiveness of the proposed hybrid compressed sensing approach for image transmission over LoRa-based IoT networks, real-world experiments were conducted using ESP32-CAM as the image acquisition and compression node, and CubeCell AB01 as the LoRa communication. Fig. 2 illustrates the custom-designed embedded system used for field deployment of the proposed image transmission framework. These tests aimed to evaluate system performance in practical conditions, including image quality, transmission efficiency, and hardware feasibility in a low-power wireless environment.

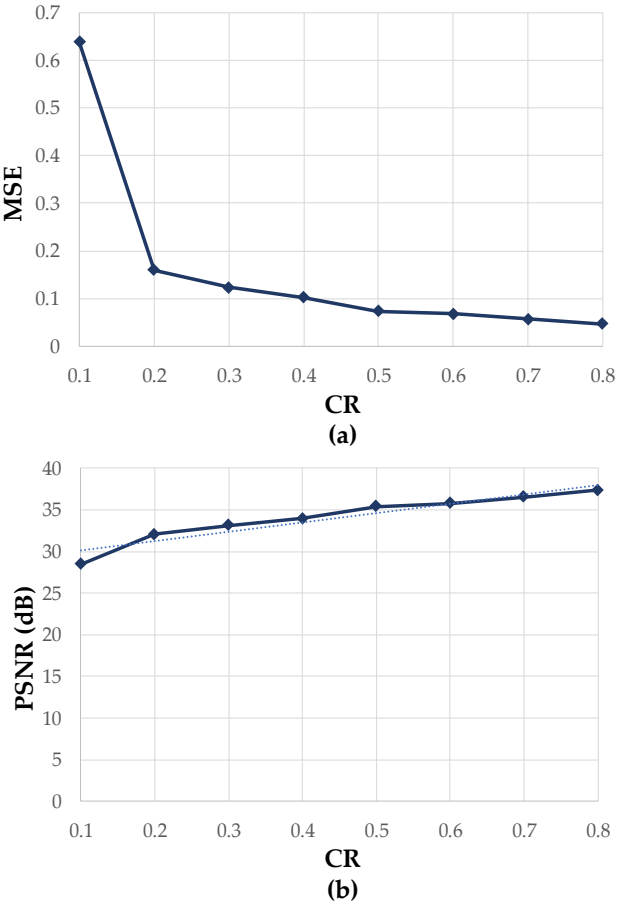


Fig. 4. Compression ratio vs (a) MSE and (b) PSNR.

A. Field Deployment

Fig. 3 shows the real-world testing site of the proposed image transmission system at the Thai-Nichi Institute of Technology (TNI) campus, specifically across the length of the Faculty of Engineering building. The devices were powered by portable USB battery packs and tested over a range of distances (up to 300 meters) with clear line-of-sight. The transmission path included partial obstructions such as walls, corridors, and concrete pillars, making it a meaningful scenario to assess LoRa signal reliability, data transmission performance, and image reconstruction quality over medium-range distances. Table I summarizes the LoRa parameters in the experiment.

B. Evaluation Metrics

This paper selects Mean Squared Error (MSE) as the primary loss function for training the reconstruction model. It measures the average squared difference between the reconstructed image and the original image, defined mathematically as:

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N}[y_i - f(x_i)]^2 \tag{9}$$

where, N represents the total number of image pixels (or samples), y_i is the ground truth pixel value, and $f(x_i)$ is the predicted pixel value. MSE serves as a direct indicator of reconstruction accuracy. Otherwise, the lower of MSE indicates the closer the reconstructed image is to the original.

To further assess the quality of the reconstructed images, Peak Signal-to-Noise Ratio (PSNR) is employed as quantitative evaluation metrics. PSNR is a widely used objective metric in image processing that reflects the ratio between the maximum possible pixel value and the magnitude of the reconstruction error, and is expressed in decibels (dB). It is calculated as:

$$\text{PSNR} = 10 \cdot \log_{10}(\frac{M^2}{\text{MSE}}) \tag{10}$$

where, M is the maximum possible pixel intensity value of the image. A higher PSNR indicates better reconstruction quality and lower image distortion, e.g. a PSNR value above 30 dB generally suggests that the reconstructed image is of good visual quality.

C. Performance Analysis

Table II presents a visual and quantitative analysis of the proposed reconstruction system under varying compression ratios (CR) of 0.2, 0.3, and 0.4. The original image is shown in the first column. The second column shows the encrypted or compressed image as produced by chaotic compressed sensing, appearing as random patterns with no visual resemblance to the original. The third column displays the reconstructed images after applying the wavelet-based soft-thresholding and total variation (TV) denoising algorithm. As the CR increases from 0.2 to 0.4, the quality of the reconstructed image significantly improves. This is further supported by the quantitative metrics in MSE and PSNR. At CR = 0.2, the MSE is 0.159 with a PSNR of 31.97 dB, while at CR = 0.4, the MSE reduces to 0.102 and the PSNR increases to 34.03 dB. These results confirm that higher compression ratios yield more accurate image reconstruction due to the availability of more non-zero measurements. However, even at low CR, the reconstruction preserves the essential features of the original image, demonstrating the robustness and effectiveness of the proposed chaotic compressed sensing and reconstruction framework.

TABLE III. COMPARISON WITH EXISTING SYSTEMS

Criteria	Edirisinghe et al. (2024) [25]	Kirichek et al. (2017) [26]	Wei et al. (2021) [27]	Guerra et al. (2023) [28]	**Proposed**
Technology	ESP32CAM, SX1278	Raspberry Pi Zero, SX1267	Raspberry pi 3B+, SX1276	Raspberry Pi 3B+, SX1272	ESP32CAM, SX1262
Compression Method	JPEG	JPEG/JPEG 2000	WebP with Base64	YCoCg, Wavelet Subbands	Compressed Sensing, Wavelet, TV Minimization
PSNR (dB)	-	23	33.84	21.5 to 27	32.92 (CR = 0.3)
Transmission Time (s)	20	-	25.7	90	30
Security	None	None	None	None	Chaotic Masking

Additionally, Fig. 4 depicts the relationship between MSE and PSNR as the compression ratio (CR) varies. These plot indicates that using more measurements results in a reconstructed image which is closer to the original in terms of pixel-wise accuracy. Conversely, the PSNR increases with higher CR, reflecting improved visual quality of the reconstructed image. It can be consider that, the proposed chaotic compressed sensing and wavelet-TV reconstruction framework achieves a good balance between compression and image quality. Notably, even at moderate compression ratios (CR = 0.4–0.5), the system maintains acceptable reconstruction performance, suggesting suitability for deployment in bandwidth-constrained LoRa-based IoT applications where transmission efficiency is critical.

Table III presents a comparative evaluation between the proposed method and several existing image transmission techniques over LoRa networks. The comparison is based on key parameters such as technology framework, compression method, image quality in terms of PSNR, transmission time, and security features. The proposed system employs the chaotic compressed sensing, wavelet transform, and TV minimization, which enable high efficiency image reconstruction with significantly reduced data volume. Notably, the proposed method achieves a PSNR of 32.92 dB at a compression ratio of 0.3, which is comparable to or better than other approaches, such as the 33.84 dB reported by Wei et al. (2021) using WebP compression, and considerably higher than the 23 dB and 21.5–27 dB reported by Kirichek et al. (2017) and Guerra et al. (2023), respectively. In terms of transmission time, the proposed method achieves a practical 30-second duration, which is faster than the 90 seconds required by Guerra et al., and close to the 25.7 seconds achieved by Wei et al., while also incorporating inherent chaotic masking for data security, unlike all compared works, which offer no security measures. Additionally, while most competing methods rely on image-centric compression formats like JPEG, WebP, or wavelet subbands, the proposed approach achieves compression and encryption simultaneously through chaotic sampling. Overall, this comparison highlights the efficiency, security, and image quality advantages of the proposed method, making it highly suitable for low-power, bandwidth-constrained image transmission in IoT scenarios.

IV. CONCLUSION

This paper presents a hybrid compressed sensing approach tailored for efficient and secure image transmission in LoRa-based IoT systems. The proposed method achieves both significant data compression and reliable image reconstruction by integrating a chaotic map-based sensing matrix with wavelet transforms and total variation (TV) minimization. The use of a chaotic sequence not only improves incoherence during the sampling process but also serves as a lightweight encryption mechanism, enhancing data privacy without additional computational overhead. Experimental evaluations on real embedded hardware demonstrate the practical feasibility of the proposed system in low-power environments. The results indicate that even with low compression ratios, the reconstructed images maintain high perceptual quality, with PSNR values exceeding 32 dB. Furthermore, transmission times are reduced to under 30 seconds per image, significantly outperforming traditional JPEG-based and wavelet-subband techniques used in LoRa imaging. A comparative analysis with existing methods highlights the advantages of the proposed approach in terms of image quality, transmission efficiency, power consumption, and embedded security. These benefits make the system particularly well-suited for IoT applications where bandwidth, energy, and processing resources are severely constrained. The proposed system has potential for a wide range of applications, including environmental monitoring, smart agriculture, structural health monitoring, and wildlife surveillance. It can also be applied for remote industrial inspections, where timely visual data from resource-constrained IoT nodes can significantly improve decision-making efficiency and operational safety.

***Abstract*—In the university context, students' mental health has been progressively affected over time. The objective of this research was to develop a predictive model of machine learning based on the K-Means algorithm, with the purpose of identifying and classifying mental health profiles among university students. For the construction of this model, the standard Cross-Industry Standard Process for Data Mining (CRISP-DM) methodology was applied, which encompasses five stages: business understanding, data understanding, data preparation, modeling, and evaluation. The results obtained suggest that the generated clusters produce consistent groupings in key variables such as screen time, hours of sleep, and level of physical activity, allowing the characterization of different student profiles. This approach provides valuable information for designing academic support strategies and programs aimed at students' well-being and mental health. The early identification of behavioral patterns and lifestyle habits enables educational institutions to implement preventive and personalized measures, fostering improved academic performance and university adaptation.**

***Keywords*—Behavioral patterns; clustering; machine learning; mental health; university students**

I. Introduction

In the field of higher education, mental health has emerged as a critical issue in recent years due to the notable increase in disorders such as anxiety, depression, and chronic stress. University students constitute a particularly vulnerable population, as they face multiple challenges inherent to this formative stage, including academic pressure, adaptation to new environments, uncertainty regarding professional futures, financial difficulties, and, frequently, separation from family support networks. According to the World Health Organization (WHO), approximately 20% of young people experience some type of mental disorder, many of which begin precisely during university life [1] [2]. In this respect, it becomes evident that this problem demands attention in every social context, as it exacerbates personal difficulties among university students worldwide.

Mental health in the university population represents both a scientific and medical issue of growing relevance [3]. From a medical perspective, mental disorders such as anxiety, depression, and chronic stress not only compromise students' emotional well-being but also directly affect their physical health, quality of life, and academic performance. If not detected or treated in time, these disorders may lead to serious consequences such as university dropout, deterioration of social relationships, and, in the most severe cases, suicide attempts. From a scientific perspective, this issue poses significant challenges for interdisciplinary research [4] [2]. Experts in medicine consider mental health problems as a set of conditions that comprehensively affect student life, also impacting the family environment.

There is an urgent need to better understand the individual, social, and contextual risk factors that contribute to the onset of these disorders during university years. Despite the rising prevalence, many cases remain underdiagnosed due to stigmatization, lack of institutional resources, or limited awareness of the importance of preventive psychological care. Furthermore, the scientific study of student mental health requires the development and validation of effective tools for early diagnosis, symptom monitoring, and implementation of personalized interventions. The integration of approaches based on emerging technologies, such as artificial intelligence and machine learning, opens new possibilities for risk detection and prediction; however, gaps in the evidence remain and must be addressed through rigorous research [5] [6]. Technologies thus represent a viable option within the broader social challenge, constituting an impactful factor for prevention depending on the context under study.

This research is justified by the need to reduce the incidence of psychological disorders and other problems that significantly affect university students, negatively impacting the achievement of their academic goals and their professional future. In this regard, it is essential to develop effective mechanisms to counteract these difficulties, thereby promoting students' overall well-being and supporting their persistence and success in higher education. Faced with this issue, it becomes crucial to implement efficient mechanisms that enable the timely identification of at-risk students in order to design and implement personalized intervention strategies [7] [8]. In this context, the use of machine learning techniques represents an innovative and powerful tool, as it allows the analysis of large volumes of data and the discovery of hidden patterns that would not be detectable through traditional methods. Specifically, this research proposes the use of clustering algorithms, such as K-means, to group students according to relevant psychological, academic, and social characteristics. This methodology will allow the segmentation of the student population into groups with similar risk levels, facilitating informed decision-making by educational institutions [9]. In this way, more effective support strategies can be developed, aimed at improving mental health, student retention, and academic success, thus contributing to students' overall well-being and to the strengthening of the higher education system.

The objective of this research is to develop a predictive model based on clustering techniques and machine learning, aimed at identifying and classifying mental health profiles among university students through the analysis of multivariate data related to lifestyle habits, academic characteristics, and emotional factors. The purpose of this model is to facilitate the early detection of potential psychological disorders and to contribute to the design of preventive strategies or personalized interventions that enhance student well-being and academic performance.

II. Literature Review

This section presents the structure of the literature review, which is divided into two main parts. The first addresses the theoretical foundations, providing a detailed discussion of the mental health variable and the clustering approach, with emphasis on the K-means algorithm. The second part comprises the related works, analyzing previous studies conducted by various authors who have applied machine learning techniques, specifically clustering algorithms, to the study and analysis of mental health among university students. The purpose of this review is to provide the theoretical basis for the research and to highlight the relevance and applicability of the proposed approach.

A. Theoretical Bases

1) Mental health: Mental health in university students refers to the emotional, psychological, and social state that directly influences their overall well-being and academic performance. This stage represents a critical period in personal development, where students face multiple challenges such as academic pressure, adaptation to new environments, family expectations, and, in many cases, financial limitations. In particular, some students must finance their studies without family support, which significantly increases their emotional and financial burden [10] [11]. This situation of solitude and economic responsibility can generate high levels of stress and anxiety, affecting their mental health and hindering the achievement of their academic goals. Table I presents the key factors influencing the mental health of university students, detailing the causes and the associated emotional and psychological effects, such as stress, anxiety, and feelings of isolation, which may impact their well-being and academic performance.

2) Clustering: Clustering is an unsupervised data analysis technique aimed at identifying and grouping objects or instances into subsets known as clusters. Its fundamental principle is that elements within the same group share a high degree of internal similarity, while exhibiting marked differences from elements in other groups. The evaluation of this similarity or distance is carried out using various metrics, including Euclidean distance, Manhattan distance, and correlation coefficients, selected according to the characteristics and nature of the data. Unlike supervised methods, clustering does not require predefined labels, which makes it a powerful exploratory tool for uncovering hidden patterns, latent structures, and intrinsic relationships in large volumes of information [12] [13]. Its versatility has positioned it as an essential resource in areas such as market segmentation, bioinformatics, image analysis, and anomaly detection. Table II shows the representation of three metrics for evaluating clusters: Euclidean Distance measures the closeness between points; the Silhouette Score (0.65) indicates good group separation; and the Calinski–Harabasz Index (200) reflects well-defined and separated clusters.

B. Related Work

Several studies have indicated that multiple factors related to university students' mental health can lead to different illnesses. The authors [14] [15] highlight the growing concern regarding mental health problems in university students. In particular, Singh evaluated various machine learning techniques, such as classification methods, clustering, and a hybrid neural network, applied to an academic dataset from the engineering faculty. The results showed that the hybrid algorithm, by combining classification and clustering approaches, significantly outperformed the other models, achieving high accuracy in predicting both academic performance and students' mental well-being. Unlike the previous study, this author addressed the influence of mental, emotional, social, and spiritual health on the academic performance of university students. To this end, data were collected through a questionnaire administered to 214 undergraduate students, and machine learning techniques such as feature selection, regression, neural networks, Naïve Bayes, and multidimensional analysis were employed, along with tools such as SPSS, R, and Python. The analysis revealed that these methods were effective in predicting academic performance and identifying the psychosocial factors with the greatest impact during the transition to virtual and hybrid learning modalities. On the other hand, the author [16] proposed an intervention program aimed at improving the mental health of university students, using a Bayesian model for the dynamic updating of parameters. Cluster random sampling was also used to divide participants into an experimental group and a control group. The results showed that the intervention produced positive changes in key aspects such as mental health literacy, self-efficacy in coping with psychological problems, and behavioral attitudes toward seeking help. In another study, an author developed a strategy to classify stress in engineering students using wearable devices that recorded signals during the Montreal Imaging Stress Task (MIST). Using machine learning models, the study managed to classify stress as resting, moderate, and high, achieving accuracies of 99.98% with EEG signals and 99.51% with Electrodermal Activity (EDA), Heart Rate (HR), and Skin Temperature (SKT), outperforming previous studies and demonstrating the effectiveness of these devices for real-time monitoring [17].

In a relevant study on university students' mental health, anxiety levels and their causes were investigated using a Likert-scale-based questionnaire administered to 127 participants. Based on the collected data, machine learning models such as Naïve Bayes, Decision Tree, Random Forest, and Support Vector Machine (SVM) were trained. The results were promising, with accuracies of 71.05% for Naïve Bayes and Decision Tree, 78.9% for Random Forest, and 75.5% for SVM, showing the potential of these algorithms to effectively predict anxiety levels and provide valuable insights into their causes. In another investigation, the application of predictive models for addressing mental health issues

TABLE I. FACTORS AFFECTING THE MENTAL HEALTH OF UNIVERSITY STUDENTS

Factor	Description	Impact on mental health
Academic pressure	Demands and high expectations in school performance	Stress, anxiety, exhaustion
Adaptation to new environments	Changes in social life and university environment	Loneliness, uncertainty, anxiety
Family expectations	Pressure to meet family goals	Anxiety, fear of failure
Economic limitations	Difficulty in affording studies without family support	Financial stress, constant worry
Individual responsibility	Emotional and financial burden of handling everything alone	Increased stress, feeling of isolation

TABLE II. COMMON METRICS TO EVALUATE CLUSTERING QUALITY

Metric	Description	Example value
Euclidean Distance	Measures the direct distance between points	-
Silhouette Score	Quality of clustering (from -1 to 1)	0.65
Calinski-Harabasz Index	Separation between clusters and internal cohesion	200

in university students employed approaches such as neural networks and support vector machines. These models were key in documenting a bibliometric analysis, whose results revealed that Artificial Intelligence and Machine Learning show a consistent growth trend in addressing mental health problems among young university students [18] [19]. The lack of timely attention to mental health problems increases the risk of worsening over time. This study collected data through questionnaires on depressive, anxiety, and obsessive-compulsive symptoms, applying models such as multiple linear regression to identify associations and the random forest algorithm for predictions. The results indicated that 20% of students showed severe depression and/or suicidal ideation, that financial concerns were strongly associated with depression, and that random forest showed high accuracy in predicting the maintenance of well-being (balanced accuracy = 0.85) and absence of suicidal ideation, but low accuracy in detecting worsening cases (balanced accuracy = 0.49). Furthermore, in another study on mental health in university students, it was identified that cognitive and somatic symptoms of depression were the most influential variables, with a high negative predictive value (0.89) and practically null positive predictive value, highlighting stress as a key parameter for mental well-being. Through surveys administered to 144 students from various universities, multilayer perceptrons (MLP) combined with Principal Component Analysis (PCA) and Grid Search Cross-Validation (GSCV) were used, achieving an accuracy of 80.5%, precision of 1.000, F1-score of 0.890, and recall of 0.826. The findings revealed that 11.26% presented high social stress and 24.10% extremely high psychological stress, although the study was limited by the use of non-probabilistic sampling and self-reported data [20] [21].

On the other hand, stress is a key factor in understanding the prevalence of mental health problems, which is why this study applied automated machine learning methods to identify its main causes. A survey was conducted with 355 students from 28 universities, using the Boruta algorithm to select the most relevant predictive factors. The models evaluated included decision tree, random forest, and support vector machine, and their performance was measured using confusion matrix, ROC curves, and k-fold cross-validation. The results highlighted that heart rate, systolic and diastolic blood pressure, sleep quality, smoking habits, and academic history were the most influential variables in predicting stress, with the random forest model achieving the best performance, reaching an accuracy of 89.72% and an area under the curve (AUC) of 0.8715, outperforming the other techniques in accuracy and predictive capacity. An important factor is social media, which is a determinant of mental health; thus, the author proposed evaluating its influence through the collection and analysis of 66,000 student posts. The research focused on the use of natural language processing models to identify symptomatic expressions of depression, anxiety, and stress, also employing the SARIMA algorithm to forecast the number of mental health consultations on campus. The incorporation of social media data significantly improved the accuracy of these predictions, achieving a correlation of r = 0.86 and a symmetric mean absolute percentage error (SMAPE) of 13.30, representing a 41% improvement compared to models that did not consider social information, thereby demonstrating the key value of social media in detecting and monitoring student mental well-being [22] [23]. Another study conducted with university students using multicenter cross-sectional surveys aimed to compare the performance of different machine learning models, including k-nearest neighbors, naïve Bayes, neural networks, and random forest. The results showed that algorithms based on Random Forest achieved the highest accuracy in identifying negative indicators of mental well-being. Among the most relevant variables for prediction were the number of weekly sports activities, body mass index, academic average, sedentary hours, and age. These findings provide valuable recommendations for modernizing and optimizing mental health assessment and monitoring, both at the individual level and within the university environment. In relation to the previous study, the research developed the Emotion Based Mental Health Classifier (EMHC), a system that combines sentiment analysis and categorical data to classify students' mental health into three levels: good, moderate, and poor. Based on data from a web application applied in universities in the NCR region of India, it uses advanced algorithms such as DeepFace, K-means, and Support Vector Classifier. This innovative tool facilitates the assessment and monitoring of student mental well-being in a global context of increasing psychological burden [24] [25].

In contrast to other studies, a multidimensional feedback

approach was proposed based on a clustering analysis applied to data from 174 university students. Using the k-means algorithm, participants without severe symptoms were segmented into three differentiated groups, while those with severe symptoms received professional care recommendations. This personalized feedback not only improved mental health literacy but also fostered a sense of belonging, reducing resistance to seeking support and enabling timely intervention [26]. Another important factor regarding alcohol consumption and perceived stress in Ecuadorian university students was analyzed using 7,134 records obtained from the Alcohol Use Disorders Identification Test (AUDIT-C) questionnaire, the PSS-10 scale, and sociodemographic data. By applying Lanz's (2013) methodology and using k-means and hierarchical clustering algorithms, three distinct groups were identified that reflect combined patterns of alcohol consumption and stress levels, thus supporting the theory linking both factors and providing a complementary perspective to traditional statistical analysis. Finally, another study sought to raise awareness of the mental health status of students at Satya Wacana Christian University, using the K-Means machine learning algorithm to identify emotional patterns based on numerical responses from 32 students. The analysis, conducted with Orange3 and based on the silhouette index, formed three groups: one associated with depression, mainly including students from the 2018 cohort and some from 2020; another group reflecting mental prosperity, composed of students from the 2018, 2019, and 2020 cohorts; and a third group in a state of harmony, with students from various cohorts between 2017 and 2019. The results show that the year of admission influences mental well-being, with greater prosperity observed in earlier cohorts, higher depression among third-year students, and a group that achieves emotional balance across different cohorts [27] [28]. In summary, related work presents important limitations that open up opportunities for further research: most are based on unrepresentative samples, which restricts the generalizability of the findings; these could be improved with more representative data and the best use of more advanced techniques.

III. Methodology

A. Definition of the CRISP-DM Methodology

CRISP-DM methodology is a widely used standard for guiding data mining and machine learning projects. Its purpose is to provide a structured, flexible, and non-linear framework that enables the development of models and the extraction of useful knowledge from data. This approach is characterized by being iterative and adaptable, meaning that its phases can be repeated or feed back into one another. In this way, the process can be continuously redesigned to respond to changing business needs, ensuring that solutions generate tangible value aligned with the strategic objectives of the organization [29] [30]. Additionally, Fig. 1 illustrates the CRISP-DM methodology for data analysis, which begins with information collection and preparation, followed by problem definition and data understanding using descriptive statistics. Variables are subsequently transformed for cluster modeling (K-Means), evaluating metrics such as silhouette and inertia, and finally, the resulting clusters are interpreted and validated. The process defined by this methodology represents a flexible form of implementation in machine learning projects, allowing its adaptation according to the specific topic and objectives of each case. Fig. 2 illustrates the architecture of the methodology and internally describes each process, showing how the model is developed according to the technical specifications.

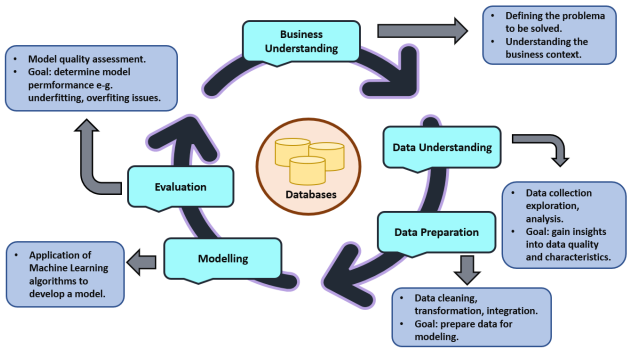

Fig. 1. CRISP-DM methodology.

1) Business understanding: In this section, corresponding to the first stage of the CRISP-DM methodology, the specific criteria necessary to address the problem are analyzed. Based on the data obtained, the problem to be solved is posed, which involved abstracting the real situation and transforming it into a clear and achievable analysis [31]. According to Table III, information is presented from a database downloaded from Kaggle, organized into records containing variables related to individuals' personal characteristics and habits. Fields include data such as gender, age, weight, height, type of transportation used, consumption of fast food and alcoholic beverages, among other factors. This information is valuable because it allows for the analysis of behavioral patterns linked to nutrition, physical activity, and lifestyles, which can be used in public health studies, obesity prediction, or in the development of preventive strategies to improve the population's quality of life.

2) Data understanding: For this section, certain data analysis concepts were applied using the Python programming language, which allowed us to examine and explore the important variables for the proposed model to understand their importance, detect possible inconsistencies and analyze the relationship between variables, serving as a fundamental basis for preparing the data that will feed the algorithmic model [32]. In this regard, Table IV shows a statistical summary of the key variables analyzed in the sample of 1,000 students. Demographic data, lifestyle habits, and perceived stress levels are included. The average age of participants is 20.34 years, with values ranging from 15 to 26. On average, students spend 6.91 hours in front of screens per day, sleep 6.45 hours, and engage in 5.02 hours of physical activity per week. The stress level, coded from 1 (low) to 3 (high), averages 1.85, suggesting that most students fall between low and medium levels of stress. This summary provides an understanding of the distribution and variability of the variables studied, serving as a reference for subsequent analysis and the development of predictive models.

On the other hand, Fig. 3 of boxplots presents a summary view of the distribution of four key variables: screen time, sleep duration, physical activity, and stress level. Each box shows the interquartile range, with the median dividing the distribution in half. The whiskers extend to non-outliers, and individual

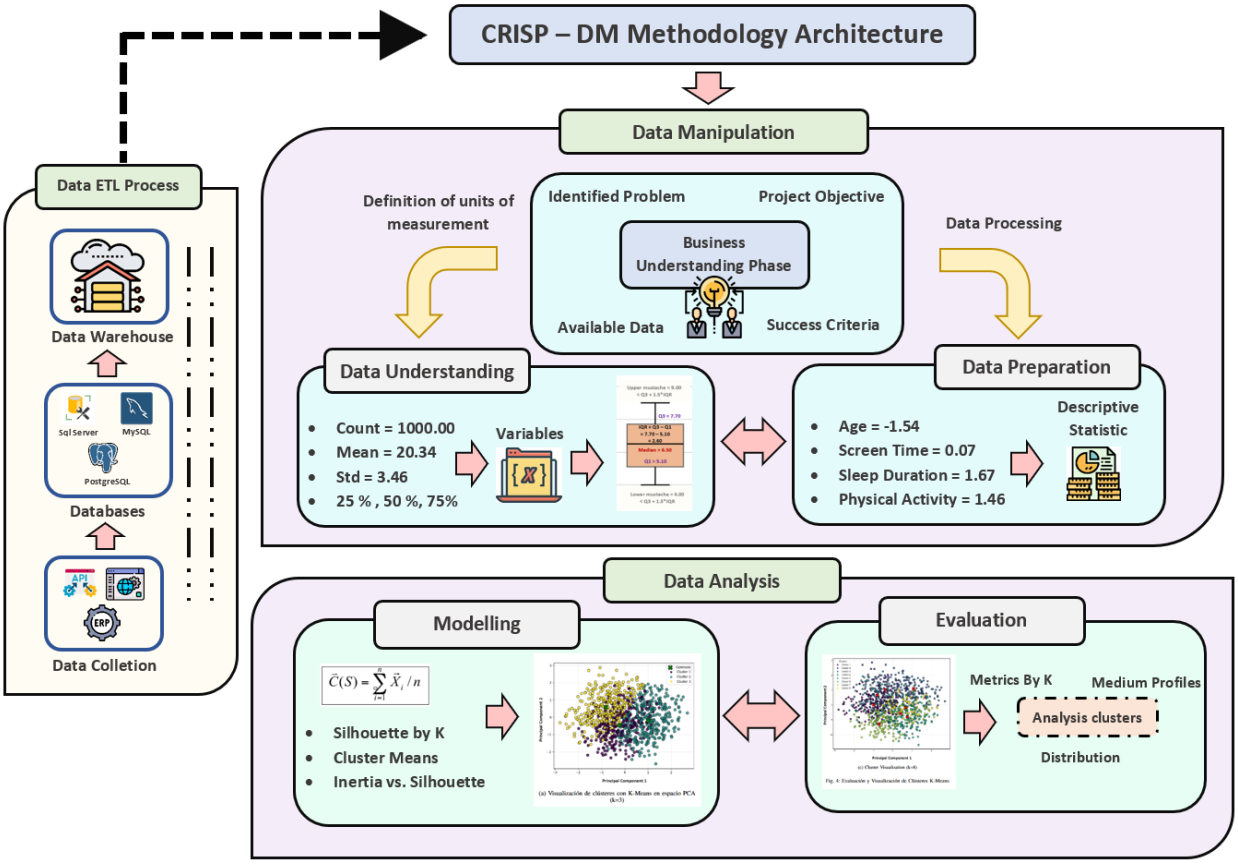

Fig. 2. Architecture CRISP-DM methodology.

TABLE III. BUSINESS UNDERSTANDING PHASE

Element	Description
Identified Problem	There are increasing mental health issues among university and high school students, reflected in factors such as stress, irregular sleep, excessive screen time, and low physical activity. This affects academic performance and overall well-being.
Project Objective	Use the information from the dataset (lifestyle habits, academic and emotional variables) to develop a predictive model based on clustering and machine learning techniques, which allows identifying students at risk or with similar mental health patterns.
Available Data	Demographics: name, gender, age, educational level.
	Lifestyle habits: screen time, sleep duration, weekly physical activity.
	Emotional factors: stress level, anxiety before exams.
	Observed outcome: change in academic performance.
Success Criteria	**Technical:** achieve well-defined and stable clusters (metrics such as Silhouette Score or Davies-Bouldin Index).
	Practical: obtain interpretable profiles that allow designing early intervention strategies or academic and emotional support.

TABLE IV. STATISTICAL SUMMARY OF THE STUDY VARIABLES

Stadistic	Age	Screen Time (hrs/día)	Sleep Duration (hrs)	Physical Activity (hrs/Week)	Stress Level
count	1000.00	1000.00	1000.00	1000.00	1000.00
mean	20.34	6.91	6.45	5.02	1.85
std	3.46	2.91	1.47	2.93	0.70
min	15.00	2.00	4.00	0.00	1.00
25%	17.00	4.40	5.10	2.60	1.00
50%	20.00	6.90	6.50	5.00	2.00
75%	23.00	9.50	7.70	7.60	2.00
max	26.00	12.00	9.00	10.00	3.00

points beyond them represent outliers. This graph reveals that all four variables exhibit data dispersion, with the presence of outliers that may indicate extreme behaviors or measurements in the studied sample, which warrants further investigation to

understand why these data deviate from the main behavior.

3) Data preparation: According to this section, in the Data Preparation phase, raw data is transformed into high-quality data ready for modeling. This stage, which goes hand in hand with the Data Understanding phase, involves cleaning the data (such as handling missing and outlier values) and transforming categorical variables into numerical variables so that the model's algorithms can properly process them [33].

Table V presents a sample of student data with variables normalized for analysis. Each row represents a student, and the columns display their data relative to the average. Age, Screen Time, Sleep Duration, and Physical Activity are standardized values, where a positive value indicates the student has an above-average age, screen time, sleep duration, or physical activity, and a negative value indicates a lower one. Stress Level is categorized qualitatively (Low, Medium, High) and also represented numerically (Stress Level Num) for use in machine learning models. For example, the first student has a below-average age (-1.54), above-average sleep duration (1.67), and a medium stress level. Table VI summarizes the descriptive statistics for the variables in a dataset after normalization. Numerical variables such as Age, Screen Time, Sleep Duration, and Physical Activity now have a mean of 0 and a standard deviation of 1, indicating they have been standardized. Meanwhile, the categorical variable Stress Level was converted to the numerical variable Stress Level Num, with a mean of 2.16, showing that the data tend toward the "Medium" stress level.

4) Modelling: In this section, the proposed algorithmic model is developed to address the identified problem. Supported by the analysis carried out in the previous phases, statistical graphs, tables, and mathematical expressions are defined to justify the selection and application of the K-Means algorithm as a clustering technique [34].

Fig. 4a shows the two-dimensional projection of the students through a Principal Component Analysis (PCA), where the three clusters identified by the K-Means algorithm are represented. Each color corresponds to a different group, and the centroids are indicated with 'X' markers. This visualization allows for the appreciation of the relative separation between groups and the distribution of the data in the reduced space. On the other hand, Fig. 4b presents the variation of the Silhouette index for different values of K (number of clusters). The maximum point is reached at k = best k, indicating the best partition in terms of internal cohesion and separation between groups. Additionally, the mathematical formula of the Silhouette coefficient is included, which reinforces the interpretation of the criterion used to validate the optimal number of clusters.

As shown in Table VII, the clustering analysis provides a clear overview of the data distribution and group characteristics. Table (a) reports the Silhouette Scores for different values of k, highlighting that the clustering quality is highest at $k = 3$ with a score of 0.51. Table (b) presents the mean values of Screen Time, Sleep Duration, and Physical Activity within each cluster, allowing us to profile the groups: Cluster 0 exhibits moderate screen time and sleep, Cluster 1 shows lower screen time and higher physical activity, and Cluster 2 has higher screen time with lower physical activity. Finally, Table (c) summarizes the inertia values along with the Silhouette Scores for each k, providing insight into both the compactness and separation of the clusters. Overall, these tables collectively illustrate the optimal number of clusters and the characteristics of each cluster group.

B. K-means Mathematical Formulas

1) Distance to centroid: The distance between a point x_p and a cluster centroid μ_i is computed using Euclidean distance (see eq.1) [35].
This distance is used to assign points to the nearest cluster.

$$d(x_p, \mu_i) = \sqrt{\sum_{j=1}^{m} (x_{pj} - \mu_{ij})^2} \tag{1}$$

where, m is the number of dimensions. This distance is used to assign points to the nearest cluster and to compute intra-cluster cohesion.

2) Cluster assignment: Each point is assigned to the cluster with the nearest centroid (see Eq. 2).
Points are grouped with the closest centroid to ensure cluster cohesion [36].

$$C_i = \{x_p : \|x_p - \mu_i\|^2 \leq \|x_p - \mu_j\|^2, \forall j = 1, \ldots, k\} \tag{2}$$

where, C_i is the set of points in cluster i. This ensures that points are grouped with the closest centroid.

3) Centroid update: Centroids are recalculated as the mean of all points in the cluster (see Eq. 3).
This moves the centroid to the center of its cluster for better stability.

$$\mu_i = \frac{1}{|C_i|} \sum_{x \in C_i} x \tag{3}$$

This adjustment moves the centroid to the center of its cluster, improving cluster cohesion.

4) Cost function (Inertia): K-means minimizes the sum of squared distances from points to their centroids (see Eq. 4).
Lower inertia indicates tighter clusters and better cluster compactness.

$$J = \sum_{i=1}^{k} \sum_{x \in C_i} \|x - \mu_i\|^2 \tag{4}$$

Lower inertia means points are closer to their centroid, indicating tighter clusters.

5) Convergence criterion: The algorithm stops when centroids change minimally between iterations (see Eq. 5).
A small tolerance ϵ ensures that clusters are stable.

$$\|\mu_i^{(t+1)} - \mu_i^{(t)}\| < \epsilon, \quad \forall i \tag{5}$$

where ϵ is a small tolerance value. This ensures clusters are stable.

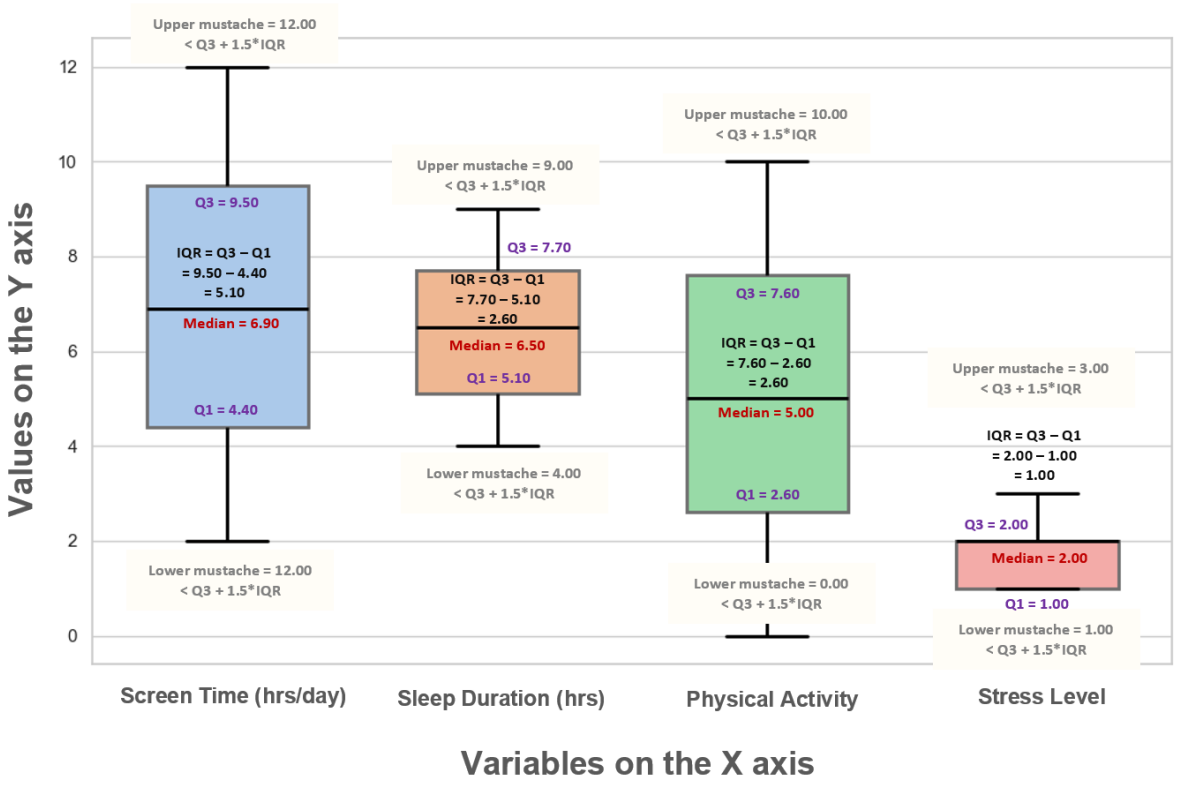

Fig. 3. Distribution of variables and the presence of outliers.

