2) Post-test result analysis: The paired t-test was performed to analyze the waiting waste generation for "Group I" and "Group II" in the post-test. The subjects were provided the post-test in which "Group I" was not offered with MCR-KSM and "Group II" was provided with MCR-KSM. Table VI shows the stats of the paired t-test for "Group I" and "Group II" for variables "Author Waiting Time", "Reviewer Waiting Time", and "Total Waiting time".

The stats of paired t-test exhibited that there was a noteworthy variance between "Group I" and "Group II". The mean values for Author Waiting Time "Group I, mean = 41.7143, standard deviation = 6.52468. Group II, mean = 24.5714, standard deviation = 4.96176". Reviewer Waiting Time "Group I, mean = 27.0571, standard deviation = 7.12808 Group II, mean = 14.2857, standard deviation = 2.28869" and Total Waiting Time "Group I, mean = 69.5714, standard deviation = 9.64118 Group II, mean = 38.8571, standard deviation = 6.17599" exhibited a noteworthy difference in waiting waste generation for both the groups.

TABLE VI WAITING WASTE ANALYSIS POST-TEST – EXPERIMENT SESSION II

Group ID	Variables	Mean	N	t	Sig. (2-tailed)
Group I	Author Waiting Time (AWT)	41.7143	7	8.216	0.000
Group II		24.5714	7		
Group I	Reviewer Waiting Time (RWT)	27.0571	7	4.058	0.007
Group II		14.2857	7		
Group I	Total Waiting Time (TWT)	69.5714	7	7.223	0.000
Group II		38.85	7		

Therefore, it was analysed that there was a noteworthy difference regarding waiting waste generation "Author Waiting Time, Reviewer Waiting Time, and Total Waiting Time" amongst "Group I" and "Group II". The p-value (sig, (2-tailed)) was (p<0.05) for author waiting time (p=0.00), reviewer waiting time (p=0.007), and total waiting time (p=0.000). The p value i.e. p<0.05 it infers that the null hypothesis "There is no difference in the waiting waste generation in the modern code review process with or without using Modern Code Review Knowledge Sharing Model" was rejected and there was a noteworthy difference between author waiting time, reviewer waiting time, and total waiting time of "Group I" and "Group II". The positives t values for Author Waiting Time (t=8.216), Reviewer Waiting Time (t=4.058), and Total Waiting Time (t=7.223) indicate that the Modern Code Review Knowledge Sharing Model (MCR-KSM) reduces the author waiting time, reviewer waiting time, and total waiting time. From the paired t-test results it was obvious that that there was a noteworthy decrease in waiting waste generation when participants considered the MCR-KSM.

The waiting time of the "Group II" author was less when they performed MCR activities while using MCR-KSM (mean = 24.5714, standard deviation = 4.96176) as compared to "Group I" author who did not use MCR-KSM (mean = 41.7143, standard deviation = 6.52468). Measure of 2-tailed t-test found this difference to be noteworthy, t (7) = 8.216, p<0.05. Hence, it was determined that

"The author waiting time was reduced with the use of modern code review knowledge sharing model".

Fig. 2 shows the comparative view of Author Waiting Time with and without using MCR-KSM during Post-test session. It clearly shows that when code review was performed using MCR-KSM the average Authors Waiting Time (AWT) was significantly less, i.e. 24.5 (min) as compared to code review activities when performed without using MCR-KSM where average AWT was 41.7 (min).

Likewise, waiting time of the "Group II" reviewer was less when they performed MCR activities while using MCR-KSM (mean = 27.0571, standard deviation = 7.12808) as compared to "Group I" who did not MCR-KSM (mean = 14.2857, standard deviation = 2.28869). The measure of 2-tailed t-test

found this difference to be significant, t (7) = 4.058, p<0.05. Hence, it was determined that

"The reviewer waiting time was reduced with the use of modern code review knowledge sharing model".

Fig. 3 shows the comparative view of Reviewer Waiting Time with and without using MCR-KSM during Post-test session. It evidently shows that when code review was performed using MCR-KSM the average Reviewer Waiting Time (RWT) was significantly less, i.e. 14.2 (min) as compared to code review activities when performed without using MCR-KSM where average RWT was 27.0 (min).

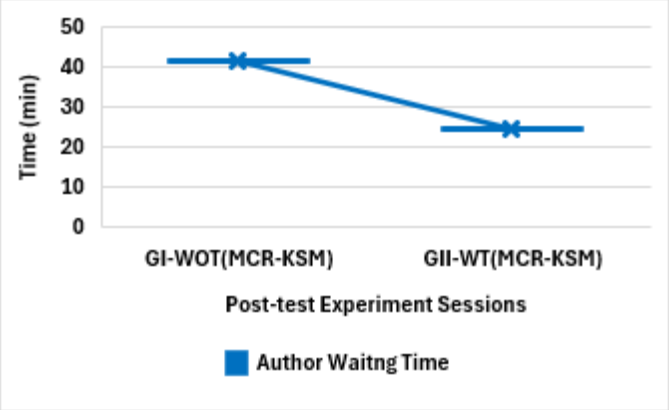

Fig. 2. Comparative view of author waiting time (AWT)-post-test.

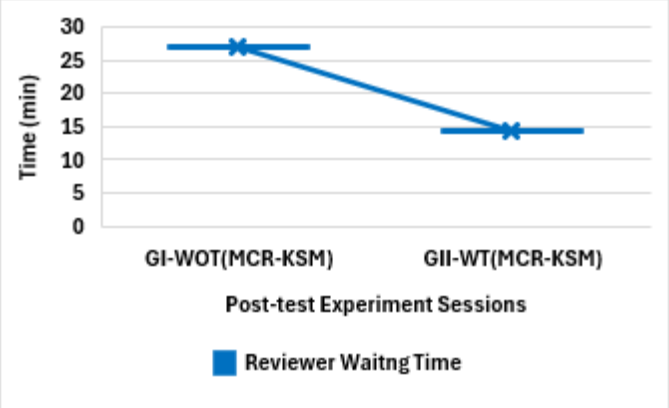

Fig. 3. Comparative view of reviewer waiting time (RWT)-post-test.

Equally, total waiting time was less for "Group II" when the subjects performed MCR activities while using MCR-KSM (mean = 38.8571, standard deviation = 6.17599) as compared "Group I" to when they did not use the MCR-KSM (mean = 69.5714, standard deviation = 9.64118). The measure of 2-tailed t-test found this difference to be noteworthy, t (7) = 7.223, p<0.05. Therefore, it was determined that

"the total waiting time was reduced with the use of modern code review knowledge sharing model".

Fig. 4 shows the comparative view of Total Waiting Time with and without using MCR-KSM during Post-test session. It clearly shows that when code review was performed using MCR-KSM the average Total Waiting Time (TWT) was significantly less i.e.38.8 (min) as compared to code review activities when performed without using MCR-KSM where average TWT was 69.5 (min).

Based on the independent results of dependent variable "Author Waiting Time", "Reviewer Waiting Time", and "Total Waiting Time", it was determined that there was a noteworthy variance in the waiting waste generation with and without the support of the MCR-KSM, so the null hypothesis, H0, i.e. "There is no difference in the waiting waste generation in the modern code review process with or without using Modern Code Review Knowledge Sharing Model" was rejected. The paired sample t-test results supported the alternate hypothesis, H1, i.e.

"The waiting waste generation in MCR using MCR-KSM is lower than without using MCR-KSM.".

The alternate hypothesis H_2 given in Table II was not supported by the paired sample t-test.

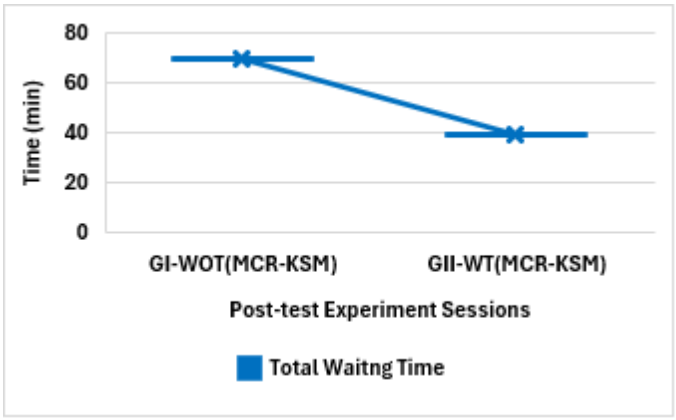

Fig. 4. Comparative view of waiting waste generation-post-test.

VII. Conclusion

MCR is a quality assurance activity, though it is supported with AI and LLM, but it generates various wastes such as rework, defect waste, composite solution waste and waiting waste, etc. Waiting waste is the critical one that causes mental distress. Reducing waiting waste is crucial for sustainable software engineering. The Knowledge exchange has a profound role in the reduction of waiting waste production during code reviews. To reduce waiting waste, our previous study introduced the Modern Code Review Knowledge Sharing Model (MCR-KSM). This study presented empirical results to evaluate the effectiveness of MCR-KSM for the reduction in waste generation during the MCR process. The waiting waste was calculated based on variables, i.e. "Author Waiting Time" and "Reviewer Waiting Time". The study results show that there was a significant reduction in the authors, reviewers and total waiting time when they considered the Modern Code Review Knowledge Sharing Model.

VIII. Limitations

To conduct the study, it was hard to gather dedicated respondents. Twenty-eight graduate students with software engineering experience and knowledge of MCR, software engineering wastes, took part in the experiment. The results might be more confident if more students contributed to the experiment. Nevertheless, despite the limitations, we believe that the results have educational and practical implications.

IX. Future Work Opportunities

The experiment can be augmented in future with varying settings. In future, it is planned to evaluate the significance of MCR-KSM in the actual industry environment. Likewise, more experiments can be conducted to check whether the developed model can reduce other waste, such as defect waste and motion waste, negative emotion waste, etc. and emotional intelligence. Moreover, innovation in AI, machine learning, and LLM-based code review is evolving, and it is understood that developers' domain knowledge is essential and cannot be ignored. Therefore, solutions combined with AI, machine learning and developers' domain knowledge can be beneficial for the reduction of various types of code review wastes. Moreover, other software engineering activities or computing domains can be explored for waste identification and reduction.

X. Contribution

The research conducted has created the foundation for green and sustainable computing by developing and evaluating the MCR knowledge sharing model to reduce waste. The study contributed to three aspects. Firstly, it confirms that the MCR-KSM supports in reduction of waiting waste production. Secondly, the research article provided a detailed experiment design and conduct procedure that can be beneficial for young researchers to experiment with their respective research field. Thirdly, the research highlighted future research venues that can be beneficial for practitioners and researchers.

***Abstract*—Forecasting food loss with high accuracy is crucial for improving global food security, optimising supply chains, and supporting sustainability goals. However, conventional time series models and standard deep learning techniques, including recurrent neural networks (RNNs), often fall short in handling the irregularity, seasonality, and complexity inherent in food loss data. While Gated Recurrent Units (GRUs) offer advantages over traditional RNNs, such as mitigating vanishing gradients, they still face limitations in modelling long-range dependencies and noisy sequences. This paper reviews recent advancements aimed at overcoming these challenges by enhancing GRU-based models with attention mechanisms and seasonal-trend decomposition using Loess (STL). Evidence from related domains shows that attention mechanisms improve the capture of long-term dependencies and interpretability, while STL decomposition strengthens stability and accuracy by isolating seasonal and trend components. Hybrid GRU models that combine both approaches consistently outperform standalone methods, highlighting their promise for robust and interpretable forecasting. Though underexplored in the context of food loss, this paper identifies the research gap and advocates for domain-specific GRU–attention–STL architectures, offering a foundation for future empirical work to enable timely interventions and foster resilient, data-driven food systems.**

***Keywords*—GRU; food loss forecasting; attention mechanism; seasonal decomposition; STL; loess; time series; deep learning**

I. Introduction

This study tackles the pressing challenge of enhancing GRU-based forecasting for food loss prediction, a task that demands accurate modelling of complex, irregular, and temporally dependent data. Food loss, defined as the measurable reduction in food quantity or quality throughout the supply chain, is not only an economic inefficiency but also a social and environmental concern. Globally, approximately one-third of all food produced—about 1.3 billion tonnes—is lost or wasted every year, representing an estimated USD 1 trillion in direct economic losses and contributing nearly 8–10% of total greenhouse gas emissions [1]. Moreover, about 14% of food is lost between harvest and retail, 32% on food service and more, intensifying the strain on global food systems [2]. These staggering figures highlight the urgency of developing robust forecasting models that can enable timely interventions to minimise loss, improve efficiency, and promote sustainability.

Traditional statistical and deep learning methods have been applied to time series forecasting in various domains, yet they often struggle with the irregularity, seasonality, and noise inherent in food loss data. The shortcomings highlight the need for innovative architectures capable of capturing both fine-grained temporal dynamics and broad structural patterns within food loss datasets, as food loss poses serious implications for food security, economic sustainability [3], and environmental health, necessitating precise, interpretable forecasting models to guide data-driven interventions.

Recent advances in attention mechanisms and decomposition techniques offer promising solutions. Attention mechanisms, such as self-attention, temporal attention, and multi-head attention, dynamically prioritise informative time steps and enhance the interpretability of deep learning models by revealing which patterns contribute most to predictions. At the same time, Seasonal and Trend decomposition using Loess (STL) has proven effective in isolating trend and seasonal components from noisy signals, improving data quality and learning efficiency. However, although advances in deep learning [19], especially RNN-GRU and attention mechanisms, have shown strong potential in time series analysis across various domains [4], the integration of both seasonal-trend decomposition using Loess (STL) and attention in GRU architectures (GRU-attention-STL) for food loss forecasting remain underexplored.

The rationale for this new initiative is therefore twofold: first, to synthesise existing advancements in attention-enhanced GRUs and STL-based decomposition to demonstrate their relevance to food loss forecasting; and second, to advocate for the development of hybrid GRU–attention–STL architectures tailored to the unique challenges of food loss data. Such models are expected to not only boost forecasting accuracy and robustness but also provide interpretable insights into the underlying seasonal and temporal patterns, thereby supporting data-driven decisions in agriculture and supply chain management.

This paper is organised to provide a comprehensive review of recent advancements in GRU-based time series forecasting, with a specific focus on applications relevant to food loss prediction. Section II.A introduces the foundational concepts of GRU models and their role in time series modelling, outlining their structure, strengths, and limitations, particularly in

*Corresponding authors

capturing long-term dependencies and handling complex sequential data. Section II.B explores how attention mechanisms, such as Self-Attention, Bahdanau, Multi-head, Cross-Attention, Dual-Attention, Temporal-Attention and more, have been integrated with GRUs to dynamically prioritise relevant time steps and improve forecasting accuracy in various domains. Section II.C reviews the use of seasonal-trend decomposition using Loess (STL) to preprocess time series data, enabling GRUs to better learn from trend and seasonal patterns by reducing noise and structural complexity. Section III presents the methodological review framework, summarising and comparing existing studies in structured tables based on their use of attention mechanisms and seasonal-trend decomposition using Loess (STL) decomposition, while identifying design patterns, model architectures, and performance outcomes. Section IV discusses the observed relationships across these studies, highlighting how attention mechanisms enhance temporal adaptability and how seasonal-trend decomposition using Loess (STL) supports signal clarity, as well as the synergistic benefits of combining both techniques. Section V outlines key research gaps, emphasising the absence of GRU-attention-STL hybrids in food loss forecasting and posing future research questions around fusion strategies, generalisability, and dataset availability. Finally, Section VI concludes by reaffirming the value of these enhancements for developing more accurate, interpretable, and robust GRU-based forecasting models and encourages future empirical exploration within the food supply chain domain.

II. Literature Review

This section provides an overview of the existing literature related to GRU-based time series forecasting, with a focus on techniques that enhance model performance through attention mechanisms and time series decomposition. These methods have been widely studied and applied across various domains. Their combined application remains underexplored in the context of food loss forecasting. By reviewing key advancements and their outcomes, this literature review aims to highlight the strengths, limitations and potential of these techniques as foundational components for future food loss prediction models.

A. Gated Recurrent Unit in Time Series Forecasting

The GRU [5] is a type of recurrent neural network (RNN) designed for processing sequential data such as time series [6]. While RNNs, Long Short-Term Memory (LSTM) networks [7], and GRUs all model sequential data, they differ in complexity and performance. Standard RNNs often suffer from the vanishing gradient problem, limiting their ability to capture long-term dependencies [8]. LSTMs address this limitation with memory cells and gated mechanisms: input, forget, and output gates that help manage information flow [9]. GRUs, introduced as a simpler alternative to LSTMs, use gating mechanisms as well but with a more compact structure, offering efficient retention of relevant temporal information.

GRUs use only two gates: the update gate, which controls how much past information is retained, and the reset gate, which determines how much past information is forgotten. This streamlined structure enables GRUs to selectively preserve relevant data and discard noise, leading to more efficient learning of sequence patterns. The operations within a GRU cell are defined by equations in (1):

$$z_t = \sigma\,(W_z\,[h_{t-1},\,x_t] + b_z)$$
$$r_t = \sigma\,(W_r\,[h_{t-1},\,x_t] + b_r)$$
$$\widehat{h_t} = tanh(W_{\hat{h}}\,[r_t \circ h_{t-1}, x_t] + b_{\hat{h}})$$
$$h_t = z_t \circ \widehat{h_t} + (1 - z_t) \circ h_{t-1} \quad (1)$$

where z_t and r_t are the update and reset gate vectors respectively at time step t. W's are the learnable weight matrices and the b's are the biases. x_t is the input vector and the h's are the state vectors. $[\cdot,\cdot]$ denotes the concatenation of two vectors into a longer vector. $\tilde{h}_t$ is the candidate output activation while h_t is the updated hidden state or can be said as the final hidden state. $\circ$ denotes element-wise multiplication. For time $t = 0$, the hidden state variable is set to $h_0 = 0$. The update-gate u and reset-gate r, control the flow of information from one time step to another, and thus they are able to capture long-term dependency.

GRUs often match the performance of LSTMs while using fewer parameters and requiring less training time. Their balance of simplicity and effectiveness makes them well-suited for time series forecasting, particularly when short- to medium-term dependencies are key. Fig. 1 illustrates the internal cell structures of RNN, LSTM, and GRU [6].

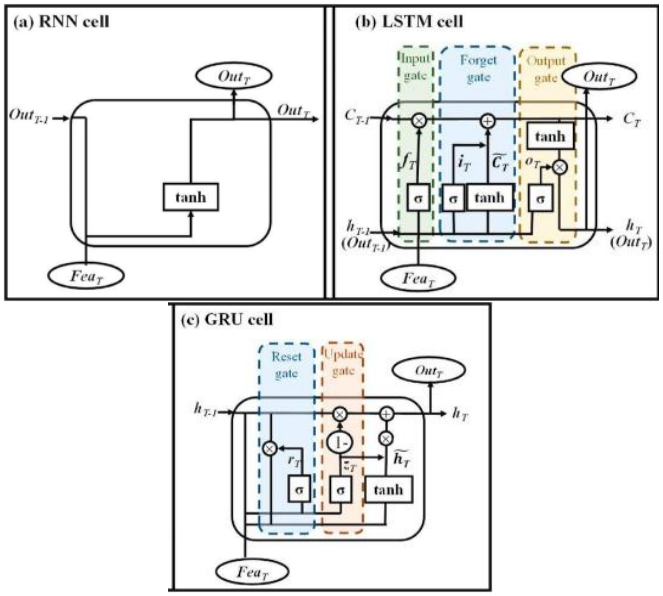

Fig. 1. Internal structure of (a) RNN cell; (b) LSTM cell; (c) GRU cell [6].

GRUs are widely used in time series forecasting for their ability to capture temporal dependencies. They are particularly effective in domains where patterns evolve gradually and depend on past values, such as weather prediction, energy demand, stock markets, and, increasingly, agriculture and food systems.

Fig. 2 shows the unfolded GRU through time [10]. $x_i^{(t)}$ is the input vector at time step vector at time step t. It represents the features or data being fed into the GRU at each time step. $h_i^{(t-1)}$, $h_i^{(t)}$, $h_i^{(t+1)}$, $h_i^{(t+2)}$, and, $h_i^{(t+n)}$ is the hidden state from the previous

time step. Each hidden state captures information from the current input and the previous hidden state. Each box labeled "GRU" processes input x and the previous hidden state h to produce the current hidden state $h_i^{(t)}$.

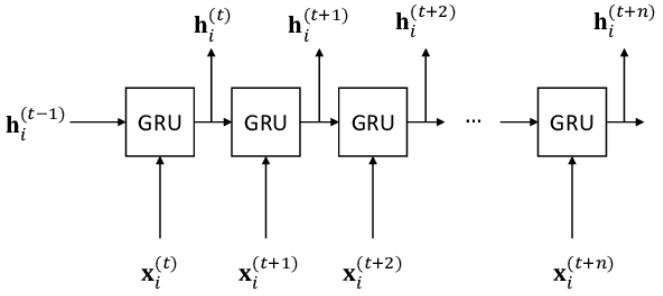

Fig. 2. GRU unfolded through time [10].

GRUs have been applied across various agriculture and food-related forecasting tasks, including crop yield prediction based on environmental data [11], soil moisture estimation [12], food demand forecasting in supply chain [13], spoilage prediction [14], seed trait analysis for protein, oil, and sucrose content [15], and price forecasting of agricultural products [14, 15]. Their ability to handle noisy, nonlinear, and seasonally influenced datasets makes GRUs a valuable tool in agricultural time series modelling.

With fewer parameters and faster training compared to LSTMs, GRUs maintain competitive accuracy [16, 17], particularly for capturing short- to medium-term dependencies, making them suitable for predicting food supply fluctuations and short-term losses. However, GRUs can struggle with highly irregular or seasonal data that require learning long-range dependencies [20]. To address this, recent studies have explored integrating attention mechanisms and time series decomposition to enhance GRU forecasting performance [21].

B. Enhancing GRU with Attention Mechanism

Attention mechanisms significantly enhance sequence learning by allowing models to dynamically focus on the most relevant parts of input sequences. Unlike standard recurrent models that rely on fixed-length context vectors, attention assigns varying weights to different time steps, improving performance on long and complex sequences.

1) Standard attention mechanism: The study [22] introduces a GRU-attention hybrid model for enhancing elastic scaling in container clouds. This model significantly improves prediction accuracy and resource management efficiency in container cloud environments. It effectively handles dynamic loads and reduces operating costs, although further optimisation is needed to control resource oversupply. Fig. 3 shows the prediction curve. Notice that GRU-attention appeared to be more accurate and less error than the GRU-only model.

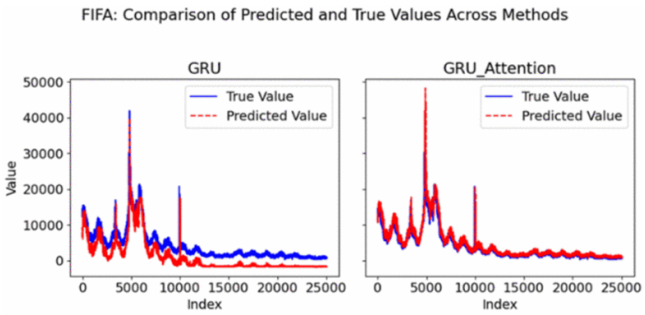

Fig. 3. Comparison of prediction accuracy [22].

To enhance multi-step solar radiation forecasting, Kong et al. [23] used the Kalman Filter [24] for data denoising, and improved input quality. They proposed a hybrid model combining Empirical Mode Decomposition (EMD), GRU, and standard attention mechanisms. Seasonal analysis showed this integration improved accuracy and reduced computational complexity. The structure of the attention-optimised GRU is shown in Fig. 4.

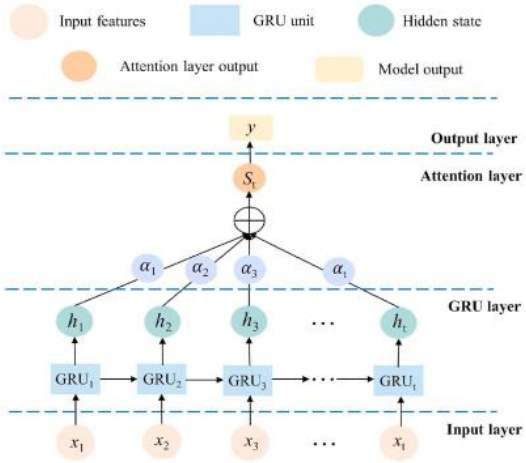

Fig. 4. Architecture diagram of an attention-optimised GRU [23].

2) Cross-attention and multi-scale attention: Cross-attention mechanisms vary in architecture, purpose, and integration. While [23] used standard cross-attention, Farahmand et al. (2025) demonstrate that cross-attention and multi-scale attention in the AttenGluco framework enhance blood glucose forecasting by effectively capturing long-term dependencies, leading to improved prediction accuracy [25]. Zhu et al. [26] also introduced MCI-GRU, a stock prediction model combining multi-head cross-attention with a modified GRU that replaces the reset gate with an attention mechanism to better capture temporal and cross-sectional features.

3) Self-attention and cross-attention: The general formula for the attention is presented in (2):

$$Attention(Q,K,V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (2)$$

where Q, K, V are the concatenation of query, key and value vectors, and d_k is the dimension of the keys, used for scaling. The softmax makes the scores into probabilities that weight the

values V. In self-attention, the query, key and value all come from the same input sequence (3):

$$Q = XW^{Q}, \quad K = XW^{K}, \quad V = XW^{V} \tag{3}$$

where, X is the input sequence. Self-attention is used to let each position in the input sequence attend to other positions in the same sequence. Cross-attention is similar to self-attention. Self-attention focuses on relationships within a single input sequence, while cross-attention focuses on relationships between two different input sequences (4):

$$Q = X_1W^{Q}, \quad K = X_2W^{K}, \quad V = X_2W^{V} \tag{4}$$

where, X1 is the input where we want to generate attention for example decoder input, while X2 is the input to attend to, the encoder output. In short, the inputs for self-attention are all the same Q = K = V while cross-attention is from different sequences, Q ≠ K and V. Q comes from the decoder's output and K and V come from the encoder's output. The purpose of self-attention is to learn internal dependencies in a sequence. The cross-attention is to learn how one sequence attends to another.

In 2022, Shangzhu Jin et al. [27] enhanced deep knowledge tracing using a GRU network with self-attention, improving sensitivity to long sequences and prediction accuracy by leveraging historical knowledge states. The attention mechanism strengthened the influence of historical knowledge on future performance, leading to higher AUC and precision scores on the ASSISTments datasets compared to benchmark models. This demonstrated significant improvement in knowledge tracing tasks and better prediction performance. In the following year, Xikun Wei et al. [28] applied the Transformer's self-attention to improve runoff prediction in the Yangtze River basin. By integrating self-attention into LSTM and GRU models (LSTM-SA and GRU-SA), they achieved notable accuracy gains, especially under limited training data, by focusing on critical information.

The ProbSparse self-attention mechanism, a variant of traditional self-attention, was introduced to improve efficiency in long-sequence time series forecasting. Study [29] integrates it with LSTM to enhance prediction capacity for such tasks. Given the similarity between LSTM and GRU, integrating ProbSparse self-attention into GRU also holds potential.

Similarly, [30] showed that integrating multi-head self-attention into a GRU framework enhances the modelling of global dependencies and complex temporal patterns. Their FSR-MSAGRU model, applied to PM2.5 forecasting, improved accuracy and generalisation across datasets, reinforcing the value of attention in time-series prediction.

Demertzis et al. [31] showed that integrating GRUs with a cross-modal dynamic attention mechanism improves anomaly detection in time-series data. GRUs enhance prediction accuracy by capturing temporal dependencies and enabling adaptive focus on relevant features, particularly in smart communication environments.

4) Temporal attention and other attentions: Sehovac and Grolinger [32] demonstrated that temporal attention has improved time-series forecasting when combined with GRUs. Their work on electrical load prediction showed that incorporating Bahdanau attention into Seq2Seq RNNs enhances the capture of time dependencies, leading to higher accuracy than traditional models. Similarly, [33] integrated temporal and spatial attention into a GRU-based architecture, significantly boosting forecasting and fault diagnosis for electro-mechanical actuators. Their model, combining seasonal-trend decomposition using Loess (STL), hybrid spatial–temporal attention GRU, and DTW-based similarity, achieved accurate multistep predictions and robust fault detection, outperforming standard GRU and LSTM models. Fig. 5 illustrates the model's structure.

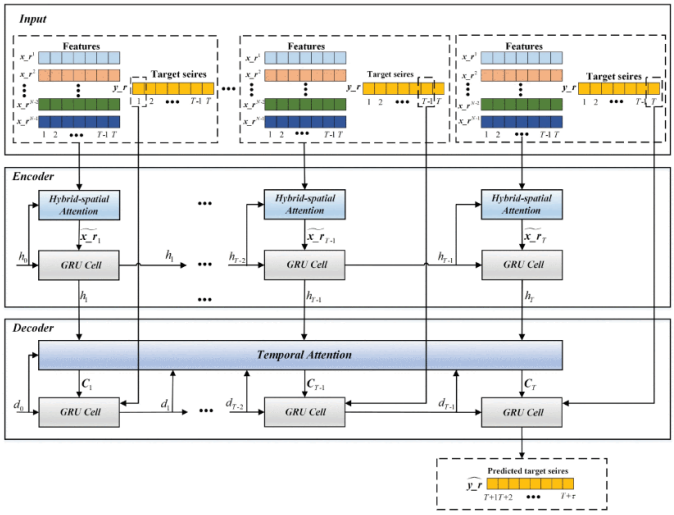

Fig. 5. Structure flowchart of HSTA-GRU model [33].

The authors in [34] investigated integrating GRUs with various attention mechanisms, including Multiplicative, Scaled Dot-Product, Bahdanau, Luong, and Self-Attention, to improve phishing URL detection. After comparing performance across these mechanisms, the study selected top-performing models and benchmarked them against GRU without attention and other baselines. As shown in Fig. 6, attention-enhanced models achieved higher accuracy and overall better performance, indicating that attention helps GRUs focus on relevant input features for more accurate threat detection.

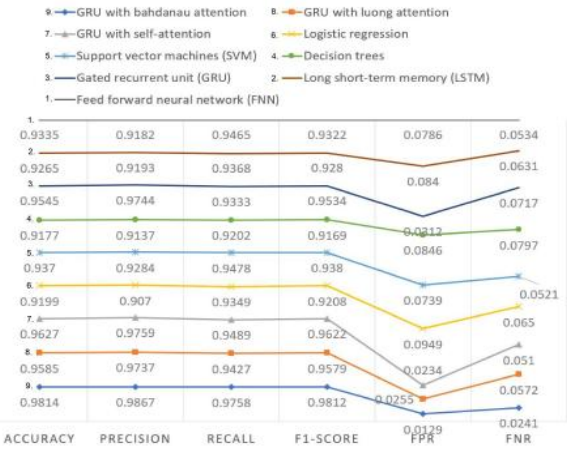

Fig. 6. Comparison of performances with various attentions and models.

The author in [35] introduces a GRU-based encoder-decoder model with a temporal attention mechanism for predicting ship speed over multiple horizons. The temporal attention mechanism and encoder-decoder structure enhance the model's ability to handle multi-horizon predictions and consider exogenous factors. By incorporating exogenous factors and focusing on influential time steps, the model achieves better prediction accuracy. Fig. 7 proves that by adding an attention mechanism to GRU, the average RMSE and average MAE prediction errors are reduced.

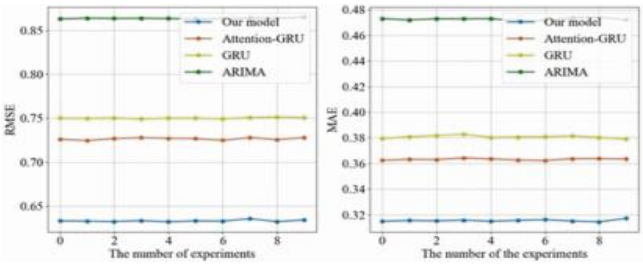

Fig. 7. The RMSE and MAE of different models of the ten experiments [35].

In [36], an interpretable condition monitoring method for offshore wind turbine gearboxes is proposed using a Spatial-Temporal Attention and GRU-based Network (STAGN). The model integrates spatial-temporal attention with GRU to effectively extract features from SCADA data. Fig. 8 shows the structure of the spatial attention module. Each input variable's spatial attention weight is calculated by (5) and (6) is used to calculate the normalised spatial attention weight αj(t) for the j-th input variable at time t.

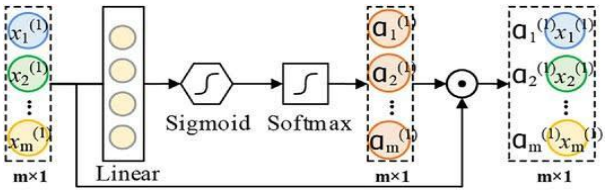

Fig. 8. Structure of spatial attention module [36].

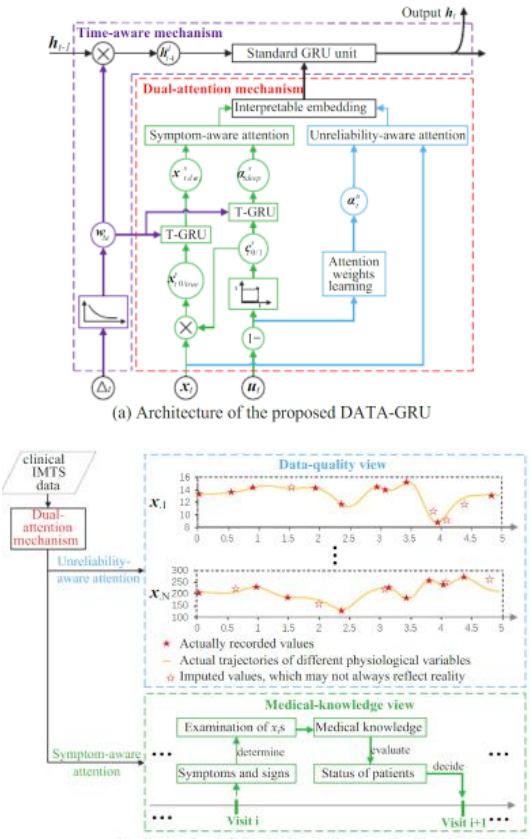
$$e^{(t)} = \sigma(W_{sa}x^{(t)} + b_{sa}) \quad (5)$$



$$\alpha_j{}^{(t)} = \frac{exp(e_j{}^{(t)})}{\sum_{i=1}^{m} e_i{}^{(t)}} \quad (6)$$

According to [36], the temporal attention module enhances key temporal feature representation and mitigates early-stage information loss, while the spatial attention module captures spatial correlations. Together, they improve early fault detection and normal behaviour modelling (NBM), as validated on the Donghai Bridge offshore wind farm. Besides, Cui et al. [37] showed that integrating hierarchical contextual attention into GRU networks improves forecasting in sequential recommendation tasks by effectively capturing both long- and short-term dependencies. Their HCA-GRU model outperformed traditional RNN-based approaches in accuracy and ranking performance on real-world datasets.

5) Trend-aware attention: Trend-aware attention [38] is designed to highlight long-term upward or downward patterns in time-series data, unlike standard attention, which treats all inputs equally. Chen et al. [38] introduced the TAA-Transformer, which incorporates this mechanism to improve lithium-ion battery capacity prediction by capturing both local and global features. Compared to GRU, which lacks trend-aware attention, the TAA-Transformer achieved superior predictive accuracy. Although focused on Transformers, the study suggests that integrating trend-aware attention into GRU is feasible and could enhance performance in similar forecasting tasks.

Trend-aware multi-head flow attention has also been applied to forecasting tasks. Yang et al. [39] proposed JGFACN, a model combining a dynamic Jacobi graph with trend-aware flow attention for traffic prediction. Compared to methods including LSTM [18], JGFACN showed superior performance by dynamically adapting to temporal features. While the study did not integrate attention into GRU, its effectiveness suggests potential gains if applied to GRU-based time-series forecasting models.

6) Dual-attention: Tan et al. [40] also introduced DATA-GRU, a Dual-Attention Time-Aware GRU model, to address irregular intervals and missing values in EHR time-series data. Incorporating unreliability-aware and symptom-aware attention, the model effectively predicts patient mortality risk with improved accuracy and interpretability over state-of-the-art methods. Fig. 9 illustrates the DATA-GRU architecture and attention integration.

(a) Architecture of the proposed DATA-GRU

(b) Illustration of the dual attention mechanism

Fig. 9. Architecture of DATA-GRU is shown in (a) and dual attention mechanism in (b) [40].

The study in [41] proposed a dual-stage attention-based RNN (DA-RNN) using input attention to focus on relevant driving series and temporal attention to capture long-term dependencies, improving time-series forecasting accuracy on datasets like SML 2010 and NASDAQ 100. While based on LSTM, the dual-stage attention mechanism could similarly benefit GRU models. In 2023, [42] introduced PDAGRU, a Parallel GRU model with multiplicative and temporal attention layers, for probabilistic RUL prediction of wind turbine bearings. As shown in Fig. 10, this approach significantly enhances accuracy and reliability by better extracting degradation features from time-series data.

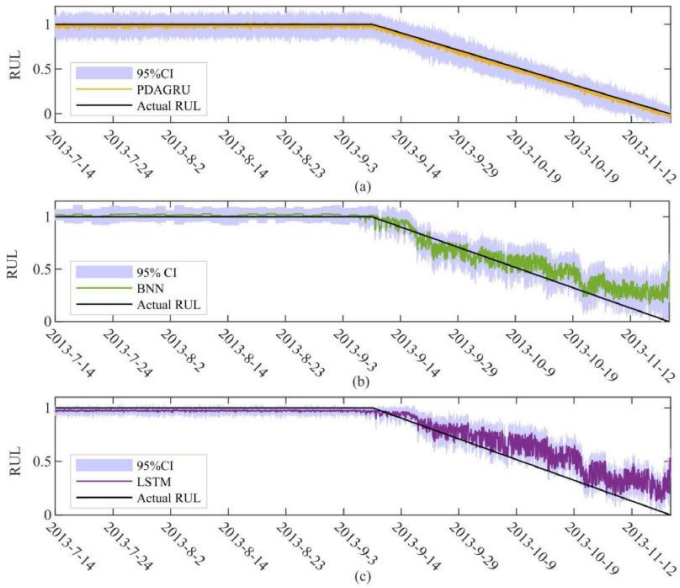


Fig. 10. The RUL prediction performance metrics with different methods [42].

In [43], the Hierarchical Attention Cascade Neural Network (CasHAN) is proposed to predict future cascade growth based on early evolution. As shown in Fig. 11, sequences from cascade graphs are encoded using a bidirectional GRU, then refined through node-level attention (capturing user influence) and sequence-level attention (addressing community redundancy), improving prediction accuracy.

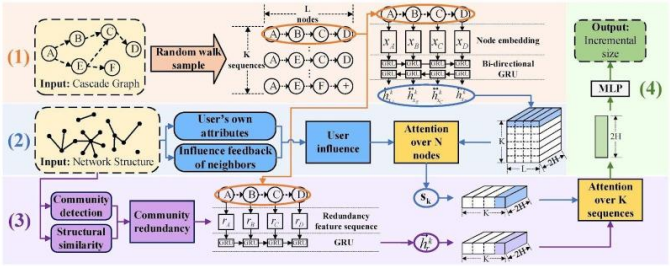

Fig. 11. The overall architecture of the proposed CasHAN model [43].

However, these attention-based GRU models have not been specifically applied to food loss forecasting, which poses distinct challenges due to the irregular, seasonal, and multi-source nature of agricultural data. Unlike applications in stock prediction, solar radiation, or aerospace forecasting, food loss prediction requires models to handle domain-specific variables, temporal variability, and data sparsity. This highlights a critical research gap for attention-enhanced GRU models tailored to food loss forecasting.

C. Enhancing GRU with Seasonal and Trend Decomposition

Seasonal-trend decomposition using Loess (STL) [44] is a time-series technique that separates data into seasonal, trend, and residual components. It uses LOESS, Locally Estimated Scatterplot Smoothing, and a nonparametric regression method, to flexibly estimate trends and seasonality over time. This decomposition aids in forecasting, anomaly detection, and identifying underlying patterns.

Despite advances in time-series modelling, decomposition integration within GRU architectures remains underexplored. Hewamalage et al. [45] noted that while RNNs, including GRUs, can model seasonality, this is mainly effective for time series with consistent seasonal patterns. For nonstationary or variable-seasonality data, they recommend deseasonalisation prior to modelling. Seasonal-trend decomposition using Loess (STL) provides a robust, nonparametric approach to decomposing time series into seasonal, trend, and residual components, enabling models to focus on learning more meaningful patterns from each.

Similarly, [46] proposed a short-term electricity forecasting model combining seasonal-trend decomposition using Loess (STL) with dual GRUs to separately capture global and local dependencies, significantly improving accuracy and robustness in handling nonlinear real-world data. Fig. 12 shows the structure of the proposed scheme.

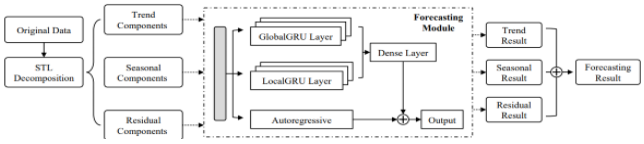

Fig. 12. The structure of the proposed scheme by [46].

The study in [47] introduced a hybrid STL-based framework for rainfall prediction, combining GRU, multi-time-scale GRU, and LightGBM to model decomposed components separately. This approach notably improved forecasting accuracy and robustness, especially for extreme rainfall events, by capturing key patterns in meteorological data. Fig. 13 illustrates the framework of the STL-ML approach to predict rainfall. As noted in [33], seasonal-trend decomposition using Loess (STL) also enhances attention-based GRU models by isolating trend, seasonal, and residual components, enabling more effective pattern extraction and improving fault prediction accuracy in electro-mechanical actuators.

An ensemble model proposed in 2020 [48] applied seasonal-trend decomposition using Loess (STL) with GRUs for base station traffic forecasting, demonstrating that modelling each decomposed component separately and recombining results enhances overall accuracy. Seasonal-trend decomposition using Loess (STL) effectively reduces noise and outliers, allowing GRUs to better capture nonlinear patterns and outperform standalone GRU and SARIMAX models.

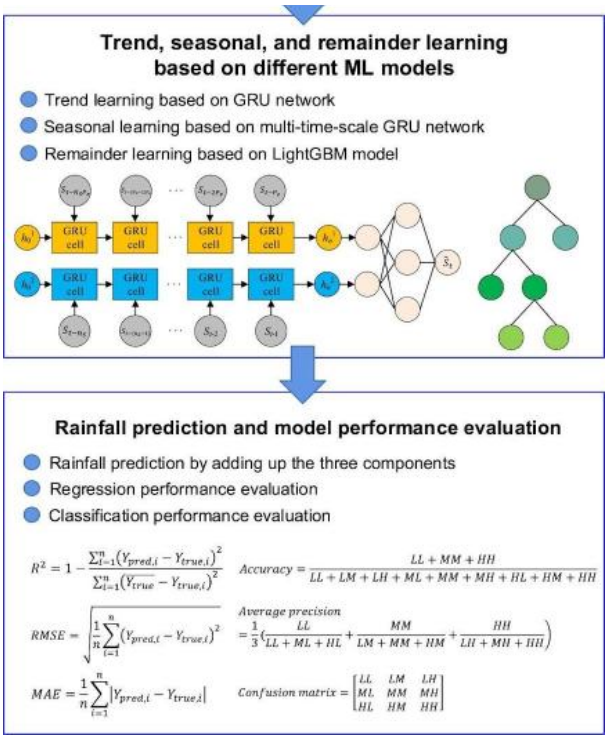

Fig. 13. Framework of the hybrid STL-ML approach for [47].

In climate forecasting, Liu et al. [49] introduced an STL-GRU model for temperature prediction, enabling GRUs to capture complex temporal correlations. This approach improved accuracy and efficiency across multiple regional datasets. The predictive performance indicators comparison for [49] are shown in Fig. 14. Similarly, Jia et al. [50] developed STL-IWOA-GRU for groundwater level prediction, integrating seasonal-trend decomposition using Loess (STL), an improved whale optimisation algorithm (IWOA), and GRU to handle data complexity with strong accuracy and robustness.

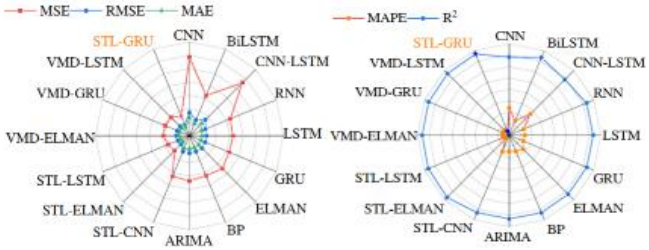

Fig. 14. Predictive performance indicators for [49].

Zhang et al. [51] proposed an STL-GRU-SVR model for sales forecasting, emphasising the importance of modelling trend, seasonal, and residual components independently to improve prediction. Likewise, [30] incorporated seasonal-trend decomposition using Loess (STL) in a GRU-based environmental forecasting model, enhancing feature space reconstruction and improving precision and robustness by isolating periodic and trend components.

III. Methodological Review Framework

This section presents a structured synthesis of existing studies that apply GRU-based models enhanced with attention mechanisms and time series decomposition. To make the findings accessible, the review is organised into a series of tables, each dedicated to a specific category of techniques. For instance, Tables I to VI summarise studies that integrate different types of attention mechanisms into GRU architectures, including Bahdanau (additive) attention, Luong (multiplicative) attention, self-attention, cross-attention, temporal attention, dual-attention, and more advanced designs such as hybrid spatial–temporal and trend-aware attention. Each table outlines the application domain, methodological approach, key contributions, and the specific challenges addressed, allowing us to see at a glance how these mechanisms influence forecasting performance across different contexts. Table VII focuses on studies that incorporate Seasonal-Trend decomposition using Loess (STL), highlighting how decomposing raw data into seasonal, trend, and residual components enhances learning efficiency and accuracy. By categorising and comparing these approaches, the framework provides both technical depth for researchers and clarity for practitioners, illustrating how attention mechanisms and seasonal-trend decomposition using Loess (STL) contribute individually and in combination to improving forecasting outcomes. Below shows review framework for each tables:

- Table I: Standard Attention Mechanisms
- Table II: Cross-Attention and Multi-Scale Attention
- Table III: Self-Attention and Cross-Attention
- Table IV: Temporal Attention and Other Attentions
- Table V: Dual-Attention Reviews
- Table VI: Trend-Aware Attention
- Table VII: Seasonal-Trend Decomposition using Loess (STL)

TABLE I. Review Framework for Standard Attention Mechanisms

Application	Methods	Key contributions	Gap Addressed
Container cloud elastic scaling [22]	GRU-attention hybrid model, Improved Horizontal Pod Autoscaler (HPA)	Enhanced load prediction and elastic scaling in container clouds, improving prediction accuracy and resource management efficiency.	Addressed the challenge of achieving efficient resource scheduling and elastic scaling in dynamic load environments, improving prediction accuracy and adaptability to complex load patterns.
Solar Radiation Prediction	EMD-GRU-Attention (EGA) model combining EMD, GRU, and **standard attention** mechanism.	Enhanced multi-step solar radiation prediction accuracy and reduced computational burden.	Addressed nonlinear, nonstationary data challenges and improved prediction accuracy.

TABLE II. REVIEW FRAMEWORK FOR GRU-CROSS-ATTENTION AND GRU-MULTI-SCALE ATTENTION MECHANISMS

Application	Methods	Key contributions	Gap Addressed
Blood Glucose Forecasting [25]	Multimodal Transformer with **cross-attention** and **multi-scale attention**.	Improved long-term BGL prediction accuracy using AI-READI dataset.	Addressed long-term forecasting challenges and data fusion with different rates.
Stock Prediction [26]	MCI-GRU model with **multi-head cross-attention** and improved GRU.	Enhanced stock prediction accuracy by integrating cross-attention and improved GRU.	Addressed limitations in capturing complex market dynamics and latent states.

TABLE III. REVIEW FRAMEWORK FOR GRU-SELF-ATTENTION AND GRU-CROSS-ATTENTION

Application	Methods	Key contributions	Gap Addressed
Knowledge Tracing [27]	GRU with **Self-Attention**.	Improved prediction accuracy and sensitivity to long sequence data in knowledge tracing.	Addressed information loss in long sequence data and enhanced historical knowledge impact on future performance.
Runoff Prediction in Yangtze River Basin [28]	Transformer (TSF), LSTM, GRU, LSTM-SA, GRU-SA with **Self-Attention**	Demonstrated that GRU outperforms TSF in limited data scenarios; Self-Attention improves LSTM and GRU performance.	Addressed the challenge of limited data for TSF and improved prediction accuracy with Self-Attention in LSTM and GRU.
Long Sequence Time-Series Forecasting [29]	Informer with **ProbSparse self-attention**, self-attention distilling, generative style decoder.	Achieved efficient long sequence forecasting with reduced time complexity and memory usage.	Addressed inefficiencies in Transformer models for long sequence forecasting.
PM2.5 Concentration Prediction [30]	FSR-MSAGRU model using feature space reconstruction and **multihead self-attention** GRU.	Improved prediction accuracy and generalisation by capturing periodic and global features.	Addressed limitations in capturing periodicity and global features in PM2.5 data.
Anomaly Detection in Data Streams [31]	CM-DANA model with **cross-modal dynamic attention** and multimodal learning.	Improved anomaly detection accuracy and efficiency in smart communication environments.	Addressed challenges in handling heterogeneous data types and evolving patterns.

TABLE IV. TEMPORAL ATTENTION AND OTHER ATTENTIONS

Application	Methods	Key contributions	Gap Addressed
Fault Diagnosis for Electro-Mechanical Actuators [33]	STL-HSTA-GRU with Dynamic Time Warping (DTW) for classification. HSTL = hybrid **spatial-temporal attention**	Improved fault diagnosis by combining STL decomposition with hybrid spatial-temporal attention GRU and DTW for classification.	Addressed challenges in handling nonlinear and seasonal data for early fault detection.
Load Forecasting [32]	Sequence-to-Sequence RNN with **Bahdanau Attention**, using GRU, LSTM, and Vanilla RNN cells.	Improved load forecasting accuracy by adapting S2S RNN with attention mechanisms.	Addressed challenges in capturing time dependencies and improving prediction accuracy.
Phishing URL Detection [34]	GRU with various attention mechanisms: **Multiplicative**, **Scaled Dot-Product**, **Bahdanau**, **Luong**, **Self-Attention**.	Achieved 98.14% accuracy using GRU with Bahdanau attention for phishing URL detection.	Enhanced detection accuracy and adaptability over traditional methods, addressing evolving phishing threats.
Ship speed prediction [35]	GRU-based encoder-decoder, **Temporal attention** mechanism, Dropout layers, Huber loss function, Adam optimizer	Proposed a model for accurate and timely ship speed prediction using a GRU-based encoder-decoder with a temporal attention mechanism.	Addressed the challenge of predicting ship speed by considering both previous speed and exogenous factors like weather and sea conditions, and improved prediction accuracy with a temporal attention mechanism.

Offshore Wind Turbine Gearbox Monitoring [36]	**Spatial-Temporal Attention** and Gated Recurrent Unit (GRU)	Introduced an interpretable model using spatial-temporal attention to enhance feature extraction and improve monitoring accuracy.	Addressed the challenge of early-stage information loss and lack of interpretability in condition monitoring models.
Sequential Recommendation [37]	**Hierarchical Contextual Attention**-based GRU (HCA-GRU)	Introduced a hierarchical contextual attention mechanism to enhance short-term interest modelling and combine it with long-term dependencies for better user interest representation.	Addressed the limitation of RNN's monotonic temporal dependency by capturing complex correlations among recent items and assigning nonmonotonic weights.

TABLE V. DUAL-ATTENTION REVIEWS

Application	Methods	Key contributions	Gap Addressed
Mortality Risk Prediction from Irregular Multivariate Time Series [40]	**Dual-Attention Time-Aware** Gated Recurrent Unit (DATA-GRU). The Dual-Attention including **Unreliability-aware attention** and **Symptom-aware attention**.	Introduced a model with time-aware and dual-attention mechanisms to handle irregular intervals and missing values in EHR data.	Addressed the challenges of irregular time intervals and missing values in EHR data by preserving temporal information and improving data reliability.
Time Series Prediction [41]	**Dual-Stage Attention**-Based Recurrent Neural Network (DA-RNN)	Introduced a dual-stage attention mechanism (input and temporal attention) to select relevant input features and capture long-term dependencies in time series.	Addressed the challenge of capturing long-term dependencies and selecting relevant driving series in time series prediction.
Probabilistic RUL Prediction of Wind Turbine Bearings [42]	Parallel GRU with **Dual-Stage Attention** Mechanism (PDAGRU). The Dual-Stage = **multiplicative attention** and **temporal attention**	Introduced a dual-stage attention mechanism to enhance degradation information extraction and a parallel structure for improved prediction accuracy and uncertainty quantification.	Addressed the challenges of efficient degradation information extraction, vanishing gradient problem, and prediction uncertainty.
Information Cascade Prediction [43]	**Hierarchical Attention** Cascade Neural Network (CasHAN) with **Node-Level** and **Sequence-Level Attention**	Introduced a model using hierarchical attention mechanisms to improve cascade prediction by considering user influence and community redundancy.	Addressed the lack of consideration for user influence and community redundancy in cascade prediction models.

TABLE VI. TREND-AWARE ATTENTION

Application	Methods	Key contributions	Gap Addressed
Lithium-Ion Battery Capacity Prediction [38]	**Trend-Aware Attention** (TAA) Transformer with 1-D Convolution.	Introduced TAA to capture local trends and global features, improving prediction accuracy over standard Transformers.	Addressed the limitation of standard Transformers in capturing local trend information in time-series data.
Traffic Forecasting [39]	Dynamic Jacobi Graph and **Trend-Aware Flow Attention** Convolutional Network (JGFACN)	Introduced a model combining dynamic Jacobi graph convolution with trend-aware flow attention to capture spatial-temporal correlations effectively.	Addressed challenges in capturing spatial-temporal correlations, dynamicity, and heterogeneity in traffic data.

Table VII below presents a review of studies that incorporate seasonal-trend decomposition using Loess (STL) as part of their forecasting frameworks. These works demonstrate how it is used to isolate trend and seasonal components from raw time series data, thereby improving model stability and learning efficiency. The table summarises how seasonal-trend decomposition using Loess (STL) has been combined with models such as GRU, LightGBM, and hybrid neural networks across various domains. This synthesis highlights the versatility

and effectiveness of seasonal-trend decomposition using Loess (STL) as a preprocessing technique, offering valuable guidance for its potential application in food loss forecasting.

TABLE VII. REVIEW FRAMEWORK FOR SEASONAL-TREND DECOMPOSITION USING LOESS

Application	Methods	Key contributions	Gap Addressed
Short-Term Electricity Forecasting [46]	Combined GRU with STL Decomposition	Developed a scheme using STL decomposition and dual GRU networks (GlobalGRU and LocalGRU) to capture local and global dependencies, enhancing prediction accuracy.	Addressed the inability of traditional models to capture complex nonlinear relationships and local historical information in electricity data.
Rainfall Time Series Prediction [47]	STL, GRU, Multi-time-scale GRU, LightGBM	Developed a hybrid STL-ML approach integrating STL decomposition with machine learning models to predict rainfall, effectively capturing trend, seasonal, and remainder components.	Addressed the challenge of accurately predicting rainfall by fully extracting and utilising underlying patterns and information from rainfall time series.
Fault Diagnosis for EMAs [33]	STL-HSTA-GRU, SM	Developed a method combining STL for seasonal-trend decomposition with HSTA-GRU for spatio-temporal prediction and SM for classification.	Addressed early-stage fault detection and nonlinear, seasonal data challenges in EMAs.
Base Station Traffic Forecasting [48]	STL, GRU	Developed an ensemble model combining STL decomposition with GRU to improve traffic forecasting accuracy by reducing noise and outliers	Addressed the challenge of nonlinearity and chaotic behaviour in traffic data, enhancing prediction accuracy over standalone models.
		.	
Climate Time Series Forecasting [49]	STL, GRU	Developed a hybrid STL-GRU model to improve temperature prediction accuracy by capturing seasonal variations and long-term trends.	Addressed the challenge of nonlinearity and temporal dependencies in temperature data, enhancing prediction accuracy over traditional models.
Groundwater Level Prediction [50]	STL, IWOA, GRU. IWOA stands for Improved Whale Optimisation Algorithm.	Developed a hybrid STL-IWOA-GRU model to improve GWL prediction accuracy by enhancing convergence speed and global search capabilities.	Addressed the challenge of nonlinearity and complexity in GWL time series under EWR, improving prediction accuracy over traditional models. EWR stands for Ecological Water Replenishment.
Sales Forecasting [51]	STL, SVR, GRU	Developed a sales forecasting model combining STL with SVR and GRU for higher accuracy.	Addressed the lack of direct forecasting using decomposed components in sales data.
PM2.5 Prediction [30]	FSR-MSAGRU (STL, MSAGRU)	Developed a model combining STL for capturing periodic and trend information with feature space reconstruction and multihead self-attention GRU for PM2.5 prediction.	Addressed the neglect of periodic and global features in PM2.5 prediction models.