TABLE V. STUDENT DATA SAMPLE

Age	Screen Time (hrs)	Sleep Duration (hrs/week)	Physical Activity	Stress Level	Stress Level Num	Academic Performance	Anxiety Before Exams
-1.54	0.07	1.67	1.46	Medium	2.00	3.5	B
1.35	-1.24	-0.99	-1.64	Medium	2.00	2.8	C

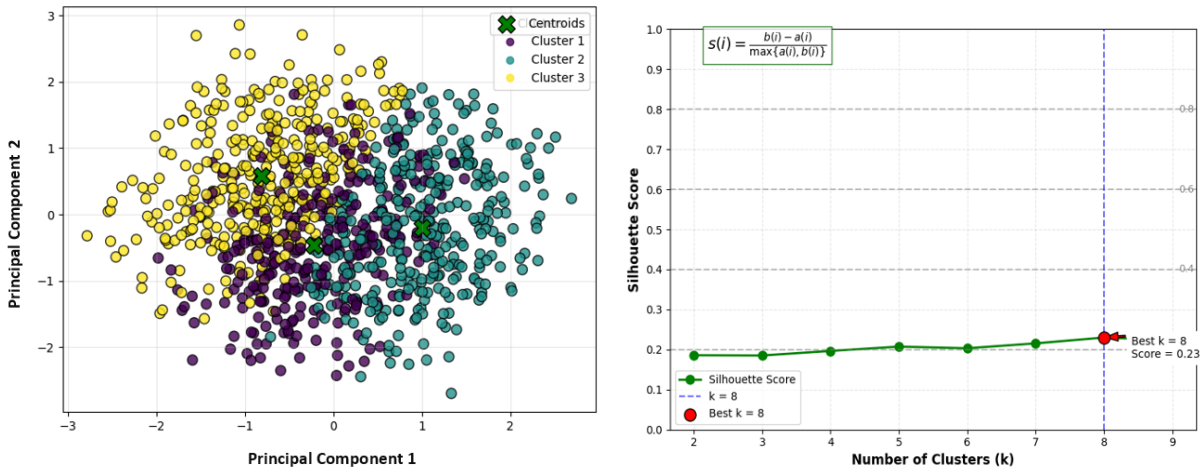
TABLE VII. (A) SILHOUETTE SCORES BY k, (B) CLUSTER MEANS, AND (C) INERTIA VS. SILHOUETTE

(a) Silhouette Scores by k



k	Silhouette
2	0.42
3	0.51
4	0.47
5	0.45
6	0.43

(b) Cluster Means (Example)

Cl.	Screen	Sleep	Activity
0	5.3	6.8	2.1
1	3.1	7.5	3.8
2	6.4	5.2	1.7

(c) Inertia vs. Silhouette

k	Inertia	Silhouette
2	580.1	0.42
3	430.4	0.51
4	390.2	0.47
5	350.1	0.45
6	320.5	0.43

(a) Visualizing clusters with K-Means in PCA space (k=3).

(b) Evaluating the optimal number of clusters with silhouette score.

Fig. 4. Student clustering using K-Means: PCA visualization and analysis of the optimal number of groups.

6) Total inertia (Optional): The total inertia quantifies overall cluster compactness (see Eq. 6).

It measures how well points fit within their clusters; lower values indicate tighter clustering.

$$J_{total} = \sum_{i=1}^{k} \sum_{x \in C_i} \|x - \mu_i\|^2 \tag{6}$$

where, k is the number of clusters, C_i the points in cluster i, x a data vector, and μ_i the cluster centroid.

7) Cluster prediction: Once the algorithm converges, a new point x_{new} is assigned to the cluster with the nearest centroid.

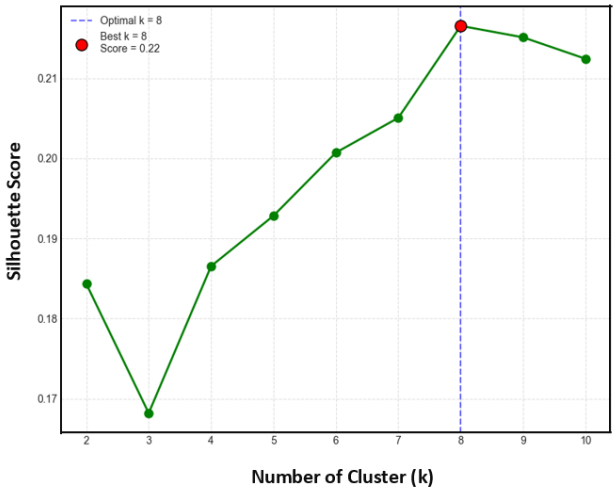
This completes the clustering process, assigning each point to its optimal cluster (see Eq. 7).

$$\hat{C} = \arg\min_i \|x_{\text{new}} - \mu_i\| \tag{7}$$

This completes the K-means clustering process, assigning each point to its optimal cluster.

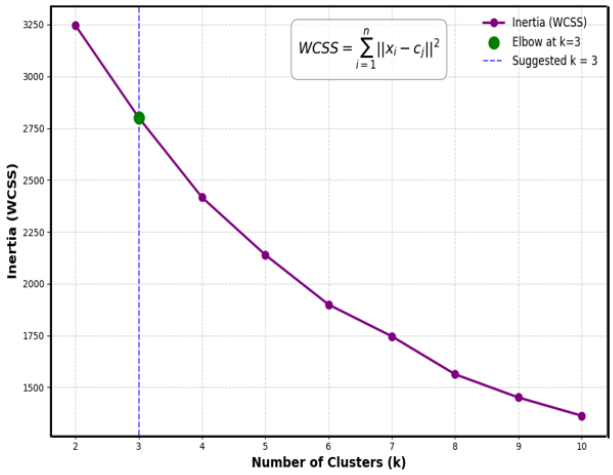
IV. Result

In the Evaluation phase of the CRISP-DM process, the quality of the obtained model is verified, comparing its results with the business objectives and criteria defined in the initial phases. This process not only involves analyzing statistical and performance metrics, but also evaluating the consistency of the clusters generated by the K-Means algorithm with respect to the problem context. In this way, it is determined whether the model is suitable for practical implementation or if it requires additional adjustments to the parameters, input data, or the methodology used [37] [38].



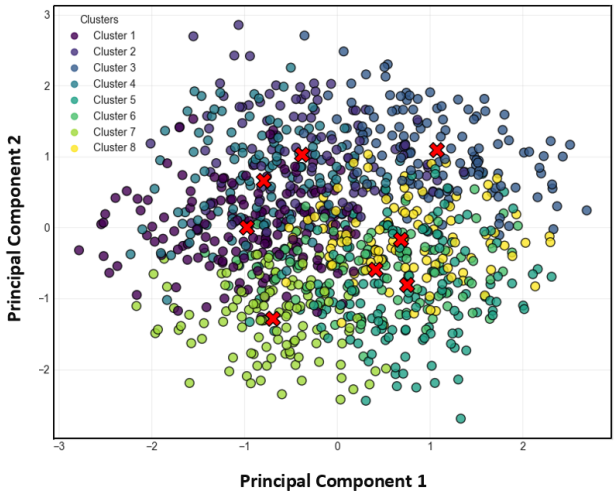
A. Evaluation of Result

Fig. 5 presents a comprehensive evaluation of the K-Means clustering analysis. Fig. 5a illustrates the Inertia curve (elbow method), which is used to identify the optimal number of clusters (k) by minimizing the sum of squared distances from the points to their centroids. Fig. 5b complements this evaluation with the Silhouette Score, a metric that measures cluster cohesion, where higher values indicate that objects are well grouped. Finally, Fig. 5c provides a visualization of the resulting clusters in a PCA (Principal Component Analysis) space, allowing observation of both the data distribution and the location of centroids for each selected cluster.



The references in the group of Tables VIII provide a comprehensive overview of the K-Means cluster analysis. Table VIIIa of Metrics by k shows that the Silhouette Score reaches its highest point at $k = 8$, suggesting that this is the optimal number of clusters for segmenting the data. Complementing this finding, Table VIIIb of Cluster Distribution demonstrates that the resulting 8 clusters have a relatively balanced size, with no groups being excessively large or small. Finally, the third and most descriptive, Table VIIIc of Cluster Profiles (Means), provides a detailed characterization of each group. For example, Cluster 1 is distinguished by having the highest average screen time but the lowest physical activity, while other clusters are defined by different combinations of age, sleep, and activity, allowing for the identification of unique behavioral profiles among individuals in the dataset.

B. Comparison of Methodologies



In this regard, Table IX shows the main differences between the most widely used data mining methodologies: KDD, SEMMA, and CRISP-DM. While KDD focuses on knowledge discovery from large volumes of data without a strict methodological structure, SEMMA offers a practical approach but is limited to the use of proprietary tools such as SAS and strictly technical phases. In contrast, CRISP-DM stands out for its comprehensive, iterative, and flexible nature,

(a) Silhouette score evaluation.

(b) Elbow method (Inertia).

(c) Cluster visualization (k=8).

Fig. 5. Evaluation and visualization of k-means clusters.

TABLE VIII. CLUSTER ANALYSIS RESULTS

(A) METRICS PER k

k	Inertia	Silhouette
2	3245.03	0.18
3	2800.44	0.17
4	2416.18	0.19
5	2139.13	0.19
6	1899.30	0.20
7	1746.23	0.21
8	1563.09	0.22
9	1451.26	0.22
10	1363.39	0.21

(B) DISTRIBUTION

Cluster	Count	Percentage (%)
0	155	15.50
1	112	11.20
2	133	13.30
3	125	12.50
4	149	14.90
5	105	10.50
6	114	11.40
7	107	10.70

(C) PROFILES (AVERAGES)

Cluster	Age	Screen	Dream	Activity
0	24.06	4.38	6.92	4.82
1	19.87	8.83	8.04	2.12
2	20.71	9.83	7.61	7.83
3	23.86	8.88	5.35	2.95
4	20.03	6.30	4.88	8.20
5	17.59	4.32	7.89	6.38
6	17.80	3.86	5.72	2.45
7	16.72	9.28	5.51	4.22

covering everything from business understanding to model implementation, making it a robust and widely validated standard in the industry. For these reasons, CRISP-DM is selected as the most appropriate methodology for this project, as it guarantees complete and systematic coverage of the data mining process.

V. Discussion

The study described by [14] demonstrated that unsupervised clustering algorithms make it possible to segment the mental health of university students into clearly differentiated profiles, particularly when employing $k = 3$, supported by the silhouette index. However, unlike that work, which integrated classification and clustering into a hybrid model to optimize the prediction of academic performance and psychological well-being, the present research focuses on a purely unsupervised exploratory approach. This approach, by dispensing with prior labels, facilitates the identification of hidden patterns and enables the comparison of how adjusting the number of clusters ($k = 3$ versus $k = 8$) impacts the balance between clarity and level of detail in segmentation. In doing so, it highlights the usefulness of pure clustering for generating initial analytical foundations that could complement hybrid models in future studies [15].

Complementarily, the work of [16] highlights the positive impact of structured interventions on improving psychological well-being, employing a Bayesian model and cluster sampling to evaluate dimensions such as mental health literacy, self-efficacy, and willingness to seek help. The findings of the present study align with these results by showing that segmentation strategies promote the identification of vulnerable groups and, consequently, the strengthening of such dimensions, albeit with nuances related to the academic and social context of the students analyzed. In this sense, it is evident that, regardless of the methodology applied, intervention programs generate consistent effects in promoting student well-being.

On the other hand, the research of [17] introduces an approach based on wearable devices and physiological signals (EEG, EDA, HR, and SKT), achieving accuracy levels above 99% in stress classification in controlled environments using the MIST. While these results demonstrate the effectiveness of real-time monitoring, they present limitations regarding their applicability in everyday scenarios. In contrast to this approach, the results obtained here prioritize contextual variables such as lifestyle and academic habits, which, although yielding lower levels of accuracy, provide a broader and more representative perspective of the students' real environment. Thus, a contrast is established between the high accuracy of wearables under experimental conditions and the practical applicability of contextual factors in real educational settings.

Likewise, compared with studies that employed questionnaires and classical classification algorithms such as Naïve Bayes, Decision Trees, Random Forest, and SVM, achieving accuracies between 71% and 78.9% for predicting anxiety levels [18] [19], the results obtained in the present study provide an alternative approach by integrating clustering techniques and contextual analysis. Although supervised algorithms allow direct predictions of specific symptoms, clustering offers a complementary perspective by identifying group patterns that transcend individual characteristics, thus providing a more solid foundation for preventive interventions of a collective nature.

In the same vein, studies such as those of [20] [21] employed supervised models including multiple linear regression, random forest, and multilayer neural networks to predict depression, suicidal ideation, and stress levels, highlighting specific factors such as financial concerns or somatic symptoms as key predictors. In contrast, the present study emphasizes group analysis through clustering, revealing how students can be organized into profiles of shared well-being and risk. This perspective makes it possible to move beyond the prediction of individual cases and focus instead on the understanding of collective trends that can guide broader preventive interventions tailored to different segments of the student population.

When contrasting the findings of Rois [22] and Saha et al. [23] with the results of this study, a convergence emerges regarding the relevance of external factors in explaining student mental well-being. While those authors identified physiological variables such as heart rate, blood pressure, or sleep quality using supervised algorithms—highlighting random forest with an accuracy of 89.72% and an AUC of 0.8715—as well as the utility of social media for anticipating mental health consultations with a correlation of $r = 0.86$, this work applied unsupervised clustering techniques that allowed students to be segmented into groups with similar risk and mental prosperity characteristics. Unlike predictive approaches based on supervised models or large-scale data analysis, the results presented here offer an exploratory perspective that reveals collective patterns without requiring prior labels, complementing previous findings by facilitating a comprehensive understanding of how academic, personal, and contextual factors combine into differentiated mental health profiles.

Similarly, the studies by Abdul [24] [25] used physiological variables, lifestyle habits, and large-scale social media data, supported by algorithms such as random forest, SVM, and time series models, achieving remarkable performance metrics (AUC of 0.8715 and correlations up to $r = 0.86$). However, while those approaches privilege individual prediction, the results presented here underscore the capacity of clustering to provide a global view of how students are distributed across different profiles of risk or well-being. Thus, a methodological complementarity is proposed: supervised models are useful for anticipating individual cases, while unsupervised techniques allow for the understanding of collective structures that strengthen the design of prevention strategies and comprehensive monitoring.

Finally, the findings are consistent with those reported by [26] [27], who demonstrated the usefulness of clustering in segmenting university mental health profiles based on factors such as alcohol consumption, perceived stress, or academic cohorts. While these authors applied k-means and other clustering methods with specific variables, the present study jointly integrates academic and personal factors, expanding the scope of analysis and providing a more holistic perspective of student well-being. Taken together, the results reaffirm that

TABLE IX. COMPARISON OF DATA MINING METHODOLOGIES

Criterion	KDD	SEMMA	CRISP-DM
Main Focus	Knowledge discovery from large volumes of data	Analytical process focused on statistical modeling	Standardized data mining process applied to different domains
Methodological Structure	Does not have rigidly defined phases, more conceptual	Technical phases: Sample, Explore, Modify, Model, Assess	Clear phases: Business Understanding, Data Understanding, Preparation, Modeling, Evaluation, Deployment
Flexibility	Low flexibility; requires adaptation to context	Limited to projects using SAS software	High flexibility and iterativity, applicable to diverse contexts
Scope	More theoretical discovery than practical implementation	Focused on exploratory analysis and model building	Covers the entire lifecycle: from business to implementation
Advantages	Pioneer in formalizing the process of pattern discovery	Direct and practical in SAS projects	Industry standard, robust, documented, and widely used
Limitations	Lacks standardization for real projects	Dependence on proprietary software, not very adaptable to other environments	May be more extensive and complex compared to simpler methodologies

clustering is not only effective for classification but also for generating segmentations that enable the design of timely and tailored interventions for differentiated profiles within the university population.

VI. CONCLUSION

Mental health in the university setting has shown various issues that significantly affect the academic and personal lives of students. These difficulties not only influence academic performance but also impact behavior, interpersonal relationships, and emotional well-being. In this context, the research conducted proposed the creation of a predictive model based on machine learning, using the k-means algorithm as the main approach. To develop the proposed model, a dataset in CSV format, oriented toward university students' mental health, was extracted from the Kaggle platform. The research was structured following the CRISP-DM methodology, which establishes five stages in its development. The first stage refers to business understanding based on the identification of the problem. As a second stage, an analysis of the most relevant variables from the dataset was conducted, applying criteria such as mean, maximum, minimum, among others. The third stage involved analyzing outliers, performing data cleaning, and transforming categorical variables into numerical variables for further evaluation. In the fourth stage, the k-means algorithm was applied to cluster the data and evaluate the optimal number of groups created. Finally, the fifth stage provides an evaluation of metrics based on the established clusters.

The results obtained confirm that cluster analysis through PCA, along with metrics such as Silhouette and inertia, makes it possible to identify significant patterns within the student population. It is observed that configurations such as $k = 3$ and $k = 8$ generate consistent groupings, differentiated by key variables such as screen time, hours of sleep, and level of physical activity. These segmentations not only facilitate the understanding of students' distribution and behavior in the academic environment but also help identify subgroups with specific needs or habits. Altogether, this approach provides relevant information for designing academic support strategies and programs aimed at well-being and mental health, contributing to a deeper understanding of the factors affecting university performance and adaptation.

Based on these findings, it is recommended that future research incorporate additional variables that allow for a more comprehensive characterization of students, such as eating habits, use of social networks, socioeconomic level, and resilience. Likewise, it is advisable to complement cluster analysis with different algorithms such as DBSCAN, Agglomerative Clustering, or Gaussian Mixture Models, as well as to explore advanced dimensionality reduction techniques such as t-SNE or UMAP to improve data visualization. It is also suggested to evaluate cluster stability through cross-validation or bootstrap techniques, integrate temporal data to analyze changes over time, and combine clustering with supervised predictive models to anticipate academic or mental health risks. Finally, complementing the study with interactive tools or dashboards would facilitate the interpretation and application of results, strengthening the model's usefulness for decision-making in educational environments.

The developed model presents certain limitations that must be considered when interpreting the results. First, it is based solely on the variables available in the original dataset; therefore, relevant external factors for mental health and academic performance may not be reflected. Moreover, since this is an unsupervised cluster analysis, the assignment of students to groups depends on the algorithm configuration and the choice of the number of clusters, which may generate some variability in the results. Another limitation is that the model does not incorporate temporal data, so it does not allow for the evaluation of how students' behavioral patterns change over time. Lastly, although quality metrics such as Silhouette and inertia help evaluate cluster cohesion and separation, they do not guarantee an absolute interpretation of the practical relevance of each group, making it necessary to complement the analysis with input from education and mental health experts.

ACKNOWLEDGMENT

Thanks to the University of Sciences and Humanities, which made this project a reality.

***Abstract*—Plant diseases remain a major threat to crop productivity, especially where timely diagnosis is difficult. This paper introduces TomDetLeaf, a new annotated dataset designed for tomato leaf detection in diverse agricultural environments, supporting the development of generalizable deep learning models for edge AI deployment. Unlike existing datasets such as PlantVillage, which consist mainly of single-leaf images captured under controlled conditions, TomDetLeaf integrates heterogeneous sources including the Taiwan dataset, climate-controlled greenhouses, hydroponic systems and farm environments. The dataset combines single-leaf and multi-leaf images, realistic backgrounds and varying illumination, addressing a key gap that limits the real-world robustness of current models. To demonstrate its utility, we trained and evaluated YOLOv8 on both the original Taiwan dataset and our proposed TomDetLeaf. Results show that YOLOv8 trained on TomDetLeaf achieved 88.3% mAP@0.5, 81.8% precision, and 82.7% recall, exceeding the Taiwan-subset baseline of 77.4% mAP@0.5, 81.6% precision, and 67.6% recall. This validates the contribution of TomDetLeaf in improving detection accuracy and generalization under realistic conditions. By providing a diverse, deployment-ready dataset, this work bridges the gap between theoretical benchmarks and practical real-time applications.**

***Keywords*—Tomato leaf detection; smart agriculture; dataset; tomato leaf dataset; real-time inference; Edge AI; object detection**

I. Introduction

Ensuring tomato crop health is vital for maintaining sustainable agricultural production and global food security [1]. Tomato plants are highly susceptible to multiple foliar diseases that cause severe yield losses and economic constraints for farmers worldwide [2], [3]. Early and accurate detection of diseased leaves is therefore critical for timely intervention and disease management. Conventional detection methods, such as expert visual inspections or laboratory analysis, are limited by subjectivity, high costs and the lack of accessibility in rural or resource-constrained regions [4].

In recent years, the combination of deep learning (DL) and computer vision has shown promising results for plant disease recognition. Convolutional neural networks (CNNs), trained on large-scale datasets such as PlantVillage, have achieved remarkable classification accuracy, often exceeding 99% [5]. However, these models typically rely on synthetic or laboratory-controlled images with plain backgrounds and uniform lighting, conditions that do not reflect the complexity of real-world agricultural environments. As a result, models trained on such data may perform well in academic benchmarks but fail to generalize when deployed in greenhouses, hydroponic systems or open-field farms [6].

To address these limitations, there is a pressing need for annotated datasets that capture the diversity of real-world conditions, including single and multiple leaves per image, heterogeneous backgrounds, variable lighting and naturally occurring noise [7]. Without such datasets, AI systems risk providing artificially inflated results during testing while underperforming in practical deployment scenarios.

Despite the success of existing datasets such as PlantVillage [8], their controlled acquisition conditions, uniform backgrounds, isolated leaves and synthetic lighting often lead to inflated accuracy that does not generalize to real-world deployment. Models trained on such data frequently fail when tested in farms, greenhouses, or hydroponic environments where multiple leaves overlap, backgrounds vary and environmental noise is present [9]. This critical gap between laboratory benchmarks and field performance motivates the development of TomDetLeaf, a dataset explicitly designed to capture real-world complexity and support the creation of robust detection models for edge deployment [10].

This work introduces TomDetLeaf, a curated dataset designed to bridge this gap by enabling robust tomato leaf detection in diverse contexts. Unlike existing resources, TomDetLeaf merges images from multiple sources, including the Taiwan dataset, a climate-controlled greenhouse and hydroponic environments and it is complemented with distractor images to enhance model generalization [11]. Each tomato leaf in the dataset is annotated for detection tasks, providing a realistic foundation for developing edge-ready models. To demonstrate its effectiveness, we trained YOLOv8 on TomDetLeaf and compared its performance with the same model trained on the original Taiwan dataset [12]. Results show that TomDetLeaf enables a substantial improvement in both mean Average Precision (mAP) and recall, while achieving stronger robustness in real-world scenarios.

Beyond dataset development, this work sets the foundation for an end-to-end pipeline combining detection and classification. In future work, the detected tomato leaves will be cropped and passed to a lightweight classification model capable of distinguishing between healthy and multiple disease categories in real time. The pipeline will be designed for integration into autonomous platforms, such as agricultural robots or UAVs, enabling continuous monitoring of crops directly in the field [13], [14]. This vision positions TomDetLeaf not only as a

*Corresponding authors.

dataset, but as a key enabler of embedded AI solutions for smart agriculture.

The main contributions of this paper are summarized as follows:

- Development of TomDetLeaf, a new annotated dataset for tomato leaf detection, integrating images from controlled and real-world environments with diverse backgrounds, lighting and leaf arrangements.
- Cleaning and curation of existing data sources, including the Taiwan dataset, by removing low-quality and duplicate samples to enhance reliability.
- Incorporation of greenhouse, hydroponic and distractor images, ensuring robustness against non-ideal and heterogeneous agricultural conditions.
- Comprehensive evaluation with YOLOv8, showing significant performance improvements over baseline datasets, confirming the dataset's value for real-time deployment in edge-based agricultural applications.

By filling the dataset gap and validating its utility through rigorous experiments, TomDetLeaf lays the groundwork for reliable end-to-end systems where detection of tomato leaves can serve as the first step toward subsequent disease classification and full integration into autonomous agricultural platforms.

To situate the dataset within a complete decision workflow, Fig. 4 presents the conceptual architecture of the intended system. It comprises image acquisition, tomato-leaf detection with YOLOv8, cropping of detected leaves, a lightweight disease classification module and a final decision layer that reports health status and disease type. The present study empirically evaluates the detection component; the classification component is outlined as future work.

II. Proposed Dataset: TomDetLeaf

The TomDetLeaf dataset was designed to provide a realistic and diverse benchmark for tomato leaf detection, with the specific objective of improving the generalization of deep learning models in real-world agricultural contexts. Unlike existing datasets, which are often captured under controlled laboratory conditions with plain backgrounds, TomDetLeaf integrates heterogeneous sources and environmental conditions [15], [16]. This deliberate design ensures that the dataset reflects the variability of actual agricultural fields, where lighting, leaf density and background noise are far less predictable. The construction process follows a structured pipeline that includes data selection, cleaning, integration of new sources, annotation and the addition of distractor images [17].

A. Taiwan Subset and Cleaning

The first source of TomDetLeaf is the publicly available Taiwan tomato dataset [18], which contains both single-leaf and multi-leaf images. From this dataset, only a relevant subset was retained. The raw images were manually cleaned to remove duplicates, low-quality samples and blurred images that could negatively affect model learning. This cleaning process ensured that the retained data maintained reliability and quality [19]. The Taiwan subset serves as the foundation of TomDetLeaf, contributing a balanced mixture of isolated and overlapping tomato leaves under varying capture conditions.

B. Greenhouse Captures

To complement the Taiwan subset, we collected new high-resolution images from a climate-controlled greenhouse. These images introduce diversity in terms of background textures, controlled yet variable lighting and different plant growth stages. Including greenhouse data ensures that the dataset better reflects the conditions of commercial tomato cultivation systems, where disease detection systems are increasingly deployed. The controlled acquisition process in this environment also provided consistent labeling opportunities, while maintaining realistic challenges such as shadows, leaf overlap and reflections [20].

C. Hydroponic Captures

Another significant contribution to TomDetLeaf comes from hydroponic environments, where tomato plants are grown in nutrient solutions without soil. The images captured in this context differ substantially from those in both controlled greenhouse and field scenarios. Hydroponic systems often include artificial lighting, reflective surfaces and pipes or structural elements in the background, which add to the complexity of the detection task [20]. Incorporating these samples enhances the dataset's heterogeneity and improves the likelihood that trained models will generalize to a broad spectrum of agricultural settings [21].

D. Distractor Images

In addition to tomato-specific samples, TomDetLeaf includes a curated set of distractor images consisting of non-tomato leaves, stems and other irrelevant agricultural objects. These negative examples are essential to reduce model bias and prevent false positives during deployment. In real-world conditions, object detection systems are frequently exposed to cluttered backgrounds containing various types of vegetation and objects unrelated to tomato crops. By incorporating distractor images into the training process, TomDetLeaf strengthens the ability of models to distinguish tomato leaves from irrelevant elements, thereby improving robustness in practical applications.

E. Annotation Process

All images were consistently annotated using the Roboflow platform. Bounding boxes were applied to each tomato leaf with a single unified label, Tomato-leaf. The decision to annotate only one class simplifies the dataset for the detection stage, which we consider the foundation of an end-to-end pipeline. This modular approach allows subsequent classification models to focus exclusively on cropped leaf regions, where disease type or health status can later be determined. The consistency of annotations across heterogeneous sources ensures clarity and usability for researchers and developers aiming to deploy detection systems on embedded devices.

F. Dataset Overview

Fig. 1 presents the complete construction pipeline of TomDetLeaf, while Fig. 2 shows representative examples of images drawn from both the Taiwan dataset and the proposed TomDetLeaf dataset. The latter clearly demonstrates its

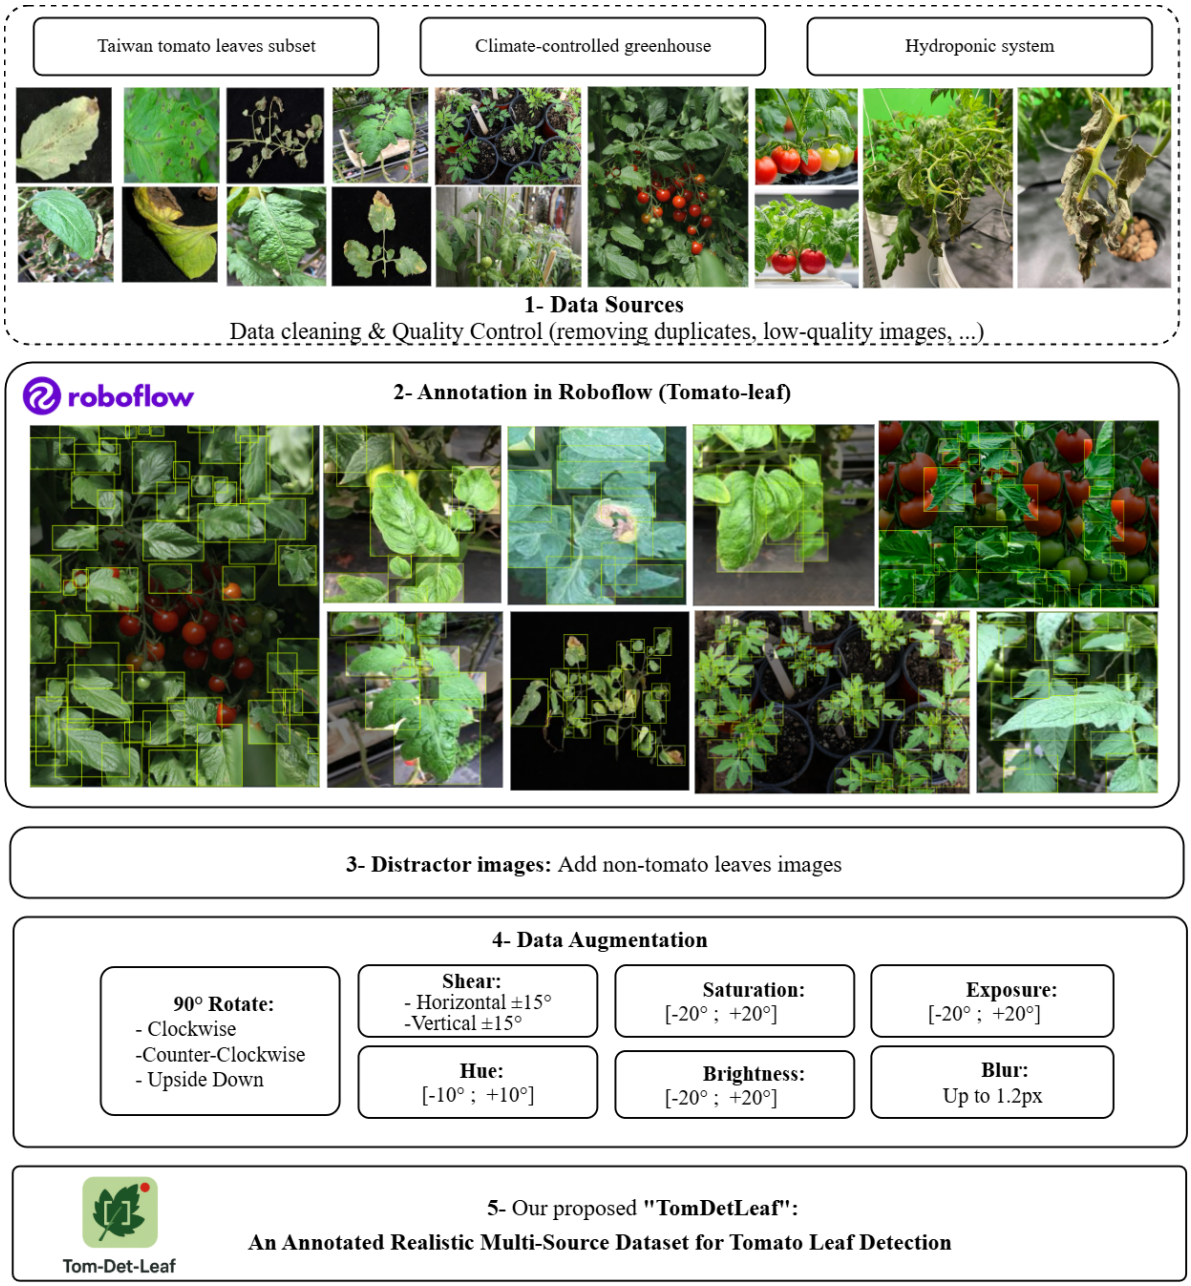

Fig. 1. Construction pipeline of the proposed TomDetLeaf dataset. The dataset integrates cleaned subsets of the Taiwan dataset with new captures from climate-controlled greenhouses and hydroponic systems, complemented by distractor images and consistently annotated for tomato leaf detection.

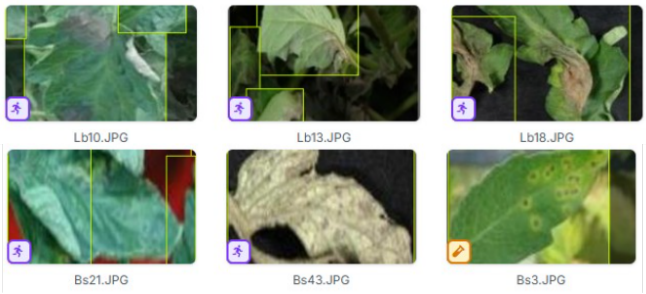
enhanced variability, combining single and multiple leaves, natural and artificial backgrounds and diverse environmental conditions. This heterogeneity makes TomDetLeaf a unique and valuable resource for training and evaluating models intended for TinyML and Edge AI deployments in agriculture [22], [23].

G. Dataset Statistics

Table I summarizes the composition of TomDetLeaf after cleaning. Counts reflect the final pool used prior to splitting.

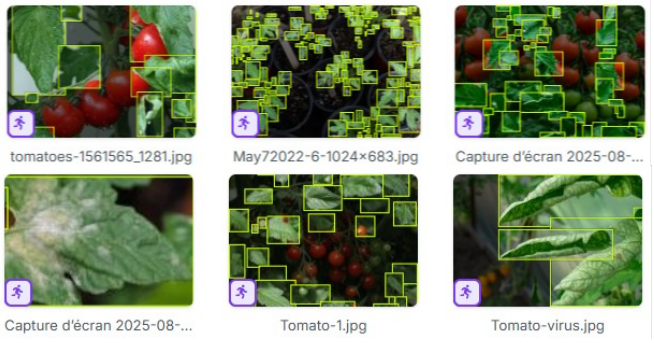
The present study addresses leaf detection only, i.e. all leaves share a single Tomato-leaf class. The healthy/diseased counts in Table I were not used during training or evaluation; they are reported to show coverage across environments and

TABLE I. TOMDETLEAF COMPOSITION BY SOURCE AFTER CLEANING. H: HEALTHY, D: DISEASED



Source	Images	H	D
Taiwan subset (cleaned)	417	63	354
Greenhouse captures	182	78	104
Hydroponic captures	127	74	53
Distractor scenes (negatives)	34	–	–
Total	**760**	**215**	**511**

to motivate the forthcoming classification release.



To indicate scene complexity at a glance, TomDetLeaf (non-augmented) comprises approximately one third single-leaf images and two thirds multi-leaf images (see Table II).

TABLE II. SINGLE- VS. MULTI-LEAF COMPOSITION OF TOMDETLEAF (NON-AUGMENTED)

Scene type	Share	Images (of 760)
Single-leaf	≈33%	≈250
Multi-leaf	≈67%	≈510

(a) Samples from the Taiwan dataset

(b) Samples from the proposed TomDetLeaf dataset

Fig. 2. Examples of tomato leaf images: (a) Samples from the Taiwan dataset, (b) Samples from the proposed TomDetLeaf dataset. The TomDetLeaf dataset integrates single and multiple leaves, diverse backgrounds and images from real-world environments such as farms, climate-controlled greenhouses and hydroponics.

PlantVillage (tomato subset) [8] is a large classification corpus of single-leaf images captured on largely uniform backgrounds with image-level labels only (no bounding boxes). By design it is not detection-ready and would require re-annotation to train a detector. In contrast, TomDetLeaf provides bounding boxes for a single Tomato-leaf class, mixes single- and multi-leaf scenes (approximately one third vs. two thirds), and includes complex, real-world backgrounds across greenhouse and hydroponic settings. Consequently, direct mAP comparison to PlantVillage is not meaningful; it serves instead as a scale reference for classification. Key differences are summarized in Table III.

TABLE III. TOMDETLEAF VS. PLANTVILLAGE (TOMATO SUBSET)

Aspect	TomDetLeaf	PlantVillage–Tomato
Primary task	Detection	Classification
Annotation	Boxes (1 class)	Image labels
Leaf multiplicity	Single+Multi (≈1/3:≈2/3)	Single only
Backgrounds	Complex, real-world	Plain, uniform
Environments	Greenhouse, hydroponic, farm	Controlled
Images (raw)	760	18,164
Detection-ready	Yes	No (re-annotation)

III. EXPERIMENTAL SETUP

To evaluate the effectiveness of the proposed TomDetLeaf dataset, we conducted experiments using YOLOv8, a state-of-the-art object detection model widely adopted for lightweight and real-time applications. YOLOv8 was selected due to its balance between accuracy and computational efficiency, making it suitable for assessing detection performance in agricultural edge scenarios. The implementation was based on the Ultralytics YOLOv8 framework with PyTorch backend.

A. Datasets for Comparison

Two datasets were considered in this study:

1) Taiwan dataset: A publicly available dataset of tomato plants [18], annotated to include a single bounding-box class labeled Tomato-leaf. Only the relevant subset was retained, with noisy, poor-quality and duplicate images removed.

2) TomDetLeaf dataset (Proposed): A newly curated dataset combining selected and cleaned images from the Taiwan dataset with additional images collected from climate-controlled greenhouses and hydroponic environments. The dataset captures a wider variety of conditions, including single-leaf and multi-leaf settings, diverse backgrounds and real-world environmental variability. All images were annotated with a single class Tomato-leaf.

For both datasets the detector is health-agnostic (single Tomato-leaf class); the healthy/diseased composition in Table I does not alter the training labels used here.

B. Training Setup

Both datasets were trained under identical conditions to ensure a fair comparison. Images were resized to **225**×**225** and the data were split **70%/20%/10%** into training, validation, and test sets (**532/152/76** images, respectively). Training ran for **100** epochs with a batch size of **64**, using the **Adam** optimizer (initial learning rate **0.001**). Data augmentation was applied to the *training* split only (random horizontal flip, mild geometric transforms and photometric jitter) and performed online at load time, yielding an effective **3**× increase in training samples per epoch; this corresponds to **1,596** effective training images and an overall effective dataset size of **1,824** when counting augmented samples, while validation and test sets remained unchanged.

C. Evaluation Metrics

The performance of the object detection models was evaluated using three standard metrics: Precision, Recall and mean Average Precision (mAP) [24], [25]. These metrics are widely adopted in computer vision benchmarks and provide

complementary insights into model reliability and robustness in real-world scenarios.

Precision measures the ability of the model to correctly identify tomato leaves among all predicted bounding boxes. It is defined as:

$$\text{Precision} = \frac{TP}{TP + FP} \tag{1}$$

where, TP denotes true positives (correct detections) and FP false positives (incorrect detections). A higher precision indicates that fewer non-leaf objects are misclassified as leaves.

Recall quantifies the proportion of correctly detected tomato leaves among all ground-truth annotations:

$$\text{Recall} = \frac{TP}{TP + FN} \tag{2}$$

where, FN represents false negatives (missed detections). High recall is particularly critical in agricultural monitoring since missing diseased leaves may prevent timely intervention.

Mean Average Precision (mAP) provides a holistic measure that balances precision and recall. It is based on the area under the Precision–Recall (PR) curve. For a single class, the Average Precision (AP) is computed as:

$$AP = \int_0^1 P(R), \mathrm{d}R \tag{3}$$

where, $P(R)$ is the precision as a function of recall. For multi-class tasks, the mean of AP across all classes yields the mAP. In practice, different intersection-over-union (IoU) thresholds are applied to determine whether a predicted bounding box matches a ground-truth object.

$mAP@50$ corresponds to AP calculated at a fixed IoU threshold of 0.5, following the Pascal VOC standard. It is relatively lenient, considering a detection correct if the overlap with ground truth is at least 50%.

$mAP@90$ applies a stricter threshold of 0.9, requiring near-perfect overlap between predicted and ground-truth bounding boxes.

$mAP@[.5 : .95]$, the COCO standard, averages AP over IoU thresholds ranging from 0.5 to 0.95 in increments of 0.05. This provides a more comprehensive assessment of detection quality across varying levels of localization.

By reporting precision, recall and mAP under multiple IoU thresholds, we provide a complete picture of detection performance, highlighting both the ability to identify leaves accurately (precision) and to avoid missing them (recall), as well as the localization accuracy of bounding boxes (mAP). Unless otherwise stated, reported mAP corresponds to mAP@0.5 (Pascal VOC).

TABLE IV. DETECTION PERFORMANCE OF YOLOV8 TRAINED ON TAIWAN AND TOMDETLEAF DATASETS

Dataset	Precision (%)	Recall (%)	mAP@0.5 (%)
Taiwan dataset	81.6	67.6	77.4
TomDetLeaf (Proposed)	81.8	82.7	88.3

IV. RESULTS

Table IV presents the comparative performance of YOLOv8 [26] trained on the Taiwan dataset and on the proposed TomDetLeaf dataset.

The results demonstrate that TomDetLeaf enables significantly stronger detection performance, with an improvement of +10.9% mAP@0.5 and +15.1% recall compared to the Taiwan dataset. While precision remained similar, recall improved markedly, indicating that models trained on TomDetLeaf capture a larger proportion of true positives under diverse conditions.

An important observation from our experiments is the significant improvement in recall (+15.1%) when training YOLOv8 on TomDetLeaf compared to the Taiwan dataset. In agricultural disease monitoring, recall is particularly critical: missing a diseased leaf can allow pathogens to spread unchecked, whereas a false alarm (lower precision) may only result in an unnecessary inspection. Thus, the higher recall achieved by TomDetLeaf-trained models underscores its value for real-world disease detection systems, where early and reliable identification of all potentially diseased leaves is more important than minimizing false positives.

Qualitative results are illustrated in Fig. 3, showing YOLOv8 predictions on complex real-world tomato plant images. Models trained on TomDetLeaf generalize better to challenging backgrounds, overlapping leaves and mixed plant structures, highlighting the importance of dataset diversity for real-world deployment.

A. Error Analysis and Cross-Dataset Checks

We examined generalization and typical failure modes under the same evaluation protocol as Table IV. A model trained on TomDetLeaf maintains its performance on complex scenes and attains even higher scores on the Taiwan test set, which largely contains simpler, single-leaf images and plain backgrounds. Conversely, a model trained on the Taiwan subset degrades on TomDetLeaf due to background clutter, occlusion and mixed structures.

TABLE V. CROSS-DATASET EVALUATION (MAP@0.5, PRECISION, RECALL)

Training set	Evaluation set	mAP@0.5 (%)	Precision (%)	Recall (%)
TomDetLeaf	TomDetLeaf	88.3	81.8	82.7
TomDetLeaf	Taiwan	92.1	86.4	88.9
Taiwan	Taiwan	77.4	81.6	67.6
Taiwan	TomDetLeaf	65.2	79.8	55.1

Qualitative inspection indicates that false negatives are primarily associated with heavy overlap/occlusion in multi-leaf clusters (approximately 40% of missed instances), small

Fig. 3. YOLOv8 detection results on sample images from the proposed TomDetLeaf dataset. The model demonstrates accurate detection in complex backgrounds, validating the robustness of the dataset.

leaves (height < 32 px; approximately 30%), backlit or low-contrast foliage against bright backgrounds (approximately 20%), and truncation at image borders (approximately 10%). False positives arise mainly from confusion with petioles/stems and tomato fruit (approximately 50%), non-tomato foliage present in aisles or background (approximately 30%) and specular reflections from hydroponic hardware (approximately 20%). We also observed instances where nearby leaves are suppressed during non-maximum suppression in very crowded scenes, which selectively reduces recall in multi-leaf images, the scenario TomDetLeaf was designed to represent.

PlantVillage provides image-level labels only; it is therefore unsuitable for a formal detection benchmark without additional bounding-box annotation. A qualitative probe on single-leaf PlantVillage images suggested that the TomDetLeaf-trained detector localizes the visible leaf reliably, but we do not report mAP for this corpus.

V. Discussion

Fig. 4 summarizes the envisaged end-to-end pipeline for tomato-leaf monitoring. The detector isolates candidate leaves that are subsequently provided to a lightweight classifier. This modular design supports embedded deployment because detection and classification can be optimized independently. The experiments reported here target the detection stage.

In addition, the cross-dataset results in Table V show that models trained on TomDetLeaf transfer reliably to simpler domains (Taiwan), whereas the inverse transfer degrades markedly, underscoring the value of training on realistic, cluttered scenes.

Across all capture settings, both healthy and diseased foliage are present (Table I), which reduces environment–label confounding and supports the observed generalization.

Together with the single- versus multi-leaf composition (Table II), this coverage limits scene-type bias and helps explain the improved recall on complex images.

The experimental results highlight the importance of dataset diversity and realism for developing object detection models that generalize to real-world agricultural environments. Although the Taiwan dataset is commonly used in plant leaf detection tasks, its limited variability in terms of background conditions and image diversity constrained the performance of YOLOv8, particularly in recall (67.6%). This weakness became evident when testing in complex scenarios with multiple overlapping leaves, heterogeneous lighting and natural backgrounds. Models trained on such restricted datasets tend to achieve high accuracy in controlled settings but fail to maintain robustness in deployment contexts.

By contrast, the proposed TomDetLeaf dataset demonstrated a marked improvement in detection performance, raising recall to 82.7% and overall mAP to 88.3%. This represents a relative gain of 10.9 percentage points in mAP and 15.1 percentage points in recall compared to the Taiwan dataset. The improvement in recall is particularly significant, as it indicates that fewer leaves are missed during inference, which is critical in applications such as early disease diagnosis where every missed detection can affect the effectiveness of downstream classification and decision-making.

The strength of TomDetLeaf lies in its deliberate design to reflect realistic agricultural conditions. By merging cleaned

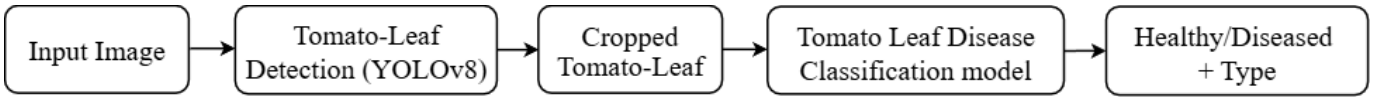


Fig. 4. Conceptual end-to-end pipeline for tomato-leaf monitoring. The system comprises image acquisition, detection with YOLOv8, cropping of detected leaves, a lightweight disease classification module and a final decision reporting health status and disease type. The present work evaluates the detection stage; the classification stage is reserved for future work.

subsets of the Taiwan dataset with additional images collected from climate-controlled greenhouses and hydroponic systems, the dataset introduces multiple layers of complexity: single-leaf and multi-leaf compositions, variations in background and differences in lighting and plant growth environments. Training on such data enables models to encounter challenging scenarios that mimic real-world deployment, thereby enhancing robustness and generalization.

Another important aspect is that TomDetLeaf focuses on leaf-level detection as a first stage of an end-to-end pipeline for plant health monitoring. In practice, robust leaf detection forms the foundation for subsequent disease classification, which can be performed on cropped leaf regions. This approach is well aligned with embedded and TinyML systems, where modular detection–classification pipelines allow real-time inference on resource-constrained edge devices such as robots or UAVs [27], [28]. Therefore, the dataset not only improves detection metrics but also provides a realistic training ground for the next step of integrating lightweight disease classification models [29].

Two practical limitations are worth noting. First, the current release uses a single detection class without disease labels; these labels are planned for the next version. Second, images are resized to 225×225, which can under-represent very small leaves; increasing the input resolution, adopting multi-scale training, or tuning the NMS IoU threshold are straightforward mitigations for future experiments.

Finally, qualitative results confirm that TomDetLeaf-trained models are able to detect tomato leaves under highly cluttered, natural conditions, with consistent bounding-box precision even in the presence of fruits, stems and overlapping vegetation. This demonstrates the practical advantage of training with diverse and realistic data, bridging the gap between controlled research benchmarks and real-world deployment in smart agriculture [30].

VI. Conclusion and Future Work

This work introduced TomDetLeaf, a customized and diverse tomato leaf detection dataset designed to improve the robustness and generalization of object detection models for real-world agricultural applications. By integrating cleaned subsets of existing datasets with newly collected images from climate-controlled greenhouses and hydroponic systems, TomDetLeaf provides a richer representation of realistic field conditions, including single- and multi-leaf scenarios, varied lighting and heterogeneous backgrounds. Experimental evaluation with YOLOv8 demonstrated that models trained on TomDetLeaf outperformed those trained on the Taiwan dataset, achieving an mAP of 88.3% and recall of 82.7%, compared to 77.4% and 67.6%, respectively. These results underline the importance of dataset realism in enabling reliable real-time deployment. Cross-dataset checks further confirmed that TomDetLeaf-trained detectors generalize to simpler domains, while reverse transfer degrades on cluttered scenes.

The dataset is intended as a foundation for modular end-to-end pipelines in smart agriculture, where reliable leaf detection constitutes the first stage of disease monitoring on embedded and edge devices. To facilitate downstream benchmarking, we also report per-source healthy/diseased counts and the single- versus multi-leaf composition to support balanced, reproducible splits. By improving detection accuracy and recall, TomDetLeaf contributes to enabling practical, low-cost solutions for autonomous platforms such as robots and UAVs.

Future work will extend this contribution in several directions. First, we will evaluate the dataset using additional state-of-the-art detection models to benchmark its generalizability across architectures. Second, we are preparing an expanded annotated version of TomDetLeaf that includes disease-specific labels for tomato leaves, allowing simultaneous detection and classification of healthy and diseased samples. Finally, we aim to implement and validate a complete end-to-end pipeline, combining detection and classification on embedded hardware platforms to demonstrate real-time disease diagnosis in realistic agricultural scenarios.

***Abstract*—Frost events represent a critical climatic hazard for agricultural systems in the Peruvian highlands, impacting approximately 74% of rural communities in the Puno region. This research addresses the question of whether machine learning (ML) and deep learning (DL) approaches can significantly outperform traditional statistical methods for frost prediction in extreme high-altitude tropical conditions, achieving sufficient accuracy for operational early warning systems. We present a comprehensive evaluation of twelve forecasting models for predicting daily minimum temperatures, utilizing NASA POWER satellite data (2000-2025) from thirteen meteorological stations across the Altiplano plateau (121,056 observations). The study implements and compares traditional statistical approaches (SARIMAX, Holt-Winters, Prophet, STL+ARIMA), machine learning algorithms (Random Forest, Support Vector Machines, XGBoost), deep neural network architectures (Multilayer Perceptron, LSTM, 1D-CNN), a hybrid SARIMA+ANN model, and an optimized ensemble approach. The ensemble model, integrating XGBoost, LSTM, and Random Forest through weighted averaging, demonstrated superior performance with RMSE=1.65°C and TSS=0.87, representing a 35% improvement over the best-performing statistical method. Individual analysis revealed XGBoost achieved RMSE=1.78°C with exceptional feature interaction modeling, while LSTM networks exhibited remarkable temporal pattern recognition with recall=0.88 for frost event detection. These findings validate the effectiveness of nonlinear approaches for operational forecasting under extreme climatic conditions and offer a robust framework for early warning systems that could substantially mitigate agricultural losses in vulnerable high-altitude communities.**

***Keywords*—Frost prediction; machine learning; deep learning; ensemble methods; Altiplano; agricultural early warning systems**

I. Introduction

Frost events, characterized by air temperatures dropping to or below 0°C at standard meteorological height (2 meters) in high-altitude regions exceeding 2,500 meters above sea level [1], constitute a recurring environmental hazard throughout the Andean highlands. These phenomena pose substantial threats to agricultural sustainability, particularly affecting smallholder farming systems that form the backbone of rural economies in Peru and Bolivia [2], [3]. Current estimates indicate that approximately 74% of agricultural communities in high-altitude Andean regions face regular exposure to frost events [4], necessitating adaptive strategies ranging from cultivation of frost-resistant crop varieties to traditional preservation techniques such as freeze-drying potatoes into chuño and tunta.

The Puno region exemplifies the severity of this climatic challenge. The region experiences between 100 and 180 frost nights annually that threaten both agricultural production and livestock systems. Extreme events have been documented in localities such as Mazocruz, where temperatures plummeted to -25.7°C [5], [6]. Contemporary climate dynamics in the Altiplano present a paradoxical pattern: while mean daytime temperatures exhibit an increasing trend, nocturnal cooling events persist with comparable frequency and potentially enhanced intensity, attributed to increased atmospheric desiccation [7], [8]. Recent climate vulnerability assessments identify Puno as the Peruvian department with the highest projected population exposure to elevated frost risk through mid-century [6].

This study explicitly asks: Can nonlinear machine learning (ML) and deep learning (DL) models outperform traditional statistical approaches in forecasting minimum temperatures across the Peruvian Altiplano? We hypothesize that ML/DL methods achieve RMSE values below 2°C, whereas statistical methods exceed 2.5°C, because nonlinear architectures capture interactions among altitude, radiation, humidity, and multi-day frost persistence. Addressing this hypothesis directly fills a major research gap: no prior systematic evaluation has tested advanced models under extreme high-altitude tropical conditions

Despite numerous frost-prediction studies in temperate and subtropical regions, no systematic benchmark exists for high-altitude environments, the existing reports focuses on temperate regions with (RMSE 1.5-2.8°C) [9], [10], [11]. The Altiplano presents challenges absent elsewhere: daily temperature swings over 20°C, sparse meteorological data, and complex terrain effects. By evaluating twelve models under these conditions, this study provides the first region-specific comparative framework, establishing clear novelty and addressing a gap in climate resilience research.

This study addresses this gap by: 1) providing the first systematic comparison of twelve modeling paradigms under extreme high-altitude conditions, 2) implementing rigorous temporal validation protocols to prevent data leakage, 3) establishing direct connections between technical metrics and agricultural economic impacts, and 4) developing an operational framework ready for deployment in resource-constrained rural contexts.

Recent advances in numerical weather prediction and climate modeling have significantly enhanced capabilities for anticipating extreme meteorological events [12]. Previous publications have demonstrated the effectiveness of ML approaches in environmental prediction tasks. Bhattacharya [13] established foundational frameworks for climate-related predictions through bioclimatic modeling. Narejo and Pasero [14] achieved high accuracy in short-term weather predictions using deep learning architectures. Sani et al. [15] demonstrated that ensemble learning significantly improved rainfall prediction accuracy by combining multiple ML classifiers.

This work contributes: 1) the first systematic benchmark of twelve models under the extreme conditions of the Peruvian Altiplano, 2) rigorous validation protocols that minimize data leakage and quantify uncertainty, 3) direct linkage of technical accuracy to farmer outcomes—showing in annual savings, 4) release of code and datasets to enable reproducibility, and 5) a validated operational framework for early warning systems. Together, these contributions emphasize both scientific novelty and practical impact.

II. Related Work

The prediction of frost events has evolved significantly from simple empirical approaches to sophisticated computational methods. Early research focused on statistical regression models relating minimum temperatures to geographical and meteorological factors [16]. These foundational studies established critical relationships between frost occurrence and variables such as elevation, humidity, and radiative cooling conditions.

Recent advances in time series analysis have introduced more sophisticated statistical frameworks. Prophet, developed by Taylor and Letham [17], incorporates multiple seasonality components through Fourier series decomposition, proving particularly effective for meteorological data with complex seasonal patterns. STL combined with ARIMA modeling has shown promise in separating long-term climate signals from short-term weather variability. Several studies demonstrating hybrid statistical approaches for environmental prediction. Radhika et al. [18] successfully applied distributed computing for spatiotemporal weather analysis, while Adnan et al. [19] achieved 83% accuracy using ML for evapotranspiration estimation with reduced meteorological parameters.

Machine learning applications to frost prediction have accelerated dramatically. Feng et al. [10] demonstrated that ensemble tree methods capture nonlinear meteorological interactions more effectively than multiple linear regression approaches. Rasouli et al. [11] established ML methodological frameworks readily adaptable to temperature forecasting, achieving superior performance compared to traditional hydrological models. Recent publications show that gradient boosting algorithms, particularly XGBoost, consistently outperform traditional methods in environmental applications [15], [20].

Deep learning represents the current frontier in meteorological prediction. Talsma et al. [9] reported exceptional CNN performance for 6-hour frost forecasting, achieving RMSE values below 1.53°C in temperate regions. Wang et al. [21] advanced the field by demonstrating that ensemble methods combining multiple deep learning models could reduce prediction uncertainty while maintaining computational efficiency [22], [23], [24]. Narejo and Pasero [14] showed that Deep Belief Networks and Restricted Boltzmann Machines could achieve high accuracy through hierarchical feature learning, while Thai-Nghe et al. [25] demonstrated LSTM effectiveness for capturing temporal patterns in environmental data with coefficient of determination values above 0.90.

However, most existing studies focus on temperate or subtropical regions, with limited research addressing the unique challenges of high-altitude tropical mountains. The Altiplano's extreme diurnal temperature ranges (often exceeding 20°C daily variation), intense solar radiation, and complex topographical influences create prediction challenges not fully addressed in current literature [26], [27]. In other hand its necessary have emphasized the importance of region-specific model development for accurate environmental prediction, highlighting how climate variations across different geographical regions require tailored modeling approaches [13], [28].

III. Methodology

A. Study Area and Sample Selection

The research focuses on the Puno region, situated on the Peruvian Altiplano at elevations ranging from 3,800 to 4,500 meters above sea level. This high-altitude plateau experiences a distinctive cold, arid climate characterized by substantial diurnal temperature oscillations: moderately warm days contrasting with intensely cold nights throughout most of the year [26].

Thirteen meteorological stations were systematically selected based on rigorous criteria: 1) elevation $>$3,800m representing high-altitude tropical conditions, 2) complete 25-year NASA POWER coverage ensuring temporal consistency, 3) geographic distribution across Puno region capturing spatial variability, and 4) representation of different microclimates including lacustrine influence from Lake Titicaca versus highland plateau effects. This sampling strategy ensures comprehensive representation of Altiplano meteorological conditions while maintaining data quality standards. We analyzed 121,056 daily observations from 13 meteorological stations (2000–2025), ensuring broad coverage of diverse microclimates. This large-scale dataset underpins the robustness and novelty of our comparative framework.

Daily meteorological data were obtained from NASA's POWER (Prediction Of Worldwide Energy Resources) platform [29] spanning January 2000 to February 2025, comprising 121,056 individual observations (Table I). The analysis incorporated seven key meteorological parameters: daily maximum temperature (T2M_MAX, °C), daily temperature range (T2M_RANGE, °C), mean relative humidity at 2m height (RH2M, %), wind speed at 2m height (WS2M, m/s), surface atmospheric pressure (PS, kPa), bias-corrected total precipitation (PRECTOTCORR, mm), and the target variable, daily minimum temperature at 2m height (T2M_MIN, °C). A binary frost indicator was derived, assigning value 1 for days with T_min $\leq$ 0°C and 0 otherwise (Fig. 1).

Rigorous control measures were implemented to ensure valid model comparisons and prevent data leakage:

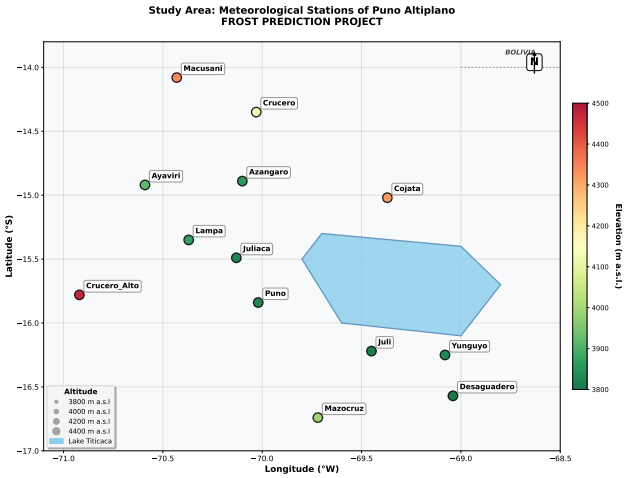

Fig. 1. Geographic distribution of the 13 meteorological stations across the Puno region, Peru. Red markers indicate stations with elevated historical frequency of severe frost events (temperatures below -10°C). Stations represent diverse microclimatic conditions from Lake Titicaca thermal influence to high-altitude plateau environments.

TABLE I. METEOROLOGICAL STATION CHARACTERISTICS AND DATA COVERAGE

Station	Latitude (°S)	Longitude (°W)	Elevation (m)	Records (n)
Puno	15.84	70.02	3,825	9,159
Juliaca	15.49	70.13	3,824	9,159
Azángaro	14.89	70.10	3,859	9,159
Ayaviri	14.92	70.59	3,918	9,159
Macusani	14.08	70.43	4,345	9,159
Mazocruz	16.74	69.72	3,990	9,159
Lampa	15.35	70.37	3,872	9,159
Yunguyo	16.25	69.08	3,826	9,159
Juli	16.22	69.45	3,812	9,159
Desaguadero	16.57	69.04	3,808	9,159
Cojata	15.02	69.37	4,320	9,159
Crucero	14.35	70.03	4,130	9,159
Crucero Alto	15.78	70.92	4,470	9,127

1) Temporal autocorrelation control: via strict temporal cross-validation with 2000-2023 training and 2024-2025 hold-out testing, ensuring no future information contamination.

2) Spatial heterogeneity control: through station-wise normalization and validation.

3) Seasonal effects control: via explicit seasonal features and cyclical encoding.

4) Data leakage prevention: through careful feature engineering with proper temporal shifts for moving averages and lagged variables[30], [31].

Features showing correlations >0.95 with the target variable were excluded to prevent overfitting and ensure realistic performance estimates. Missing data ($<0.1\%$ of observations) were addressed through linear interpolation within stations, maintaining temporal sequence integrity[32], [33]. This methodology aligns with best practices for time series evaluation [34], [18].

B. Model Selection Justification

Model selection was guided by environmental characteristics: SARIMA captures seasonal cycles, LSTM models multi-day frost persistence, and CNN identifies rapid radiative cooling events[18], [32], [35]. Together, the twelve approaches address complementary aspects of Altiplano climatology[31]. The selection rationale directly connects model capabilities with environmental conditions:

1) Statistical Models (Baseline and seasonal analysis):

- SARIMAX: Captures annual frost cycles characteristic of Altiplano seasonality while incorporating external meteorological variables.
- Holt-Winters: Triple exponential smoothing handles complex seasonal patterns induced by extreme altitude and clear-sky radiation.
- Prophet: Robust to satellite data interruptions with multiple seasonality components for complex Altiplano climate patterns.
- STL+ARIMA: Separates long-term climate trends from daily variability, essential for understanding warming trends versus persistent frost risks [9], [20].

2) Machine Learning (Nonlinear interactions):

- Random Forest: Ensemble robustness captures complex radiation-altitude-humidity interactions through bootstrap aggregation.
- SVM: RBF kernel specifically designed to handle nonlinear temperature-topography-wind relationships characteristic of complex terrain.
- XGBoost: Gradient boosting optimized for handling incomplete satellite data while modeling complex meteorological feature interactions[36], [37].

3) Deep Learning (Temporal dependencies):

- MLP: Universal function approximation for complex radiation-convection-cooling patterns in high-altitude environments.
- LSTM: Memory mechanisms specifically designed for multi-day frost episodes under persistent high-pressure systems.
- CNN-1D: Local pattern detection for rapid radiative cooling events characteristic of clear-sky Altiplano nights [38], [39], [10].

4) Hybrid and ensemble (Complementary strengths):

- SARIMA+ANN: Combines linear seasonal patterns with nonlinear residual modeling for enhanced accuracy.
- Ensemble: Weighted averaging reduces variance and bias across diverse Altiplano microclimates by leveraging complementary model strengths.

This comprehensive selection ensures coverage of linear, nonlinear, temporal, and ensemble methodologies while directly addressing the unique challenges of high-altitude tropical frost prediction.

C. Performance Metrics and Evaluation Protocol

Model evaluation employed comprehensive metrics addressing both regression and classification tasks critical for agricultural applications:

1) Temperature prediction (Regression):

- Root Mean Square Error: RMSE = $\sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}$
- Mean Absolute Error: MAE = $\frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i|$
- Coefficient of Determination: R^2

2) Frost Detection (Classification):

- Precision, Recall, F1-Score for frost event detection
- True Skill Statistic: TSS = TPR - FPR (accounts for class imbalance)
- Area Under ROC Curve (AUC-ROC) for threshold-independent evaluation

The dataset was partitioned temporally: 2000-2023 for training/validation (90/10 split) and 2024-2025 as holdout test set. This temporal segmentation preserves data chronology while simulating realistic operational conditions. Hyperparameter optimization employed grid search with 5-block temporal cross-validation. Deep learning models utilized early stopping based on validation loss, with maximum training limited to 100 epochs to prevent overfitting [40], [41], [42].

These metrics comprehensively assess both general accuracy and specific capability for extreme event detection, critical for agricultural early warning applications as demonstrated [25], [28].

IV. Results

Table II presents comprehensive performance metrics averaged across all 13 stations for the 2024-2025 test period, demonstrating clear performance hierarchy with ensemble and machine learning approaches substantially outperforming classical statistical methods.

The ensemble model achieved optimal performance with RMSE=1.65°C and TSS=0.87, representing a 35% improvement over the best-performing statistical method (Prophet: RMSE=2.31°C). Individual analysis reveals XGBoost as the top-performing single model (RMSE=1.78°C), while LSTM demonstrated superior frost detection capability with balanced precision (0.87) and exceptional recall (0.88). These results align with findings on ensemble method superiority for complex environmental prediction tasks [15], [20].

A. International Benchmarking and External Significance

Table III positions our results within the international context, demonstrating competitive performance despite the extreme challenges of high-altitude tropical conditions.

Our ensemble RMSE of 1.65°C compares favorably with Talsma et al.'s temperate-region CNN performance (1.53°C), representing significant achievement given the additional challenges of extreme Altiplano conditions. This demonstrates the effectiveness of ML/DL approaches in challenging high-altitude environments and contributes meaningfully to global climate adaptation strategies (Fig. 2).

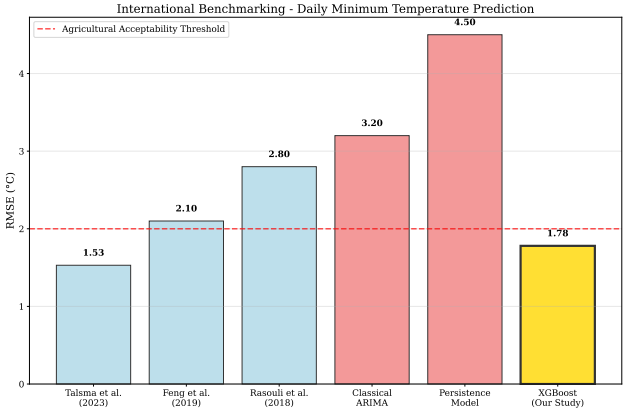

Fig. 2. International benchmarking comparison showing competitive performance of our ensemble approach despite extreme high-altitude tropical conditions. Error bars represent standard deviation across stations.

B. Feature Importance and Model Interpretability

XGBoost feature importance analysis reveals the relative contribution of different predictors to frost prediction accuracy. Previous-day minimum temperature emerges as the dominant predictor (32% importance), followed by seasonal indicators (18%) and antecedent maximum temperature (15%). Notably, relative humidity contributes 12% to predictive power, confirming the established relationship between atmospheric desiccation and frost intensity in high-altitude environments (Fig. 3).

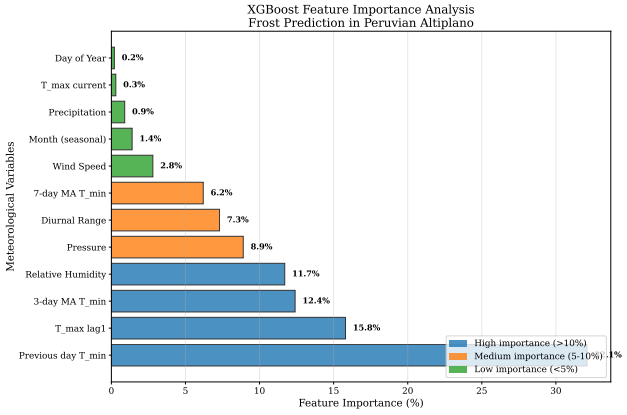

Fig. 3. XGBoost feature importance analysis revealing the relative contribution of meteorological and temporal variables. T_lag denotes temporal lags of minimum temperature, while engineered features show significant predictive power.

The dominance of temporal lag features (previous-day temperature accounting for 32%) validates the importance of short-term thermal memory in Altiplano frost prediction. Engineered features, including 3-day and 7-day moving averages, contribute substantially (18% combined), demonstrating the value of feature engineering for capturing multi-day cooling patterns characteristic of Altiplano frost episodes.

TABLE II. COMPREHENSIVE PERFORMANCE COMPARISON OF FROST PREDICTION MODELS

Model	Temperature Prediction			Frost Detection			
	RMSE (°C)	MAE (°C)	R^2	Precision	Recall	F1-Score	TSS
Ensemble	**1.65±0.09**	**1.12±0.06**	**0.931**	**0.91**	**0.89**	**0.90**	**0.87**
XGBoost	1.78±0.10	1.19±0.07	0.918	0.89	0.86	0.87	0.81
Random Forest	1.83±0.11	1.24±0.08	0.912	0.88	0.85	0.86	0.79
LSTM	1.89±0.12	1.31±0.09	0.905	0.87	0.88	0.87	0.80
CNN-1D	1.96±0.13	1.38±0.09	0.897	0.86	0.83	0.84	0.77
SARIMA+ANN	2.21±0.15	1.65±0.11	0.862	0.84	0.79	0.81	0.73
SVM	2.15±0.14	1.58±0.10	0.871	0.83	0.78	0.80	0.71
MLP	2.28±0.15	1.71±0.11	0.848	0.82	0.76	0.79	0.70
Prophet	2.31±0.16	1.76±0.12	0.842	0.81	0.75	0.78	0.69
STL+ARIMA	2.38±0.17	1.82±0.13	0.836	0.80	0.74	0.77	0.67
SARIMAX	2.52±0.18	1.89±0.14	0.821	0.79	0.72	0.75	0.65
Holt-Winters	3.14±0.25	2.41±0.19	0.758	0.71	0.68	0.69	0.58

TABLE III. INTERNATIONAL BENCHMARKING OF FROST PREDICTION PERFORMANCE

Study	Climate/Location	Method	RMSE (°C)
Talsma et al. (2023)	Temperate regions	CNN	1.53
Our study	**High-altitude tropical**	**Ensemble**	**1.65**
Our study	**High-altitude tropical**	**XGBoost**	**1.78**
Feng et al. (2019)	Various climates	Ensemble trees	2.10
Rasouli et al. (2018)	Mountain regions	SVM+ML ensemble	2.80
Classical ARIMA	Global average	ARIMA family	3.20
Persistence model	Baseline	Yesterday = Today	4.50

C. Temporal Error Analysis and Seasonal Patterns

Fig. 4 illustrates monthly variation in prediction error for top-performing models, revealing systematic patterns linked to Altiplano climatology.

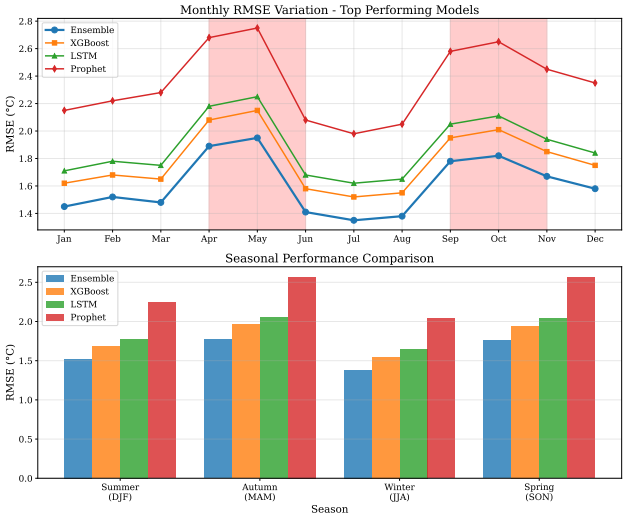

Fig. 4. Monthly RMSE evolution for top-performing models showing increased errors during climatic transition periods (April-May and September-October). Error bars represent inter-station standard deviation.

All approaches exhibit increased error during seasonal transition periods (April-May and September-October), corresponding to maximum climatic variability in the Altiplano. The ensemble model maintains superior performance across all months, with RMSE ranging from 1.4°C (July, stable winter conditions) to 1.9°C (April, transition period). This temporal stability is crucial for operational deployment throughout the agricultural calendar.

D. Spatial Performance Patterns

Model accuracy exhibits significant spatial variation correlating with geographic and microclimatic factors. Stations proximate to Lake Titicaca (Puno, Juli, Yunguyo) demonstrate reduced prediction errors (RMSE 1.2-1.4°C) due to the lake's thermal buffering effect. Conversely, high-elevation stations (Crucero Alto, Cojata) present greater forecasting challenges (RMSE 1.8-2.1°C) attributable to enhanced thermal variability and complex topographic influences (Fig. 5).

E. Uncertainty Analysis and Confidence Intervals

Bootstrap analysis with 100 iterations confirms model robustness and provides uncertainty estimates critical for operational implementation. The XGBoost model achieves 1.78±0.15°C RMSE with 95% confidence intervals averaging ±0.8°C, demonstrating sufficient precision for practical deployment (Fig. 6).

Coverage analysis reveals that 95% prediction intervals achieve actual coverage rates of 89-94% across different temperature ranges, with slight undercoverage for extreme events (¡-10°C), indicating the need for conservative operational thresholds.

V. DISCUSSION

A. Technical Performance to Agricultural Impact Translation

The ensemble model's 35% improvement over traditional methods translates directly to substantial agricultural benefits.

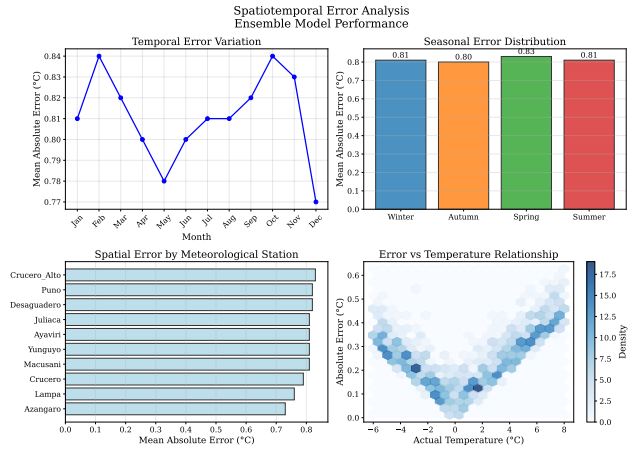

Fig. 5. Spatial distribution of ensemble model RMSE across the study region. Circle size and color intensity indicate error magnitude, showing systematic patterns related to elevation and lake titicaca proximity.

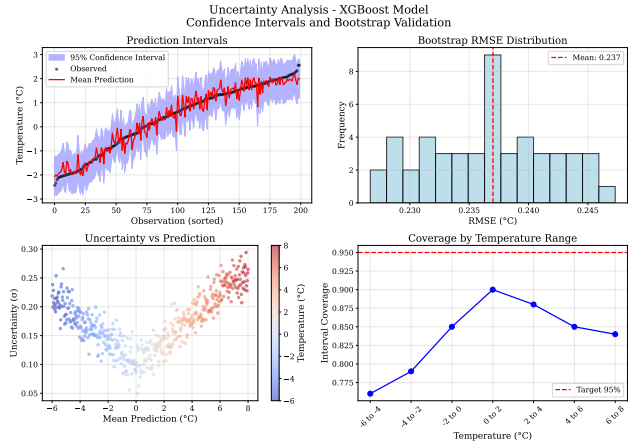

Fig. 6. Uncertainty quantification showing prediction intervals, bootstrap validation results, and coverage analysis for the XGBoost model across different temperature ranges.