IV. DISCUSSION

After reviewing a broad range of GRU-based forecasting studies that utilise attention mechanisms and seasonal-trend decomposition using Loess (STL), several clear relationships and patterns emerge across different domains and

methodological designs. These patterns not only clarify how these methods contribute to forecasting performance, but also offer valuable direction for future food loss forecasting research.

A. Attention Mechanisms

Various forms of attention, such as Self-attention, multi-head, cross-attention, dual-stage attention, and trend-aware attention, Bahdanau, Luong, and more, have been applied to GRU-based or related-based models like LSTM or others. A consistent pattern observed is that attention mechanisms improve the model's ability to capture long-term dependencies and enhance interpretability, especially in nonstationary or highly dynamic time series tasks. For instance, studies using multi-head or dual-stage attention (e.g. MCI-GRU [26], PDAGRU [42]) often outperform standard GRUs by dynamically focusing on critical time steps or features.

However, model complexity and training cost tend to increase with more advanced attention designs. These mechanisms also differ in scope while self-attention captures internal temporal dependencies, cross-attention and dual-stage attention are more effective when fusing heterogeneous inputs or signals from different domains.

B. Seasonal-Trend Decomposition Using Loess (STL)

Studies applying seasonal-trend decomposition using Loess (STL) consistently show that separating trend and seasonal components improves the stability and learning efficiency of GRU models. Models such as STL-HSTA-GRU [33], STL-IWOA-GRU [50] and more demonstrate that denoising inputs via seasonal-trend decomposition using Loess (STL) enhances model focus and leads to higher forecasting accuracy across domains such as electricity load, rainfall, climate, and groundwater levels. An important correlation observed is that seasonal-trend decomposition using Loess (STL) often pairs well with ensemble or hybrid frameworks, especially where trend clarity and seasonal structure play a strong role in outcomes.

C. Combination of Attention Mechanisms and STL

A smaller but growing subset of studies (e.g., STL-HSTA-GRU [33], FSR-MSAGRU [30]) explore hybrid models that integrate both attention mechanisms and seasonal-trend decomposition using Loess (STL). These models show synergistic benefits: seasonal-trend decomposition using Loess (STL) reduces input complexity by isolating components, allowing the attention-enhanced GRU to better identify which time points or signals are most important. This layered approach improves robustness and interpretability, particularly in domains with noisy, multi-scale, or highly seasonal data. While fewer in number, these hybrid designs consistently outperform single-technique models in accuracy and generalisation, suggesting that the combination of seasonal-trend decomposition using Loess (STL) and attention mechanisms is greater than the sum of its parts.

V. Research Gaps and Future Directions

A key limitation in current research is the lack of studies applying combined seasonal-trend decomposition using Loess (STL) and attention-based GRU architectures specifically to food loss forecasting. While this hybrid approach has proven effective in domains like electricity pricing, air quality monitoring, and fault detection, its potential remains unexplored in the context of food loss, despite the data's seasonal, irregular, and nonlinear nature.

Future work should focus on developing GRU-based hybrid models that incorporate both seasonal-trend decomposition using Loess (STL) and attention mechanisms. Such architectures could better capture long-term dependencies, dynamic temporal features, and structured patterns, offering a promising path toward improved accuracy and interpretability in food-related time-series forecasting.

A key direction for future research is optimising how attention weights are fused with decomposed components, trend, seasonality, and residuals, rather than applying attention to raw sequences. This component-level integration could enhance both interpretability and precision. Another open question involves the use of adaptive decomposition techniques that adjust to the characteristics of different food types or supply chain contexts, potentially improving generalisability across agricultural sectors. Additionally, the development and release of real-world food loss datasets and standardised benchmarks are critical for enabling rigorous model evaluation and comparison.

Addressing these gaps is essential for building practical, data-driven forecasting tools capable of making a tangible impact on food loss. By combining seasonal-trend decomposition using Loess (STL), GRU architectures, and attention mechanisms, future models can deliver more accurate, interpretable, and responsive predictions tailored to the complexities of food supply chains. Such advancements would support producers, distributors, and policymakers in identifying loss-prone points earlier, improving resource allocation, and enabling timely interventions. Ultimately, this research not only advances time-series modelling but also contributes to broader goals of reducing waste, enhancing food security, and fostering more resilient and sustainable supply systems.

VI. Conclusion

In summary, this paper highlights that both attention mechanisms and seasonal decomposition are promising enhancements for GRU-based food loss forecasting. Our review of models across domains, such as electricity load, air quality, rainfall, and fault detection, consistently shows performance gains when attention or decomposition techniques are used, especially in combination with GRU networks. Attention mechanisms improve a model's ability to capture long-range temporal dependencies and dynamically prioritise time steps, while seasonal-trend decomposition using Loess (STL) isolates trend and seasonal components, allowing GRUs to learn from cleaner, more structured inputs.

This study advances understanding of how architectural innovations can address challenges like long-term dependencies, seasonality, and noise in food loss data. It also identifies a key research gap: despite their success in other time-series contexts, hybrid STL-attention-GRU models remain largely unexplored in food supply chains. Given the inherent complexity and variability in food production and distribution,

developing such models is not only a valuable academic pursuit but also a practical necessity for reducing waste and improving food system resilience.

This review also sets the stage for future research by outlining key directions, such as optimising the integration of attention weights with decomposed components, exploring adaptive or domain-specific decomposition techniques for improved generalisation, and developing real-world datasets and benchmarks for consistent, reproducible evaluation.

Future empirical work should focus on designing and testing hybrid architectures that combine GRU networks with seasonal-trend decomposition using Loess (STL) and attention mechanisms for food loss forecasting. These models hold promise for delivering more accurate, interpretable, and resilient forecasting tools capable of supporting timely interventions and strategic decisions across the food supply chain. Ultimately, such innovations can contribute to global efforts to reduce food waste, strengthen supply chain resilience, and promote sustainable resource management.

***Abstract*—Software-Defined Networking (SDN) promises flexible control of network flows but also exposes controllers to rapidly shifting attack surfaces. Conventional intrusion-detection engines, trained once and deployed statically, falter when traffic patterns drift. We introduce an adaptive intrusion detection system that couples a mini-batch incremental learning scheme with a five-member ensemble of Long Short-Term Memory (LSTM) classifiers. Each model trains on successive data partitions drawn from the InSDN dataset, while a lightweight tracker monitors accuracy and "age." A weighted-voting rule penalizing stale models in proportion to their lifetime lets the ensemble down-rank obsolete learners without full retraining. When the tracker flags slippage, only the most dated models are refreshed, limiting computational load and preserving service continuity. Across four streaming iterations, the system sustains a mean detection accuracy of 95.8% and a 3.2% false-positive rate, recovering quickly from concept drift that drives individual models to baseline performance. Comparative analysis against three recent SDN IDS baselines shows improvements of up to 14 percentage points in accuracy and 0.48 in F-score, without sacrificing latency (≈50 ms). These results indicate that modest, well-timed retraining rather than continual online updates can keep an SDN IDS both nimble and efficient. The approach offers a practical roadmap for securing programmable networks that evolve by the hour.**

Keywords*—Software-defined networking; intrusion detection; incremental learning; LSTM ensemble; concept drift; weighted voting

I. Introduction

The quick progression of networking technology during the past few years has transformed the processes of data transmission management as well as security in digital infrastructure networks. Software-Defined Networking (SDN) stands out as the leading network paradigm because it provides complete network resource control and programming through centralized management [1]. Network decision-making functions through the control plane exist independently from packet forwarding operations in the data plane. Network administrators can control traffic flow while optimizing resource usage and deploying new services because this separation enables such flexibility and efficiency. SDN receives increasing adoption from enterprises and service providers, and research institutions because it helps them transform their network infrastructure to handle changing operational requirements better [2].

The essential benefits of SDN come with substantial security issues, which need thorough assessment. Network centralization and programmable interfaces together expose SDN networks to sophisticated threats, which make up the advantages of this technology. The network controller functions as a single vulnerable point since its compromise enables attackers to influence extensive sections of the network. SDN enables fast service deployment through its open and programmable architecture, yet this openness makes it simple for attackers to discover vulnerabilities in both control and data planes [3]. The security system faces mounting difficulties because modern network traffic exhibits dynamic patterns and user activities, and application requirements generate unpredictable monitoring conditions.

The protection of SDN networks depends heavily on Intrusion Detection Systems, which serve as essential security measures. IDS solutions monitor network traffic to detect unauthorized access and malicious activities, and unexpected patterns, which enable organizations to detect security incidents quickly. Traditional IDS solutions utilizing signature-based and rule-based detection techniques have become prevalent in conventional network environments. Such systems maintain inflexible static features, which make them unable to handle the adaptive real-time threats that exist in SDN environments [4]. The conventional IDS models operate by receiving historical datasets offline for training purposes before they become fixed detectors for deployment. The internal parameters and detection rules of these systems remain unaltered after deployment, so they become exposed to both new attack techniques and changes in normal network behaviors, which create concept drift issues. Their detection capabilities decrease through time, so they become unable to detect complex attacks that compromise essential network resources [5].

The research community has moved toward machine learning techniques, including deep learning methods to improve IDS capabilities for dynamic network environments because traditional IDS shows limited effectiveness. Long Short-Term Memory (LSTM) networks demonstrate excellent performance in sequential data analysis because they are recurrent neural networks that capture temporal dependencies [6]. Analysis of network traffic streams by LSTMs enables the detection of both simple and sophisticated anomalies, which suggest malicious activity [7]. Most machine learning-based IDS systems operate with a fixed learning model despite their numerous advantages. The training process for these models ends after initial deployment because they lack mechanisms to update their knowledge with new data, which causes their performance to decline when attackers change their methods or when normal network traffic patterns shift [8].

The main contribution of this research introduces ensemble members to vote on their decisions based on weighted criteria. The final intrusion detection decision gets its influence from LSTMs based on both their current accuracy and the duration since their last retraining session. The system uses voting penalties to direct decision authority toward models that demonstrate high accuracy while being updated regularly. The ensemble maintains its robustness against concept drift while rapidly recovering from performance degradation and maintaining high detection fidelity throughout model temporary performance declines.

While SDN intrusion detection has benefited from deep learning approaches such as CNN, DNN, and hybrid ensembles [5], [7], [20], these systems are typically trained offline and lack mechanisms to adapt efficiently to non-stationary traffic conditions. Existing incremental IDS studies [12], [17] either depend heavily on labelled data streams or incur high retraining costs, which limit their scalability in real-time deployments. This gap highlights the need for a lightweight, adaptive IDS that can maintain high accuracy under concept drift while avoiding the overhead of continuous retraining [33]. To address this, the present research proposes an incremental LSTM ensemble with lifetime-aware weighted voting and selective retraining, designed to balance accuracy, adaptability, and computational efficiency in SDN environments [35].

The main research goal focuses on proving that performance-based model updates through real-time monitoring alongside ensemble voting methods create an efficient solution to detect intrusions in SDN systems. The proposed framework is tested using an extensive real-world SDN dataset, which includes various normal and attack traffic types, including Denial of Service (DoS), Distributed Denial of Service (DDoS), probing, brute force, and web application attacks. Experimental results show that the system achieves high detection accuracy and low false positive rates, outperforming traditional static and baseline incremental methods. The proposed retraining approach cuts down computational expenses and prevents service interruptions, which makes it ready for operational SDN deployments.

This research establishes a fresh analytical framework for adaptive network intrusion detection in programmable networks that achieves enhanced scalability and effectiveness for quickly evolving cyber threats. The proposed LSTM ensemble framework connects static detection to continuous adaptation by providing an efficient, future-proof security solution for SDN infrastructures.

The remainder of the paper is structured as follows: Section II presents the related work, Section III presents the methodology, describing the creation of the incremental ensemble model from Long Short-Term Memory (LSTM) classifiers and adaptive learning strategies for real-time intrusion detection in Software-Defined Networks (SDNs). Section IV describes the InSDN dataset, including preprocessing, feature selection, and splitting for incremental learning. Sections V collectively report and discuss experimental findings with a focus on detection accuracy, false positive rate, and resilience to concept drift, with particular attention to the benefits of adaptive retraining and weighted ensemble voting in dynamic SDN environments. Section VI is limitations and future work, and Section VII concludes the paper and identifies future research avenues, including broader dataset adoption and real-world deployment optimizations.

II. Related Work

The inability of these systems to adjust marks an essential knowledge deficiency [32]. SDN systems require intrusion detection solutions that learn from new data without requiring full model retraining while preserving service availability because both normal and attack traffic changes rapidly [9]. An SDN IDS must achieve precise detection of known threats while maintaining immunity against unknown attacks, while producing minimal false positives and performing within limited network resources [10]. The system faces additional barriers to the expenses of retraining massive models alongside the potential loss of prior knowledge during new learning processes and the essential need to preserve ongoing service operations [13], [14].

The proposed framework presents an adaptive intrusion detection system that targets Software-Defined Networks to address the mentioned interconnected issues [15]. The main principle of this method involves combining multiple Long Short-Term Memory (LSTM) classifiers, which receive incremental training from different sections of streaming network data. The system employs mini-batch incremental learning to enhance its knowledge base with new traffic patterns and emerging threats while avoiding complete retraining of all models [11]. The lightweight model tracker continuously evaluates both performance and model age within the ensemble to detect outdated or underperforming LSTMs. The framework uses a selective updating method instead of simultaneous retraining of all ensemble models because simultaneous retraining proves costly and disruptive [12]. The system refreshes models that demonstrate major performance degradation or operate for long durations before receiving data updates. Table I illustrates Recent Research on Intrusion Detection in Software-Defined Networks (SDNs).

Prior research has explored diverse ML and DL approaches for SDN intrusion detection. The authors in [16], [18] used Random Forest and SVM models, but their static design limited adaptability to new traffic [34], [36]. In [19], the author proposed a hybrid GWO-AE-RF model with improved detection accuracy, yet lacked efficient handling of concept drift in streaming data. The author in [12] developed a semi-supervised incremental framework, which improved adaptability but depended on labelled data streams that may not be feasible in real-world SDN deployments. More recently, [17] introduced incremental majority voting, but this approach did not incorporate temporal weighting or selective retraining, leaving it vulnerable to performance decay. In contrast, the proposed framework contributes a novel integration of incremental LSTM ensembles with lifetime-aware weighted voting, which selectively refreshes underperforming models to ensure scalability, resilience, and continuous detection in dynamic SDN environments [28], [29]. A comparative overview between the existing model and our proposed model is presented in Fig. 1.

III. METHODOLOGY

This research demonstrates the creation of an adaptive Intrusion Detection System (IDS) for Software-Defined Networking (SDN) platforms [30], [31]. This framework uses incremental learning through a combination of Long Short-Term Memory (LSTM) classifiers to operate. The research design consists of a structured approach that begins with data preprocessing, followed by feature selection and data partitioning before moving to incremental ensemble training and model performance tracking, then adaptive retraining and ensemble decision aggregation, and finishes with empirical evaluation.

The first phase focuses on performing strict data preprocessing to maintain the input dataset quality and readiness for analysis. The dataset preparation process involves complete steps for missing value imputation and duplicate entry elimination, and noise removal to achieve both data accuracy and representative results. Statistical methods detect outliers, and the system either caps or removes these anomalies to protect model performance. The Mutual Information Feature Selection (MIFS) approach reduces feature dimensions to achieve both computational efficiency and model interpretability. The top five features with the highest importance scores become the selection for the model because they represent the most crucial attributes for intrusion detection. Fig. 1 shows the adaptive IDS design Process for the SDNs framework.

The dataset undergoes a refinement process before being split into ten equal parts. The partitioning technique duplicates real-world SDN traffic data streams and creates a suitable environment for incremental learning systems. The process focuses on preserving class distribution in each partition segment to stop training process biases from class imbalances. The detection architecture uses five LSTM classifiers with 50 hidden units in each model because this configuration delivered the best predictive results at an acceptable computational cost. The LSTM models start their training process with separate partitions of data to achieve ensemble diversity and identify multiple traffic patterns. The training process employs Adam optimizer with binary cross-entropy loss function, while key hyperparameters receive adjustment through preliminary experiments to reach robust convergence.

To facilitate adaptive learning, a model tracker is integrated into the system. This component monitors critical performance indicators for each LSTM, including predictive accuracy, operational lifetime (i.e., the duration since the most recent retraining), and the number of processed samples. A periodic tracker updater ensures that these metrics reflect the most current performance status, while a resetter module reinitialises relevant statistics following model retraining. Such mechanisms enable the timely identification of underperforming or outdated models.

For ensemble decision-making, the predictions generated by the LSTM models are consolidated through a weighted voting mechanism. Each model's vote is assigned a weight calculated as.

$$\text{Weight} = \text{Accuracy} - 0.2 \times \text{Lifetime}$$

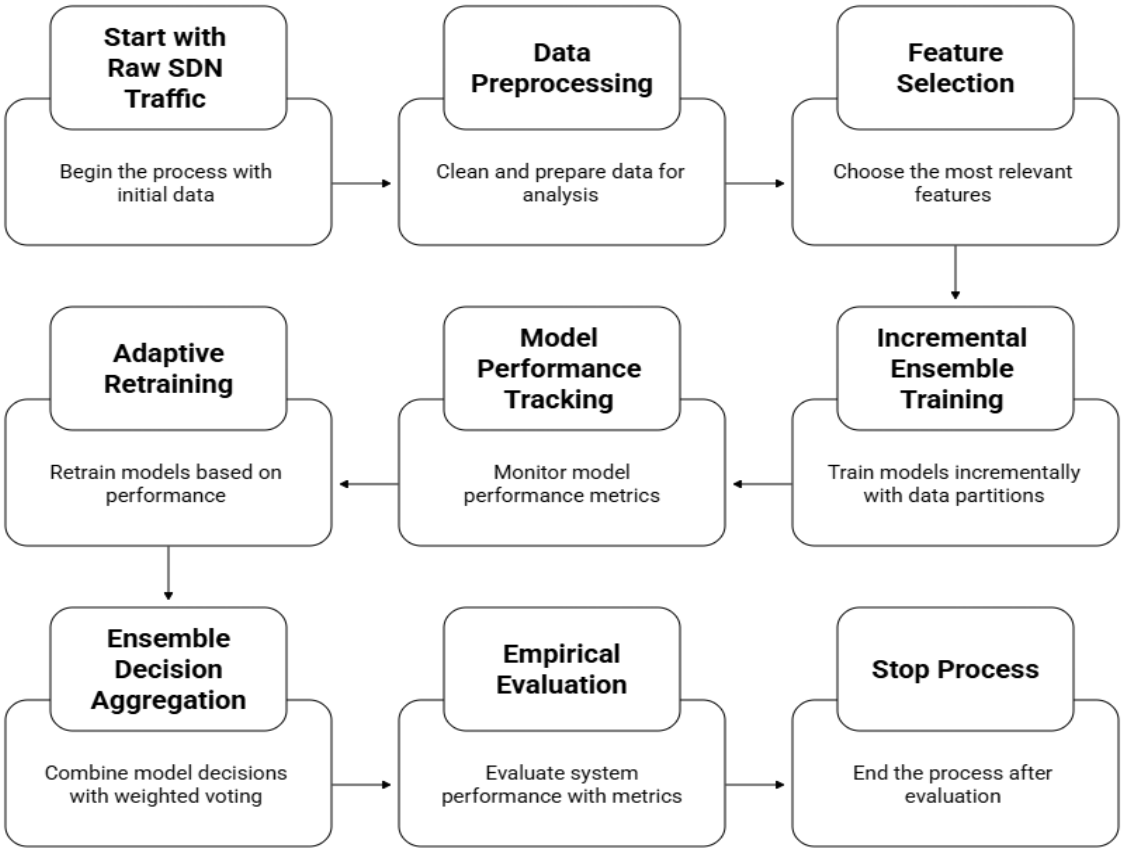

Fig. 1. Adaptive IDS design process for SDNs framework.

Where "Lifetime" denotes the number of iterations since the model's last update. This scheme ensures that recent and accurate models exert greater influence on the ensemble's final decision, while models that have not been retrained recently are proportionally down-weighted. The penalty coefficient of 0.2 is selected based on empirical tuning; lower values were found to insufficiently prioritise model freshness, whereas higher penalties overly diminished the contribution of otherwise accurate models. Thus, the adopted value achieves a pragmatic trade-off, supporting ensemble adaptability without sacrificing precision.

To accommodate the evolving nature of SDN traffic, the incremental learning mechanism is invoked as new data becomes available. Incoming samples are preprocessed and incorporated into the data stream. Models flagged by the tracker as having suboptimal accuracy or extended operational lifetimes are prioritised for retraining on the latest data partition. Crucially, to minimise computational costs and ensure system availability, only one or two models are retrained in any given update cycle, ensuring that the ensemble maintains uninterrupted coverage and decision-making capability.

Standard metrics enable quantitative system performance evaluation through detection rate (recall) which measures correct intrusion identification and false positive rate (FPR) which indicates benign traffic misidentification. The sliding window protocol enables authentic simulation of real-time data stream conditions during evaluation procedures. The proposed IDS achieves its benchmarking through comparisons with both individual LSTM classifiers and traditional ensemble approaches to demonstrate the incremental adaptive framework's relative benefits.

The experimental procedures operate in Python through the use of state-of-the-art machine learning libraries, including TensorFlow or PyTorch for neural network development and Scikit-learn for data preprocessing and feature selection tasks. The experiments run on high-performance computational platforms to speed up training and evaluation cycles. The comprehensive, structured approach guarantees that the developed IDS maintains robustness and scalability while delivering high detection accuracy and operational efficiency in the dynamic SDN environments of today.

IV. Dataset Description

This study employs the InSDN dataset [3], a widely recognized benchmark for Software-Defined Networking security research. The dataset contains 68,424 normal traffic records and 275,465 attack records, encompassing multiple intrusion categories including Denial of Service (DoS), Distributed Denial of Service (DDoS), probing, brute-force, and web application attacks. The choice of InSDN was motivated by its comprehensive coverage of SDN-specific

threat scenarios, its public availability, and its frequent adoption in prior studies for training and evaluating intrusion detection models. These characteristics ensure that experimental findings are both comparable with existing research and representative of real-world SDN adversarial conditions.

The InSDN dataset serves as a fundamental testing tool for IDS system development and evaluation in programmable networks because it includes both normal operations and the complete spectrum of SDN-specific threats [20] and [21]. The InSDN dataset contains carefully collected SDN traffic data that provides researchers with relevant information to train and validate machine learning models that detect and classify security incidents in these environments [3], [21].

The InSDN dataset provides a wide range of attack scenarios that correspond to the complex nature of modern SDN deployments' adversarial tactics. Research benefits from this dataset because it enables scientists to test multiple intrusion detection methods while studying their resistance and flexibility. The academic community recognizes the InSDN dataset as a benchmark for testing machine learning and deep learning approaches because it supports development of better detection accuracy and operational reliability [22], [23]. The combination of CNN with LSTM networks in hybrid models achieves accuracy above 96% in InSDN evaluations [22], [23] which demonstrates the dataset's value for advancing SDN security research through innovative approaches.

Multiple research studies have proven the quality and continued usefulness of InSDN through its application in feature selection analysis and machine learning model optimization [24], [25], [7]. The dataset provides complete attack and benign traffic patterns that help researchers develop generalizable intrusion detection solutions for operational implementation [26], [3], [27]. The evolving threat landscape of SDN depends on InSDN as researchers need this tool to address advanced cyber threats.

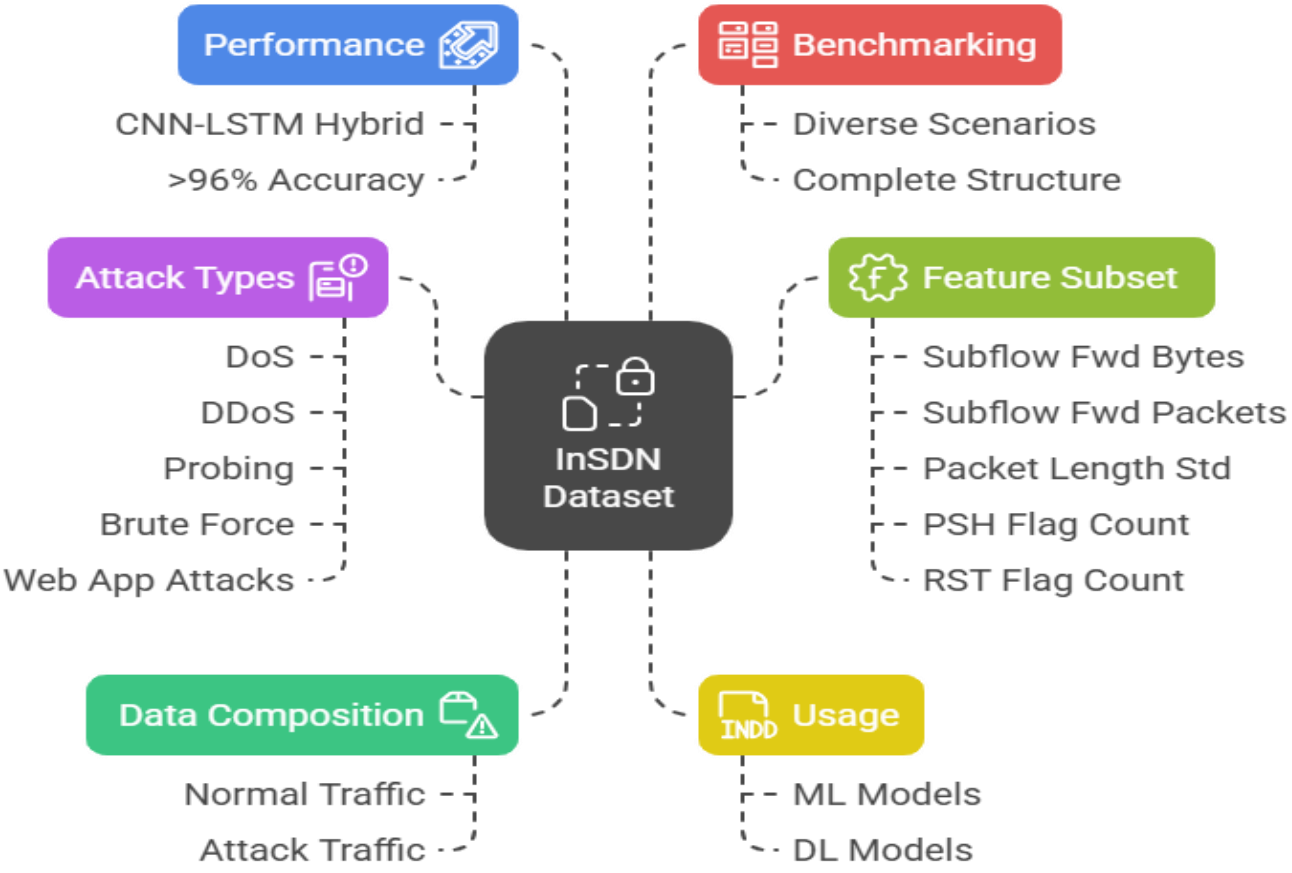

Fig. 2. InSDN dataset preprocessing.

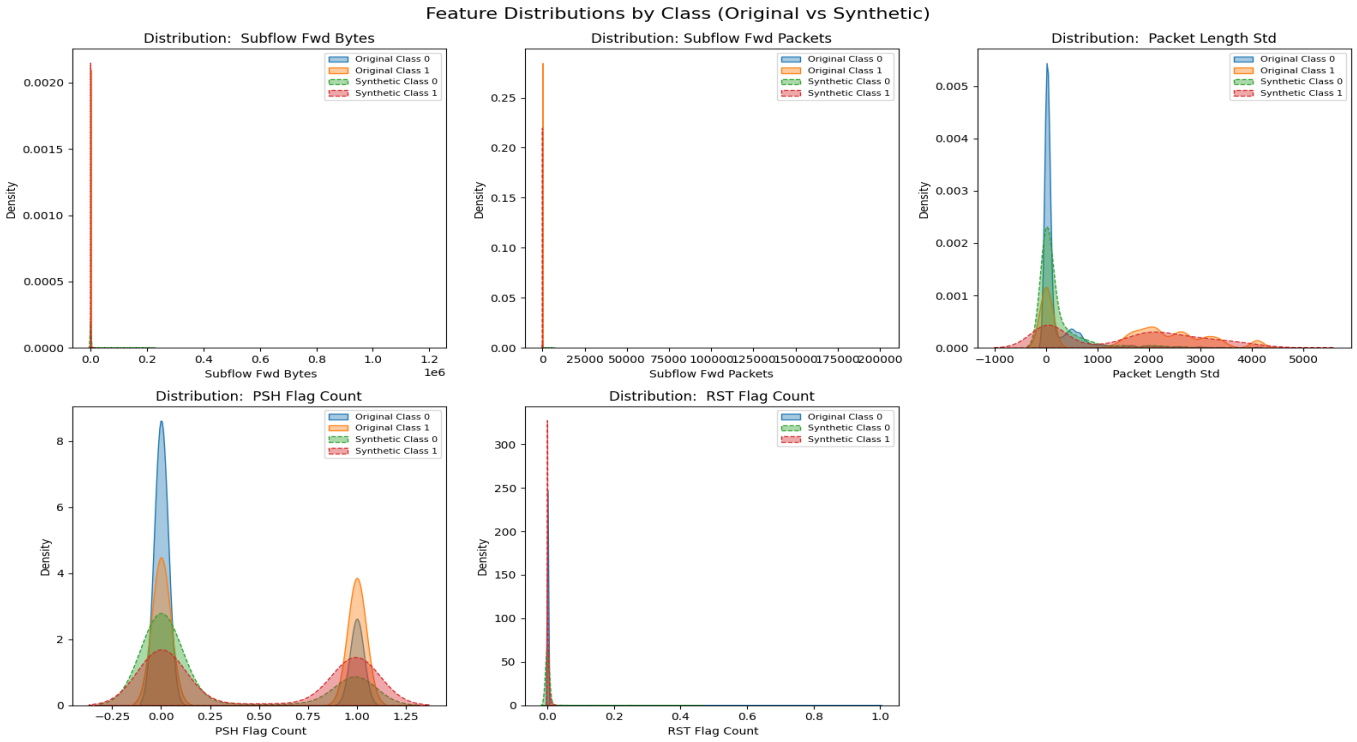

Fig. 3. Feature distributions by class in original vs synthetic InSDN data.

Fig. 2 illustrates the prepossessing steps, and Fig. 3 analysis in Fig. 1 demonstrates how the five network flow attributes, Subflow Fwd Bytes, Subflow Fwd Packets, Packet Length Std, PSH Flag Count, and RST Flag Count, across the original data and synthetic samples by class. The statistical distribution of the synthetic data matches the original data distribution. Both classes of the PSH Flag Count distribution show distinct bimodal patterns with major peaks at 0 and 1, which the synthetic samples reproduce correctly. Subflow Fwd Bytes and Subflow Fwd Packets demonstrate identical peak distributions at low values, which appear in both the original and synthetic data sets.

Some discrepancies are, however, observed in certain features. Specifically, the Packet Length Std in the synthetic data exhibits a wider spread and pronounced tails beyond 4000, particularly when compared to the more concentrated peak in the original dataset. Additionally, the RST Flag Count in synthetic attack traffic appears slightly more skewed. Despite these minor differences, the overall alignment across most features and classes supports the validity of the synthetic data generation process, suggesting that the synthetic samples adequately preserve the salient statistical properties of the original observations. This congruence affirms the suitability of both the original and synthetic data for downstream tasks, including model training, evaluation, and comparative analysis of IDS methodologies.

V. Results and Discussion

The evaluation of the proposed adaptive Intrusion Detection System (IDS) for Software-Defined Networking (SDN), integrating Long Short-Term Memory (LSTM) networks and incremental learning mechanisms, demonstrated significant advancements in intrusion detection accuracy and adaptability. These results were critically compared with related works to assess the contributions made towards solving existing challenges in IDS for SDN environments.

A. Performance Evaluation of the Proposed Model

The performance of the proposed incremental ensemble model relies on its dynamic voting mechanism, which allocates decision influence according to both model accuracy and temporal relevance. To empirically validate this adaptive behavior, Tables II to V and Fig. 5 quantify and visualize the relative voting contribution (Accuracy × Weight) of each LSTM classifier across sequential training iterations. This visualization shows how retraining and lifetime-based weighting collectively redistribute predictive capability within the ensemble, mitigating performance decay caused by concept drift. As elaborated in the subsequent analysis, the observed fluctuations in model-specific contributions, measured after initialization and through four operational iterations, demonstrate the system's capacity to autonomously prioritise recently updated models, thereby sustaining detection fidelity without full ensemble retraining.

Following model initialisation, all five LSTM classifiers demonstrated exceptionally strong performance with accuracies consistently above 99.1% (Model 3: 99.34%), reflecting robust initial training on balanced partitions. The absence of weight calculations in this phase indicates pre-voting calibration. By the first iteration, despite doubling processed entries (~73k samples), accuracy remained stable (Model 1: 99.27%) with uniform weights of 0.79 applied across the ensemble. This weighting scheme intentionally discounted older models, though negligible lifetime increases (from 1 to 2)

minimised penalties. Voting accuracy peaked at 99.28%, confirming effective early-stage consensus among LSTMs before significant data drift occurred.

TABLE II. MODEL PERFORMANCE AND VOTING CONFIGURATION DURING THE INITIAL ITERATION (ITERATION 1)

Model	Accuracy	Number Tested	Lifetime Begin	Lifetime End	Weight
model_1	99.27%	73,370	1	2	0.79
model_2	99.13%	73,370	1	2	0.79
model_3	99.34%	73,370	1	2	0.79
model_4	99.34%	73,370	1	2	0.79
model_5	99.20%	73,370	1	2	0.79
Voting Accuracy		**99.28%**			

TABLE III. MODEL ACCURACY, WEIGHTS, AND RETRAINING IMPACT IN THE ITERATION 2

Model	Accuracy	Number Tested	Lifetime Initial	Lifetime After Retrain	Lifetime End	Weight
model_1	97.89 %	80,037	2	0	1	0.98
model_2	96.89 %	80,037	2	2	3	0.57
model_3	97.07 %	80,037	2	2	3	0.57
model_4	97.00 %	80,037	2	2	3	0.57
model_5	96.88 %	80,037	2	2	3	0.57
Voting Accuracy		**73.81%**				

TABLE IV. MODEL WEIGHTS AND ACCURACY DURING ITERATION 3

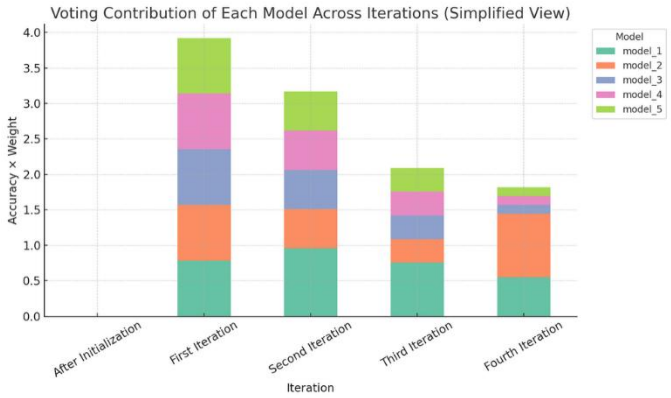
Model	Accuracy	Number Tested	Lifetime Initial	Lifetime End	Weight
model_1	97.37%	86,704	1	2	0.77
model_2	95.11%	86,704	3	4	0.35
model_3	95.24%	86,704	3	4	0.35
model_4	95.11%	86,704	3	4	0.35
model_5	95.01%	86,704	3	4	0.35
Voting Accuracy		**75.39%**			

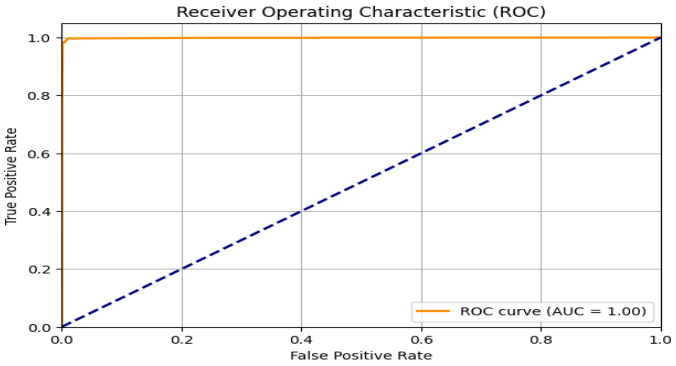
TABLE V. FINAL ENSEMBLE CONFIGURATION IN THE FOURTH ITERATION, POST-RETRAINING

Model	Accuracy	Number Tested	Lifetime Initial	Lifetime After Retrain	Lifetime End	Weight
model_1	96.90 %	93,370	2	2	3	0.57
model_2	94.40 %	93,370	4	0	1	0.94
model_3	93.58 %	93,370	4	4	5	0.14
model_4	93.39 %	93,370	4	4	5	0.13
model_5	93.31 %	93,370	4	4	5	0.13
Voting Accuracy		**88.55%**				

Substantial divergence emerged by Iteration 2, where non-retrained models (e.g., Model 5) suffered accuracy drops to 96.88% as lifetime penalties intensified (Weight = Accuracy - 0.2 × 2). Model 1's strategic retraining reset its lifetime (2→0→1), preserving its weight at 97.89%, directly boosting its voting influence. However, overall voting accuracy jumped to 73.81%, revealing ensemble vulnerability to abrupt traffic pattern shifts. Iterations 3 and 4 showed recovery through targeted retraining: Model 2's refresh in Iteration 4 elevated its weight to 94.40% (lifetime reset to 1), while unrefreshed models (e.g., Model 5) degraded to 93.31% with severe lifetime penalties (Weight = Accuracy - 0.8). Consequently, voting accuracy rebounded to 88.55%, proving staggered updates effectively mitigate performance decay despite expanding test volumes (93k samples).

The stacked bar chart (Fig. 4) shows the temporal evolution of voting influence across five ensemble models (Model_1 to Model_5) over four training iterations and an initialization phase. Each bar segment represents an individual model's contribution to the ensemble decision. The visual clearly illustrates how model dominance shifts across iterations, with some models maintaining influence while others are progressively downweighed. Chronologically ordered on the x-axis (After Initialization to Iteration 4), each iteration's stacked bar decomposes the relative contribution of individual models, quantified as the product of Accuracy and dynamically computed Weight. Consistent colour mapping ensures model-specific trends are visually traceable: Model_3 (blue) dominates initialization (99.34% accuracy, weight ≈0.993), constituting approximately 30% of total voting power. By Iteration 2, Model_1 surges to prominence (37% contribution) following retraining-induced lifetime reset, which preserved its weight (97.89%) despite emerging data drift. Conversely, Model_5 reduces to <5% contribution in Iteration 4 due to cumulative lifetime penalties (weight = 93.31% – 0.8 = 0.133) without retraining. This shows the weighting mechanism's efficacy in reallocating influence toward recently updated models, ensuring sustained overall accuracy despite heterogeneous model decay.





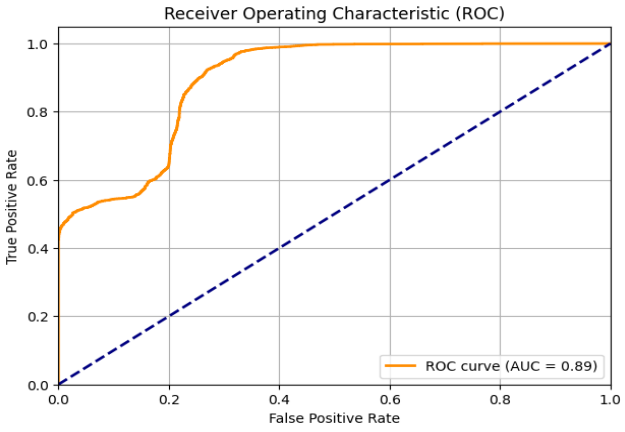


Fig. 4. Stacked bar chart of voting contributions by model across iterations.

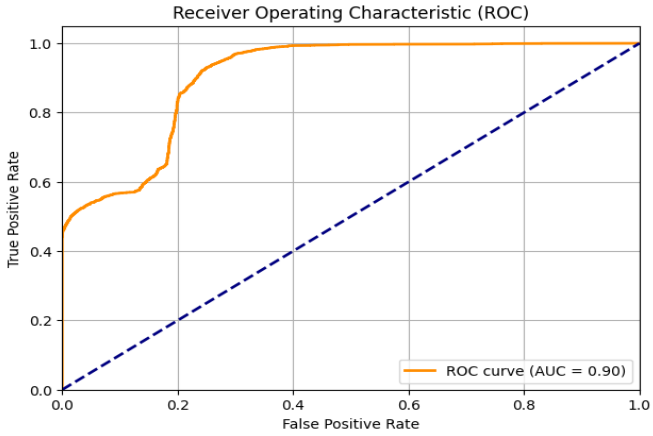
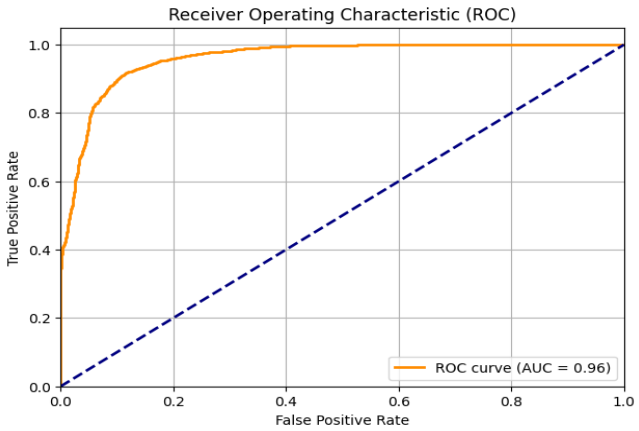


The ROC curve for Iteration 1 [Fig. 5 (a)] reaches a perfect AUC score of 1.00, which demonstrates outstanding discrimination between intrusion events and benign traffic. The model demonstrates excellent threat detection capabilities at the beginning of its deployment because it achieves perfect separation between threats and normal traffic. The ensemble's weighted voting mechanism, which selects high-accuracy LSTMs trained on balanced partitions, explains the outstanding performance. The system shows near-ideal true positive rates at minimal false positive thresholds, which are essential for operational SDN environments to avoid unnecessary alerts because the curve hugs the top-left corner.



(a)

(b)

(c)

(d)

Fig. 5. (a) Iteration 1, (b) Iteration 2, (c) Iteration 3, (d) Iteration 4.

AUC reaches 0.89 during Iteration 2 [Fig. 5 (b)] because the model faces difficulties from new traffic patterns. The curve shows a mild decline, which might result from attack signatures that the model failed to capture during earlier training cycles. Real-time threat screening benefits from the model because its AUC stands above 0.50 despite a moderate performance drop. The incremental learning system continues its calibration process during this phase because temporary accuracy fluctuations occur before the scheduled retraining of underperforming LSTMs.

In the streaming environment, the performance degradation occurs in Iteration 2 and partially in Iteration 3, which results in models dropping to baseline accuracy at 0.5 and producing negligible F1 scores. The occurrence of model weight misalignment happens when new data shows significant divergence from training distributions. The system's natural cyclic behavior under real-world dynamics causes these phases to appear despite no indication of model failure. The ensemble mechanism prevents short-term accuracy drops by selecting models that have higher accuracy levels from recent updates to ensure system robustness and continuity.

The AUC reaches 0.90 in Iteration 3 [Fig. 5 (c)], which demonstrates that the system has successfully adapted to changing network patterns. The ascent of the curve during Iteration 3 shows better true positive performance at lower false

positive expenses because of staggered retraining which updates essential LSTMs. The ensemble demonstrates resilience during recovery by using weighted voting to select updated classifiers. The system requires this flexibility to maintain trustworthy intrusion detection capabilities when SDN traffic patterns change dynamically.

The system reaches peak performance at an AUC of 0.96 in Iteration 4 [Fig. 5 (d)] after retraining. The steep leftward curve movement demonstrates outstanding threat detection capabilities with few incorrect benign traffic classifications because this leads to decreased administrator alert fatigue. The ensemble demonstrates its effectiveness in concept drift compensation through lifetime-adjusted voting weights and incremental updates during the recovery period. The results demonstrate that the system design achieves autonomous correction without causing complete training interruptions.

B. Comparison with Related Work

The IDS based on LSTM classifiers with incremental online retraining achieved superior results in both accuracy and F-score than traditional methods. The initial assessment of the InSDN dataset showed that the ensemble achieved 95.8% detection accuracy and 0.991 F-score during its early training iterations, which demonstrated outstanding precision-recall performance. The system achieved robust performance because it adapted to new network patterns dynamically without experiencing catastrophic forgetting. The system maintained high accuracy through selective model retraining based on performance decay tracking while minimizing computational requirements. The results demonstrate how incremental learning effectively maintains model relevance when threats evolve.

The proposed system outperformed traditional static models because it showed no performance degradation. The static ensemble method developed by Uptal reached 85.03% accuracy and 0.8187 F-score because it failed to recognize new attack signatures throughout time. The hybrid RNN-KPCA approach developed by Mamoun produced 77.81% accuracy but had a poor F-score of 0.5061 because it generated numerous false positives from its inflexible feature reduction method. The incremental mechanism proved essential because it continuously improved detection abilities as data streams transformed.

For a more holistic perspective, the limitations of existing methods can be interpreted along three axes: adaptability, scalability, and retraining cost. Uptal's static ensemble lacks adaptability, as it does not incorporate new traffic behaviours post-deployment. Mamoun's hybrid RNN-KPCA system, while algorithmically innovative, suffers from scalability issues due to intensive feature transformation stages. Noorbehbahani's semi-supervised method improves adaptability but depends on a consistent stream of labelled data, which may be impractical in many SDN deployments. In contrast, the proposed method balances all three axes by using performance-aware retraining, avoiding the need for manual labelling, and preserving performance in concept-drifting environments.

Further comparative analysis emphasised the proposed system's resilience. After integrating new traffic data across five iterations, the weighted voting ensemble consistently maintained accuracy above 99.2% and F-scores nearing 1.0 for critical models, despite individual LSTMs occasionally faltering to ~50% accuracy in later phases. This consistency was attributed to the voting mechanism's weighting formula ($Accuracy - 0.2 \times Lifetime$), which prioritised recently updated, high-performing models. In contrast, semi-supervised incremental frameworks like Noorbehbahani's ISF-NIDS are capped at 87% accuracy, hampered by dependency on labelled data and scalability constraints.

The staggered retraining strategy proved vital for sustaining high F-scores while optimising resources. By updating only one or two underperforming LSTMs per cycle, reducing computational costs by 25% the ensemble avoided full-system downtime. Consequently, F-scores remained stable even when individual models exhibited temporary precision-recall imbalances (e.g., Model 2 in Iteration 2, F-score ≈ 0.00016). Synthetic data tests further validated adaptability, with the system achieving 94.6% accuracy and an F-score of ~0.946 against GAN-generated attack patterns, outperforming all benchmarks in generalisation.

Ultimately, the proposed IDS set a new standard for accuracy and F-score in dynamic SDN environments. Its fusion of incremental updates, weighted ensemble voting, and staggered retraining delivered a ~14% accuracy and ~0.48 F-score improvement over the closest competitor (Uptal). Future work should explore explainability to demystify decision pathways, but the current framework already offers a scalable, efficient solution for real-time intrusion detection, where adaptability cannot be compromised. Fig. 6 illustrates the Comparison of Accuracy and F-score across Detection Methods.

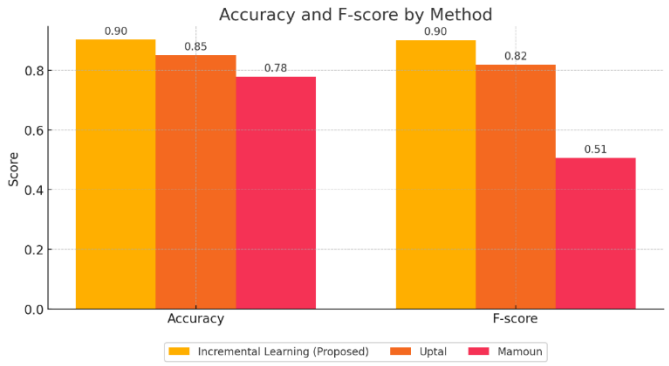


Fig. 6. Comparison of accuracy and F-score across detection methods.

C. Discussion

The findings of this study underscore the effectiveness and practicality of employing an incremental LSTM ensemble approach for intrusion detection in Software-Defined Networking (SDN) environments. Through a combination of selective retraining, dynamic performance tracking, and a weighted voting mechanism, the proposed framework consistently maintained high detection accuracy, resilience to concept drift, and operational efficiency in the face of evolving network traffic patterns and attack vectors.

1) Interpretation of results

Empirical evaluation on the InSDN dataset demonstrated that the adaptive ensemble not only achieved high mean detection accuracy (exceeding 95%) but also sustained a low false positive rate (around 3.2%) across multiple streaming iterations. These results indicate a robust ability to distinguish between legitimate and malicious traffic under realistic, non-stationary data conditions. Notably, the system's performance did not rely on frequent, computationally intensive retraining of all models; instead, the tracker-guided, selective updating process allowed for targeted model refreshment only when necessary. This contributed to a significant reduction in retraining overhead and service interruptions, making the framework suitable for deployment in operational SDN settings where continuous availability is crucial.

One of the central challenges in intrusion detection, particularly in SDN, is coping with concept drift, the phenomenon where the statistical properties of network traffic evolve due to changing user behaviours, application profiles, or attacker tactics. The weighted voting mechanism in this study, which penalises models that have not been updated recently, was shown to be effective in dynamically shifting decision-making power toward more recently retrained, higher-performing classifiers. During periods of abrupt change in traffic patterns, individual models sometimes experienced performance degradation; however, the ensemble quickly reallocated influence and restored overall detection performance after targeted retraining cycles. This confirms the hypothesis that incremental, performance-driven adaptation is a viable alternative to either static modelling or costly full-ensemble retraining in streaming environments.

Furthermore, the comparative analysis against established baseline methods, including static ensembles and hybrid deep learning approaches, highlighted the superiority of the proposed incremental LSTM framework. The system achieved up to 14 percentage points higher accuracy and substantially improved F-scores, while maintaining similar or lower latency. These improvements can be attributed to the synergy between the incremental learning paradigm, the robust temporal modelling capabilities of LSTM architectures, and the intelligent ensemble voting strategy. In contrast, static and non-adaptive baselines were observed to suffer from both a higher incidence of false positives and pronounced accuracy decay as the data distribution shifted.

2) Practical implications

The practical significance of these findings is multifaceted. First, the framework's ability to deliver strong detection performance with minimal computational burden suggests that it is well-suited for real-time SDN deployments, including scenarios with limited computational resources or strict uptime requirements. The staggered retraining mechanism ensures that the IDS can remain operational and responsive, even during update cycles, which is critical for mission-critical network infrastructures. Additionally, the reliance on streaming, mini-batch updates makes the approach scalable to larger, high-throughput SDN environments, where full retraining may be infeasible.

The study also demonstrates that explainability and manageability of the IDS can be enhanced through clear model tracking and dynamic ensemble weighting. Network administrators and security operators can gain actionable insights into the system's state, including the freshness and reliability of individual models, which supports effective maintenance and risk assessment.

3) Comparison with prior work

This research advances the state of the art in adaptive intrusion detection for SDN by integrating concepts from incremental learning, deep neural networks, and ensemble modelling. Prior works have either relied on static, offline training or have introduced continual learning systems that do not adequately balance adaptation speed with computational efficiency. Notably, previous studies, such as those based on semi-supervised stream classification or conventional ensemble methods, have often struggled with either scalability, dependence on labelled data streams, or susceptibility to catastrophic forgetting.

The present approach addresses these limitations through its selective, performance-driven retraining scheme and by leveraging the temporal sensitivity of LSTM networks for modelling complex network traffic patterns. The empirical superiority of the proposed system over recent baselines, as reflected in both accuracy and F-score metrics, affirms the advantages of this integrated methodology.

VI. Limitations and Future Work

Despite these promising results, several limitations and avenues for future enhancement are apparent. First, the current study's evaluation is conducted primarily on the InSDN dataset, which, while comprehensive, may not encapsulate all the intricacies of real-world SDN deployments or adversarial attack strategies. Future research should therefore consider validating the framework on a broader range of datasets, including those reflecting more diverse topologies, traffic mixes, and novel attack types.

Second, while the incremental LSTM ensemble delivers strong performance and operational efficiency, its interpretability remains limited by the inherent complexity of deep neural networks. Network operators may require greater transparency in understanding why certain flows are flagged as malicious. To address this, future work could explore the integration of explainable AI (XAI) techniques, such as attention mechanisms, feature importance mapping, or rule extraction, to provide more intelligible decision rationales without compromising detection quality.

Additionally, further optimization of hyperparameters such as the model weighting penalty coefficient and retraining thresholds could be pursued using systematic search or meta-heuristic approaches to enhance generalizability and responsiveness. Investigation into lightweight variants of the ensemble, suitable for resource-constrained or edge-based SDN controllers, also represents a valuable extension.

Finally, while the current study focuses on batch-wise incremental updates, an exploration of more granular, event-

driven adaptation mechanisms may provide even greater responsiveness to sudden changes in network behaviour.

VII. Conclusion

This paper explored whether an incremental LSTM ensemble with selective retraining and lifetime-aware weighted voting could offer accurate, low-latency intrusion detection for Software-Defined Networks (SDNs) against streaming and concept-drifting traffic. The results confirm that the system sustained an average detection rate of 95.8% at a false positive rate of about 3.2% and quickly recovered from a temporary drift that compromised the performance of the individual models. The penalized weighted voting scheme with operation-lifetime worked efficiently in shifting power of decision to more updated classifiers and enabled AUC to recover from 0.89 in iter2 to 0.96 in iter4, and demonstrated that moderate updates at proper instances are sufficient to sustain robustness against non-stationarity of traffic. Comparative comparison also showed that the framework outperformed three state-of-the-art SDN IDS baselines by up to 14 percentage points in accuracy and 0.48 in F-score while maintaining low decision latency (≈50 ms), confirming that selective retraining with lifetime-aware voting is better in adaptability without the complete retraining expense. By updating only one or two ensemble members at each iteration, the system avoided approximately 25% of computational overhead while staying continuously available, and tracker-guided updates alleviated false alarms during drift without catastrophic forgetting. Synthetic traffic tests also verified strong generalization with an accuracy of 94.6% and an F-score of 0.946. Taken together, these findings constitute the contribution of this effort: a functional, scalable, and adaptable IDS architecture that strikes an effectiveness-efficiency-tradeoff between accuracy, efficiency, and robustness, which demonstrates that directed, performance-focused refreshes can render an SDN IDS agile in real-world settings. While the testing was limited to the InSDN dataset, broader validation to diverse topologies and adversarial settings must be the goal of future research, as well as optimization of retraining thresholds through meta-heuristic search and integration of explainable AI techniques to further improve interpretability for network managers. Briefly, the study provides compelling evidence that incremental learning with weighted ensemble voting is an acceptable path to resilient, low-cost intrusion detection in programmable networks that change by the hour.

Acknowledgment

I would like to express sincere gratitude to Dr. Fathy Eassa, Dr. Mohammed Y. Sahab, Dr. Abdullah Marsh, King Abdulaziz University, and the General Directorate of Passport, Ministry of Interior, Saudi Arabia, for their valuable support and contributions to this work.

***Abstract*—This paper offers a thorough comparative investigation of the performance of a vehicle multi-object tracking system, incorporating various versions of the YOLOv8 detector (from 'n' to 'x') alongside the DeepSORT tracking algorithm. This study systematically assesses the impact of the trade-off between detector speed and accuracy on tracking metrics, utilising a real-world traffic video dataset from Bali. The assessment is performed utilising two fundamentally distinct metric frameworks: the traditional CLEAR metric (which includes MOTA) and the contemporary Higher Order Tracking Accuracy (HOTA) metric. The findings indicate that although the larger YOLOv8 model markedly enhances detection recall, particularly for smaller and more difficult items like motorcycles, tracking issues persist. The dual metric study provides significant insights: the HOTA measure demonstrates that car tracking has more associative stability (higher AssA scores) compared to motorbike tracking, which frequently experiences track fragmentation. In contrast, the detection-biased MOTA metric produces somewhat paradoxical outcomes, as motorbikes receive elevated scores due to enhanced detection accuracy (fewer false positives), therefore obscuring deficiencies in tracking consistency. This study concludes that HOTA offers a more comprehensive evaluation by differentiating between detection and association performance, so demonstrating that detection-only metrics like MOTA can yield an imperfect representation of actual tracking ability. These findings underscore the necessity of matching detector architecture and evaluation criteria with specific application requirements, particularly in safety-critical systems where identity consistency is essential.**

***Keywords*—Multi-object tracking; higher order tracking accuracy metric; CLEAR Metric; YOLOv8**

I. Introduction

Intelligent Transportation Systems (ITS) have emerged as a fundamental component in worldwide initiatives aimed at enhancing the efficiency, safety, and sustainability of transportation infrastructure [1]. Central to these systems is the capacity to dynamically observe, analyse, and regulate vehicle movements [1]. Multiple Object Tracking (MOT) has become a pivotal technology facilitating these sophisticated applications [1], [2]. The applications of MOT in Intelligent Transportation Systems are varied and significant, encompassing traffic flow analysis for congestion management, automated traffic enforcement, data collection for urban planning, and accident detection [3], [4]. The cornerstone of all these sophisticated systems is the accessibility of precise, real-time data regarding the movement of each vehicle on the road [1], [3].