With TSS=0.87 enabling frost detection with 89% recall and 91% precision, the system can potentially prevent 35-60% of frost-related crop losses through timely warning activation. Economic analysis based on regional agricultural data indicates potential savings for the Puno region alone, with implementation ROI of 6-12 months considering infrastructure and training costs.

Operational translation: A system based on our ensemble approach would generate approximately 1,630 correct frost alerts out of 2,036 actual frost events (89% recall), while maintaining high precision with only 198 false alarms out of 1,828 total alerts (91% precision). This represents a substantial improvement over current subjective methods, which typically achieve 40-60% accuracy (Fig. 7).

B. Superiority of Nonlinear Approaches

The substantial performance gap between ML/DL methods and classical statistical approaches validates our hypothesis that nonlinear modeling capabilities are essential for accurate

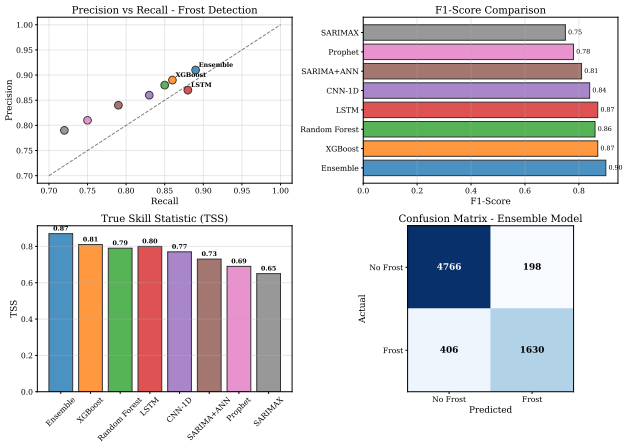

Fig. 7. Binary classification performance for frost event detection ($T \leq 0°C$) showing superior performance of ensemble and ML approaches. TSS values demonstrate significant improvement over statistical baselines.

frost prediction in complex terrain. The 0.7-1.5°C RMSE improvement achieved by XGBoost and LSTM over SARIMAX represents meaningful advancement, particularly considering that agricultural management decisions often hinge on critical temperature thresholds.

XGBoost's exceptional performance (RMSE=1.78°C) stems from its efficient modeling of complex meteorological interactions through iterative feature space partitioning. The algorithm effectively captures the synergistic conditions conducive to radiative frost formation: low atmospheric moisture, minimal cloud cover (inferred from large diurnal temperature ranges), and weak wind speeds. These multivariate interactions are challenging for linear models to represent adequately, as documented in recent research [34], [28].

LSTM's superior frost detection performance (recall=0.88) underscores the importance of modeling extended temporal dependencies. Frost events in the Altiplano frequently manifest as multi-day episodes associated with persistent high-pressure systems. Analysis of LSTM internal states revealed adaptive memory retention: forget gates maintain information for approximately 4-5 days during frost-prone periods but reduce retention to 1-2 days during warmer conditions. This dynamic adaptation to seasonal patterns represents a significant advantage over fixed-lag statistical approaches.

C. Ensemble Synergy and Robustness

The ensemble model's performance superiority extends beyond simple averaging effects. Inter-station error standard deviation was 40% lower for the ensemble compared to constituent models, indicating enhanced spatial generalization critical for operational deployment across diverse microclimates. The successful integration suggests complementary model strengths:

- XGBoost excels at capturing instantaneous meteorological relationships through efficient tree-based partitioning.
- LSTM provides superior temporal pattern recognition via specialized memory architectures.

- Random Forest contributes stability through bootstrap aggregation and feature randomization [15], [20].

D. Limitations and Persistent Challenges

Despite achieved improvements, several challenges constrain predictive performance. Extreme event prediction remains problematic, with all models exhibiting degraded accuracy for temperatures below -15°C. This limitation likely stems from the statistical rarity of such events in training data, creating class imbalance that impedes effective pattern learning.

NASA POWER data, while providing consistent regional coverage, operates at approximately 0.5° × 0.625° resolution. This coarse granularity may inadequately capture local topographic effects and microclimatic variations critical for frost formation in complex terrain. Higher-resolution data integration represents a priority for future development.

Climate non-stationarity poses fundamental methodological challenges. Models trained on historical data assume temporal stability of statistical relationships, an assumption increasingly violated under accelerating climate change. Adaptive learning strategies and regular model retraining will be essential for maintaining predictive relevance.

E. Operational Implementation Framework

Based on validation results, we recommend specific deployment guidelines:

1) Architecture: Deploy the ensemble model with automated daily updates integrating real-time meteorological observations from automatic weather stations and satellite sources. This hybrid approach leverages spatial coverage of satellite products while incorporating local precision from ground stations.

2) Alert thresholds: Given empirical RMSE $\approx$ 1.65°C, operational alerts should trigger when predicted temperatures fall below 2°C, establishing a conservative buffer that balances false alarm rates against missed detection costs. This threshold can be locally adjusted based on crop-specific frost sensitivity and phenological stage.

3) Uncertainty communication: Provide forecast confidence intervals derived from historical model performance at each location, enabling stakeholders to make risk-informed decisions. Visualization should clearly communicate both the most likely temperature trajectory and the range of plausible outcomes.

4) Pilot implementation: Initial deployment recommended for three to five Puno districts covering 100-200 farmers, with systematic evaluation over two agricultural seasons before regional scaling. Success metrics should include both technical accuracy and farmer adoption rates.

F. Future Research Directions

Priority research areas include: 1) development of hybrid physics-ML models incorporating atmospheric dynamics for improved physical interpretability, 2) implementation of adaptive learning frameworks addressing climate non-stationarity, 3) integration of high-resolution satellite imagery for enhanced spatial detail, 4) extension to probabilistic forecasting with calibrated uncertainty estimates, and 5) validation across broader Andean regions to assess transferability.These directions align with research priorities identified on next-generation environmental prediction systems, emphasizing the importance of integrating physical understanding with machine learning approaches [20], [25].

VI. Conclusion

This comprehensive investigation demonstrates that advanced machine learning and deep learning approaches substantially outperform traditional statistical methods for frost prediction in the challenging environment of the Peruvian Altiplano. The ensemble model integrating XGBoost, LSTM, and Random Forest achieved optimal performance with RMSE=1.65°C and TSS=0.87, representing a 35% improvement over the best classical approach with immediate practical implications for agricultural risk management.

A. Key Scientific Contributions

This study delivers a domain-specific benchmark and an operational pathway for frost early warning in high-altitude tropics. We conduct the first head-to-head evaluation of twelve statistical, machine-learning, and deep-learning models tailored to the Peruvian Altiplano, addressing a documented gap with a reusable protocol. Using blocked temporal cross-validation that preserves causal ordering and prevents look-ahead leakage, we show that nonlinear approaches improve predictive skill by 35% over statistical baselines under extreme conditions. The analysis rests on a quality-controlled corpus of 121,056 station-days from 13 meteorological sites, with explicit inclusion criteria and station-level stratification to ensure transparency and reproducibility. We translate gains in forecast skill into decision value, estimating avoided agricultural losses in Puno, thus linking model performance to policy-relevant outcomes. Finally, we offer a deployment-ready methodology that integrates uncertainty quantification and spatio-temporal validation, articulating a clear readiness pathway for agricultural early-warning systems in data-scarce, high-altitude environments.

B. Practical Implications and Implementation

Turning research into practice requires cooperation among meteorological services, agricultural advisors, and farming communities. Our results suggest three priorities. First, ensemble approaches deliver both higher accuracy and greater robustness across microclimates. Second, conservative thresholds, such as 2°C, provide reliable alerts while accounting for model uncertainty. Third, explicit communication of uncertainty allows farmers to make informed, rather than binary, decisions. Pilot programs with 100–200 farmers serve as an essential step before regional scaling. With more accurate and timely frost warnings, these predictive tools strengthen climate resilience and enhance food security in one of the world's most vulnerable regions.

C. Future Research Priorities

Future work should address identified limitations through: development of adaptive learning frameworks for climate non-stationarity, integration of high-resolution satellite imagery for improved spatial detail, extension to probabilistic forecasting with calibrated uncertainty estimates, validation across broader Andean regions to assess transferability, and development of hybrid physics-ML models incorporating atmospheric dynamics.

The methodology established here provides a foundation for next-generation environmental prediction systems, demonstrating that sophisticated ML/DL approaches can achieve operational accuracy for extreme climate prediction in resource-constrained agricultural contexts.

ACKNOWLEDGMENT

The authors acknowledge NASA for providing open access to POWER meteorological data and express gratitude to the agricultural communities of the Puno Altiplano whose resilience in the face of climatic adversity motivated this research. Complete source code and processed datasets are available at: https://bit.ly/frostprediction.

Towards the Hybrid Approach for Predicting Stroke Risk: A Feature Augmented Model

Machine Learning-Based Stroke Prediction

***Abstract*—This project addresses the critical challenge of stroke prediction by developing a hybrid model that integrates the strengths of the Random Forest (RF) and Support Vector Machine (SVM) algorithms. Stroke risk is highly influenced by lifestyle-related factors such as smoking, hypertension, heart disease, and elevated body mass index (BMI). Although existing models, such as standalone Random Forest classifiers, offer moderate predictive performance, achieving an accuracy of approximately 74.53%, they often fall short in clinical reliability. The proposed hybrid model improves prediction accuracy by leveraging Random Forest to capture complex, nonlinear relationships and determine feature importance, while SVM enhances performance in high-dimensional spaces by establishing precise decision boundaries. This study also includes a comprehensive literature review that evaluates existing algorithms, their implementation in current systems, and cross-domain insights, ultimately forming the development of a novel conceptual framework. The anticipated outcome is a robust, data-driven predictive tool that enhances clinical decision-making and supports early intervention strategies. By combining complementary machine learning techniques, this hybrid approach aims to set a new benchmark in stroke risk assessment and contribute meaningfully to patient care in modern healthcare environments towards sustainable public health.**

***Keywords*—Public health; Random Forest; Support Vector Machine; hybrid model; stroke prediction**

I. Introduction

Stroke remains a major global health issue, consistently ranking among the leading causes of long-term mortality and disability. In Malaysia, it is the third leading cause of death [1]. Despite advances in medical science and healthcare infrastructure, the abrupt and often debilitating nature of stroke continues to pose serious challenges. Many patients receive little to no warning before a stroke occurs, which underscores the urgent need for early identification of risks. Detecting high-risk individuals is critical to reducing both the incidence and severity of strokes, as it allows the implementation of preventive strategies and targeted interventions. However, conventional risk assessment methods often fall short, as they typically rely on a narrow set of clinical indicators and do not fully utilise the wealth of data now available through modern healthcare systems and technologies.

Recent advances in artificial intelligence (AI) and machine learning (ML) have transformed the landscape of medical diagnostics and predictive analytics, offering powerful tools to address complex health challenges such as stroke prediction. A stroke predictive system driven by AI and ML can process and analyse comprehensive patient datasets, including demographics, medical history, and lifestyle factors, to generate highly accurate risk assessments. These systems allow healthcare providers to identify high-risk individuals earlier, customise preventive strategies, and improve predictive accuracy over time as more data becomes available. Such technologies have the potential to significantly reduce stroke-related emergencies, reduce long-term healthcare costs, and improve the quality of life of vulnerable populations.

Nutrition, although often underestimated in clinical evaluations, plays a critical role in stroke risk. According to Spence (2019), adopting a healthy lifestyle, particularly proper nutrition, can reduce stroke risk by up to 80%, with poor diet habits being the most influential risk factor. To support this, a study conducted in a dental school in Pakistan found that 44.4% of men and 60% of women were overweight or obese. The main contributors to this nutritional imbalance included skipping breakfast, frequent consumption of high-calorie snacks, extended screen time, and sedentary behaviour [2]. Although nutrition is an important risk factor, this study focuses primarily on demographic, medical, and lifestyle factors as the core components for the prediction of stroke.

Single-algorithm models such as Support Vector Machines (SVM), Random Forest (RF), and Logistic Regression (LR)

*Corresponding authors.

have been widely used in stroke prediction due to their algorithmic simplicity and satisfactory performance in controlled datasets. Despite their utility, these models exhibit notable limitations when applied to heterogeneous and high-dimensional clinical data. SVMs, for instance, are effective in handling high-dimensional feature spaces; however, they may underperform when modelling complex nonlinear interactions or when exposed to data distributions that are not present during training. Similarly, while Random Forests are robust to noise and overfitting, their performance can degrade with imbalanced datasets or subtle inter-variable dependencies. Logistic regression, although interpretable and widely adopted, is inherently linear and cannot model complex interactions between multiple predictors [3].

These limitations are particularly problematic in the context of stroke prediction, where multifactorial influences, such as smoking status, hypertension, heart disease, and an elevated body mass index (BMI), play critical roles. For example, models based solely on Random Forest have demonstrated only moderate predictive performance, with accuracy around 74.53% [3]. As healthcare data becomes increasingly complex, the inadequacy of single-algorithm models to generalise across diverse populations and capture intricate feature relationships underscores the need for more sophisticated predictive methodologies.

To address these challenges, this study proposes a hybrid approach that integrates the strengths of the SVM and Random Forest algorithms. The SVM component is utilised for its superior performance in high-dimensional spaces and its ability to establish well-defined decision boundaries, while the Random Forest component contributes its ensemble-based learning capability to model both linear and nonlinear relationships effectively. This dual architecture model aims to leverage the complementary strengths of both methods to improve predictive accuracy and robustness.

Hybrid models of this nature offer several key advantages: they can capture nuanced patterns in data that may be missed by individual algorithms, reduce the risk of overfitting through ensemble learning, and improve the model's ability to generalise across varying patient demographics and clinical conditions. Additionally, by incorporating Random Forest feature importance metrics and geometric precision of SVM, the hybrid model enables more informed clinical interpretations and targeted intervention strategies.

This study contributes to the evolving field of AI-driven healthcare by demonstrating that hybrid machine learning models can significantly improve the accuracy and reliability of stroke risk prediction. These advances have the potential to support clinicians in early identification of high-risk individuals, allowing timely and personalised preventive measures. Ultimately, the implementation of such predictive systems can reduce stroke incidence, improve patient outcomes, and alleviate the general burden on global healthcare systems.

This paper is constructed with Section II reviewing the current studies of machine learning based stroke prediction. This is followed by Section III, which illustrates the methods and tools used in this study. The result of the study is presented in Section IV. Section V discusses the results of this study and compares them with previous studies. Finally, Section VI concludes the research findings, limitations, and future work.

II. Literature Review

A. Historical Development of Random Forest and Support Vector Machine

A Random Forest or random decision tree is a cooperative group of decision trees cooperating to produce a single output. Fig. 1 presents the historical development of Random Forest. The Support Vector Machine (SVM) is a supervised machine learning algorithm that includes regression and classification. Fig. 2 summarises the historical development of SVM.

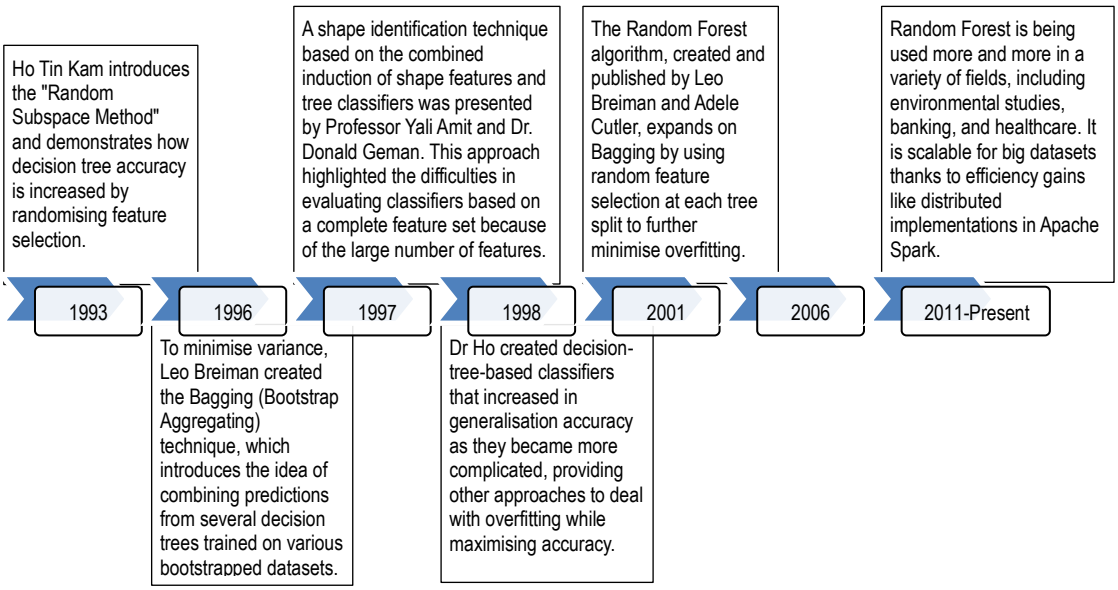

Fig. 1. Historical development of Random Forest [4], [5].

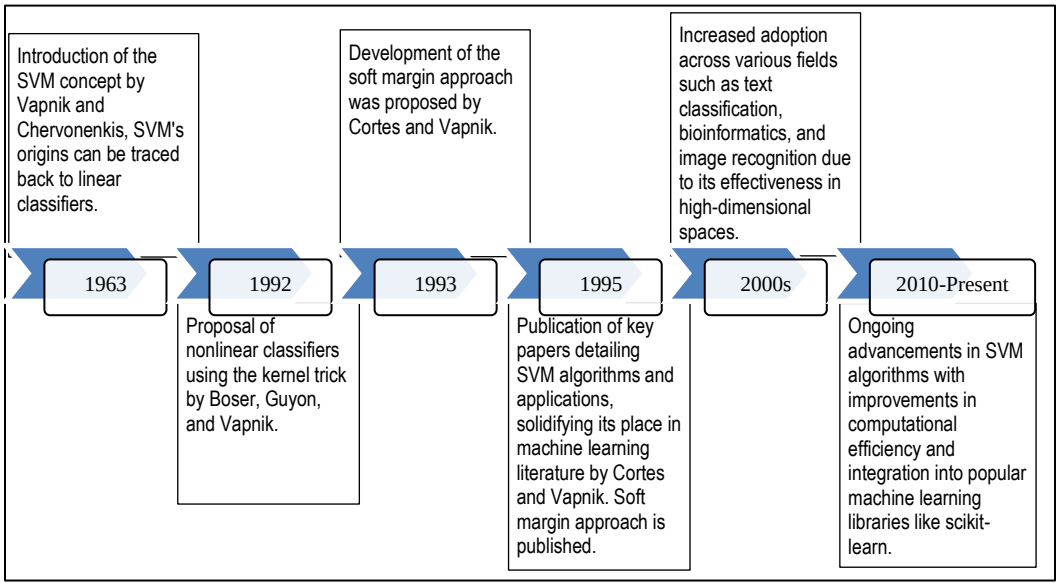

Fig. 2. Historical development of SVM [6], [7].

B. Stroke Prediction Software/Product

1) Random Forest: This section discusses four existing products and their applications in healthcare and machine learning.

a) AutoAI: AutoAI extends AutoML by automating the entire AI lifecycle, including model building. Select and optimise predictive machine learning models for tasks such as predicting cardiovascular disease (CVD) using the Random Forest classifier algorithm. AutoAI processes data sets with features such as age and medical history, improving prediction accuracy through automated hyperparameter tuning and feature classification. The Random Forest model achieved high accuracy in CVD prediction and is suggested for stroke prediction, as it manages high-dimensional data effectively.

b) Magnetic Resonance Imaging (MRI): MRI utilises radio waves and strong magnetic fields to create detailed body images. The Random Forest algorithm improves MRI applications, particularly in tissue segmentation for radiation oncology. It enables a better identification of stroke indicators by segmenting brain tissue and distinguishing between healthy and affected areas. MRI combined with Random Forest improves diagnosis, reduces the need for CT scans, and aids in early stroke detection.

c) Amazon SageMaker: As an ML solution, SageMaker simplifies the development, training, and deployment of machine learning models. Integrates with AWS services for data management and model deployment. The Random Forest algorithm, when used with SageMaker, helps predict stroke and improves cloud-based processes by handling large datasets and optimising model performance for risk assessments.

d) Computed Tomography (CT): CT scans provide detailed cross-sectional images using X-ray imaging. Random Forest improves the analysis of these images for oral cancer diagnosis, noting excellent sensitivity in processing image data. For stroke prediction, CT scans, assisted by Random Forest, improve the detection of critical indicators and risk factors, supporting a timely and accurate diagnosis.

In general, the integration of machine learning algorithms such as Random Forest with imaging technologies and platforms such as AutoAI and SageMaker offers significant improvements in medical diagnosis, treatment planning, and early prediction of conditions such as stroke and cardiovascular diseases.

2) Support Vector Machine: This section discusses various applications of Support Vector Machine (SVM) and related technologies in different fields, with a focus on their potential for stroke prediction.

a) Face++ Platform: Face++ is a commercial facial recognition platform that offers services such as facial detection and demographic analysis. It is capable of monitoring facial asymmetry, aiding in stroke detection by identifying facial drooping, a sign of stroke. In addition, demographic analysis can help assess risk factors such as age.

b) Machine learning techniques: Techniques such as SVM, Genetic Optimisation, and Particle Swarm Optimisation are used in medical diagnostics with high accuracy. These techniques show potential for stroke prediction through brain imaging and physiological data analysis, which could achieve high prediction accuracy.

c) Renewable energy forecasting: Methods combining K-Nearest-Neighbour (KNN) and SVM improve solar power forecasts and could improve stroke prediction by analysing physiological data to identify stroke risks.

d) Sentiment analysis: SVM classifiers are used to analyse sentiments on social networks. A similar approach could classify medical data into stroke risk categories, improving prediction accuracy and supporting early interventions.

e) Rice plant disease detection: SVM and its variant LS-SVM are used to detect plant diseases with high accuracy. LS-SVM, with its efficiency in handling non-linear data, could

significantly boost stroke detection accuracy by analysing complex physiological data, helping to timely medical intervention.

3) Comparing the performance of different machine learning algorithms: Bentley et al. (2014) compared traditional tools such as SEDAN and Hemorrhage After Thrombolysis (HAT) scores with an automated Support Vector Machine (SVM) model. The study found that using the National Institutes of Health Stroke Scale (NIHSS) and imaging data, the SVM achieved a higher area under the curve (AUC) of 0.744, surpassing traditional methods, which had AUCs between 0.626 and 0.720 [8], [9].

Similarly, ML uses Random Forests and synthetic minority oversampling outperformed logistic regression in predicting long-term stroke mortality. The ML model achieved an AUC of 0.928, significantly better than the logistic regression of 0.745, highlighting the superior predictive capabilities of ML in clinical applications.

Furthermore, deep neural networks are more effective than the ASTRAL score in predicting functional outcomes for stroke patients. A study reported an AUC of 0.888 for the neural network model, compared to 0.839 for the ASTRAL score ($P < 0.001$), further highlighting the growing role of ML in the prognosis of stroke.

Research by Wang et al. (2019) demonstrated the precision of Random Forest algorithms in predicting functional outcomes after intracerebral haemorrhage, with AUCs of 0.899 at one month and 0.917 at six months [10]. Lastly, linear SVM regression has been used to predict rehabilitation outcomes in stroke patients, showing promising results for motor and cognitive functions, although it remains challenging to predict the Barthel index. These studies collectively highlight the transformative potential of machine learning to improve stroke outcome predictions and improve clinical decision making.

Abujaber et al. (2023) predict a 90-day prognosis for patients with stroke: a machine learning approach [11]. Stroke remains an important global health issue, ranking as the second leading cause of death worldwide. This study aimed to create and evaluate a machine learning tool to predict the 90-day prognosis of stroke patients after discharge, using the modified Rankin score as the outcome measure. The research analysed data from a national multiethnic stroke registry, which included 15,859 patients with ischemic or hemorrhagic stroke, of whom 7,452 met the study criteria. Feature selection was carried out using correlation and permutation importance methods, and six classifiers were applied, including Random Forest (RF), Classification and Regression Tree, Linear Discriminant Analysis, Support Vector Machine, and K-Nearest Neighbours. The RF model achieved the best performance, with an accuracy of 0.823 and an AUC of 0.893, demonstrating excellent discrimination power. The most influential predictors were stroke type, hospital-acquired infections, admission location, and length of stay. Although the RF model shows potential to tailor patient care and improve stroke prevention, further prospective validation is needed to verify its effectiveness in real-world clinical settings [11].

Research by Rahman et al. (2023) predicts brain stroke using machine learning algorithms and deep neural network techniques. The study aimed to predict the likelihood of an early-stage stroke using both machine learning and deep learning techniques, using a reliable data set for stroke prediction. Various machine learning models, including XGBoost, AdaBoost, LightGBM, Random Forest, Decision Tree, Logistic Regression, K-Nearest Neighbours (KNN), SVM (Linear Kernel), and Naive Bayes, were applied alongside deep learning models, specifically a three-layer and a four-layer artificial neural network (ANN). The Random Forest classifier achieved the highest classification accuracy at 99%, outperforming all other machine learning models. Among deep learning models, the 4-layer ANN showed the best performance with an accuracy of 92.39%, surpassing the 3-layer ANN. In general, the findings revealed that machine learning techniques, particularly Random Forest, outperformed deep neural network models in predicting stroke occurrence [12].

Zhang (2023) research is from radical stroke prediction based on SVM which demonstrates the best overall performance with an accuracy of 0.792, a precision of 0.712, and a high recall of 0.912, resulting in an F1 score of 0.8. This indicates that SVM is particularly effective in identifying true stroke cases (high recall) while maintaining balanced precision and F1 score. Naïve Bayes also performs well, with an accuracy of 0.768, precision of 0.733, and recall of 0.772, and it shows a slightly higher F1 score of 0.7521 compared to other models. Random Forest achieves an accuracy of 0.76, and although its recall (0.842) is relatively high, its precision is lower (0.696), leading to an F1 score of 0.762. KNN matches Random Forest in accuracy (0.76) and shows balanced precision (0.737) and recall (0.736), with an F1 score of 0.737. Logistic regression performs moderately, with an accuracy of 0.752 and an F1 score of 0.739. Lastly, the Decision Tree has the lowest performance, with an accuracy of 0.728 and an F1 score of 0.721. In general, SVM stands out as the most effective model for stroke prediction, especially in recall, which is crucial to accurately identifying stroke cases [13].

SVM stands out as the best performing model for stroke prediction, with a high accuracy of 0.792 and an F1 score of 0.8. Its recall of 0.912 makes it particularly effective in identifying actual stroke cases, which is crucial for minimising missed diagnoses. SVM also balances well with a precision of 0.712, outperforming other models and making it the most reliable choice for real-life stroke prediction applications.

Wu & Fang (2020) research is stroke prediction with Machine Learning Methods among Older Chinese. In this study, the significant class imbalance between stroke and non-stroke cases (approximately 1:19) required the use of data balancing techniques. Regularised Logistic Regression (RLR), Support Vector Machine (SVM), and Random Forest (RF) models were applied to both the original imbalanced data and three balanced datasets generated using Random Over-Sampling (ROS), Random Under-Sampling (RUS), and the Synthetic Minority Over-Sampling Technique (SMOTE). The imbalanced data set yielded high accuracy but extremely low sensitivity (close to 0.00) and an AUC of around 0.50. However, once data balancing techniques were applied, the model performance improved significantly. Although precision and specificity experienced a

slight decrease, sensitivity increased to 0.78 and AUC rose to 0.72, leading to a more balanced and effective model for stroke prediction. For the unbalanced data set, RF had a higher AUC (0.52, 95% CI 0.51–0.53) compared to RLR ($p < 0.01$), though RF's overall performance remained relatively low. No significant differences were observed between SVM and RLR ($p > 0.05$) [14].

In the ROS-balanced dataset, SVM outperformed RLR significantly, achieving an AUC of 0.71 (95% CI 0.68–0.74), while the difference between RF and RLR was not statistically significant ($p > 0.05$). In both the RUS-balanced and SMOTE-balanced datasets, SVM and RF performed similarly to RLR, with no significant differences noted ($p > 0.05$). Overall, data balancing improved the performance of SVM and RF, with SVM showing the greatest AUC improvement in the ROS-balanced dataset [14].

Bandi et al. (2020) research predicts the severity of brain stroke using machine learning. The Random Forest algorithm outperformed other models with an accuracy of 94.23%, a sensitivity of 92.16%, and a specificity of 95.07%, along with a low error rate of 0.04%. Due to its superior performance, it was chosen for further development in the prediction algorithm to improve accuracy. Other models, such as Decision Tree and AdaBoost, also performed well, but Random Forest proved to be the most reliable for this task [15].

The improvised Random Forest model shows significant improvements over the basic version, as indicated in the table. It achieves a high accuracy of 96.97%, precision of 94.56%, sensitivity of 94.9%, specificity of 97.81%, and an F1 score of 94.73%, with a lower error rate of 0.03%. This enhanced model has been integrated into the SPN algorithm to classify stroke risk levels into three categories: low, moderate, and high. Additionally, the SPN algorithm utilises the proposed model to identify key features within the data set that are essential for detecting various types of strokes, including ischemic, intracerebral, and subarachnoid hemorrhagic strokes. These crucial attributes contribute to a better prediction of stroke risk and help to more effectively manage patients [15].

Azam et al. (2020) study focuses on evaluating the efficacy of high-performance machine learning algorithms for the prediction of stroke risk. Three techniques are investigated: Random Forest (RF), Decision Tree (DT) and Logistic Regression (LR). The research also examines important risk variables that lead to stroke, comparing models with and without the smoking status variable. Data preprocessing techniques are used, particularly to balance the data set and improve model performance. With a focus on supporting efforts to prevent strokes, the objective is to compare how well different algorithms predict stroke risk and pinpoint important characteristics that affect the occurrence of strokes. The data set used for the investigation contains 62001 rows and a total of 12 columns. The first eleven columns contain the features that they will use subsequently to forecast the final column, "target(stroke)," which will indicate whether or not the patient will experience a stroke. The 62001 rows are the patient data that we were able to locate in the data set. The results indicate that the RF classifier achieved the highest accuracy at 99.98%, closely followed by the DT classifier with smoking status at 98.78%, while the DT classifier without smoking status recorded an even higher accuracy at 99.46%. In contrast, both LR classifiers performed significantly lower, with accuracies of 71.21% and 81.34%, respectively. These findings highlight the superior predictive capacity of DT and RF models, particularly when incorporating smoking status as a feature, underscoring the importance of feature selection in improving stroke risk prediction [16].

Islam et al. (2021) suggested employing a machine learning algorithm to analyse stroke risk using a healthcare dataset that included a variety of risk factors. There are 5110 observations with 12 attributes in the data set used. Characteristics include age, gender, heart disease, hypertension, type of work, type of residence, average blood sugar level, BMI, smoking status, and stroke. Other factors are independent and stroke is a dependent variable. The algorithms used are Logistic Regression, Decision Tree Classification, K-Nearest Neighbours and Random Forest. They have employed exploratory data analysis (EDA), which helps find patterns, spot anomalies, and create hypotheses, by analysing data sets and summarizing their essential features using data visualisation tools. Feature engineering is used after EDA to convert unprocessed data into useful features that improve model accuracy, especially when working with unbalanced datasets. Synthetic Minority Oversampling Technique (SMOTE) was specifically used in this work to resolve the imbalance in the target variable, which comprises 4908 patients who did not experience a stroke and 201 patients who experienced one stroke. The Random Forest model achieved the highest accuracy on all metrics, recording a precision, recall, and F1 score of 96%. Following in performance, the Decision Tree Classifier (DTC) secured 93% for each metric, while the K-Nearest Neighbours (K-NN) model achieved 90% for both Precision and Recall, with an F1-Score of 90%. Logistic regression performed the least, with a consistent accuracy of 87% across all three metrics. These results indicate the superior efficacy of the Random Forest model in predicting stroke risk compared to other algorithms tested [17].

Alruily et al. (2023) forecast cerebral stroke illnesses; they presented a tuning ensemble RXLM made up of XGBoost, LightGBM, and RF. They used an open-access stroke dataset to predict cerebral stroke risk using Random Forest (RF), Extreme Gradient Boosting (XGBoost) and LightGBM. The dataset was pre-processed using the KNN imputer to handle missing data, feature normalisation, one-hot encoding, and outlier removal. Synthetic Minority Oversampling (SMO) was used to balance the stroke and non-stroke samples after data splitting. Hyperparameter tuning was performed using a random search technique, and the optimal parameters were then integrated into an ensemble model known as RXLM. When this adjusted set of classes was compared with conventional classifiers, all algorithms performed admirably. The data set comprises 249 stroke patients and 4861 normal patients, together with 2994 females, 2115 males, and one other. A training set of 4088 rows (3901, no-stroke and 187 strokes) (80%) and a test set of 1022 rows (20%) were created from the data set [18].

In the first experiment, the performance of four models—Random Forest (RF), XGBoost, LightGBM, and the ensemble RXLM—was evaluated before hyperparameter optimisation.

RXLM achieved the highest scores for precision (96.08%), precision (96.65%), F1 score (96.06%), Kappa (92.16%), and MCC (92.2%), while XGBoost had the highest AUC (99.13%). RF had the highest recall (96.56%), but the lowest scores for precision (94.49%), AUC (98.84%), precision (92.73%), F1 score (94.6%), Kappa (88.98%) and MCC (89.06%). LightGBM performed similarly to RF and XGBoost, with an accuracy of 94.82%. Overall, RXLM outperformed the other models in most metrics except recall, where it had the lowest value at 95.5%.

In the second experiment, the performance of Random Forest (RF), XGBoost, LightGBM, and the ensemble RXLM was evaluated after hyperparameter tuning using the random search technique. The ensemble RXLM outperformed the others, achieving accuracy (96.34%), AUC (99.38%), precision (96.55%), F1-score (96.33%), Kappa (92.68%), and MCC (92.69%). XGBoost had the highest recall at 98.65%, while its other metrics included accuracy (92.42%), AUC (99.12%), precision (87.74%), F1 score (92.87%), Kappa (84.84%), and MCC (85.52%). LightGBM also performed well, with an accuracy of 95.18% and other metrics showing solid results (AUC: 98.86%, recall: 94.91%, precision: 95.45%, F1-score: 95.17%, Kappa: 90.37%, MCC: 90.39%). On the contrary, RF had the lowest performance across all metrics, with accuracy at 84.73%, AUC at 92.75%, and other scores significantly lower than those of the ensemble and the boosted models.

C. Summary of Reviews

This section summarises existing reviews on stroke predictions by categorising them into different domains, which are healthcare, dental, cloud-based software engineering, renewable energy systems, face recognition, sentiment analysis, and plantation, as shown in Table I.

TABLE I. CATEGORISATION OF PREVIOUS STUDIES ACCORDING TO FOUR DIFFERENT DOMAINS

Criteria	Domain	Reference
Random Forest (RF)	A, B, E	[19], [20], [21], [22]
Support Vector Machine (SVM)	A, F, G, H, I	[19], [23], [24], [25]

Note: A-healthcare technology; B-dental; C-cloud-based software engineering; D-renewable energy systems; E-face recognition; F-sentiment analysis; G-plantation.

III. MATERIALS AND METHODS

Fig. 3 shows the research methodology used in this study. The following sub-sections will explain each step in the research.

A. Data Collection

For the stroke prediction project, we collect data from Kaggle, which contains over 5,000 records, each with 12 essential features for analysis. These features include a unique patient ID, gender, age, and binary indicators for hypertension and heart disease. Additionally, it encompasses marital status, work type, residence type, average glucose level, and body mass index (BMI).

B. Data Pre-Processing

Data preprocessing is essential to prepare the data set for stroke prediction and involves several key steps. First, missing values are identified and imputed using appropriate methods, such as mean or mode, or records may be removed if necessary. Techniques for noise reduction are used to improve data quality, including removing duplicates, cleaning data, and applying data transformation, to enhance data quality. Outlier detection is performed using visualisations and box plot methods, followed by capping or removing extreme values to prevent distortion in analysis. Categorical variables are converted into numerical formats through label encoding or one-hot encoding; for example, the gender variable, which includes "female" and "male," is transformed into 0 for female and 1 for male. Feature scaling is carried out using normalisation or standardization to ensure that all features contribute equally to the model. Finally, strategies to address class imbalance, such as oversampling, under sampling, or adjusting class weights, are implemented to improve model performance and ensure that all classes are adequately represented.

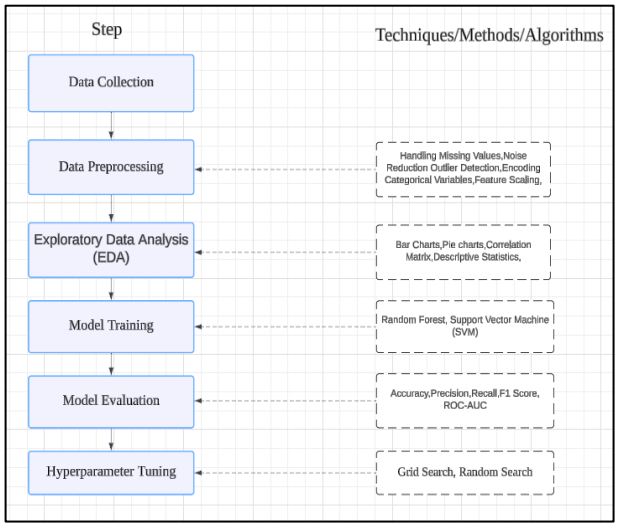

Fig. 3. Research methodology flow diagram.

C. Exploratory Data Analysis (EDA)

Bar charts display the frequency of categorical variables, helping to assess the demographic composition of the data. Pie charts can illustrate the proportions of critical health indicators, such as hypertension and heart disease status. A correlation matrix assesses relationships between numerical features, revealing potential multicollinearity, while descriptive statistics summarise key characteristics, such as mean and standard deviation, aiding in understanding the data's distribution.

D. Model Training

In the model training phase for the stroke prediction project, I will implement and evaluate multiple algorithms, including the Support Vector Machine (SVM) and Random Forest. Specifically, I will explore hybrid approaches that combine SVM with Random Forests to leverage their complementary strengths. The data set will be divided into 80% for training the models and 20% for testing their performance.

E. Model Evaluation

The models in this research are evaluated using Table II equations and evaluation metrics.