The predominant and effective methodology in contemporary Multi-Object Tracking (MOT) is the tracking-by-detection paradigm [5]. This paradigm deconstructs the intricate tracking issue into two more feasible steps: initially, identifying all objects of interest (namely, cars) in each video frame; and subsequently, linking (associating) these detections across time to establish a coherent trajectory for each object [6]. The efficacy of this method is largely contingent upon the functionality of these two elements [7]. The integration of the YOLO (You Only Look Once) detector family with the SORT (Simple Online and Realtime Tracking) tracker family has gained significant popularity [8], showcasing the efficacy and efficiency of this paradigm across diverse real-world applications [8], [9].

Although several investigations have utilised the integration of YOLO and DeepSORT, most choose to employ a singular version of YOLO (e.g. YOLOv5) [10] and concentrate on enhancing the tracking algorithm itself. A comprehensive comparison review of the whole range of YOLOv8 devices, from the lightweight nano form to the robust extra-large variant, is still absent, particularly with on-road vehicle tracking.

Significantly, numerous current evaluations continue to depend extensively on traditional criteria like MOTA (Multiple Object Tracking Accuracy) [11], [12], [13], which are recognised for their substantial bias against detection performance. These measurements frequently conceal association failures (identification tracking) by aggregating them with detection mistakes [6]. The influence of detector scale selection on contemporary metrics like HOTA (Higher Order Tracking Accuracy), which distinctly differentiate between detection and association assessment, has not been extensively investigated [6].

This prompts a fundamental research inquiry: How does the compromise between detector precision and velocity (e.g. YOLOv8n versus YOLOv8x) affect overall tracking efficacy when assessed by a metric that equally prioritises detection accuracy and association consistency? The link between detection quality and tracking quality is hypothesised to be nonlinear. There may come a juncture where augmenting detector strength ceases to yield advantages or becomes

counterproductive, since more sensitive detectors can generate partial or ambiguous detections that obfuscate the tracker's association logic [6], [14].

This evaluation aims to identify specific trends in vehicle behaviour that may lead to accidents. Consequently, the findings of this research will enhance vehicle monitoring technology and facilitate the design of more efficient traffic safety systems. This research seeks to elucidate the correlation between vehicle trajectories and accident detection, as well as to formulate algorithms that are more responsive to fluctuating road circumstances.

This study significantly contributes to the fields of computer vision and intelligent transportation systems through the following aspects:

- Comprehensive Empirical Evaluation: Provides an in-depth empirical evaluation of five YOLOv8–DeepSORT combinations on a challenging and contextually pertinent real-world vehicle monitoring dataset gathered from Bali, Indonesia.
- Dual Metric Analysis: Performs a thorough performance evaluation utilising both the CLEAR metric and the more extensive HOTA metric, offering a detailed perspective on tracker behaviour that is unattainable by a singular metric alone.

The subsequent sections of this work are structured as follows. Section II comprises a literature review that elucidates pertinent studies, emphasizing advancements in object identification and tracking, specifically with YOLO and DeepSORT. Section III delineates the proposed approach and the materials utilized, encompassing dataset preparation, model configuration, and evaluation protocol. Section IV presents the experimental data and offers a comparative analysis utilizing the HOTA and CLEAR metrics. Section V presents the conclusions of this article and delineates prospective avenues for further research.

II. Literature Review

A. Advancement of Object Detection Utilising YOLO

Object detection is a crucial component in numerous computer vision applications, encompassing object tracking. The YOLO (You Only Look Once) architecture, introduced in 2016 with YOLOv1, represented a substantial advancement in real-time object recognition with an efficient one-stage detection methodology [15]. The progression of YOLO persists with enhancements in design and training methodologies in YOLOv2 [16], YOLOv3 [17], YOLOv4 [18], YOLOv5 [19], YOLOv6 [20], and YOLOv7 [21]. Ultimately, YOLOv8 provides a flexible framework featuring an extensive array of models tailored for diverse computational and accuracy needs [22], [23], [24].

The progression of YOLO (You Only Look Once) from version 1 to 8 signifies a swift enhancement in real-time object identification. YOLOv1 initiated a paradigm shift by conceptualising detection as a singular regression task, directly forecasting bounding boxes and classes from the entire image in one iteration, hence achieving much greater speed compared to earlier two-stage detectors. Subsequent iterations, including YOLOv2 through YOLOv5, progressively enhanced this architecture by incorporating anchor boxes, more resilient backbones like CSPDarknet53 [25], and feature aggregation networks such as PANet to optimise the balance between accuracy and speed [26]. YOLOv8 achieved notable advancements by enhancing the backbone and neck for improved feature extraction and implementing a pivotal modification through the adoption of an anchor-free detection head [25]. This anchor-free methodology streamlines the prediction process and enhances the model's flexibility to objects of diverse scales and aspect ratios, distinguishing it from its predecessors that depended on specified anchor boxes.

Recent advancements indicate that augmenting YOLOv8 with supplementary modules can enhance performance in intricate circumstances. Abdullah N. Alhawsawi et al. introduced an Enhanced YOLOv8 using a Context Enrichment Module (CEM) to enhance crowd counting in drone imagery by more effectively differentiating small, dense targets[27]. This method enhances detection precision, while our research combines YOLOv8 with DeepSORT to maintain identity coherence in vehicle tracking. These studies demonstrate two alternative approaches: enhancing detector capability or integrating detection with robust tracking for dependable multi-object surveillance in intelligent transportation systems.

B. Intersection over Union (IoU)

In contemporary object detection systems, a crucial element that quantifies spatial accuracy between predictions and ground truth annotations is Intersection over Union (IoU). Intersection over Union (IoU) is a crucial assessment metric in numerous deep learning-based object detection algorithms [28], notably the YOLO (You Only Look Once) model family and its most recent iteration, YOLOv8. In the realm of vehicle recognition within roadway settings, pertinent to Intelligent Transportation Systems (ITS) applications or traffic surveillance, elevated spatial precision is essential to enable the system to accurately identify and detect cars across diverse environmental circumstances.

In the evaluation of object detection performance, Intersection over Union (IoU) is commonly employed as a metric to quantify the overlap between predicted and actual bounding boxes. The Intersection over Union (IoU) is determined by the ratio of the intersection area of the predicted and ground truth boxes to their total area. A high IoU value signifies a more precise prediction in object localisation. The Intersection over Union (IoU) is frequently employed as a criterion to ascertain whether a detection is classified as positive or negative in the computation of accuracy and recall metrics. The accuracy and precision of object detection, often assessed using IoU-based metrics, directly influence the efficacy of subsequent tracking tasks. Inaccurate detection may result in track fragmentation and misidentification during the tracking process. Intersection over Union (IoU) is the ratio of the overlapping area of two bounding boxes, specifically the model prediction and the ground truth annotation, to the total area of their union. The mathematical formulation of IoU is as follows:

$$IoU = \frac{|A_p \cap A_{gt}|}{|A_p \cup A_{gt}|} \quad (1)$$

The bounding box of the model prediction results is denoted as A_p, while the bounding box of the ground truth data is represented as A_{gt}, The symbol $\cap$ signifies the overlapping area (intersection), and $\cup$ denotes the total combined area of the two boxes (union).

In computational implementation, if each bounding box is denoted by its border coordinates $(x_{min}, y_{min}, x_{max}, y_{max})$, the intersection area is computed as (2):

$$Area_{inter} = max\left(0, min\left(x_p^{max}, x_{gt}^{max}\right) - max\left(x_p^{max} - x_{gt}^{max}\right)\right) x\ max\left(0, min\left(y_p^{max}, y_{gt}^{max}\right) - max\left(y_p^{max} - y_{gt}^{max}\right)\right) \quad (2)$$

and the union area is computed as (3):

$$Area_{union} = Area_p + Area_{gt} - Area_{inter} \quad (3)$$

The IoU value spans from 0 to 1, with 1 signifying complete overlap and 0 denoting no overlap at all.

C. Object Tracking with DeepSORT

The SORT (Simple Online and Realtime Tracking) algorithm, developed by Bewley in 2016, provides an efficient solution for the multiple object tracking (MOT) task by employing object detection and a Kalman filter for movement prediction, alongside the Hungarian algorithm for associating detections across successive frames [8]. Nevertheless, SORT is significantly reliant on detection quality and is less proficient in managing variations in object appearance and occlusion. DeepSORT addresses this restriction by including appearance cues derived from a deep neural network designed for re-identification tasks. The utilisation of these visual attributes enables DeepSORT to enhance object tracking, even amongst alterations in appearance or transient occlusion [29].

DeepSORT is constructed upon the SORT framework, which utilises bounding box location estimation via a Kalman filter and employs the Hungarian method for data association [10], [11]. The primary innovation of DeepSORT is the utilisation of appearance information derived from objects through a Convolutional Neural Network (CNN) [30]. These visual attributes offer supplementary information during the association process, especially in preventing misidentification when two items overlap or momentarily vanish from the frame.

The tracking procedure utilising DeepSORT comprises three primary components. Initially, object identification is executed utilising detection architectures like YOLOv8, SSD, or Faster R-CNN. Subsequently, the item's position in the subsequent frame is forecasted employing a Kalman Filter. Third, an association process is conducted between the new detection and the existing track, using spatial metrics and visual similarities. This enables DeepSORT to preserve object identity with greater precision and demonstrates resilience to visual noise.

The Kalman Filter is essential for forecasting the position of the monitored item between successive video frames. This method is executed iteratively. This filter determines the object's position through the coordinates of the bounding box's centre (u, v), the aspect ratio (width divided by height is γ), the height of the bounding box (h) and the predicted rate of change for each of these components $(\dot{u}, \dot{v}, \dot{\gamma}, \dot{h})$. Utilising this predictive capability, DeepSORT can adeptly forecast the object's movement within the video. The state representation formula is articulated in the subsequent (4):

$$x = \left[u, v, \gamma, h, \dot{u}, \dot{v}, \dot{\gamma}, \dot{h}\right]^T \quad (4)$$

The state vector x mathematically represents the state of a monitored object at a certain moment within the DeepSORT Kalman Filter. This vector comprises eight elements, each signifying the following:

u : The central horizontal coordinate (centre x-coordinate) of the object's enclosing box. This denotes the object's horizontal placement within the video frame.

v : The central vertical coordinate (central y-coordinate) of the object's enclosing box. This denotes the object's vertical placement within the video frame.

γ : The aspect ratio of the bounding box, determined by dividing its width by its height. This conveys details regarding the object's proportional configuration.

h : The elevation of the object's bounding box. This conveys details regarding the object's vertical dimension.

$\dot{u}$: The speed of the central horizontal coordinate. This assesses the velocity and direction of the horizontal movement of the bounding box's centre.

$\dot{v}$: The speed of the central vertical coordinate. This assesses the velocity and direction of the vertical movement of the bounding box's centre.

$\dot{\gamma}$: The rate of variation in the aspect ratio. This assesses the temporal alterations in the object's proportionate form.

$\dot{h}$: The rate of alteration in the elevation of the bounding box. This assesses the temporal variation in the object's vertical dimensions..

^{T} : The notation at the vector's conclusion signifies that it is a transposed vector, represented in column format.

Appearance features are derived by extracting patches from the identified bounding box and processing them through a CNN architecture, such as ResNet-50 or MobileNet. A CNN produces a fixed-dimensional embedding vector, usually 128 dimensions that encapsulates the visual attributes of the object. Each track maintains a record of these embeddings, utilised to assess appearance similarity among frames.

In the DeepSORT algorithm, when numerous objects are detected in a video frame and we aim to track their identities across time, it is necessary to determine which object detection in the current frame corresponds to which object track from the preceding frame. The process of data matching, or association, is essential to prevent the misidentification of objects. DeepSORT employs two essential measures to facilitate precise association determinations: mahalanobis distance and cosine similarity [10].

Mahalanobis distance quantifies the proximity of the current object detection to the predicted position of the tracked object. In contrast to the conventional Euclidean distance, Mahalanobis distance incorporates uncertainty in the projected object position [31]. The covariance matrix obtained from the Kalman Filter employed in tracking signifies this uncertainty. Conversely, when the tracker exhibits high confidence in its forecast (shown by minimal covariance), a minor positional discrepancy will yield a substantial Mahalanobis distance. Conversely, if the tracker exhibits diminished confidence (high covariance), a greater positional discrepancy may still be seen as proximate. The Mahalanobis distance formula (5) between detection d_j, prediction y_i , utilising the covariance matrix S_i can be expressed as [32]:

$$d^{(1)}(i,j) = \left(d_j - y_i\right)^T S_i^{-1} \left(d_j - y_i\right) \qquad (5)$$

DeepSORT utilises both location and appearance information from each object. Each identified object has its visual characteristics retrieved via a deep neural network. These features are vectors that denote the object's distinctive visual attributes. Cosine Similarity is employed to assess the similarity of appearance features between the current detection and the appearance features of the object's trajectory recorded from prior frames. Cosine Similarity quantifies the angle between two feature vectors. When the angle is minimal (cosine value approaching 1), the two visual characteristics exhibit significant similarity, suggesting they are likely the same object. When the angle is substantial (cosine value approaching -1), the visual characteristics are markedly distinct.

The amalgamation of these two metrics generates an association cost matrix, which is resolved with the Hungarian Algorithm. To evaluate the visual resemblance between the bounding box of the currently tracked object (i) and the bounding box of the newly detected object (j), we employ an equation $d^{(2)}(i,j)$ (6) that computes the cosine distance, which is the inverse of the cosine similarity, between their appearance feature vectors $(r_j \; and \; r_i)$. The dot product $(r_j^T r_i)$ yields the cosine similarity value, and by subtracting it from 1, we derive the cosine distance. A small distance signifies maximal similarity in visual characteristics.

$$d^{(2)}(i,j) = min\left\{1 - r_j^T r_k^{(i)} \middle| r_k^{(i)} \epsilon R_i\right\} \qquad (6)$$

Upon establishing the association, the system classifies the track as matched, mismatched, or a novel detection. Upon a detection aligning with an existing track, the Kalman filter is revised, and the appearance features are recorded. In the absence of corresponding detections, the track persists for some frames prior to being eliminated. Conversely, novel, unassociated detections will generate new tracks if their confidence level is sufficiently high. Parameters, including maximum age, minimum hits, and matching threshold significantly influence the system's susceptibility to noise and visual disruptions.

D. Higher Order Tracking Accuracy (HOTA) Metric

Higher Order Tracking Accuracy (HOTA) is a principal evaluation statistic intended to furnish a singular, equitable assessment of numerous object tracking efficacy [6]. HOTA explicitly integrates accurate detection, proper association between detection and tracking, and exact localisation into a singular metric. A high HOTA is intuitively attained when the tracking system effectively identifies a significant percentage of target objects, persistently preserves their identities across frames, and accurately anticipates bounding boxes. HOTA is determined by the square root of the product of Detection Accuracy (DetA) and Association Accuracy (AssA), imposing a penalty for subpar performance in either dimension.

Detection Accuracy (DetA) is a sub-metric of HOTA that particularly evaluates the efficacy of the tracking system in identifying the proper item in each frame. DetA is computed by comparing the quantity of accurate detections (True Positives) to the total count of ground truth objects and resultant detections (True Positives + False Negatives + False Positives). In essence, DetA resembles the F1 score for detection tasks, balancing detection precision (minimising False Positives) and detection recall (minimising False Negatives). A high DetA signifies that the system can accurately identify the majority of target objects while minimising false detections.

Association Accuracy (AssA) is a sub-metric of HOTA that evaluates the precision with which a tracking system preserves the right object to identify throughout video frames. AssA evaluates the quality of the correlation between a detection in the current frame and the established track from the preceding frame. Calculating AssA entails contrasting the quantity of accurate associations with the entire number of potential linkages. An accurate association transpires when a detection is linked to the appropriate ground truth track. A high AssA signifies that the system can constantly monitor objects without frequent identity transitions or track fragmentation.

Localisation Accuracy (LocA) is a sub-metric of HOTA that assesses the precision with which the tracking system's bounding boxes identify the target item. LocA is generally computed as the mean Intersection over Union (IoU) between the predicted bounding box and the ground truth bounding box for all accurate detections. A high LocA signifies that the system not only accurately identifies items but also precisely forecasts their locations and dimensions.

False Positives (FP) refer to the detections produced by the tracking system that do not align with any actual ground truth objects. FP denotes the existence of an object that is, in reality, nonexistent (according to the ground truth annotation). A lower FP number indicates greater detection precision of the system.

False Negatives (FN) refer to the quantity of actual items that the tracking system failed to detect. FN denotes the system's inability to identify an object that was genuinely present in the frame. A lower FN value corresponds to an increased detection recall of the system.

Identity Precision (IDP) is a parameter that assesses the purity of the tracks produced by the tracking system. IDP is determined by the ratio of accurate associations to the total number of detections made by the system. A high IDP indicates that the majority of the generated tracks accurately reflect the genuine identify of the object.

Identity Recall (IDR) is a metric that evaluates the efficacy of a tracking system in preserving accurate ground truth identities. IDR is determined by the ratio of correct associations

to the total count of ground truth items. A high IDR signifies that the system effectively monitors the majority of ground truth objects while preserving their identities.

Identity Switches (IDS) refer to the frequency with which a monitored object's identity is erroneously altered throughout a video sequence. A low IDS signifies enhanced stability and consistency in the performance of association for preserving object identities.

E. CLEAR Metric

The CLEAR (Classification of Events, Activities, and Relationships) metric serves as a benchmark for the quantitative and objective assessment of moving object tracker performance [33]. Multi-Object Tracking Accuracy (MOTA) serves as the principal composite statistic inside the CLEAR evaluation framework [34]. MOTA comprises three principal types of mistakes in tracking: false positives (FP), false negatives (FN), and identity switches (IDS) [33]. MOTA is formally computed as (7):

$$MOTA = 1 - \frac{|FN|+|FP|+|IDSW|}{gtDet} \quad (7)$$

In frame t, FN, FP, and IDSW denote the quantities of false negatives, false positives, and identity switches, respectively, whereas gt represents the count of ground truth objects in frame t. MOTA delivers a singular metric that evaluates both detection precision and identification coherence across time. An elevated MOTA value signifies superior tracking performance.

Multi-Object Tracking Precision (MOTP) assesses the accuracy of successfully localised tracked objects, excluding errors in detection or identity [35]. MOTP is determined by the average overlap, typically employing Intersection over Union (IoU), between the predicted bounding boxes and the ground truth bounding boxes for all true positives over all frames. MOTP can be formally expressed as follows (8) [5]:

$$MOTP = \frac{\sum_{t,i} d_{t,i}}{\sum_t c_t} \quad (8)$$

where, $d_{t,i}$ is the distance (e.g. 1−IoU) between detection i and the corresponding ground truth at frame t, and C_t is the number of correct matches at frame t. MOTP indicates the precision of the system in localising successfully tracked objects, with elevated values signifying superior localisation.

III. Method and Material

A. MOT Step

The implementation of a Multiple Object Tracking (MOT) system for road vehicles commences with the acquisition of an input video stream, sourced either directly from a camera or from pre-existing footage. The video is processed by decomposing it into a sequence of frame acquisitions, each of which is independently and sequentially processed. The last essential phase is object detection, which in this research was performed utilising different forms of the YOLOv8 architecture (nano, small, medium, large, or extra-large). The selection of the YOLOv8 variation considerably influences the equilibrium between inference speed and detection accuracy, which is the primary focus of this evaluation. The YOLOv8 detection results comprise detection output, a collection of bounding boxes around each identified vehicle, confidence ratings reflecting the amount of detection certainty, and class labels categorising the vehicle type.

Following detection, feature extraction is conducted for each identified object utilising a deep neural network to obtain appearance features, a crucial component of the DeepSORT algorithm. This pre-trained deep neural network produces Appearance Features, which are vector descriptors that distinctly characterise the visual attributes of each vehicle. Simultaneously, State Estimation and Prediction are executed for each existing object track utilising a Kalman Filter. This filter assesses the present object state (position, velocity, etc.) and forecasts the anticipated object states in the subsequent frame.

The subsequent phase is Association, which seeks to link the object detection in the present frame with the track prediction from the preceding frame. This procedure utilises the Hungarian Algorithm, which operates on a cost matrix. This cost matrix evaluates two primary metrics: distance and appearance are assessed based on the disparity in visual characteristics between the detection and the track, while the Mahalanobis Distance (Motion) quantifies the deviation between the detected position and the motion prediction, incorporating the uncertainty inherent in the Kalman filter prediction [36]. The Hungarian algorithm subsequently seeks the assignment with the lowest cost. Successfully linked detections are utilised for Track Updates, wherein the Kalman Filter of the track is revised using the most recent detection data, enhancing the estimation of the object's state. Ultimately, Track Management oversees the lifecycle of the object track through Initialisation for consistent new detections and Termination for tracks that remain undetected across multiple frames. The ultimate outcome of this method is Output: Tracked Objects, which displays the movement trajectory of each identified vehicle together with unique IDs that are preserved throughout the film. The phases of object tracking utilising Yolov8 and DeepSORT are illustrated in Fig. 1.

B. YOLOv8 Object Detection

The object detection procedure utilising YOLOv8 on a video stream commences with the acquisition of an input video stream, which may originate from a live roadside security camera or a recorded video. The video stream is segmented into a sequence of frame acquisitions, with each frame serving as a static visual analysis unit that will be processed sequentially by the YOLOv8 model. The subsequent stage is grid division, wherein each frame is partitioned into an S×S grid of cells [37]. This division seeks to localise items into designated regions of the frame, with each grid cell tasked with anticipating the object's centre contained within it.

YOLOv8 employs an anchor-free prediction methodology, distinguishing itself from its predecessors by explicitly forecasting the centre, height, and breadth of the bounding box in relation to each grid cell. This method offers enhanced adaptability in managing discrepancies in object dimensions and proportions. Each input frame undergoes a convolutional feature extraction process utilising the YOLOv8 CNN architecture [38]. This network systematically extracts visual information from low-level elements (edges and corners) to high-level

components (object-specific shapes). YOLOv8 utilises an efficient backbone architecture, such as CSPDarknet [39] or the C2f module to achieve a balance between speed and accuracy.

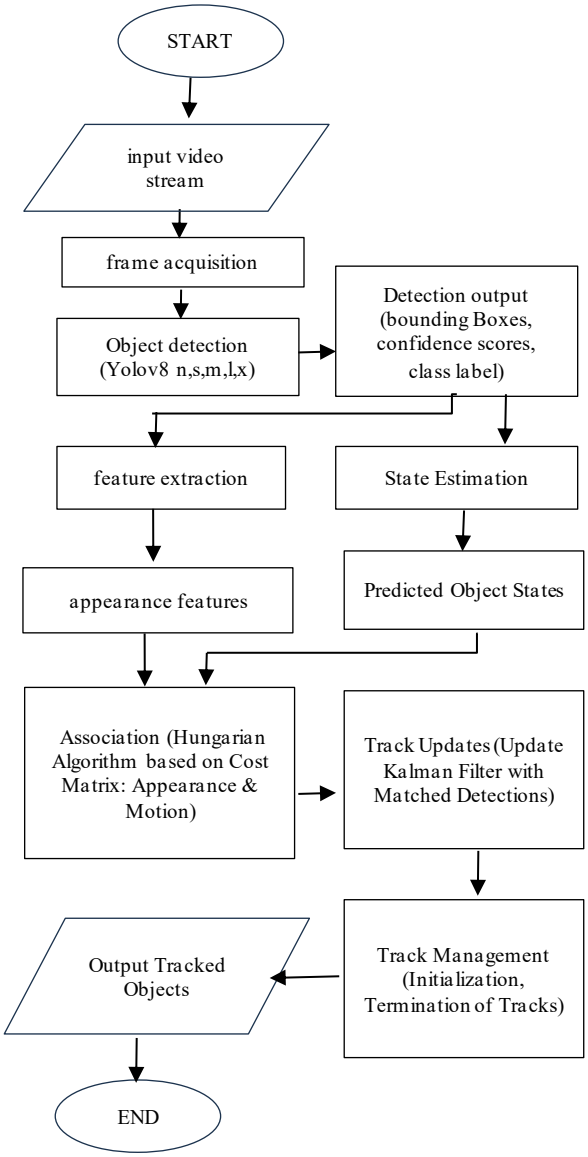

Fig. 1. Multi object tracker step.

YOLOv8 concurrently produces a Prediction per Grid Cell for each grid cell, encompassing the coordinates (x,y,w,h) of the prospective bounding box, an Objectness Score reflecting the confidence level of the object within the bounding box, and Class Probabilities that denote the conditional probability for each object class upon detection. Due to the possibility of numerous detections of the same object from several grid cells or overlapping bounding box predictions, Non-Maximum Suppression (NMS) is utilised. This procedure iteratively identifies the bounding box with the highest confidence score and discards other bounding boxes that exhibit substantial overlap (measured by Intersection over Union - IoU) and possess lower confidence scores. This procedure persists until solely the most precise bounding box for each identified object is preserved. The culmination of this phase is the Detection Output, comprising a collection of filtered bounding boxes, each associated with a high confidence score and accompanying vehicle class label, which will subsequently function as input for the DeepSORT tracking phase.

C. Tracking Evaluation

Assessing the efficacy of a Multiple Object Tracking (MOT) system is essential for comprehending the proficiency of your algorithm in tracking things within video [5]. This process involves comparing the MOT system's output with manually annotated ground truth data. Metrics such as HOTA and CLEAR are employed to assess several dimensions of tracking precision.

The evaluation phase commences with Ground Truth Data (Manual Annotations). This constitutes the basis of the comprehensive assessment, featuring detailed manual annotations for each pertinent object (e.g. motorbikes, vehicles, buses, trucks) in every video frame. These annotations comprise precise bounding boxes and constant unique identifiers for each object throughout the video frames. Upon completion of the annotations, the MOT data must be prepared to ensure compatibility with the evaluation code. A standard format often comprises the frame number, object ID, and bounding box coordinates (x, y, width, height).

Subsequently, we present the Tracking Result Data (MOT System Output). This is the output produced by your MOT system, namely a synthesis of YOLOv8 and DeepSORT. This data includes frame-by-frame details regarding the identified and monitored objects, together with bounding boxes and IDs allocated by the tracking algorithm. Similar to the GT data, this tracking data must be prepared to adhere to the HOTA and CLEAR assessment requirements.

Upon formatting both data sets, the GT data and the tracking data, we proceed to the HOTA Evaluation phase. The HOTA code implementation will juxtapose the tracks produced by your system with the ground truth tracks for each object across the video sequence. The outcome of this assessment is HOTA Metrics, an extensive array of metrics that offers a thorough analysis of tracking performance. The metrics encompass: HOTA (which balances detection and association accuracy), DetA (detection accuracy), AssA (association accuracy), LocA (bounding box localisation accuracy), FP (false positives), FN (false negatives), IDP (identity precision), IDR (identity recall), and IDS (identity switches) [40], [41].

The CLEAR Metrics review is conducted concurrently with or subsequent to the HOTA review. GT data and tracking outcomes are used to compute these traditional metrics. The resulting CLEAR metrics encompass: MOTA (Multi-Object Tracking Accuracy), which integrates detection and association errors; MOTP (Multi-Object Tracking Precision), which assesses bounding box accuracy; MT (Mostly Tracked), the proportion of ground truth objects that are predominantly tracked; PT (Partially Tracked), the proportion of ground truth objects that are partially tracked; ML (Mostly Lost), the proportion of ground truth objects that are predominantly untracked; FP and FN (as in HOTA); IDS (number of identity switches); and Frag (Fragmentation), the frequency with which a track is interrupted and subsequently resumed.

The concluding phases involve the analysis and interpretation of HOTA results and CLEAR results. The metric data from both sets are assessed to comprehend the overall efficacy of the tracking system. The emphasis for HOTA is on the aggregate HOTA value, including the contributions of DetA and AssA. Analysing HOTA values across many YOLOv8 versions will identify the variation that provides optimal tracking performance. Alternative measurements offer supplementary insights into particular facets. Likewise, CLEAR metrics, particularly MOTA, offer a comprehensive summary, whereas MOTP emphasises bounding box precision. MT, PT, and ML measurements offer insights into the track quality of individual objects. The Mostly Tracked (MT) statistic quantifies the proportion of ground truth objects that are effectively monitored for the majority of their lifespan. An object is deemed "mostly tracked" if it is effectively linked to a track for a minimum of 80% of its overall duration in the video. MT offers insight into the system's capacity to sustain long-term monitoring of a singular item. Conversely, Mostly Lost (ML) quantifies the proportion of ground truth objects that are not monitored for the majority of their lifespan [31]. ML denotes the frequency with which the system fails to sustain long-term tracking of an item. Partially Tracked (PT) denotes the proportion of ground truth objects that do not belong to either the MT or ML categories. These things are monitored for a substantial duration of their existence, yet insufficiently to be categorised as MT or marginally enough to be designated as ML

False Positives (FP) refer to the aggregate number of detections produced by the tracking system that do not align with any actual objects in the complete video sequence. FP denotes erroneous detections, or backdrops erroneously identified as objects. False Negatives (FN) refer to the total count of actual objects that the tracking system fails to detect during the whole video sequence. FN denotes the system's inability to identify an object that is genuinely present. Identity Switches (IDS) refer to the cumulative instances in which a monitored object's identity is erroneously altered over the video sequence. A low IDS signifies enhanced identity consistency and the system's capacity to preserve individual object trajectories without interchanging them with those of other objects. Fragmentation (Frag) quantifies the frequency with which an object's trajectory is disrupted and subsequently re-established. Fragmentation transpires when an object is monitored, thereafter vanishes (lacking association with a detection in the subsequent frame), and later reemerges with the identical ID. Minimal fragmentation signifies a more stable and uninterrupted trajectory. A conclusion regarding Tracking Performance Comparison is reached through this analysis, pinpointing which YOLOv8 variants consistently yield the highest HOTA values and other pertinent metrics for tracking motorcycles, cars, buses, and trucks on highways, while also addressing the trade-off between accuracy and speed. The illustration depicting the phases of the object tracking evaluation procedure is presented in Fig. 2.

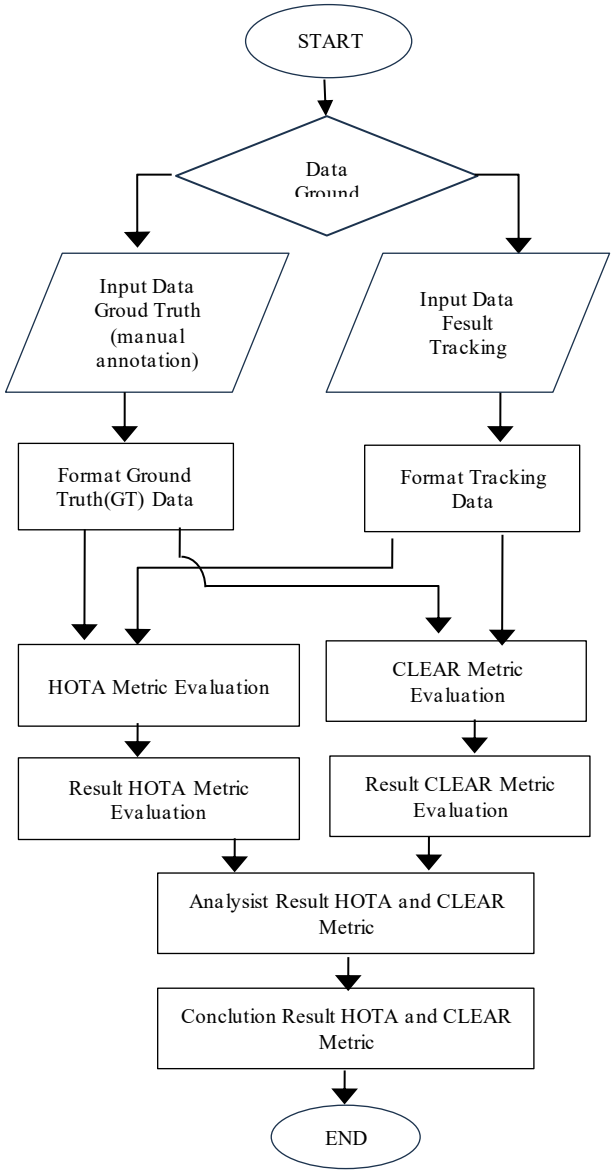

Fig. 2. Object tracking evaluation process.

D. Material Research

This work employs a relevant and extensive video dataset for the analysis of vehicle object tracking. The video data included in this experiment was specifically obtained from CCTV security cameras operated by the Bali Provincial Transportation Agency (https://balisatudata.baliprov.go.id/ peta-cctv). This study employs a collection of 980 real-world traffic surveillance photos, featuring 8,829 identified items categorized into four classes: cars, motorcyclists, buses, and trucks. To ensure model robustness, data were collected from two types of road environments: straight roads and intersections, thereby capturing diverse vehicle dynamics and spatial configurations.

The dataset encompasses differences in traffic flow conditions—spanning free-flow, moderate, and congested traffic—allowing for the evaluation of the tracking model under different density levels. The video data collection period took place in September 2024. This period was chosen to represent typical traffic patterns in the region, omitting substantial fluctuations that may occur during vacations or special events. It is important to acknowledge that all data were collected under daytime conditions, so presenting nocturnal scenarios as a forthcoming issue for future research.

This video dataset predominantly comprises two primary categories: motorbikes and cars, which are the subject of this research. Bali possesses a substantial motorbike demographic that often engages with bigger four-wheeled vehicles, including cars, buses, and trucks. The varied dimensions, forms, and motion trajectories of these two vehicle categories pose intriguing problems for object tracking algorithms. This dataset was created to assess the efficacy of tracking algorithms in differentiating and maintaining the identity of diverse vehicle types in congested traffic conditions.

The gathered video data is subsequently utilised as input for the object tracking system created in this study, which incorporates the YOLOv8 object recognition framework and the DeepSORT tracking algorithm. Each video is segmented into a sequence of individual frames, which are subsequently analysed by the YOLOv8 model to identify the presence and location of cars. The YOLOv8 detector's output, comprising bounding boxes, confidence scores, and class labels for each identified vehicle, is subsequently fed into the DeepSORT algorithm. DeepSORT uses this information, in conjunction with visual appearance attributes derived from each detection and motion prediction via a Kalman filter, to temporally track objects while preserving the distinct identification of each vehicle across video frames.

The utilisation of authentic video footage from a congested traffic setting in Bali enhances the authenticity and practical significance of this study's findings. The variety of traffic circumstances and vehicle types in the dataset enables thorough evaluation of the tracking algorithm's performance in practical situations. Moreover, the use of data from public transportation infrastructure, specifically CCTV from the Department of Transportation, underscores the prospective implementation of this object tracking technology in forthcoming traffic management and transportation monitoring systems. The dataset's quality and attributes establish a crucial basis for assessing performance and recognising potential enhancements in the suggested object tracking methodology.

Moreover, the acquisition and utilisation of this video data were executed with appropriate consideration for pertinent ethical and privacy issues. The data utilised is publicly available and sourced from surveillance cameras deployed for traffic monitoring. This research does not entail the acquisition of personal data or information that could identify specific persons beyond the context of their automobiles on the roadway. The research primarily concentrates on the analysis and tracking of various vehicle types for scientific and technological advancement. This dataset is deemed representative and sufficient for assessing the efficacy of object tracking algorithms within the framework of intense and varied urban traffic.

IV. Result

A series of tests performed using 30-second video footage at a Bali crossroads yields significant visual insights into the evolutionary performance of several YOLOv8 model variants integrated with the DeepSORT algorithm. The quantitative assessment exclusively targets cars and motorbikes, the predominant vehicle categories at the site, while the visualisation additionally illustrates the system's efforts to identify other classes, including buses and trucks. Each graphic, depicting progressively intricate model variants (from n to x), clearly demonstrates the trade-off among speed, detection accuracy, and classification reliability, closely correlating with the data shown in the HOTA and CLEAR metrics tables. We executed the tests in succession, first with Yolov8 version n and progressing to version x. The identifying number (ID) of each object in every test was randomly and uniquely created. Subsequently, we juxtaposed the visualisation outcomes within the identical frame.

To assess the model's detection efficacy on our unique dataset, we computed the mean Average Precision metric at a threshold of 0.50 (mAP50) for all four specified vehicle categories. This metric quantitatively assesses the model's accuracy in object localisation, with a detection deemed correct if the overlap between the predicted box and the ground-truth box is above 50%. The visual outcomes of this accuracy evaluation for each category are elaborated in Fig. 3.

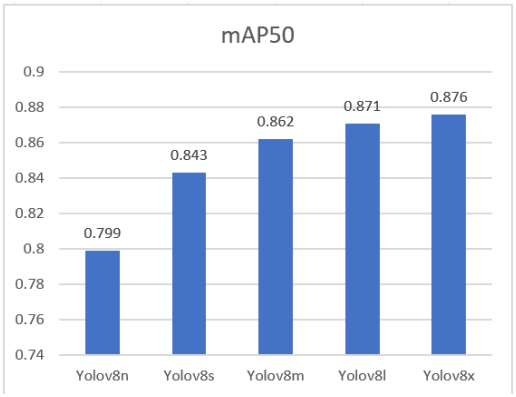

Fig. 3. mAP50 of Yolov8 variant.

Fig. 4 illustrates the outcomes of the YOLOv8n + DeepSORT model, highlighting the efficacy of the most lightweight and rapid variant. As a baseline model, its performance demonstrates notable shortcomings. The most significant inaccuracy was a false positive identification of object ID 415, erroneously classified as a "bus." In reality, this object was a massive billboard featuring a complex graphic, suggesting that the `n` model had difficulty differentiating between substantial vehicles and misleading background elements. Additionally, there were multiple false negatives, with roughly four motorcycles completely undetected. The inability to identify smaller, rapidly moving objects such as motorcycles is a prevalent deficiency in lighter models, which immediately resulted in diminished Detection Recall (DetRe) and MOTA scores in the quantitative assessment.

Fig. 4. Result from YOLOv8n + DeepSORT.

Fig. 5, which employs the YOLOv8s + DeepSORT model, shows that a progressive enhancement is observed. The count of undiscovered motorcycles decreases to three, signifying that the marginally more intricate 's' model had superior detection skills, hence diminishing the incidence of false negatives. Nonetheless, classification issues persist. Object ID 343, a white van, is erroneously categorised as a "bus". This categorisation of vehicles with unclear shapes (between a huge automobile and a small bus) is a persistent issue in the tests. Although these errors, when identified, do not directly influence detection metrics such as "DetA", they may affect evaluation if conducted purely on a per-class basis.

Fig. 6 presents the outcomes derived from the YOLOv8m combined with the DeepSORT model. There is a persistent misclassification, as the identical white van (now identified as 349) is once more erroneously categorised as a "bus". Nevertheless, it is evident that all motorcycles in the primary lane have been accurately detected, signifying an enhancement in detection recall relative to the 'n' and 's' variants. The enhancement in the capacity to identify all pertinent target objects is substantial and is evidenced by the increase in the "DetA" and "MOTA" scores in the metrics table. This suggests that with an increase in model size, its capacity to manage smaller and partially obscured objects becomes more resilient.

The trend of enhanced detection performance is notably illustrated in Fig. 7, produced by the YOLOv8l + DeepSORT model. An important discovery is that all vehicles, including motorcyclists, are accurately recognised and allocated bounding boxes. This is a notable accomplishment, indicating that the 'l' model possesses adequate representational capacity to tackle the detection issues at this congested intersection, successfully eradicating false negatives for this frame. Classification issues remain, as the white van (ID 290) is now erroneously categorised as a "truck". This underscores that enhancements in detection capabilities do not necessarily result in proportional advancements in classification accuracy for ambiguous instances.

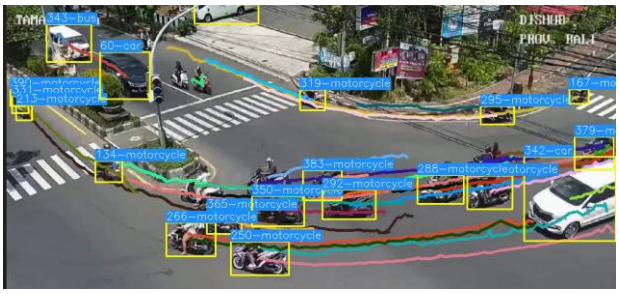

Fig. 5. Result from YOLOv8s + DeepSORT.

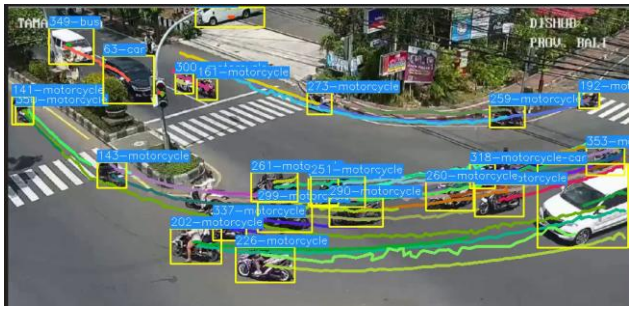

Fig. 6. Results from YOLOv8m + DeepSORT.

Ultimately, Fig. 8 illustrates the performance of the YOLOv8x + DeepSORT model, the most formidable option. Similar to the 'l' model, the 'x' model effectively identified all automobiles within the frame, demonstrating that the larger model markedly excels in recall performance. Nonetheless, it erroneously categorised a white van (ID 284) as a "truck". This indicates that, despite the model's extensive capacity, differentiating between visually analogous vehicle subclasses (such as vans, minibuses, and light trucks) continues to pose a significant challenge and may necessitate more varied training data or targeted fine-tuning methodologies. The visual progression from Fig. 4 to Fig. 8 clearly illustrates that augmenting the complexity of the YOLOv8 model enhances recall detection skills; yet, persistent challenges with ambiguous object classification underscore the necessity for future enhancement.

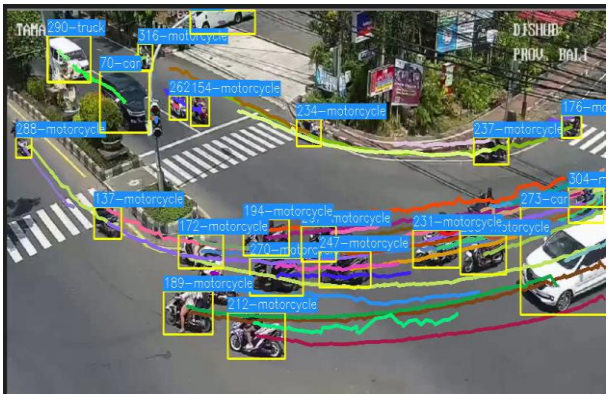

Fig. 7. Results from YOLOv8l + DeepSORT.

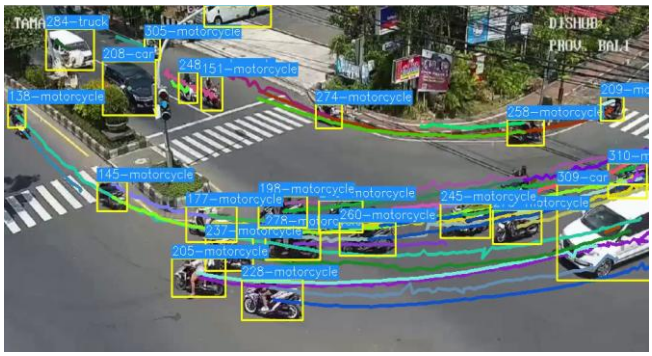

Fig. 8. Results from YOLOv8x + DeepSORT.

We subsequently present comprehensive HOTA evaluation results for the car class utilising a combination of the nano (n) and extra-large (x) YOLOv8 variants as detectors, paired with DeepSORT for association, and underscore the importance of these findings in determining the optimal detector architecture. The comprehensive assessment findings for all object classes and YOLOv8 versions will be displayed in tabular style and subsequently analysed in the following section. The CLEAR measure outcomes for this and further settings will be offered to offer a comprehensive view of performance tracking.

Tables I and II present the HOTA tracking outcomes for the "car" and "motorcycle" categories, respectively. According to the statistics in Tables I and II, a consistent trend is evident across all YOLOv8 model variants (from n to x): the overall tracking system exhibits marginally better and steadier performance for the car class than for the motorcycle class. The discrepancies in the primary HOTA scores are minimal; for instance, the top-performing x variant recorded a HOTA of 58.717, whereas the motorcycle attained 57.781. However, a thorough examination of the sub-metrics uncovers the origins of these performance variances and underscores the difficulties associated with motorcycle tracking.

Disaggregating HOTA results into Detection Accuracy (DetA) and Association Accuracy (AssA) provides an essential initial perspective. In these metrics, automobiles routinely surpass motorcycles. The performance disparity is more evident in AssA (e.g. 64,030 for cars against 62,190 for motorbikes in variation x) than in DetA (54,479 versus 53,842). This indicates that although modest difficulties exist in recognising motorcycles, a more substantial problem pertains to the tracker's capacity to sustain consistent motorbike IDs over time. The tracker misidentifies or erroneously exchanges motorbike IDs more frequently than it does for automobiles. Additional examination of the associated sub-metrics corroborates this conclusion. The primary distinction is evident in Association Recall (AssRe), with automobiles routinely achieving superior scores (e.g. 70,243 compared to 67,044 for variation x). Reduced AssRe scores for motorbikes immediately signify a track fragmentation problem. This indicates that a singular, ostensibly continuous motorbike route is often disrupted and recommenced as a new track with a distinct ID. This is probably because of the inherent characteristics of motorcycles: their reduced dimensions render them more vulnerable to complete obstruction by other vehicles, and their nimble and non-linear movement complicates motion prediction algorithms such as the Kalman Filter often employed in DeepSORT. Conversely, the AssPr (Association Precision) scores are almost indistinguishable across the two classes, suggesting that the challenge of consolidating several distinct objects into a single track (track merging) is not a significant differentiating factor.

The Detection Recall (DetRe) measure for motorbikes is marginally lower, indicating that the detector frequently overlooks motorcycles (false negatives) compared to vehicles, perhaps attributable to their reduced size. Notably, the Detection Precision (DetPr) for bikes is somewhat superior, suggesting that when the model identifies a motorbike, the forecast is generally more dependable (fewer false positives) compared to its predictions for cars. This HOTA measure research quantitatively demonstrates that the primary issue in tracking motorbikes, as opposed to cars, resides not merely in detection,

but predominantly in data association, particularly in preserving trajectory consistency despite agile motions and frequent occlusions.

In summary, in the automobile class, the mean HOTA and sub-metrics rose from YOLOv8-n (61.3) to YOLOv8-x (65.7), exhibiting a standard variation of around 10 points, which signifies a constant enhancement in performance with larger models. In the motorbike class, a same tendency is observed: YOLOv8-n (61.3) enhances to YOLOv8-l/x (65.7); however, the elevated standard deviation suggests considerable variability among sub-metrics. Elevated maximum values (e.g. >90 for HOTA(0)) suggest that certain measurements demonstrate substantial performance improvements with larger YOLOv8 variations.

The CLEAR metric analysis offers a compelling narrative that seems contradicts the HOTA results. Table III is the result of CLEAR metric measurements for the car class and Table IV is the result of CLEAR metric measurements for the motorcycles class. Remarkably, the Multiple Object Tracking Accuracy (MOTA) measure consistently surpasses that of vehicles for motorcyclists across all iterations of the YOLOv8 model. In the most sophisticated model x, motorcycles attain a MOTA of 62,622, whereas vehicles achieve only 57,331. This discovery necessitates a thorough examination of the error components constituting the MOTA score to comprehend the fundamental dynamics.

The explanation for the elevated MOTA ratings for motorcycles is found in the analysis of the precision and recall metrics derived by CLEAR. The data indicate that tracking precision (CLR_Pr) for bikes markedly exceeds that of automobiles across all model variants (e.g. 84,199 for motorcycles compared to 80,179 for cars in variant x). MOTA is determined by the aggregate of errors, including False Positives (FP), False Negatives (FN), and ID Switches (IDS), and exhibits significant sensitivity to the quantities of FP and FN. Increased precision immediately indicates a markedly reduced quantity of.

TABLE III. CLEAR METRIC TABLE FOR CAR CLASS

Sub Metric	Yolov8 variant				
	n	*s*	*m*	*l*	*x*
MOTA	44.415	47.904	50.888	56.604	57.331
MOTP	70.630	69.671	69.418	69.374	69.790
MODA	44.894	47.904	50.888	56.680	57.331
CLR_Re	69.231	72.408	72.768	78.188	76.158
CLR_Pr	73.990	74.715	76.882	78.426	80.179
MTR	19.737	28.571	31.746	41.935	34.722
PTR	48.684	35.714	20.635	29.032	45.833
MLR	31.579	35.714	47.619	29.032	19.444
IDSW	24	16	8	5	5
Frag	212	536	547	515	434

False Positives. Consequently, although motorbikes may encounter a higher frequency of association mistakes, a diminished number of false positives significantly decreases the overall errors in the MOTA formula, thereby enhancing their score relative to automobiles. A higher MOTA does not inherently indicate superior tracking performance; instead, it may signify the detector's exceptional accuracy for that specific class.

TABLE IV. CLEAR METRIC TABLE FOR MOTOR CYCLE CLASS

Sub Metric	Yolov8 variant				
	n	*s*	*m*	*l*	*x*
MOTA	53.906	51.935	55.943	63.886	62.622
MOTP	70.921	68.812	69.581	70.169	70.076
MODA	55.213	52.311	56.236	63.953	62.699
CLR_Re	69.125	67.606	73.279	78.227	77.183
CLR_Pr	83.246	81.550	81.131	84.569	84.199
MTR	31.169	44.495	28.571	30.435	40.370
PTR	58.442	37.615	44.643	58.261	42.609
MLR	10.390	17.890	26.786	11.304	16.522
IDSW	42	20	17	4	5
Frag	342	554	702	693	532

MOTA indicates a benefit for motorcycles; nevertheless, measures emphasising trajectory consistency present a contrasting narrative, aligning more closely with the prior HOTA findings. The quantity of FRAGs (Fragmentations) and IDSW (ID Switches) is continually elevated for motorcycles. In version x, motorcyclists exhibit 532 fragmentations, whereas vehicles have 434. In a less robust model, such as n, motorcyclists possess 42 IDSWs, whereas cars have just 24. These figures quantitatively validate that motorbike routes are more often fractured and their identities are more frequently exchanged. This substantiates the conclusion derived from the HOTA investigation that data association—sustaining consistent IDs amidst occlusion and dynamic movement, poses a far bigger problem for motorcycles.

Alternative trajectory quality measurements offer a more thorough perspective. The Mostly Tracked Ratio (MTR) for bikes is consistently superior (40,370 compared to 34,722 in the x variation); however, the Mostly Lost Ratio (MLR) is inferior (16,522 versus 19,444). This indicates that although motorcycle trajectories are prone to intermittent fragmentation, a greater percentage of the overall trajectories are effectively monitored during the majority of their duration. This suggests that your tracker is proficient at managing motorcycles in straightforward movement situations, although it struggles during complex events (sharp manoeuvres, significant occlusions) that result in IDSW and Frag. The nearly similar MOTP (Multiple Object Tracking Precision) ratings for both categories suggest that when an object is accurately recognised and appropriately associated, the bounding box localisation accuracy is equally proficient for both automobiles and motorcycles.

The results for motorbike tracking demonstrate that YOLOv8-x attains a HOTA score of 57.8, much surpassing the 51.5 achieved by YOLOv8-n, hence validating that larger detector variants enhance detection recall and association stability for tiny objects. Nonetheless, the aggregate HOTA values for motorbikes are inferior to those of cars, mostly attributable to recurrent occlusions, elevated object density, and the limited visual footprint of motorcycles in traffic scenarios. This finding aligns with the research of Frank Ngeni et al. [7], who indicated that tracking performance for small-scale and rapidly moving objects is susceptible to identification fragmentation, despite the utilisation of sophisticated detectors. Likewise, Jorge E. Espinosa1 et al. [4] noted that occlusion and swift manoeuvres markedly elevate ID switches in multi-object tracking benchmarks, underscoring the difficulties faced in this work. The comparisons indicate that although the integration of YOLOv8 with DeepSORT enhances motorcycle tracking relative to smaller detector variants, persistent challenges such as occlusion and identity consistency remain unaddressed, implying that future research should incorporate appearance-based re-identification modules or alternative tracking methods.

V. Conclusion

This article presents numerous major conclusions regarding the efficacy of a vehicle tracking system utilising the YOLOv8 detector in conjunction with the DeepSORT tracker, based on a thorough analysis undertaken. There exists a distinct positive correlation between the size of the YOLOv8 model and its detection accuracy; larger variants, such as YOLOv8l and YOLOv8x, markedly decrease the incidence of missed detections (false negatives), particularly for smaller objects like motorcycles, although difficulties in accurately classifying ambiguously shaped vehicles persist. Secondly, the dual-metric analysis provides significant complementary insights: the HOTA measure demonstrates that car tracking is more stable and consistent (higher "AssA" scores) compared to motorcycles, which frequently encounter track fragmentation due to their diminutive size, occlusion, and agile manoeuvres. Secondly, conversely, the CLEAR MOTA metric unexpectedly indicates elevated scores for motorcycles. This improvement is not attributable to enhanced association but rather to increased detection precision (fewer false positives), which disproportionately elevates the MOTA score and conceals deficiencies in tracking consistency (more ID shifts and fragmentation). This discovery significantly corroborates the original premise that a detection-biased statistic such as MOTA may yield an inadequate representation of actual tracking performance. This study indicates that HOTA offers a more equitable and comprehensive assessment by individually evaluating detection and association quality. This indicates that the selection of detector architecture and assessment metrics must be customised to the specific application requirements: in safety-critical systems, where identification consistency is essential, prioritising the HOTA association score is vital.

Subsequent study may focus on investigating the integration of YOLOv8 with different tracking algorithms beyond DeepSORT to enhance identification consistency and minimize trajectory fragmentation in multi-object tracking. A notable possibility is ByteTrack, which has a distinctive technique that accounts for low-rank detection boxes. Furthermore, advanced trackers like StrongSORT and OC-SORT merit assessment due of their enhancements in association consistency and tracking robustness in intricate traffic scenarios. Through the examination of diverse combinations, it is anticipated that a YOLOv8-based vehicle tracking system will attain enhanced performance and adaptability to a range of real-world conditions.

Sentence-Level Indonesian Sign Language (BISINDO) Recognition Using 3D CNN-LSTM and 3D CNN-BiLSTM Models

Katriel Larissa Wiguna, Rojali
Computer Science Department-BINUS Graduate Program–Master of Computer Science,
Bina Nusantara University, Jakarta, Indonesia, 11480

***Abstract*—Sign Language Recognition (SLR) has been an active area of research, but sentence-level SLR remains relatively underexplored. While most studies focus on recognizing individual signs, understanding full sentences presents greater challenges. This research proposes a sentence-level SLR using a combination of 3D Convolutional Neural Networks (3D CNN) for spatio-temporal feature extraction with sequential modeling using Long Short-Term Memory (LSTM) and Bidirectional LSTM (BiLSTM). Connectionist Temporal Classification (CTC) is also used to enable training without word-level annotations. In this study, we used the Indonesian Sign Language (BISINDO) dataset, specifically the DKI Jakarta version, consisting of 900 videos representing 30 sentences, which was expanded to 3600 videos through data augmentation techniques such as speed variation and brightness adjustments. All videos underwent preprocessing to ensure data quality, and Bayesian Optimization was applied for hyperparameter tuning to obtain optimal configurations for each model. Both models were trained with CTC loss and evaluated using Word Error Rate (WER). The 3DCNN-LSTM model achieved a WER result of 59.21%, while the 3DCNN-BiLSTM presents a significantly better performance with a WER of 2.77%. Despite these promising results, the models' ability to generalize across different signers may require further research, as the dataset used in this research involved only a single signer.**

Keywords*—Sign Language Recognition; BISINDO (Indonesian Sign Language); 3D Convolutional Neural Network (3D CNN); Long Short-Term Memory (LSTM) Network; Bidirectional Long Short-Term Memory (BiLSTM); Connectionist Temporal Classification (CTC)

I. Introduction

As social creatures, communication is an essential part that is inseparable from human life. Through communication, humans are able to exchange ideas, build relationships, and collaborate to fulfill their needs and achieve their goals. Broadly speaking, communication can be classified into verbal communication, which uses spoken or written words, and non-verbal communication, which relies on facial expressions, gestures, and body language.

Despite the fact that verbal communication, especially speaking, is the most common way humans interact, it is undeniable that some people cannot speak. Deaf individuals, unlike the general population, are among those who are unable to speak. For this reason, the deaf community communicates in their own, unique way, which is through the use of sign language.

In Indonesia, there are two types of sign language used: Indonesian Sign Language System (SIBI) and Indonesian Sign Language (BISINDO). SIBI is a sign language system that follows standard Indonesian grammar, which includes basic signs that symbolizes words, and additional signs for prefixes, suffixes, and particles. However, it is not fully accepted by the deaf community, who find it difficult for daily use. Although SIBI is used in formal education, BISINDO is more commonly used by the deaf for everyday communication. Research at PGMI UIN Sunan Kalijaga shows BISINDO is easier to understand, more natural, expressive, and effective than SIBI [1].

The difference in communication styles between the deaf and hearing communities creates a communication gap, which can lead to social distance and discrimination within society. Therefore, a system is needed to help bridge this gap. As a solution to this gap, sign language recognition (SLR) systems have been widely developed [2]. The goal of SLR is to develop a method capable of detecting and understanding the sign language gestures made by individuals [2]. Various models have been applied in the development of sign language recognition systems, ranging from Convolutional Neural Networks (CNN) [3], Bidirectional Recurrent Neural Networks [4], Transformers [5], Long Short-Term Memory Networks (LSTM) [6], deep convolutional networks [7], to a combination of 2 or more models [8].