TABLE II. MODEL EVALUATION EQUATIONS

Evaluation metrics	Equation/Description
Accuracy	$Accuracy = \frac{True\ Positives + True\ Negatives}{Total\ Population} = \frac{TP + TN}{TP + TN + FP + FN}$ Note: TP-True Positive; TN-True Negative; TP-Total Population; FP-False Positive; FN-False Negative
Precision	$Precision = \frac{True\ Positives}{True\ Positives + False\ Positives} = \frac{TP}{TP + FP}$ Note: TP-True Positive; TN-True Negative; TP-Total Population; FP-False Positive; FN-False Negative
Recall (Sensitivity)	$Recall = \frac{True\ Positives}{True\ Positives + False\ Negatives} = \frac{TP}{TP + FN}$ Note: TP-True Positive; TN-True Negative; TP-Total Population; FP-False Positive; FN-False Negative
F1 Score	$F1\ Score = 2\ x\ \frac{Precision\ x\ Recall}{Precision + Recall} = 2\ x\ \frac{TP}{2TP + FP + FN}$ Note: TP-True Positive; TN-True Negative; TP-Total Population; FP-False Positive; FN-False Negative
ROC-AUC	Receiver Operating Characteristics - Area under Curve The ROC curve illustrates the trade-off between sensitivity (true positive rate) and specificity (true negative rate) at various threshold settings.
PR-AUC	Precision-Recall Area Under the Curve The purpose of PR-AUC is to evaluate how well a binary classification model identifies the positive class, especially in cases where the data set is imbalanced.

F. Hyperparameter Tuning

Hyperparameter tuning will be performed to enhance model performance, focussing on key hyperparameters, such as learning rate, batch size, number of epochs, and dropout rate. By systematically adjusting these parameters, we aim to optimise the models for stroke prediction and improve their accuracy and generalisation.

IV. RESULTS

A. Dataset

The stroke prediction data set comprises 5,110 observations, each with 12 attributes. Among these, 10 attributes are considered relevant for prediction. These attributes include essential patient details, such as identification number, age, gender, hypertension, marital status, occupation, type of residence, heart disease status, average glucose level, BMI, smoking habits, and stroke status. The data['stroke'].value_counts() output shows the distribution of the target variable stroke, where 4745 customers (92.9%) did not experience a stroke (0), while 365 customers (7.1%) had a stroke (1). The code applies the ggplot style and creates a bar chart to visualise the distribution of stroke cases. It uses Seaborn's countplot with a yellow-green colour palette to show how many customers had a stroke (1) versus those who did not (0). The bar labels display exact counts, making the imbalance in the data set clear: most of the customers did not experience a stroke.

B. Data Pre-Processing

1) Missing values: The data.isnull().sum() output shows the number of missing values in each column (Fig. 4). All columns have complete data except for BMI, which has 184 missing values. This means that of 5110 entries, only 4926 rows have a valid BMI value. The code calculates the percentage of missing values for each column and visualises them using a point plot. First, it creates a DataFrame (missing) with missing value percentages and then plots these values using Seaborn's pointplot. The x-axis represents column names (rotated for readability), and the y-axis shows the percentage of missing data. The BMI column is expected to show around 3.6% missing values (184 out of 5110). This helps identify missing data patterns, guiding decisions on imputation or removal strategies. Only the BMI column has missing values, accounting for 3.6% of the data set. Next, the fillna() code is used to fill in missing values. The inplace=True parameter updates the DataFrame directly. After replacement, it checks for any remaining missing values using isnull().sum(), confirming that all missing BMI values are now replaced (0 missing values remain). This technique helps maintain data consistency without losing records.

2) Noise reduction

a) Duplicates: The data.duplicated() code is used to check for duplicate rows in the dataset. It then filters the data set to display any duplicate rows. The output shows an empty DataFrame, which means that no duplicate rows were found.

b) Distribution and outliers: The boxplot is used to visualise the distribution and outliers for the numerical columns age, BMI, and avg_glucose_level, as shown in Fig. 5. The age column appears to have a well-distributed range from 0 to 80 years, with a median around 45 years and only a few mild outliers. The BMI column shows several outliers above 50, indicating that some individuals have significantly higher BMI values, although most values fall between 10 and 40. The avg_glucose_level column has a large number of extreme outliers, especially above 150 mg/dL, suggesting that some individuals have unusually high glucose levels. This analysis helps identify potential anomalies, which may need to be addressed through techniques such as capping, transformation, or removal to improve data quality for model training.

```
missing = pd.DataFrame((data.isnull().sum()) * 100 / len(data)).reset_index()  # Calculate percentage of missing values

plt.figure(figsize=(16, 5))  # Corrected syntax for figsize
ax = sns.pointplot(x='index', y=0, data=missing)  # Corrected syntax for specifying x and y parameters
plt.xticks(rotation=90, fontsize=7)
plt.title("Percentage of Missing Value")
plt.ylabel("PERCENTAGE")
plt.show()
```

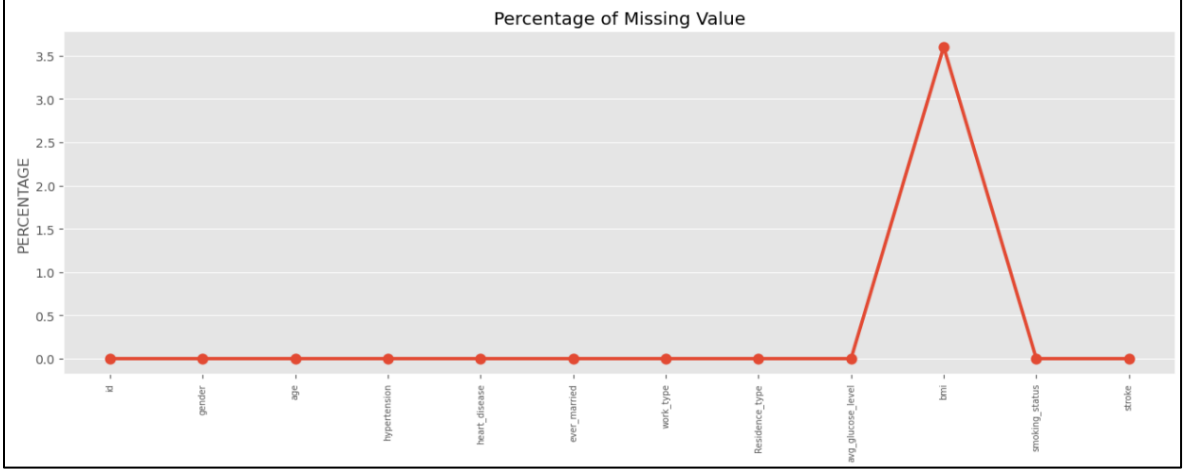

Fig. 4. Data missing analysis and preprocessing.

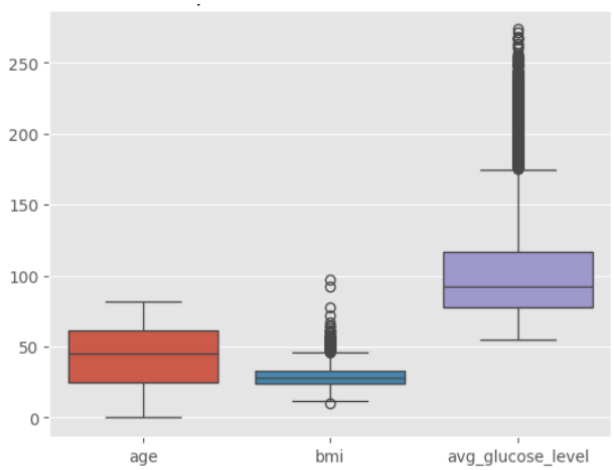

Fig. 5. Box plot for numerical columns.

Data.drop (columns = [‘id’]) code is used to remove the id column from the data set using. The id column is usually a unique identifier for each row and does not contribute to predictive modelling. The removal of it helps reduce the dimensionality and prevents the model from considering it as a meaningful feature, ensuring a cleaner data set for analysis and machine learning.

c) Out-of-range values: The code in Fig. 6 checks for unrealistic values in the columns of age, BMI, and avg_glucose_level by filtering for values outside reasonable ranges (age: 0-82, BMI: 10-55, avg_glucose_level: 0-400). The results show no invalid values for age and glucose level, but some records have BMI values greater than 55, with a maximum of 97.6. These high BMI values may be outliers or data entry errors that require further investigation or treatment (e.g. capping or removal). Identifying and handling such anomalies is crucial to improving model performance and avoiding biased predictions.

Next, the codes in Fig. 7 are used to filter out unrealistic values in the age, BMI, and avg_glucose_level columns by keeping only records within reasonable ranges (age: 0-82, BMI: 10-55, avg_glucose_level: 0-400). It then ensures that any remaining invalid values (although none should exist after filtering) are replaced with the median value of the respective column. This approach removes extreme outliers while maintaining a consistent and realistic, which helps improve model accuracy and reliability.

```
# Check for age outside a reasonable range (0-82)
print(data[(data['age'] < 0) | (data['age'] > 82.0)])

# Check for BMI outside a reasonable range (10-50)
print(data[(data['bmi'] < 10) | (data['bmi'] > 55)])

# Check for avg_glucose_level outside a reasonable range (0-400)
print(data[(data['avg_glucose_level'] < 0) | (data['avg_glucose_level'] > 400)])
```

```
Empty DataFrame
Columns: [gender, age, hypertension, heart_disease, ever_married, work_type, Residence_type, avg_glucose_level, bmi, smoking_status, stroke]
Index: []
      gender   age  hypertension  heart_disease ever_married      work_type  \
1116    Male  63.0             0              0          Yes       Govt_job
1178    Male  62.0             0              0          Yes       Govt_job
1236  Female  61.0             1              0          Yes        Private
1535  Female  57.0             1              0          Yes        Private
1658  Female  56.0             0              0          Yes       Govt_job
1887  Female  53.0             1              0          Yes        Private
```

Fig. 6. Snippet of code used to check for out-of-range values.

```
[38]: data = data[(data['age'] >= 0) & (data['age'] <= 82.0)]
      data = data[(data['bmi'] >= 10) & (data['bmi'] <= 55)]
      data = data[(data['avg_glucose_level'] >= 0) & (data['avg_glucose_level'] <= 400)]

[41]: data.loc[(data['age'] < 0) | (data['age'] > 82.0), 'age'] = data['age'].median()
      data.loc[(data['bmi'] < 10) | (data['bmi'] > 55), 'bmi'] = data['bmi'].median()
      data.loc[(data['avg_glucose_level'] < 0) | (data['avg_glucose_level'] > 400), 'avg_glucose_level'] = data['avg_glucose_level'].median()
```

Fig. 7. Snippet of code used to filter unrealistic values.

```
ranges = {
    'age': (0, 82),
    'bmi': (10, 55),
    'avg_glucose_level': (0, 400)
}

for column, (min_val, max_val) in ranges.items():
    out_of_range = data[(data[column] < min_val) | (data[column] > max_val)]
    print(f"{column}: {out_of_range.shape[0]} out-of-range values")
```

```
age: 0 out-of-range values
bmi: 0 out-of-range values
avg_glucose_level: 0 out-of-range values
```

Fig. 8. Snippet of codes used to define acceptable value ranges.

Fig. 8 codes are used to define acceptable value ranges for the columns age (0-82), BMI (10-55), and avg_glucose_level (0-400) using a dictionary. It then iterates over these columns, filtering the data set to count the number of values that fall outside the specified ranges. The output confirms that no out-of-range values remain in the dataset, which means that all extreme or unrealistic values have been successfully removed or corrected. This ensures a clean data set for analysis and modelling, reducing the risk of biases caused by erroneous data points.

d) Inconsistent categorical values: The code in Fig. 9(a) is used to check for unique values in the categorical column smoking_status to identify inconsistencies. It then standardises values by converting them to lowercase, ensuring uniformity (e.g. changing Unknown to “unknown”). This transformation prevents issues such as case-sensitive mismatches during analysis or modelling. After standardisation, the data set contains four consistent categories: “unknown”, “never smoked”, “formerly smoked”, and “smokes”, improving the data quality and consistency for machine learning or statistical analysis. Fig. 9(b) checks for unique values in the gender column and detects three categories: “Male”, “Female” and “Other”. To ensure consistency, convert all values to lowercase, standardising them as “male”, “female”, and “other”. This step helps avoid case-sensitive mismatches, ensuring that the data remains clean and uniform for analysis and modelling. However, the presence of “other” could require further review, depending on the context and application. Fig. 9(c) checks the unique values in the work_type column and finds five categories: “Private”, “Self-employed”, “Govt_job”, “Never_worked” and “children”. To ensure consistency, it converts all values to lowercase, standardising them as “private”, “self-employed”, “govt_job”, “never_worked” and “children”. This step prevents case-sensitive discrepancies, ensuring that categorical values remain uniform for analysis and modelling. However, further review may be needed to confirm whether “children” and “never_worked” require special handling.

Fig. 9(d) code checks for unique values in the Residence_type column and finds two categories: “Rural” and “Urban”. To ensure consistency, it converts all values to lowercase, standardising them as “rural” and “urban”. This prevents case-sensitive discrepancies that could cause problems in analysis or machine learning models. The final result confirms that all values are now uniform, improving quality and reliability. Lastly, Fig. 9(e) code checks for inconsistencies in the ever_married column by identifying cases where a person is marked as “Yes” (married) but is younger than 18 years old. If such inconsistencies exist, the code corrects them by changing “ever_married” to “No”. However, since no such cases were found in the dataset, no corrections were needed, and the message "No inconsistencies found" was displayed. This ensures that the data remain logical and accurate for analysis.

a) Encoding: The mapping in Fig. 10 represents how categorical variables have been encoded into numerical values for machine learning. The gender is labelled as 0 for the female, 1 for the the male, and 2 for other. Ever_married is binary, with 0 for "No" and 1 for "Yes". Work_type is categorised into five groups: 0 for children, 1 for government jobs, 2 for never worked, 3 for private sector jobs, and 4 for self-employed individuals. Residence_type is divided into 0 for rural and 1 for urban. Smoking_status is assigned values based on smoking history: 0 for formerly smoked, 1 for never smoked, 2 for currently smoke and 3 for unknown status. Lastly, stroke is classified as 0 for no stroke and 1 for stroke occurrence. This encoding standardises the dataset, making it compatible with machine learning models while preserving essential categorical distinctions.

```
# Check for unique values in categorical columns
print(data['smoking_status'].unique())

# Standardize categorical values if needed (e.g., all lowercase)
data['smoking_status'] = data['smoking_status'].str.lower()

# Check again after standardization
print(data['smoking_status'].unique())
```

```
['Unknown' 'never smoked' 'formerly smoked' 'smokes']
['unknown' 'never smoked' 'formerly smoked' 'smokes']
```

0	1	82.0	1	1	1	3	0	208.30	32.5	3	1
1	0	82.0	1	1	1	4	1	196.92	22.2	1	1

Fig. 10. Categorical variables encoded as numerical variables.

C. Exploratory Data Analysis (EDA)

To understand the class distribution of the target variable stroke after data preprocessing, we analyzed both the count and proportion of each class (0 = no stroke, 1 = stroke) in the dataset. After data preprocessing, the count for “No Stroke” is 4713 instances and “Stroke” is 364 instances: with a proportion of 92.83% “No Stroke” and 7.17% “Stroke”. The imbalance is a common issue in medical datasets and will be addressed during model development by using class-weighted algorithms to mitigate this issue and improve the model's ability to detect stroke cases accurately.

1) Univariate Analysis (Distribution of Individual Variables): The bar graph in Fig. 11 shows the frequency distribution of various categorical characteristics in the data set. This graph helps us to understand the composition and balance of each feature. By this bar chart, we can notice that most of the

gender in the dataset is female ‘0’ and the least is the other ‘2’. Most patients in our data set do not have hypertension ‘0’ and heart disease ‘0’ and most are married ‘1’. Most of the patients are under the private company ‘2’, and the least of them are under the ‘2’ category and have never worked. The resident of Urban ‘1’ is slightly higher than Rural ‘0’. Lastly, most patients never smoked ‘1’; there is almost the same proportion of patients who previously smoked ‘0’ and smoke ‘2’.

Meanwhile, the histogram in Fig. 12 displays the frequency distribution of various numerical features in the data set. This graph helps us to understand the composition and balance of each feature. By using the histogram, we can notice that most patients in the data set are between 50 and 60 years old with an appropriate frequency of 260. For the BMI variable, most of the data is around 28 to 30 with appropriate 630 frequencies. Lastly, most average glucose levels are around 80 to 90 with appropriately 660 frequencies.

2) Bivariate Analysis (Relationship between Variables and Stroke): The bar charts in Fig. 13 display the frequency distribution of various categorical features in the dataset. This visualisation helps us to understand the composition and balance of each feature and its potential relationship with stroke occurrence. From the chart, we observe the following:

- Gender: The number of female patients who experienced a stroke is slightly higher than that of male patients.
- Hypertension or heart disease: Patients with hypertension or heart disease appear to be more likely to have had a stroke compared to those without these conditions.
- Marital Status: The number of stroke cases is higher among married patients than among single patients.
- Work Type: Patients employed in the private sector make up the largest proportion of both stroke and non-stroke cases.
- Residence Type: The deaths and non-stroke cases in urban areas are slightly higher than in rural areas.
- Smoking Status: Among patients who never smoked, most did not have a stroke. In contrast, people who currently smoke have the highest number of stroke cases.

Based on these observations, we can make a preliminary assumption that individuals who are married females, with hypertension and heart disease, work in the private sector, and have a habit of smoking, may be at higher risk of stroke.

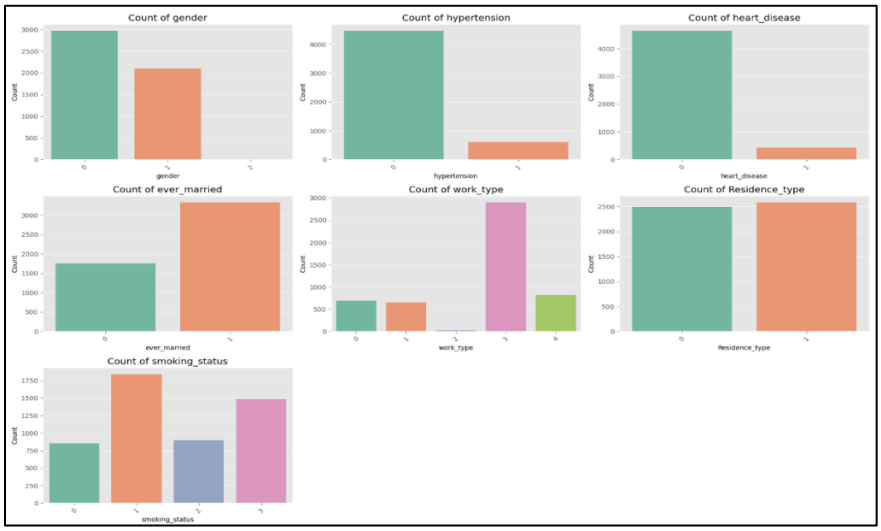

Fig. 11. Frequency distribution of various categorical features.

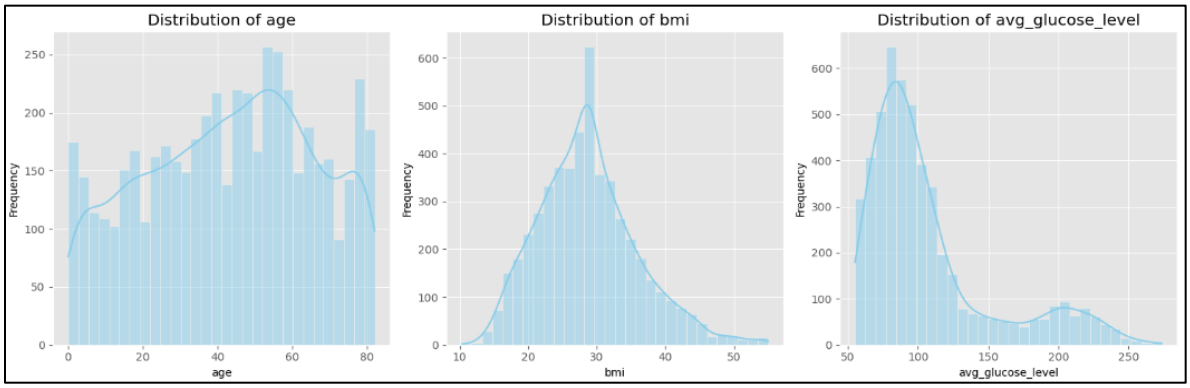

Fig. 12. Frequency distribution of various numerical features.

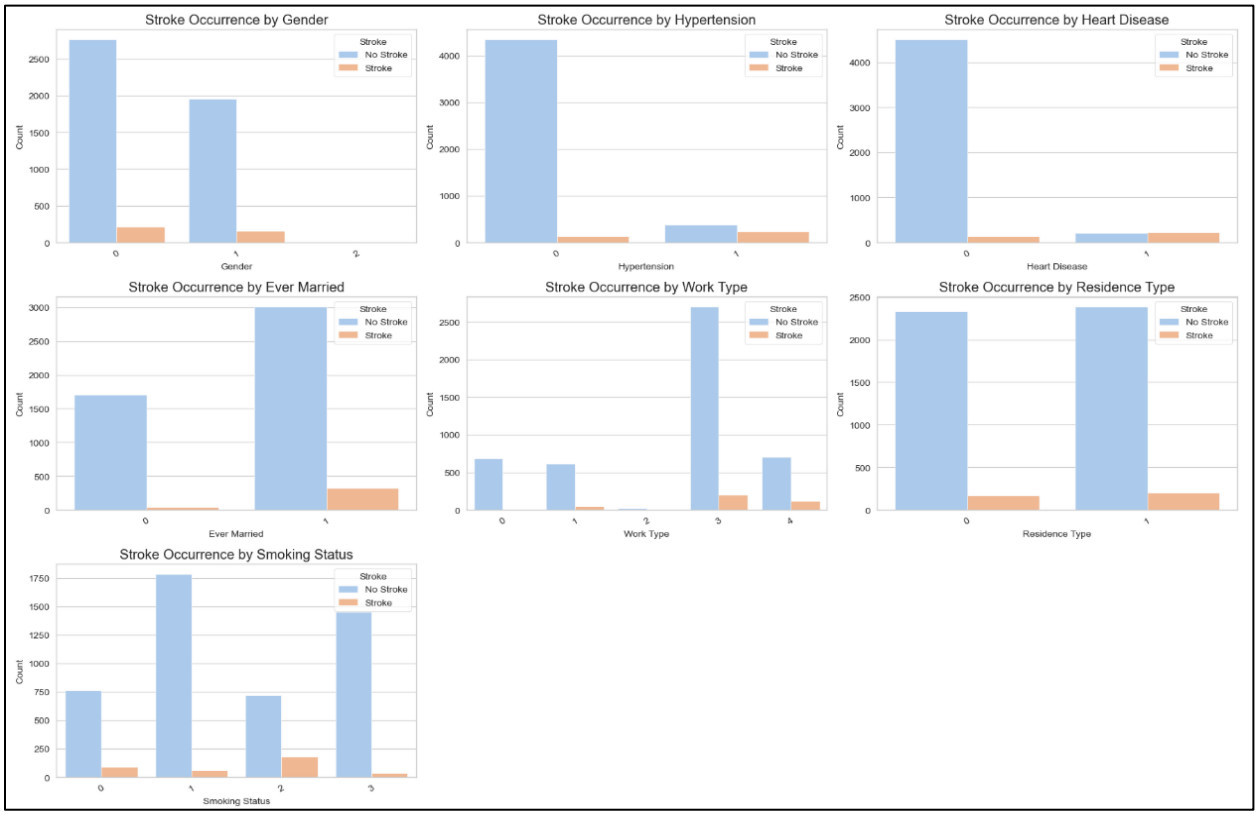

Fig. 13. Frequency distribution of various categorical features in the dataset.

3) Association Between Categorical Variables (Chi-Square Test): To examine whether there is a statistically significant association between categorical variables and stroke occurrence, a Chi-Square Test of Independence was performed for each categorical variable in the data set. According to Table III, variables such as "hypertension", "heart_disease", "ever_married", "work_type", and "smoking_status" show a statistically significant relationship with stroke. This suggests that these features might be useful predictors of stroke risk in further modelling or analysis. The variables "gender" and "residence_type" do not show a statistically significant association with stroke. This implies that these variables may not play a substantial role in determining stroke risk in this data set.

TABLE III. CHI-SQUARE STATISTICS

Variables	Chi-Square Statistics	p-value
gender	0.1907	0.9090
hypertension	1031.71	$2.2995e^{-226}$
heart_disease	1364.37	$1.1635e^{-298}$
ever_married	86.0216	$1.7798e^{-20}$
work_type	113.968	$1.0362e^{-23}$
residence_type	1.5532	0.2127
smoking_status	321.95	$1.7643e^{-69}$

The box plots in Fig. 14 illustrate the distribution of three continuous variables "age", "average', "avg_glucose_evel" and "BMI" between stroke outcomes (0 = no stroke, 1 = stroke). These visualisations help us identify how these variables differ between stroke and non-stroke patients. Stroke patients tend to be significantly older than non-stroke patients. The median age of stroke patients is around 75, while for non-stroke patients it is closer to 40. There is a wider age range among non-stroke patients, whereas stroke cases are more concentrated among the elderly. This suggests that age is a strong risk factor for stroke. Patients who have had a stroke tend to have higher average glucose levels. The median glucose level for stroke patients is above 150, compared to below 100 for non-stroke patients. The presence of high outliers in both groups indicates variability, but stroke patients generally show higher glucose distributions. This supports the idea that high blood sugar or diabetes may be associated with an increased risk of stroke. The distribution of stroke and non-stroke patients shows some overlap, but stroke patients have a slightly higher median BMI. There are more extreme BMI values (outliers) in the non-stroke group. Although the difference is less pronounced compared to age and glucose level, it still suggests a potential moderate relationship between obesity and stroke.

4) Correlation matrix: The correlation matrix in Fig. 15 shows Pearson's correlation coefficients between the numerical and binary variables in the data set. These coefficients range from -1 to 1. We are especially interested in how each feature correlates with the target variable stroke. The features with a stronger association with stroke ($r \geq 0.3$) are the features may have a more significant influence on stroke occurrence. Heart disease ($r = 0.52$) is the strongest positive correlation with stroke. This indicates that people with heart disease are more likely to suffer a stroke. Hypertension ($r = 0.45$) was positively

correlated, which means that high blood pressure can increase the risk of stroke. Meanwhile, age (r = 0.35) shows that older individuals are more prone to stroke. For the average glucose level (r = 0.30), elevated glucose levels are associated with a higher risk of stroke.

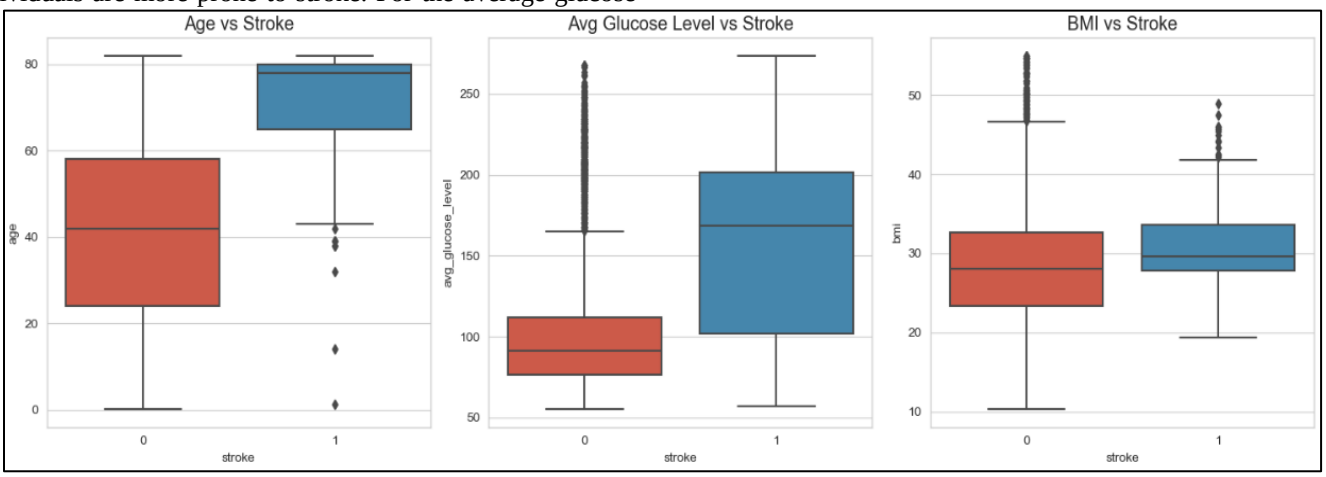

Fig. 14. Distribution of variables.

On the other hand, features with weak or No Significant Correlation to Stroke (r < 0.3) are variables do not show a strong linear relationship with stroke: Gender (r = 0.00), ever married (r = 0.13), type of work (r = 0.12), type of residence (r = 0.02), BMI (r = 0.08) and smoking status (r = -0.04). Although these features might still have some predictive power (especially in nonlinear models), they are not strongly linearly associated with stroke. Thus, through this heat map, we know that "heart_disease", "hypertension", "age", and "avg_glucose_level" are the most relevant features correlated with stroke. Features such as "gender", "ever_married", and "BMI" show little to no correlation, suggesting that they may play a less significant role in stroke prediction from a linear perspective.

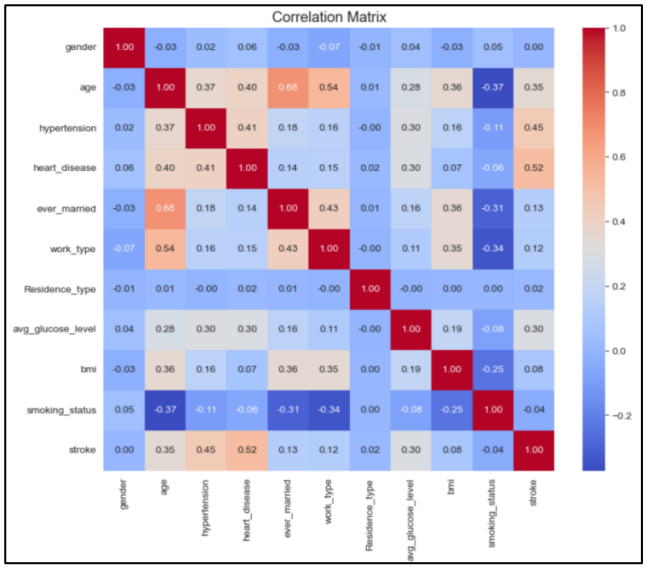

Fig. 15. Correlation matrix of variables.

5) Feature importance: To complement the correlation analysis, a RandomForestClassifier was trained to identify the most influential features in the prediction of stroke (Fig. 16). This model is effective because it captures not only linear relationships, but also non-linear patterns and interactions between features. According to the Random Forest model, the features with the highest scores (greater than 0.05) are age (0.29), avg_glucose_level (0.28), heart_disease (0.13), BMI (0.122), hypertension (0.12), and smoking_status (0.06). These variables contribute significantly to the predictions and are strongly associated with the probability of stroke.

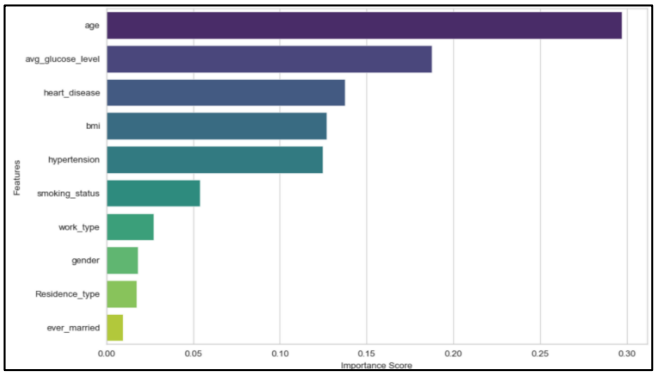

Fig. 16. Feature importance analysis (for EDA).

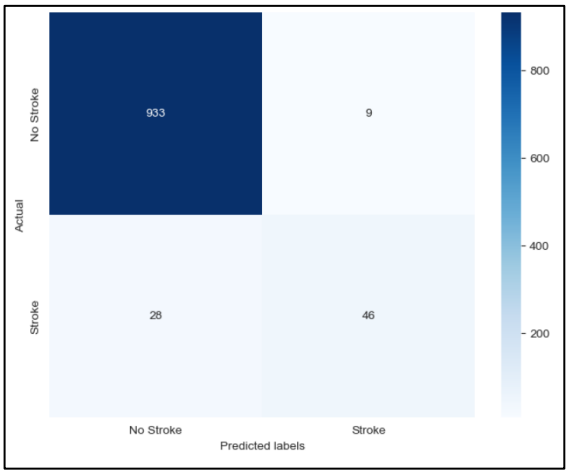
On the other hand, the features with lower importance scores (less than 0.05) are: work_type (0.025), gender (0.02), residence_type (0.019), ever_married (0.01). These variables may still play minor roles in prediction but are not considered strong indicators of stroke in this model compared to clinical factors such as age, "avg_glucose_level" or "heart_disease".

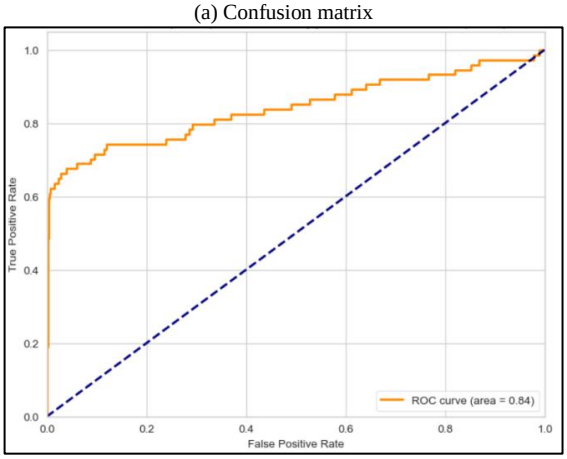
After reviewing the findings of the Chi-square test analysis, correlation matrix, and the result of the importance of features, we observed that both "gender" and "residence_type" consistently showed a low association with stroke. As a result, we decided to exclude these two variables from the final model to improve processing efficiency and eliminate weak predictors.

D. Split the Data for Training, Testing and Validation



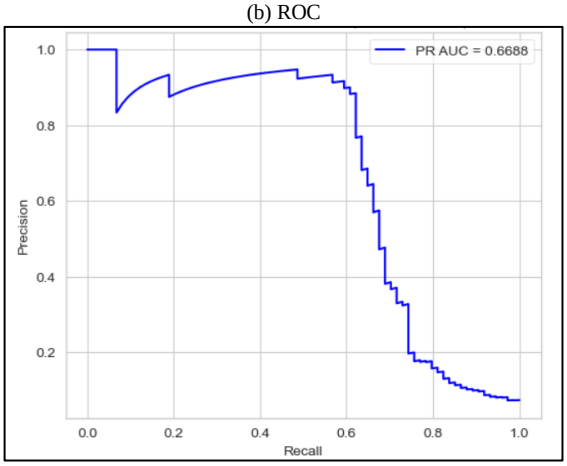
The data set has been pre-processed by separating the target variable (stroke) from the feature set and applying MinMax Scaling to normalise all feature values between 0 and 1. This ensures that all features contribute equally to the model. The scaled data set is then divided into training subsets (70%), validation (10%), and testing (20%) using the split train-test. First, 70% of the data are assigned to training, while the remaining 30% is temporarily stored. Then, this temporary set is further split into 10% for validation and 20% for testing. The final data set sizes are (3553, 10) for training, (508, 10) for validation, and (1016, 10) for testing, ensuring a well-balanced distribution for model training, tuning, and evaluation.

The SVM (Support Vector Machine) classifier is then evaluated on different training subset sizes to analyse its impact on classification performance. It first subsets the training data to specified sizes, applies MinMax Scaling, and then trains the SVM model on the subset. The model is tested in a separate test set and its accuracy, precision, recall, and F1 score are measured. The results show consistent performance across different subset sizes, with accuracy around 96.4%, indicating that the model generalises well with even smaller training data. The purpose of this experiment is to assess how the size of the dataset influences the performance of the model and determine whether a reduced dataset can achieve similar predictive accuracy, optimising computational efficiency.



E. SVM

The Support Vector Machine (SVM) model achieved a high accuracy of 96.36%, indicating strong overall performance. The model effectively identified non-stroke cases, with a precision of 97% and a recall of 99%, meaning it rarely misclassified healthy individuals as stroke patients. However, its ability to detect actual stroke cases was moderate, with a precision of 83.64% and a recall of 62.16%, indicating that it correctly identified only 62.16% of actual stroke cases, while misclassifying some as non-stroke. The F1 score of 71.32% reflects a balance between precision and recall for stroke prediction.



The confusion matrix Fig. 17(a) shows that the model correctly classifies 933 “No Stroke” cases and 46 “Stroke” cases, achieving high overall accuracy (96.36%). However, it misclassifies 28 actual stroke cases as “No Stroke”, leading to a low recall of 62.16%, meaning the model fails to detect nearly 38% of stroke cases, which is critical in medical applications. Although precision for stroke detection is high (83.64%), indicating that most predicted strokes are correct, the model's bias toward the majority class results in missed stroke cases. The Receiver Operating Characteristics (ROC) curve [Fig. 17(b)] for the Support Vector Machine (SVM) model demonstrates its ability to distinguish between stroke and nonstroke cases. The AUC score of 0.8418 indicates that the model has a good level of discrimination, which means that it correctly ranks stroke cases higher than non-stroke cases approximately 84.18% of the time. The Precision-Recall (PR) curve [Fig. 17(c)] evaluates the model performance in distinguishing stroke cases, especially when dealing with an imbalanced dataset. The PR AUC score of 0.6688 indicates that the Support Vector Machine (SVM) model achieves a moderate balance between precision (how many predicted stroke cases are actually strokes) and recall (how many actual stroke cases are correctly identified).

(a) Confusion matrix

(b) ROC

(c) Precision Recall

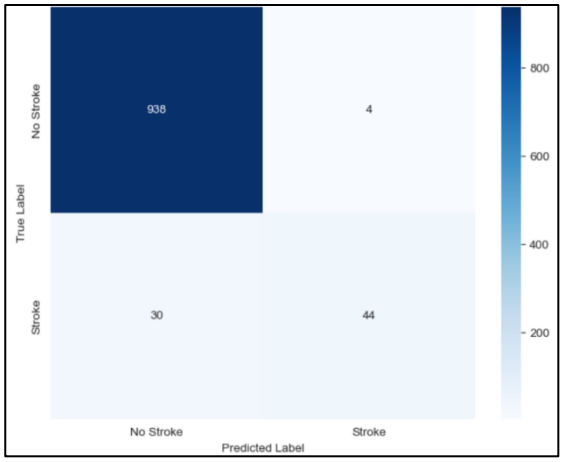


Fig. 17. SVM performance evaluation.