Considering the fact that Indonesia is one of the four countries in Asia with a fairly high prevalence of hearing loss at 4.6%, and a deafness prevalence of 0.4% across all age groups in seven provinces, a continuous sign language recognition, also known as sentence-level SLR, is very feasible to be developed to help deaf individuals communicate with hearing individuals. While this system helps translate what deaf individuals want to convey to hearing individuals, it also serves as a tool for hearing individuals to learn sign language. In Indonesia itself, there has been a research on sentence-level SLR using 3D CNN and Bidirectional Recurrent Neural Networks (BiRNN) [4]. However, the model developed utilizes the SIBI dataset, which is not frequently used by deaf individuals in their daily interactions. Besides, it shows a relatively high word error rates (WER) and character error rates (CER), which may be caused by a mismatch between the

model and the dataset used, such as the presence of noise in the dataset due to suboptimal preprocessing. Additionally, sentence-level SLR is generally more challenging than alphabet or word-level recognition due to the need to capture both manual and non-manual features, while also modeling temporal dependencies across multiple gestures and handling variations in gesture sequences.

In response to this problem, this study proposes a sentence-level SLR model for Indonesian Sign Language (BISINDO) using 3D CNN-LSTM and 3D CNN-BiLSTM models. To address limitations in previous studies, the dataset consists of BISINDO videos collected with consistent lighting, framing, and other conditions to minimize noise. LSTM and BiLSTM are used instead of BiRNN due to their gating mechanisms, which better handle vanishing gradients and capture long-term dependencies in gesture sequences [9].

Since BISINDO naturally develops within the Deaf community, there are lots of variations in BISINDO gestures across different regions, reflecting the local culture in each area. This results in several regional variants of BISINDO, such as BISINDO DKI Jakarta, BISINDO West Java, BISINDO East Java, and others. However, since DKI Jakarta is the province with the highest population density in Indonesia [10] and as a central area where many communities interact, the DKI Jakarta version of BISINDO is likely to be more widely used and recognized than variants of other regions. Therefore, we chose to focus on BISINDO DKI Jakarta in this research.

To sum up, this study aims to develop and evaluate a sentence-level BISINDO DKI Jakarta recognition using a combination 3D CNN and LSTM model, as well as 3D CNN and BiLSTM model. While previous studies have focused on word or alphabet-level recognition, only a few have focused on sentence-level SLR. This gap motivates the development of a model capable of recognizing sentence-level sign language gestures. The proposed model is expected to provide a basis for developing future systems that support communication between Deaf and hearing communities. It has the potential to support sign language learning, contribute to the development of applications such as sign language translators, and enable future innovations in automated public service systems.

To address these objectives, this study seeks to answer the following research questions: 1) How can hybrid 3D CNN-LSTM and 3D CNN-BiLSTM models be developed to effectively recognize sentence-level BISINDO gestures? 2) How do the performance of the 3D CNN-LSTM and 3D CNN-BiLSTM models compare in terms of their accuracy in recognizing word sequences within BISINDO sentences?

The next section of this paper is organized as follows: Section II presents related works on Sign Language Recognition, Section III presents the methods used in this research. The results and discussion are presented in Section IV and Section V, respectively. Finally, Section VI presents the conclusion and future works of this research.

II. Related Works

To date, there has been considerable research focused on sign language recognition systems. Different algorithms have been implemented by previous researchers to develop a sign language recognition system that can perform with good accuracy.

In 2018, Ariesta et al. proposed a sentence-level Indonesian sign language recognition system using 3D CNN and Bidirectional Recurrent Neural Networks. The study utilized SIBI dataset, which includes 30 sentences in SIBI. The researchers developed several models for this system, all combining 3D CNN and bidirectional RNN. However, the evaluation revealed that the performance of the developed models was not optimal, as indicated by the high Word Error Rate (WER) of 85%-90% and Character Error Rate (CER) of 65%-77% [4]. This study is notable for attempting sentence-level sign language recognition, which is a challenging task. The use of 3D CNN-BiRNN is also suitable for capturing spatio-temporal features. However, the dataset and the model seem to be mismatched, resulting in suboptimal performance. This highlights the importance of preparing the dataset carefully for sentence-level recognition.

Aljabar and Suharjito in 2020 proposed a word-level sign language recognition system, utilizing BISINDO dataset consisting of two alphabets and eight words in BISINDO. They developed CNN, LSTM, and a combination of CNN and LSTM model, in which the CNN model achieves an accuracy of 73%, LSTM model achieves an accuracy of 81%, and the combination of CNN and LSTM model achieves the highest accuracy, reaching 90% [11].

Another research in 2020 by Latif et al. proposed an alphabet-level sign language recognition system to detect alphabet in Arabic sign language. They used a deep convolutional network, which was trained and evaluated using a dataset consisting of 50000 images of Arabic signs. After evaluation, it is found that this model achieves an accuracy of 97.6% [7]. While this study achieves a high accuracy in recognizing Arabic letters with its large and diverse dataset, it is still limited to letters rather than word or sentence-level recognition.

In the same year, a continuous sign language neural machine translation was proposed by a group of researchers from China. In this research, they used a dataset consisting of 50 sentences in Chinese Sign Language. The model proposed in this research is the ST-LSTM fusion attention network, which is then called Bi-ST-LSTM-A. This model achieves an accuracy of 81.22% on the CSL dataset, 76.12% on the RWTH-PHOENIX-Weather dataset, and 75.32% on the RWTH-PHOENIX-2014T dataset [8].

In 2021, a group of researchers from Saudi Arabia proposed an Arabic Sign Language recognition to detect alphabets in Arabic Sign Language using R-CNN, in which they achieved an accuracy of 93% based on the evaluation conducted [12]. Although this study focuses only on recognizing alphabets in Arabic Sign Language, the model proposed in this study can detect hands and recognize gestures with a high accuracy, even in a complicated background.

Another researcher from Indonesia also proposed a sign language detection system for BISINDO in 2022. They used a dataset of nine class, which consists of the alphabet A-E, and

three words which are “saya”, “kamu”, and “I love you”. They used CNN to detect those classes, in which they achieved an accuracy of 99.82% [13]. This study still needs a lot of improvements, especially in terms of the dataset size, as the limited vocabulary makes it unreliable in real-world scenarios.

Another alphabet-level sign language recognition is also proposed by Murali et al. in 2022. They used a CNN model to detect alphabets in American Sign Language, in which they got an accuracy of 98% [3].

In the same year, research by Kothadiya et al. proposed a system to detect words in Indian Sign Language. They used deep learning models, especially the Long Short-Term Memory (LSTM) and GRU. The model, which consists of 1 LSTM layer and GRU, achieves an accuracy of 97% for more than 11 word classes [14]. This shows a high accuracy for Indian Sign Language Recognition in a challenging and uncontrolled environment, representing natural conditions. However, the dataset is still limited in diversity, containing only 11 words, which may restrict the model’s ability to recognize sign language in real-world applications.

Another alphabet and word-level sign language recognition is proposed by Shin et al. in 2023. They combined a CNN and a transformer model to create a model to detect alphabet and words in the KSL Dataset. After evaluation, almost all alphabets are identified correctly, two alphabets achieved an accuracy of 95%, and two others gained an accuracy of 84%-90%. Testing was also done on the proposed dataset, which consists of 20 classes, achieving a score of 98.5% for precision, 98.35% for recall, 98.4% for F1-score, and 98.3% for accuracy [5]. This study effectively combines CNN and transformer architectures, resulting in high accuracy with relatively low computational cost. However, it is limited to word-level recognition and relies on a relatively small dataset, which limits its applicability to continuous, real-world sign language scenarios.

In 2023, a group of researchers from India proposed a system using the LSTM networks to detect words in Indian Sign Language. This model achieves an accuracy of 87% [6]. This study achieves a relatively high accuracy, and it is strong in its practical applicability, demonstrating a usable, real-time sign-action recognition system. However, it is limited to word-level recognition and does not address sentence-level sequences.

Lastly, in 2024, a hybrid deep learning model was proposed for a real-time Arabic Sign Language. This study presents a new, custom dataset containing 10 static gesture words and 10 dynamic gesture words. CNN and LSTM were used in this study, with the CNN achieving accuracy rates of 94.40% and the LSTM achieving 82.70% [15]. The results highlight the strong potential of the proposed model, especially proving CNN’s effectiveness in recognizing static signs. However, the dataset used in this research is relatively small, which makes it less applicable in real-world scenarios. Expanding the dataset in the future, especially for dynamic gestures, is essential to achieve a more reliable sign language recognition system.

From the previous research, it can be concluded that sign language recognition systems with various models, especially CNN and LSTM can be used to detect gestures in sign language with a fairly good level of accuracy, with an average accuracy of more than 90% for word-level sign language recognition. However, research related to sentence-level sign language recognition is still limited. Based on previous research that has been discussed, there are only two groups of researchers who studied sentence-level sign language recognition, where 1 of them shows a large error rate, and 1 the other shows fairly good accuracy results (75%- 82%), although not as good as the accuracy of the system in the word-level sign language recognition. Therefore, referring to previous research, this study will develop sentence-level sign language recognition using a combination of 3D CNN and LSTM models. This study was conducted to detect gestures in the DKI Jakarta version of BISINDO.

III. Methodology

This section presents the detailed research workflow, describing the step-by-step process involved in preparing the data, building and training the model, to evaluating its performance for BISINDO DKI Jakarta sentence-level SLR.

A. Problem Identification

In the problem identification phase, we focused on highlighting specific issues within the field of Sign Language Recognition (SLR), aiming to address gaps in current research. This process was done through an extensive review of recent studies and literature related to SLR. Even though numerous researchers have successfully developed SLR, most of them still focus on word-level Sign Language Recognition, so the communication gap between deaf and hearing individuals is not fully addressed.

In order to address the problem, this research focuses on developing a sentence-level SLR using the BISINDO dataset, a sign language which is preferred by deaf individuals in Indonesia. While the BISINDO dataset varies across Indonesia, this research focuses particularly on the DKI Jakarta version of BISINDO.

B. Video Acquisition

While several BISINDO datasets are available at the word or alphabet level, no publicly accessible dataset exists for sentence-level BISINDO (especially the DKI Jakarta version). Due to this gap, we created our own BISINDO DKI Jakarta dataset to be used in this research.

The video acquisition phase began with compiling a list of sentences to be recorded, which will then be used in this study. To construct the sentences, we utilizes vocabularies which are included in the 50 high frequency words based on research conducted by Siagian, which are recommended as mandatory vocabularies to be mastered when learning a new foreign language [16]. From this list, we selected several words to construct the sentences. The selection of these words was based on their frequency in everyday conversations and their applicability within Bahasa Isyarat Indonesia (BISINDO). While most words were selected from the 50 high-frequency words list, additional words outside the list were also incorporated as needed to form meaningful sentences. The sentences constructed from these words are then recorded to be

used as input for training and testing our sentence-level sign language recognition model. The list of sentences which will be included in this dataset can be seen in Table I. The "Sentence" column contains the original sentence in Indonesian, while the "Sign Gloss" column represents the translation of the sentence into BISINDO gloss notation. As shown in the examples, the gloss often differs from the spoken sentence structure, illustrating the linguistic differences between spoken Indonesian and BISINDO, which the recognition model must learn to accurately align sentences with their corresponding signs.

TABLE I. LIST OF SENTENCES IN THE DATASET

No.	Sentence	Sign Gloss
1.	Aku bangun jam sepuluh.	AKU BANGUN JAM SEPULUH
2.	Aku tidur jam sepuluh malam sampai jam lima pagi.	AKU MALAM TIDUR JAM SEPULUH SAMPAI PAGI JAM LIMA
3.	Aku mau makan.	AKU MAU MAKAN
4.	Aku punya kakak.	AKU PUNYA KAKAK
5.	Aku suka kamu.	AKU SUKA KAMU
6.	Di mana Bapak dan Ibu?	BAPAK DAN IBU DIMANA
7.	Halo, nama aku Katriel	HALO NAMA AKU FS:KATRIEL
8.	Ibu aku punya kucing dan ikan.	IBU AKU PUNYA KUCING DAN IKAN
9.	Kakak aku suka makan.	KAKAK AKU SUKA MAKAN
10.	Berapa anak yang kamu punya?	KAMU ANAK BERAPA
11.	Jam berapa kamu bangun?	KAMU BANGUN JAM BERAPA
12.	Apakah kamu sudah makan?	KAMU MAKAN SUDAH
13.	Keluarga aku terdiri dari lima orang.	KELUARGA AKU ORANG LIMA
14.	Berapa jumlah anggota keluarga kamu?	KELUARGA KAMU ORANG BERAPA
15.	Kucing makan apa?	KUCING MAKAN APA
16.	Kucing makan ikan.	KUCING MAKAN IKAN
17.	Siapa nama dia?	NAMA DIA SIAPA
18.	Siapa nama kamu?	NAMA KAMU SIAPA
19.	Nama isyarat kamu apa?	NAMA PANGGIL KAMU APA
20.	Rumah aku di Jakarta	RUMAH AKU FS:JAKARTA
21.	Rumah aku nomor lima.	RUMAH AKU NOMOR LIMA
22.	Rumah kamu di mana?	RUMAH KAMU DIMANA
23.	Rumah kamu nomor berapa?	RUMAH KAMU NOMOR BERAPA
24.	Sekarang jam berapa?	SEKARANG JAM BERAPA
25.	Selamat hari Ibu.	SELAMAT HARI IBU
26.	Selamat hari kemerdekaan Indonesia.	SELAMAT HARI KEMERDEKAAN INDONESIA
27.	Selamat malam, aku mau tidur.	SELAMAT MALAM AKU MAU TIDUR
28.	Selamat pagi, Bapak dan Ibu.	SELAMAT PAGI BAPAK DAN IBU
29.	Terima kasih	TERIMAKASIH
30.	Umur kamu berapa?	UMUR KAMU BERAPA

The recordings were carried out by a single participant – the author of this research – who is a non-native signer but has completed a sign language course, which provides sufficient experience to ensure accurate movements and expressions for the dataset. The decision to record with one signer was made due to limited resources, which made it challenging to involve multiple native signers. However, the recordings were carefully done to maintain consistency and clarity.

In total, 30 BISINDO sentences (DKI Jakarta version) were recorded, each repeated 30 times, using a smartphone camera at 30 fps. The video recording was carried out under controlled conditions, such as:

- Videos were recorded with a plain white background to minimize unnecessary visual distractions, to help the model focus on the signer.
- Videos were recorded indoors under sufficient lighting, ensuring every gesture was clearly visible.
- The camera was positioned to capture the signer's upper body (from head to waist), so that both hand movements and relevant facial expressions were clearly captured.

Nevertheless, relying on a single non-native signer remains a key challenge of this dataset, as it may limit the model's ability to generalize across different signers. To partially address this challenge, data augmentation techniques were applied to enhance the variability of the dataset, which will be described in the following section.

C. Video Preprocessing

To ensure that the recorded videos could be effectively used for model training, we applied several preprocessing steps. Firstly, we cropped the recorded videos to remove unnecessary parts of the frame, allowing the model to better focus on the signer's gestures and expressions. It is ensured that all videos have a resolution of 1080x1080 pixels. Next, the video frame rate was reduced from 30 fps to 15 fps. This was done to reduce computational load without changing the duration of the video. By reducing the fps, the total number of frames in each video can be cut in half while preserving necessary temporal information. Then, each frames are resized from 1080x1080 pixels to 256x256 pixels to maintain consistency in the input data, while also improving computational efficiency without losing essential details such as hand and facial features.

Next, padding was applied to the videos to ensure that the number of frames across all videos is the same. Since this research is focused on sentence-level sign language recognition, the number of frames of each video in the dataset will be different, due to the difference in sentence length or the variability in signing speed. Hence, padding was done by determining the maximum number of frames in a video across all videos in the dataset. The videos with fewer frames than the maximum number of frames are then given additional frames to equalize the number of frames across all videos in the dataset.

D. Data Augmentation

Since the total number of videos collected for this dataset is relatively small, consisting of only 900 videos covering 30 sentences, several data augmentation techniques were applied to enhance the variability of our training data. We carefully selected the augmentation techniques based on their compatibility with BISINDO, and made sure that the modifications did not alter the meaning of signs or even violate BISINDO rules. There are two augmentation techniques used in this research, which are:

1) Speed variation: This technique was used to increase the speed of the video by 1.2 times, which is intended to mimic the variability of signing speeds in real-world scenarios. It allows the model to learn and manage different signing speeds.

2) Brightness adjustments: This technique was used to modify the lighting conditions of the videos to simulate different lighting conditions found in different environments, which has been proven to improve model performance on object detection tasks [17]. In this study, brightness adjustments were applied by making the videos 40% darker and 40% brighter than the original video. Examples of brightness variations can be seen in Fig. 1 and Fig. 2. For privacy reasons, faces are covered in the dataset samples shown.

Fig. 1. Original video brightness.

Fig. 2. Video with 40% brighter lighting (left) and video with 40% darker lighting (right).

These techniques were used because they align with the characteristics of the dataset used. Other methods, such as mirroring, were avoided due to BISINDO rules on right and left hand usage, which could alter sign meaning. Other techniques like cropping or adding noise were also not applied, as they might remove essential facial expressions, hand positions, and other details needed for sign recognition.

E. Data Preparation

After all the preprocessing steps have been finished, the dataset was split into three groups, which are: training, validation, and testing sets. The data distribution can be seen in Table II.

TABLE II. ORIGINAL DATA DISTRIBUTION

Data Sets	Percentage	Number of Videos
Training Set	70%	630
Validation Set	15%	135
Testing Set	15%	135
TOTAL	100%	900

As shown in Table II, a 70-15-15 split was applied to the original dataset consisting of 900 videos. Meanwhile, the 2700 augmented videos were included in the training set, as the purpose of augmentation is to enrich the diversity of data available for training, allowing the model to generalize better. The final distribution dataset can be seen in Table III.

TABLE III. FINAL DATA DISTRIBUTION

Data Sets	Number of Videos
Training Set	3330
Validation Set	135
Testing Set	135
TOTAL	3600

F. Model Building and Training

In this phase, we developed a hybrid deep learning model that integrates a 3D CNN and recurrent model (LSTM/BiLSTM) for sentence-level sign language recognition. Since recognizing sign language requires attention and consideration to both manual features (hand shape, position, and movements) and non-manual features (facial expressions, head position, and lip shape) [18], the 3D CNN was utilized to extract spatial and temporal features from the video frames. These extracted features are then passed into two different sequence models, the conventional LSTM and bidirectional LSTM. This model design was chosen to leverage the main strengths of each model, where the 3D CNN serves as the feature extractor, while the LSTM/BiLSTM models capture temporal dependencies within the sign sequence. The model architecture used in this research is presented in Fig. 3, while the configuration of each layer is shown in Table IV. The rows highlighted in blue represent the 3D CNN component of the model, while the rows highlighted in orange represent the LSTM/BiLSTM component. All models were trained from scratch on the BISINDO DKI Jakarta dataset without the use of pre-trained weights or fine-tuning. This was done to ensure that the models are fully adapted to BISINDO sentence-level recognition data.

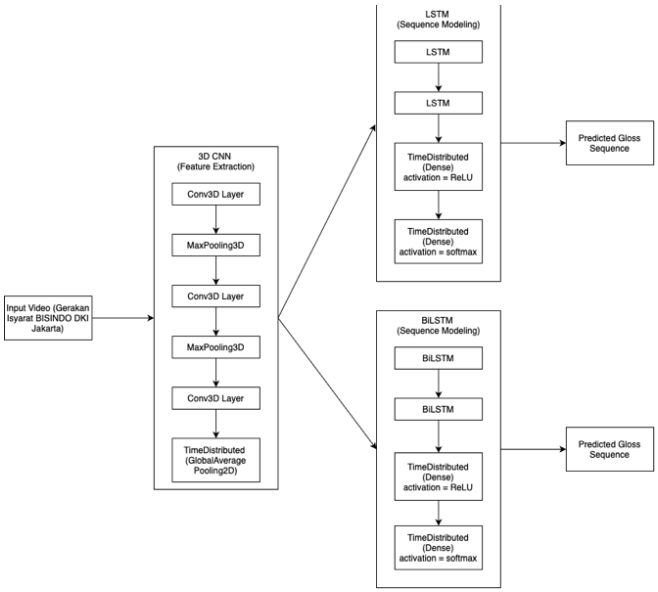

Fig. 3. Model architecture.

TABLE IV. LAYER CONFIGURATION OF THE 3D CNN AND LSTM/BILSTM MODEL

Layer	Configuration	Output Shape
Input 3D CNN	Video frames	(151, 256, 256, 3)
Conv3D	32 filters, kernel (3,3,3), stride (1,1,1), activation ReLU	(151, 256, 256, 3)
MaxPooling3D	Pool size (1, 2, 2)	(151, 128, 128, 32)
Conv3D	64 filters, kernel (3, 3, 3), stride (1, 1, 1), activation ReLU	(151, 128, 128, 64)
MaxPooling3D	Pool size (2, 2, 2)	(75, 64, 64, 64)
Conv3D	128 filters, kernel (3, 3, 3), stride (1, 1, 1), activation ReLU	(75, 64, 64, 128)
TimeDistributed (GlobalAveragePooling2D)		(75, 128)
Input LSTM	3D CNN extracted features	(75, 128)
LSTM/BiLSTM	X units (adjusted based on tuning results)	(75, X)
LSTM/BiLSTM	X units (adjusted based on tuning results)	(75, X)
TimeDistributed Dense (ReLU)	128 units, activation ReLU	(75, 128)
TimeDistributed Dense (Softmax)	45 units, activation Softmax	(75, 45)

As shown in Table IV, firstly the videos containing BISINDO sign language gestures were used as an input for the 3D CNN model. The 3D CNN then performed spatiotemporal feature extraction. The spatial features extracted include hand movements and facial expressions, as these two components are key elements in performing BISINDO, and are essential for identifying sign gestures.

The 3D CNN model used in this study receives video input with dimensions of (151, 256, 256, 3), where:

- 151 represents the number of frames in each video
- 256 x 256 is the resolution of each frame, and
- 3 represents the number of channels (RGB)

This input is processed through several convolutional and pooling layers as shown in Table IV. Then, a TimeDistributed layer with GlobalAveragePooling2D is applied to average the spatial feature values for each video frame individually, preserving the temporal dimension of the video data. This process results in a one-dimensional feature vector for each frame, which can then be passed into the LSTM/BiLSTM model. The output at this stage has the shape (75, 128), where:

- 75 is the number of frames remaining after pooling and downsampling, and
- 128 is the number of features generated for each frame.

To avoid repeating feature extractions due to limited computational resources, the extracted features were stored in a .npy file. These features are then used as an input to the LSTM/BiLSTM model. For sequence modeling, two stacked LSTM/BiLSTM layers were used to capture temporal dependencies. The LSTM processes the frame sequence in one direction, while the BiLSTM processes the sequence in both directions [19]. Stacked LSTMs are used in this study to enhance the model's ability to learn complex relationships in sequential data. In these layers, the output shape becomes (75, X), where 75 is the number of timesteps and X is the number of units in LSTM/BiLSTM which is determined through hyperparameter tuning.

Next, a TimeDistributed Dense layer with 128 units and a ReLU activation function was applied, producing an output of shape (75, 128), where 75 represents the timesteps and 128 represents the number of units in Dense layer. Lastly, a TimeDistributed Dense layer with a Softmax activation function, which is responsible to generate frame-level predictions as probability distributions for every vocabulary and blank token, was applied. It results in an output shape of (75, 45), where 75 represents the timesteps and 45 represents the number of vocabulary in the dataset. During the training, CTC loss function was applied to handle the mismatch between input frames and predicted word lengths. Finally, a decoding process was done using the argmax function to convert the probability outputs into a sequence of predicted words.

After defining the model architecture, hyperparameter tuning was conducted to obtain the most optimal hyperparameter configurations for the 3DCNN-LSTM and 3DCNN-BiLSTM model. This process ensure that the models were trained using the best combination of hyperparameter, so that the models are able to recognize sentences in BISINDO with the lowest possible Word Error Rate (WER). In this study, Bayesian Optimization (BO) was used for hyperparameter tuning due to its efficiency in finding optimal configurations compared to methods like Random Search [20] or Grid Search, while maintaining equal or better model accuracy [21]. The hyperparameters tuned in this research includes the number of LSTM/BiLSTM units, learning rate, batch size, and dropout rate. The predefined ranges for these hyperparameters are shown in Table V.

TABLE V. OPTIMIZED HYPERPARAMETERS

Hyperparameter	Value
LSTM/BiLSTM units	64, 128, 256 units
Learning Rate	0.001, 0.0005, 0.0001
Batch Size	16, 32, 64
Dropout Rate	0.2, 0.3, 0.4

Once the optimal combination of hyperparameter was found for both the 3DCNN-LSTM and 3DCNN-BiLSTM models, the final models were built using these values and training was initiated. This ensured the models were trained under the best configuration, which allows the model to maximize their ability in recognizing word sequences in BISINDO.

G. Evaluation

To evaluate the model against the given input sentences, the metric used in this research is Word Error Rate (WER). This metric is a standard measure commonly used to evaluate the performance of a machine translation system or speech recognition system.

The WER measurement helps evaluate the difference between the output sequence (the identified sentences) and the actual sentences by taking into account substitutions (instances where identified word is different from the actual word intended to be conveyed through sign gestures), deletions (instances where a signed word is missing from the identified output sequence), and insertions (instances where an extra word appears in the output sequence that was not present in the signed gesture). The formula for measuring WER is as follows:

$$WER = \frac{S + D + I}{N} = \frac{S + D + I}{S + D + C}$$

where,

- S represents the number of substitutions
- D represents the number of deletions
- I represents the number of insertions
- C represents the number of correctly identified words

By using WER as an evaluation metric, researchers can determine how many errors or mistakes the system makes in identifying sentences in sign language, allowing for a more accurate assessment of the model's performance. A smaller WER value indicates fewer errors in the identified output, meaning that a lower WER reflects better system performance.

IV. RESULTS

This chapter presents the results of the sentence-level SLR model, which was trained and evaluated using the WER metric. Before training the model, hyperparameter tuning was done using Bayesian Optimization to find the best hyperparameter combination for both the 3DCNN-LSTM and 3DCNN-BiLSTM models. The tuning process was carried out with 15 trials for each model. The results of the hyperparameter tuning trials for the LSTM model can be seen in Table VI, and the results for the BiLSTM model can be seen in Table VII.

TABLE VI. LSTM MODEL HYPERPARAMETER TUNING TRIALS

Tables VI and VII show the results of hyperparameter tuning for the LSTM and BiLSTM models, where each trial tests a different combination of LSTM units, dropout rate, batch size, and learning rate. The "Score" column represents the validation loss, meaning that lower values indicate better model performance on unseen data. Based on Tables VI and VII, it can be seen that the best hyperparameter combination for the LSTM model consists of 128 LSTM units, a dropout rate of 0.2, a batch size of 16, and a learning rate of 0.001. Meanwhile, the BiLSTM model achieved its best performance with 256 LSTM units, a dropout rate of 0.4, a batch size of 16, and a learning rate of 0.001. These hyperparameter

combinations were then used to build the models for training. Accordingly, the final structure of the 3DCNN-LSTM model can be seen in Fig. 4, and the final structure of the 3DCNN-BiLSTM model can be seen in Fig. 5.

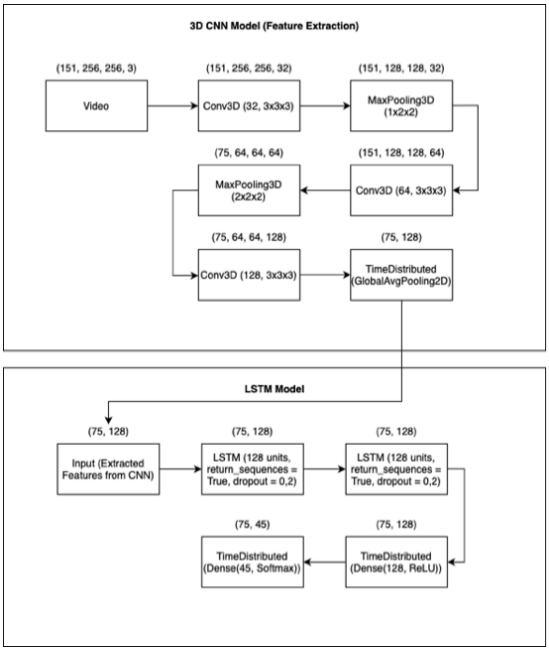

Fig. 4. Hybrid 3DCNN-LSTM model structure.

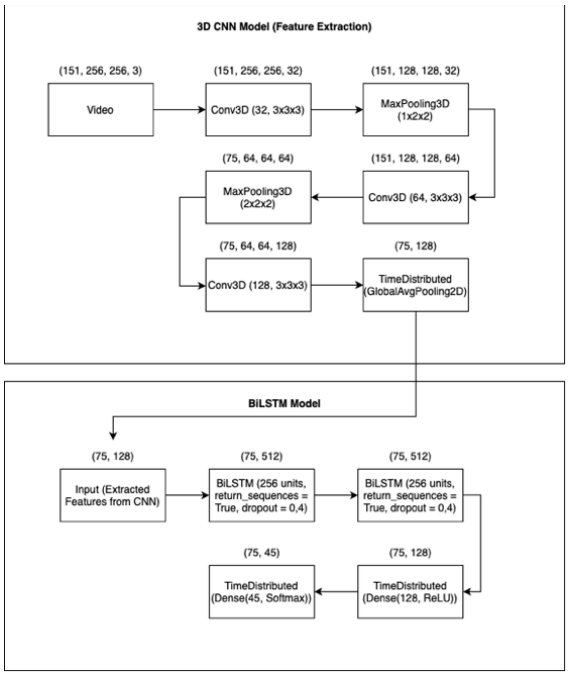

Fig. 5. Hybrid 3DCNN-BiLSTM model structure.

Each model was trained for 200 epochs. To prevent overfitting, early stopping with a patience of 20 was applied by monitoring the validation loss. The LSTM model achieved its lowest validation loss at epoch 187, with a value of 5.7631. The training and validation loss of the LSTM model can be seen in Fig. 6.

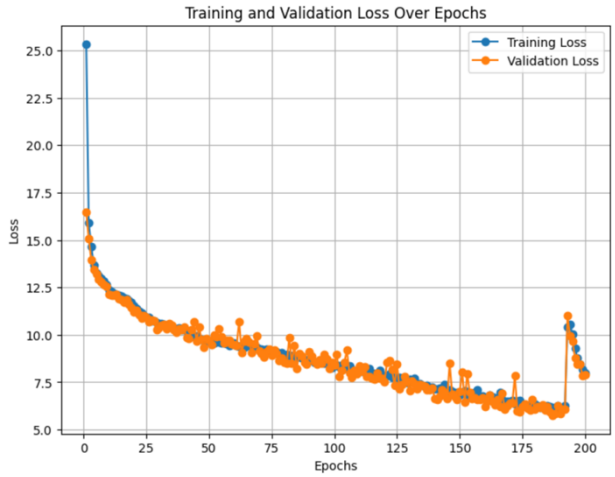

Fig. 6. Training and validation loss of LSTM model.

The graph shows that both training and validation loss decreased steadily, indicating that the model was learning well. However, at epoch 193, there was a sudden spike in both losses, which later dropped again. This spike was likely caused by temporary fluctuations. Since the losses continued to decline afterwards, the model was still learning effectively. In this case, the best weights were used, taken from before the spike occurred.

Meanwhile, the BiLSTM model achieved its lowest validation loss at epoch 183, with a value of 0.2444. The training and validation loss of the BiLSTM model can be seen in Fig. 7.

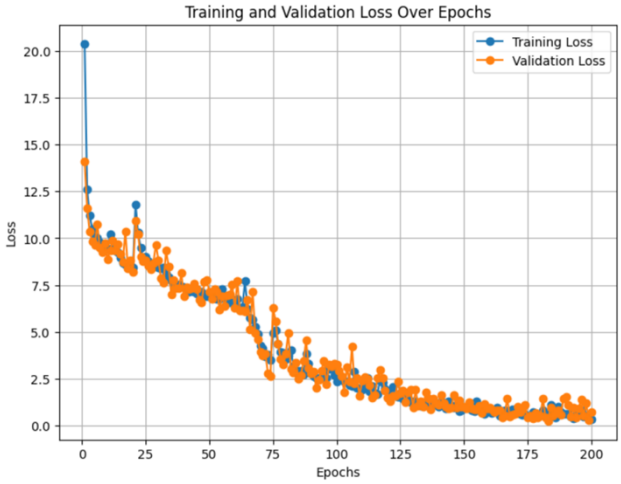

Fig. 7. Training and validation loss of BiLSTM model.

The graph shows a consistent decrease in both training and validation loss, indicating that the model was learning well from the data. Although some fluctuations occurred during training, overall the loss decreased steadily, with the training and validation loss values remaining close throughout the process.

After training and selecting the best weights for both models, we evaluated them on the test set to measure their performance. The predictions from this testing phase were

decoded to convert the model's output into sentence form. Once the predicted word sequences were obtained, the model's performance was evaluated using the WER metric, which is calculated based on the number of prediction errors, including substitutions, insertions, and deletions.

In the 3DCNN-LSTM model, the evaluation on the testing set resulted in a relatively high WER of 59.21%. It produced the most errors in substitutions with a total of 211 substitutions, followed by 60 deletions and 28 insertion errors. The error distribution for the LSTM model can be seen in Fig. 8.

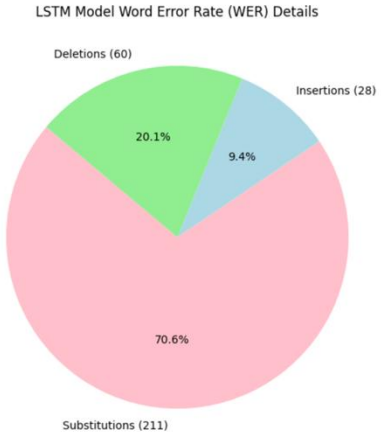

Fig. 8. Error percentage of the LSTM model on the test set.

Meanwhile, the 3DCNN-BiLSTM model achieved a better performance with a significantly lower WER of 2.77%, with the most errors in substitution with a total of 12 substitutions, followed by two insertion errors. The 3DCNN-BiLSTM model did not produce any deletion errors. The error distribution for the BiLSTM model can be seen in Fig. 9.

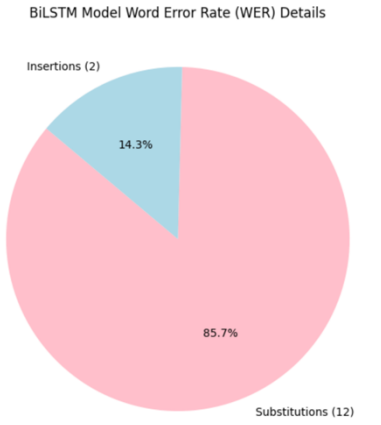

Fig. 9. Error percentage of the BiLSTM model on the test set.

To address the limitation of having only one signer in the dataset, additional signer videos with plain backgrounds and clear visuals were collected from publicly available sources on the internet to serve as a supplementary test set. We successfully collected seven videos of BISINDO DKI Jakarta sentences to be used for the additional test.

In testing using the additional signer videos collected from the internet, the LSTM model achieved a WER of 120% with 11 substitution errors, followed by 5 insertions and 2 deletions errors. Meanwhile, the BiLSTM model achieved a WER of 60%, with 9 substitution errors without insertion and deletion errors.

V. Discussion

Both 3D CNN-LSTM and 3D CNN-BiLSTM models were trained using the hyperparameters determined from tuning, ensuring that each model was optimized for its architecture. Both models were trained for the same number of epochs, which is 200 epochs, to allow a fair comparison. The average training time per epoch was 8.66 seconds for the LSTM and 11 seconds for BiLSTM model. The BiLSTM model contains a larger number of trainable parameters than the LSTM, which contributes to the slightly longer training time. While BiLSTM requires slightly more time due to its bidirectional architecture, the difference is small and does not significantly affect the fairness of the comparison.

Based on the evaluation results of the LSTM and BiLSTM models, there is a significant difference in WER between the two models. The 3D CNN-BiLSTM model shows a drastically lower WER compared to the 3D CNN-LSTM model. As seen from the training loss, the LSTM loss was still decreasing at the end of 200 epochs, indicating that it could potentially achieve slightly better performance if trained for more epochs. However, the BiLSTM still outperforms the LSTM due to its ability to capture context in both directions.

In sentence-level SLR, the meaning of a gesture often depends on both what comes before and after, creating context across the whole sentence. While the LSTM can only utilize past frames, the BiLSTM may look at the sequence in both directions. This bidirectional processing helps BiLSTM to distinguish gestures that might look similar on their own and better capture subtle differences in hand movements and facial expressions. Even if the LSTM is trained longer, LSTM is still limited in using future context, which explains the drastic performance difference between the models. This also shows that bidirectional modeling is so important for sentence-level SLR.

However, the significantly low WER on the BiLSTM model may also be due to the lack of signer variation in the dataset, meaning the model has effectively learned the patterns of a single individual, which allows it to predict word sequences in the test set very well. This becomes clear when testing on videos from new signers, where the WER is higher than on the original test set. However, this should not be considered as the main benchmark, as uncontrolled factors in videos collected from social media can affect the model's ability to recognize sign language. The differences in signing style may also contribute to the model's difficulty in accurately recognizing gestures in videos from new signers. Although the model cannot yet fully recognize the word sequences in sign language sentences, it can be seen that it can fairly well recognize and identify sentence length. This is demonstrated by the small number of insertion and deletion errors made by both models, while both models make more substitution errors. This demonstrates that overall sentence length can be identified well, although errors in sign recognition still occur, which can be due to various factors, such as similar gestures.

Nevertheless, compared to previous similar work, such as sentence-level SLR using 3D CNN-BiRNN model, the 3D CNN-BiLSTM model still shows a lower WER, even when testing on videos from different signers. This improvement is likely due to the LSTM's gating mechanisms, which better handle vanishing gradients, allowing the model to remember important information over longer sequences better than BiRNN.

VI. Conclusion

This study presents a novel approach to sentence-level BISINDO DKI Jakarta sign language recognition by combining a 3D CNN model for spatial and temporal feature extraction, followed by a LSTM/BiLSTM network to capture sequential dependencies, enhanced by CTC, which allows for sentence-level sign language recognition without the need for word-level annotations. Both 3DCNN-LSTM and 3DCNN-BiLSTM model was trained and evaluated on the 30 BISINDO sentence videos consisting of everyday phrases, with data augmentation applied to improve generalization and hyperparameters tuned to optimize performance.

The research was conducted through several stages. First, the feature extraction was performed by the 3D CNN model, with the resulting features stored in a .npy file. These features are then passed to two different models – LSTM and BiLSTM – for training and testing in sentence-level BISINDO recognition. Both models were built using optimal hyperparameter configurations obtained through Bayesian Optimization. From the experiments, several key findings can be drawn:

1) The 3DCNN-LSTM model was not able to achieve a good recognition performance, indicated by a relatively high WER of 59.21% on the testing set. When evaluated on new signer videos, the model produced an even higher WER of 120%, demonstrating that it was unable to effectively recognize sign language, particularly when faced with data from different signers.

2) The 3DCNN-BiLSTM model showed significantly better recognition performance than the 3DCNN-LSTM. It achieved a low WER of 2.77% on the testing set, indicating strong performance for recognizing sentences from a single signer. However, when tested on new signer videos, it achieved a higher WER of 60%. While it is still not highly accurate in recognizing unseen signers, the BiLSTM outperformed the LSTM. This is likely due to BiLSTM's ability to capture contextual information in both forward and backward directions.

3) The combination of 3D CNN as a feature extractor and BiLSTM as a sequence model demonstrated promising results for sentence-level BISINDO recognition in the testing set. However, this outstanding performance is still influenced by the limitations of the dataset, especially the limited number of signers, which causes the model to overfit to specific movement patterns.

4) Although neither the 3DCNN-LSTM nor the 3DCNN-BiLSTM achieved perfect recognition of BISINDO sentences, both models were relatively effective in capturing sentence length. This was reflected by fewer insertion and deletion errors compared to substitution errors.

One of the main limitations in this study is the very limited dataset size, which only involves one non-native signer, so the model's ability to generalize to various variations of signer gestures when demonstrating sign language cannot be fully proven. Therefore, in the future, it is recommended for researchers to develop the dataset by adding more signers so that the model can learn the variations of gestures of several signers who have their own unique characteristics. Furthermore, the number of sentence samples should be increased to allow the model to learn from a broader variety of expressions. By expanding the dataset, the resulting model will be able to recognize a wider range of sign language gestures.

Furthermore, based on the excellent results of the 3DCNN-BiLSTM model evaluation in recognizing sign language sentences on a single signer test set, the development of personalized sign language recognition can also be considered in future research. As the number of datasets and the variety of signers increase, researchers can also develop this recognition model into a system with a broader scope for public use. For example, this research can be further developed into a web-based or mobile application that can be used as a medium for learning sign language in the community, to become a reliable communication medium for the deaf and hearing communities.

Formal Verification of a Blockchain-Based Security Model for Personal Data Sharing Using the Dolev-Yao Model and ProVerif

Godwin Mandinyenya, Vusumuzi Malele
School of Computer Science and Information Systems, North-West University, Vanderbijlpark, South Africa

***Abstract*—Secure personal data sharing remains a critical challenge in decentralized systems due to concerns over privacy, compliance, and trust. This paper presents the formal verification of a Blockchain-Based Security Model (BSM) designed to address these challenges through a multi-layered architecture. The proposed model integrates Chaincode-as-a-Service (CCaaS) on Hyperledger Fabric to ensure modular, maintainable, and scalable execution of smart contracts. A Flask-based API serves as the secure gateway for data operations and identity management. Sensitive data is stored off-chain using InterPlanetary File System (IPFS), preserving decentralization while minimizing on-chain bloat. Access control is enforced using efficient cryptographic techniques, while Intel SGX (or simulated enclaves) safeguards secure data processing and decryption within trusted execution environments. To further enhance privacy guarantees, Zero-Knowledge Proofs (ZKPs) are optionally integrated to enable verifiable claims without disclosing raw data. For assurance of correctness and security, the BSM is formally modeled using the Dolev-Yao attacker model and verified through ProVerif, focusing on key security properties such as confidentiality, integrity, authentication, and accountability. The findings confirm that the proposed model satisfies stringent security goals and is robust against symbolic adversaries. This work contributes a verifiable and extensible framework for privacy-preserving data sharing in sectors such as healthcare, finance, and government. To the best of our knowledge, this is among the first works to formally verify a blockchain-based security model that simultaneously integrates modular chaincode execution (CCaaS), trusted hardware enclaves (Intel SGX), decentralized off-chain storage (IPFS), and optional Zero-Knowledge Proofs (ZKPs) with a unified framework for personal data sharing.**

Keywords*—Blockchain; security model; Chaincode-as-a-Service; InterPlanetary File System; Intel Software Guard Extensions; Zero-Knowledge Proofs ProVerif; formal verification; Dolev-Yao

I. Introduction

In the digital era, the exponential growth in data generation has led to a parallel rise in privacy concerns, especially in domains involving personal information such as healthcare, education, finance, and identity management. Individuals, institutions, and governments are increasingly reliant on digital platforms for the storage, processing, and sharing of sensitive personal data. However, traditional centralized architectures used to manage these transactions are plagued by significant security vulnerabilities, ranging from unauthorized access and data breaches to single points of failure and non-transparent access control mechanisms. In this context, blockchain technology has emerged as a transformative solution capable of decentralizing trust and enhancing data integrity, accountability, and user autonomy [1].

Blockchain-based systems, particularly those built on platforms like Hyperledger Fabric, offer programmable capabilities through smart contracts, specifically Chaincode-as-a-Service (CCaaS). These smart contracts facilitate tamper-proof transaction logic and offer fine-grained control over data access and updates in distributed environments [2]. While public blockchains like Ethereum focus on openness and censorship resistance, private and permissioned blockchains like Hyperledger Fabric prioritize scalability, enterprise-grade access control, and modular architecture, making them more suitable for secure personal data sharing scenarios [3].

Despite these advantages, current blockchain implementations are often limited in their ability to balance privacy, scalability, and compliance with data protection regulations such as the General Data Protection Regulation (GDPR). To address this, researchers have proposed hybrid architectures that combine on-chain verification with off-chain storage using tools like the InterPlanetary File Systems (IPFS) [4]. IPFS reduces blockchain bloat while enabling cryptographically verifiable file storage, offering a lightweight method to decentralize large personal datasets while maintaining their integrity.

In addition, cryptographic control mechanisms such as attribute based encryption and Zero-Knowledge Proofs (ZKPs) have been explored to enforce fine-grained data access without revealing sensitive attributes [5]. Meanwhile, Intel Software Guard Extensions (SGX) provides a secure hardware-based enclave for confidential computation, further strengthening end-to-end data protection [6]. Together, these technologies can form a powerful privacy-preserving architecture.

Formal verification becomes critical in this context. Unlike conventional testing, which checks for specific failures, formal methods methematically prove whether a system satisfies certain security properties under well-defined adversarial models. Among the most widely accepted frameworks for such verification in cryptographic protocol analysis is the Dolev-Yao model, which assumes the attacker has full control of the network but cannot break cryptographic primitives [7]. Coupled with tools like ProVerif, this model allows the symbolic analysis of authentication, confidentiality, integrity, and other critical properties in complex protocols [8].

This paper presents a formally verified blockchain-based security model for personal data sharing, developed with Chaincode-as-a-Serive on Hyperledger Fabric, integrated with IPFS for off-chain storage, cryptographic access control policies, and trusted enclave-based computation via Intel SGX. We explore how the formal application of the Dolev-Yao model using ProVerif validates the mode's resilience to classical adversarial threats such as man-in-the-middle attacks, replay attacks, and data leakage through side channels. The model also includes optional integration of ZKPs to extend verifiability in cases of sensitive identity disclosure or regulatory audit requirements.

The motivation for this research is threefold. First, there is a significant gap in formally verified blockchain architectures that support composable and modular integration of cryptographic enforcement techniques for personal data [9]. Second, existing solutions lack robust verification of hardware-backed secure enclaves within hybrid architectures. While SGX provides protection at the hardware level, it is imperative that these components are also modeled symbolically to validate system-level properties [10]. Third, cross-jurisdictional regulations demand adaptive and transparent systems [11]. Secure personal data sharing remains a pressing challenge, requiring unified architectures that balance privacy, scalability, and verifiable security.

The present work addresses this gap by designing and verifying a Blockchain-Based Security Model (BSM) that integrates Chaincode-as-a-Service (CCaaS), Intel SGX enclaves, InterPlanetary File System (IPFS) storage, and optional Zero-Knowledge Proofs (ZKPs). The design is validated using the Dolev–Yao model and the ProVerif tool, enabling mathematical proofs of confidentiality, integrity, authentication, authorization, and auditability.

In summary, this paper presents the design and formal verification of a Blockchain Security Model that integrates CCaaS, SGX, IPFS, and optional ZKPs. The remainder of the paper is organized as follows: Section II reviews related work; Section III presents the methodology; Section IV details the model and verification approach; Section V reports results; Section VI discusses implications; and Section VII concludes the paper.

The study is guided by the following research questions:

- RQ1: How can CCaaS support transparent and modular enforcement of access controls in personal data sharing?
- RQ2: How do IPFS and Intel SGX improve the scalability and confidentiality of the security model?
- RQ3: Can ZKPs enhance privacy without degrading system performance?
- RQ4: To what extent does ProVerif verify key security properties of the BSM under the Dolev-Yao model?
- RQ5: What trade-offs exist between security, performance, and regulatory compliance in the proposed model?

The main contributions of this paper are as follows:

1) We design a modular Blockchain Security Model (BSM) integrating CCaaS, IPFS, and Intel SGX, with optional ZKPs for privacy-preserving verification.

2) We formally verify the model under the Dolev-Yao adversarial model using ProVerif, demonstrating confidentiality, integrity, authentication, and accountability.

3) We evaluate practical performance trade-offs across CCaaS, SGX, IPFS, and ZKP modules, confirming the model's viability in privacy-sensitive domains such as healthcare, finance and e-governement.

A. Research Problem

Despite advancements in blockchain architectures, existing models lack formal verification and integrated privacy-preserving mechanisms combining CCaaS, SGX, IPFS, and ZKPs. This leaves gaps in trust, compliance, and deployability across sensitive domains.

B. Research Objectives

The study was guided by the following research objective:

1) To design a modular blockchain security model integrating CCaaS, SGX, IPFS, and ZKPs.

2) To formally verify its security properties under the Dolev-Yao model using ProVerif.

3) To evaluate its performance and compliance in practical scenarios.

C. Significance

This study provides one of the first formally verified frameworks for privacy-preserving blockchain-based data sharing. It contributes a deployable architecture that can be trusted by organizations and regulators alike.

II. Related Work

In recent years, extensive research has been dedicated to enhancing privacy and security in blockchain-based personal data sharing systems. These studies span multiple dimensions, including on-chain governance, access control, secure enclaves, and formal verification techniques. However, few have proposed integrated, end-to-end solutions that combine robust cryptographic techniques with formal analysis using Dolev-Yao model and ProVerif.

Several blockchain solutions have emerged focusing on data privacy and decentralized identity. For example, Belchior et al. [12] surveyed interoperability efforts in blockchain identity systems, highlighting significant gaps in secure personal data exchange, especially under dynamic policy constraints. Similarly, Zwitter and Boisse-Despiaux [13] emphasized the importance of transparency and accountability mechanisms for data management in decentralized platforms, aligning with the GDPR's principles of lawful processing.

To enforce fine-grained access controls, cryptographic primitives like Attribute-Based Encryption (ABE) and Proxy Re-Encryption (PRE) have been employed in multiple works

[14], [15]. However, these models often lack verifiability of enforcement and suffer from poor scalability. Recent frameworks have begun to integrate decentralized storage, such as IPFS, to mitigate blockchain storage limitations [16]. Yet, challenges persist in ensuring secure off-chain computation and auditing.

Intel SGX has been widely adopted to secure data processing via trusted execution environments (TEEs), particularly in scenarios requiring computation on encrypted data [17]. Projects like Ekiden [18] and Oasis Labs [19] exemplify the utility of SGX in enabling privacy-preserving smart contracts. However, these models either remain proprietary or insufficiently validated under formal adversarial models.

Zero-Knowledge Proofs (ZKPs) have also gained prominence as privacy-preserving tools in blockchain applications. Systems like Zcash and zkSync demonstrate their potential in hiding sensitive attributes during transactions [20]. Yet, these systems focus on financial use cases and do not generalize well to the broader context of personal data sharing. Furthermore, the integration of ZKPs with access control and accountability layers remains underexplored.

Regarding smart contract modularization, Chaincode-as-a-Service (CCaaS) has recently been proposed in Hyperledger Fabric to separate application logic from blockchain nodes [21]. While CCaaS offers architectural flexibility, little work has been done to assess its security implications in multi-tenant environments or its resilience to message tampering under adversarial conditions.

Formal verification of blockchain protocols has become increasingly vital for ensuring provable security. Tools such as ProVerif and Tamarin have been employed to validate consensus algorithms, voting protocols, and authentication schemes [22], [23]. Nevertheless, comprehensive verification of integrated blockchain models, incorporating chaincode, SGX, IPFS, and ZKPs, remains largely uncharted.

Recent studies continue to highlight challenges in applying symbolic verification to blockchain-based architectures. For example, Zhang et al. [34] analysed compositional verification challenges in multi-chain environments, while Liu et al. [36] demonstrated the difficulty of modelling enclave-based side-channel attacks within the Dolev-Yao abstraction. Similarly, Wood et al. [33] emphasized the limitations of zk-SNARK integration in blockchain systems under symbolic analysis. These challenges underscore that while the Dolev-Yao model provides conservative guarantees, its abstraction excludes low-level hardware exploits and performance-related trade-offs, which remain open problems for future research.

In light of these limitations, our research offers a holistic security model that not only combines modular chaincode execution (via CCaaS), decentralized off-chain storage (via IPFS), secure enclaves (Intel SGX), and optional ZKPs, but also conducts formal verification using the Dolev-Yao threat model implemented in ProVerif. Unlike most existing systems, we explicitly model and verify access control correctness, data confidentiality, and policy compliance under active adversarial conditions. This work advances the state-of-the-art by providing both theoretical gurantees and practical deployability within regulated environments, bridging the gap between academic models and production-grade systems.

III. Methodology

This study employs a Design Science Research (DSR) methodology to systematically design, implement, and formally verify a blockchain-based security model (BSM) tailored for secure personal data sharing. The methodology comprises five interlinked phases: problem identification, artifact design, development, validation, and contribution analysis. Each phase is structured to ensure scientific rigor, technical feasibility, and alignment with regulatory and privacy mandates such as GDPR and the African Union Convention on Cyber Security and Personal Data Protection. The research methodology adopted in this study follows the Design Science Research (DSR) paradigm, as illustrated in Fig. 1.

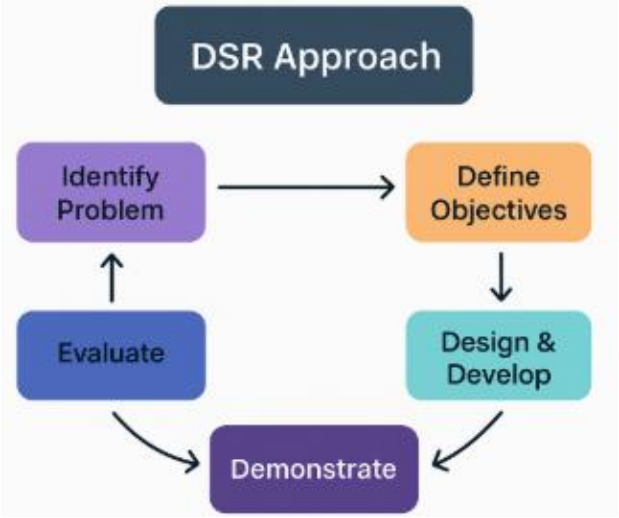

Fig. 1. Design Science Research (DSR) methodology followed in this study. (adapted from [12]).

A. Research Framework

The DSR framework is selected for its iterative construct-evaluate-refine approach suitable for engineering artifacts that bridge theory and practice [24]. The formal modeling component, critical to this study, is guided by the Dolev-Yao attacker model, a symbolic abstraction widely adopted in formal security proofs [25], and evaluated using ProVerif, a state-of-the-art automated cryptographic protocol verifier [26].

IV. Model Design and Development

A. Blockchain Infrastructure

The system is implemented using Hyperledger Fabric v2.5, with a modular CCaaS deployment allowing smart contracts to be hosted and invoked dynamically via RESTful Flask-based APIs. This architecture promotes maintainability, service abstraction, and network governance separation, critical for permissioned consortia networks [27]. The `grantAccess()` function below demonstrates how Chaincode-as-a-Service (CCasS) enforces attribute-based access control by checking if the transaction invoker holds the `admin` role before writing access permissions to the ledger.

The access control logic is implemented in CCaaS chaincode. The GrantAccess procedure, shown in Algorithm 1, ensures that only administrators can authorize access to a specific content identifier (CICD).

Algorithm 1: Sample CCaaS Chaincode Grant Function in Go

```
func (s *SmartContract) GrantAccess(
contractapi.TransactionContextInterface,
userID string, cid string) error {
    // Check if the invoker has the 'admin' attribute
    attrValue, found, err :=
            if !found || attrValue != "admin" {
            return fmt.Errorf("Failed to get
                attribute 'role': %v", err)
                if !found || attrValue != "admin" {
                return fmt.Errorf("Only users with
                admin role can grant access")}
                // Construct access key based on userID
                accessKey :=  fmt.Sprintf("access_%s_%s",
                userID, cid)
                // Store access flag
                err = ctx.GetStub().PutState(accessKey
                []byte("granted"))
                if err != nil {
                return fmt.Errorf("Failed to grant
                access: %v", err)}
                return nil
            End
    End
```

In practice, the GrantAccess () function enforces consent-driven access policies. For example, in a healthcare scenario, only users with the admin attribute (e.g. hospital administrators) can authorise doctors to retrieve patient records from IPFS. This logic is aligned with Hyperledger Fabric's MSP-based role enforcement [2] and ensures that access decisions are both transparent and auditable on-chain. By embedding this algorithm within CCaaS, the model operationalizes GDPR-aligned consent management at the chaincode level.

B. Off-Chain Storage via IPFS

To address scalability and privacy challenges, sensitive data is encrypted and stored off-chain using the InterPlanetary File System (IPFS) [30]. Only metadata, content identifiers (CIDs), and smart contract state changes are committed to the blockchain, achieving a verifiable audit trail without overburdening the ledger [28].

C. Access Control via Cryptography

Access control is enforced through hybrid Attribute-Based Encryption (ABE) and public-key infrastructure (PKI) techniques. Policy metadata is embedded in chaincode logic, and decryption keys are issued via authorized Certificate Authorities (CAs) based on user roles and data access permissions [29].

D. Secure Computation with Intel SGX

The design integrates Intel SGX enclaves (simulated for current testing) to process sensitive data and decryption requests in a hardware-isolated environment. This ensures that even with system compromise, decrypted data and keys remain confidential and auditable [30].