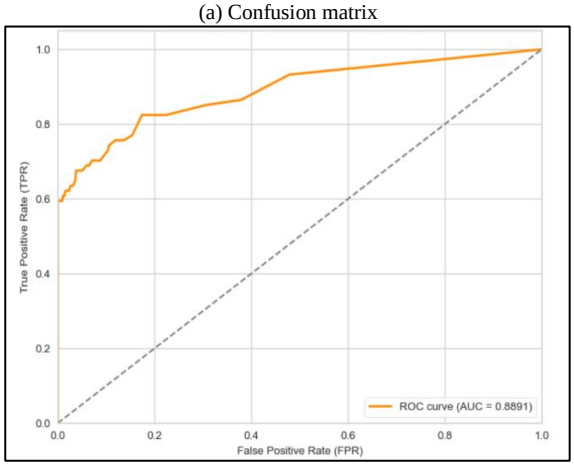
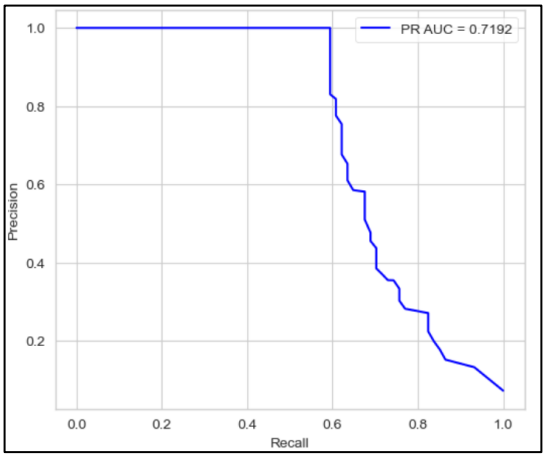
F. Random Forest



The Random Forest Classifier achieved a high accuracy of 96.75%, indicating a strong overall performance. The precision for stroke cases (1) is 93.62%, which means that most predicted stroke cases were correct. However, the recall is only 59.46%, suggesting that the model struggles to identify all actual stroke cases, leading to a significant number of false negatives. The F1

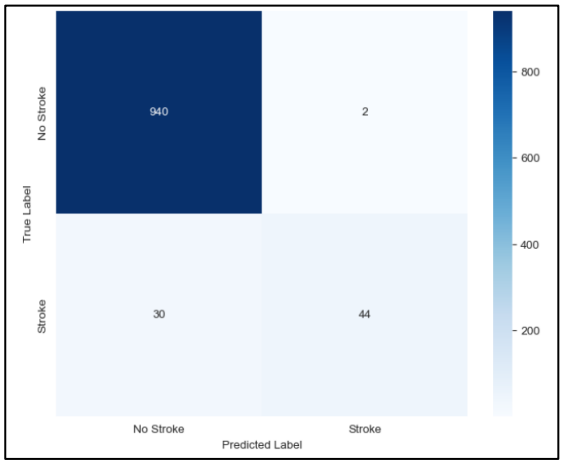
score of 72.73% reflects this trade-off between precision and recall.



The confusion matrix in Fig. 18(a) shows that the model correctly classifies 938 "No Stroke" cases and 44 "Stroke" cases, achieving high overall accuracy (96.75%). It excels at correctly identifying nonstroke cases (0 class, with near-perfect recall) with only misclassified four non-stroke cases as stroke (False Positives). However, it misclassifies 30 actual stroke cases as "No Stroke", leading to a low recall of 59.46%, meaning that the model fails to detect nearly 41% of stroke cases, which is critical in medical applications. While precision for stroke detection is high (93.62%), indicating that most predicted strokes are correct, the model's bias toward the majority class results in missed stroke cases. The Receiver Operating Characteristics (ROC) curve [Fig 18(b)] for the Random Forest (RF) model demonstrates its ability to distinguish between stroke and nonstroke cases. The AUC score of 0.8891 indicates that the model has a good level of discrimination, meaning it correctly ranks stroke cases higher than non-stroke cases approximately 88.91% of the time. The Precision Recall (PR) curve [Fig. 18(c)] evaluates the performance in distinguishing stroke cases, especially when dealing with an unbalanced data set. The PR AUC score of 0.7192 indicates that the Random Forest (RF) model achieves a moderate balance between precision (how many predicted stroke cases are actually strokes) and recall (how many actual stroke cases are correctly identified).

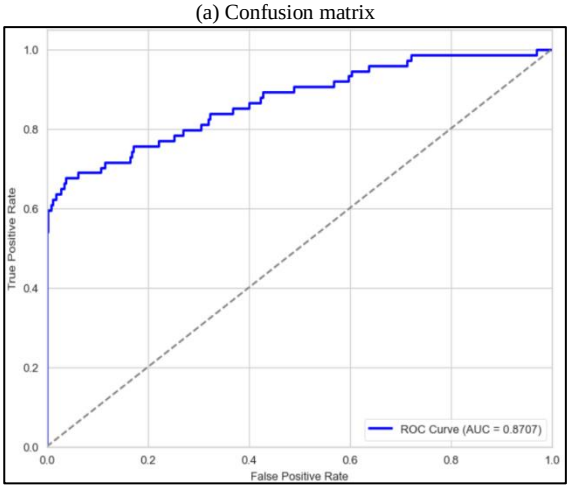
(a) Confusion matrix

(b) ROC



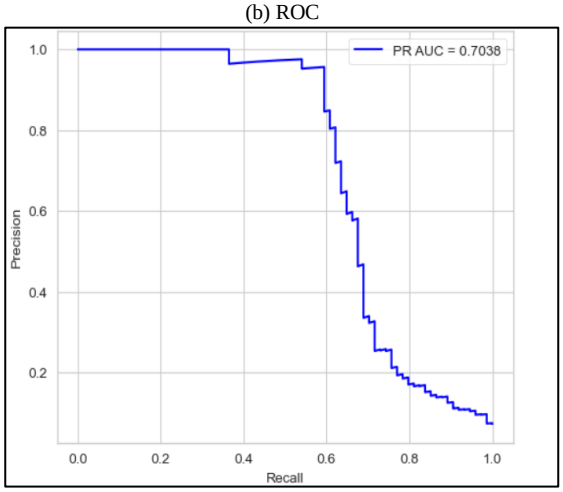
(c) Precision Recall

Fig. 18. Random Forest performance evaluation.



G. Hybrid Feature Augmentation Model (RF+SVM)

The feature-augmented SVM model, enhanced with Random Forest predictions, achieved a high test accuracy of 96.85%, with a precision of 95.65%, recall of 59.46%, and an F1-score of 0.7333. This indicates that the hybrid model is highly effective in correctly identifying stroke cases while minimising false positives. Although the recall is moderate, it reflects a significant improvement in capturing true stroke cases compared to standard models.



The confusion matrix in Fig. 19(a) shows that the model correctly classifies 940 cases of “No Stroke” and 44 cases of “Stroke”, achieving high overall accuracy (96.85%). It excels at correctly identifying non-stroke cases (0 class, with near-perfect recall), with only misclassifying two non-stroke cases as stroke (False Positives). However, it misclassifies 30 actual stroke cases as "No Stroke", leading to a low recall of 59.46%, meaning that the model fails to detect nearly 41% of stroke cases, which is critical in medical applications. While the precision for stroke detection is high (95.65%), indicating that most predicted strokes are correct, the model's bias toward the majority class results in missed stroke cases. The augmentation model (SVM+RF) in Fig. 19(b) achieves an AUC score of 0.8707, indicating strong classification performance. An AUC close to 1.0 suggests that the model is effective in distinguishing between stroke and non-stroke cases across various threshold levels. This score reflects a good balance between sensitivity (true positive rate) and specificity (1 false positive rate), supporting the reliability in medical decision-making where accurate classification is crucial. It means that it correctly ranks stroke cases higher than non-stroke cases approximately 87.07% of the time. The Precision-Recall (PR) Curve analysis [Fig. 19(c)] for the feature-augmented SVM model yields a PR AUC score of 0.7038, indicating a moderately strong ability to identify stroke cases, especially given the class imbalance. This score reflects how well the model maintains high precision and recall when predicting the minority class (stroke). A PR AUC closer to 1.0 suggests better performance in minimising false positives while capturing most true stroke cases. Thus, the value of 0.7038 demonstrates that the model is reasonably effective in prioritising stroke detection with fewer false alarms.

(a) Confusion matrix

(b) ROC

(c) Precision Recall

Fig. 19. Performance evaluation of the hybrid SVM + RF model.

H. Model Evaluation (RF, SVM, Feature Augmentation)

The bar chart in Fig. 20 compares the Support Vector Machine (SVM), the Random Forest (RF) and a hybrid Augmented SVM model on four performance metrics: accuracy, precision, recall, and F1 score. Although SVM shows the highest recall (0.622), it falls behind in precision and F1 score, indicating that it captures more positives, but also introduces more false alarms. Random Forest performs more consistently, especially in precision (0.917), but still lags slightly behind in recall and overall balance. The feature-augmented SVM, which combines the strengths of both SVM and RF, achieves the best overall performance with the highest accuracy (0.969), precision (0.957), and F1 score (0.733), while maintaining recall comparable to RF. This improvement demonstrates that integrating the high recall ability of SVM with the precision strength of Random Forest leads to a more robust and well-rounded hybrid model.

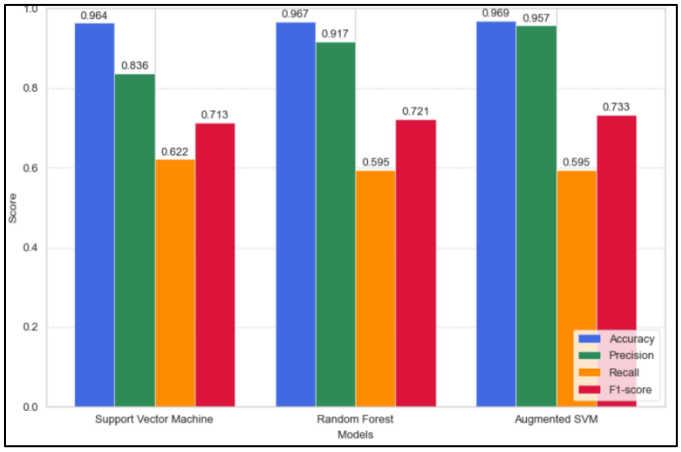


Fig. 20. Performance comparison between Random Forest, Support Vector Machine, and hybrid model (SVM+RF).

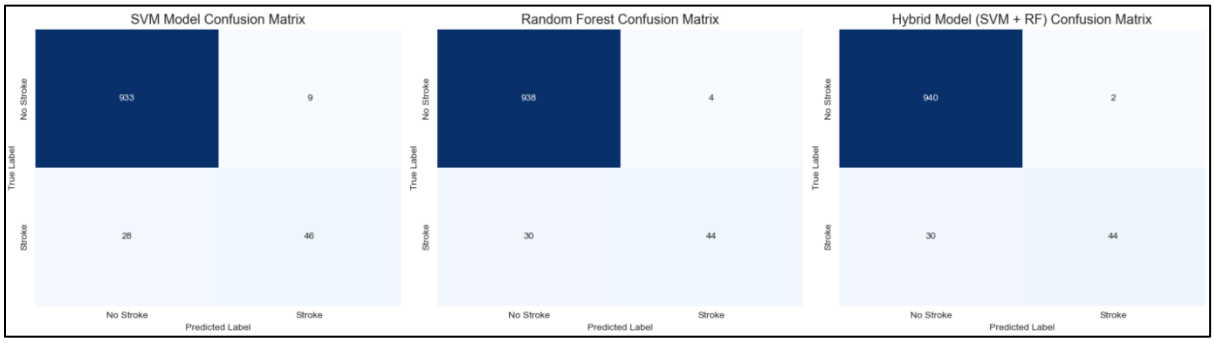
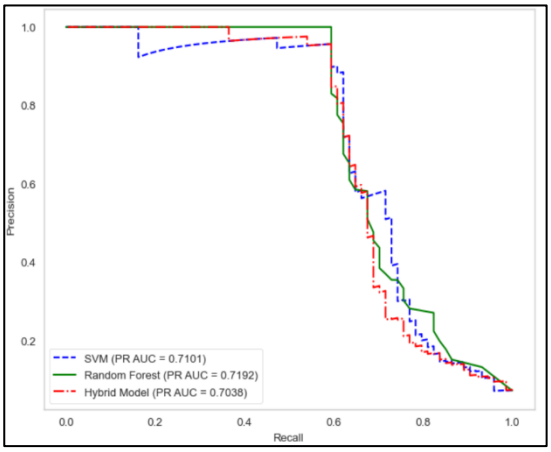
The confusion matrices for the SVM, Random Forest (RF), and Feature-Augmented Model (SVM+RF) in Fig. 21 illustrate how each model performs in classifying stroke and non-stroke cases. The SVM model correctly predicts 933 nonstroke cases and 46 stroke cases, while misclassifying 9 non-stroke cases as stroke and 28 stroke cases as non-stroke. Both the RF and Feature-Augmented models correctly predict 44 stroke cases and misclassify 30 stroke cases as non-stroke. However, RF correctly classifies 938 non-stroke cases and misclassifies 4 as stroke, while the Feature-Augmented model improves further by correctly predicting 940 non-stroke cases and misclassifying only 2. This demonstrates that combining the strengths of SVM and RF reduces the number of false positives (non-stroke cases wrongly classified as stroke), enhancing the model's precision by reducing unnecessary stroke predictions, leading to a more reliable and balanced classification system.

The comparison of the Precision Recall (PR) curve in Fig. 19 illustrates the trade-off between precision and recall for the SVM, Random Forest, and Feature-augmented model. Among the three, Random Forest achieves the highest PR AUC score (0.7192), indicating a more stable performance across all thresholds. Although the hybrid model shows superior point metrics (higher precision and F1 score at the default threshold), its slightly lower PR AUC (0.7038) suggests less consistent performance across varying thresholds. Similarly, the SVM has a PR AUC of 0.7101, reflecting moderate performance. In general, the hybrid model demonstrates strong effectiveness at the default classification threshold, while the Random Forest offers more reliable confidence across a range of threshold values.





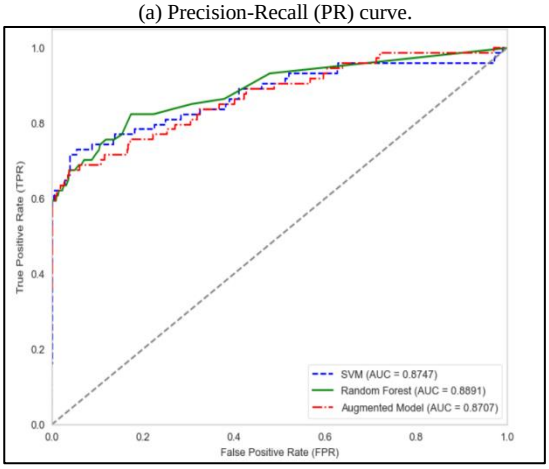


Fig. 21. Confusion matrices for the SVM, Random Forest (RF), and Feature-Augmented Model (SVM+RF).

(a) Precision-Recall (PR) curve.

(b) ROC AUC scores.

Fig. 22. Performance comparison for the SVM, Random Forest (RF) and hybrid model (SVM+RF).

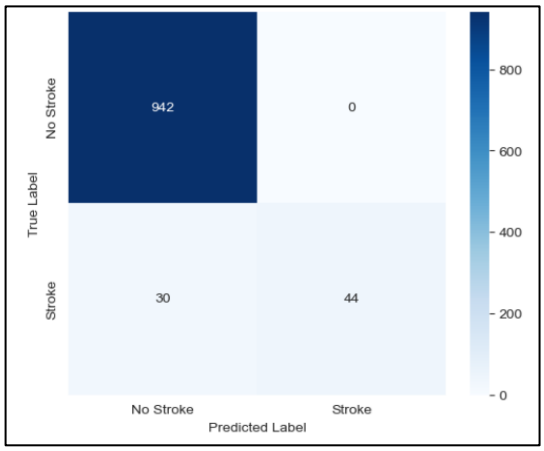
The ROC AUC scores for the models are as follows: the Augmented (Hybrid) model achieved 0.8707, the Random Forest model achieved 0.8891, and the SVM model achieved 0.8747 (Fig. 22). These scores reflect the ability of each model to distinguish between stroke and non-stroke cases, with the Random Forest model showing the highest performance in this regard. The Augmented (Hybrid) model, although slightly lower in the ROC AUC compared to Random Forest, demonstrated improvements in other key evaluation metrics, such as precision and the F1 score, compared to the individual models. This suggests that the hybrid model effectively balances performance across different metrics, making it a viable alternative in stroke classification tasks.

I. Hyperparameter-Tuning Feature Augmented Model (SVM+RF)

1) Grid search: The feature augmented model was developed to improve model performance in predicting stroke cases using a VotingClassifier that combines Support Vector Machine (SVM) and Random Forest (RF) classifiers. Both models were optimised using GridSearchCV with 5-fold cross-validation and class weight adjustments to address class imbalance. The best SVM model used a linear kernel, C = 10, and class_weight = "balanced", while the best RF model used 200 estimators, max_depth = 10, min_samples_split = 5, and class_weight = "balanced_subsample". The final ensemble applied soft voting based on predicted probabilities. An optimal decision threshold (0.5805) was selected using the precision-recall curve to maximise the F1-score. The tuned model achieved an accuracy of 96.85%, a precision of 95.65%, a recall of 59.46%, and an F1 score of 73.33%. Furthermore, the model achieved a PR AUC of 0.7262 and a ROC AUC of 0.9031, indicating strong overall performance and improved ability to identify stroke cases while effectively managing the class imbalance.

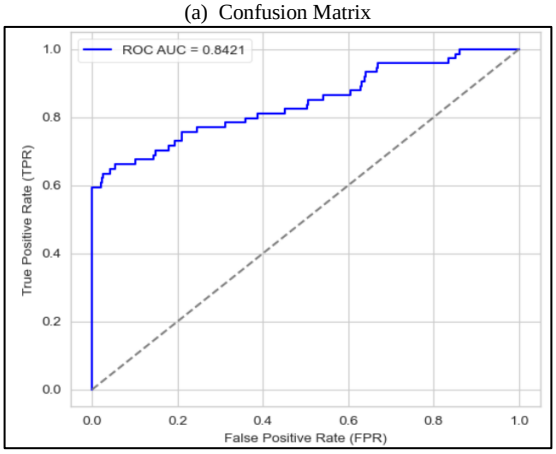
2) Random search: Another way to perform hyperparameter tuning is to optimise Random Forest using RandomizedSearchCV with 5-fold cross-validation, and its predicted probabilities and class labels were appended as new features to the original dataset. These augmented data were used to train an SVM, also optimised via RandomizedSearchCV. Evaluated on a test set with an optimised for recall, the hybrid model achieved an accuracy of 97.05%, perfect precision (1.0000), a recall of 59.46%, and an F1 score of 0.7458. Despite slightly lower ROC AUC scores (0.8421) and PR AUC (0.6886) compared to the standalone Random Forest, the tuned hybrid approach significantly improved precision while maintaining reasonable recall, demonstrating its efficacy in balancing high precision with improved detection of stroke cases.

After comparing the results of the two hyperparameter tuning methods, we decided to proceed with the Random Search outcome, as it demonstrated superior classification performance compared to Grid Search. This decision aligns with the objective



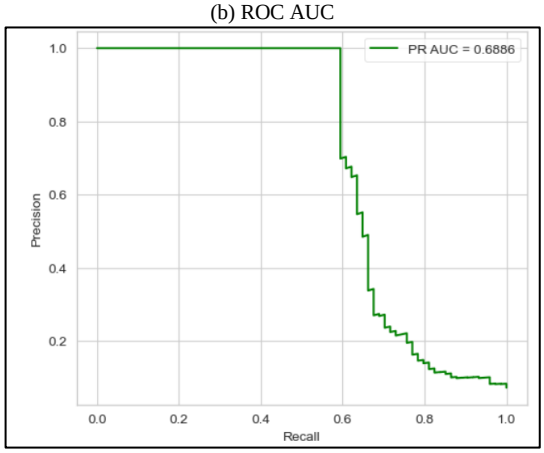
of this investigation, which is to improve the overall performance of the model. The tuned feature augmented model performance is saved for later development usage.

3) Performance evaluation: The confusion matrix in Fig. 23(a) shows that the model correctly classifies 942 "No Stroke" cases and 44 "Stroke" cases, achieving high overall accuracy (97.05%). It excels at correctly identifying non-stroke cases (0 class, with near-perfect recall) without misclassifying any non-stroke cases as stroke (False Positives). However, it misclassifies 30 actual stroke cases as "No Stroke", leading to a low recall of 59.46%, meaning the model fails to detect nearly 41% of stroke cases. Although precision for stroke detection is high (100%), indicating that most predicted strokes are correct, the model's bias toward the majority class results in missed stroke cases. The ROC AUC score for the hybrid model [Fig. 23(b)] after applying random search for hyperparameter tuning is 0.8421, indicating the strong ability to distinguish between stroke and non-stroke cases. The ROC curve rises steeply towards the top left corner, reflecting a high true positive rate (TPR) and a low false positive rate (FPR), suggesting effective classification performance. The Precision-Recall (PR) Curve analysis [Fig. 23(c)] for the feature-augmented SVM model resulted in a PR AUC score of 0.7038, indicating a moderately strong ability to identify stroke cases, particularly in the context of class imbalance. After tuning through Random Search, the model's PR AUC score decreased slightly decreased to 0.6886. This change reflects the model's performance adjustment after the tuning process, aiming for an improved balance between precision and recall.



J. *Model Evaluation After Hyperparameter Tuning (SVM, RF, SVM+RF, Tuned SVM+RF)*

The bar chart in Fig. 24 compares the performance of four models: Support Vector Machine (SVM), Random Forest, Feature-Enhanced SVM and Tuned Feature Augmented SVM using accuracy, precision, recall, and F1 score. Among them, the tuned Augmented SVM achieved the highest accuracy (0.970), high precision (1.000), and F1 score (0.746), indicating a strong ability to correctly identify positive cases while balancing precision and recall. Although its recall (0.595) matches that of Random Forest and Feature Augmented SVM, its exceptional precision significantly increases its overall effectiveness. Random Forest showed high accuracy (0.967) and strong precision (0.917), but a lower recall (0.595) reduced its F1 score to 0.721. The standard SVM performed well with high accuracy (0.964) and better recall (0.622), resulting in an F1 score of 0.713. The enhanced SVM improved over the standard SVM with higher precision (0.957) and an F1 score (0.733), although its recall remained unchanged. Overall, the Tuned Augmented SVM demonstrated the best balance between metrics, highlighting the impact of augmentation and hyperparameter tuning.



The confusion matrices of the four models reveal a consistent reduction in the number of false positives (cases where "No Stroke" was incorrectly classified as "Stroke") (Fig. 25). The SVM model had 9 false positives, whereas the Random Forest model reduced this to 4. The hybrid model (SVM + RF) further reduced the number to 2. The tuned hybrid model achieved zero false positives, correctly classifying all 942 "No Stroke" cases. Importantly, the number of correctly classified "Stroke" cases remained consistent at 44 across all models, and the number of False Negatives (Stroke cases misclassified as "No Stroke") remained at 30.

(a) Confusion Matrix

(b) ROC AUC

(c) PR AUC

Fig. 23. Performance evaluation after hyperparameter tuning.

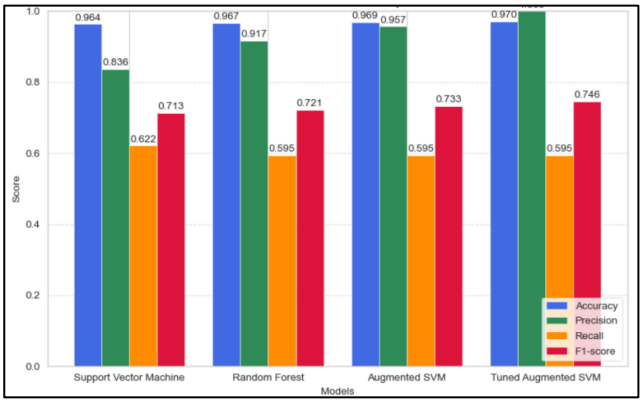


Fig. 24. Performance evaluation among four models.

According to Fig. 26(a), the tuned hybrid model achieved an AUC score of 0.842, slightly lower than the Random Forest (0.889) and SVM (0.875) models. However, it demonstrated a significant advantage by eliminating all false positives, as indicated in the confusion matrix, correctly classifying all 942 "No Stroke" cases. Despite a minor decrease in AUC, the tuned hybrid model maintained consistent performance in identifying true stroke cases, achieving a balanced outcome between sensitivity and specificity. In the performance comparison of Fig. 26(b), the Random Forest model achieved the highest PR AUC of 0.724, followed by the SVM with a PR AUC of 0.709, and the hybrid model with a PR AUC of 0.703. The tuned hybrid model achieved a PR AUC of 0.688, showing a slight drop compared to the other models.

V. Discussion

In this project, the metrics used to evaluate the model performance included accuracy (overall correctness), precision (the proportion of predicted positives that are actually correct), recall (the proportion of actual positives correctly identified), F1-score (the harmonic mean of precision and recall), confusion matrix (detailed breakdown of predictions), ROC AUC (model's ability to distinguish between classes), and PR AUC (trade-off between precision and recall, particularly valuable for imbalanced datasets).

The confusion matrix highlights four key components: True Positive (TP), where the model correctly predicts a positive case; False Negative (FN), where the model correctly predicts a negative case for a positive instance; True Negative (TN), where the model correctly predicts a negative case; and False Positive (FP), where the model incorrectly predicts a positive case for a negative instance.

The standalone SVM achieved an accuracy of 96.36%, a precision of 83.64%, a recall of 62.16%, an F1 score of 71.32%, an ROC AUC of 0.8418, and a PR AUC of 0.6688, with a confusion matrix of 933 TN, 9 FP, 28 FN, and 46 TP. For Random Forest (RF), the performance improved with an accuracy of 96.75%, a precision of 93.62%, a recall of 59.46%, an F1 score of 72.73%, an ROC AUC of 0.8891, and a PR AUC of 0.7192, with a confusion matrix of 938 TN, 4 FP, 30 FN, and 44 TP. The feature-augmented model achieved 96.85% accuracy, 95.65% precision, 59.46% recall, 73.33% F1 score, 0.8707 ROC AUC, and 0.7038 PR AUC, with 940 TN, 2 FP, 30 FN and 44 TP.

The feature-augmented model demonstrated an improvement in accuracy, precision and F1-score, particularly in identifying stroke cases. Despite a slight decrease in the ROC AUC and PR AUC scores, the reduction in false positives (from 9 and 4 to 2) suggests that the model is more reliable, with fewer false alarms. This makes the model more robust for real-world deployment, especially where false positives could lead to unnecessary tests, anxiety, and increased healthcare costs.

To further enhance model performance, a Random Search hyperparameter tuning was applied. After tuning, the model achieved 97.05% accuracy, 100% precision, 59.46% recall, 74.58% F1-score, 0.8421 ROC AUC, and 0.6886 PR AUC. The confusion matrix showed 942 true negatives, 0 false positives, 30 false negatives, and 44 true positives.

The tuned feature-augmented model showed improvements in accuracy, precision and F1 score, although recall remained the same. The reduction of false positives to 0 and the slight increase in true negatives (from 940 to 942) indicate that the tuning process further optimised the model. This highlights the importance of minimising false alarms, particularly in medical applications, as false positives can result in unnecessary tests, increased anxiety, and additional healthcare costs.

This final tuned model provides a reliable and precise tool for stroke prediction, making it highly applicable in clinical environments where timely and accurate decision-making is essential. By reducing false positives and improving prediction reliability, the system is well suited for deployment in real-world applications, ensuring better health outcomes.

VI. Conclusions

In this project, a stroke prediction system is developed and evaluated using machine learning techniques. The hybrid model, combining Support Vector Machines (SVM) and Random Forest (RF), demonstrated a significant improvement over standalone models, achieving better accuracy, precision, and F1 score. The feature-augmented model, which incorporated additional features, further enhanced predictive performance, showing improved classification metrics, including a reduction in false positives and an increase in true negatives.

Through the process of hyperparameter tuning using Random Search, the model's performance was further optimised. The final tuned model achieved a high level of precision (100%), improved accuracy (97.05%), and maintained the same recall (59.46%) compared to the original feature-augmented model. Although there was a slight reduction in the ROC AUC and PR AUC, the ability to minimise false positives and improve true negatives makes it more reliable and suitable for real-world deployment in medical applications.

The practical implications of this project are significant, as it shows the potential of machine learning models to improve stroke prediction and aid healthcare providers in identifying high-risk patients. By reducing false alarms and increasing prediction accuracy, the model can help streamline healthcare processes, reduce unnecessary tests, and ultimately lower healthcare costs. This system has the potential to revolutionise stroke prediction by enabling early detection and intervention, thus significantly reducing the burden of stroke-related healthcare challenges globally.

Despite the strong performance, there are a few limitations. A major challenge is class imbalance, which is common in medical data sets, where positive stroke cases are significantly fewer than negative cases. This imbalance can affect recall, as seen with the relatively lower recall rate of 59.46%, suggesting that some true stroke cases are still being missed. There is also room for improvement in recall, which would ensure fewer missed stroke cases. Although high precision is critical, improving recall is equally important to ensure that at-risk patients are not overlooked.

To enhance the performance and utility of the stroke prediction system, several directions for future development can be considered.

- Incorporating additional features: Including more comprehensive patient data, such as laboratory test results, imaging data, or genetic markers, could improve the model's ability to detect subtle risk factors.
- Handling imbalanced datasets: Given the natural imbalance in stroke datasets (fewer stroke cases than non-stroke cases), applying techniques such as SMOTE (Synthetic Minority Oversampling Technique), ADASYN, Random Oversampling, or cost-sensitive learning can help improve recall without sacrificing precision.
- Exploring advanced ensemble techniques: Approaches like Gradient Boosting Machines (e.g. XGBoost, LightGBM) or stacking multiple models could potentially yield better performance by capturing complex patterns more effectively.

Socio-Technical Factors Influencing Business Intelligence Adoption in SMEs

Ibrahim Abdusalam Abubaker Alsibhawi, Hazura Binti Mohamed, Jamaiah Binti Yahaya
Faculty of Information Science and Technology, Universiti Kebangsaan Malaysia, Malaysia

***Abstract*—This study explores the major challenges that Small and Medium-sized Enterprises (SMEs) encounter when adopting Business Intelligence Systems (BIS), particularly in complex socio-political environments, such as Libya. It aims to understand how internal constraints, like limited financial capacity, resistance to change among management, and weak knowledge-sharing practices, combined with external socio-political factors, influence BIS adoption in developing economies. A cross-sectional survey approach was employed, targeting 297 SME owners and managers in Libya. Data was collected using a structured questionnaire and analyzed with SmartPLS to examine the relationships among key variables: facilitating conditions, information quality, perceived ease of adoption, perceived usefulness, and social influence. The findings highlight that social influence, especially from peers and industry experts, plays a crucial role in shaping SMEs' adoption behavior. Moreover, the quality of information emerged as a significant determinant in the successful adoption of BIS. The study offers both practical and policy-level insights, suggesting that with the right support, BIS adoption can significantly enhance SMEs' competitiveness, decision-making capabilities, and operational efficiency.**

Keywords*—*Information quality; social influences; perceived usefulness of Business Intelligence Adoption; perceived ease of adoption of Business Intelligence System; Business Intelligence System adoption

I. Introduction

In today's fast-paced and ever-changing economic environment, organizations are compelled to utilize tools that support optimal decision-making and help them adapt effectively without incurring financial losses. One growing trend is the adoption of Business Intelligence Systems (BIS), which are recognized for giving companies a significant competitive edge. A study by Tantawy and Ismail (2021) examined a large retail company operating in multiple countries that implemented BIS to enhance decision-making, operational efficiency, and customer satisfaction. The implementation led to notable performance improvements, including increased revenue, better inventory management, and improved customer segmentation. In 2017, Holiday Retirement collaborated with Prorize LLC to develop a revenue management system utilizing operations research. This system provided optimal pricing recommendations across more than 300 senior living communities, resulting in consistent revenue increases of over 10%. In this same vein, Continental Airlines reported increased revenues and cost savings, resulting in a 100% return on investment (ROI). The key to such success lies in accessing accurate and timely information to guide strategic decisions [59]. However, as noted by [10], poor BI adoption can lead to adverse operational impacts, including loss of market share and a declining customer base.

Nevertheless, some studies emphasized that knowledge serves as a valuable organizational resource capable of generating wealth. However, simply possessing knowledge is insufficient; it must be directed and applied effectively to support sound decision-making. Organizations can enhance their existing knowledge base through the implementation of Business Intelligence (BI) initiatives. The success of such initiatives is influenced by various elements, including the quality of information available [16], the ease with which systems can be used [85], and their perceived benefits. Numerous studies have highlighted that the most crucial contributors to the successful implementation of BI systems are related to how organizations manage their information technology, particularly through practices like knowledge sharing and managing organizational change.

In the case of Libyan SMEs, there exists a lack of sufficient knowledge about BIS and its potential benefits, which hinders informed decision-making regarding their adoption. Many Libyan SMEs face resistance to adopting new technologies due to a preference for traditional business practices and a lack of change management strategies. These and many challenges require targeted strategies that will provide clear key success factors for BIS adoption.

Despite the global recognition of BIS as a driver of competitiveness, the adoption rate among SMEs in developing economies—particularly in Libya—remains considerably low. Limited infrastructure, inadequate technical expertise, and cultural resistance to digital transformation exacerbate the challenge. This creates a gap between the proven benefits of BIS in advanced markets and the unrealized potential within Libyan SMEs. Consequently, the absence of evidence-based strategies tailored to this context leaves decision-makers without practical guidance on how to overcome implementation barriers.

This research, therefore, addresses a critical problem: identifying the underlying factors that influence BIS adoption in Libyan SMEs. By investigating organizational, technological, and environmental conditions that either enable or constrain adoption, the study seeks to bridge the gap between theoretical promise and practical application. The objective is to provide a framework that highlights key success factors and offers actionable insights for SMEs, policymakers, and industry stakeholders aiming to enhance competitiveness through digital transformation.

The significance of this study lies not only in its contribution to academic discourse but also in its practical relevance. For Libyan SMEs, understanding how to leverage BIS effectively could improve efficiency, foster innovation, and support long-term sustainability in an increasingly competitive marketplace. For policymakers, the findings will offer evidence-based recommendations to design supportive policies and capacity-building programs that encourage technological adoption across the SME sector.

To achieve these aims, the paper is structured as follows: following this introduction, a literature review examines existing studies on BIS adoption and highlights the gaps within the Libyan context. The methodology section then outlines the research design, data collection, and analysis techniques employed. This is followed by the presentation and discussion of findings, where key success factors are identified and critically examined. The paper concludes by summarizing the implications for practice and policy while suggesting directions for future research.

Based on this, the current research aims to identify the key success factors for BIS adoption, emphasizing their significance in the context of Libyan Small and Medium Enterprises (SMEs).

II. Literature Review

A. Business Intelligence System

Business Intelligence System (BIS) has been seen as a product that is made up of several processes, such as perception, storage, learning, communication, and decision [14]. Accordingly, there are various views on BIS in terms of gathering, processing, interpreting, and communicating the necessary information in the decision-making processes, and with a similar approach. One could conclude that this conceptualizes recognizing the value of external environmental information for shaping organizational actions through managing the information life cycle, which includes perspectives from information systems and their impact context, enhancing value-added informational processes, and facilitating decision-making processes.

Within the context of small and medium-sized enterprises (SMEs), intelligence is not simply a characteristic or inherent quality, but rather a dynamic capability that develops at individual, group, and organizational levels. This development is shaped by interactive communication and relationships across these levels, particularly through problem-solving and actions that support the creation and transfer of knowledge. [14] define business intelligence as an organization's ability to respond to new challenges and tasks, and to strategically adapt by generating and utilizing knowledge. In this view, intelligence is a capacity that enables organizations to adjust to external changes, while the creation and application of knowledge underpin both business intelligence and strategic decision-making. However, success and long-term viability of SMEs in competitive markets rely heavily on the ability to extract valuable insights from data, recognize patterns, and identify trends to make informed decisions [15]. In the past, SMEs lacked the technological infrastructure to process information efficiently, resulting in strategic, tactical, and operational decisions being made largely on intuition. Over time, certain automated systems capable of receiving raw data and quickly distributing relevant information to appropriate users was conceived. This system utilizes methods such as automatic document summarization, encoding, and user profile updates. But, these early techniques, primarily statistical in nature, were limited in effectiveness without adequate communication systems and input/output tools. Gradually, the proposed approaches evolved, giving rise to advanced concepts and methodologies designed to enhance decision-making based on factual data and led to the broader development of what became known as "Business Intelligence System" (BIS), a term later coined by [29]. Today, BIS encompasses a wide range of applications, technologies, and methods that facilitate the collection, organization, transformation, and analysis of structured data. This process can involve direct access tools like queries and reports, or more complex analytical techniques that turn raw data into actionable knowledge [85].

However, the effectiveness of BIS relies not only on advanced methodologies and technologies but also on understanding both internal and external factors, such as economic, environmental, market behavior, legislation, currency exchange rate, internal communication, and operations that affect an organization (Singh, Thakur, & Sharma, 2016). These factors generally influence all stakeholders in a business (customers, competitors, partners, and many more), collectively guiding business decisions and enabling the creation of significant competitive advantages. According to [23], "The best way to analyze the environment is not to try to understand it as a collection systems and organizations, but to treat it as information that the company must access through research activities." He also emphasized that "what truly matters is not just the suppliers or customers themselves, but the information that the company possesses about their goals, interests, relationship conditions with SMEs, and many other aspects of their behavior. This information helps identify their characteristics and expectations for the SMEs. Pas studies similarly asserted "The rapid pace of product innovation and market changes requires that future firms have a clear and expensive view of the business environment." In response to tight deadlines, successful SMEs must proactively explore new applications for emerging technologies, initiate product development ahead of demand, cultivate and stimulate demand, and establish market penetration strategies in anticipation of future needs. Additionally, SMEs must develop a high sense of anticipation of possible agreements or technological developments of rival companies. The use of business intelligence has evolved by leaps and bounds in proportion to the rise of information technology and the growth of the global industry. Experts in the field have provided numerous definitions of business intelligence. It is often described as the process of transforming data into knowledge to obtain a competitive advantage.