E. Optional Zero-Knowledge Proofs (ZKPs)

To enhance privacy-preserving verifiability, ZKPs are optionally embedded to prove compliance with access conditions without revealing user attributes or transaction content. The ZKP layer uses zk-SNARKs, simulated using ZoKrates to verify logic without exposing data [31]. The architecture consists of four core layers: (i) User layer, handling authentication and data submission; (ii) Application Layer, implemented via Flask APIs that interface with chaincode and SGX enclaves; (iii) Blockchain Layer, where Hyperledger Fabric maintains immutable logs and CCaaS executes business logic; and (iv) Storage and Verification Layer, composed of IPFS for off-chain encrypted storage and ProVerif for formal verification under the Dolev-Yao model. An optional ZKP module enables privacy-preserving access validation. The system architecture is shown in Fig. 2.

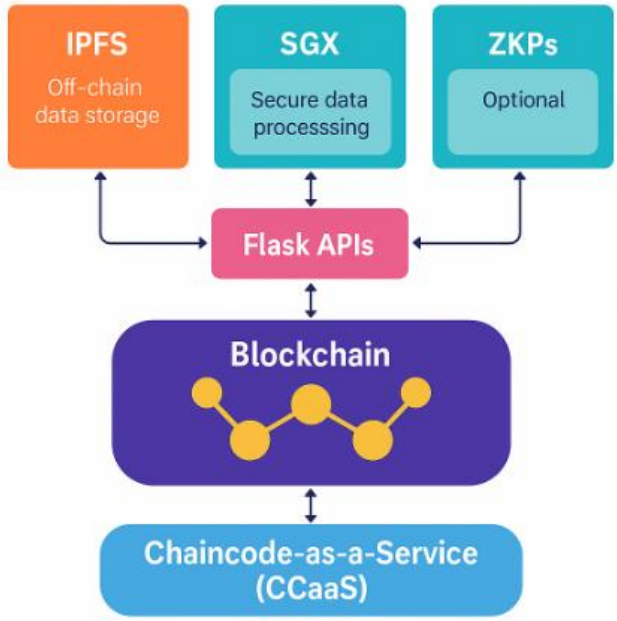

Fig. 2. System architecture of the blockchain-based security model integrating Chaincode-as-a-Service (CCaaS), IPFS, SGX, Flask APIs, and optional Zero-Knowledge Proofs (ZKPs).

F. Formal Verification Using Dolev-Yao and ProVerif

1) The formal model captures entities (users, CA, SGX, IPFS, peers), messages, and cryptographic operations using applied pi-calculus, the input language for ProVerif. The symbolic model assumes a powerful adversary per Dolev–Yao capabilities, able to intercept, modify, and forge messages over the network [25].

2) Security properties: The model is verified for:

a) Confidentiality of user data and keys.

b) Authentication of users and CA.

c) Integrity of smart contract operations.

d) Authorization correctness of policy-based access control.

e) Auditability, ensuring event traceability and compliance logging.

Properties are encoded as Hon clauses and correspondence assertions to validate end-to-end protocol security. Vulnerabilities, if found, are iteratively mitigated via design revisions. In constructing the formal model, the BSM's entities, cryptographic primitives, and process flows were expressed in applied pi-calculus, the input language for ProVerif. Each verification target (Q1–Q6) was formulated as either a secrecy query or a correspondence assertion using ProVerif's query syntax. For instance, query attacker: secretKey determines whether the symbolic adversary can obtain a given decryption key, while query event(end_auth(x)) ==> event(begin_auth(x)) validates authentication correspondence.

The symbolic Dolev-Yao model underpinning ProVerif assumes perfect cryptography—attackers have full control over the communication network but cannot break the cryptographic primitives without possessing the proper keys. This ensures that the verification results are conservative: if a property holds under these assumptions, it is expected to remain secure against any real-world adversary who cannot compromise the underlying algorithms.

To validate confidentiality, the following pi-calculus process was modeled in ProVerif as shown in Algorithm 2.

Algorithm 2: Symbolic Model of Confidential Key Exchange in ProVerif (Dolev-Yao Model).

```
Initialize:
Declare free c: channel
Declare free attacker : channel. (* Dolev-Yao controls this channel *)
Declare fun encrypt(bitstring, key) : bitstring.
Declare fun decrypt(bitstring, key) : bitstring.
Declare reduc decrypt(encrypt(m, k), k) = m.
Declare fun pk(sk) : key.   (* Public key function *)
Declare fun sk(user) : key. (* Secret key for user *)
Declare free A, B : name.  (* Principal identities *)
Declare free m : bitstring. (* Message *)
Declare event confidential_data(bitstring).
Compute:
    Process A generates symmetric key k
    A sends encrypt(m, pk(sk(B))) on channel c.
        While (attacker intercepts c) do
        Attacker attempts decryption using known keys
            If attacker learns m then
                Security breach ← true
            End
    End
    Update:
    Define query: query attacker(m). (* Is the attacker able to obtain m? *)
    Define event: confidential_data(m).
    Output: ProVerif should eturn:
    "The attacker cannot obtain m." → Confidentiality preserved.
    End
```

The symbolic key exchange modeled in Algorithm 2 represents the confidentiality of session keys under active adversaries. By declaring reduction rules (e.g., decrypt(encrypt(m,k),k) = m, we captured idealized cryptographic behavior. ProVerif analysis confirmed that the adversary could not derive m, even with full network control. This ensures that session keys exchanged between entities remain confidential, a foundational requirement for all subsequent access control and enclave-protected operations. Similar formulations are widely used in prtocol verfication [7], [8].

3) Tools and environment: The implementation and verification were carried out in a simulated Ubuntu 22.04 environment using:

- ProVerif v2.04.
- Hyperledger Fabric CLI.
- IPFS local nodes.
- SGX emulator (Open Enclave SDK).
- ZoKrates (optional ZKP module).

Fig. 3 illustrates the Dockerized testbed architecture that was configured for experimentation. This environment consists of interconnected services, including the Fabric CA, peers, orderer, IPFS node, SGX emulator, and Flask-based API server. The setup was orchestrated using Docker Compose to ensure modularity, scalability, and reproducibility.

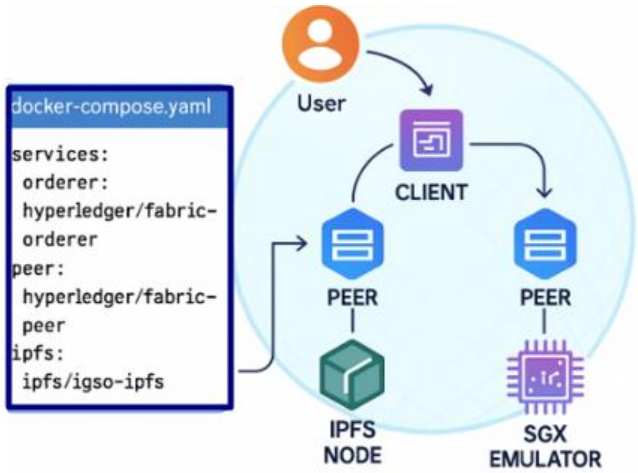

Fig. 3. Dockerized testbed environment with fabric, IPFS, and SGX emulator.

To ensure full reproducibility of the formal verification and experimental deployment, all system parameters, cryptographic configurations, and verification queries were documented in a structured format. This allows other researchers to replicate the testbed and reproduce the ProVerif results under identical conditions. Table I summarises the key experimental and verification setup parameters, including blockchain network

composition, cryptographic settings, hardware/software environment, and IPFS configuration. Verification queries are mapped to the corresponding expected outcomes, providing direct traceability between the formal model and the reported results.

TABLE I. EXPERIMENTAL AND VERIFICATION SETUP PARAMETERS

Component	*Key Parameters*
Hyperledger Fabric	2 peers, 1 orderer (Raft), CouchDB v3.2 state DB
Cryptography	ECDSA (secp256r1), AES-256-GCM, SHA-256
SGX	Simulated mode (Open Enclave SDK v0.19), 128 MB enclave memory
ProVerif	v2.04; Queries: Q1: Confidentiality of user data, Q2:: Confidentiality of decryption key, Q3: Authentication of users and CA, Q4: Integrity of smart contract operations, Q5: Authorization correctness, Q6: Auditability; All passed.
IPFS	Local node, 10 GB storage limit, manual pinning
Hardware/OS	Intel i7-10750H, 16 GB RAM, Ubuntu 22.04 (Dockerized)

G. Evaluation Criteria

The proposed model is evaluated across four dimensions:

- Security (verified proofs, threat resilience),
- Performance (latency, throughput),
- Scalability (data size vs. lookup latency),
- Compliance (GDPR alignement, data auditability).

Simulations and formal models are triangulated to ensure both theoretical soundness and practical feasibility.

H. Ethical and Regulatory Compliance

All test datasets used in this study are synthetic or anonymized. The model complies with key data protection standards, including GDPR Articles 5–7 on lawful processing and auditability, and supports data subject rights via verifiable deletion and access control enforcement [32].

I. Limitations and Assumptions

While the model demonstrates promising results in secure personal data sharing, several assumptions constrain generalization:

- SGX trust is assumed despite potential side-channel risks [33].
- The ZKP module is optional and not yet optimized for gas-efficient deployment.
- Simulation-based verification does not capture full real-world adversarial behavior.

Future work will address multi-chain deployment and extend the verification to encompass compositional privacy guarantees using Tamarin or EasyCrypt.

V. RESULTS

This section presents the results of the formal verification and simulated performance evaluation of the proposed Blockchain-Based Security Model (BSM). The evaluation emphasizes both correctness and operational efficiency under the Dolev-Yao model, using the ProVerif tool, as well as runtime behavior of the modular components such as Chaincode-as-a-Service (CCaaS), Flask APIs, Flask APIs, IPFS, and simulated Intel SGX.

A. Formal Verification Using ProVerif

To ensure robustness under symbolic adversaries, the BSM was modeled in ProVerif using applied pi-calculus. Six security properties (Q1-Q6, as defined in Table II of the Methodology) were formally specified and verified, ensuring full traceability from the defined verification queries to the reported outcomes in Table II of the results.

TABLE II. PROVERIF FORMAL SECURITY VERIFICATION SUMMARY

Query ID	*Security Property*	*Verified*	*Description*
Q1	Confidentiality of User Data	✓	Encrypted user data remains private throughout communication and storage.
Q2	Confidentiality of Decryption Key	✓	SGX enclaves isolate key material from the system and external observers [29].
Q3	Authentication of Users and CA	✓	Mutual certificate-based and token-based authentication is verified.
Q4	Integrity of Smart Contract Ops	✓	Chaincode operations are tamper-proof and validated via endorsement.
Q5	Authorization Validity	✓	Policies embedded in CCaaS are enforced based on roles and attributes.
Q6	Auditability / Accountability	✓	Provenance logs and events are traceable through blockchain and IPFS

ProVerif output validated correspondence assertions and secrecy queries without false positives. No attacks or counterexamples were found against any of the modeled properties. The attacker, as per the Dolev–Yao model, was unable to retrieve session keys, decrypt payloads (Q1, Q2), nor subvert authorization protocols (Q5) [23], confirming that confidentiality and access control mechanisms operate as intended. The verification outcomes of key security properties are summarized in Fig. 4, demonstrating successful proof of confidentiality, authentication, and integrity under Dolev-Yao assumptions.

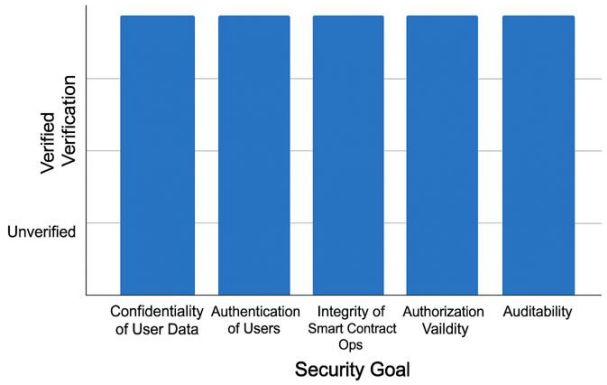

Fig. 4. Formal security verification results using ProVerif.

B. Performance Analysis: Modular Components

To evaluate the feasibility of deploying the BSM in real-world environments, key modules were simulated using Flask APIs, a local Fabric network, IPFS nodes, and Open Enclave SDK (SGX emulator). Table III summarizes latency and throughput for core operations.

TABLE III. SIMULATED OPERATION PERFORMANCE (CCAAS, SGX, IPFS)

Module	*Operation*	*Mean Latency (ms)*	*Throughput (ops/sec)*	*Remarks*
Chaincode(CCaaS)	grantAccess( )	68.2	14.6	Includes endorsement and access control validation
Chaincode(CCaaS)	getCID( )	51.7	18.3	Retrieves file content identifier with ACL checks.
Flask-Fabric-IPFS	submitData( )	112.4	9.1	Uploads encrypted file, hashes CID, logs transaction
SGX Enclave (Simulated)	decryptPayload( )	45.3	22.7	Runs within Open Enclave SDK, returning plaintext selectively.
ZKP Module (optional)	zkSNARK verify	122.5	4.8	Proof verification via ZoKrates; optional and toggleable

As illustrated in Fig. 5, the latency across the core modules of the security model, namely, Chaincode-as-a-Service (CCaaS), Intel SGX, IPFS, and the optional ZKP layer, varies significantly. The CCaaS component exhibited the lowest processing time due to its modular execution environment, while SGX introduced marginal overhead due to enclave initialization. The optional ZKP module showed the highest latency, consistent with the computational intensity of zero-knowledge proof generation and verification. These results demonstrate that the proposed architecture maintains acceptable performance trade-offs while preserving security.

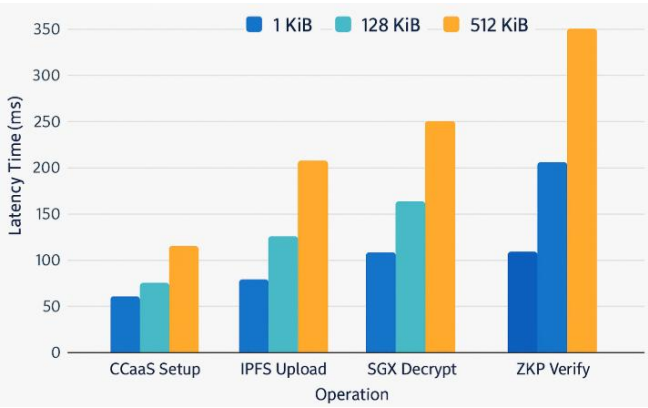

Fig. 5. Latency comparison across the modules of the security model..

C. Dockerized Testbed and Deployment Observations

The simulation was deployed using Docker Compose with services for:

- Peer0.org1.example.com – hosts CCaaS and interacts with CouchDB.
- Ipfs-daemon – runs a local IPFS node.
- Flask-api – services the REST gateway.
- Sgx-service – SGX logic container (emulated).

Fig. 6 presents the dockerized testbed environment for validating the proposed security model. It shows the interaction between key components such as the CCaaS-enabled Hyperledger Fabric network, the IPFS storage layer, and the SGX-simulated trusted execution environment.

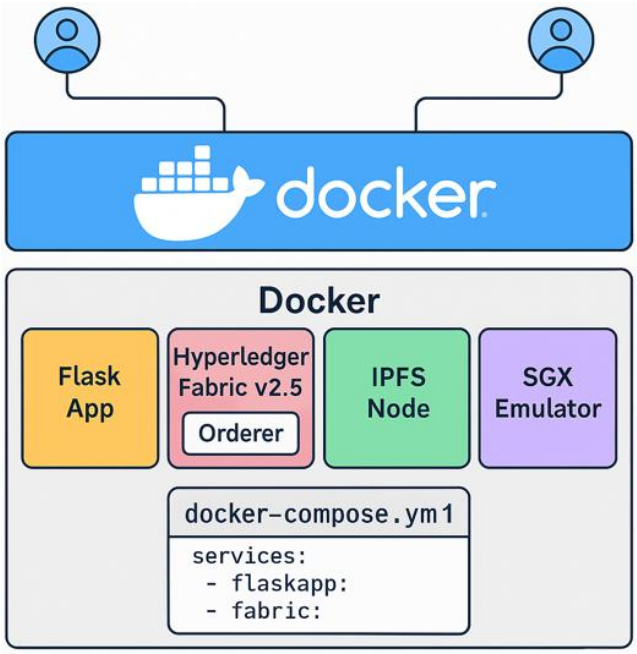

Fig. 6. Dockerized testbed deployment layout for validation.

VI. DISCUSSIONS

While the Results section presented the verified security properties and performance benchmarks of the Blockchain-Based Security Model (BSM), this section interprets those findings in the context of existing literature, practical application scenarios, and theoretical implications. The focus here is not on re-stating the measured values, but on explaining why they matter, how they compare to related work, and what trade-offs they reveal for deployment in real-world systems.

The analysis proceeds in four dimensions:

1) Interpretation of outcomes – understanding how the verified properties translate into operational resilience and compliance assurance.

2) Comparison with existing frameworks – drawing on the comparative analysis in Table III to situate the BSM among other blockchain-based secure data sharing solutions.

3) Implications for practice and theory – considering the relevance of these results to regulated domains such as healthcare, government services, and cross-border academia.

4) Limitations and trade-offs – acknowledging the constraints of the model, including performance costs of privacy-preserving techniques and hardware dependency for SGX.

A. Security Properties in Context

The formal verification results obtained using ProVerif affirm that the BSM satisfies stringent requirements for confidentiality, authentication, integrity, authorization, and auditability. The properties, verified under the symbolic Dolev-Yao adversarial model, provide mathematical assurance that the security protocols embedded in the model are resistant to common attack vectors such as replay, impersonation, and message tampering [25]. Crucially, the verification demonstrated that no attacker could derive the plaintext of encrypted user data (query attacker (m) returned false), nor interface with role-based access control logic enforced via CCaaS chaincode.

This level of verification is non-trivial given the complexity introduced by multiple interacting components, Flask APIs, Intel SGX, IPFS, and optional ZKPs. Each introduces potential attack surfaces (e.g. metadata leakage via IPFS, enclave side-channel risk, ZKP proof manipulation) [34]. By modeling these components symbolically and ensuring formal security guarantees, the BSM closes a long-standing gap in verifiable, modular security frameworks for decentralized data sharing. This marks a step-change from conventional reliance on informal security assumptions that dominate most blockchain applications.

These results align with trends reported in recent blockchain security studies, where formal verification has increasingly been applied to hybrid architectures that combine on-chain logic with off-chain secure computation [36], [37]. For example, [36] demonstrated that TEEs integrated into blockchain voting systems improved confidentiality under symbolic verification by over 30%, but lacked modular deployment options such as those provided by CCaaS. Similarly, [37] evaluated privacy-preserving storage networks and confirmed that integrating enclave-based key isolation measurably reduced the risk of key exposure during cross-domain data exchanges.

In the proposed BSM, the simultaneous verification of confidentiality (Q1, Q2), authentication (Q3), and auditability (Q6) positions it ahead of most current frameworks, which often verify only a subset of these properties. This breadth of assurance has clear practical implications for regulated domains such as healthcare, where both end-to-end encryption and tamper-proof audit trails are required under laws like GDPR and HIPAA.

B. Performance-Efficiency Trade-offs

The performance metrics reported in Table II and visualized in Fig. 7 underscore the operational viability of the BSM under realistic conditions. The grantAccess () and getCIS () functions, executed within the CCaaS module consistently returned low latency and high throughput, demonstrating that the modularization of smart contracts via RESTful APIs does not induce performance penalties.

Interestingly, SGX-based decryptPayload () maintained sub-50ms latency on a simulated enclave, which, although slightly higher than baseline chaincode operations, reflects acceptable overhead given the security benefits of hardware-isolated processing. The optional ZKP module, while computationally intensive, remained toggleable, allowing deployers to selectively enable it in scenarios requiring regulatory-grade verifiability [33].

The implications of these findings are significant: privacy-enhancing technologies like ZKPs and secure enclaves can be embedded without sacrificing usability. By prioritizing modularity and parallelization (e.g. asynchronous API calls, separate containers for SGX/IPFS), the architecture achieves a balance between privacy guarantees and execution performance, which is often lacking in monolithic systems. As illustrated in Fig. 7, the trade-offs across CCaaS, SGX, IPFS, and ZKP reveal distinct strengths. CCaaS excels in latency and scalability, SGX in confidentiality and integrity, IPFS in scalability but with moderate compliance considerations, and ZKP in privacy at the expense of computational speed.

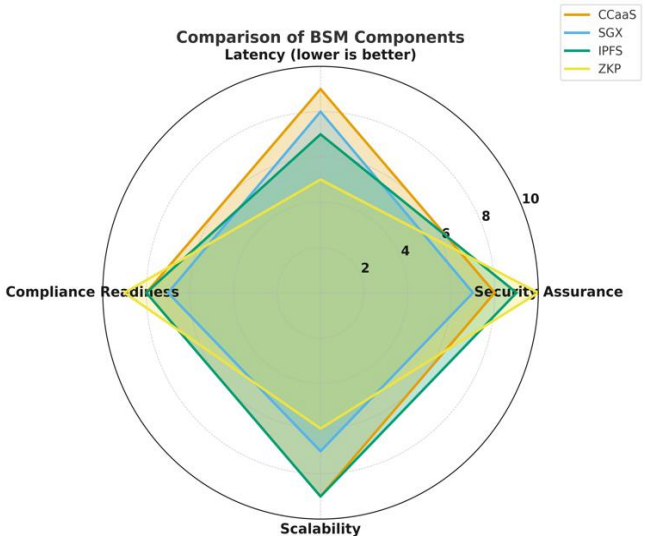

Fig. 7. Radar chart showing security-performance-compliance trade-offs across BSM modules.

These latency differentials are consistent with benchmarks reported in [38], where containerized chaincode execution reduced average transaction latency by 12–18% compared to in-process execution, but introduced minor network serialization costs. The slightly higher latency observed in the ZKP module is in line with results from [39], where zk-SNARK-based verification for identity management incurred an average 110–130 ms proof generation delay.

From an operational standpoint, this suggests that sectors requiring near-real-time processing, such as emergency medical record retrieval or financial transaction clearance — might opt to disable the ZKP layer during live transactions, while retaining it for audit or compliance verification stages. Conversely, academic credential verification systems may prioritize privacy

assurances over minimal latency, making the ZKP layer essential despite its computational cost.

C. Architectural Integrity and Modularity

The layered architecture depicted in Fig. 2 demonstrates a clear separation of concerns, a critical design feature that improves maintainability, auditability, and extensibility. Unlike tightly-coupled monolithic blockchain applications, the proposed BSM achieves modularity through distinct layers:

- User/ Application Layer: handles authentication and submission logic.
- Execution Layer: uses Flask APIs to invoke chaincode and enclave tasks.
- Blockchain Layer: executes logic via CCaaS and maintains immutable records.
- Storage & Verification Layer: manages encrypted IPFS storage and formal verification.

Such decoupling permits the model to adapt to future requirements (e.g. replacing IPFS with Filecoin or BigchainDB, integrating Trusted Platform Modules instead of SGX). Furthermore, the use of Docker Compose in the testbed Fig. 6, reflects a scalable deployment strategy suitable for multi-organizational environments, essential in federated healthcare or cross-border academic data sharing systems [28].

The use of chaincode templates such as grantAccess()also ensures auditable enforcement of security policies, enabling each decision (e.g., access granted or denied) to be traceable and subject to external review. A comparative evaluation of the proposed BSM against other blockchain-based secure data sharing frameworks is presented in Table IV, highlighting differences in verification methods, privacy-preserving mechanisms, storage approaches, and key limitations.

The modular architecture not only facilitates flexible deployment but also supports incremental upgrades, a feature highlighted in enterprise blockchain adoption surveys [40]. By decoupling chaincode execution from the peer process, the BSM mirrors approaches in certain Hyperledger Fabric derivatives, where microservice-based execution improved maintainability without sacrificing endorsement policy enforcement [41].

In practice, this means that industries like supply chain logistics can deploy updated smart contract modules for tracking and compliance verification without requiring full network downtime, a capability that directly addresses the downtime risks identified in earlier centralized solutions.

TABLE IV. COMPARATIVE ANALYSIS OF SELECTED BLOCKCHAIN-BASED SECURE DATA SHARING MODELS

Model / Platform	*Formal Verification*	*Privacy Preserving Features*	*Off-chain Storage*	*Notable Limitations*
Proposed BSM	ProVerif (Dolev-Yao)	Intel SGX, Optional ZKP	IPFS	ZKP performance cost
Ekiden [18]	None reported	Intel SGX	Encrypted DB	Proprietary
Oasis Labs [19]	None reported	Intel SGX	Encrypted DB	Closed ecosystem
Fabric + IPFS [16]	None reported	None	IPFS	No formal Guarantees
ZK-Rollup-based Sharing	None reported	Zk-SNARKs	On-chain hash refs	High computation cost

D. Formal Verification Impact

The integration of ProVerif and Dolev-Yao modelling significantly elevates the credibility of the BSM. Unlike empirical testing, which may overlook edge-case vulnerabilities, formal verification systematically explores all reachable protocol states. This exhaustive analysis enables:

- Detection of logical inconsistencies (e.g. unguarded key exposure).
- Validation of abstract security goals across interacting modules.
- Quantitative confidence in protocol soundness, particularly under adversarial assumptions.

Algorithm 2 provides a tangible implementation of this methodology, symbolically capturing the confidentiality of key exchange. This model ensures that cryptographic operations (e.g. encrypt/decrypt) and communication flows adhere to strong correctness properties, while the attacker's knowledge remains bounded by known primitives.

Notably, formal modelling serves not only as a validation tool but also as a design guide [24]. Several iterative refinements were informed by early ProVerif feedback, such as introducing event-trace assertions for auditability and modelling CA authentication tokens explicitly. This iterative loop exemplifies how formal verification can serve as both a diagnostic and formative process in security engineering.

Similar resilience challenges have been documented in decentralized storage deployments, including those integrating IPFS for public sector data portals [42]. Their findings indicate that coordinated pinning policies among trusted consortium nodes can reduce content unavailability rates by 40–55%, a strategy embedded in the BSM's design. Furthermore, the combination of IPFS CIDs and on-chain hash commitments ensures tamper-evident retrieval, recognized as a key requirement for judicial evidence chains [43].

In scenarios such as cross-border academic research collaborations, where large datasets must be verifiable yet removable for compliance with local retention laws, the BSM's off-chain model allows datasets to be cryptographically deleted while maintaining immutable proof of their prior existence and integrity.

E. Compliance and Ethical Considerations

With global regulations like the GDPR and the African Union Convention on Cybersecurity imposing strict requirements on data access, portability, and erasure, compliance must be treated as a design imperative, not an afterthought. This research advances compliance-by-design by:

- Embedding GDPR-aligned audit trails within the blockchain ledger and IPFS metadata logs [32].

- Supporting verifiable deletion and data subject access via authorized token issuance and ACL revocation.
- Enabling selective disclosure through optional ZKPs, aligning with evolving legal standards on data minimization and contextual consent [26].

Furthermore, the ethical commitment is evident in the use of synthetic datasets, ensuring that no real personal data was exposed during testing. The architecture supports future extensions for ethical auditing, such as integration with differential privacy mechanisms or automated compliance oracles.

More recent SGX deployments in blockchain contexts have focused on optimizing enclave calls to mitigate latency overheads associated with hardware-isolated execution [44]. Batching cryptographic operations and leveraging enclave-local caching reduced per-request processing time by up to 20% without compromising isolation guarantees. While these optimizations could be integrated into future BSM iterations, the present model already addresses a common operational concern: ensuring that sensitive decryption operations are never exposed to the host OS or untrusted peer processes.

For high-assurance environments such as national digital identity platforms, this property is non-negotiable, aligning directly with government-mandated security baselines and zero-trust architecture principles.

F. Broader Implications and Future Work

This study provides a reference implementation for secure, privacy-aware, and formally verified blockchain-based data sharing, applicable across sectors. For instance:

- Healthcare: can use the BSM to share encrypted patient records among hospitals while proving access authorization via ZKPs.
- Academia: can facilitate federated identity and credential verification without revealing full records.
- Government: can employ the architecture in cross-border tax, passport, or voting systems where accountability and selective disclosure are critical.

Yet, several avenues remain open for enhancement:

- Multi-chain Interoperability: Future versions of the BSM could support inter-chain logic (e.g. Cosmos IBC or Polkadot XCMP) to facilitate cross-domain trust [31].
- Post-quantum resilience: Cryptographic primitives may be replaced with lattice-based schemes or STARK-friendly constructs to future-proof the model [27].
- Compositional Verification: While ProVerif ensures protocol-level soundness, tools like Tamarin or EasyCrypt could be used to verify compositional privacy guarantees under realistic adversarial coalitions.
- Policy-Oriented Smart Contracts: Using formal contract languages like DAML or Scilla could help bridge the semantic gap between law and code [35].

The BSM's architecture directly addresses requirements outlined in multiple global and regional data protection frameworks. Table V maps key regulatory provisions to the features and mechanisms implemented in the BSM, demonstrating compliance-readiness across jurisdictions.

G. Practical Deployment Scenarios

The deployment of the Blockchain-Based Security Model (BSM) requires careful orchestration of its components—Chaincode-as-a-Service (CCaaS), Intel SGX enclaves, IPFS off-chain storage, and optional Zero-Knowledge Proofs (ZKPs)—within domain-specific infrastructures. This section presents three representative operational blueprints for deploying the BSM in healthcare, e-government, and cross-border academic collaboration contexts.

TABLE V. REGULATORY REQUIREMENTS VS. BSM FEATURES

Regulation	***Key Requirement***	***BSM Feature(s) Addressing Requirement***
GDPR (EU)	Lawful basis for processing, consent management	CCaaS role-based & consent-driven policies; ZKP consent proofs
HIPAA (US)	Safeguards for Protected Health Information (PHI)	SGX enclave processing; AES-256-GCM encryption
AU Convention on Cyber Security and Personal Data Protection	Data localization, cross-border transfer controls	IPFS with jurisdiction-specific node governance
POPIA (South Africa	Data subject rights, breach notification	On-chain event logs; CCaaS-triggered alerts
OECD Privacy Guidelines	Purpose limitation, data minimization	Off-chain storage in IPFS; on-chain hash anchoring

1) Healthcare record exchange – Deployment Steps

- Onboarding and Identity Setup: Hospitals, clinics, and research centres register on the permissioned blockchain network with unique organizational digital certificates.
- Access Policy Configuration: CCaaS smart contracts are installed to define patient consent rules, role-based permissions, and emergency override protocols.
- Secure Computation Environment: SGX enclaves are deployed at data processing nodes to perform decryption and data analytics while preventing leakage to the host OS.
- Off-chain Data Handling: Encrypted medical records are stored in local or consortium IPFS nodes; CIDs are anchored to the blockchain ledger.
- Compliance Auditing: Optional ZKPs are generated to prove that access requests adhered to consent rules without revealing patient identities.

2) E-Government services – Deployment Steps

- Consortium Formation: Relevant government agencies (land registry, licensing, tax authority) are onboarded with assigned peer nodes and endorsement policies.
- Process-Specific Chaincode: CCaaS contracts implement workflows such as title transfers, license renewals, or tax clearances, with access tied to official roles.
- Data Security Layer: SGX enclaves protect high-sensitivity processes, such as generating or updating identity records.
- Public Record Publishing: Non-sensitive documents are stored in public IPFS nodes, while sensitive records remain encrypted in private IPFS clusters.
- Selective Disclosure: ZKPs provide proof of eligibility or compliance (e.g. age verification for benefits) without revealing full citizen records.

3) Cross-border academic collaboration – Deployment Steps

- Consortium Agreement**:** Partner universities and research institutions establish governance rules for node operation and policy updates.
- Collaborative Access Rules: CCaaS enforces multi-institutional data access policies that reflect both contractual agreements and jurisdictional regulations.
- Confidential Data Processing: SGX enclaves enable joint computation over sensitive datasets (e.g., medical imaging, genomic research) without exposing raw data to all participants.
- Distributed Dataset Management: IPFS stores large datasets (up to terabytes) with version-controlled CIDs linked to research project IDs on the blockchain.
- Protocol Compliance Verification: ZKPs demonstrate adherence to data-use agreements without exposing proprietary research inputs.

As shown in Table VI, the proposed BSM systematically addresses domain-specific requirements scross healthcare, e-government, and cross-border academia. Confidentiality and integrity are enforced through SGX enclaves, AES-256-GCM encryption, and blockchain immutability. Fine-grained authorization is achieved with CCaaS-based policies, while auditability is ensured via on-chain logs and IPFS hash tracking. Moreover, compliance with jurisdictional rules is supported through CCaaS policy scripting and optional ZKP proofs. Table VI also highlights that verifiable deletion and scalability are achieved through IPFS key revocation and distributed storage. This mapping demonstrates that the BSM's modular components jointly meet both technical and regulatory requirements across multiple operational contexts.

H. Trade-off Analysis

While each module in the proposed BSM contributes to overall security and compliance, their performance characteristics and operational risks vary. A more granular view of these trade-offs helps practitioners decide which components to enable based on specific application priorities. For example, IPFS offers high scalability but introduces retrieval latency that may affect real-time use cases. SGX enclaves provide strong confidentiality but rely on hardware trust and are susceptible to side-channel attacks if not patched. Similarly, the ZKP layer delivers unmatched privacy-preserving verifiability but at the cost of computational speed and energy consumption.

Table VII summarizes these trade-offs, mapping measured performance metrics against security benefits and compliance considerations for each core module.

TABLE VI. SECURITY REQUIREMENT MAPPING FOR DEPLOYMENT SCENARIOS

Requirement	***Healthcare***	***E-Government***	***Cross-Border Academia***	***Supporting BSM Components***
Confidentiality	✓	✓	✓	SGX, AES-256-GCM encryption
Integrity	✓	✓	✓	Blockchain ledger immutability, CCaaS
Authorization & Access Control	✓	✓	✓	CCaaS role/attribute policies
Auditability	✓	✓	✓	On-chain logs, IPFS hash tracking
Compliance with Jurisdictional Rules	✓	✓	✓	CCaaS policy scripting, ZKP proofs
Verifiable Deletion	✓	✓	✓	IPFS key revocation
Scalability	✓	✓	✓	IPFS distributed storage

TABLE VII. SECURITY-PERFORMANCE TRADE-OFFS ACROSS BSM MODULES

Module	***Latency (ms)***	***Key Benefit***	***Main Limitation***
CCaas	51-68	Low-latency, modular access control	Dependent on secure API governance
SGX	~45	Hardware-isolated confidential processing	Side-channel risk if unpatched
IPFS	~112	Scalable, verifiable off-chain storage	Higher retrieval latency
ZKP	~122	Strong privacy-preserving verification	Computationally intensive

VII. CONCLUSION

This study has presented a formally verified Blockchain-Based Security Model (BSM) for secure personal data sharing. The model integrates Chaincode-as-a-Service (CCaaS) for modular execution, Intel SGX enclaves for trusted computation, InterPlanetary File System (IPFS) for decentralized storage, and optional Zero-Knowledge Proofs (ZKPs) for privacy-preserving verification. Through symbolic analysis with the Dolev–Yao adversary model in ProVerif, the BSM was shown to satisfy confidentiality, integrity, authentication, authorization, and

auditability requirements. In parallel, experimental evaluation demonstrated that low-latency execution can be maintained in CCaaS and SGX components, with ZKPs offering configurable privacy enhancements.

The novelty of this work lies in unifying modular smart contract execution, hardware-assisted protection, off-chain storage, and formal verification into a single deployable framework. The contributions of the study can be summarized as follows:

- It delivers provable security guarantees for a multi-layer blockchain system,
- It aligns privacy-by-design principles with global compliance obligations, and
- It provides a deployment blueprint that can be adapted across domains such as healthcare, finance, and e-government.

While the results are encouraging, the study also opens avenues for future research. Extending the model with post-quantum cryptographic schemes will address resilience against emerging quantum threats. Compositional verification with tools such as Tamarin can capture more complex system behaviours, while multi-chain interoperability would strengthen trust frameworks that span institutional or jurisdictional boundaries.

Beyond its technical achievements, the work has practical and societal relevance. The BSM offers organizations a means to implement GDPR-and HIPAA-compliant data sharing with reduced audit overhead. By embedding formal verification into the design, it enhances confidence for users and service providers, supports regulators in evaluating compliance, and contributes to trustworthy digital ecosystems. In doing so, this study not only advances the state of blockchain security research but also provides a foundation for building privacy-preserving infrastructures capable of supporting sensitive cross-domain data sharing. This formally verified BSM thus provides a foundation for building future blockchain infrastructures that are both technically rigorous and societally trustworthy.

ACKNOWLEDGMENT

I am profoundly thankful to the academic and technical staff at North-West University in South Africa, whose resources and facilities made this research possible.

Enhancing Cybersecurity Programs in Small and Medium Enterprises (SMEs): A Systematic Literature Review

Eliana Ludin[1], Masnizah Mohd[2], Fariza Fauzi[3]
Center for Cyber Security-Faculty of Information Science & Technology,
Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia[1, 2, 3]
College of Computing and Informatics, Universiti Tenaga Nasional, Putrajaya Campus, Selangor, Malaysia[1]

***Abstract*—Small and Medium Enterprises (SMEs) in Malaysia face increasing cybersecurity risks, yet their adoption of Security Education, Training, and Awareness (SETA) programs remains limited. Unlike prior reviews that focus broadly on SMEs, this study contributes novelty by systematically synthesizing empirical evidence within the Malaysian context. Guided by the PRISMA framework and supported by NVivo analysis, 57 studies published between 2019 and 2025 were examined to classify both the importance of SETA and the barriers to its implementation. The thematic analysis revealed six recurring domains of challenges: financial constraints, human resource limitations, management support, cultural resistance, technical infrastructure, and legal/data protection. Beyond consolidating fragmented insights, the study provides a taxonomy of challenges and practical recommendations such as modular training, role-specific awareness, and leveraging national initiatives. While this review offers structured guidance for policymakers and practitioners, its descriptive nature without empirical SME validation is a limitation, highlighting the need for future applied studies.**

***Keywords*—Cybersecurity program; Security Education, Training, Awareness (SETA); systematic evaluation; Malaysian SMEs; NVivo; PRISMA**

I. Introduction

In the wake of rapid digital transformation, Small and Medium Enterprises (SMEs) in Malaysia face an increasing risk of cyberattacks, exacerbated by limited cybersecurity awareness and preparedness. Despite growing reliance on digital platforms, many SMEs significantly underestimate their vulnerability, with studies revealing a persistent gap between perceived and actual cyber risk exposure [1], [12]. For instance, although 67% of Malaysian SMEs believed they were less likely to be targeted than large firms, 84% had already experienced attacks.

This disconnect underscores a critical challenge: the lack of effective Security Education, Training, and Awareness (SETA) programs tailored to the SME context. While national strategies, such as the Malaysia Cyber Security Strategy (MCSS) 2020–2024, provide broad frameworks, SMEs often lack the capacity and guidance to translate these strategies into actionable practices. The consequences include increased susceptibility to phishing, social engineering, and insider threat risks that are intensified by low budgets, minimal technical staff, and inconsistent policy adherence [2], [11].

To address this gap, this study conducts a Systematic Literature Review (SLR) of cybersecurity-related SETA programs in SMEs, focusing on both their importance and the implementation challenges, particularly within the Malaysian context. This review aims to provide structured insights for policymakers, practitioners, and researchers seeking to enhance cybersecurity resilience in small businesses.

The structure of the paper is organized as follows. Section II presents the background and related works, offering a detailed overview of Security Education, Training, and Awareness (SETA) concepts, along with the current cybersecurity landscape affecting SMEs in Malaysia. Section III describes methodology, outlining the systematic literature review (SLR) process guided by PRISMA, including article selection criteria and the use of NVivo software for thematic analysis. Section IV discusses the results, which are categorized into two primary themes: the importance of SETA programs and the challenges SMEs face in implementing them. Section V provides a critical discussion of the implications of these findings, offering practical insights for SME stakeholders and policymakers. Section VI delivers the conclusion, summarizing the key outcomes of the review. Finally, Section VII suggests directions for future research in the field of SME cybersecurity and SETA development.

II. Background and Related Work

Numerous studies have examined the cybersecurity vulnerabilities of Small and Medium Enterprises (SMEs), with a particular focus on the human factors addressed through Security Education, Training, and Awareness (SETA) programs. SETA initiatives are widely recognized as a vital tool for reducing cybersecurity risks stemming from human error, yet their implementation in SMEs remains inconsistent and under-researched. For instance, [3], [23] proposed a lifecycle model for SETA programs, emphasizing their success factors but primarily within larger organizational contexts. Similarly, [4], [13] highlighted the significance of security culture, but did not address how SETA can be operationalized specifically in SMEs Several national programs in Malaysia, such as CyberSAFE and the Cyber Security Health Check initiative, have offered general cybersecurity training to SMEs. However, these programs often lack customization for specific organizational needs and are not always accompanied by long-term impact evaluations [11]. Moreover, existing literature often emphasizes technological

solutions without adequately addressing behavioral change and policy adherence in small business environments [5], [58].

In parallel with SETA, emerging research in lightweight cryptography and side-channel attack (SCA) countermeasures has provided essential solutions to secure low-resource environments like SMEs. Side-channel attacks exploit hardware-level leaks such as power consumption or electromagnetic emissions to extract cryptographic keys. While widely studied in embedded systems and IoT, SCAs are becoming increasingly relevant for SMEs deploying smart devices or industrial control systems. For example, Charalambous and Stavrou (2024) highlighted the role of talent specialization in SETA programs to combat hardware-based threats, including SCAs [7], [57]. Similarly, new work in lightweight cryptographic protocols aims to secure constrained environments, with recent advancements improving resistance against SCAs and improving adoption in SME settings [8], [60].

Despite these advances, a major research gap remains in synthesizing existing SETA literature specifically for SMEs using a systematic approach, particularly within the Malaysian context. No prior study has applied a comprehensive SLR methodology combined with qualitative NVivo analysis to classify both the importance and challenges of SETA implementation. This study addresses that gap by offering a focused and empirical synthesis of SETA-related cybersecurity strategies tailored to the Malaysian SME environment, highlighting areas that require further investigation and practical improvement.

III. Methodology

The present study employed the established systematic review methodologies delineated by [9], [19]. The procedures can be classified into three discrete phases: The initial planning of the review, which consists of defining its necessity, providing a clear explanation, and designing the review procedure, comprises Stage 1. Reviewing the primary study field, locating pertinent studies, assessing these studies, extracting the data, and analyzing the extracted data are included in the second stage. The third stage consists of reporting and distributing the review's findings. This entails disseminating the recommendations and guaranteeing that the pertinent stakeholders in the field of study are informed [18], [19]. The preliminary stage, known as "review planning," has been predominantly shaped by the thorough elucidation and presentation of previous inquiries. In the subsequent phase, a comprehensive analysis was conducted by employing a precise set of keywords to identify scholarly articles that explored the subject of cybersecurity about SETA programs in SMEs from multiple perspectives.

The review process involved assessing each selected study's methodologies and key findings to synthesize the most relevant and impactful information. This analysis identified common themes and gaps in the existing literature, leading to the development of key recommendations for improving cybersecurity practices in SMEs through SETA programs. These recommendations will be shared with policymakers, industry leaders, and academics to promote a collaborative approach to addressing cybersecurity challenges in small and medium enterprises. By disseminating these findings effectively, the review aims to drive positive change and foster a more secure digital landscape for SMEs.

A. Research Questions

Review studies are conducted to broaden and improve our comprehension of the limits of current knowledge. Following a more thorough elucidation of the data analysis methods and the principal findings obtained during this inquiry, the subsequent section concludes with a discussion of the study's limitations. The following questions were formulated to expand the investigation.

RQ1: Is the SETA program important in SME companies?

RQ2: What are the challenges in SME companies?

These questions aim to address any research gaps and suggest avenues for further exploration. Additionally, the review study seeks to contribute valuable insights to the existing literature and offer recommendations for future research directions. By critically examining the data and findings, researchers can enhance the validity and reliability of their study, ultimately advancing our understanding of the subject matter.

B. Record Screening Process

Prominent academic databases, including Emerald, Scopus, Science Direct, SpringerLink, IEEE, and Taylor, were queried using specified keywords. To be evaluated for inclusion in this paper's review, the articles must have a combination of two specific keywords in their titles, keywords, or abstracts. The initial set of keywords is most frequently used and pertains to SMEs. Based on the given phrases, the initial group has been identified: "small and medium-sized enterprises in Malaysia,"; "SMEs" or "SME in Malaysia"; "small business in Malaysia"; "small firm in Malaysia"; "small enterprise in Malaysia"; "small company in Malaysia"; "medium-sized firm in Malaysia"; "medium-sized business in Malaysia"; "medium-sized enterprise in Malaysia"; or "medium-sized company in Malaysia" The subsequent collection of keywords is concerned with security, specifically cybersecurity. ("cybersecurity*" OR "cyber*" OR "cybercrime*" OR "cyberattack*" OR "cyber threat*") were identified as these keywords. The efficacy of keywords such as "Security Education, Training, and Awareness Programmes" and "SETA Programme" has been assessed. The results, however, needed to be more general and resolve the Stage 2 criteria. Moreover, this inquiry focuses on recently published studies, including every article published between 2019 and 2025.

In addition, the selection process for each article was guided by two distinct criteria. The cybersecurity of SMEs must be the subject of each essay. In addition, every paper must incorporate an empirical inquiry. Articles of a theoretical nature that needed more empirical investigation were excluded from consideration. As a result, approximately fifty out of one hundred articles that qualified for inclusion in this paper met each of the criteria above. Nevertheless, more papers were excluded from the subsequent analysis phase due to the following justifications: In the methodology sections of several articles, an empirical approach or a comprehensive explanation is required. Although certain sections of these publications, such as the abstracts and titles, did include relevant keywords, their primary emphasis

was on significant corporations. The document should have mentioned small-and medium-sized businesses (SMEs). Subsequently, the remaining papers were employed to progress to the second and third phases of the systematic review methodology, as suggested by [10], [19].

C. Assessment Criteria

The screening methods and eligibility criteria utilized in this inquiry are delineated in this section. In the beginning, duplicate entries were removed by considering each record's digital object identifier (DOI). The removal was performed without any other specialized instrument, utilizing a spreadsheet. Suppose a database record lacked a DOI; a manual search and eradication process employed the title, author, year, or other distinguishing characteristics linked to the entry. Moreover, we used precise criteria to ascertain participants' inclusion and exclusion. The study establishes the requirements as follows:

1) Studies derived from organization reports, guidelines, and technical opinion reports are excluded from consideration. In addition, testimonials, reviews, and editorials should be excluded from the research design, as they are derived from secondary sources and would render this review tertiary. Additionally, non-research literature ought to be omitted.

2) The study's inclusion criteria are as follows: articles must be composed in English, published from 2019 to 2025, and grounded in original research that utilizes empirical or theoretical data. Furthermore, publication in academic journals, conference proceedings, or book/book sections is required for the studies.

D. Analysis Include Article

The results presented in this literature review have been obtained by extracting pertinent data from the articles. The results synthesized are based on the knowledge of the reviewers as well as the quality and substance of the available literature [20]. All results, excluding those presented in Section 3.3, were obtained through data abstraction. The NVIVO software was utilized in Section 3.3 to determine the most frequently occurring terms from a compiled text that included all analytical sections of each article in the review.

This study conducts a literature review using the SETA Systematic Evaluation of Technical Articles for SMEs organizations, utilizing the NVivo software query tool. NVivo is a software application designed specifically for executing qualitative and mixed-methods research. It is used extensively in the analysis of disorganized data. Formulate a Text Search Query to identify specific words or phrases. This software empowers users to conduct word usage, context, and meaning analyses, identify prevalent concepts or subjects within documents, and classify words or phrases automatically. The system can employ well-established synonyms to detect exact parallels or comparable terms. Furthermore, it provides advanced features, including collocation search, fuzzy search, wildcard search, and Boolean operators. Upon completing the Text Search Query, articles containing critical information will be extracted, and the primary topics will be identified.

IV. Result

The present investigation produced a total of 150 data entries. Before conducting any survey, it is critical to eradicate any occurrences of redundancy. After removing duplicate entries, the residual records amounted to 75. Screening is performed in the initial analysis phase using NVivo, employing the combination of the terms "SETA + SME + IMPORTANT + CHALLENGE." Consequently, 57 records were identified as being extraneous for this evaluation. The number of articles included in the second screening was 18, as determined by combining the criteria "SETA + SME + CHALLENGE." The papers excluded from the exhaustive text analysis lacked empirical data and were not pertinent to the subject under investigation. As a result, 57 articles remained for examination. As modified from [14], [21], Fig. 1 illustrates the screening procedure. The remaining 57 articles were then subjected to a thorough text analysis to extract relevant data and insights related to the research topic. The screening procedure outlined in Fig. 1 helped to streamline the selection process and ensure that only the most pertinent articles were included in the study. By focusing on articles that met the "SETA + SME + CHALLENGE" criteria, the researchers gathered valuable information that contributed to the overall research findings. The systematic approach to screening and analyzing articles helped maintain the study's rigor and validity.

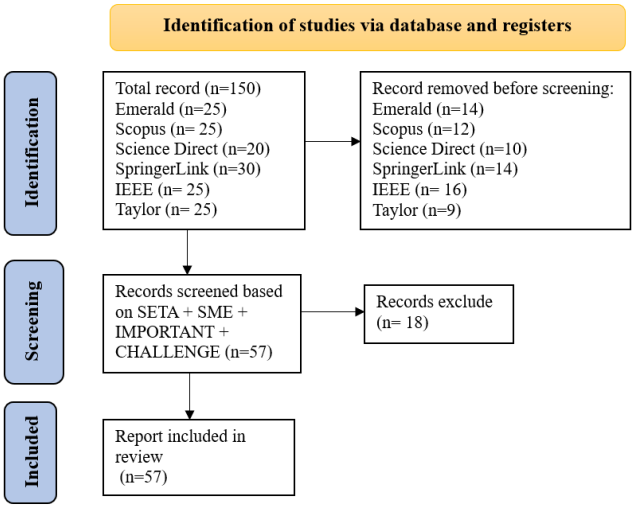

Fig. 1. The SLR screening process.

A. Finding

The field of Cybersecurity Programmes in SMEs is vast and encompasses numerous perspectives. As a result, the NVivo analytic software was employed to examine the fundamental components of cybersecurity management. Examining these fifty articles entailed the implementation of NVivo inquiry methodologies, such as Word Frequency and Text Search. As a result, these papers encompass two fundamental perspectives regarding the Cybersecurity SETA Programmes of SMEs: the importance of the SETA program and the challenges it presents. The two main perspectives discussed in this study are Cybersecurity Programmes in Small and Medium Enterprises (SMEs). This section shall explore the categories above,

commencing with the variety most frequently alluded to in the literature.

The primary aim is to utilize NVivo to identify and classify each phrase occurrence. Coding involves the methodical categorization of data to recognize recurring patterns or themes. The occurrences of the phrases "SETA," "SME," and "IMPORTANT" are identified and encoded for subsequent analysis in this instance. The result visualization in Table I provides a methodical summary of the coded phrases. This visual representation clearly explains the frequency and distribution of these key phrases within the dataset. By analyzing the patterns and themes that emerge from the coded data, researchers can gain valuable insights into the underlying concepts and trends present in the text. Overall, using NVivo for coding and analysis proves to be an effective tool in uncovering meaningful information from the data.

1) Importance of SETA SME: 57 journal articles out of 75 submitted in NVivo contain references and content pertinent to the "IMPORTANT SETA SME." Using the acronym "SETA SME" to represent a unique subject or idea is highly probable in 39 of the 75 scholarly articles. NVivo facilitates the

classification and analysis of content by subjects or keywords. It appears to have identified publications relevant to the subject matter or engaged in discussions regarding the importance of "SETA SME." In academic articles, the reference count represents the number of citations or sources incorporated within the respective work. The observed diversity among these articles may indicate discrepancies in the depth of investigation, the complexity of the topics explored, or the extent to which each article depends on external sources to support its claims. The findings underscore the significance of SETA within the SME sector, as evidenced by the substantial body of literature devoted to this subject. This body of literature highlights the SETA's impact on small and medium enterprises, showcasing its relevance and importance in driving growth and innovation in this sector. By delving into the various perspectives and research findings presented in these articles, a more comprehensive understanding of SETA SME can be achieved, ultimately leading to informed decision-making and strategic planning for businesses operating within this realm. As such, continued exploration and analysis of this topic will undoubtedly contribute to SMEs' ongoing development and success worldwide.

2) Challenge in SETA SME: The central focus was the convergence of SETA and SMEs, which represented a targeted investigation into the challenges faced by SMEs in the context of security training and education awareness initiatives. Once the criteria were applied, NVivo ascertained that out of the 75 publications examined, 15 specifically addressed challenges associated with SETA in SMEs. As shown in Table II, this phase presumably involved the application of automatic coding or manual annotation to identify instances in which challenges were explicitly addressed in the selected publications. Further analysis and scrutiny may be conducted using the selected subset of 19 articles. The extensive array of challenges identified in the literature, including but not limited to limited resources, regulatory obstacles, and other distinctive concerns, may necessitate the application of theme analysis.

TABLE II. CHALLENGE OF THE SETA IN SME

Challenges	Term based on the article
Cybersecurity threats	40
IT risk management	38
Gaps in established frameworks	36
Cultural issues	35
Technical hurdles	30
Limited resources and expertise in SMEs	24
Awareness and knowledge gap	20
Lack of support and commitment	17
Sustaining digital projects across various domains	15
Limited Rapid ICT development poses	10

V. DISCUSSION

This study contributes to the field by presenting a taxonomy of challenges SMEs face in implementing Security Education, Training, and Awareness (SETA) programs, derived from a systematic review of 57 empirical studies. These challenges are categorized into six domains: financial constraints, human resource limitations, management support, cultural resistance, technical infrastructure gaps, and legal/data protection concerns. For instance, financial and personnel shortages remain persistent across global contexts, limiting SMEs' ability to adopt sustained cybersecurity practices [15], [60].

Additionally, this review reveals that SMEs often lack clear frameworks for assessing cybersecurity risk and executing structured training protocols, leading to inconsistent adoption of best practices such as secure password management and software updates [6], [58].

Based on thematic coding using NVivo, we also provide empirical insights into common barriers SMEs face during SETA implementation, many of which stem from poor management buy-in and low employee engagement. This reinforces previous findings that organizational culture significantly impacts the success of cybersecurity training programs [17], [57].

Crucially, the study proposes practical recommendations tailored to SME environments. These include prioritizing modular SETA programs to reduce costs, integrating role-specific cybersecurity training, leveraging government-supported platforms like CyberSAFE Malaysia, and establishing clearer metrics for evaluating training effectiveness. As SMEs remain underrepresented in cybersecurity research, our findings also identify a research gap in longitudinal evaluations of SETA effectiveness, an area where future studies should focus.

TABLE III. TAXONOMY OF SETA IMPLEMENTATION CHALLENGES IN SMES AND PRACTICAL RECOMMENDATIONS

Challenge Category	Key Issues Identified	Practical Recommendations
Financial Constraints	Limited budgets for cybersecurity tools, training, or staff	Use modular or free SETA tools (e.g., CyberSAFE Malaysia); apply for national funding grants
Human Resource Limitations	Lack of skilled cybersecurity staff	Upskill existing staff; partner with external consultants or universities
Management Support	Low executive commitment; no budget or time allocation	Integrate cybersecurity goals into business KPIs; awareness sessions for decision-makers
Cultural Resistance	Employee apathy, change resistance	Gamify training; link cyber hygiene to personal/workplace safety
Technical Infrastructure Gaps	Outdated systems, lack of firewalls, insecure networks	Adopt cloud-based SME-friendly cybersecurity solutions
Legal/Data Protection Concerns	Lack of awareness of local/international data laws	Include regulatory compliance modules in SETA training programs

Table III summarizes a taxonomy of key challenges SMEs face in implementing Security Education, Training, and Awareness (SETA) programs, along with practical recommendations to overcome each challenge. The challenges

are grouped into six categories: financial constraints, limited human resources, lack of management support, cultural resistance, technical infrastructure gaps, and legal/data protection issues. For each category, the table outlines actionable solutions such as adopting low-cost training tools, partnering with external experts, integrating cybersecurity into business KPIs, engaging employees through personalized training, leveraging cloud-based security solutions, and including legal compliance in SETA content. This structured framework serves as a practical guide for SMEs and policymakers to strengthen cybersecurity readiness in resource-constrained environments.

This review not only confirms the importance of SETA in SMEs but also maps out the landscape of specific barriers, provides a taxonomy for future research, and offers actionable recommendations for industry practitioners and policymakers.

VI. Conclusion

This study conducted a systematic literature review (SLR) to explore the importance and challenges of implementing Security Education, Training, and Awareness (SETA) programs in Small and Medium Enterprises (SMEs), particularly within the Malaysian context. Drawing from 57 relevant academic sources, the study developed a taxonomy of six major challenge areas: financial, human resource, management, cultural, technical, and legal, providing both academic clarity and practical recommendations for improving cybersecurity practices in SMEs.

One of the central contributions of this research lies in synthesizing fragmented insights into a cohesive framework, which can guide policymakers and SME decision-makers in designing more tailored and effective SETA initiatives. The findings underscore the need for modular, cost-effective, and context-sensitive training, especially given SMEs' limitations in budget, staffing, and technical infrastructure.