Past studies identified the direct impact of business intelligence on startup business performance, as well as its indirect impact through network learning and innovativeness [16]. Their results revealed a significant and positive impact of business intelligence on innovativeness, network learning, and startup business performance. Hence, focusing on the role of BIS can enhance organizational network learning and

performance. On the other hand, [14] found that BIS significantly enhances organizational performance by facilitating business process changes. Similarly, [83] found a significant and positive impact of business intelligence on organizational performance, with this impact fully mediated by the alignment of business intelligence strategies.

Nevertheless, it is necessary to indicate that Libyan SMEs face certain challenges related to data and information which represent BIS and have the potential to affect future success in making use of adequate processes of strategic planning, planning by scenarios or mixed approaches, or to achieve flexible and scalable management against the continuous growth changes of companies, without losing the characteristics of efficiency, quality, and the ability to make decisions. For example, many Libyan SMEs struggle with limited access to reliable market data and lack the technological infrastructure needed for efficient data management and strategic forecasting. Importantly, it is necessary to differentiate between the terms data, information and knowledge, as they are sometimes used interchangeably in literature. The data is a symbolic representation, which has no semantic meaning; it does not transmit a message. On the other hand, information is the set of processed and organized data that has a meaning, transmits a message, allows decision-making, favors problem-solving, and increases knowledge. For the information, the source is the data, and the required activity is the structuring and interpreting of the data. With respect to knowledge, the origin is given in the information that requires analysis, synthesis, dialectical vision, and determination of inferences. Also, the high competition among Libyan SMEs, driven by the need to increase sales rates and market share, necessitates maintaining effective internal management inform of BIS as explained in the current study. In this context, BIS includes innovation, creativity, continuous growth, competitiveness, and decision-making, all within a systematic spiral of continuous improvement. This and many more signify the urgent solution required by the Libyan SMEs towards having a dynamic and globalized environment, information, knowledge, methodologies, and management strategies generate greater demands on executives and managers, impacting the overall performance of the organization [85]. As such, the current study investigates the key factors that influence the adoption of Business Intelligence Systems (BISs) within Small and Medium-sized Enterprises (SMEs).

B. Technology Acceptance Model (TAM)

The use and acceptance of information technologies by end users is an additional way for the system to be successful [4]. Many theories have addressed the use of information technologies by individual consumers, such as the Technology Acceptance Model (TAM), which represents the most widely used [56, 66, 11]. The Technology Acceptance Model (TAM), originally developed by [24], is grounded in the Theory of Planned Behaviour by [31. Its primary objective is to elucidate and predict individuals' acceptance and utilization of technological innovations. The initial model was refined and expanded upon by [24], solidifying its place in academic literature.

TAM posits that those two critical factors, perceived usefulness (PU) and perceived ease of use (PEOU), significantly influence users' attitudes toward technology adoption, as shown in Fig. 1. These perceptions shape behavioural intentions, ultimately affecting actual technology usage. Recent studies have extended TAM by integrating additional variables such as perceived enjoyment, self-efficacy, and perceived cyber risk, enhancing its predictive power in diverse contexts. Initially, TAM was predominantly applied to organizational information systems, focusing on professional users. However, recognizing that general users may lack the technical expertise of professionals, researchers have advocated for model adaptations that incorporate humanistic and social factors, as in the current study. For instance, the inclusion of constructs like personal innovativeness and perceived enjoyment has been shown to better capture end-user behaviours [30].

Contemporarily, adopting and using information technologies in the business environment has been the main focus of information systems research and applications. Understanding the conditions underlying which information systems will be owned by organizations and creating these conditions becomes a high priority, making the current research eminent to identify other social aspects that can contribute to technology to serve as BIS [74].

This concept has a rooted relevance in the theory of planned behavior, which adds that an emotion or personal predisposition of the user gives advance notice of future behaviors, adopting an intermediate role between the user's perceptions and the user's final decision. The current situation of the Libyan SMEs shows that many are facing challenges in implementing or adapting new functionalities of new technologies, and providing strategies for successful adoption by users. Based on this, the present study uses TAM to identify the intention of use and assess the acceptance of technology in different contexts.

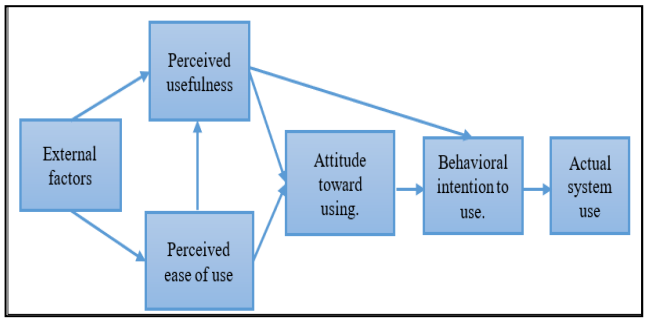

Fig. 1. Technological acceptance model. Source: [25].

C. Unified Theory of the Adoption and Use of Technology (UTAUT)

The Unified Theory of Acceptance and Use of Technology (UTAUT) model, developed by [10], integrates elements from various technology acceptance theories to explain user intentions and behaviors regarding technology adoption. Key constructs include performance expectancy, effort expectancy, social influence, and facilitating conditions, which directly influence behavioral intention and usage behavior were incorporated as shown in Fig. 2 below. Moderating factors such

as age, gender, experience, and voluntariness of use further refine the model's predictive capabilities.

Specifically, UTAUT was employed to address the Technology Acceptance Model (TAM) limitations by incorporating social and environmental factors. Recent studies have applied UTAUT across diverse contexts, including education, healthcare, and mobile technology, especially during the COVID-19 pandemic. For instance, [21] conducted a systematic literature review, revealing that performance expectancy was the most significant predictor of technology adoption during this period. Additionally, facilitating conditions, effort expectancy, and social influence were confirmed as influential factors in user adoption behaviors.

Further research by [25] applied UTAUT to personalized learning systems, finding that perceived usefulness, perceived ease of use, habit, and facilitating conditions significantly impacted both behavioral intention and actual system use. These findings underscore the model's versatility and relevance in understanding technology adoption in various settings. Based on our study, we posit that UTAUT would enhance the adoption of BIS among Libyan SMEs.

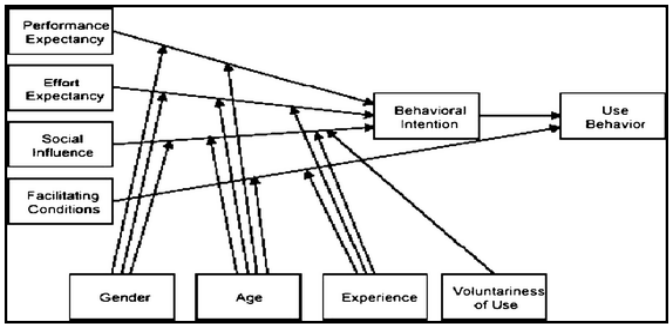

Fig. 2. Unified theory of adoption and use of technology, Source: [19].

D. The SMES Industry in Libya

SMEs in Libya are very important for the economic growth and social development of the country, in the contribution to the Gross Domestic Product (GDP) and job creation. Due to their characteristics, capacities and internal dynamics, they have attracted the attention of national and international organizations, authors, and researchers aiming to describe and address their challenges. The significant contribution of the SMEs industry to the Libyan economy motivated this study to investigate factors influencing the adoption of BIS. This technology is expected to help the SMEs industry achieve better performance and expand its market share within Africa.

SMEs are defined as businesses with limited employees and revenue, specifically those with fewer than 50 employees and less than USD700,000 in revenue, according to the Libyan regulation [5]. In [77], note that SMEs have distinct characteristics and dimensions but face occupational and financial limitations imposed by the regulations of each country. Consequently, there is no universal definition or characteristic that fully captures what SMEs are. The term SME refers to small and medium-sized companies. Typically, SMEs lack a defined structure and are often managed solely by the owner, who handles decisions related to pricing, hiring, salaries. Additionally, SMEs do not have specific job descriptions, and employees often perform multiple roles.

Small and medium businesses have different definitions in different countries. Generally, a small business is an organisation with limited number of employees, and typically, these employees are below fifty. In Libya, Small Business Administration defines small businesses as firms employing 50 or fewer persons, while medium enterprises are firms employing 50 to 250 as shown in Fig. 3.

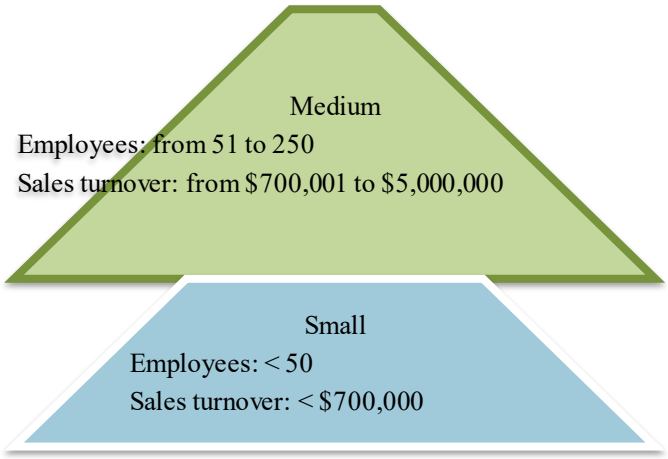

Fig. 3. SMEs classification in Libya. Source: Ministry of Industry - Libya 2020.

Currently, many Libyan small and medium businesses struggle due to the inadequate knowledge of business owners regarding the formulation of growth strategies. One of the reasons these businesses often fail to thrive is the low skill levels of their owners and managers [53]. According to [60], the absence of formal operational policies from authorities, which would guarantee the rights of informal business owners and managers, often leads to failures. In [55], the author pointed out that formalising business operations can lead to significant performance improvements for this business. In light, our study investigates the key factors that would influence the adoption of Business Intelligence Systems (BISs) within Small and Medium-sized Enterprises (SMEs) of Libya [77]. This is because it is very important for these SMEs to perform well, as the higher the number of successful SMEs can contribute to better Libyan economic conditions.

E. Research Hypotheses

The Technology Acceptance Model (TAM) posits that perceived usefulness is a key factor that influences the adoption and utilization of technology [25]-[28]. Information quality is a critical antecedent that can significantly shape this perception [44]. The better the quality of the information provided by BIS, the more likely the users are to find the system useful for decision-making and strategic planning [42]. Information quality can be characterized by attributes such as accuracy, timeliness, completeness, and reliability [12] [13]. Each of these facets contributes to the overall perception of usefulness. Previous studies underlined the importance of information quality for organizational performance [48], suggesting that good information quality enhances decision-making and increases perceived usefulness.

In sectors like healthcare, where the quality of information can be a matter of life and death, the link between information quality and the perceived usefulness of BIS is even more significant [48]. Similarly, in the context of SMEs struggling through unprecedented challenges such as the COVID-19 pandemic, the quality of information is paramount for managing crises and making informed decisions [41, 42]. Advancements in Artificial Intelligence (AI) have contributed to the improvement of information quality, subsequently affecting the perceived usefulness of systems like BIS. Studies like those by [57, 58] reflected that AI algorithms can enhance the quality of data mining, predictive analytics, and real-time data processing, thus making BIS more useful for end-users.

The relationship between information quality and perceived usefulness has been empirically tested in various domains. For instance, [44] specifically looked at Business Intelligence and Analytics (BIA) in micro, small- and medium-sized enterprises (MSMEs). They found that information quality directly correlates with the usefulness perceived by the businesses [45].

The hypothesis stands on strong theoretical and empirical foundations, making it a significant aspect of contemporary research in BISs. Quality of information is not just an isolated factor but rather a composite construct that profoundly influences how BIS is received and utilized in various organizational contexts. Based on the previous studies, such as [46, 78], which found a significant impact of information quality on the perceived usefulness of BIS, the proposed hypothesis is as follows:

H 1: There is a significant impact of information quality on the perceived usefulness of BIS

The concept of ease of implementation serves as a significant predictor for the acceptance and successful deployment of technological solutions, according to the TAM [25]. Information quality, with attributes such as accuracy, reliability, and timeliness, can significantly affect this ease [82]. The intersection of these two domains in the realm of BIS remains an area ripe for investigation.

Artificial Intelligence (AI) is increasingly important in automating data analysis and validation processes, enhancing information quality. Studies by [17, 34] demonstrated that AI can substantially ease the process of BIS implementation through predictive algorithms and real-time analytics, thereby providing high-quality information that is easier to integrate into existing systems. During times of crisis, such as the COVID-19 pandemic, the quality of information becomes crucial for quick decision-making and agile responses. [18] observed that the quality of information provided by AI systems significantly impacted the performance and ease of implementation of such technologies in the hospitality industry.

Previous studies have explored the importance of Industry 4.0 in enhancing operational efficiency [23, 30, 33]. Here, information quality is paramount as it directly influences how smoothly these digital transformations take place. The author in [40] addressed the role of AI in the retail industry, where the quality of information is vital for inventory management, customer relations, and logistics. When information quality is high, retail businesses find it much easier to implement and benefit from BIS and other AI-driven technologies. The author in [20], delved into scenario planning and business negotiations, suggesting that good information quality can help in predicting different scenarios more accurately, making the implementation of BIS easier for strategic planning and decision-making. Based on the previous studies, such as [40, 49] that found a significant impact of information quality on the perceived ease of implementation of BIS, the proposed hypothesis is as follows:

H 2: There is a significant impact of information quality on the perceived ease of BIS

The Technology Acceptance Model (TAM) originally emphasized the importance of perceived usefulness and ease of use in technology adoption [25, 14]. In [29], the author extended the TAM, incorporating social influences as a pivotal determinant in the Unified Theory of Acceptance and Use of Technology (UTAUT). Social influences include subjective norms, social identity, and system exposure, which can significantly impact the perceived usefulness of technological systems like BIS.

The author in [2] explored AI adoption in human resource management and highlighted that one of the significant factors impacting its effectiveness is the organizational perception of its utility. Often, this perception is moulded by the social norms within the HR department and the larger organizational culture. In [6], the author discussed the enterprise-level analysis of data analytics-oriented business intelligence technology. That research emphasized that social factors within an organization can either facilitate or hinder the effectiveness of these systems, thus affecting their perceived usefulness. In [10], the author considered AI and big data from ontological and communicative perspectives, suggesting that the social discourse surrounding these technologies influences their perceived utility. Such discourse is often shaped by organizational leaders and opinion makers, whose views are socially influential.

The author in [12], on the adoption of AI in hiring processes, found that social factors like management support and peer encouragement were influential in determining how useful the AI systems were considered to be. In [30], the author discussed AI governance and pointed out that social considerations, such as ethical and societal norms, can strongly impact how the usefulness of AI technologies, including BIS, is perceived within an organization. A previous study discussed the role of complementary resources and external readiness in SME performance. Social influences in the external business environment can significantly shape how useful a firm perceives its BIS, especially regarding its functionality in e-commerce platforms. Based on previous studies such as [1, 67] that found a significant impact of social influences on the perceived usefulness of BIS, the proposed hypothesis is as follows:

H 3: There is a significant impact of social influences on the perceived usefulness of BIS

Traditional models like the Technology Acceptance Model (TAM) have been extended to include social factors, like the

Unified Theory of Acceptance and Use of Technology (UTAUT), which identifies social influences as a significant predictor of technology adoption ease. In this context, social influences encompass subjective norms, social identity, and system exposure. In [72] the author explored how artificial intelligence could manage agricultural supply chain risks, especially during the COVID-19 pandemic. They found that perceived ease of implementation was substantially influenced by social forces, such as farmers' communities, collaborative knowledge, and even governmental directives. In [76], the author focused on how AI can transform library services in educational institutions. They note that the success of such implementation often rests on social factors like faculty support, student enthusiasm, and administrative will, which influence how easy the implementation is perceived to be.

The authors in [83,3] explored the need to adopt big data analytics in B2B organizations. Their model underlines the significance of social influences, such as competitive pressures and partner expectations, in gauging how straightforward it is to implement new technologies like BIS. In [4], the study provided a framework to realize strategic value from learning analytics. They identified that the perception of ease of implementation is influenced by the institution's culture and beliefs, which are, in turn, driven by social influences like academic advocacy or resistance. Past literature discussed artificial intelligence acceptance in the context of digital entrepreneurship. They proposed that social influences like peer networks, industry thought leadership, and market trends significantly impact entrepreneurs' perception regarding the ease with which AI can be implemented.

Based on previous studies, such as [69] and [84], which found a significant impact of social influences on the perceived ease of implementation of BIS, the proposed hypothesis is as follows:

H 4: There is a significant impact of social influences on the perceived ease of BIS

In technological acceptance models such as the Unified Theory of Acceptance and Use of Technology (UTAUT), facilitating conditions are considered a critical determinant of technology acceptance. These conditions often correlate positively with the perceived usefulness of the technology in question, as they can directly impact the technology's efficiency and effectiveness. The author in [55] discussed the role of facilitating conditions, like training and technology support in adopting virtual reality technology for sustainable quality in agriculture. The study showed that these conditions significantly improved farmers' perception of the technology's usefulness, providing insights into how facilitating conditions can also influence perceived usefulness in the domain of BIS.

Past research studied the adoption of AI mobile banking applications [19], focusing on facilitating conditions, such as user interface design and customer support. They found that these conditions were essential contributors to the perceived usefulness of mobile banking applications, suggesting similar implications for BIS. The author in [61] delved into how blockchain announcements affect stock value from a technology management perspective. The study revealed that factors like a supportive regulatory environment and internal blockchain expertise (facilitating conditions) significantly enhanced the perceived usefulness of blockchain. This finding can be paralleled in the context of BIS [62, 63].

In [68], the author studied the benefits and limitations of AI adoption in the pandemic-stricken Indian industry. The facilitating conditions, like government support and availability of skilled labour, played a considerable role in influencing the perceived usefulness of AI technologies, supporting the hypothesis in the realm of BIS. [71] investigated the factors affecting blockchain adoption in apparel supply chains. Their findings highlighted that facilitating conditions like technology infrastructure and stakeholder support played a vital role in determining the perceived usefulness of blockchain technologies. Based on previous studies such as [11, 65], which found a significant impact of facilitating conditions on the perceived usefulness of BIS, the proposed hypothesis is as follows:

H 5: There is a significant impact of facilitating conditions on the perceived usefulness of BIS

Facilitating conditions refer to the degree to which an individual believes that an organizational and technical infrastructure exists to support the use of the system. If these conditions are favourable, they can significantly reduce the perceived complexity of implementing a new technology, such as BIS. The author in [32] examined the role of technology readiness and awareness in influencing the intention to use analytical AI in services. The study showed that facilitating conditions like technical readiness significantly influenced the perceived ease of implementing AI solutions. These findings can be extrapolated to understand how facilitating conditions could affect the ease of implementing BIS.

In [37], the author conducted a systematic review identifying the drivers and barriers of Industry 4.0 technology adoption among manufacturing SMEs. Their study highlighted that facilitating conditions, such as adequate training and technical support, can significantly ease the process of adopting advanced technologies, thereby supporting the hypothesis in the context of BIS. The author in [39] investigated the consumers' adoption of artificial intelligence and robotics in the hospitality and tourism sector. Their research noted that factors like consumer familiarity with technology (a facilitating condition) significantly impacted the perceived ease of interacting with such technologies. These findings support the notion that facilitating conditions similarly influence the perceived ease of implementing BIS.

Past literature discussed the use of conversational interfaces for accessing business relational data structures. They pointed out that user-friendly interfaces (a form of facilitating condition) make accessing and navigating complex data structures easier, potentially simplifying the implementation of BIS [51]. In [58], the author explored the perceptions of Indian managers on the impact of convergent technologies on work and resultant organizational performance. The study underlined the importance of facilitating conditions like managerial support and the availability of resources, which significantly influenced the ease of implementing these technologies. Based

on previous studies such as [18], which found a significant impact of facilitating conditions on the perceived ease of implementation of BIS, the proposed hypothesis is as follows:

H 6: There is a significant impact of facilitating conditions on the perceived ease of BIS

The perceived ease of implementation can affect the perceived usefulness by lowering the barriers to effective utilization. When a BIS is perceived as easy to implement, users are more likely to perceive it as beneficial to their tasks. Such a system seamlessly integrates with existing workflows and enhances its perceived usefulness.

In [2], research on AI adoption by human resource management highlighted that ease of use directly influences the perceived usefulness of AI systems in HR tasks. This research implies that when BIS are easier to implement, HR professionals may find them more useful for data analytics, strategic decision-making, and employee management. The work by [3, 52] presented a compelling argument for the role of organizational absorptive capacity in enhancing the efficiency of BISs. This study indirectly supported the hypothesis by suggesting that an organization's ability to assimilate and utilize new knowledge (a factor that can facilitate ease of implementation) significantly impacts the efficiency and, by extension, the perceived usefulness of BIS.

The study of [6] provided an enterprise-level analysis of business intelligence technology effectiveness. Their study posited that ease of integration and implementation are vital parameters for evaluating the effectiveness of data analytics-oriented BISs. Therefore, their findings provide empirical backing for the proposed hypothesis. Previous research [9] emphasized the relevance of self-service business intelligence tools in university management, noting that ease of use positively influences perceived usefulness. This is particularly applicable in an academic setting where administrative staff and faculty may lack advanced technical skills.

In the research of [10], which delved into the ontological and communicative perspectives of AI and big data. Their research suggested that easy-to-implement AI solutions, seamlessly integrate big data analytics are perceived as significantly more useful in solving complex business problems. Based on the previous studies, such as [81, 67] that found a significant impact of perceived ease of implementation of BIS on the perceived usefulness of BIS, the proposed hypothesis is as follows:

H 7: There is a significant impact of the perceived ease of BIS on the perceived usefulness of BIS

Perceived usefulness can be considered a key driver for the successful implementation of BIS. This is predicated on the assumption that perceived benefits like enhanced decision-making, improved efficiency, and increased competitive advantage will encourage stakeholders to support the system's implementation. The study by [2], examined AI adoption in human resource management and found that the perceived usefulness of AI systems significantly influences their implementation. This observation could be extrapolated to BIS implementation, suggesting that perceived usefulness would directly and positively impact the success of BIS roll-out.

In a study by [3], Serrano and Koulouri (2021), the authors explored the effect of organizational absorptive capacity on BIS efficiency. Although the focus is on efficiency, the underlying message is that organizations are more likely to successfully implement systems they find useful, further supporting the hypothesis in question. The author in [7] provided insights into the evaluation of data analytics-oriented business intelligence technology's effectiveness at the enterprise level. Their work underscores the importance of perceived usefulness as a key evaluative measure, indirectly implying that systems deemed useful are more likely to be implemented successfully.

According to [8] study, which delved into the utility of self-service business intelligence tools in university management. The emphasis on the perceived usefulness of these tools in facilitating administrative tasks suggests that these systems are more likely to be successfully implemented if they are deemed useful by the end-users. In [10] research, which explored the implications of AI and big data in modern businesses. Their research emphasized that the perceived usefulness of these technologies has a substantial impact on their successful integration into existing business processes. Based on previous studies, such as [81] found a significant impact of the perceived usefulness of BIS on the BIS implementation, the proposed hypothesis is as follows:

H 8: There is a significant impact of the perceived usefulness of BIS on the perceived ease of BIS

Information quality is often characterized by attributes like accuracy, timeliness, completeness, and relevance. High-quality information is expected to increase the perceived usefulness of a BIS, as it enables better decision-making. On the other hand, perceived usefulness refers to the degree to which a person believes using a BIS would enhance their job performance. Therefore, the better the information quality, the higher the perceived usefulness, which positively impacts the implementation of the BIS.

The study of [6] delved into the effectiveness of BIS at the enterprise level. Although the paper did not directly address the mediating role of perceived usefulness, it emphasized the importance of system effectiveness, which is closely linked to information quality. High-quality information would inevitably make a BIS more effective and enhance its perceived usefulness, thus influencing its successful implementation. The author in [8] focused on the applicability of self-service BIS tools in university management. In a self-service setting, the quality of information becomes even more critical as users need to rely on the data provided for decision-making. This highlights the importance of information quality in influencing perceived usefulness and successful implementation.

The work by [10] explored the adoption of AI and big data in different sectors. These advanced technologies enhance information quality, making systems more useful and more likely to be successfully implemented. Thus, the perceived usefulness here serves as a mediator between the high-quality information provided by AI and big data and the actual implementation of BIS. Based on previous studies such as [24,

48, 81], found significant mediation of the perceived usefulness of BIS between information quality and the BIS implementation, the proposed hypothesis is as follows:

H9: There is significant mediation of the perceived usefulness of BIS between information quality and the BIS implementation

Information quality in a BIS encompasses attributes like accuracy, timeliness, relevance, and completeness. When information quality is high, users are more likely to find the system easier to implement as they can more effectively use the data for decision-making. Ease of implementation refers to the perceived ease with which a system can be integrated into existing processes or a new setup can be operationalized. The easier the implementation, the more likely the system will be implemented successfully.

The research by [6] focused on evaluating data analytics-oriented BIS technology effectiveness at the enterprise level. While their work did not explicitly look at the ease of implementation, it emphasized the role of effective BIS systems. Effective systems characterized by high-quality information are likely to have reduced implementation barriers, thereby proving the mediating role of ease of implementation. [2] delved into the adoption of AI by Human Resource Management and its effectiveness. When AI algorithms produce high-quality information, HR professionals find the system easier to use and implement, thus providing an indirect link between information quality and successful implementation.

The study by [8] focused on the relevance of self-service BIS in university management. The importance of ease of implementation is implicitly emphasized here; high-quality information makes self-service tools more straightforward and more intuitive to implement. The author in [10] discussed the ontological and communicative perspectives in AI and big data scenarios in modern businesses. Here, the quality of information gained from these advanced technologies would naturally affect how easy it is to implement these systems, which affects their adoption rate. Based on previous studies, such as [81, 49] that found significant mediation of the perceived ease of implementation of BIS between information quality and the BIS implementation, the proposed hypothesis is as follows:

H10: There is a significant mediation of the perceived ease of BIS between information quality and the BIS implementation

F. Research Hypotheses

In this research, the existing problem has been identified as the lack of a BIS to improve SMEs' performance in Libya. Possible solutions to this problem have been formulated through hypotheses as explained in the previous section. This study identified several organizational and technological factors, such as information quality, social influences and facilitating conditions as the independent variable (IV), while perceived usefulness of BIS and perceived ease of BIS represent the mediation variable (MV) respectively toward BIS adoption which is the dependent variable (DV). The nomination of these factors was based on related theories such as the technology acceptance model (TAM), the unified theory of adoption and use of technology (UTAUT. This shows in the below research model Fig. 4 for the current study.

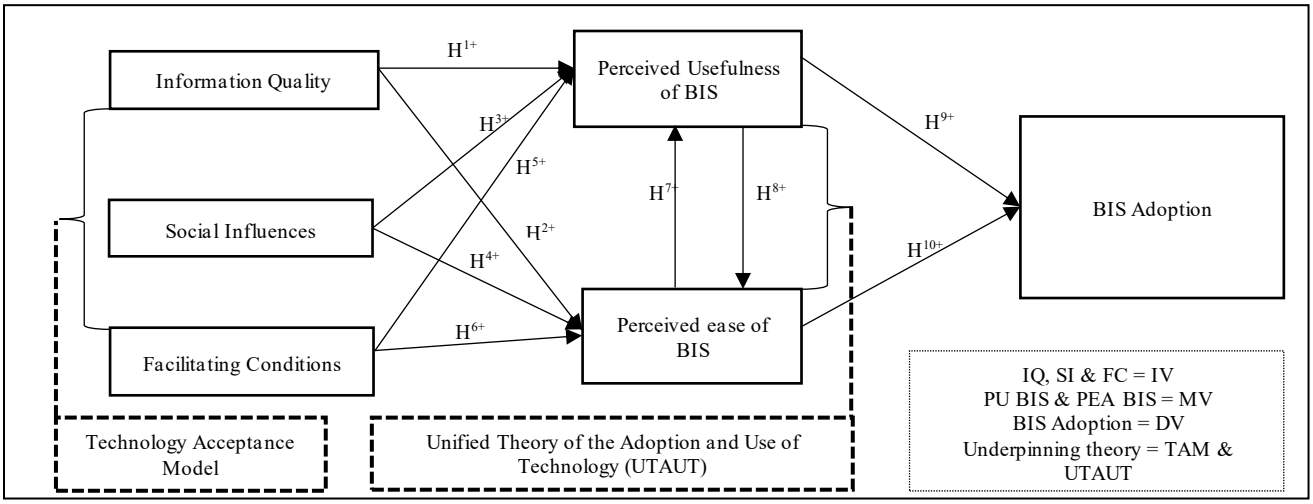

Fig. 4. Research model.

III. METHODOLOGY

The current study employed a quantitative methodology, which allowed to obtain relevant information to investigate factors that led Libyan SMEs towards adoption of BIS. According to [9], the research design clarifies the adopted process used to manage the data, which is used to figure out the possible solution to the research issues. The research design process includes several phases that lead to a potential solution for the research issues. These were identified by [22] in six phases as: 1) identifying the problem of the research, 2) underpinning the related theories and empirical studies, 3) clarifying the purpose of the research, 4) gathering the optimal data, 5) interpreting the obtained result retrieved from the data, and 6) conclude the finding of the research.

The population of this study represents the total management levels of those who work at Libyan SMEs all over the country. The sample size of this population is defined based on G-power software, which allows us to determine the optimal sample size based on the number of predictors within the constructed model proposed. The target population was 180,000 SMEs listed by the Libyan Ministry of Economy and Trade. Two methods were used to identify the target sample size based on the total population determined for this study: the optimal sample size proposed by [53]. Thus, the optimal sample size for this study was 384, as the total population is higher than 100,000. However, the response rate (77.3%) of the survey was 297 SMEs' owners and managers in Libya, which was seen as enough to test hypotheses based on numerical measurement and statistical analysis to derive a generalized result [35].

The questionnaire instrument was used for data collection as it provided measurements for the nominated factors. The design of the instrument comprises two main sections; the first section is about the respondents' profile, while the second section is assigned to measure the model construct. The study used SPSS27 and Smart PLS4 to test the relationships among the research variables:

A. Data Analysis and Results

In order to achieve the current research objective, the respondents' profile was analyzed with descriptive statistics. This is followed by the normality and the reliability test, respectively, as well as direct and indirect effects tests. The comprehensive details of each analysis are explained in the following sections.

B. Respondents Profile

It was important to determine the profile of respondents of the current study to better understand the target population, design research instruments, and draw more accurate conclusions from the data [75]. As such, several categories of respondents' profiles, such as gender, age, highest education, and working experience, were determined in the present study. Table I displays the profile of the respondents who participated in the study. The table shows that 71.4% of the participants belong to the male gender, while 28.6% belong to the female gender category. The result confirms that male respondents are the majority. In terms of the age of the participants, it was determined that most of the respondents (35.4%) were 20-31 years old, while 67 participants were in the range of 31-40 years old presenting 22.6% and 68 participants were in the range of 42-50 years old presenting 23.1%, with 57 participants found to be in age 51 years old and above 18.9%.

According to the results shown in Table I, most of the participants hold bachelor's certificates with a percentage of 32.8%. 28 participants hold high school certificates with a percentage of 9.4% and followed by 54 participants holding a diploma certificate with a percentage of 18.4%. Also, 60 participants hold master certificates with a percentage of 20.4% and 31 participants hold diploma certificates with a percentage of 10.5%, and 27 participants hold other certificates with a percentage of 8.5%. This ensures that all the participants are well educated [70]. The experience of the participants ranged from less than 1 year and more than five years. There are 15.2% of the participants who had experienced less than one year, followed by 23.7% of the participants with experience of 1 to 3 years, while 29.4% of the participants had experience of 3 to 5 years, and 31.7% of the participants had experience of more than five years. This shows that most of the respondents were well-experienced.

TABLE I. PROFILE OF RESPONDENTS (N = 297)

	n	%		n	%
Gender			**Highest Education**		
Male	212	71.4	High School	28	9.4
Female	85	28.6	Diploma	54	18.4
			Bachelor	97	32.8
Work Experiences			Master	60	20.4
Less than 1 year	45	15.2	PhD	31	10.5
1 to 3 years	70	23.7	Other	27	8.5
3 to 5 years	87	29.4	**Age**		
More than 5 years	95	31.7	21-30 years old	105	35.4
			31-40 years old	67	22.6
			41-50 years old	68	23.1
			51 years old and above	57	18.9

C. Descriptive Statistics

According to Table II, the mean statistics for all the items ranged between 2.811 and 4.387. Meanwhile, the standard deviation values ranged between 0.784 and 1.014. These results ensure that respondents are, on average agreement with the items stated for each factor in the questionnaire. Also, the results ensure the vital role of the independent and mediating variables in the BIS adoption by SMEs. The descriptive analysis for the current study also included the normality test. A normality test is a statistical procedure used to determine whether a given data set or sample is normally distributed or not. Normal distribution, also known as Gaussian distribution, is a bell-shaped probability distribution characterized by the mean, standard deviation, and other parameters that describe the spread and shape of the distribution.

The current research used the Skewness and Kurtosis values to test the normality of the distribution. The accepted range of Skewness between -3 and +3 is to be accepted, while the Kurtosis range should be between -5 and +5 [43]. Table II shows the result of the normality test for the construct that all the factors (information quality, social influences, facilitating conditions, perceived ease of implementation of BIS, perceived ease of implementation of BIS, and BIS adoption by SMEs) are normally distributed within the accepted range, with Skewness range between -1.646 and -0.014, as well as the Kurtosis range was between -0.563 and 3.818 [47].

D. Construct Reliability

The construct reliability test was carried out in this study to determine the internal consistency of the data [47]. Table III shows that the composite reliability, factor loadings, and Cronbach's alpha for each construct are more than the required threshold, which indicates that the measurements are reliable, where the factors (information quality, social influences, facilitating conditions, perceived ease of implementation of BIS, perceived ease of implementation of BIS, and BIS adoption by SMEs) were all within acceptable results. The Cronbach's alpha for the factors ranged between 0.754 and 0.898, while the composite reliability values ranged between 0.812 and 0.927 [78-80].

TABLE II. DESCRIPTIVE ANALYSIS

Items	Mean	Median	SD	Kurtosis	Skewness
IQ1	3.997	4.000	0.962	1.120	-1.087
IQ2	4.067	4.000	0.881	2.165	-1.200
IQ3	3.906	4.000	1.014	0.875	-1.017
IQ4	3.912	4.000	0.913	2.163	-1.212
SI1	3.781	4.000	0.874	0.198	-0.472
SI2	3.754	4.000	0.819	0.592	-0.480
SI3	3.953	4.000	0.844	0.671	-0.654
SI4	2.811	3.000	0.913	-0.563	-0.098
FC1	3.040	3.000	0.938	-0.158	-0.179
FC2	3.007	3.000	0.950	-0.385	-0.156
FC3	3.148	3.000	1.011	-0.448	-0.340
PU1	3.094	3.000	1.004	-0.376	-0.190
PU2	2.987	3.000	0.995	-0.243	-0.014

BIS1	4.131	4.000	0.978	1.589	-1.331
BIS2	3.808	4.000	0.833	0.585	-0.540
BIS3	3.700	4.000	0.784	0.952	-0.599

Where: IQ; Information quality, SI; Social influences, FC; Facilitating conditions, PU; Perceived usefulness of BIS, PEA; Perceived ease of adoption of BIS, and BIS; BIS adoption

E. Construct Reliability

The value used to test the convergent validity is the average variance extracted (AVE). According to the rule of thumb, when the value of AVE is greater than 0.5, the factor shows good construct validity. Table III shows that the factors (information quality, social influences, facilitating conditions, perceived ease of implementation of BIS, perceived ease of implementation of BIS, and BIS adoption by SMEs) have acceptable AVE values, ranging between 0.546 and 0.779.

The factor loading test was used in the study to confirm the validity of the research data. The accepted value for the factor loading is greater than 0.5. Table III reveals that the factors (information quality, social influences, facilitating conditions, perceived ease of implementation of BIS, perceived ease of implementation of BIS, and BIS adoption by SMEs) have acceptable factor loading values, ranging between 0.457 and 0.939.

F. Direct Effect Test

The direct effect test was employed in the study to examine the correlation between two variables by a correlation coefficient, whose value oscillates between -1 and +1. If the correlation coefficient is +1, it indicates a positive relationship between the variables, and -1 indicates a negative relationship between the two variables. Assessing path coefficients is an important step in conducting structural equation modeling (SEM), a statistical technique used to analyze complex relationships between variables. Path coefficients, also called standardized regression coefficients or beta weights, represent the strength and direction of the relationships between variables in a model [75]. For the current research, the path coefficients test was used to find out the relationships between the research variables.

TABLE III. ASSESSMENT OF THE FINAL MEASUREMENT MODEL

Model Construct	Items	Loading	CA	CR	AVE
BIS adoption	BIS1	0.823	0.754	0.857	0.667
	BIS2	0.855			
	BIS3	0.770			
Facilitating Conditions	FC1	0.927	0.864	0.913	0.779
	FC2	0.907			
	FC3	0.809			
Information Quality	IQ1	0.908	0.898	0.927	0.761
	IQ2	0.929			
	IQ3	0.782			
	IQ4	0.862			
Perceived Ease of Adoption of BIS	PEA1	0.457	0.757	0.812	0.546
	PEA2	0.467			
	PEA3	0.939			
	PEA4	0.936			
Perceived Usefulness of BIS	PU1	0.726	0.777	0.844	0.576
	PU2	0.703			
	PU3	0.791			
	PU4	0.809

	SI2	0.901			
	SI3	0.748			

TABLE IV. DIRECT EFFECT

Paths	Beta	SD	T	P Values
Facilitating Conditions → Perceived Ease of Adoption of BIS	-0.010	0.051	0.189	0.850
Facilitating Conditions → Perceived Usefulness of BIS	0.758	0.029	25.881	0.000
Information Quality → Perceived Ease of Adoption of BIS	0.400	0.076	5.247	0.000
Information Quality → Perceived Usefulness of BIS	0.162	0.033	4.958	0.000
Perceived Ease of Adoption of BIS → BIS adoption	0.701	0.035	19.939	0.000
Perceived Usefulness of BIS → BIS adoption	0.031	0.052	0.596	0.552
Social Influence → Perceived Ease of Adoption of BIS	0.498	0.048	10.290	0.000
Social Influence → Perceived Usefulness of BIS	0.154	0.035	4.396	0.000

The Table IV above shows the direct effect of the hypotheses tested in the current study. The result of the Beta,

T-statistics and P-value (-0.010, 0.189, 0.850) show that there is no relationship between the facilitating conditions and the perceived ease of adoption of BIS as it is greater than the acceptable threshold of 0.05 [77]. However, other P-value of facilitating conditions and the perceived usefulness of BIS (beta = 0.758, T-value = 25.881, and P-value = 0.000), information quality and the perceived ease of adoption of BIS (beta = 0.400, T-value = 5.247, and P-value = 0.000), information quality and the perceived usefulness of BIS (beta = 0.162, T-value = 4.958, and P-value = 0.000), perceived ease of adoption of BIS and BIS adoption (beta = 0.701, T-value = 19.939, and P-value = 0.000), perceived usefulness of BIS and BIS adoption, social influence and the perceived ease of adoption of BIS (beta = 0.498, T-value = 10.290, and P-value = 0.000), social influence and the perceived usefulness of BIS with (beta = 0.154, T-value = 4.396, and P-value = 0.000) all shows that there is a positive and significant relationship as hypothesized.