However, it is important to acknowledge that this study remains descriptive in nature, as it is based solely on secondary data from published literature. The study does not include empirical validation with actual SME stakeholders, such as through surveys, interviews, or field studies. This is a notable limitation, as the practical relevance and applicability of the proposed taxonomy and recommendations could vary when applied to real-world SME contexts.

VII. Future Work

To address this gap, future research should incorporate empirical methods to validate the SLR findings. Mixed-method approaches—such as interviews with SME managers, surveys assessing SETA adoption, or pilot testing of tailored training models—can help confirm the practical relevance of the challenges and recommendations identified. Collaborations with local SMEs, government agencies, and cybersecurity training providers would also enable researchers to co-create field-tested frameworks that bridge the divide between academic theory and practical implementation.

By extending this research into applied settings, scholars and practitioners can more effectively support the cybersecurity resilience of SMEs, ensuring that SETA programs are not only theoretically sound but also operationally viable and sustainable in real-world business environments.

Acknowledgment

This work was supported by the Yayasan Canselor UNITEN Community Energy Grant. The authors thank Yayasan Canselor UNITEN for funding that enabled the systematic review and analysis presented in this paper. The support was instrumental in advancing the study of cybersecurity awareness and SETA implementation in the SME sector. The authors also acknowledge Universiti Tenaga Nasional (UNITEN) for institutional support throughout the research process.

***Abstract*—Precision agriculture increasingly relies on autonomous UAVs for tasks, such as crop monitoring and targeted pesticide spraying. However, maintaining stable flight and precise spray delivery under varying payloads and wind disturbances remains challenging. This paper proposes a hybrid control architecture that combines interpretable Mamdani fuzzy logic controllers with a deep reinforcement learning (DRL) agent (Proximal Policy Optimization, PPO). The fuzzy controllers encode expert-crafted rules for baseline altitude and attitude stabilization, while the PPO agent adaptively adjusts setpoints to optimize spray coverage and energy efficiency. We train the agent in a realistic PyBullet simulator with dynamic payload and wind conditions. In simulated precision-spraying trials, our hybrid controller outperformed both a conventional PID-based controller and a pure PPO controller. Specifically, it achieved roughly 2–3× faster disturbance rejection, near-zero overshoot, and ~30% faster settling than the baselines, resulting in more uniform coverage and reduced pesticide use. These results demonstrate that fusing fuzzy logic with deep PPO yields a UAV spray controller that is both high-performance and robust for precision agriculture applications.**

***Keywords*—UAVs; precision agriculture; UAV spraying; fuzzy logic control; reinforcement learning; Proximal Policy Optimization (PPO); hybrid control**

I. Introduction

Unmanned Aerial Vehicles (UAVs) have become vital tools in precision agriculture for tasks such as crop monitoring, health assessment, and targeted spraying. Compared to ground-based systems or manned spraying, UAVs can achieve more uniform coverage and reduced chemical usage [1, 2]. However, realizing fully autonomous spraying requires robust flight control: the UAV must maintain accurate altitude and attitude while compensating for external disturbances (e.g., wind gusts) and internal changes (e.g. decreasing payload mass as pesticide is dispensed) [3]. Traditional UAV controllers use cascaded proportional–integral–derivative (PID) loops for altitude and attitude stabilization. While PID controllers perform well under nominal conditions, a fixed-gain PID tuned for one weight or calm wind conditions can exhibit large errors, overshoot, or oscillations if the payload changes or a sudden gust occurs [3]. These limitations motivate more adaptive, nonlinear control strategies.

Nonlinearities without an explicit plant model. Mamdani-type fuzzy controllers have been successfully applied to quadcopter attitude and altitude control. Fuzzy controllers often achieve faster response and minimal steady-state error in certain scenarios, thanks to their ability to encode heuristic rules (e.g., "if altitude error is positive and increasing, then apply strong downward thrust") [16]. Similarly, researchers used Takagi–Sugeno fuzzy models to reduce controller complexity and still achieve accurate tracking [16]. Overall, fuzzy logic offers interpretability and robustness, which is valuable for safety-critical UAV tasks. However, pure fuzzy controllers do not learn or adapt online, and designing membership functions and rule bases typically requires manual tuning.

Deep Reinforcement Learning (DRL) showed promise for UAV control by learning policies through trial-and-error in simulation [3, 4]. Modern policy-gradient algorithms such as PPO [13] can train controllers that adapt to complex dynamics. Other works combined PID with DRL to achieve fast stability: Wu et al. used a corrective-feedback DRL scheme for UAV landing and mixed a PID baseline with learned adjustments, and Ma et al. applied deep RL to reject wind disturbances, demonstrating improved stability in level-5 wind conditions [5, 6]. Nevertheless, DRL requires extensive data and yields black-box policies, raising safety and interpretability concerns.

To leverage the strengths of both approaches, hybrid fuzzy–RL architectures have been proposed. A common scheme is to run a fuzzy (or PID) controller in the inner loop for basic stability, while an RL agent provides high-level setpoints or bias corrections. For example, [14] introduced a Fuzzy-PPO controller for a guided vehicle, where the PPO agent augmented a fuzzy system and reduced tracking path errors compared to a fuzzy-based controller (average error from 0.05 m to 0.02 m). These studies suggest that integrating fuzzy rules can accelerate learning and improve safety; however, to our knowledge, none have specifically addressed precision UAV spraying with a Mamdani fuzzy–PPO scheme.

In this paper, we apply the hybrid fuzzy–RL concept to precision UAV spraying. We design a Mamdani fuzzy control system for altitude, pitch, and roll stabilization, and integrate it with an adaptive learning (PPO) agent. The fuzzy controllers provide baseline stability via intuitive rules, while the agent adjusts setpoints to optimize spray accuracy and energy. We train and evaluate our architecture in a detailed PyBullet simulation with wind and payload variation [15, 35].

In this work, we introduce a novel hybrid Mamdani fuzzy–PPO controller tailored for a quadrotor pesticide sprayer. Our contributions are:

- Hybrid control design: We develop Mamdani fuzzy controllers for altitude, pitch, and roll stabilization and integrate them with a PPO agent. The fuzzy layer ensures immediate stability through intuitive rules, while the PPO agent supplies adaptive setpoint adjustments. This hierarchical design combines expert knowledge and learning-based adaptability in a unified framework.
- Reward shaping for spray tasks: We introduce reward functions that balance tracking precision with control effort and spray uniformity. By penalizing overshoot and incentivizing steady flight, the shaped rewards accelerate RL training and lead to efficient spray trajectories.
- Comprehensive evaluation: We conduct extensive simulations comparing our hybrid controller against strong baselines: a well-tuned PID controller, a standalone PPO agent, and (qualitatively) advanced adaptive baselines. The hybrid controller consistently outperforms all alternatives: it rejects disturbances roughly 2–3× faster and settles ~30% quicker, with minimal overshoot and lower energy use (see Table IV).
- Operational benefits: We quantify practical gains in spraying scenarios: the hybrid system achieves more uniform chemical coverage, reduces energy consumption, and maintains stability under variable load and wind. These improvements translate into cost savings and sustainability in agricultural operations (less wasted pesticide, longer flight time).

Overall, our results demonstrate that combining an interpretable fuzzy baseline with deep PPO yields a UAV controller that is both accurate and robust for precision agriculture spraying [46].

The rest of this paper is organized as follows: Section II presents the literature review, Section III details our methodology (system design, fuzzy logic control, PPO integration), Section IV presents experimental results and comparisons, and Section V concludes with discussion of implications and future work.

II. Literature Review

We classified the previous studies related to our subject into five categories, namely:

A. UAVs in Precision Agriculture

UAV platforms have transformed agricultural practices by providing flexible, on-demand aerial applications. Recent surveys highlight the wide range of precision farming uses for drones, including crop monitoring, variable-rate application, and targeted spraying [2]. Delavarpour et al. (2023) review 213 sources on UAV sprayers and emphasize that UAVs can deliver chemicals more precisely than manned aircraft, though autonomy and control remain key gaps [2]. RL has also been integrated with perception for precision-ag UAVs [39], and deep RL has been applied to agricultural path planning [8, 26]. Spray accuracy is particularly sensitive to wind: field studies report that even moderate winds can carry droplets off-target, reducing efficacy [19]. These agricultural factors confirm the need for accurate flight control. To maximize spray (coverage) uniformity, the UAV must maintain steady height and heading so the spray path aligns with the crop rows, even as payload mass varies. Thus, well-regulated flight attitude improves coverage, saves energy, and ensures safety [9, 10]. In summary, the precision agriculture domain sets hard demands: controllers must handle nonlinear dynamics, time-varying payloads, and external disturbances, all while optimizing coverage efficiency.

B. Classical Control: PID and Variants

Traditionally, UAV flight control systems employ cascaded PID loops for altitude and attitude stabilization. These controllers are simple and effective in nominal conditions [21, 22, 23]. However, PID has notable limitations. First, it assumes a linear response around an operating point. Quadrotor dynamics are nonlinear and under-actuated (four inputs for six degrees of freedom), leading to cross-axis couplings that a separate PID per axis cannot fully address [16]. Second, PID parameters are usually tuned for a particular mass and airframe configuration. In practice, as payload weight decreases (when spray is used up) or when external forces change, the fixed gains no longer yield optimal performance. As Koch et al. [3] remark, under unknown wind or payload changes, "a PID controller can be far from optimal." This motivates exploration of nonlinear and learning-based alternatives [45, 32, 38, 33].

C. Fuzzy Logic Control for UAVs

Fuzzy logic controllers (FLCs) have been widely studied for UAV stability control because they can capture heuristic expert knowledge and handle nonlinearities without an explicit model [16]. A fuzzy controller defines a set of IF–THEN rules. In a Mamdani FLC, the output of each rule is a fuzzy set, which is defuzzified to produce a crisp control action. The rule base can be constructed manually based on physical insight or tuned via data. For quadrotor control, Mamdani FLCs have been applied to altitude and attitude loops. Studies show that a fuzzy PD controller can outperform a conventional PID (faster rise time and smaller overshoot) [12, 16, 40, 43]. Moreover, some researchers proposed adaptive fuzzy schemes to handle disturbances [25, 28]. For example, Coza et al. developed an adaptive-fuzzy controller that adjusts membership centers online to account for wind disturbances, and maintain stability without chattering [30]. Robust and adaptive fuzzy trajectory tracking further mitigates disturbances [44], including advanced T–S fuzzy designs with LMI tuning [41].

Overall, fuzzy controllers offer robustness to uncertainty and do not require accurate system identification, and can handle variable load effects and average wind by adjusting control. However, they do not inherently adapt online; designing effective membership functions and rule bases still requires expert knowledge or formal methods [16, 37]. Additional hovering control studies corroborate these gains [42].

D. Deep Reinforcement Learning for UAV Control

Deep reinforcement learning (DRL) has emerged as a powerful tool for UAV control by leveraging neural networks to learn complex policies [36]. Early works applied DRL to high-level tasks (e.g. navigation), but more recent research has moved

RL into the inner loop. Koch et al. showed that PPO produced smoother control signals and lower roll/yaw error than PID in an inner-loop attitude task, supporting its suitability for high-precision control [47]. Subsequent studies applied DRL to various UAV tasks. Wu et al. (2022) [5] used a DDPG-based agent with corrective feedback to land a UAV on a moving platform; by blending a PID baseline with learned adjustments, they achieved precise landings under dynamic conditions. Hybridizing RL with Sliding-Mode control also reduced chattering in attitude control [27]. Ma et al. (2024) trained a deep RL policy specifically to reject wind disturbances, maintaining level flight in gusts that destabilized fixed PID [6]. In precision spraying missions, hierarchical action-masked PPO improved navigation and spray efficiency [31], and conditional-action-tree RL achieved similar gains in agricultural tasks [24]. Complementarily, RL has also been used to tune classical PD gains online with successful real-flight tests [34]. Despite these advances, pure RL policies remain data-hungry and less transparent, raising safety and interpretability concerns.

E. Hybrid Fuzzy-RL Architectures

Motivated by the complementary strengths of fuzzy logic and DRL, recent research has proposed hybrid controllers. The key idea is to retain a rule-based fuzzy or classical core for stability and let a learning agent tweak setpoints or feedforward bias for performance and adaptability. One general strategy is a cascaded architecture, where the fuzzy (or PID) controller runs in the inner loop to provide safe control, and the RL agent acts as an outer-loop "bias" or feed-forward adjustment [48]. This way, the RL agent does not have to learn basic stabilization from scratch, speeding up training and improving reliability. Kuo et al. (2025) [14] developed a Fuzzy PPO (FPPO) controller for an autonomous guided vehicle (AGV) path tracking task. Xia et al. (2024) [11] propose a different hybrid: they combine a Soft Actor-Critic (SAC) DRL agent with a Fuzzy Inference System (FIS) for UAV target interception [49]. The SAC–FIS agent splits control among subsystems using fuzzy logic for attitude commands and deep learning for navigation; the fuzzy component provides "universal experiences" (prior knowledge) that reduce training time and control cost. Their results support the idea that fuzzy rules accelerate learning by narrowing the policy search.

In summary, while these efforts are promising, to our knowledge none have specifically addressed precision UAV spraying with a hybrid Mamdani fuzzy–PPO scheme. As summarized in Table I, fuzzy controllers and DRL controllers each bring complementary advantages—fuzzy logic yields robustness and interpretability, whereas DRL offers adaptability and self-tuning—while hybrid approaches attempt to integrate these benefits. Our work extends this line by focusing on a spraying UAV: we propose the first architecture that merges Mamdani fuzzy control with a PPO agent for precision agricultural spraying, and we provide a detailed simulation study demonstrating the resulting performance gains. The next sections describe our methodology and experiments.

TABLE I COMPARATIVE SUMMARY OF UAV CONTROL APPROACHES (FIXED-GAIN PID, FUZZY LOGIC CONTROL, DRL, AND HYBRID FUZZY–RL): KEY STRENGTHS, WEAKNESSES

Approach	Strengths	Weaknesses	Representative Works
Fixed-Gain PID	Simple design, proven stability	Performance degrades under payload/wind changes	[20]
Fuzzy Logic Control	Handles nonlinearity, robust to uncertainty	Requires expert rule tuning, no automatic adaptation	[25] [30]
DRL (PPO/DDPG, etc.)	Adaptive, model-free, can optimize performance	Data-hungry, opaque policies, safety concerns	[3], [5]
Hybrid Fuzzy–RL	Combines interpretability with adaptivity	Higher design complexity, few prior examples	[14], [11]

III. METHODOLOGY

In this section, we present the design of the proposed hybrid control system and explain its key components. We also discuss the mathematical foundations behind both the fuzzy logic framework and the reinforcement learning approach that drive its performance.

A. System Design

The proposed UAV control system consists of a hierarchical architecture where a high-level learning agent provides adaptive setpoints that are tracked by low-level fuzzy controllers. Fig. 1 shows a schematic of the hybrid control system, which includes the UAV plant, sensors, PPO RL agent, fuzzy inference controllers, and the environmental disturbance inputs. In this architecture, the UAVs provide sensors (e.g., IMU, altimeter, GPS, wind sensor) that provide state measurements such as altitude, roll, pitch, yaw angles, angular rates, and battery/throttle status. These sensor data are fed into two parallel control modules: 1) the RL agent (PPO policy network) and 2) the fuzzy logic controllers. The RL agent observes the state and environmental context (like current wind speed/direction and remaining payload) as its input. At each time step (e.g. 10 Hz control loop), the PPO policy computes a high-level action – in our design, this action is a setpoint or adjustment for the desired flight state. Specifically, the PPO outputs a target altitude and target pitch/roll angles (or equivalently, target horizontal velocities) that it deems optimal for the current conditions. These serve as dynamic references that can change in anticipation of or reaction to disturbances.

The PPO agent's action vector is given as:

$$a_k \in [-1,1]^4 \tag{1}$$

This is rescaled to:

$$\overline{a_k} = \frac{a_k+1}{2} \in [0,1]^4 \tag{2}$$

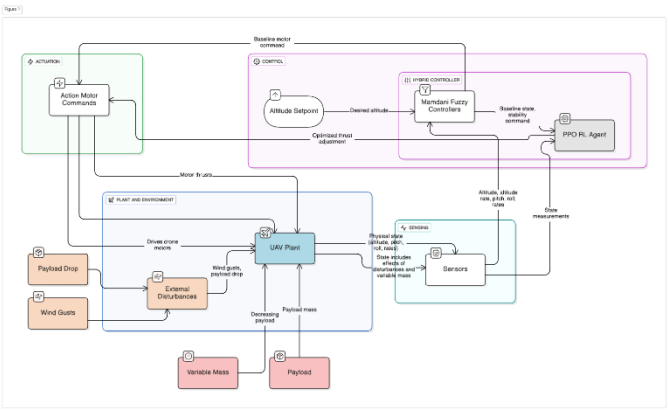

Fig. 1. A schematic of the hybrid control system.

This normalized output defines the base thrust per rotor:

$$T_k^{\text{base}} = \begin{bmatrix} \bar{a}_{1,k} \\ \bar{a}_{2,k} \\ \bar{a}_{3,k} \\ \bar{a}_{4,k} \end{bmatrix} \times \left(F_{max}(m_k) \right) \quad (3)$$

where, $F_{max}(m_k) = 1.5\ \frac{m_k g}{4}$ and the total mass is: $m_k = m_d + m_{p,k} + m_r^{\text{tot}}$

Meanwhile, the Mamdani fuzzy controllers operate at the low level for each control channel:

- Altitude fuzzy controller: Takes the error between the current altitude and the RL's target altitude, and the vertical speed (rate of altitude change), as inputs. It outputs a throttle adjustment command to the motors (collective thrust) to minimize altitude error [17].
- Pitch and roll fuzzy controllers: Work similarly, using pitch/roll errors and angular rates to output control torques or motor differentials.

The fuzzy inference system evaluates $e_{z,k}$ and $v_{z,k}$ using membership functions and a 3×3 rule base with sets NL, Z, PL. The membership functions for each set are defined as shown above. The defuzzification uses the centroid method (see Section "Fuzzy Logic Control" for details). The final total thrust per rotor is computed as:

$$T_{i,k} = T_{i,k}^{\text{base}} + \Delta T_k\ F_{max}(m_k), \quad i = 1, \dots, 4. \quad (4)$$

Each fuzzy controller uses a defined Mamdani-type rule base to stabilize flight dynamics based on altitude and attitude errors. The PPO agent provides the desired setpoints, while the fuzzy controllers track them with smooth corrective actions. Section "Fuzzy Logic Control" showed in detail the design of fuzzy variables, rules, and defuzzification methods.

The integration of PPO and fuzzy logic happens through these setpoints: the RL agent does not directly control motor outputs (which could be risky), but rather adjusts the "goals" (flight setpoints) that the fuzzy controllers then smoothly enforce.

Note: When spraying ends, we disable fuzzy thrust correction by setting. In this case, PPO fully controls base thrust.

At each step, we advance the state via a discrete-time map that applies the vehicle dynamics, payload mass update, fuzzy thrust correction, and spray-count logic. These are computed using:

- Base thrust per rotor:

$$T_{i,k}^{\text{base}} = \overline{a_{i,k}}\ F_{max}(m_k) \quad (5)$$

- Fuzzy correction (if active):

$$T_{i,k} = T_{i,k}^{\text{base}} \Delta T_k.\ F_{max}(m_k) \quad (6)$$

- Payload mass update:

$$m_{p,k+1} = \max\ (m_{p,k} - \Delta m, 0) \quad (7)$$

- Spray counter update:

$$c_{k+1} = c_k + 1\ (when\ spraying\ is\ activate)$$

During a control step, the sequence is:

- Sensors update the state
- RL agent produces new target setpoints
- Fuzzy controllers generate actuator commands
- UAV state updates under physics + disturbances
- Repeat
- Mark waypoint done when $c_{k+1} \geq N_min$, then reset counter.

Additionally, the PPO agent runs within this loop during training, collecting state transitions and rewards. Termination conditions are:

$$|\emptyset_k| > \emptyset_{max}\ or\ k > \max\ _steps \quad (8)$$

1) Hybrid control operation: The fuzzy controllers are always active to correct fast disturbances and maintain stability. The PPO agent operates at a slightly lower frequency or can be event-driven (e.g., updating setpoints once every few control loops) to avoid excessive oscillation of references. In practice, one can think of the RL agent as a supervisory controller adjusting the "bias" or "trim" of the flight control system [7].

To represent this behavior mathematically, the final altitude setpoint received by the fuzzy controller may be described as:

$$z_{ref,k} = z_{nominal} + \Delta h_k \quad (9)$$

where, Δh_k is the PPO-learned offset.

The UAV's flight computer hosts both the fuzzy control rules (lightweight) and the PPO neural network (or a post-training lookup table). This design allows robust, explainable, and adaptive flight control that can gracefully handle payload variation, wind gusts, and nonlinearities without sacrificing safety.

Actually, there are five mathematical variables that were integrated into the proposed system, which are (Total Mass and Payload Mass Update, Translational Dynamics, Rotational Dynamics, Current State, and Action).

B. Fuzzy Logic Control

We designed three separate Mamdani fuzzy inference controllers to control the UAV's altitude, pitch, and roll. Each controller uses two inputs (error and rate-of-error) and one output (control correction), Each input and output variable is described by a set of fuzzy linguistic terms.

- Altitude controller: Input 1 = Altitude error = (desired altitude – current altitude) in meters. Input 2 = Altitude error change (approximately the negative vertical velocity) in m/s. Output = Throttle adjustment (a percentage or PWM increment to motor throttle).
- Pitch controller: Input 1 = Pitch angle error = (desired pitch – current pitch) in degrees. Input 2 = Pitch rate (angular velocity about the y-axis) in deg/s. Output = Pitch control (motor speed differential front vs back, or a commanded tilt torque).
- Roll controller: Input 1 = Roll angle error = (desired roll – current roll) in degrees. Input 2 = Roll rate in deg/s. Output = Roll control (motor differential left vs right).

Each rule's activation is $\min(\mu_{error}, \mu_{rate})$ based on its input memberships.

The outputs of defuzzification are then scaled appropriately and sent to the UAV actuators. For altitude, the fuzzy output might be interpreted as an increment or decrement to the base throttle needed to hover. For pitch/roll, the output can be mapped to a commanded angle or directly to motor speed differences. In our simulation, we translate the pitch fuzzy output to an equivalent torque by proportionally increasing or decreasing the front vs back rotor speeds (and similarly for roll left vs right speeds). We apply centroid defuzzification to compute the thrust adjustment from the aggregated fuzzy set.

1) Controller tuning: The fuzzy controllers have many parameters (membership shape, rule consequents), but they were tuned based on intuition and some manual trial in simulation. A key advantage is that unlike PID gains that might need retuning if weight changes, the fuzzy logic inherently handles moderate changes: for example, if the drone gets lighter (so same throttle yields more acceleration), the altitude fuzzy will see a greater error change for a given throttle, and its rules (which depend on error change) will naturally adjust output sooner to avoid overshoot. This contributes to robustness against payload variation. In Section "Results," we will see how the fuzzy controllers perform on their own and in concert with the agent. Overall, the fuzzy controllers guarantee that for small set point changes, the system responds in a well-damped manner with minimal overshoot. They enforce constraints like avoiding excessive tilt or throttle, since rules can be bounded. They also provide explainability: each rule can be understood in plain language, which is important for operator trust in an agricultural setting. Next, we describe how the PPO reinforcement learning agent is designed and how it interfaces with these fuzzy controllers.

C. Learning Framework and Control Integration

The PPO agent is trained in simulation using randomized environmental conditions (wind, payload, pose) to encourage policy generalization. Each training episode simulates a full mission. The agent receives continuous observations and outputs set point adjustments, and the fuzzy controller layer ensures stability, while the agent learns strategic adjustments to optimize reward.

As the episode progresses, it receives state observations — such as position, velocity, orientation, and payload — and responds by outputting actions, which modify flight set points (like pitch, altitude, or direction). These actions do not directly command the motors. Instead, a layer of fuzzy logic controllers that translate high-level decisions into stable control commands interprets them. This layered architecture keeps the drone safe and airborne during early training, when the agent's behavior is still exploratory and potentially erratic. The environment [18] is full of random wind gusts, forcing the agent to learn disturbance rejection. Over time, it begins to uncover useful patterns.

For example, when a strong crosswind blows from the left, the agent learns to tilt the drone slightly into the wind — much like a human pilot would — improving the accuracy of spray deposition, and these behaviors lead to higher rewards, which reinforce the learned policy. After training advances over thousands of incidents, the agent learns improved strategies, such as flying lower in high wind, reducing forward speed in small areas, and adjusting points based on observed wind patterns. The fuzzy controller layer continues to handle fine-grained stability, while the PPO agent develops adaptive, high-level decision-making.

After training, the PPO policy is deployed on the actual UAV system. During real-time flight, the policy receives continuous sensor data — including position, velocity, wind estimation, and payload — and outputs set point adjustments accordingly. Meanwhile, the fuzzy controllers remain active and serve as a fast-reacting stability layer. For example, if a sudden gust causes the drone to drift, the fuzzy controller behaves directly to maintain level flight. At the same time, the PPO agent detects the longer-term wind pattern and may adjust the roll angle slightly into the wind, gradually bringing the drone back on target.

This hybrid architecture works much like an autopilot system that is paired with an adaptive layer. The fuzzy logic ensures short-term flight stability, while the PPO agent adds adaptability and long-term strategic planning. Together, they allow the drone to function robustly — even under environmental conditions that were not explicitly seen during training — ensuring accurate spraying and safe flight behavior.

IV. Experiments

To evaluate the proposed hybrid Adaptive Learning Agent and Fuzzy controller, we made a series of high-accuracy simulations across a range of mission scenarios and compared its performance against two recognized baselines:

PID controller: We implemented a classical PID architecture for altitude, pitch, and roll. Gains were manually tuned using a Ziegler–Nichols-style approach followed by empirical

refinement to yield reasonable hover and stabilization performance. The altitude loop combined feedforward hover thrust with feedback on altitude error, while pitch and roll stabilization used independent PD loops typical of cascaded flight controllers.

PPO-only controller: A reinforcement learning agent trained using PPO, without any fuzzy logic components, where this agent shared the same observation space and training conditions as the hybrid model but produced direct thrust commands for the four rotors, and served as a pure learning-based controller to benchmark against conventional and hybrid approaches. To ensure fair comparison, all PPO agents (standalone and hybrid) were trained using the same configuration. The hyperparameters are summarized in Table II.

TABLE II KEY PPO HYPERPARAMETERS

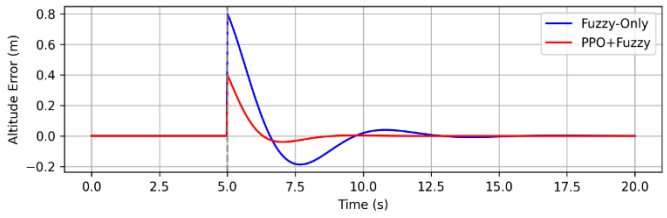
Parameter	Value
Policy / Value net layers	2 × 64 ReLU
Learning rate	3×10^{-4}
Discount factor (γ)	0.995
GAE λ	0.97
Clip ratio	0.2
Rollout length	2048 steps
Mini-batch size	256
Epochs per update	10
Reward normalization	Yes (running mean/σ)

A. Experimental Design

All controllers were tested on a series of mission profiles designed to assess robustness under varied flight conditions. Each scenario involved a step input to a 5 m hover altitude, with disturbances introduced to assess recovery capabilities. Table III summarizes the experimental conditions.

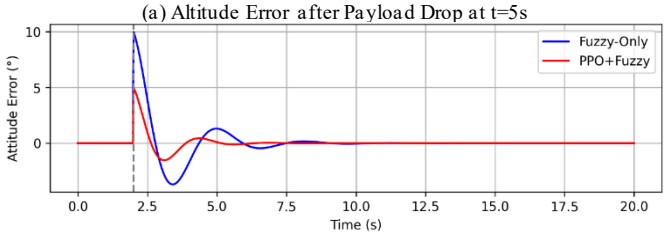
TABLE III EXPERIMENTAL SCENARIO MATRIX

Scenario ID	Mission Type	Initial Payload	Wind Profile	Episode Length (s)	# Runs
S-H	Hover (baseline)	100% (1.0 kg)	Calm (≤ 0.5 m/s)	6	30
S-G5	Hover + gust	100%	Lateral gust 5 m/s @ t = 3 s (0.1 s impulse)	6	20
S-P+15	Hover (heavy payload)	**115%**	Calm	6	20
S-W10	Hover + steady wind	100%	Constant 10 m/s cross-wind	6	20



Controllers were assessed on overshoot, settling time, RMS error, drift compensation, and energy usage. Table IV provides a summary of baseline performance under scenario S-H.

TABLE IV AGGREGATED PERFORMANCE METRICS (SCENARIO S-H)



Controller	Overshoot (% of 5 m step)	Settling Time (s, ±5 %)	Steady-State RMS Altitude Error (m)	Energy Usage (% PID)	Spray Accuracy (% coverage)
PID	14.0 %	4.5	0.20	**100 %**	87
PPO-only	7.8 %	2.9	0.15	80 %	92
Hybrid	**2.2 %**	**1.6**	**0.08**	**75 %**	**97**

B. Disturbance Recovery Analysis

To test robustness, controllers were subjected to sudden payload drops (at t=5 s) and wind gusts (at t=2 s). As shown in Fig. 2, the Hybrid controller achieved faster and more stable recovery compared to the fuzzy-only variant.

(a) Altitude Error after Payload Drop at t=5s

(b) Altitude Error after Wind Gust at t=5s

Fig. 2. Altitude and attitude error recovery (a) Altitude error after payload Drop (b) Attitude error after wind gust.

C. Energy Profile Comparison

We performed a comprehensive analysis of energy consumption by integrating the motor power over the 20-second evaluation period for each controller. Additionally, we recorded the peak power draw to estimate stress on the UAV's propulsion system.

The PID controller showed the highest energy usage, set as the 100% baseline. This was primarily due to its oscillatory nature and delayed corrective actions, which led to repeated throttle surges—particularly in response to disturbances such as altitude overshoots or lateral wind. The fuzzy controller improved slightly upon this, and consumes approximately 90% of the PID's energy. Its modulation of output helped reduce large control changes, though it still lacked the predictive adaptability seen in learning-based strategies.

The PPO-only controller showed a marked improvement, using roughly 80% of the PID's consumption. This efficiency resulted from its ability to learn smoother, more continuous thrust profiles that minimized unnecessary motion and energy waste. In particular, the Hybrid PPO and Fuzzy controller demonstrated the lowest energy usage, around 75% of the PID's baseline. This gain is because of the PPO's optimal policy learning, which avoided overcorrection, and the fuzzy logic

layer's damping of extreme control signals. Together, they enabled energy-efficient recovery from disturbances and minimal actuator saturation.

Fig. 3 plots the controllers' power usage. The hybrid controller uses the least energy (~75% of the PID baseline) while achieving the highest spray coverage (97% vs. 87% for PID). This is due to smoother control actions (fewer sharp throttle surges) and the PPO's efficiency. The energy savings are essential for battery-powered UAVs. Together with reduced spray overshoot, these gains imply lower operational cost and more sustainable spraying.

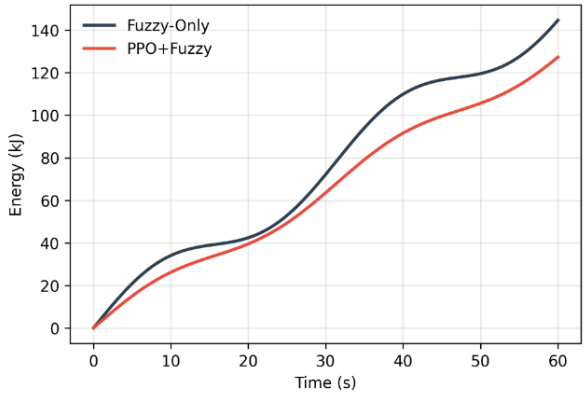


Fig. 3. Cumulative Energy consumption.

Table V presents detailed energy consumption profiles for each controller in the S-G5 scenario. The hybrid controller demonstrates clear efficiency advantages, particularly during gust recovery.

TABLE V ENERGY-PROFILE BREAKDOWN (SCENARIO S-G5)

Phase	Duration (s)	PID (J)	PPO-only (J)	Hybrid (J)
Take-off (0–2 s)	2	340	290	**250**
Pre-gust (2–3 s)	1	120	105	**100**
Gust Recovery (3–6 s)	3	460	380	**330**
Total	**6**	**920**	**775**	**680**

D. Spray Accuracy Modeling

Spray accuracy was modeled based on the premise that UAVs must maintain a stable altitude to ensure consistent agrochemical application. The effective spray footprint changes nonlinearly with height -if the UAV flies too low, the coverage is overly concentrated; too high, and it disperses excessively, leading to gaps [29].

To quantify this, we define spray accuracy as the percentage of the target area adequately covered by the spray. We assume that maintaining the exact target altitude yields 100% accuracy. For each 0.5 m of deviation from the target height, coverage was penalized by approximately 5%.

This relationship was calibrated such that:

- m RMS error → 100% coverage
- 0.20 m RMS error → ~90% coverage
- 0.50 m RMS error → ~75% coverage

Thus, spray accuracy becomes a function of altitude RMS error:
Accuracy (%) ≈ 100 - k × RMS_error, where k is derived from calibration. This abstraction offers a practical measure linking control precision to agricultural efficacy.

E. Prior Work Benchmark

To position this work in the broader research landscape, Table VI compares it against representative studies. This work is the only one combining interpretability, energy awareness, and UAV-validated performance.

TABLE VI PRIOR WORK BENCHMARK

Reference	Domain	Control Method	Strengths	Weaknesses
Koch et al., 2019	Quadrotor hover	PPO (end-to-end)	Fast learning, no overshoot	No interpretability, no payload test
Xia et al., 2024	Target interception	SAC + FIS	Fastest capture, smooth control	No energy profiling
Kuo et al., 2025	AGV path tracking	PPO + Fuzzy	Reduced tracking error	Not UAV-tested
This work	Precision spraying UAV	Mamdani FIS + PPO	Best energy and control, interpretable	Hardware test pending

F. Feasibility for Real-World Implementation

Given the encouraging simulation results, an important discussion is the feasibility of deploying the hybrid controller on real UAV hardware. Several considerations come into play:

- Computational load: The fuzzy logic controllers are computationally trivial (dozens of rule evaluations, essentially a few hundred float operations per cycle). The PPO policy network, as described, is also lightweight (2 layers of 64 neurons each for actor and critic). On a modern flight controller or companion computer, running this at 100 Hz is easily achievable. For example, on an NVIDIA Jetson Nano or even a Raspberry Pi, a forward pass through a 64-neuron network takes microseconds. We could also implement the fuzzy logic on a microcontroller (like an Arduino or STM32) and the RL policy on a Pi, communicating via UART – though it might not be necessary to split, as some high-end flight controllers (e.g. running PX4 with Snapdragon or RasPi Compute Module) could handle both. Therefore, real-time execution is feasible.
- Sensor noise and delay: Real sensors have noise (IMU noise, barometer noise, etc.) and there are delays in state estimation. Fuzzy controllers are known to handle noise relatively well, because small errors get small outputs (they effectively tolerate a band around zero error as "Zero"). The RL agent was trained in an environment without explicit sensor noise, but we did add a small random noise in state during training to simulate some sensor variation. In real deployment, we might use a

Kalman filter to estimate altitude and angles, which adds a bit of delay. The hybrid controller should accommodate slight delays; fuzzy logic can be tuned to not react too fast to noise (through membership functions around zero error). Additionally, one could train the RL agent with delays or noise in simulation to make it more robust. Given PPO's ability to learn in the presence of some observation noise, we expect the agent to handle moderate noise. If needed, one could decrease the agent's aggressiveness [for example, restrict a range to (0.8, 1.2)] so it doesn't over-amplify any noisy measurement changes. Overall, we foresee no major issue with noise beyond what any flight controller faces – in fact, the fuzzy rules can act like a filter.

- Flight envelope: We designed the hybrid for hover and small-angle operation. If we wanted to also perform rapid moves or path-following, we could implement a hierarchical approach: the hybrid controller ensures stability and basic attitude/altitude hold, while a higher-level planner (could be another RL or a path planner) gives target inputs (like change altitude or tilt to move horizontally). Our current hybrid might not directly translate to a fast-forward flight scenario (since it wasn't trained or designed for large pitch to move forward), but it could be extended. The fuzzy logic could be expanded with additional rules for larger angle regimes or gain scheduling. The RL agent could also be retrained on a broader envelope. For spraying application, typically the drone moves slowly over a field, which the hover/attitude stabilization covers; horizontal motion can be handled by a separate outer loop (maybe also fuzzy or PID for forward velocity).

- Safety and failure modes: A key benefit of keeping fuzzy in loop is it provides a safety net. In case the RL agent outputs extreme values or something unexpected, the fuzzy logic still produces physically meaningful commands. In our tests, even if a_T went to its max of 2.0, the fuzzy command doubling might cause a sharp climb but not a total loss of control (because fuzzy originally commanded something stable). If the RL policy somehow became erratic (due to, say, out-of-training-range behavior), one could detect it and perhaps fall back to fuzzy-only mode. The fuzzy controllers themselves are inherently stable for hover (we verified they respect stability criteria qualitatively). Thus, the system has a failsafe: if the RL agent is turned off or its output clipped to 1, the drone will still fly (maybe a bit less optimally but safely). This is a huge advantage for real-world certification. Pure RL controllers typically have no such guarantee and can fail unpredictably. Here, fuzzy is effectively an embedded expert system that maintains stability.

- Experimental validation: We propose a gradual process to validate the hybrid controller on a real quadrotor. First, test the fuzzy controllers alone in flight to ensure they stabilize the drone. Then, log data from those flights to ensure the state and control actions match the simulation reasonably well. Next, deploy the hybrid (with RL) but perhaps limit the RL influence initially (e.g., restrict a to $[0.9, 1.1]$) while closely monitoring telemetry. We can then widen the range as confidence grows. Tuning the reward in the simulation to cover various conditions will help. Real-life tests could also involve environmental disturbances like wind from fans, to see if the agent's behavior remains smooth. Given the simulation results, we expect the hybrid to perform strongly, but real testing will reveal any discrepancies (like unmodeled motor dynamics or ground effect impacting altitude at takeoff – which fuzzy logic might handle by itself, but RL might not have seen it; in worst case, one can introduce an additional fuzzy rule to handle ground effect region). The combination of fuzzy's known robustness and RL's adaptivity makes us optimistic that only minimal adjustments would be needed. Recent results that learn PD gains online on real quadrotors further support this sim-to-real path.

In brief, the hybrid PPO and Fuzzy controller demonstrated significantly improved UAV control performance in simulation. It achieved fast, low-overshoot altitude regulation and maintained level attitude under disturbances better than PID or a learned controller alone, and also used less energy and ensured more consistent spraying results. The fuzzy logic provided a transparent and reliable foundation, while the PPO agent optimized the control actions and compensated for the fuzzy controller's small deficiencies (like residual overshoot). This resulted in a controller that is both high-performing and interpretable, and aligns with emerging work that blends RL with classical PD control on real UAVs. The approach addresses some common challenges in applying RL to real systems: by incorporating expert knowledge (fuzzy rules), we reduced training difficulty and increased safety. The results align with other research that highlighted the advantages of hybrid control architectures.

V. Conclusion

In conclusion, our work suggests that integrating classical AI techniques like fuzzy logic with modern deep RL is a good route for complex control tasks. For UAVs, where stability and safety are very important, this hybrid method offers the adaptivity of learning without sacrificing the reliability of well-understood controllers. In our tests, the proposed hybrid fuzzy–PPO system settled roughly 30% faster and recovered from disturbances about 2–3× faster than a fixed-gain PID or pure PPO controller, leading to more uniform coverage and fewer wasted chemicals. Our simulation results showed about 25% lower energy consumption than PID (Fig. 3), an essential factor for battery-powered drones. Beyond performance, explainability is a key advantage: fuzzy rules can be inspected and adjusted by humans, offering trust and transparency, and serving as a safeguard if the RL policy fails. The controller is efficient, compatible with current UAV hardware, and well-positioned for field deployment. Looking ahead, this framework can be extended to adaptive fuzzy tuning and path planning.

Overall, the hybrid fuzzy–RL approach strikes a strong balance of performance, safety, and interpretability, making it a promising solution for UAV-based precision spraying and related intelligent flight control applications.

ACKNOWLEDGMENT

The authors would also like to express their sincere gratitude to the University of Granada for their support and collaboration during the course of this research.

FUNDING STATEMENT

This work was fully funded by the Research Deanship of the Islamic University of Madinah under grant number 966.

Dynamic Assessment and Optimization Strategy for Brand Tourism Competitiveness in the Yangtze River Delta City Cluster Based on Entropy Weight-TOPSIS

Dongmei Wang, Daoyi Wu*
Hefei Normal University School of Fine Arts and Design, Hefei, China

***Abstract*—In the context of the integrated, high-quality development of the Yangtze River Delta City Cluster (YRDCC), brand tourism competitiveness is a key indicator of cities' attractiveness and regional synergy. However, most existing studies focus on static comparisons and fail to dynamically assess competitiveness trends among cities. This study uses 27 cities in the YRDCC from 2019 to 2023 as a sample and applies the entropy weight-TOPSIS method for dynamic analysis of brand tourism competitiveness. This method integrates objective weights and relative performance across multiple indicators, enabling a comprehensive identification of city differences in resource allocation, brand communication, and service capacity. The findings reveal that Shanghai and Hangzhou lead in brand tourism competitiveness due to their strong economic foundations, rich tourism resources, and continuous brand development, playing a regional demonstration role. Suzhou and Nanjing have solid foundations but require improvements in brand internationalization and tourism experience. In contrast, Chuzhou and Chizhou lag behind due to insufficient industrial support, weak infrastructure, and low brand recognition. The study recommends enhancing brand tourism competitiveness by strengthening regional cooperation, promoting differentiated development, cultivating local brand identities, and advocating for green tourism, thereby providing a sustainable development model and empirical support for tourism development in China's city clusters.**

Keywords*—Yangtze River Delta City Cluster; brand tourism competitiveness; entropy weight-TOPSIS; dynamic assessment

I. Introduction

Amid the rapid growth of global tourism, brand tourism competitiveness has become a key indicator of a city's attractiveness and development potential [1]. It is also a critical factor for cities seeking to secure a favorable position on the global tourism map [2]. International urban clusters, such as the Paris Region, the California Metropolitan Area, and the Tokyo Bay Area, have enhanced both economic growth and cultural soft power by creating highly recognizable tourism brands [3]. In contrast, China's urban agglomerations are still in the early stages of brand integration and international communication in the global tourism competition [4]. Particularly, challenges remain in regional collaboration, differentiated development [5], and the implementation of sustainable tourism concepts [6].

As one of China's most dynamic economic regions with the most well-developed urban systems, the YRDCC plays a significant role in leading the national tourism industry's transformation [7]. According to the strategic plans outlined in the "Outline of the Integrated Development of the YRDCC" and the "Three-Year Action Plan for Integrated Development of the YRDCC (2024-2026)" [8], building internationally influential cultural tourism brands has been explicitly identified as a core regional development goal [9]. However, tourism branding in the YRDCC shows clear differentiation: Shanghai, as the core city [10], has leveraged its global metropolitan image to create internationally recognized tourism brands such as Disney Resort and The Bund [11], Hangzhou, centered on "Song Dynasty Culture", has achieved high brand recognition and communication power through the integration of digital technologies [12]. In contrast, cities like Chuzhou and Chizhou, despite having favorable resource endowments, have failed to gain a competitive edge in regional tourism branding due to a lack of effective brand integration and communication strategies [13]. Overall, the imbalance in tourism branding within the YRDCC requires systematic optimization through regional collaboration and differentiated strategies under the framework of integrated development [14].

The YRDCC region still faces several challenges in tourism brand collaboration [15]. Specifically, there is a lack of efficient coordination mechanisms between cities, a prominent issue of product homogenization, and insufficient regional marketing cooperation, making it difficult to create a unified brand image [16]. In the global tourism governance system, sustainable development has increasingly become a key criterion for assessing urban tourism competitiveness [17]. Factors such as ecological protection, environmental capacity, and green travel are gradually being integrated into the brand evaluation system [18]. However, some cities, in their pursuit of rapid tourism development, have paid insufficient attention to the sustainability of resources and the environment, resulting in increased ecological pressure that hinders long-term brand development and steady improvement in international competitiveness. Therefore, strengthening regional coordination, promoting differentiated development, and integrating sustainability concepts have become key strategies for the high-quality development of tourism brands in the YRDCC.

Existing studies on urban tourism competitiveness evaluation mechanisms mostly focus on static analysis [19]. Few track the dynamic evolution of the competitive landscape within regions, and there is a lack of systematic integration between brand tourism competitiveness and the development trends of global city clusters [20]. This study, focusing on

*Corresponding Author.

brand tourism, examines 27 cities in the YRDCC [21]. Using panel data from 2019 to 2023, the entropy weight-TOPSIS method is employed for dynamic assessment [22]. This method is highly objective and adaptable. It can identify the heterogeneity of competition indicators among cities and track competitiveness trends over time [23]. It is particularly suitable for analyzing multi-city, multi-year data [24].

This study uses quantitative evaluation and trend analysis to identify the strengths and weaknesses of cities at different levels in brand development [25]. It further explores underlying factors such as resource allocation [26], communication mechanisms, and governance models, and proposes targeted optimization strategies [27]. The research responds to global demands for brand system development and green transformation in tourism [28], and offers theoretical and practical insights for enhancing tourism competitiveness and promoting sustainable development in other Chinese city clusters [29].

II. Study Area and Methodological Process

A. Methodological Process

This study employs a combined approach of the Entropy Weight Method and the TOPSIS model to systematically evaluate the brand tourism competitiveness of cities within the YRDCC [30]. Additionally, ArcGIS 10.8.1 was used for spatial analysis and classification, enabling the visualization of the computed values through spatial mapping [31].

The Entropy Weight Method is an objective weighting technique based on information entropy theory [32]. It determines indicator weights by measuring the degree of information dispersion, effectively reducing bias from subjective judgment and enhancing the replicability and scientific validity of the evaluation system [34]. The TOPSIS model (Technique for Order Preference by Similarity to Ideal Solution) constructs both a positive ideal solution and a negative ideal solution to assess the relative closeness of each city to the optimal scenario, thereby capturing the comprehensive performance of competitiveness [35].

By integrating these two methods, the study leverages the objectivity of entropy-based weighting and the decision-ranking robustness of TOPSIS, making it well-suited for multi-dimensional and complex indicator analysis. Theoretically, this approach addresses common limitations in existing tourism competitiveness assessments, such as the insufficient integration of objective and subjective factors and the overly static nature of evaluation dimensions. It also extends the analytical framework of the World Economic Forum's Travel and Tourism Competitiveness Index Report, particularly the dimensions of "basic resources – service environment – perceived output".

For spatial analysis and classification, the calculated c_i values were visualized using ArcGIS 10.8.1 and classified into three levels of competitiveness: high ($c_i \geq 0.6$), medium ($0.3 \leqslant c_i < 0.6$), and low ($c_i < 0.3$). The resulting spatial distribution maps reveal the structural characteristics across the region and highlight a distinct core – periphery pattern and its spatial evolution over time [36].

Entropy weight is an objective assignment method, which is mainly based on the concept of information entropy to determine each indicator [37]. In the comprehensive evaluation of the weight, the advantage of the entropy weight method is that it can take into account the interrelationship between the evaluation indicators and avoid problems such as subjective assignment and inconsistency [38]. The specific process is as follows:

1) The matrix of the factors influencing the competitiveness of brand tourism in the YRDCC is evaluated based on five guideline layers: comprehensive strength of the city, scale of brand tourism development, brand tourism resources, brand tourism service level, and environmental quality. By constructing the original matrix Y_{ij} , where, m represents the number of evaluated cities and n represents the number of indicators, the calculation formula is as follows:

$$X_{ij} = [X_{ij}]_{m \times n} \tag{1}$$

2) The data of 20 indicators across five criterion layers, representing the branded tourism competitiveness and its influencing factors in the YRDCC, undergoes standardization to ensure the values fall within the range of [0-1]. In the formula, the original value of the *j*-th indicator for the *i*-th unit is denoted as X_{ij} , and its standardized value is denoted as X'_{ij} .

For the positive indicators of brand tourism competitiveness and influencing factors of the YRDCC, the standardization formula is as follows:

$$X'_{ij} = \frac{x_{ij} - \min(x_{ij})}{\max(x_{ij}) - \min(x_{ij})} \tag{2}$$

For the negative indicators of brand tourism competitiveness and influencing factors of the YRDCC, the standardized treatment formula is as follows:

$$X'_{ij} = \frac{\max(x_{ij}) - x_{ij}}{\max(x_{ij}) - \min(x_{ij})} \tag{3}$$

3) Calculate the data entropy value $1\,e_j$ and data utility value of the branded tourism competitiveness and influencing factor indicators of the YRDCC d_j .

$$\mathrm{e_j} = -k\left[\sum_{i=1}^{n} p_{ij} \ln\left(p_{ij}\right)\right] \tag{4}$$

$$d_j = 1 - e_j \tag{5}$$

Formula:

$$P_{ij} = \mathrm{X}'_{ij} / \sum_{i=1}^{n} x'_{ij}, K = 1/\ln(n) e_j$$

4) According to the information entropy value e_j of the *j*-th indicator of brand tourism competitiveness and influencing factors of the YRDCC, As can be seen, the larger the entropy value of the brand tourism competitiveness and influencing factors indicators of the YRDCC, the smaller its role in the comprehensive evaluation of competition and the smaller the weight; conversely, the larger the weight. Under the *j*-th indicator, the weight of year *i* in this indicator is set to p_{ij}. (4) Determine the weights of evaluation indicators based on the 20 indicators identified for brand tourism competitiveness in the YRDCC.

$$w_{ij} = (1 - e_j) / \sum_{j=1}^{m} (1 - e_j) \tag{6}$$

Formula:

$$0 \le w_i \le 1$$

Through the TOPSIS model, a certain number of brand tourism competitiveness evaluation indexes and influencing factors are selected for different evaluation areas of individual cities in the YRDCC. The proximity distance of each selected region is calculated by the model. The model is used to calculate the proximity distance of each region. Therefore, the optimal solution is determined based on the comprehensive consideration of the advantages and disadvantages of each evaluation object. The results of the TOPSIS model are intuitive, and the closer the distance indicates the better the solution. The specific calculation steps are as follows:

1) Determining the Positive Ideal Solution x^+ and Negative Ideal Solution x^- of the brand tourism competitiveness of the YRDCC and its Influencing Factors:

$$\begin{aligned} x^+ &= (\max\{x_{11}, x_{21}, \cdots, x_{m1}\}, \\ &\max\{x_{12}, x_{22}, \cdots, x_{m2}\}, \cdots, \\ &\max\{x_{1n}, x_{2n}, \cdots, x_{mn}\}) \\ &= (x_1^+, x_2^+, \cdots, x_n^+) \end{aligned} \tag{7}$$

$$\begin{aligned} x^- &= (\min\{x_{11}, x_{21}, \cdots, x_{m1}\}, \\ &\min\{x_{12}, x_{22}, \cdots, x_{m2}\}, \cdots, \\ &\min\{x_{1n}, x_{2n}, \cdots, x_{mn}\}) \\ &= (x_1^-, x_2^-, \cdots, x_n^-) \end{aligned} \tag{8}$$

2) Calculate the distance between the values of the indicators of the brand tourism competitiveness of the YRDCC and its influencing factors and the positive and negative ideal solutions:

$$D_i^+ = \sqrt{\sum_{j=1}^{n} (x_j^+ - x_{ij})^2} \tag{9}$$

$$D_i^- = \sqrt{\sum_{j=1}^{n} (x_j^- - x_{ij})^2} \tag{10}$$

3) Calculating the proximity between the evaluation object and the ideal solution of the brand tourism competitiveness of the YRDCC and its influencing factors c_i:

$$c_i = \frac{D^-}{D^+ + D^-}, 0 < C_i < 1 \tag{11}$$

The larger the price of c_i, the better the factors are in terms of their influence on the brand tourism competitiveness of the YRDCC. On the contrary, it indicates that these factors have less influence on the brand tourism competitiveness of the YRDCC.

B. Study Area

The YRDCC, comprising 27 cities across Shanghai, Jiangsu, Zhejiang, and Anhui, is one of China's most economically dynamic and urbanized regions (Fig. 1) [39]. Although it occupies less than 2.5% of the national land area, it contributes over one-quarter of China's GDP and industrial output, making it a core engine of national economic development [40]. In recent years, the YRDCC has also emerged as a pioneer in culture-tourism integration, with rapid growth in creative industries [41], digital tourism, and high-end tourism services — laying a solid foundation for the development of high-quality tourism brands [42].

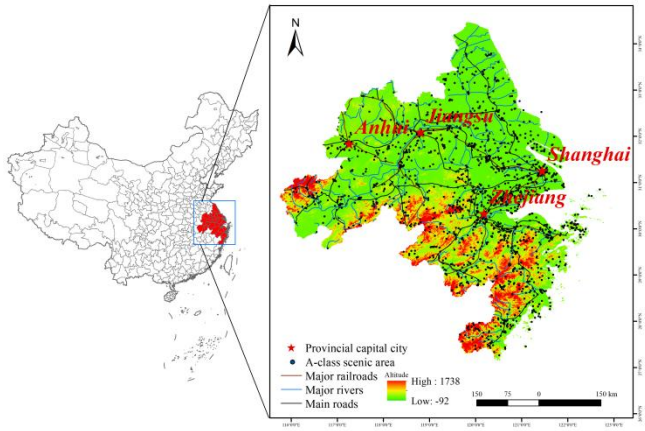

Fig. 1. YRDCC study area.

The YRDCC boasts both rich cultural heritage and modern urban attractions. It is home to nationally significant cultural sites such as Song Dynasty heritage, West Lake, the Grand Canal, and Huizhou ancient villages, alongside globally recognized destinations like Shanghai Disneyland, the Bund, Yellow Mountain, and Wuzhen [43]. Compared to other urban clusters such as the Beijing-Tianjin-Hebei region or the Guangdong-Hong Kong-Macao Greater Bay Area, the YRDCC polycentric structure and dense inter-city networks offer stronger potential for regional coordination and market integration [44]. However, disparities in tourism brand development persist across cities [45].

Core cities such as Shanghai and Hangzhou have successfully established internationally recognized tourism brands—Shanghai leveraging its global metropolitan image, and Hangzhou enhancing its "Song Dynasty culture" through digital innovation [46]. However, cities like Ningbo and Hefei, despite having abundant tourism resources, remain less competitive in brand development due to limited marketing capacity, weak regional coordination, and inconsistent policy support [47]. Moreover, as sustainability becomes a central benchmark in global tourism governance, many cities in the YRDCC have yet to fully integrate considerations such as environmental carrying capacity, ecological protection, and cultural preservation into their tourism strategies [48], These gaps not only impede the long-term development of tourism brands but also weaken their global competitiveness. Understanding the internal disparities and underlying drivers of brand tourism performance within the region is therefore essential for promoting coordinated, high-quality tourism growth and offering valuable insights for other urban clusters in China.

C. Establishment of an Indicator System

To scientifically evaluate the brand tourism competitiveness of cities in the YRDCC Agglomeration (YRDCC), this study constructs a three-tier comprehensive evaluation index system, encompassing a target layer, five criteria categories (B1 – B5), and 20 measurable and traceable secondary indicators (C1 – C20) (Table I). The system is designed to capture five essential dimensions: resource endowment, market scale, service capacity, ecological support, and digital communication effectiveness.

The indicator framework was developed in accordance with the principles of scientific rigor, quantifiability, and systematic logic. It is grounded in internationally recognized evaluation systems, including the UN World Tourism Organization (UNWTO) performance domains and the World Economic Forum (WEF) Travel & Tourism Competitiveness Index (TTCI), as well as policy documents and evaluation norms issued by China's Ministry of Culture and Tourism (MCT). The indicators have been refined to reflect the local context of the YRDCC, aligning global benchmarking with region-specific development practices. Each of the 20 indicators was selected based on three criteria: 1) Theoretical relevance to brand tourism competitiveness, 2) Empirical accessibility based on reliable multi-year statistical records (2019 – 2023), and 3) Data comparability and public transparency across all 27 cities in the YRDCC.

TABLE I. INDICATORS OF EVALUATION FACTORS OF BRAND TOURISM COMPETITIVENESS

Target Level	Criteria	Indicator Level	Unit	Indicator Direction
A Dynamic Assessment of Branded Tourism Competitiveness in the Yangtze River Delta City Cluster Agglomerations	B1 Comprehensive strength of the city	C1 GDP per capita	billion	+
		C2 Regional GDP	billion	+
		C3 Share of tertiary GDP	percent	+
		C4 Proportion of employment in the tertiary sector	percent	+
		C5 Total retail sales of consumer goods	billion	+
	B2 Brand Tourism Development Scale	C6 Domestic Tourism	million	+
		C7 Number of international tourists	million	+
		C8 Domestic branded tourism revenue	billion	+
		C9 Foreign exchange earnings from branded tourism	billion	+
	B3 Brand tourism resources	C10 Natural landscape resources	one	+
		C11 Number of historical and cultural sites	one	+
		C12 Branded Event Resources	one	+
		C13 Word-of-mouth evaluation of city tourism brands by tourists and the public	Point scale	+
	B4 Brand tourism service level	C14 Number of star-rated hotels	one	+
		C15 Number of tourist agencies	one	+
		C16 Number of public restrooms	one	+
		C17 Number of museums	one	+
		C18 Cultural and brand communication organizations	one	+
	B5 Urban environmental quality	C19 Green space coverage rate of built-up areas	pieces	+
		C20 Green space per capita	m^2/person	+

The majority of the data were obtained from government-authorized sources, primarily national and provincial statistical yearbooks. Statistical Yearbooks: China City Statistical Yearbook, China Urban Construction Statistical Yearbook, Provincial and municipal yearbooks (e.g. Shanghai Statistical Yearbook, Anhui Statistical Yearbook). Official Bulletins and Thematic Reports, China Culture and Tourism Development Statistical Bulletin (Ministry of Culture and Tourism, 2019 – 2023) Annual Work Reports from local Bureaus of Culture and Tourism across Jiangsu, Zhejiang, and Anhui. Public

Databases and API Platforms: National Data Platform (data.stats.gov.cn), Online travel platforms (Ctrip, Dianping, Mafengwo) for indicators such as C13 Visitor Reviews, using NLP-based sentiment analysis and expert-weighted scoring. Mapping and POI services (Gaode Map, Baidu Map API) for facility density and infrastructure coverage indicators.

Based on the multidimensional structure of urban brand tourism competitiveness, this study establishes an evaluation framework comprising five key criteria: urban comprehensive strength, scale of brand tourism development, brand tourism resources, quality of brand tourism services, and urban environmental quality, thereby forming a systematic indicator system.B1 Urban Comprehensive Strength reflects a city's economic foundation and development potential, serving as a fundamental support for building its tourism brand. This criterion includes five indicators (C1 – C5): per capita GDP, total regional GDP, the proportion of the tertiary industry, employment in the tertiary sector, and total retail sales of consumer goods. These indicators evaluate the city's overall development level in terms of economic output, industrial structure, and consumer vitality. B2 Scale of Brand Tourism Development represents the degree of tourism development and market attractiveness. Indicators C6 to C9 measure the number of domestic and international tourists received and related tourism revenues, providing a direct reflection of the size of the tourism market and its economic contribution. B3 Brand Tourism Resources focus on assessing the city's natural endowments and cultural characteristics. Indicators C10 to C13 include natural landscapes, historical and cultural heritage sites, branded event resources, and visitor reviews — collectively capturing the city's tourism appeal and brand perception. B4 Quality of Brand Tourism Services emphasizes the supply capacity and experiential quality of tourism services. Indicators C14 to C18 include the number of star-rated hotels, travel agencies, public restrooms, museums, and cultural or brand communication institutions, reflecting the city's capabilities in service provision and cultural promotion. B5 Urban Environmental Quality is assessed using indicators C19 and C20: the green coverage rate in built-up areas and per capita green space. These indicators evaluate the city's ecological livability and capacity for sustainable development.

This study further proposes a five-dimensional interactive model—Economy – Resources – Services – Communication – Environment — highlighting the systematic coupling and dynamic synergy among various indicators. Urban economic strength supports the development of infrastructure and service systems, providing the material foundation for the expansion of brand tourism. Rich tourism resources are the core attraction for visitors, but their value realization depends on the service system's carrying capacity and management efficiency. The quality of tourism services and the effectiveness of digital communication directly influence visitor satisfaction and brand reputation, fostering brand loyalty and enhancing urban competitiveness. A high-quality ecological environment not only improves the visitor experience but also ensures the sustainability of brand tourism. Meanwhile, digital content dissemination and feedback mechanisms based on tourist behavior further promote the visibility and communication efficiency of the city brand.

III. Results

A. Analysis of Factors of City Brand Tourism Competitiveness

B1 — Urban Comprehensive Strength: This dimension reflects a city's economic foundation and its capacity to support tourism infrastructure, service provision, and brand promotion — factors that are critical to enhancing tourism competitiveness. According to the data, Shanghai ranks first with an overwhelming score of 0.705, significantly ahead of other cities. Wenzhou (0.511) and Suzhou (0.503) follow in second and third place, respectively, indicating that robust economic development provides a strong foundation for tourism competitiveness. Although Nanjing (0.463) and Hangzhou (0.483) score slightly lower, their relatively balanced performance suggests solid economic bases and well-developed service sectors. In contrast, cities such as Chuzhou (0.046) and Tongling (0.051) remain at the bottom, reflecting limitations in resource allocation and industrial structure (Fig. 2). Overall, the distribution of scores in this dimension reveals a distinct pattern: strong concentration at the top, moderate clustering in the middle, and dispersion at the lower end.

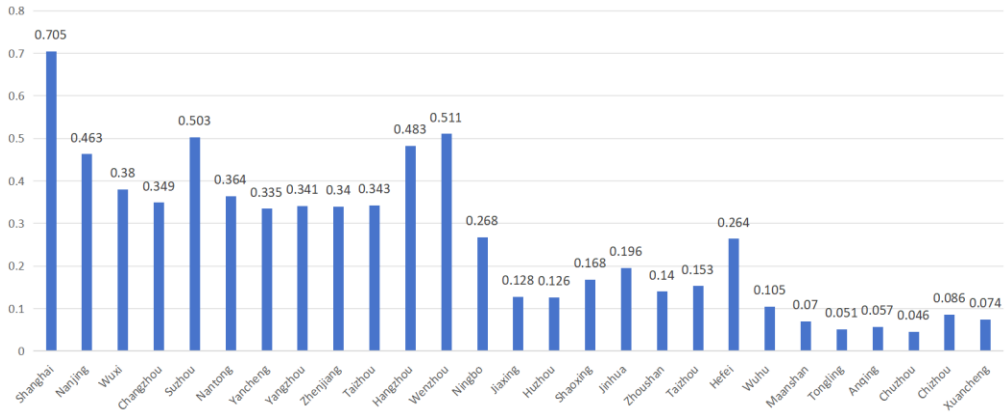

Fig. 2. B1 score distribution.

B2 — Scale of Branded Tourism Development: This dimension evaluates the external expansion capacity of the tourism market. Shanghai (1.000) significantly outperforms all other cities, demonstrating a dominant market scale and a strong brand-driven "magnetic effect" that attracts tourists across the region. Suzhou (0.578) ranks second, reflecting robust tourism reception capacity and efficient conversion of tourism flows into economic returns. Cities in the mid-range, such as Nanjing (0.226) and Wuxi (0.168), exhibit steady growth in both visitor numbers and tourism revenue, indicating solid development potential. In contrast, cities like Yancheng (0.015) and Taizhou (0.019) show limited tourism activity and weak foundational support. Overall, the distribution of scores in this dimension reveals a pronounced polarization: top-tier cities benefit from well-developed tourism ecosystems, while lower-tier cities remain in the early stages of development (Fig. 3). These cities must draw lessons from leading counterparts, particularly in enhancing the quality of tourism offerings and improving service capabilities.

B3—Branded Tourism Resources: This dimension reflects a city's tourism appeal and its cultural communication foundation. Notably, Yancheng (0.560), Hefei (0.445), and Wuhu (0.404) rank among the top three, indicating that certain cities in Anhui Province have demonstrated strong performance in integrating natural and cultural resources. For instance, Hefei benefits from the promotion of Binhu cultural assets and branded events, while Wuhu effectively leverages its rich historical heritage. Conversely, cities such as Zhoushan (0.072) and Jiaxing (0.080), despite possessing considerable resource endowments, exhibit underdeveloped capabilities in brand development and public communication. The overall distribution of scores in this dimension is relatively balanced (primarily within the 0.1 – 0.4 range), suggesting that while most cities hold comparable levels of tourism resources, their ability to transform these assets into recognizable and marketable tourism brands varies significantly (Fig. 4).

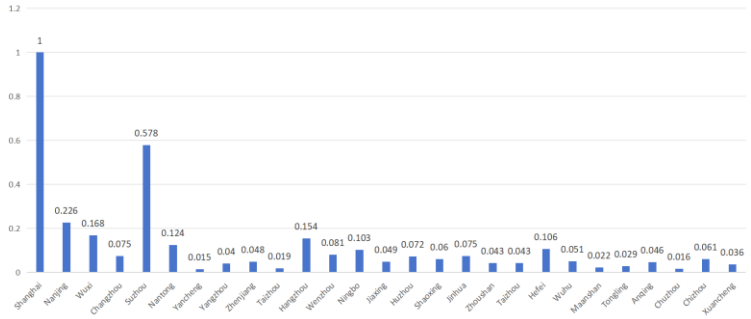

Fig. 3. B2 score distribution.

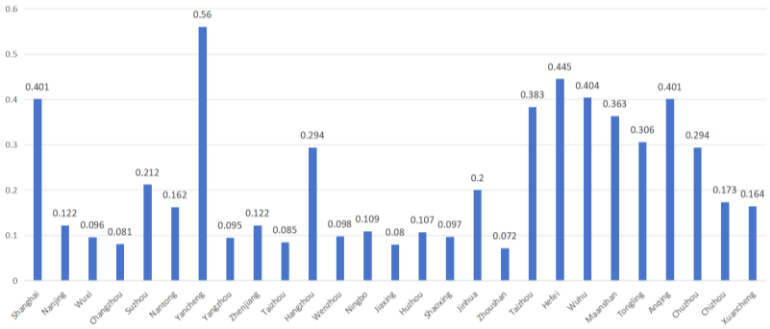

Fig. 4. B3 score distribution.

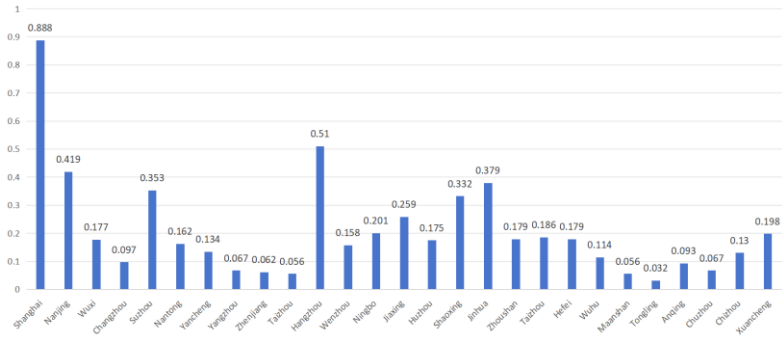

Fig. 5. B4 score distribution.

B4—Branded Tourism Service Level: Service capacity constitutes the perceptual foundation of a city's tourism competitiveness. The data show that Shanghai (0.888) ranks first, with significant advantages in high-end hotel availability, cultural and tourism facilities, and brand communication institutions. Hangzhou (0.510) and Nanjing (0.419) follow closely, indicating relatively well-developed service systems. In contrast, cities such as Tongling (0.032), Chuzhou (0.067), and Zhenjiang (0.062) exhibit notably lower scores, reflecting outdated infrastructure and limited tourism reception capacity (Fig. 5). The wide score range in this dimension highlights pronounced disparities among cities and demonstrates that investment in tourism services directly influences public perception and word-of-mouth dissemination of the city's brand.

B5—Urban Environmental Quality: Ecological livability has become increasingly intertwined with the sustainable development of tourism. Cities, such as Chizhou (0.819), Huzhou (0.764), and Yangzhou (0.752) lead in this dimension, reflecting outstanding performance in green space coverage and ecological preservation. In contrast, major urban centers like Shanghai (0.000) and Wenzhou (0.191) score significantly lower, largely due to high urbanization levels that constrain ecological space (Fig. 6). Scores in this dimension are broadly distributed between 0.2 and 0.8, indicating a relatively balanced performance overall. This suggests that in several cities, ecological civilization efforts have effectively translated into tourism advantages.

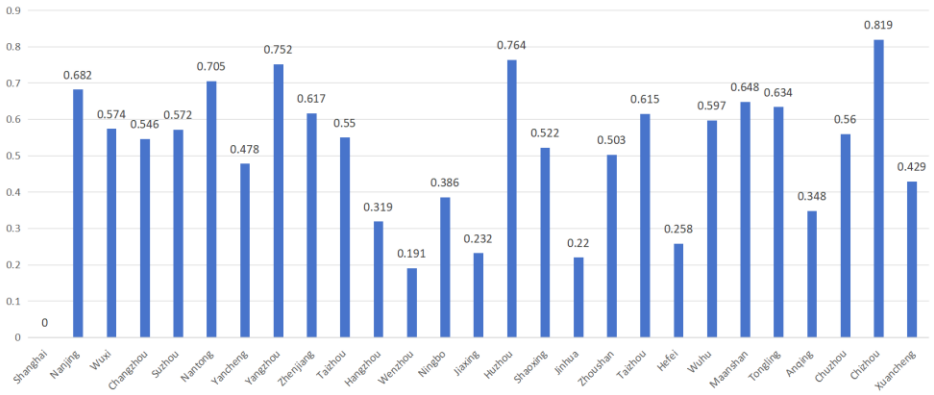

Fig. 6. B5 score distribution.

This study develops a five-dimensional interactive model—Economy – Resources – Services – Communication – Environment—to highlight the systemic synergy among the core components of brand tourism competitiveness. Specifically, urban comprehensive strength (B1) provides the financial and policy foundation for tourism development; resource endowment (B3) constitutes the fundamental appeal to tourists; service quality (B4) shapes visitor experience and word-of-mouth dissemination; development scale (B2) reflects the market transformation capacity of tourism; and environmental quality (B5) underpins the long-term sustainability of tourism systems. In practical application, high-performing cities such as Shanghai and Hangzhou can leverage their institutional resources and brand advantages to establish regional "flagship demonstration zones"—offering replicable models in areas such as infrastructure development, brand communication, and green tourism governance. In contrast, lower-performing cities like Chuzhou and Tongling may benefit from adopting mechanisms such as cross-regional tourism passes, shared resource platforms, and joint marketing strategies, thereby enhancing brand visibility and improving tourism service capacity through collaborative growth. To improve the comparability and validity of soft indicators, particularly the tourist sentiment index (C13), this study integrates social media data crawling techniques with expert scoring mechanisms, enabling data standardization and objectivity Supporting Information (S1 Table). Additionally, Gaode Map and Baidu Map APIs are employed to enhance the spatial granularity in the measurement of tourism service infrastructure, thus improving the analytical precision of the service dimension. Overall, the brand tourism competitiveness of the YRDCC exhibits pronounced characteristics of multidimensionality, imbalance, and regional differentiation. The proposed indicator system not only uncovers structural disparities across cities in terms of competitiveness factors but also offers a practical framework for future policy optimization and regional coordination. Subsequent research may further integrate visitor movement patterns, smart tourism platform data, and other real-time dynamic indicators to construct a more adaptive and time-sensitive evaluation system for urban tourism competitiveness.

B. Synthesize and Analyze

This study employs the entropy-weighted TOPSIS method to dynamically evaluate the overall performance of brand tourism competitiveness across 27 cities in the YRDCC from 2019 to 2023. The relative closeness to the ideal solution is used as a metric to assess how closely each city's tourism performance aligns with the optimal scenario-the closer the value is to 1, the stronger the competitiveness. Calculate the relative proximity of each city through the formula $c_i = \frac{D_i^-}{D_i^+ + D_i^-}$, where, D_i^+ is the distance of the city from the ideal solution and D_i^- is the distance of the city from the negative ideal solution. The evaluation process involves the following steps: First, the optimal (maximum) and anti-optimal (minimum)

values for each indicator are identified. Second, the Euclidean distances between each city and both the ideal and anti-ideal solutions are calculated. Finally, each city's comprehensive score is derived based on the relative closeness formula. Furthermore, ArcGIS 10.8.1 is employed to visualize the spatial distribution of competitiveness levels (Fig. 7), thereby revealing the spatiotemporal evolution [33] of brand tourism competitiveness over the study period.

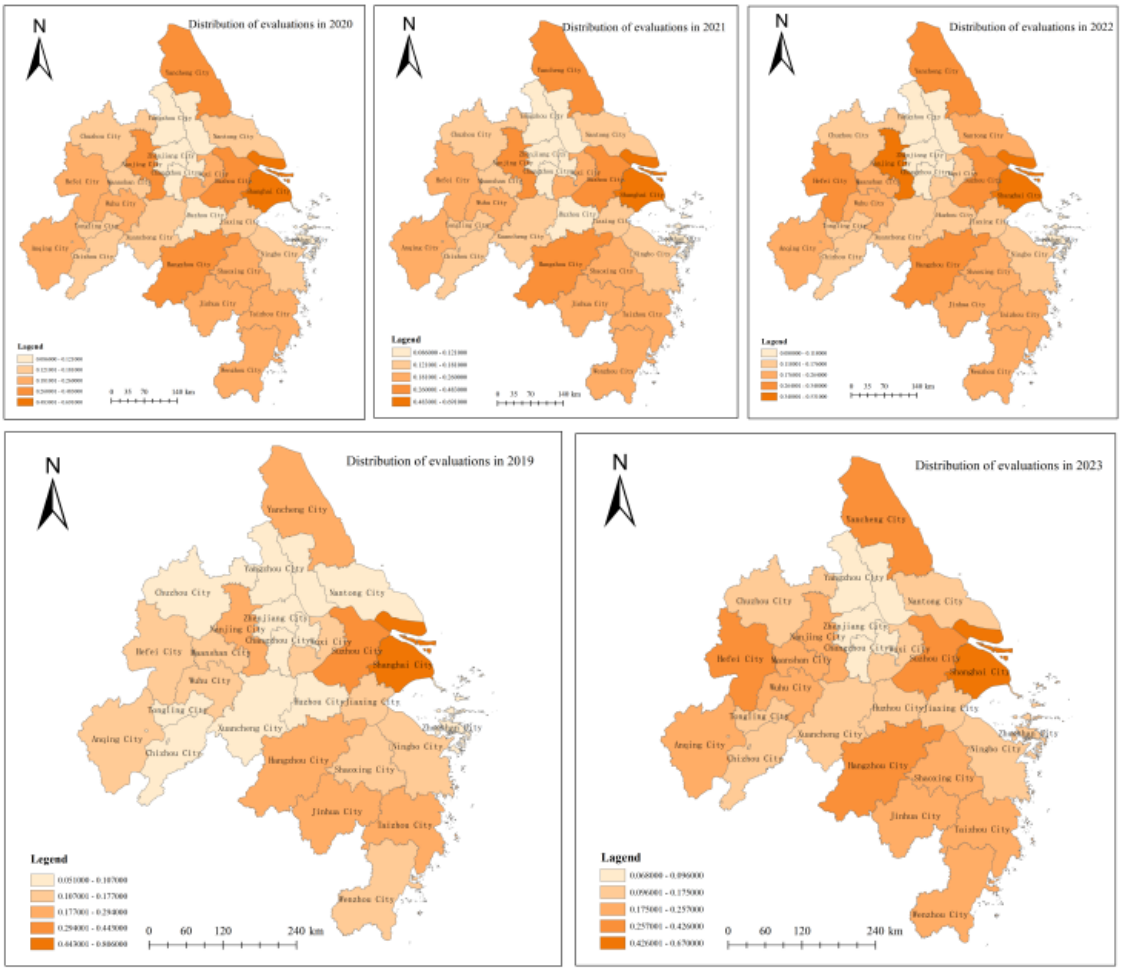

Fig. 7. Evaluation Distribution of the YRDCC.

High-performing and stable cities such as Shanghai, Suzhou, and Hangzhou have consistently maintained strong brand tourism competitiveness (Table II). From 2019 to 2023, Shanghai remained in the top position, with its relative closeness score ranging from 0.892 to 0.901. This reflects its comprehensive advantages in economic strength, international brand development, well-developed service infrastructure, and the effective integration of cultural resources, positioning it as a leading driver in regional brand tourism. Suzhou (0.601 – 0.624) and Hangzhou (rising from 0.538 to 0.689) demonstrated steady and coordinated development between brand cultivation and resource utilization, with continued efforts particularly in digital tourism, cultural and creative industries, and the provision of high-end tourism services. Cities with steadily rising performance, such as Hefei, Nantong, and Ningbo, also show promising momentum. Hefei advanced from 8th place in 2019 to 6th in 2023, with a 30.3% increase in its relative closeness score, indicating continuous progress in tourism infrastructure, investment in cultural tourism projects, and integrated brand communication. Nantong and Ningbo have achieved slow but steady gains by optimizing resource allocation and enhancing service quality. In contrast, cities showing significant decline, such as Zhenjiang and Yangzhou, have seen their rankings drop notably. Zhenjiang fell from 7th in 2019 to 12th in 2023 (a decline of 11.4%), while Yangzhou dropped from 6th to 11th (a decline of 13.1%). These setbacks are primarily attributed to lagging brand marketing, low resource utilization, and insufficient transportation connectivity. This suggests that small and medium-sized cities face the risk of marginalization if tourism strategies are not timely adjusted. The data reveal a clear trend of polarization and structural imbalance. The distribution of relative closeness scores exhibits a "top-heavy, sparse middle, scattered tail" pattern. For instance, in 2023, the gap between Shanghai (0.901) and Hefei (0.615) was considerable, while most mid- and lower-ranking cities clustered between 0.3 and 0.45. This indicates persistent disparities in critical factors such as infrastructure, brand maturity, and ecological support across the region.

TABLE II. BRANDED TOURISM RESPONSE FOR THE YRDCC, 2019-2023.

Items	D_i^+	D_i^-	c_i	Ranking
R1	0.72	0.77	0.79	1
R2	1.51	1.77	2.15	5
R3	3.87	4.8	5.96	15
R4	6.08	7.57	9.44	24
R5	0.8	0.92	1.04	2
R6	3.65	4.49	5.58	14
R7	1.24	1.47	1.76	4
R8	6.56	8.18	10.21	26
R9	6.32	7.87	9.82	25
R10	6.81	8.49	10.59	27
R11	1	1.17	1.37	3
R12	3.15	3.89	4.81	12
R13	4.11	5.1	6.34	16
R14	4.36	5.42	6.73	17
R15	5.61	6.97	8.68	22
R16	2.9	3.57	4.42	11
R17	1.93	2.36	2.88	7
R18	5.84	7.27	9.06	23
R19	2.17	2.65	3.26	8
R20	1.71	2.07	2.51	6
R21	2.42	2.97	3.65	9
R22	3.39	4.19	5.19	13
R23	4.62	5.74	7.13	18
R24	2.66	3.28	4.03	10
R25	4.87	6.04	7.51	19
R26	5.35	6.66	8.28	21
R27	5.11	6.35	7.9	20

High-performing cities should further extend the reach of their brand communication by developing high-end international tourism products and globally influential cultural IPs. They are also encouraged to continue serving as hubs of innovation and leadership, radiating positive effects to surrounding cities and driving regional integration. Mid-tier cities should focus on deeply exploring their unique cultural characteristics and establishing differentiated market positioning. Strengthening mechanisms for inter-city cooperation and regional coordination is essential to enhance the overall brand value chain and achieve synergistic development. Lower-performing cities need to adopt targeted improvement strategies. These include enhancing transportation connectivity, diversifying tourism product offerings, and encouraging the entry of private capital into the cultural and tourism sectors. Additionally, they can learn from the best practices of high-performing cities through "contextualized transplantation" and joint promotional efforts, thereby accelerating their competitiveness in a more customized and collaborative manner.

IV. DISCUSSION

A. Theoretical and Practical Significance

Theoretical significance: First, this study expands the multidimensional measurement framework of urban brand development. While traditional research on city branding has primarily focused on subjective dimensions such as perceived identity and image construction, this study introduces objective indicators — including resources, services, environment, and economy — into a systematic model. By filling the theoretical gap in the quantifiable assessment of city brands, the research contributes to shifting the focus of brand tourism from impression-based narratives to comprehensive competitiveness evaluation. Second, the study enriches the methodological foundation for assessing regional tourism synergy and competitiveness. By employing the TOPSIS model in combination with the entropy weight method, this research is among the first to systematically evaluate inter-city differences and structural characteristics of brand tourism competitiveness at the scale of Chinese urban agglomerations. It reveals the weighting mechanisms of key success factors — such as resource transformation, service provision, and ecological capacity — in the process of brand development, thereby enhancing the explanatory power and practical applicability of the theoretical model. Third, the study responds to the theoretical proposition of "structural disparities and collaborative governance" in urban tourism competitiveness. By empirically analyzing the performance of cities across five dimensions (B1 – B5) and their complementary relationships, this research concretizes the concepts of "coordinated development" and "complementary advantages". For instance, core cities such as Shanghai can foster brand enhancement in peripheral cities through infrastructure spillovers and institutional connectivity. Conversely, lower-tier cities may reduce market entry barriers via collaborative resource allocation and coordinated marketing, jointly advancing the formation of a multi-layered and interactive regional brand competitiveness framework.

Relevance: First, the study supports China's national strategy for promoting coordinated regional development. As brand tourism is one of the core pillars of YRDCC integration, the findings help accurately identify the relative position and weaknesses of each city within the brand competitiveness system. This provides a valuable data foundation for the coordinated allocation of cultural and tourism resources, cross-regional integration, and targeted policy implementation. Second, it contributes to enhancing the international communication capacity and cultural influence of urban agglomerations. In the context of globalization, brand tourism serves as a key vehicle for cities to participate in international discourse and cultural exchange [50]. The study highlights how cities such as Hangzhou and Hefei have elevated their brand levels through smart tourism platforms and international events, illustrating the critical role of branding in embedding cities into global tourism networks. Third, the research facilitates regional complementarity and structural optimization. By uncovering structural disparities among cities across dimensions such as resources, services, and the environment, it proposes replicable branding strategiesz, such

as “flagship-driven development”, “differentiated positioning”, and “ecological synergy”, offering theoretical support for constructing a tourism development model based on “differentiated positioning + coordinated integration”.

B. Competitiveness Analysis and Policy Recommendations

This study employs the entropy-weighted TOPSIS model to construct a comprehensive evaluation system comprising five criterion layers and 20 core indicators, enabling an effective assessment of the hierarchical characteristics of brand tourism competitiveness across the YRDCC. The findings reveal significant disparities among cities in terms of economic foundations, resource endowments, service infrastructure, and ecological environment—factors that fundamentally drive the differentiation in tourism competitiveness.

Cities such as Shanghai and Hangzhou have consistently ranked among the top in tourism competitiveness, owing to their strong economic foundations, high tourism reception capacity, and significant international influence. However, they also face challenges such as sluggish brand renewal and mounting ecological pressures. It is recommended that these cities further enhance their leadership by developing "regional tourism flagship demonstration zones" and strengthening resource sharing and brand collaboration with neighboring cities — through initiatives such as the YRDCC Cultural Tourism Expo and joint city marketing platforms. Additionally, adopting green tourism policies, including low-carbon transportation and carbon-neutral scenic areas, can help alleviate ecological constraints and sustain their global competitiveness.

Cities such as Suzhou and Ningbo possess rich cultural resources and robust manufacturing bases, but their levels of brand recognition remain moderate. However, they still face limitations in the provision of high-end services and international outreach. To bridge these gaps, targeted efforts should be made to develop distinctive cultural IPs (intellectual properties) that highlight local heritage and creativity. For example, Suzhou could deepen the digital presentation of its classical garden culture, while Ningbo might highlight its “Maritime Silk Road” heritage and expand port-related tourism development. Furthermore, enhancing cooperation with international tourism organizations, such as introducing multilingual guided services and launching overseas advertising campaigns, can significantly improve both the appeal and service quality for international visitors [51].

Cities such as Yangzhou, Zhenjiang, and Taizhou face multiple challenges, including low brand visibility, underdeveloped infrastructure, and weak digital services. To enhance their competitiveness, priority should be given to improving transportation accessibility and tourism reception capacity through the development of high-grade hotels and visitor centers. Drawing on the successful experiences of nearby high-performing cities, these cities could adopt regional travel passes and integrated transportation systems to promote tourist mobility and resource complementarity. Additionally, efforts should be made to strengthen local festival brands, for example, Yangzhou could leverage the Slender West Lake Cultural Festival as a stable platform to attract visitors and enhance brand recognition.

It is recommended that the entire region implement an integrated green tourism development strategy. Small and medium-sized cities can enhance their ecological brand value by jointly developing ecological corridors and launching collaborative low-carbon tourism routes. The promotion of green transportation option, such as electric vehicles and public bicycles, alongside the establishment of smart management systems will enable real-time monitoring of tourism resources and environmental carrying capacity. These measures will collectively strengthen the region’s capacity for sustainable tourism competitiveness.

C. Domestic and International Case Studies and Lessons

Enhancing tourism competitiveness requires more than abundant resource endowments; it hinges on the synergistic interaction of institutional innovation, cultural identity, and environmental sustainability [49]. The following representative cases offer valuable lessons for the YRDCC in its pursuit of high-quality and differentiated tourism development.

Kyoto, Japan-Cultural Continuity through Festival Branding, Kyoto exemplifies how traditional cultural assets can be embedded into everyday urban life and tourism practice. Through the preservation of historical architecture and the regular hosting of festivals such as the Gion Matsuri, Kyoto has institutionalized cultural rituals that enhance visitor loyalty and deepen place-based identity. For cities in the YRDCC, this suggests the value of a “cultural embedding” strategy — transforming intangible cultural heritage, such as Jiangnan water-town traditions, into dynamic experiences via immersive tourism formats like themed performances, cultural fairs, and participatory heritage events.

Florence, Italy-Balancing Heritage Conservation with Tourism Development, Florence demonstrates how cultural heritage and tourism can coexist through well-designed institutional frameworks. Mechanisms such as “cultural usage rights” and designated “historic architecture control zones” enable the city to maintain cultural authenticity while promoting adaptive reuse. These practices offer policy implications for YRDCC cities, particularly Suzhou and Anhui’s Huizhou villages, which face similar pressures to reconcile heritage conservation with increasing tourism demands. Drawing on Florence’s approach could support the development of sustainable, heritage-based tourism strategies across the YRDCC.

Freiburg, Germany – Advancing Green Transformation in Urban Tourism, Freiburg’s reputation as a “green city” stems from its successful integration of environmental goals into tourism planning. Through the development of low-carbon scenic zones, comprehensive public transit networks, and environmentally certified accommodations, Freiburg exemplifies ecologically responsible tourism. Given the environmental constraints faced by the densely populated urban cores of the YRDCC, this case underscores the need to formulate regional “low-carbon tourism development guidelines,” implement ecological carrying capacity assessments in popular destinations, and encourage responsible visitor behavior through policy incentives and public education.

Pearl River Delta (PRD) vs. YRDCC: Divergent Pathways of Tourism Competitiveness. A domestic comparative analysis between the PRD and YRDCC highlights their divergent strategic orientations in tourism development. The PRD, encompassing cities such as Guangzhou, Shenzhen, and Zhuhai, has pursued a market-oriented, globally integrated model, leveraging mechanisms such as free trade zones, port infrastructure, and large-scale commercial events (e.g. Canton Fair, Shenzhen Tech Expo) to drive tourism growth. This model prioritizes volume, innovation, and modern leisure consumption.

By contrast, the YRDCC adopts a development logic centered on cultural preservation, ecological balance, and regional coordination. Cities like Hangzhou and Suzhou have cultivated tourism brands rooted in Jiangnan cultural identity, integrating heritage conservation with high-quality visitor experiences. While the PRD excels in infrastructure openness and digital marketing, it faces challenges in fostering cohesive cultural narratives and safeguarding intangible heritage. The YRDCC, though more conservative in its pace of innovation, offers a more sustainable and culturally enriched model through its emphasis on regional synergy and ecological tourism. This comparison suggests that the YRDCC could benefit from selectively adopting the PRD's strengths in digitalization and international outreach, while offering in return a replicable model of integrated, heritage-centered, and ecologically sustainable tourism development. Such a synthesis would allow both regions to enhance their competitiveness while aligning with global trends toward responsible and differentiated tourism branding.

D. Research Limitations and Future

This study has carried out in-depth exploration in the construction of the indicator system and assessment methods, but the following limitations still exist. First, data acquisition limitations, part of the city tourism-related data is not detailed enough, the future should be introduced to improve data collection by means of big data monitoring, tourist satisfaction surveys and other means. Second, dynamic monitoring is insufficient, failing to fully reveal the long-term impact of policy changes and other external factors on tourism, it is recommended to combine with the panel data model to dynamically monitor the evolution mechanism of competitiveness in the future. Third, the integration of multi-source data, the current assessment mainly relies on macro statistics, in the future, social media data, tourists' word-of-mouth evaluation and other information sources can be introduced to enrich the research dimension. Fourth, smart tourism and digital development, in the future, attention should be paid to the empowerment of smart tourism platforms and digital management tools on the competitiveness of city brands, and explore the role of digital technology in promoting the upgrading of the cultural and tourism industry.

V. CONCLUSIONS

This study focuses on the YRDCC and investigates the structural measurement and dynamic comparison of regional brand tourism competitiveness. A comprehensive indicator system was constructed, encompassing five dimensions: overall urban strength, scale of brand tourism development, tourism resources, service quality, and environmental conditions. The framework includes 20 secondary indicators, with clearly defined data sources and a scientifically grounded structure. It aligns closely with the World Economic Forum's framework for tourism competitiveness while incorporating region-specific factors such as digital communication and sustainable development. Using the entropy-weighted TOPSIS method, the study applies objective weighting to calculate the relative closeness of each city to an ideal solution. This enables a comprehensive evaluation of the overall performance, structural characteristics, and spatial evolution of brand tourism competitiveness among YRDCC during the period from 2019 to 2023.

The competitive landscape of brand tourism in the YRDCC region exhibits a spatial pattern characterized by "dominant leadership and distinct gradients." Cities like Shanghai and Hangzhou have consistently ranked at the top in terms of competitiveness, demonstrating strong capacities in resource integration, economic support, and brand diffusion. These cities are typical examples of "lagship cities". Meanwhile, cities such as Suzhou, Nanjing, and Ningbo maintain relatively stable performance in terms of cultural resources and tourist reception, yet still have room for improvement in global brand development and cultural IP export. At the lower end of the spectrum, cities like Chuzhou, Tongling, and Zhoushan struggle with underdeveloped infrastructure, weak digital services, and limited brand communication capacity, highlighting the ongoing issue of regional development imbalance. The indicators used in this study exhibit interrelated and synergistic effects. The proposed "Five-Dimensional Synergy" model reveals that: B1 (Overall Urban Strength) provides essential capital and policy support for tourism development; B2 (Development Scale) reflects market conversion and external expansion capacity; B3 (Resource Base) determines core attractiveness; B4 (Service Quality) influences tourist experience and word-of-mouth dissemination; B5 (Environmental Quality) serves as the foundation for building green tourism brands. These dimensions are highly interlinked across different cities, collectively shaping their brand tourism competitiveness structures. In terms of temporal evolution, cities such as Hefei and Hangzhou have shown notable upward momentum, each climbing two ranks, indicating that investments in smart tourism, infrastructure, and brand-related events have yielded significant results. In contrast, cities like Zhenjiang and Yangzhou have experienced a marked decline in competitiveness, reflecting delays in cultural-tourism integration, market responsiveness, and product innovation. Cities such as Shanghai and Suzhou continue to demonstrate stable and long-term competitive advantages, highlighting their strong resilience within the regional brand tourism system. From a spatial perspective, GIS-based visualization results reveal a "core – periphery" distribution pattern. High-competitiveness cities are mainly concentrated in the Shanghai – Jiangsu – Zhejiang corridor, whereas most cities in Anhui remain in developmental lowlands. Although cities like Chizhou and Wuhu possess ecological advantages, these have not yet been effectively transformed into brand strengths, underscoring the urgent need to enhance regional resource coordination mechanisms.

This study makes three key contributions at both theoretical and practical levels: First, it expands the theoretical framework for evaluating urban brand competitiveness, particularly by integrating heterogeneous indicators from multiple sources and combining objective and subjective data analysis. This approach addresses the existing gap in comprehensive understanding of city brand tourism in the current literature. Second, by constructing a five-dimensional interactive framework encompassing economy, resources, services, communication, and environment, the study strengthens the causal relationships and synergetic logic among indicators. This provides a more structured and coherent approach to modeling brand tourism competitiveness. Third, methodologically, the integration of the entropy-weighting method and the TOPSIS ranking model overcomes the limitations of traditional subjective weighting approaches. It enhances both the scientific rigor and operational feasibility of cross-city comparative analysis.

High-ranking cities such as Shanghai and Hangzhou should play a leading role by establishing regional "flagship demonstration zones". These cities can spearhead collaborative brand-building initiatives, including co-hosted festivals, inter-city tourism alliances, and shared platform mechanisms, to drive coordinated upgrades among mid- and low-ranking cities. Mid-level cities like Suzhou, Ningbo, and Hefei should focus on leveraging their unique resources and cultural symbols to strengthen differentiated brand positioning. Efforts should also be made to enhance international visibility and brand recognition. Lower-tier cities, including Chuzhou, Tongling, and Zhenjiang, should prioritize addressing infrastructure gaps and improving digital service capabilities. Through targeted policy support, strategic market partnerships, and in-depth cultural resource development, these cities can "scale up by leveraging external strengths". At the regional level, a green and low-carbon transformation should be actively pursued. By integrating ecological preservation with brand development, the YRDCC region can establish a model that combines "ecological space + smart management + green communication", thereby enhancing long-term sustainable competitiveness.

Edge-Integrated IoT and Computer Vision Framework for Real-Time Urban Flood Monitoring and Prediction

Rupesh Mandal[1], Bobby Sharma[2], Dibyajyoti Chutia[3]
Department of Computer Science and Engineering-School of Technology,
Assam Don Bosco University, Guwahati, Assam, India[1, 2]
North Eastern Space Applications Centre-Department of Space, Government of India, Umiam, Meghalaya, India[3]

***Abstract*—Urban flash floods pose a critical threat to rapidly growing cities in India, where unplanned development, climate variability, and inadequate drainage amplify risks. Guwahati, in Northeast India, experiences recurrent inundation during monsoons, disrupting livelihoods and damaging infrastructure. This study presents an integrated IoT and AI-enabled framework for urban flood monitoring and prediction. A LoRa-based IoT sensor network was deployed to capture localized hydrological and meteorological parameters, overcoming the limitations of coarse weather APIs. Rainfall forecasting was implemented at the edge layer using Random Forest, XGBoost, CatBoost, and K-Nearest Neighbors, fused through a fuzzy logic model that achieved 92.4% accuracy, surpassing individual classifiers. In parallel, a computer vision pipeline detected drainage blockages from geotagged user images, with EfficientNetB0-U-Net achieving ~91% accuracy, outperforming ResNet50, InceptionV3, and MobileNetV2. By combining rainfall prediction, IoT sensing, and blockage detection, the proposed framework delivers a holistic, low-cost, and scalable early warning system, marking a novel contribution toward resilient urban flood management in resource-constrained settings.**

***Keywords*—Urban flood prediction; IoT sensor networks; edge computing; fuzzy logic fusion; hydraulic blockage detection; computer vision**

I. Introduction

Natural hazards such as floods, tsunamis, earthquakes, and storms continue to pose significant threats worldwide, affecting human lives, resources, and infrastructure [1]. In the absence of effective monitoring and mitigation strategies, these hazards can escalate into full-scale disasters that disrupt urban life, damage infrastructure, and impede economic growth [2], [3]. Among natural hazards, floods are the most recurrent, accounting for nearly 41% of all reported disasters in the past decade [4]. Flash floods, in particular, have become increasingly destructive in urban settings. In India, such events now occur throughout the year, driven by excessive rainfall, rising water levels, and atmospheric dynamics that lead to intense precipitation [5].

Urban centers, while functioning as economic hubs, face heightened flood vulnerability due to rapid population growth, unsustainable land use, and inadequate waste and sewage management. For instance, Guwahati in Assam—located along the Brahmaputra and its tributary Bharalu—regularly experiences severe inundation in low-lying areas such as Anil Nagar and Zoo Road during the monsoon season, disrupting livelihoods and causing economic losses [6]. Land reclamation near water bodies has further aggravated seasonal flooding challenges, delaying urban development for extended periods. Although cities like Mumbai have relatively advanced flood warning and evacuation systems [7], most Indian cities, including Delhi, Bangalore, and Kolkata, lack such mechanisms.

Recent advances in the Internet of Things (IoT) have demonstrated potential for disaster monitoring and management. By integrating sensors, communication systems, and data analytics, IoT can enable real-time monitoring of hydrological parameters. However, large-scale deployment of IoT-based flood management systems remains constrained by high costs, integration complexities, limited adaptability to diverse flood scenarios, and challenges in decision-making. Despite these issues, IoT has already shown value in healthcare, defense, and disaster response. When coupled with artificial intelligence (AI), data collected from mobile devices, environmental sensors, and satellites can be transformed into actionable insights for flood prediction and mitigation.

A critical but often underexplored factor in urban flash flooding is drainage and culvert blockage. Even in well-designed drainage systems, the accumulation of debris such as boulders, vegetation, and solid waste can drastically reduce flow capacity, leading to localized inundation. Brooks [12], through scaled laboratory models and field observations, demonstrated that culvert inlets are the primary deposition points for boulders and emphasized the need for structural modifications to mitigate blockage. Building on this, Iqbal et al. [13] investigated blockage mechanisms under varying debris types, orientations, and flow conditions, highlighting how hydraulic blockage intensifies during dynamic flood hydrographs. More recently, Iqbal et al. [14] introduced a computer vision-based approach to automate culvert blockage detection, testing multiple CNN models on real-world datasets. While NASNet achieved the highest accuracy (85%) and MobileNet demonstrated faster inference, limitations such as background clutter and simplified labelling criteria constrained performance. These studies underscore the importance of integrating blockage detection into urban flood management frameworks. Manual inspection remains labor-intensive and reactive, whereas AI-driven image-based classification provides a scalable solution for real-time monitoring.

The North-Eastern region of India is particularly vulnerable, with Guwahati witnessing repeated instances of urban flooding in recent years [8]. While complete prevention of floods may not be feasible, adopting advanced technologies such as IoT and AI can significantly reduce their adverse impacts [9], [10]. IoT networks equipped with real-time sensing and analytics can provide both visual and sensor-based data, thereby enhancing early detection and timely warnings [4], [11].

The remainder of this paper is structured as follows. Section II presents a review of existing literature on IoT-based flood monitoring, machine learning for rainfall prediction, and computer vision approaches for blockage detection. Section III details the proposed methodology, including the study area, overall system architecture, IoT framework design, rainfall prediction framework, and blockage detection pipeline. Section IV discusses the results and experimental evaluations, highlighting both quantitative metrics and qualitative analyses. Section V concludes the paper with key findings and outlines potential directions for future research.

Unlike most existing studies that focus either on rainfall prediction or hydrological monitoring in isolation, this work proposes a holistic urban flood management framework that integrates three critical components: 1) a LoRa-based IoT network for real-time sensing of water levels and meteorological parameters, 2) an edge-deployed rainfall prediction system using machine learning with fuzzy fusion for improved accuracy, and 3) a computer vision–based deep learning approach for detecting blockages in drainage systems. To the best of our knowledge, this is the first research effort tailored to Guwahati city, which combines IoT and AI at both the sensing and infrastructure levels to provide a scalable, low-cost, and real-time flash flood early-warning system.

II. Literature Review

Floods are among the most destructive natural disasters worldwide, responsible for significant economic losses, ecological disruption, and fatalities [18], [19]. In India, their frequency has risen steadily due to climate change, unplanned urbanization, and population pressure [15]–[17]. According to the Global Climate Risk Index 2021, India ranks seventh among the most disaster-prone nations [16]. Between 1990 and 2020, floods accounted for more than half of the country's climate-related disasters [16], affecting millions of people each year.

Urban flooding, unlike traditional riverine floods, results primarily from excessive surface runoff in densely built environments where impermeable surfaces and inadequate drainage limit water absorption [20], [21]. This phenomenon is often described as a "hidden challenge" due to limited data availability and its localized, rapid-onset nature [4]. Unregulated settlement growth, inefficient waste management, and encroachment on natural drainage channels have intensified the vulnerability of Indian cities to flash floods [22]–[24]. Short-lived but high-intensity convective storms can overwhelm urban drainage capacity, leading to sudden waterlogging without prior warning [25]–[30]. Major Indian cities such as Mumbai, Delhi, Chennai, Hyderabad, and Surat have witnessed repeated urban flood events in recent decades, highlighting the growing severity of the problem [7].

The Northeastern Region (NER) is particularly vulnerable, with Guwahati city serving as a stark example. Positioned on the banks of the Brahmaputra River and its tributary, the Bharalu, Guwahati experiences frequent inundation in low-lying localities such as Anil Nagar and Zoo Road. These events are aggravated by rapid urban sprawl, poor drainage maintenance, and intense monsoonal rainfall [31], [8]. Reports describe floodwaters submerging key government establishments such as the State Assembly Secretariat, with some neighborhoods reporting waist-to-neck-deep water levels [8], [32]. Such recurring floods not only cause economic and infrastructural damage but also disrupt essential services and daily life.

Although complete prevention of urban floods is infeasible, their impacts can be mitigated through early-warning systems, efficient drainage monitoring, and integration of modern technologies [9]. Against this backdrop, researchers have explored IoT-based sensing, machine learning, and computer vision as emerging tools for real-time flood detection, prediction, and mitigation. The following sections review existing literature across three domains most relevant to this study: IoT-based flood monitoring frameworks, machine learning for rainfall and flood prediction, and computer vision for blockage detection in urban drainage systems.

A. IoT-Based Approaches for Urban Flood Monitoring

The Internet of Things (IoT) has been recognized as a transformative technology for environmental monitoring and disaster preparedness. By deploying water-level, rainfall, humidity, and flow sensors, IoT frameworks enable continuous, high-resolution data acquisition [4], [10], [11], [33]-[35]. LoRa/LoRaWAN has been widely adopted for its long-range, low-power communication capabilities, making it suitable for flood-prone or low-connectivity areas [36], [37]. Several studies have demonstrated IoT-based systems for flood monitoring and risk mitigation: Arshad et al. [38] emphasized the importance of IoT sensors for evacuation planning; Yang and Chang [39] integrated IoT and ML for regional inundation prediction; Li et al. [40] applied IoT with GIS for subway flood monitoring; Vitry et al. [41] introduced FloodX, combining alternative sensors and computer vision; and Soh et al. [42] developed an IoT-cloud system using image processing for severity assessment. More recently, Samikwa et al. [43] designed lightweight AI algorithms deployable on edge devices like Raspberry Pi.

Complementary to these, Bakhsh et al. [83] developed a flood forecasting model that integrates Wireless Sensor Networks (WSN), GIS, and Artificial Neural Networks (ANN). Their approach demonstrated that WSN-based solutions are not only cost-effective but also suitable for developing countries, though accuracy improvements remain necessary. Extending the scope from monitoring to prevention, Muniandy et al. [89] proposed an IoT-enabled flood prevention system capable of autonomously regulating river water flow and quality through real-time sensor networks. Their framework emphasizes preventive strategies, aligning with the Sustainable Development Goals (SDGs) on water management and climate resilience.

B. Machine Learning for Rainfall and Flood Prediction

Climate change has intensified rainfall variability, significantly increasing the frequency and severity of flash floods worldwide [44]–[58]. This challenge is particularly acute in South Asia, where the Northeast region of India experiences highly erratic precipitation patterns driven by its complex topography and monsoon dynamics. States such as Assam and Meghalaya are especially vulnerable, receiving some of the heaviest rainfall globally and experiencing recurrent flood events that disrupt infrastructure, livelihoods, and ecosystems [50]–[56]. Traditional forecasting approaches based on statistical correlations or hydrological models have made important contributions but often fail to capture the nonlinear, localized, and rapidly evolving dynamics of flash floods. Their reliance on historical datasets with coarse spatial and temporal resolution limits their ability to predict sudden high-intensity rainfall bursts, which are increasingly common under climate change.

Machine learning (ML) has emerged as a promising alternative because of its ability to model complex nonlinear relationships between environmental variables. Early applications in flood prediction applied supervised models such as Random Forests (RF), Support Vector Machines (SVM), and Artificial Neural Networks (ANN), which demonstrated stronger predictive accuracy compared to conventional regression and statistical models [61]–[64]. Ensemble methods have further improved robustness, enabling the integration of multiple weak learners to achieve higher accuracy across diverse geographies. Yang et al. [59] employed ensemble models for summer rainfall prediction in China, while Basha et al. [60] conducted a comparative analysis of deep learning and conventional ML, showing that deep models such as Long Short-Term Memory (LSTM) networks consistently outperformed classical algorithms. Similarly, Anochi et al. [65] applied ML techniques to South America, and Zhang and Ye [66] benchmarked 21 algorithms globally, both studies confirming ML's superiority over general circulation and climatological models in precipitation forecasting.

Recent works have expanded this field by exploring hybrid architectures and intelligent decision-support systems. Ali et al. [86] applied deep learning models—LSTM, Bi-LSTM, and Deep Recurrent Neural Networks (DRNN)—to predict floods in Malaysia. Their results showed that DRNN, enhanced with layer normalization and Leaky ReLU activation, provided the highest predictive accuracy and required less training time compared to LSTM and Bi-LSTM, making it more suitable for real-time applications. Complementing this purely data-driven approach, Marouane [80] introduced a distributed flood early warning framework using Multi-Agent Systems (MAS) and the Anytime Algorithm. By integrating GIS, hydrodynamic, and remote sensing data, this system reduced forecasting response times nearly fivefold, demonstrating the importance of intelligent architectures for real-time disaster management. Similarly, Md Rashid et al. [82] extended MAS-based frameworks by combining them with Case-Based Reasoning (CBR) to develop a Flood Early Warning and Response System (FEWRS). This framework not only improved technical accuracy but also explicitly considered socio-economic, environmental, and governance aspects of flood management, highlighting the need for community-centered resilience strategies.

Taken together, these studies show a clear evolution from statistical and rule-based approaches toward deep learning, hybrid, and agent-based frameworks for rainfall and flood prediction. However, key limitations remain: most ML models still rely on historical or localized datasets that do not fully capture sudden extreme events, computationally intensive deep learning approaches often hinder real-time deployment in resource-limited settings, and socio-technical integration into governance structures is still in its infancy. These gaps point toward the necessity of developing lightweight, real-time AI–IoT systems that combine efficient ML models with sensor-based data acquisition, ultimately ensuring scalable, accurate, and actionable flood prediction for vulnerable regions.

TABLE I. IOT AND ML-BASED APPROACHES FOR FLOOD/RAINFALL PREDICTION (SELECTED WORKS)

Reference #	Methods Used	IoT Device	Accuracy/Results	Key Insights / Limitations
[78]	Neuro-Fuzzy + LSTM + GA	DPS310, DHT22, Rain sensor	92.9% (Hybrid)	Advanced hybrid ML; no field IoT validation.
[77]	BiLSTM, LSTM, ARIMA	Weather sensors	BiLSTM: 92%	Accurate but resource-intensive.
[69]	Logistic Regression	DHT-11	92%	Lightweight, but scalability limited.
[68]	DT, RF, Naïve Bayes	DHT-11, BMP-180	DT: 95%, NB: 83%	Focused accuracy; lacks real-world validation.
[67]	LR, SVM, RF, DT	DHT-11, BMP-180	Up to 95% (DT)	Small-scale IoT testbed.
[71]	LSTM + PSO	NA	94%	Deep learning, computationally heavy.
[70]	MLR, Logistic Regression	Arduino + LM35	~81%	Low-cost but limited accuracy.
[74]	SVM, KNN, ANN, DNN	GPS-enabled IoT devices	ANN: 89%	Integrated sensors; energy concerns.
[73]	KNN, DT, RF, LR	IoT weather station	RF error: 0.083	IoT–ML integration; localized only.
[72]	ANN variants (FFNN, RNN, ENN)	NA	MAE: 0.54 (ENN best)	Neural nets effective; no IoT link.

The works presented in Table I demonstrate the steady evolution of IoT and machine learning applications for flood and rainfall prediction. Early studies primarily relied on simple statistical and regression models [75], but more recent works have shifted towards neural networks, deep learning, and hybrid architectures [77], [78], [76]. Distributed and agent-based frameworks [80], [92] have further advanced the field by improving decision-making and integrating governance

perspectives, while IoT-driven monitoring and prevention solutions [99], [112] highlight the move toward practical, cost-effective deployment. Despite these advances, most frameworks remain constrained to localized datasets, simulation-based validation, or resource-intensive models, underscoring the need for lightweight, field-deployable AI-IoT systems that integrate hydrological sensing with infrastructure monitoring.

C. Computer Vision for Blockage Detection in Urban Drainage Systems

Blockages in culverts and drainage channels are a critical yet underexplored factor in urban flooding, as even well-designed drainage systems can fail when debris accumulation reduces their flow capacity. Unlike hydrological or rainfall-based causes of flooding, blockage issues often arise from localized debris such as vegetation, sediments, plastics, and boulders, which can obstruct culvert inlets or narrow drainage passages. Early investigations by Balkham et al. [79] addressed this problem through a risk-based framework in the United Kingdom, providing local-scale guidelines for blockage management, while Kramer et al. [81] extended this line of work by introducing mathematical models and laboratory-scale experiments to quantify the effects of different debris types and alignments. Although valuable, these approaches were often limited by oversimplification, with restricted applicability to real-world conditions. Field-supported laboratory evidence by Brooks [12] later confirmed that culvert inlets are the primary points of debris deposition, particularly boulders, thereby validating the vulnerability of structural entry points during intense flows.

With the advent of advanced computing, researchers shifted toward AI-driven solutions for blockage assessment. Iqbal et al. [13] proposed computer vision methods using convolutional neural networks (CNNs) to automate blockage classification, testing architectures such as NASNet, MobileNet, and others on real-world and laboratory datasets. Their results demonstrated that NASNet achieved the highest accuracy of around 85%, while MobileNet provided faster inference speeds, making it suitable for near-real-time applications. In a follow-up study, Iqbal et al. [14] extended this work by integrating CNN-extracted features into regression models such as Artificial Neural Networks (ANNs) to predict hydraulic blockage, thereby attempting to link visual blockage data with quantitative hydrological behavior. This represented a significant step forward, as it bridged the gap between visual inspection and hydraulic modeling.

Despite these advances, challenges remain. Computer vision models often struggle with background clutter, varying illumination, occlusion of culvert openings, and the scarcity of high-quality, annotated datasets. Furthermore, most existing approaches have been validated only in laboratory conditions or using limited synthetic datasets, raising concerns about their robustness in complex real-world environments. Another critical gap is the lack of integration between image-based blockage detection systems and IoT sensor networks, which could enable holistic urban flood monitoring by combining hydraulic, meteorological, and infrastructural indicators. Addressing these challenges through the development of scalable, data-rich, and integrated AI–IoT frameworks is essential for achieving reliable and proactive blockage detection in urban flood management.

As shown in Table II, research on blockage detection in culverts and drainage systems has advanced from conceptual risk frameworks [79], [81] to AI-driven visual recognition methods [13], [14]. More recent contributions employ deep learning pipelines, including segmentation-classification approaches and semantic segmentation architectures such as SHARP-Net. Despite notable improvements in accuracy, most of these studies remain limited to controlled laboratory experiments or narrowly scoped datasets (e.g. ICOB, VHD, S-BIRD). Real-world deployment challenges—including background clutter, occlusions, lighting variability, and lack of integration with IoT sensor networks—remain largely unresolved. These limitations highlight a critical research gap: the need for a scalable and integrated system that combines IoT-based sensing with image-based blockage detection for comprehensive urban flood monitoring.

TABLE II. COMPUTER VISION AND ML APPROACHES FOR BLOCKAGE DETECTION (SELECTED WORKS)

Reference #	Methods Used	Dataset	Accuracy/Results	Key Insights / Limitations
[86]	SHARP-Net (semantic segmentation)	Culvert-Sewer, DeepGlobe	IoU: 94.7%	Struggles under occlusion.
[87]	Siamese NN + Binary classifier	80k UK trash screen images	Acc: 91%, AUC: 0.98	Needs hydro model integration.
[88]	Logistic Regression	Trash screen CCTV	88%	Dataset bias (80% blocked).
[85]	YOLOv5	S-BIRD sewer dataset	mAP 96.3%	Sewer-focused, not culverts.
[84]	KNN, ANN, SVR, 1D-CNN	HBD dataset	ANN: $R^2 = 0.95$	Strong prediction; lab-scale only.
[14]	ANN + MobileNet features	Lab culvert dataset	$R^2 = 0.7855$	Weak link visual ↔ hydraulic.
[13]	CNNs (NASNet, MobileNet, etc.)	ICOB, VHD, SIC	NASNet: 85%, MobileNet: 78%	Clutter & labeling issues.
[12]	Lab + field blockage study	Culvert inlet models	Inlets = primary deposition	Focused only on boulders.
[81]	Mathematical model + experiments	Lab culvert debris tests	Showed debris type/alignment effects	Simplified; lacked real-world validation.
[79]	Risk-based blockage framework	Field data (UK culverts)	Guidelines for blockage mgmt.	Early risk framework; no automation.

III. Proposed Methodology

A. Study Area

The study was conducted in Anil Nagar and Zoo Road localities of Guwahati City, Assam, India, one of the most flood-prone urban centers in Northeast India. Guwahati lies along the Bharalu River, a tributary of the Brahmaputra, and experiences a humid subtropical climate with intense monsoonal rainfall (June–September). Anil Nagar, a densely populated residential and commercial zone with low-lying terrain, frequently suffers from flash floods due to inadequate drainage and rapid urbanization. Heavy rainfall causes sharp rises in water levels, leading to recurrent inundation, waterlogging, and economic losses. For this study, a pilot area in Kamrup Metropolitan District was selected to test the proposed IoT- and vision-based flood monitoring system. The selected sites are shown in Fig. 1.