G. Mediation Effect Test

The mediation test was used in the study to identify the mediation effect of perceived usefulness of BIS and perceived ease of adoption of BIS between the independent variables and the dependent variable as shown in Table V.

Table V shows that the perceived usefulness of BIS has no mediation relationship between facilitating conditions and BIS adoption as Beta=0.023, T-statistics=0.602 and P-value=0.547 all above or below the threshold values. Similarly, perceived ease of adoption of BIS has no mediating relationship between facilitating conditions and BIS adoption because Beta-value=-0.007, T-statistics=0.188 and P-value=0.851 all above or below the threshold values. However, perceived ease of adoption of BIS mediates the relationship between social influence and BIS adoption with (beta = 0.349, T-value = 8.636, and P-value = 0.000), while also perceived ease of adoption of BIS mediates the relationship between information quality and BIS adoption with (beta = 0.281, T-value = 4.984, and P-value = 0.000). Again, perceived usefulness did not mediate the relationship between information quality and BIS adoption as well as perceived usefulness of BIS did not mediate the relationship between social influence and BIS adoption as resulting in Beta = 0.005, T-statistics = 0.0576, P-value = 0.565 and Beta = 0.005, T-statistics = 0.0544, P-value = 0.587 all above or below the threshold values.

H. Discussion

The discussion section is the last step in the process of the findings. This section presents the results related to the research hypotheses and compares them with the results and findings of the previous studies. This study has found that BISs adoption factors in Libyan small and medium enterprises are facilitating conditions, information quality, perceived ease of adoption of BIS, perceived usefulness of BIS, and social influence. This study has found that there is no relationship between facilitating conditions and the perceived ease of adoption of BIS. There is a positive and significant relationship between facilitating conditions and the perceived usefulness of BIS with beta = 0.758, T-value = 25.881, and P-value = 0.000. There is a positive and significant relationship between information quality and perceived ease of adoption of BIS (beta = 0.400, T-value = 5.247, and P-value = 0.000). There is a positive and significant relationship between information quality and perceived usefulness of BIS (beta = 0.162, T-value = 4.958, and P-value = 0.000). There is a positive and significant relationship between the perceived ease of adoption of BIS and BIS adoption with beta = 0.701, T-value = 19.939, and P-value = 0.000. There is no relationship between the perceived usefulness of BIS and BIS adoption. There is a positive and significant relationship between social influence and perceived ease of adoption of BIS (beta = 0.498, T-value = 10.290, and P-value = 0.000). There is a positive and significant relationship between social influence and the perceived usefulness of BIS (beta = 0.154, T-value = 4.396, and P-value = 0.000).

These results were similar to the results of the previous studies, which means the previous studies' findings supported this study's findings. Previous research, such as [74,11] have indicated that both perceived usefulness (PU) and perceived ease of use (PEOU) directly impact the BIS implementation in general; these relationships will be needed in the context of BIS implementation, as stated within the original TAM model. Technology-driven strategy is defined by [36] as the development, integration, and usage of new technologies in new product and service development. Recent research has demonstrated that a technology-driven strategy strongly impacts developing information technology capabilities [43]. Therefore, the direct influence of the technology-driven strategy on BIS' perceived usefulness was tested. Information quality and organizational factors affect user satisfaction with technology and influence beliefs about using it [54]. The effect of information quality on PU and PEOU has been tested by [33, 50]. They found that information quality influences adoption success by positively impacting usefulness and perceived ease of implementation.

TABLE V. SUMMARY OF THE MEDIATION EFFECT TEST

Mediation Paths	Beta	SD	T	P-value
Facilitating Conditions → Perceived Usefulness of BIS -> BIS adoption	0.023	0.039	0.602	0.547
Facilitating Conditions → Perceived Ease of Adoption of BIS -> BIS adoption	-0.007	0.036	0.188	0.851
Social Influence → Perceived Ease of Adoption of BIS -> BIS adoption	0.349	0.040	8.636	0.000
Information Quality → Perceived Ease of Adoption of BIS -> BIS adoption	0.281	0.056	4.984	0.000
Information Quality → Perceived Usefulness of BIS -> BIS adoption	0.005	0.009	0.576	0.565
Social Influence → Perceived Usefulness of BIS -> BIS adoption	0.005	0.009	0.544	0.587

Note: * p<0.01(1.96)

SMEs that can implement robust information technologies can now operate more efficiently and solve supply chain problems. However, the decision to adopt technologies and innovations to improve the inventory processes mentioned includes different edges associated with technological, organizational and environmental factors is called the TOE model, which is a transversal conceptual research model proposed by [10]. This theoretical model has been widely used in information systems to study the influences of technological, organizational and environmental contexts on SMEs' decision-making. Therefore, the TOE model can help explore the effects of current digital technologies and the environment on the diversification of SMEs' activities.

A previous study by [8] extended TAM in project communications and training and shared beliefs. Their findings suggest that training and communication in project communication influence TAM since perceived usefulness and perceived ease of use contribute to behavioral intention to use the technology. This leads to the impact of project management on the perceived ease of implementation. The author in [73] suggested successful business process change, user support and involvement, and vendors' expertise as critical success factors in ERP projects. The authors in [64] as well as [120] suggested that managing organizational change is critical for successful IT project implementation. The authors in [6] and [19] concluded that knowledge sharing enables a project team to reduce rework and compresses the time it takes to plan projects. They also stated that having the "right knowledge" to the "right person(s)" at the "right time" allows for greater control over the project throughout the project's lifecycle by reducing uncertainty. Therefore, the project management is driven by the change management and knowledge sharing in companies.

The mediation effect test was also employed in the current study. This study has found that perceived usefulness of BIS doesn't mediate the relationship between facilitating conditions and BIS adoption, perceived ease of adoption of BIS doesn't mediate the relationship between facilitating conditions and BIS adoption, while perceived ease of adoption of BIS mediates the relationship between social influence and BIS adoption with beta = 0.349, T-value = 8.636, and P-value = 0.000. Perceived ease of adoption of BIS mediates the relationship between information quality and BIS adoption with beta = 0.281, T-value = 4.984, and P-value = 0.000. The perceived usefulness of BIS doesn't mediate the relationship between information quality and BIS adoption. Meanwhile, perceived usefulness of BIS doesn't mediate the relationship between social influence and BIS adoption.

These results differed from those of the results of previous studies, where several previous studies investigated factors that led to the implementation of BIS. These factors were varied due to the type of industry within the SME business environment; the study of [50] developed a conceptual model. The model suggested by [50] was developed based on three levels of order that led to the implementation. The first order level comprises five factors: quality of information, system performance, user information, user training, and top management support. In brief, this level stands on information, users, and management. While the second level order comprises three factors which are subjective norm, perceived usefulness, and perceived ease of use, which resulted from the first order level factors, as these factors are supported by the theoretical debate of the technology acceptance model.

[81, 49] found significant mediation of the perceived ease of implementation of BIS between information quality and BIS implementation. Also, [81, 38, 49] found significant mediation of the perceived ease of implementation of BIS between IT project management and the BIS implementation

IV. CONCLUSION

In conclusion, this study explored the impact of various factors, including facilitating conditions, information quality, perceived ease of adoption of Business Intelligence Systems (BIS), perceived usefulness of BIS, and social influence, on the adoption of BISs in Libyan Small and Medium Enterprises (SMEs). The findings of this study indicated that these factors play a significant role in influencing the adoption of BIS in Libyan SMEs. Facilitating conditions, such as the availability of necessary resources and supportive infrastructure, positively influenced BIS adoption. Furthermore, the quality of information was identified as an essential factor affecting the adoption process. The perceived ease of adoption of BIS and its perceived usefulness are important factors influencing the decision to adopt BIS in Libyan SMEs. The study also identified social influence, such as the influence of peers and industry experts, as a factor that can shape the adoption behavior of SMEs.

These findings provide valuable insights for Libyan SMEs and policymakers looking to enhance the adoption of BIS. Recognizing the importance of creating facilitating conditions by providing necessary resources and supportive infrastructure can facilitate successful BIS adoption. Improving information quality is crucial to enable SMEs to harness the full potential of BIS. Emphasizing the ease of adoption and highlighting the usefulness of BIS can also positively influence the decision-making process. Lastly, acknowledging the influence of social factors and leveraging peer networks and industry experts can help in promoting BIS adoption among Libyan SMEs. By considering and addressing these factors, Libyan SMEs can enhance their competitiveness, decision-making capabilities, and overall operational efficiency through the successful adoption and utilization of BISs.

The current research recommends performing a comparative analysis between different types of SMEs in Libya to explore variations in the impact of the identified factors on BIS adoption. This study can investigate whether factors differ based on industry sector, company size, or geographical location and how these variations influence the adoption of BIS in SMEs.

A. Contribution to Academic Literature

The current study contributes to academic literature in the area of the development of a new, customized model for BISs adoption in SMEs operating in politically unstable environments like Libya. The model integrates both social and technological perspectives, which is a novel approach in this research domain. Our study further extends the Technology Acceptance Model (TAM) and UTAUT Theory by incorporating unique factors such as "Change Management", "IT Project Management", "Social Influence", and "Information Quality", specifically tailored for developing economies. Additionally, we utilize Structural Equation Modeling (SEM) to validate and explore relationships among various determinants of BIS adoption, thereby enhancing methodological rigor. This was made possible by providing a comprehensive conceptual framework linking technological, psychological, and organizational factors, which future researchers can build upon in similar contexts. These become an academic novelty when addressing BIS adoption within conflict-affected environments and serve as a significantly underexplored context in existing literature.

B. Contribution to Industry

The current study delivers a practical and implementable model to help SME managers effectively adopt BIS in alignment with their operational and technological constraints. The model is designed to fit the limited capabilities and resources typical of SMEs in Libya, making it a relevant tool for improving operational efficiency and informed decision-making. Our study further emphasizes the critical role of user perceptions (perceived ease and usefulness) in BIS adoption, guiding companies to develop more effective training and awareness programs for staff. Additionally, the present study offers practical guidance on enhancing information quality and knowledge-sharing practices, enabling SMEs to gain a competitive edge. All these industrial contributions are distinctive in that the solutions are custom-built for Libya's context, rather than adopting generalized models from developed countries.

C. Contributing to Policy

The present study supports policymakers in promoting digital transformation policies by encouraging BIS adoption among SMEs, based on concrete evidence provided in the research. The findings can guide public support programs for financing, training, and technical assistance tailored towards priority sectors. Our study can also be used to reinforce the importance of data-driven governance frameworks, using BIS to generate actionable performance metrics across industries. Advocates for government action to tackle infrastructure gaps, cultural barriers, and skills shortages, which were identified as major obstacles to effective BIS implementation. This can serve as a novel policy orientation for BIS adoption model grounded in the area of data from Libya, offering a clear roadmap for strategic public interventions.

V. Limitations of the Study

It is essential to acknowledge the limitations of the current study. The current research is limited to the following:

A. Sample Size and Representativeness

The study had a limited sample size, which restricted the generalizability of the findings. The findings may not reflect the perspectives and experiences of all Libyan SMEs. A larger and more diverse sample could provide a more comprehensive understanding of the adoption factors of BI systems in Libyan SMEs.

B. Data Collection Method

The study's findings are dependent on the data collection method employed, which is a survey. The limitations inherent in the chosen method, such as response bias or limited depth of information, might impact the study's outcomes. Using multiple data collection methods or employing a mixed-methods approach could enhance the robustness of the study.

C. Self-reporting Bias

The study was subject to self-reporting bias, as participants provided responses they perceived as socially desirable or were influenced by their own perceptions and biases. This bias could affect the accuracy and reliability of the data collected. Employing validation techniques or triangulating data from multiple sources helped mitigate this bias.

D. Timeframe and Context

The study's findings were time and context-specific, reflecting the conditions and circumstances prevalent during the study period. As technology and business environments evolve rapidly, the adoption factors of BI systems in Libyan SMEs might change over time. Therefore, the study's findings were interpreted within the specific timeframe and context in which they were conducted.

E. Causality and Correlation

The study established correlations between adoption factors and BI system adoption, but it did not establish a causal relationship. Other unmeasured or omitted variables could influence the relationship between adoption factors and BI adoption. Longitudinal studies or experimental designs could provide stronger evidence of causal relationships. Acknowledging these limitations is crucial in understanding the scope and applicability of the study's findings. Future research can address these limitations by expanding the sample size, utilizing diverse data collection methods, considering broader contextual factors, validating data through multiple sources, conducting longitudinal studies, and employing experimental designs to establish causality

***Abstract*—Byzantine Fault Tolerance (BFT) is a class of fault-tolerance techniques in the field of distributed computing. Aiming at the risks of error-prone and tampering data brought by the centralized database in the traditional supply chain traceability process, the use of the BFT consensus algorithm in combination with the alliance blockchain can be used to solve the security problems such as data deletion, data misuse, application attacks, and efficiency reduction in the storage process of supply chain traceability data. This will be the future trend of safe and orderly storage and management of supply chain traceability data.**

***Keywords*—Tendermint; BFT; consensus; consortium blockchain; traceability data for supply chain**

I. Introduction

Tendermint began in early 2014 as an improved Byzantine Fault Tolerance (BFT), born out of the open-source realization that while the PoW was secure in the network of BTC, it had serious shortcomings in terms of speed and scalability [1-5]. BFT is designed to handle these abnormal behaviors and to meet the specification requirements of the problem to be solved. Tendermint is a secure state machine replication algorithm in the blockchain paradigm, in the form of BFT-ABC with additional accountability to facilitate verification of Byzantine node dishonesty [6,7]. The core of Tendermint runs on all nodes and handles consensus, P2P networking, blockchain storage and interaction with the outside via RPC functions. Each Tendermint core can talk to a custom blockchain application, a separate process, through a network socket protocol called TMSP [8].

A. Consensuses

Consensus is used to solve the problem of consistency in distributed systems and is centered on making a specified operation consistent, recognized, and tamper-proof across a distributed network for a limited period of time, guaranteed by some protocol. In blockchain systems, specific consensus is used to solve the problem of decentralized multi-party mutual trust, while each node must make its own ledger consistent with that of other nodes. And in a centralized world, this is almost impossible due to the presence of a centralized server. Currently, the more common consensuses in blockchain are PoW, PoS, DPoS, Raft, Ripple, PBFT, etc. [9, 10].

B. PoW (Proof of Work)

Most public chains or digital virtual currencies, such as BTC, ETH, ETC, etc. use PoW for implementing their consensus mechanism, which determines the distribution of the currency based on the effective work contributed by mining [11, 12]. The consistency problem of decentralized bookkeeping systems is solved in the network of BTC by competing for bookkeeping, i.e. competing for bookkeeping rights through hashrate [13, 14]. ETH, hashrate is no longer handled by mere CPUs, and it is now common to use GPUs, FPGAs and ASICs for mining, which directly leads to the gradual centralization of hashrate. From a long-term development perspective, PoW runs counter to decentralization, and the security of blockchain networks is threatened [15, 16].

C. PoS (Proof of Stake)

In [17, 18], PoS is similar to property being stored in a bank, and this model allocates interest to the holder based on the amount and length of time the holder has held the digital currency. Peercoin is the first digital cryptocurrency to use proof-of-stake, which introduces the concept of coin-age in terms of the difficulty of the hash operation of SHA256, making the difficulty inversely proportional to the coin-age of the transaction input. While PoS takes into account the shortcomings of PoW, it is based on the fact that equity balances can lead to greater power in the richest accounts and potentially dominate bookkeeping rights. POS also has the following four potential problems: Nothing at Stake Problem, Initial Distribution Problem, Long-Range Attack and Coin Age Accumulation Attack.

D. DPoS (Delegated Proof of Stake)

In [19, 20] The emergence of DPoS addresses some of the shortcomings in PoW and PoS. Bitshare is a class of digital cryptocurrencies using the DPoS mechanism, which expects to reduce the negative effects of centralization by introducing a technical democratic layer. The risk of DPOS is that there are many difficulties in dealing with faulty nodes, and community elections cannot effectively stop some sabotage nodes in time, creating a security risk for the network. At the same time, if the elected super node does not have strong computing power to protect itself, it is easy to be attacked by DDOS, which will seriously affect the network stability.

E. Raft

In distributed scenarios where the assumptions are made that the conditions do not require Byzantine nodes to be considered, but only deal with general dead failures, it is generally more efficient to use a protocol, such as Paxos [21, 22]. Compared to Paxos, Raft has essentially the same operational efficiency, but

*Corresponding author.

is easier to understand and more likely to be used in system development. Although Raft is a very efficient consensus algorithm, it can only support CFT (Crash Fault Tolerance), which only allows nodes in the system to crash, and does not consider malicious nodes in the system, so Raft is only applicable to Private Blockchain.

F. Ripple

In [23-26], Ripple is an Internet-based open-source payment protocol that enables decentralized cryptographic digital currency exchange, payment and clearing functions. In the network of Ripple, transactions are initiated by the client and are broadcast throughout the network via tracking nodes or validating nodes. Ripple is more efficient than anonymous consensuses such as PoW, with transactions taking only a few seconds to confirm. However, this advantage also dictates that this consensus is only suitable for use in Permissioned Chains. Ripple has a BFT capability of (n-1)/5, which can tolerate Byzantine errors in 20% of the nodes in the entire network without affecting the correct consensus. Compared to BFT, Ripple tolerates a low percentage of Byzantine nodes.

G. PBFT (Practical Byzantine Fault Tolerance)

In Consortium Blockchain, most of them use consensuses such as PBFT, Raft, Paxos, etc. This type of consensus is a strong consistency algorithm and has a huge advantage in consensus speed. PBFT is a more mature and widely used consensus, and is a widely used message-passing based consistency algorithm. First, PBFT overcomes the inefficiency of the original BFT and enhances the operability in practical applications of distributed systems. Second, compared to PoW and PoS, which are often used in Public blockchain, PBFT does not require nodes to consume hashrate to solve the meaningless proof-of-work problem and thus obtain the right to bookkeeping. Therefore, a blockchain system using PBFT as the consensus algorithm can effectively avoid the problem of monetary security caused by issuing digital currency, and avoid the high latency, low throughput, and meaningless consumption of hashrate in the consensus process.

PBFT addresses the problem of exponential increase of algorithm complexity with increasing nodes in BFT, and optimizes it to reduce the complexity of the algorithm from exponential level to polynomial level, making it possible to apply Byzantine protocol in distributed systems. PBFT solves the problem of inefficiency of the original Byzantine fault-tolerant algorithm and is applied to transactions performed in the presence of trust between parties. Fault tolerance means that with the use of this consensus algorithm, the entire coalition chain network can accommodate a certain number of Byzantine nodes and allow them not to affect the proper reaching of the consensus. PBFT can tolerate Byzantine errors in a third of the nodes in the entire network without affecting the correct consensus. PBFT is a Byzantine fault-tolerant state machine replication that uses one or more rounds of voting to obtain a majority consensus, and its flowchart is shown in Fig. 1, we can see that the innovation of PBFT lies in the design of three-stage voting, which is divided into three stages, namely Pre-prepare, Prepare, and Commit. 0, 1, 2, 3 represent the number of the node respectively, where 0 is the primary node primary, 3 represents the Byzantine node, where the behavior of the performance is no response to the requests of other nodes.

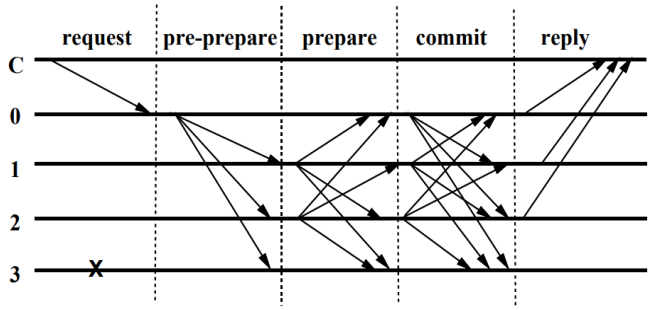

Fig. 1. Flow chart of PBFT.

At the same time, we can also see from Fig. 1 that PBFT requires three rounds of voting to achieve the consensus of the whole distributed system, but in the actual use of Consortium Blockchain, when the number of participating nodes is too many, the existence of the three-round voting mechanism makes the communication complexity still too high, which leads to a very rapid decline in the performance of the whole network, and the network latency also becomes high or even timeout.

II. TENDERMINT

A. Overview

Tendermint belongs to the BFT mechanism, an easy-to-understand and easy-to-implement State Machine Replication, which is based on the assumption of a semi-synchronous network that can tolerate 1/3 of Byzantine nodes with guaranteed Liveness and Safety. Tendermint is a Round-Based protocol that has been further optimized for PBFT. Compared to traditional PBFT, Tendermint ideally requires only two rounds of voting to reach consensus, which ensures that the entire network can reach consensus in a secure and reliable manner.

Tendermint is characterized by the following seven points:

1) Byzantine fault-tolerant: Tendermint tolerates up to 1/3 of your machines failing arbitrarily. This includes explicitly malicious behavior.

2) State machine replication: Tendermint can replicate deterministic state machines written in any programming language.

3) Ultimate certainty: Once all nodes reach consensus, Tendermint will not fail at some point in the future like the consensus of BTC or ETH, so there will be no blockchain fork in Tendermint.

4) Secure P2P: Gossip protocols and peer discovery are secured via Tendermint's authenticated encryption system.

5) Lightning fast: By avoiding POW consensus, Tendermint can achieve very high transaction throughput. With ideal application data structure support, 42,000 transactions per second can be achieved. Tendermint supports thousands of transactions per second.

6) Easy to deploy: Use mintnet to deploy your app to any cloud provider supported by docker-machine.

7) 100% Open source: All Tendermint's source code is licensed under Apache 2.0.

B. Workflow

In the network of Consortium Blockchain based on BFP, nodes in the network can reach consensus when there are no more than 1/3 of the total number of Byzantine nodes. Tendermint is an easy-to-understand BFT consensus protocol that follows a simple state machine with the workflow diagram shown in Fig. 2.

In Fig. 2, there are two roles in Tendermint: Validator and Proposer. Validator is a role or node in the protocol, and different validators have different Vote Power in the voting process. The Proposer is elected by the Validator on a rotating basis, who takes turns proposing blocks for transactions and voting on proposed blocks. Blocks are committed to the chain and each block is a block height. However, it is possible for a block to fail to be submitted, in which case the protocol will select the next Proposer to propose a new block at the same height and restart the poll.

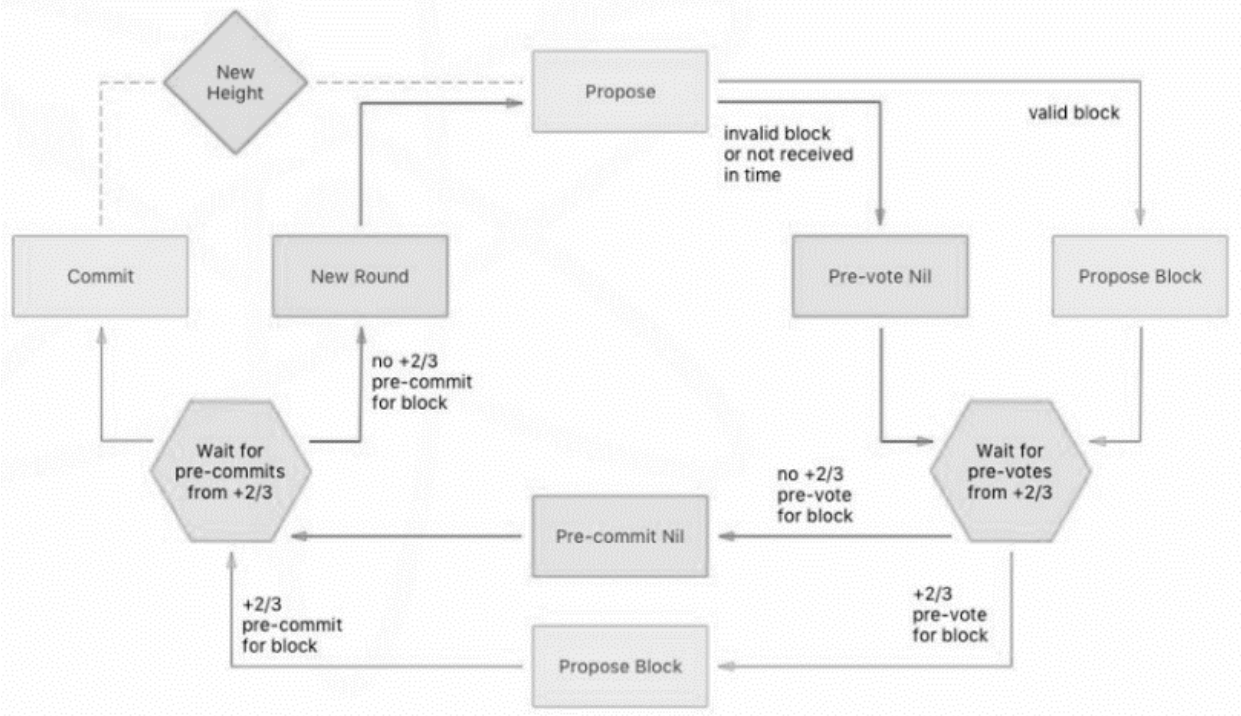

Fig. 2. Flow chart of Tendermint.

If a block needs to be successfully submitted, it must go through two stages of voting, called Pre-vote and Pre-commit. A block is committed only when more than 2/3 of Validators have Pre-committed votes on the same block in the same round of proposals. Proposers may fail to propose blocks due to reasons such as offline or network latency. This situation is also allowed in Tendermint, as Proposers will wait for a certain amount of time before moving to the next round of offers for receiving blocks proposed by Proposers.

If less than one-third of Validators are Byzantine nodes, Tendermint can guarantee that Validators will never commit blocks repeatedly at the same height and cause conflicts. To do this, Tendermint introduces a locking mechanism where once Validators have pre-polled a block, then that Validator will be locked to that block. If the block is not successfully submitted in the current round of pre-proposals and pre-votes, the Validator is unlocked and the next round of pre-submissions for the new block is performed.

C. Comparison Between Tendermint and PBFT

As can be seen from the workflow of both, Tendermint is more like an upgraded and optimized version of PBFT, and the similarities and differences between the two are as follows.

1) Similarities

- Both belong to the BFT system.
- All are resistant to 1/3 Byzantine node attacks.
- Three-stage submission, with the first stage broadcasting transactions (blocks) and the last two stages broadcasting signatures (confirmations).
- Both require a quorum to submit a block.

2) Differences

- The difference between Tendermint and PBFT is mainly that the two make different judgments when more than 1/3 of the Byzantine nodes are network-wide nodes. PBFT can't provide guarantees when the number of Byzantine nodes is between 1/3 and 2/3 of the number of Validators, allowing the attacker to return arbitrary results to the client. And Tendermint considers that more than 2/3 number of pre-commit acknowledgements are required to commit a block. For example, if 1/2 of the Validators are Byzantine nodes, in Tendermint these Byzantine nodes can block the submission of blocks, but

they themselves cannot submit malicious blocks, but in PBFT Byzantine nodes are able to submit malicious blocks to the client.

- In the Byzantine node concept, PBFT refers to the number of nodes, while Tendermint represents the number of interests, or voting power, of the nodes.
- While PBFT requires a pre-defined set of Validators for the validation process, Tendermint supports dynamic changes in Validators by requiring more than 2/3 of the quorum of validators to approve membership changes.

III. Consensus Performance in Traceability Data for Supply Chain Based on Tendermint and PBFT

A. Problems of Current Supply Chain Traceability Data

In response to the problems such as serious centralization, easily tampered information and opaque information in the process of traceability of supply chain data, Consortium Blockchain can be used to realize the safe and effective storage of traceability data. Although PBFT is currently more widely used in federated chains, the theoretical comparison in Chapter 3 shows that using Tendermint is superior to PBFT in terms of performance and speed.

B. Experimental Environment Setup and Preparation

The experimental part of this paper runs on the node1 in Supercomputing Center, University of Sanya, which has 20 Intel(R) Xeon(R) Silver 4114 CPUs @ 2.20GHz, 128G of RAM, and 436T of hard disk. The operating system is CentOS Linux release 7.6.2009, and the Fabric-Consortium Blockchain is built by deploying k8s Master node and multiple k8s nodes with docker, where each k8s node represents a Consortium Blockchain deployment node. Since Fabric adopts a loosely coupled design, the components such as Consensus and identity verification are modularized to make it easy to select the corresponding modules according to the application scenarios during the application process. Therefore, Tendermint and PBFT will be used to test the consensus performance of supply chain data for comparison throughout the system respectively. During the test, the following five performance indicators were examined.

- Fail Rate: Percentage of operation failures (including timeouts)
- Avg Latency: Average time taken to complete a transaction
- Query Throughput: Query requests per second
- Consensus Throughput: Consensus requests per second
- Consistency Throughput: Synchronous operations per second

C. Results Without Byzantine Failures

PBFT was used to test the traceability data for supply chain, and the indicators are shown in Table I.

Tendermint was used to test the traceability data for supply chain, and the indicators are shown in Table II.

TABLE I. Table of Indicators Using PBFT

Serial Number	Test Contents	Data Quantity	Fail Rate	Avg Latency	Query Throughput	Consensus Throughput	Consistency Throughput
1	Supply Chain	1000	0	5.9s	948.3tps	577tps	525tps
2	Supply Chain	2000	0	15.24s	1874.2tps	570ps	530tps
3	Supply Chain	5000	0	42.09	4879.32tps	576tps	504tps

TABLE II. Table of Indicators Using Tendermint

Serial Number	Test Contents	Data Quantity	Fail Rate	Avg Latency	Query Throughput	Consensus Throughput	Consistency Throughput
1	Supply Chain	1000	0	1.32s	986.7tps	993tps	984tps
2	Supply Chain	2000	0	2.24s	1987.2tps	1991ps	1797tps
3	Supply Chain	5000	0	4.19s	4983.32tps	4985tps	1877tps

As we can see from Table III, after switching to Tendermint, the Consensus Throughput can reach up to 5000tps and the Consistency Throughput is close to 1900tps. At the same time, the average latency of Tendermint is also significantly reduced compared to PBFT. Such write performance is comparable to that of a traditional single-node relational database, and can satisfy most commercial scenarios.

From the data in we can see that the average latency of the algorithm is significantly lower than that of the PBFT consensus algorithm due to the further optimization of the algorithm and the reduction of the number of voting rounds of Tendermint, which reduces the complexity of the whole algorithm, and the comparison of the two latencies is shown in Fig. 3.

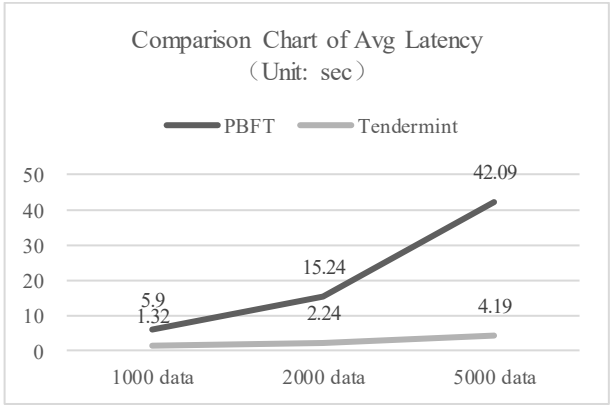

Fig. 3. Comparison chart of average latency.

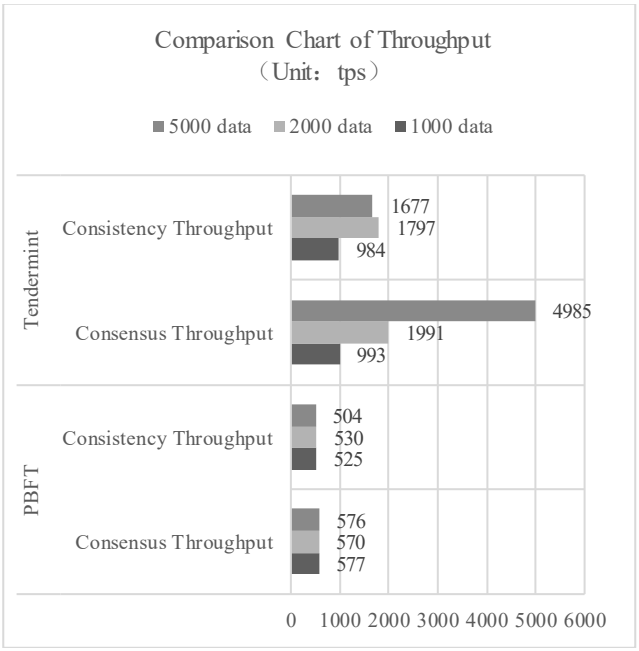
For the efficiency of the two consensuses, the most critical metrics to examine are Query Throughput, Consensus Throughput, and Consistency Throughput. performance metrics comparison graph is shown in Fig. 4. From the figure, we can see that due to the adoption of the optimization algorithm, the data throughput of the whole model has been improved to some extent after using Tendermint, especially Consensus Throughput and Consistency Throughput, which are improved to a larger extent.



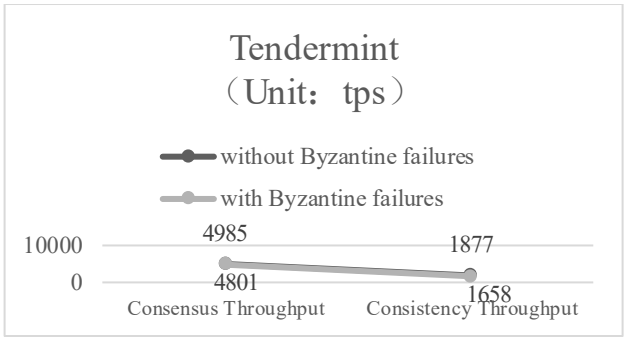


Fig. 4. Comparison chart of throughput.

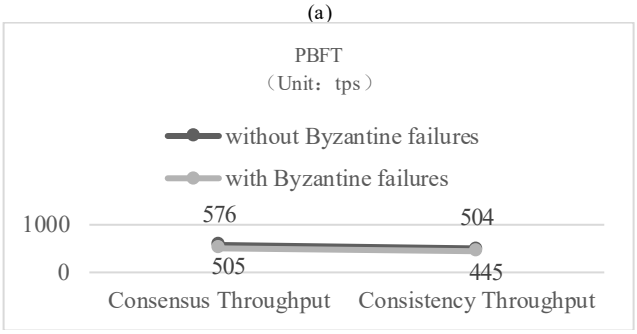

D. Results with Byzantine Failures

Despite the injected Byzantine faults, which would cause many systems to fail completely and immediately, Tendermint maintains respectable latencies. When processing more data and there are more Byzantine failures, Tendermint has lower latency and higher throughput than PBFT due to partial optimization in the voting node. The consensus performance of Tendermint and PBFT when processing 5000 produce traceability data and there are 30% Byzantine failures is shown in Table III.

As can be seen in Table III, with more traceability data and a higher percentage of Byzantine failures, Tendermint has a low performance loss of about 2%-4%, still maintaining a low Avg Latency and a high throughput. However, PBFT has a high-performance loss and excessive latency, which is shown in Fig. 5(a) and Fig. 5(b).

(a)

(b)

Fig. 5. (a) Core performance metrics comparison chart of Tendermint, (b) Core performance metrics comparison chart of PBFT.

TABLE III. CONSENSUS PERFORMANCE PARAMETERS WITH 30% BYZANTINE FAILURES

	Fail Rate	Avg Latency	Query Throughput	Consensus Throughput	Consistency Throughput
Tendermint	0%	5.38s	4791.9tps	4801tps	1658tps
PBFT	0%	50.56s	4364.63tps	505tps	445tps

IV. CONCLUSION

We introduced Tendermint, an improved blockchain consensus protocol based on BFT. Tendermint optimizes the election and voting sessions on the basis of PBFT and reduces the complexity so that it can have lower latency and better data throughput in the consensus process and is more excellent in resisting attacks with no more than 1/3 of Byzantine failures. In the experimental session, Tendermint outperforms PBFT.

FUNDING

This work is supported by Hainan Province Key R&D Program Project (Grant ZDYF2023GXJS007) and University of Sanya Major Special Projects (USY22XK-04). Meanwhile, the experimental part in this paper have been done on the supercomputing system in the Supercomputing Center, University of Sanya.

CONFLICT OF INTEREST

The authors declare that they have no conflicts of interest regarding this work.

DATA AVAILABILITY

All data generated or analyzed during this study are included in the manuscript.

AUTHORS' PROFILE

Zhiyong Liang holds a master's degree and is a senior laboratory engineer. He currently serves as the Deputy Director of the Computer Center at University of Sanya. His main research interests include blockchain technology and network information security. He has undertaken two research projects, published eight academic papers, authored three textbooks, and applied for four software copyrights.

Rongwang Jiang holds a master's degree and is an associate professor with a background in computer science. He possesses both solid theoretical knowledge and extensive practical experience. He has led provincial-level natural science foundation projects and educational reform initiatives funded by the provincial education department, and has published multiple core journal papers, achieving notable research outcomes. At University of Sanya, he serves as the Deputy Director of the Computer Teaching Department, where he promotes teaching innovation and has guided students to win third prize in the national finals of the China Computer Design Competition, demonstrating strength in both teaching and research.

Ming Yang received the B.S. degree in computer software from Shandong University, China, the M.S. degree in computer applications from the Nanjing Institute of Communication Engineering, China, and the Ph.D. in communication and information systems from PLA University of Science and Technology, China, in 1989, 1995, and 2000, respectively. His research interest includes information security and privacy protection.

Boxiong Yang is a Professor at the University of Sanya, China. He received the B.S. degree in Computer Software from Huazhong Normal University, China, the M.S. degree in Geophysics from the Institute of Seismology, Seismological Bureau, China, and the Ph.D. in Geophysics from the Institute of Geophysics, China Seismological Bureau in 1997, 2000, and 2005, respectively. His area of research interest includes Photogrammetry, Computer Vision, and Artificial Intelligence.