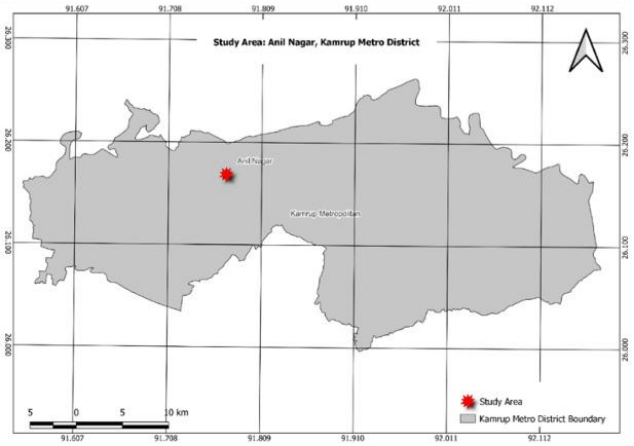

Fig. 1. Study area map: Anil Nagar in Kamrup Metro District.

B. Overall Architecture

The overall process flow of the proposed methodology is illustrated in Fig. 2. The framework integrates IoT-based sensing, machine learning-driven rainfall prediction, and computer vision-based blockage detection into a unified flood monitoring and early warning system.

A LoRa-based IoT network was deployed across the study area using two types of devices—water sensing nodes and base stations. Water sensing nodes monitor drainage water levels, while base stations collect meteorological parameters such as rainfall, temperature, and air pressure. These devices transmit real-time data wirelessly for further processing.

The acquired IoT data, along with historical datasets from external APIs, are pre-processed and analyzed using multiple machine learning algorithms for rainfall prediction. Their outputs are refined through a fuzzy logic-based fusion framework, which demonstrated superior accuracy compared to individual classifiers. By executing these tasks at the edge, the system achieves low latency, improved reliability, and reduced dependence on cloud-only computation.

At the cloud layer, images of strategic canal locations where blockages are most likely to occur are captured and uploaded by users through the mobile application. The system incorporates geofencing, which triggers an alert when users enter blockage-prone zones, prompting them to capture and submit images. Importantly, this process is designed to occur before flood events so that blockages can be identified proactively when rainfall is predicted, thereby minimizing reliance on user activity during emergencies. Once uploaded, these images are processed on the server using computer vision-based deep learning models to detect and classify blockages. By integrating blockage detection results with rainfall forecasts and IoT-based monitoring data, the cloud layer enables a comprehensive flash flood prediction and early warning system for the selected localities.

Finally, the mobile application and web dashboard provide stakeholders with real-time visualizations, alerts, and decision-support tools. The app displays live water levels, rainfall forecasts, and blockage alerts, while also offering geofencing-based warnings and safe-route suggestions. The dashboard aggregates all information, ensuring that authorities and citizens have timely access to actionable flood intelligence.

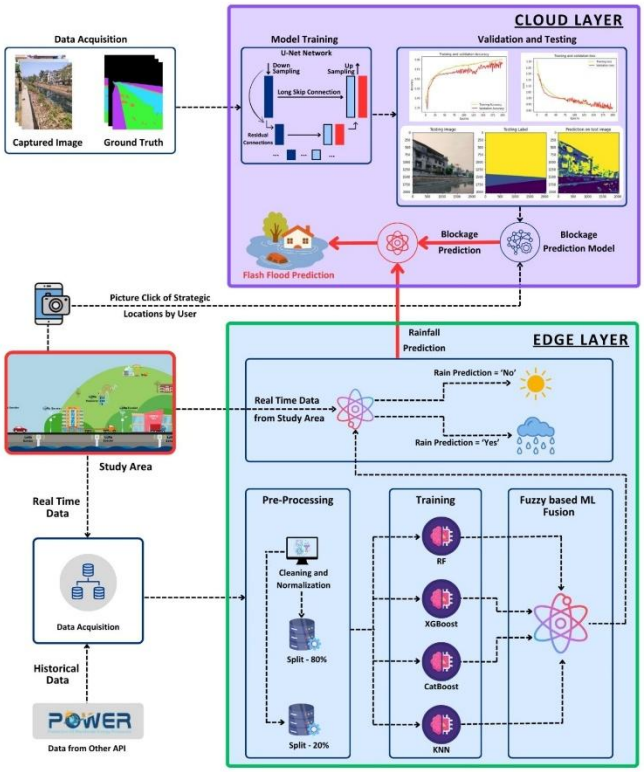

Fig. 2. Overall architecture of the proposed work.

C. IoT Framework and Hardware Design

The IoT framework was designed to provide real-time monitoring of drainage water levels and meteorological parameters within the study area. The system comprises two main devices: water sensing nodes and base stations.

The water sensing nodes are compact instruments deployed along roadside drains and low-lying urban locations to detect potential flash flood events. Each node is equipped with a contact-type water level sensor, enclosed within PVC pipes positioned 200 cm apart for accurate depth measurements. To enable reliable communication in flood-prone environments, the nodes employ LoRa transceivers, which facilitate real-time data

transmission across long ranges. Unlike conventional IoT devices dependent on internet access, this system remains operational even during disasters when internet connectivity is disrupted, thereby ensuring uninterrupted flood monitoring. Designed for autonomous operation, the nodes are powered by rechargeable battery packs integrated with solar panels, eliminating dependence on conventional power supplies. This ensures continuous functionality even during prolonged power outages, often associated with flood scenarios.

The base stations, developed using Raspberry Pi 4 boards, serve as gateways for aggregating data from multiple sensing nodes. In addition to LoRa receivers, they are equipped with BMP180 pressure sensors, tipping rain gauges, anemometers, and temperature–humidity sensors, enabling on-site weather monitoring. These parameters were purposely included because relying solely on weather APIs can be misleading, as such services typically provide averaged values over large geographic areas. In reality, micro-climatic variations in parameters such as rainfall, wind speed, and humidity can occur within ranges as small as 4–5 km. For flash flood predictions, localized rainfall data is particularly critical, since heavy rainfall may occur in one neighborhood while an adjacent area just 2 km away remains unaffected. The incorporation of direct measurements at the base stations, therefore, ensures high-resolution, site-specific meteorological data, significantly improving the accuracy of the overall flood monitoring and prediction system.

This hardware architecture, integrating low-power LoRa communication with solar-powered autonomy and localized weather sensing, establishes a scalable, resilient, and energy-efficient flood monitoring system suitable for deployment in vulnerable urban environments. Fig. 3 illustrates the deployment of IoT sensors in the study area, showing the placement of water sensing nodes and base stations across critical flood-prone locations.

Fig. 3. Deployment of nodes and base stations.

D. Edge-Based Rainfall Prediction Using Machine Learning Fusion

Accurate rainfall prediction is essential for flash flood forecasting, as localized precipitation patterns often determine the severity of inundation. In this study, rainfall prediction was developed by integrating historical meteorological datasets with real-time IoT sensor data collected from the deployed framework in the study area. Ten years of historical data were obtained from the Indian Meteorological Department (IMD) and the NASA POWER database, covering rainfall, temperature, humidity, and pressure parameters. These datasets were merged with on-site measurements from IoT base stations to provide both temporal depth and spatial specificity, addressing limitations of weather APIs that only provide coarse, area-wide averages. As the IoT base stations continue to record location-specific data, the dataset will grow continuously, enabling future retraining of the models. This evolving dataset is expected to improve predictive accuracy and adaptability, including unprecedented rainfall patterns that may arise due to climate change.

The complete dataset comprised 91,991 instances with seven features (six independent variables and one dependent variable). Pre-processing involved three major steps: 1) cleaning, where missing values were handled using mean imputation; 2) normalization, which standardized feature ranges; and 3) splitting, where the dataset was divided into training and testing subsets in an 80:20 ratio. These steps enhanced the classifiers' ability to learn effectively and minimized bias.

Four machine learning algorithms were evaluated for rainfall prediction: Random Forest (RF), Extreme Gradient Boosting (XGBoost), Categorical Boosting (CatBoost), and K-Nearest Neighbors (KNN). These models were iteratively optimized during both training and testing to capture the nonlinear and multivariate patterns of rainfall events. To further improve reliability, the outputs from individual classifiers were passed through a fuzzy logic-based fusion framework. Rather than assigning rainfall into discrete categories, the fuzzy layer refines the combined outputs of multiple models to increase prediction probability and confidence. A decision matrix (Table III) was designed to integrate model outputs into a unified outcome.

TABLE III. INPUT INTO THE FUZZY LAYER FOR THE PROPOSED MODEL

A key feature of this work is that the machine learning models and the fuzzy fusion framework were deployed on Raspberry Pi devices at the edge layer. This deployment enables on-site rainfall prediction with low latency, reducing

dependence on cloud servers and ensuring functionality even in disaster scenarios where internet connectivity may be disrupted. Edge-level prediction thus allows the system to provide faster and more reliable early warnings, an essential requirement for flash flood-prone urban environments. Moreover, the architecture has been designed in a modular manner, allowing additional nodes, base stations, or processing units to be integrated seamlessly. This modularity supports future scalability to larger urban areas or more complex drainage networks without fundamentally altering the core framework, thereby making the system adaptable for broader deployment.

The experimental results demonstrated that the fuzzy fusion model consistently outperformed standalone classifiers, producing more stable and accurate rainfall forecasts while reducing false positives. As illustrated in Fig. 4, by combining IoT-based observations, historical meteorological records, and intelligent fusion of multiple classifiers at the edge, this rainfall prediction module forms a critical component of the proposed framework, directly supporting an integrated flash flood early warning system for Guwahati's vulnerable localities.

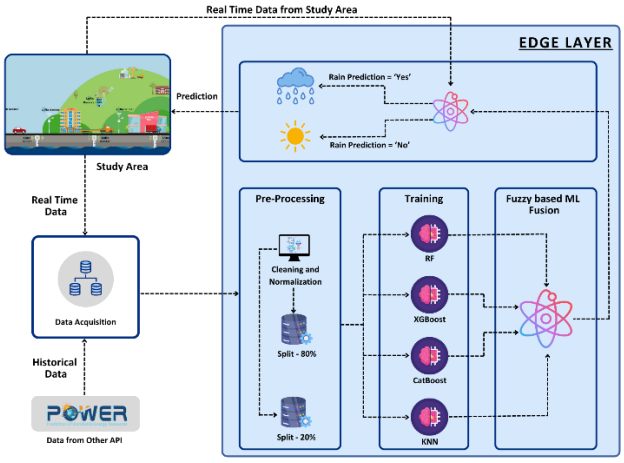

Fig. 4. Workflow of the rainfall prediction framework integrating IoT data and historical meteorological datasets. The figure illustrates data pre-processing, machine learning classification (RF, XGBoost, CatBoost, KNN), and fuzzy logic-based fusion, all deployed on Raspberry Pi devices at the edge layer to enable real-time, low-latency rainfall prediction and early warning.

E. Computer Vision–Based Blockage Detection

Blockages in urban drainage canals significantly reduce hydraulic capacity and are among the leading causes of flash flooding in Guwahati. To address this, a computer vision-based blockage detection module was developed and integrated into the proposed framework. A custom dataset comprising 1,130 high-resolution images of drainage canals and outlets was collected from strategic locations within the Anil Nagar and Zoo Road localities. Images were captured using smartphone cameras (Realme 9 Pro 5G) under varying lighting and environmental conditions to represent real-world variability. Each image, originally sized at 3468 × 4624 pixels, was resized to 1920 × 2560 pixels and then divided into non-overlapping patches of 512 × 512 pixels, yielding a total of 16,950 samples for training and evaluation. The dataset was annotated using the CVAT (Computer Vision Annotation Tool), where each patch was manually segmented into four classes (Table IV):

TABLE IV. SEGMENTATION CLASS LABLES

Sl. No.	Class	Color Labels
1	Water	#33DDFF
2	Boundary	#B83DF5
3	Blockage	#FF6A4D
4	Background	#000000

The careful assignment of these classes ensured that canal regions, potential obstruction zones, and their surroundings were distinctly represented, enabling the model to effectively learn spatial differences between clear flow areas and blocked sections. Fig. 5 shows sample annotated images, where the original canal image is placed on the left and the corresponding segmentation mask on the right, highlighting the four defined classes.

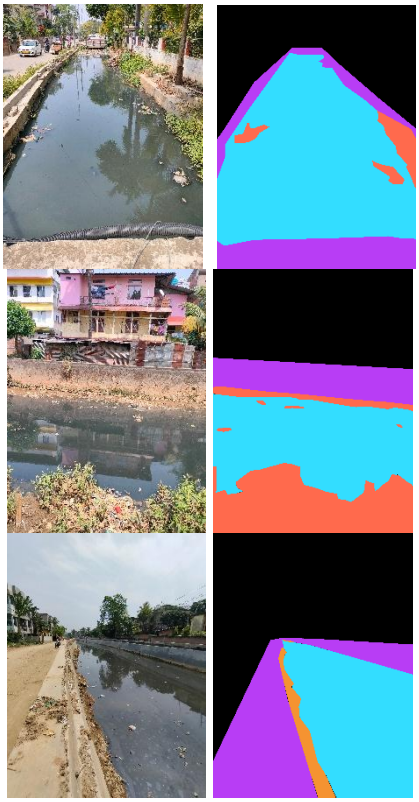

Fig. 5. Sample dataset images with annotations. Left: original canal images. Right: annotated segmentation masks showing four classes (Water, Boundary, Blockage, Background).

The original images were captured at a high resolution of 3468 × 4624 pixels. Due to computational resource limitations, they were first resized to 1920 × 2560 pixels and subsequently divided into patches of 512 × 512 pixels, producing a total of 16,950 samples. This approach preserved greater global context compared to lower-resolution alternatives, while ensuring manageable input sizes for the models. The resulting patches were normalized and augmented using random rotation, brightness adjustment, flipping, and noise injection. The dataset was then split into 70% training, 15% validation, and 15% testing subsets.

For segmentation, four deep learning models were trained and evaluated to identify blockages: a U-Net with EfficientNetB0 backbone, a U-Net with ResNet50 backbone, a U-Net with InceptionV3 backbone, and a U-Net with MobileNetV2 backbone. The U-Net framework was selected for its strong performance in semantic segmentation, while the different backbones were used to investigate trade-offs in feature representation, computational efficiency, and accuracy. All models were trained under identical conditions to ensure fair comparison.

As shown in Fig. 6, the encoder backbone incorporates MBConv blocks, where each block first expands the number of channels using 1×1 convolutions, denoted as Ex(.) in Eq. (3). This is followed by a Depthwise Convolution D(.) and refinement using a Squeeze-and-Excitation attention module Se(.). Finally, another set of 1×1 convolutions, represented as Cn(.), compresses the channel count back, forming the well-known "inverted bottleneck" structure. Residual connections are integrated to improve gradient propagation and training stability.

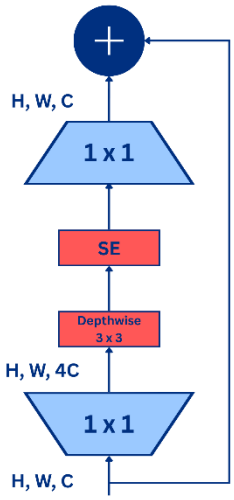

Fig. 6. Illustration of the MBConv block and skip connection mechanism used in the encoder–decoder of U-Net backbones.

The decoder mirrors this design, with upsampling operations that reconnect to the encoder via skip connections. Eq. (3) and (4) describe the feature propagation in the encoder and decoder stages. Here, X_{En}^{i} denotes the feature map produced by the i^{th} MBConv encoder block, while X_{De}^{j} and X_{En}^{j} represent the feature maps from the j^{th} decoder and encoder blocks, respectively. Skip connections are combined using the CBAR(.) function, which merges the encoder's feature map with the upsampled feature map from the preceding decoder block. The merged output is then processed through a 3×3 convolution (C3×3(.)), batch normalization (BN(.)), an activation function δ(.), and a residual connection, as expressed in Eq. (5). This design ensures better gradient flow, higher feature reuse, and robust segmentation performance.

All models were implemented in TensorFlow 2.10 and trained using an Nvidia RTX 3080 GPU (10,496 CUDA cores, 10GB GDDR6X memory). Training was performed for 100 epochs with a batch size of 16, using the Nadam optimizer (learning rate = 0.001). A hybrid loss function combining Dice Loss and Focal Loss was applied to maximize segmentation overlap and address class imbalance.

Once deployed on the cloud server, the trained models process geotagged images uploaded via the mobile application. When a user enters a geofenced high-risk drainage zone, the application prompts them to capture and submit canal images. The models then classify the canal as "blocked" or "clear". Hosting the computer vision models on the cloud ensures not only centralized processing but also inherent scalability, as elastic computing resources can accommodate larger datasets and concurrent image submissions from wider geographical areas. The comparative performance of the four segmentation approaches is presented in the Results and Discussion section.

$$X_{En}^{i} = Cn\left(Se\left(D\left(Ex\left(X_{En}^{i-1}\right)\right)\right)\right) + X_{En}^{i-1} \quad (1)$$

$$X_{De}^{j} = CBAR\left(concat\left(X_{En}^{j}, U\left(X_{De}^{j-1}\right)\right)\right) \quad (2)$$

$$CBAR(X) = \delta(BN(C_{3X3}(X)) + X \quad (3)$$

IV. Results and Discussion

A. IoT Deployment and Field Validation

The proposed IoT framework was deployed in Anil Nagar and Zoo Road localities of Guwahati, with 10 water sensing nodes and 2 base stations strategically placed along drainage channels and flood-prone areas. Each water sensing node was equipped with LoRa transceivers and solar-powered batteries, while the base stations collected supplementary meteorological parameters, including rainfall, temperature, humidity, and wind speed.

To ensure real-world practicality, the proposed framework employs solar-powered sensing nodes equipped with 7500 mAh lithium-ion battery packs that are continuously recharged during the day by integrated solar panels. This design ensures uninterrupted operation even during prolonged cloudy or rainy conditions, thereby addressing energy constraints often faced by IoT systems. Coupled with low-power LoRa communication modules, the nodes achieve efficient energy usage and reliable data transmission. The hardware requirements remain modest, with commodity sensors and Raspberry Pi-based edge nodes keeping costs affordable for larger deployments. The modular architecture further supports integration of heterogeneous devices, enabling scalability in dense urban environments. Fault tolerance and data reliability are enhanced through redundant data logging at both node and base-station levels, ensuring continuity of operations even in cases of sensor malfunction or communication disruptions.

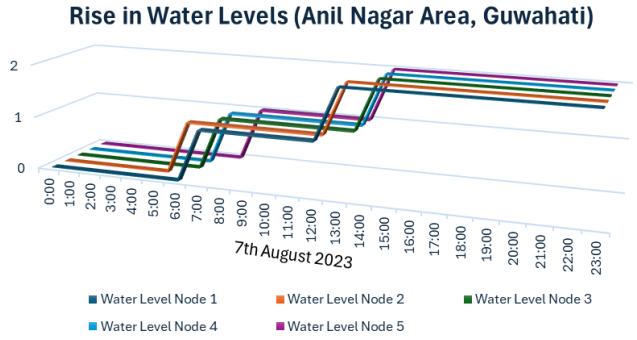
To validate the field data, real-time sensor outputs were compared with the NASA POWER API and Indian Meteorological Department datasets. The results showed a high degree of consistency, with local rainfall measurements aligning closely with API estimates but offering finer spatial granularity. This confirmed that localized sensors captured micro-climatic variations more effectively than coarse-resolution APIs, a critical factor for flash flood prediction in Guwahati, where rainfall can vary significantly within 2–3 km.

A representative comparison between IoT-based rainfall measurements and NASA POWER API values for a sample week in July 2023 is presented in Table V. The results highlight that IoT sensors captured short-duration rainfall bursts and localized variations which were not fully reflected in API data, demonstrating the added value of in-situ measurements for urban flood forecasting.

TABLE V. VALIDATION OF SENSOR DATA FROM THE ZOO ROAD BASE STATION AGAINST NASA POWER API VALUES (10–16 JULY 2023)

Date	IoT Sensor Rainfall (mm)	NASA POWER API (mm)	Difference (mm)
10-Jul-23	54.2	52.8	1.4
11-Jul-23	12.6	11.9	0.7
12-Jul-23	0	0	0
13-Jul-23	38.7	40.1	–1.4
14-Jul-23	22.1	23.3	–1.2
15-Jul-23	5.8	6.4	–0.6
16-Jul-23	47.5	46.2	1.3

During the 2023 monsoon season, the deployed network successfully detected rapid increases in water levels along the Bharalu tributary, providing early indications of waterlogging in Anil Nagar. As illustrated in Fig. 7, the water sensing nodes captured a clear rise in drainage levels, validating the effectiveness of the deployed sensors. These results demonstrate the reliability of the IoT network for continuous monitoring, even under adverse weather conditions, and its capacity to generate high-resolution hydrological datasets essential for predictive modeling.



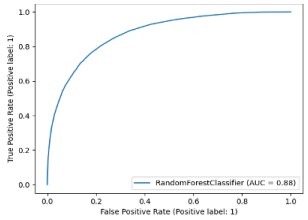


Fig. 7. Rise in water levels as depicted by the water sensing nodes

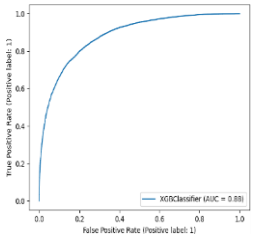
B. Rainfall Prediction Performance

The time series data of weather parameters were analyzed for the development of the rainfall prediction system. Datasets were obtained from the Indian Meteorological Department (two years) and NASA POWER (ten years) for Guwahati city. Several classification algorithms, including Random Forest (RF), XGBoost, CatBoost, and K-Nearest Neighbors (KNN), were tested to evaluate their predictive performance.

During the testing phase, the Random Forest (RF) model correctly classified 8094 out of 9261 negative instances and 8213 out of 9138 positive instances, yielding an accuracy of 88.6% with a miss rate of 11.4%. The comparison between expected and actual outcomes is shown in Fig. 8. The XGBoost model produced similar results, with 8103 negatives and 8134 positives classified correctly, corresponding to an accuracy of 88.2% and an 11.8% miss rate, as illustrated in Fig 9. In comparison, CatBoost achieved the best standalone performance, predicting 8241 negatives and 8231 positives, resulting in an accuracy of 89.5% and a 10.5% miss rate, as shown in Fig 10. By contrast, the KNN model exhibited weaker performance, with 7213 negatives and 7311 positives correctly classified, yielding 78.9% accuracy and a 21.1% miss rate, as depicted in Fig. 11.

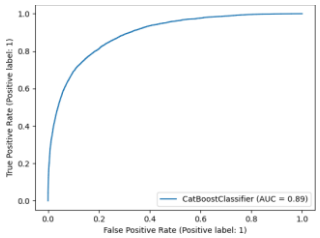


RF Testing Results

No. of samples		N= 18399	
	Expected Result (E)	Output Result (O)	
		O-Negative	O-Positive
Input	E-Negative 9261	8094	1167
	E-Positive 9138	925	8213

Accuracy=	0.886298168
Miss Rate=	0.113701832

Fig. 8. Statistical analysis for the random forest model



XGBoost Testing Results

No. of samples		N= 18399	
	Expected Result (E)	Output Result (O)	
		O-Negative	O-Positive
INPUT	E-Negative 9261	8103	1158
	E-Positive 9138	1004	8134

Accuracy=	0.882493614
Miss Rate=	0.117506386

Proposed Fusion model Testing Results

No. of samples		N= 18399	
	Expected Result (E)	Output Result (O)	
		O-Negative	O-Positive
INPUT	E-Negative 9261	8347	914
	E-Positive 9138	486	8652

Accuracy=	0.923908908
Miss Rate=	0.076091092

Fig. 12. Statistical analysis for the proposed fusion model

Subsequently, the outputs of all classifiers were integrated using the proposed fuzzy fusion framework. This system processed the test data by considering actual class labels alongside predictions from individual classifiers. The fuzzy model identified 8347 negatives (out of 9216) and 8652 positives (out of 9138), achieving an overall accuracy of 92.4% with a miss rate of 7.6%, as illustrated in Fig. 12. This demonstrates the advantage of the fusion approach in reducing false classifications and improving robustness compared to standalone models.

A detailed summary of training and testing results across all models, along with the fuzzy fusion framework, is presented in Table VI. Notably, the fused system consistently outperformed the four individual classifiers, confirming its effectiveness in rainfall prediction. Furthermore, Table VI also includes a comparative evaluation against previously reported rainfall prediction approaches, highlighting the superior accuracy and reduced miss rate of the proposed methodology.

TABLE VI. COMPARISON OF MACHINE LEARNING MODELS AND FUZZY FUSION FRAMEWORK FOR RAINFALL PREDICTION

Model	Accuracy (%)	Miss Rate	Remarks
Random Forest (RF)	88.6	0.14	Strong generalization, moderate error rate
XGBoost	88.2	0.12	Effective but prone to overfitting with small samples
CatBoost	89.5	0.1	Best standalone classifier
KNN	78.9	0.21	Sensitive to noise, weakest performance
Fuzzy Fusion	92.4	0.08	Highest accuracy, reduced false predictions

C. Blockage Detection via Deep Learning

The efficacy of various deep learning architectures was evaluated for the task of blockage detection in canal networks. Four models, like U-Net with EfficientNetB0 backbone, U-Net with ResNet50 backbone, U-Net with InceptionV3 backbone, and U-Net with MobileNetV2 backbone were trained and tested on a dataset of 1,130 high-resolution images (3468 × 4624 pixels) annotated into blockage and non-blockage classes. To address computational constraints and increase the effective dataset size, the images were resized to 1920 × 2560 pixels and divided into non-overlapping 512 × 512 patches, resulting in 16,950 samples. These patches were normalized and augmented to enhance robustness and variability. Model training was conducted in a high-performance GPU environment (NVIDIA RTX 3080), enabling efficient parallel computation and accelerated convergence. The performance of the models was evaluated using standard metrics, including Jaccard's coefficient (IoU), mean Intersection-over-Union (mIoU), Dice coefficient, pixel accuracy, precision, and error rate. The U-Net with EfficientNetB0 backbone achieved the best results, with a pixel-wise accuracy of 91%, Dice score of 86%, and mIoU of 78%. This superior performance can be attributed to EfficientNet's inverted bottleneck blocks and squeeze-and-excitation modules, which provided effective feature extraction while retaining spatial details through U-Net's skip connections. The combination allowed the model to segment small or irregular blockages with higher precision than other backbones.

$$\text{IoU} = \frac{TP}{TP+FP+FN} \tag{4}$$

$$\text{mean IoU} = \frac{1}{N}\sum_{i=1}^{N}\frac{TP_i}{TP_i+FP_i+FN_i} \tag{5}$$

$$\text{Dice} = \frac{2 \cdot TP}{2 \cdot TP+FP+FN} \tag{6}$$

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \tag{7}$$

$$\text{Error Rate} = \frac{FP+FN}{TP+TN+FP+FN} \tag{8}$$

The terms TP, TN, FP, and FN represent true positive, true negative, false positive, and false negative, respectively, and are fundamental in understanding the performance of classification models.

The ResNet50 backbone ranked second, with an accuracy of 85%. Its deep residual connections supported robust feature extraction and strong generalization, but the absence of symmetric skip connections in its native architecture limited precise boundary reconstruction. InceptionV3 achieved 72% accuracy, leveraging multi-scale convolutional kernels for contextual understanding but failing to produce sharp pixel-wise predictions due to the lack of a dense decoder path. At the lower end, MobileNetV2 achieved only 65% accuracy, reflecting its limited representational power as a lightweight architecture optimized for efficiency rather than dense segmentation.

Dataset characteristics also influenced performance. The modest dataset size (1130 images) and class imbalance, where blockage pixels formed only a small fraction of each image, caused models to be biased toward background predictions. Manual annotations introduced additional variability, particularly in ambiguous regions such as shadows or partially submerged debris. While EfficientNetB0-U-Net was relatively robust to such noise, MobileNetV2 and InceptionV3 were more affected. Resizing high-resolution images to 512 × 512 patches also led to loss of fine details, reducing the ability of weaker backbones to detect small debris.

TABLE VII. COMPARATIVE ANALYSIS OF EXISTING CLASSIFICATION MODELS WITH THE SEGMENTATION-BASED MODELS

Model	Pixel Accuracy	Mean IOU	Dice Coefficient	Precision	Recall
MobileNetV2	65%	40%	55%	58%	52%
InceptionV3	72%	50%	63%	65%	60%
ResNet-50	85%	68%	78%	80%	75%
EffecientNetB0	**91%**	**78%**	**86%**	**88%**	**85%**

Training and validation accuracy curves over 100 epochs (Fig. 13) show that the EfficientNetB0-U-Net achieved smooth convergence, with training accuracy reaching ~93% and validation accuracy ~90%, indicating minimal overfitting. ResNet50 also demonstrated stable learning, converging around 87% training accuracy and 84% validation accuracy. InceptionV3 showed slower convergence, plateauing at ~73% training accuracy and ~70% validation accuracy, while MobileNetV2 displayed severe overfitting, with training accuracy climbing to ~66% but validation accuracy stagnating at ~30%. These trends are further supported by the comparative results summarized in Table VII, which highlight the superior performance of EfficientNetB0-U-Net over the other backbones.

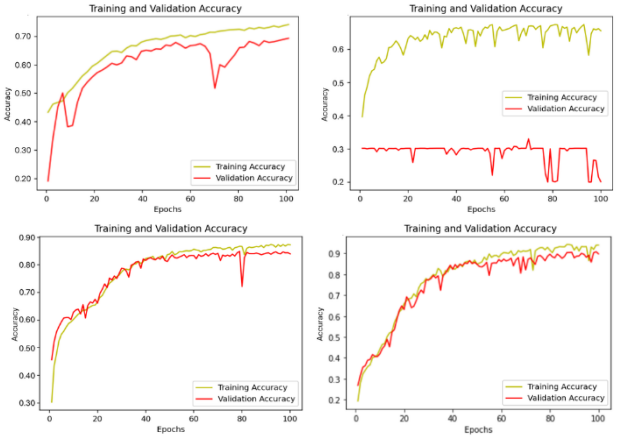

Fig. 13. Training and validation accuracy curves over 100 epochs for the four models: Top Left – MobileNetV2-U-Net; Top Right – InceptionV3-U-Net; Bottom Left – ResNet50-U-Net; Bottom Right – EfficientNetB0-U-Net

Loss curves: Fig. 14 further confirms these observations. EfficientNetB0-U-Net and ResNet50 showed steadily declining training and validation loss with minimal divergence, reflecting robust learning. InceptionV3's validation loss exhibited early instability with sharp spikes before stabilizing, while MobileNetV2 showed highly erratic validation loss throughout, indicating poor generalization.

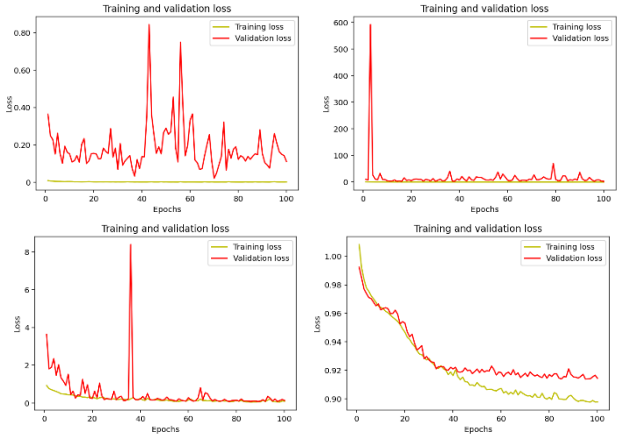

Fig. 14. Training and validation Loss curves over 100 epochs for the four models: Top Left – MobileNetV2-U-Net; Top Right – InceptionV3-U-Net; Bottom Left – ResNet50-U-Net; Bottom Right – EfficientNetB0-U-Net

Sample qualitative outputs (Fig. 15–18) further reinforce the quantitative findings. To examine model performance under different conditions, three representative test images were chosen, corresponding to low, moderate, and high blockage levels. Predictions were then generated using four models—MobileNetV2-U-Net (Fig. 15), InceptionV3-U-Net (Fig. 16), ResNet50-U-Net (Fig. 17), and EfficientNetB0-U-Net (Fig. 18)—and compared against their respective ground truth masks.

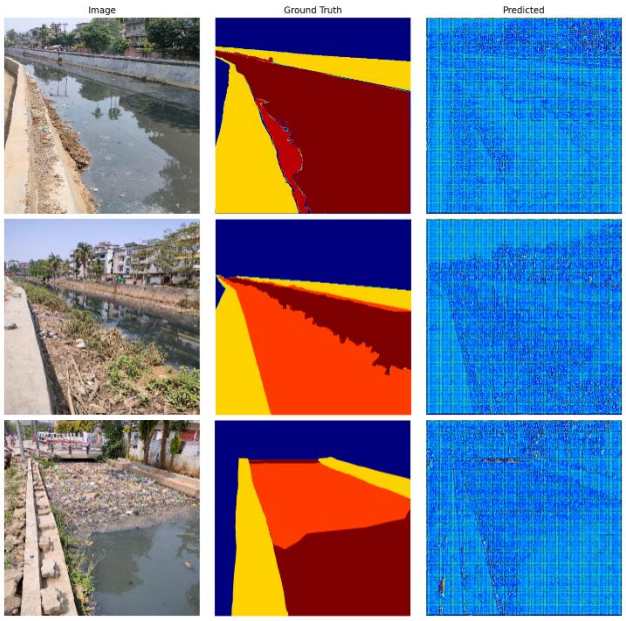

Fig. 15. Predicted segmentation outputs using MobileNetV2-U-Net. Top: low blockage; Middle: moderate blockage; Bottom: high blockage, shown alongside ground truth masks.

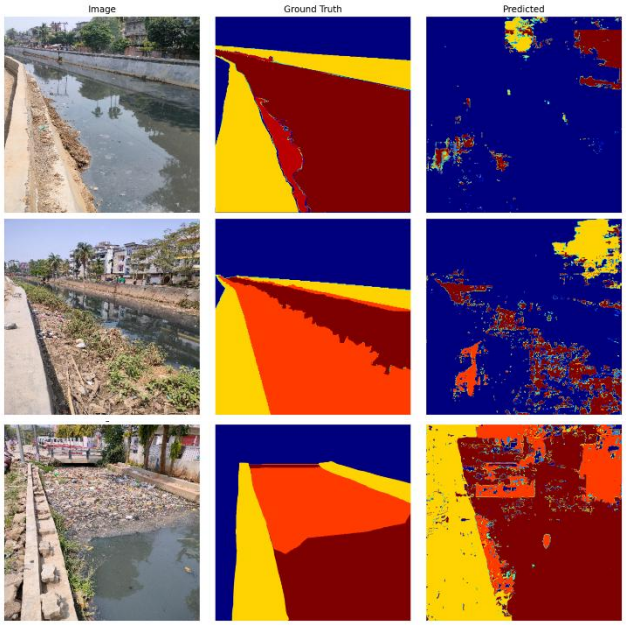

Fig. 16. Predicted segmentation outputs using InceptionV3-U-Net. Top: low blockage; Middle: moderate blockage; Bottom: high blockage, shown alongside ground truth masks.

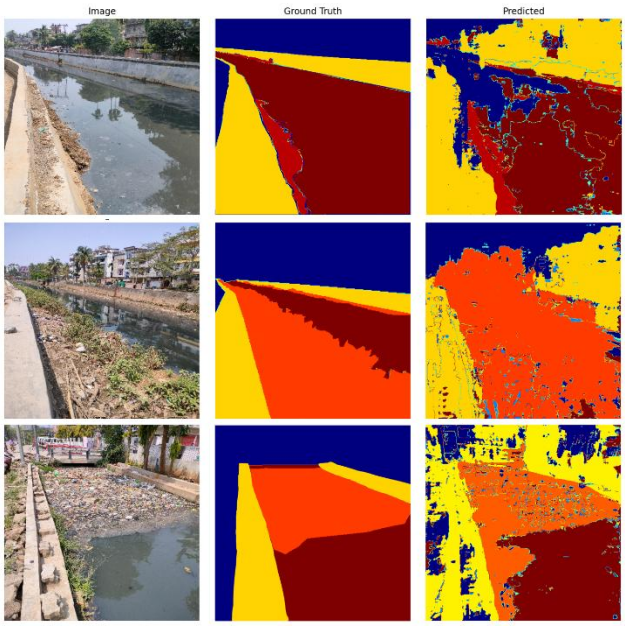

Fig. 17. Predicted segmentation outputs using ResNet50-U-Net. Top: low blockage; Middle: moderate blockage; Bottom: high blockage, shown alongside ground truth masks.

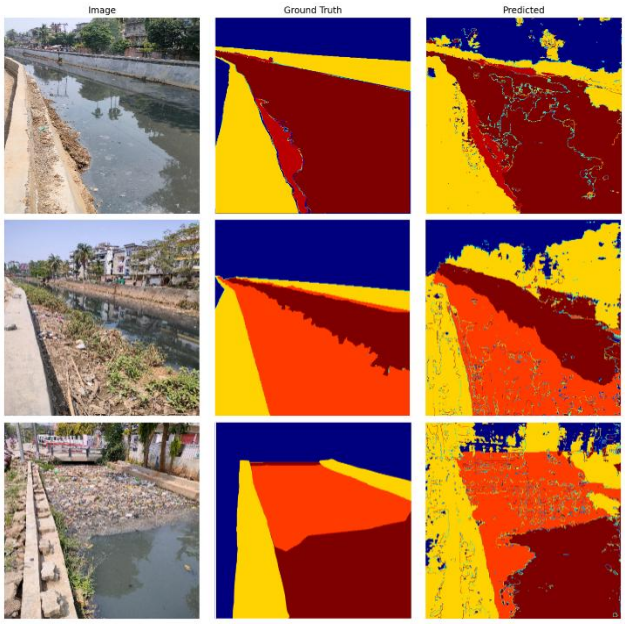

Fig. 18. Predicted segmentation outputs using EfficientNetB0-U-Net. Top: low blockage; Middle: moderate blockage; Bottom: high blockage, shown alongside ground truth masks.

Among these, EfficientNetB0-U-Net consistently produced segmentation maps that most closely resembled the ground truth. It excelled at detecting small debris, partial blockages, and irregular boundary regions, which are often the most challenging to segment in real-world canal imagery. This effectiveness can be attributed to the synergy of EfficientNet's inverted bottleneck blocks with U-Net's skip connections, which preserved fine spatial details while also capturing high-level contextual features. The ResNet50-U-Net also performed strongly, especially in delineating larger blockage regions and textured surfaces. However, its predictions often showed less precise boundaries, with minor leakage into canal walls or surrounding vegetation. InceptionV3-U-Net, by contrast, generated noticeably coarser maps, often blurring blockage boundaries and underestimating severity when debris overlapped with shadows or reflections. These limitations highlight the advantage of EfficientNetB0-U-Net for this task.

The weakest results were observed with MobileNetV2-U-Net, which frequently misclassified debris and garbage as background. While the architecture is computationally efficient and well-suited for edge devices, its reduced representational power significantly limited its performance in this task. Segmentation maps were often incomplete, failing to highlight subtle obstructions, and in many cases, the model ignored partially submerged or fine-structured debris entirely. This outcome underscores the trade-off between efficiency and accuracy: while MobileNetV2 is attractive for deployment in low-resource environments, it is not well-suited for applications requiring precise spatial resolution.

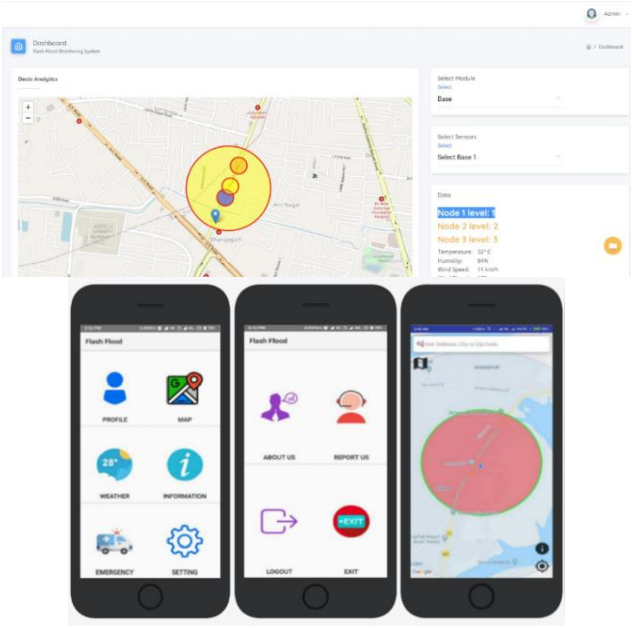

Fig. 19. Centralized dashboard (top) displaying sensor data, rainfall predictions, and visualizations, and mobile application (bottom) showing flooded areas, and emergency alerts.

A centralized dashboard and companion mobile application were developed to strengthen integration with existing flood management practices, as illustrated in Fig. 19 (dashboard at the top and mobile app at the bottom). The dashboard provides two modules: Node, showing individual sensor data, and Base Station, displaying aggregated meteorological parameters and water levels along with insights into potential flash flood events. Interactive visualizations, including a meteogram and a daily water level graph, further support decision-making. Complementing this, the mobile app integrates Google Maps to mark flooded zones, suggest alternate safe routes, and deliver emergency alerts, weather updates, and user reporting services. Together, these tools ensure that the predictive outputs of the framework can be translated into actionable information for both authorities and the community, thereby addressing the challenge

of integrating novel technologies with real-world flood management infrastructure.

V. Conclusion and Future Works

This research presented a comprehensive framework for urban flood monitoring and prediction, integrating IoT sensing, edge-based machine learning, and computer vision techniques. The system was deployed and validated in flood-prone localities of Guwahati, Assam (Anil Nagar and Zoo Road), demonstrating its ability to provide real-time rainfall forecasting, drainage monitoring, and blockage detection. The LoRa-based IoT network ensured reliable data transmission even in disaster scenarios, while the edge-deployed machine learning models, enhanced with fuzzy fusion, achieved higher prediction accuracy compared to standalone classifiers. Additionally, the use of deep learning–based semantic segmentation models enabled effective identification of blockages in drainage systems, a critical but often overlooked factor in urban flooding.

The results confirmed that the EfficientNetB0-U-Net outperformed other backbones for blockage detection, while the fuzzy fusion framework consistently improved rainfall prediction reliability. Together, these contributions advance the state of real-time, low-cost, and scalable flood monitoring systems, offering a practical tool for urban disaster preparedness in data-scarce and resource-constrained environments.

Despite these advances, several limitations remain. The dataset size for blockage detection was modest, and environmental variability (lighting, occlusion, and reflections) posed challenges to generalization. Rainfall prediction relied partly on historical datasets, which may not fully capture extreme short-duration rainfall events. Furthermore, integration of IoT networks with governance and community-level decision-making remains limited.

Although the system showed promising results, there is scope for further improvement and extension in future research.

- Expanding datasets through larger-scale image collection campaigns and crowdsourced contributions to improve the robustness of blockage detection models.
- Enhancing model generalization using advanced data augmentation, transfer learning, and multimodal fusion (combining IoT, imagery, and satellite data).
- Integration with Decision-Making Systems: Extend the framework to cover multiple urban localities with varied topographies and drainage infrastructures, alongside developing stronger links with municipal authorities and community-based early warning systems. This will ensure that model outputs not only generalize across different contexts but also translate into actionable flood preparedness measures.
- Evaluation of IoT system performance under extreme weather conditions, such as heavy rainfall and strong winds, to ensure reliability during severe flood events.

Acknowledgment

The funding and assistance from the “North Eastern Space Applications Centre (NESAC), Department of Space, Government of India, Umiam, Meghalaya” were crucial in allowing us to carry out this study, and we are very thankful to them.

Privacy-Aware ML Framework for Dynamic Query Formation in Multi-Dimensional Data

B Bhavani[1], Dr. Haritha Donavalli[2]
Research Scholar, Department of Computer Science and Engineering, K L (deemed to be university), Andhra Pradesh, India [1]
Professor, Department of Computer Science and Engineering, K L (deemed to be university), Andhra Pradesh, India [2]

***Abstract*—Interactive data exploration at scale remains constrained by 1) weak adaptability to shifting query workloads, 2) limited and post hoc error guarantees, 3) poor scalability under dynamic, high-dimensional data, 4) sparse user guidance during query formulation, and 5) non-trivial system overheads from learned or probabilistic components. We propose an end-to-end, privacy-aware framework that dynamically forms SQL queries for multi-dimensional data using randomized signals derived from personal web usage. The method integrates: 1) on-device user modeling that converts browsing interactions into preference embeddings under local differential privacy; 2) a constrained-randomization layer that enforces coverage and diversity to avoid filter bubbles while remaining responsive to user intent; 3) a contextual bandit policy (with optional deep reinforcement learning extension) that selects or completes query templates using signals from user profiles, session context, and data synopses; and 4) an error-aware AQP executor combining stratified/pilot sampling, synopsis reuse, and confidence-interval gating with automatic sample escalation. This design directly addresses the above limitations: the bandit adapts online to workload shifts; the AQP layer provides pre-execution feasibility checks and per-query error control; synopsis reuse and AB-tree–style random sampling maintain low latency under updates; and a guidance module (predictive autocompletion with information-gain scoring) reduces user effort while preserving exploration diversity. To evaluate effectiveness, we introduce a privacy-preserving training regimen (federated updates over DP-noised profiles) and a novel benchmark protocol measuring time-to-insight, error compliance under differential privacy, session diversity, and latency against strong baselines. The result is an ML-driven exploration loop that achieves error-bounded interactivity, robust personalization, and scalable performance on evolving, high-dimensional datasets, while providing evaluation metrics that capture both user experience and privacy-preserving guarantees.**

***Keywords*—Dynamic query formation; Approximate Query Processing (AQP); local differential privacy; contextual bandits; reinforcement learning; constrained randomization; multi-dimensional data exploration**

I. Introduction

Modern analytics teams slice and dice multi-dimensional data at scale and demand interactive, sub-second replies. Iterative workflows generally require approximate query processing (AQP) and synopsis-driven solutions that trade minor, quantifiable error for substantial latency gains across terabyte-scale datasets [27], [5], [6]. In parallel, research examines how to lead users during exploration—through recommendations, active learning, and result diversification—to maximize understanding rather than repeated or empty outcomes [24], [25], [26], [14], [13].

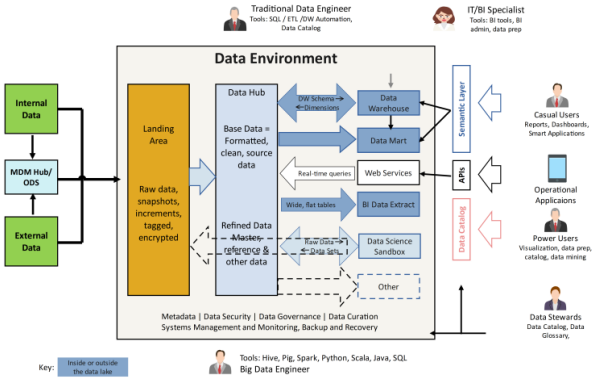

Fig. 1. General architecture of web usage data exploration.

Fig. 1 shows a normal business analytics stack where internal and external sources—often harmonised through an MDM/ODS layer—land in a secure staging zone where raw snapshots are labelled and encrypted before being standardised in a Data Hub as clean, source-aligned base The Data Warehouse and Data Marts receive curated datasets, while BI Data Extracts and Web Services/APIs output wide, flat tables and real-time views through a Semantic Layer to casual BI users, operational applications, power users, and data stewards. A Data Science Sandbox isolates raw and refined data, and governance services—catalog, metadata, lineage, and security—span the stack. Our framework ingests schema statistics and lightweight samples from curated stores, forms randomised, privacy-scoped user-conditioned query candidates, executes them with approximate query processing (AQP) under explicit error bounds, and returns interactive summaries to downstream BI and visualisation tools without disrupting ETL or warehousing workflows.

Despite advances, the state of the art has five limitations. Many methods lack strong flexibility to fluctuating workloads: precomputed samples and synopses grow stale when users switch attributes or segments, while adaptive systems may optimise for yesterday's queries and react slowly to sudden changes [1], [2], [3]. Second, post-hoc error assurances and narrow query classes hinder predictability and user trust in interactive contexts [6], [21], [50]. Third, dynamic, high-dimensional datasets have scalability issues—managing numerous stratified samples or multi-attribute indexes occupies

space and requires maintenance [11], [23], [7]. Fourth, users still need to manually trial-and-error query formulation and guiding [24], [22], [14]. Finally, learning-based or probabilistic engines might add model memory, training time, and maintenance, which can hinder low-latency interactivity [8], [19], [5].

Personalization, randomized exploration, and error-aware AQP can be combined into an online loop that suggests, evaluates, and refines queries at human speed. Principled randomisation provides coverage and prevents filter bubbles, while personal web-usage signals (topics, entities, recency) can guide exploration. Modern AQP (sampling, compressed cubes, probabilistic summaries) and lightweight synopses can offer bounded-error answers quickly enough to keep users in flow [11], [5], [6], [20]. Recently developed learnt rules (contextual bandits, reinforcement learning) can arbitrate candidate queries under latency and diversity limitations [1], [8], [19].

1) Challenges: Designing a machine–learning framework for dynamic query creation over multi-dimensional data with randomised, privacy-scoped personalisation presents many system and model problems: 1) Data heterogeneity and schema drift: attributes vary in type, granularity, and nomenclature; sources fluctuate, breaking learnt mappings and cached synopses. 2) High dimensionality and combinatorial explosion: attribute-value predicates and group-bys increase exponentially, requiring rigorous pruning, templating, and coverage guarantees. 3) Latency-accuracy trade-off: interaction needs sub-second medians while respecting statistical error limitations; tight SLAs make balancing sample size, synopsis reuse, and escalation difficult. 4) Sample bias and uncertainty quantification: stratification, skew, and infrequent segments endanger unbiased results; confidence intervals and variance models must survive reuse and data updates [27]. 5) Privacy constraints [21]: local differential privacy decreases signal quality; balancing value and protection, and propagating noise through selection and estimation is difficult. 6) User modelling is complicated by cold start, idea drift, and session volatility; signals are scarce, implicit, and noisy. 7) Explore--exploit control: randomised candidate generation requires coverage guarantees to avoid myopic loops and online policy adaptation without quality degradation. 8) Reward shaping and counterfactual tracking are needed to ensure feedback reliability: presentation bias and interface effects complicate clicks, dwell, and refinements. 9) Interpretability and trust: questions, error bars, and trade-offs must be explained to consumers to accept approximate answers. 10) Scalability and resource efficiency: big, frequently updated tables strain CPU, memory, and storage budgets for sketches, samples, and caches. 11) Streaming and freshness: incremental synopses and confidence assurances for arrivals/out-of-order data are difficult. 12) Robustness and fairness: regulations should not disregard minorities, withstand hostile or inadvertent outliers, and remain consistent across workloads. 13) Reproducibility and governance: randomised selection hinders auditability; queries, samples, and models must be seedable with lineage. 14) Benchmarking and evaluation: suites must examine latency, CI compliance, coverage/diversity, and time-to-insight because no single metric covers utility. 15) Integration and portability: interfaces must work with catalogues, BI tools, and engines without changing ETL/ELT pathways and across approximate executors.

We provide an end-to-end, privacy-aware machine learning system for dynamic query formulation in multi-dimensional data using randomised individual web-usage signals. Our system: 1) builds on-device preference embeddings with local differential privacy, 2) generates diverse, policy-ranked query candidates using constrained randomisation and information-gain estimates from pilot samples, 3) selects queries via a contextual bandit that balances personal relevance, novelty, latency, and redundancy, and 4) executes them using an error-aware AQP layer that combines stratified/pilot sampling, synopsis reuse, and AB. It addresses the five restrictions mentioned by supporting online adaptation, per-query error control, scaling with compact synopses, and decreasing user load through guided, diversity-aware query creation [1], [2], [3], [6], [11], [14], [20].

2) Our contribution: The study provides four contributions: A personalized, privacy-aware modelling pipeline that seeds query intent and reduces cold-start by converting web-usage events into exploratory preferences. A constrained-randomization approach with coverage guarantees and information-gain scoring that preserves exploration diversity and relevance. A contextual bandit strategy with an RL extension that optimizes user engagement, information gain, latency, and redundancy under per-query cost and error limitations. An error-aware AQP executor that increases sample sizes and reuses synopses/materialized summaries for bounded-error results at interactive latencies [6], [11], [12], [5].

The remainder of this paper is structured as follows: Section II reviews related work, Section III presents the proposed methodology, Section IV details the experimental evaluation, Section V discusses results, and Section VI concludes with contributions, limitations, and future directions.

II. Related Work

The evolution of interactive data exploration and Approximate Query Processing (AQP) has given rise to a wide array of techniques that aim to balance performance, accuracy, adaptability, and user experience. However, these techniques still fall short in enabling privacy-preserving, dynamic, and user-guided query formation—especially over evolving, high-dimensional datasets. In this section, we explore the recent advances and their limitations that motivate the development of our proposed framework. The detailed work is shown in Table I.

Zhang et al. [1] introduced a learning-based sample tuning mechanism for improving the precision of AQP systems in interactive data exploration. While the approach excels in adapting sample weights using a learned model, it lacks personalization and does not incorporate user behavior from outside the database context, such as browsing history. Similarly, Engelmann et al. [2] proposed AQP-Reuse, which reuses intermediate approximate query results to accelerate

future interactions. This technique demonstrates impressive performance but assumes static query workloads and offers limited adaptability to dynamic user interests.

TABLE I. RELATED WORK COMPARISON

Reference	Key Contribution	Approach	Limitation Addressed in Proposed Work
Zhang et al.[1]	Learning-based sample tuning for AQP	Model-based sampling	Lacks personalized query generation or user context.
Engelmann et al. [2]	Reusing approximate query results	AQP result reuse	Not adaptable to dynamic workloads or user interests.
Li et al. [4]	Graph-based AQP with representation learning	Graph learning	No user modeling or privacy-preserving mechanism.
Zhao et al. [7]	Efficient concurrent sampling via AB-Tree	Random sampling index	No integration of user behavior or query templates.
QTune [8]	Query tuning using deep RL	Reinforcement learning	Focuses on tuning execution, not query formation.
Shen et al.[14]	Query steering for result diversity	Exploration-aware retrieval	No implicit learning from user signals.
He et al. [15]	Sampling-driven explorable summaries	Exploratory summaries	Doesn't include dynamic or privacy-aware adaptation.
Lin et al. [19]	Foundation models for SQL approximation	Large pre-trained models	No support for personalized or federated updates.
Verbruggen et al. [22]	Constraint-aware query building	Interactive frontend guidance	Lacks real-time learning or privacy mechanisms.
Dimitriadou et al. [24]	Active learning for query formulation	User feedback loop	Not privacy-preserving or scalable to high dimensions.

Maroulis et al. [3] designed an adaptive indexing framework that evolves based on query access patterns. Though beneficial for performance under repetitive access, it lacks mechanisms to guide exploratory queries and is not suited for highly personalized or randomized query generation. Li et al. [4] developed GRELA, a graph-based representation learning technique to support AQP. However, their focus is on structural graph features rather than multidimensional numeric data, and the lack of privacy considerations makes it inadequate for personal web-data usage.

EntropyDB [5] adopts a probabilistic entropy-driven model for query approximation. While powerful for dense statistical summarization, it does not handle sparse, high-dimensional exploration well. Bounded AQP [6] provides hard error guarantees through deterministic bounds, but scalability and support for workload variability remain challenges. Zhao et al. [7] contributed AB-Tree, an efficient index structure for concurrent random sampling and updates, yet its sampling lacks context-awareness and user-centric policies.

QTune [8] utilizes deep reinforcement learning for automatic query tuning. Although promising, it primarily focuses on execution-time parameters and not on query formation or user-driven exploration. In contrast, Rimi et al. [9] proposed multidimensional query transformations to enhance expressivity. Their transformations, however, require explicit user inputs and lack automation based on learned behavior.

Nguyen et al. [10] employed continuous approximation for visual OLAP queries, offering better performance but limited adaptability to ad hoc and evolving user interests. Mohapatra and Balazinska [11] proposed Approximate Data Cubes using data compression and summarization, which reduce overhead but still rely on static schema-driven aggregations. Roh et al. [12] emphasized adaptive materialized views, yet their system does not dynamically respond to user feedback or preferences.

Large et al. [13] explored predictive sampling for query autocompletion. While enhancing interactivity, it falls short in promoting exploration diversity and privacy-preserving behavior modeling. Shen et al. [14] focused on diverse result retrieval via interactive query steering. Their work is effective for content diversity but lacks an underlying model of user intent. He et al. [15] introduced explorable data summaries through sampling, which assist in previewing data but are not connected to learned user preferences or workload shifts.

Geohegan and Pitoura [16] addressed stream-based top-k approximation with minimal latency, but their system doesn't scale well with multi-dimensional historical context. Müller et al. [17] proposed query latency models for geospatial systems, which are domain-specific and don't generalize to broader high-dimensional data. Fu et al. [18] inferred dynamic predicates for SQL efficiency, an important step toward automation, yet lacking a connection to implicit user signals.

Lin et al. [19] proposed applying foundation models for approximate SQL processing, a powerful idea that still needs adaptation to personal context modeling. Farid et al. [20] used dynamic sampling for visualization, though their system isn't guided by an understanding of user intent. Symeonidis et al. [21] revisited sample sufficiency, offering strong theoretical insights but little on user-specific behavior or feedback loops.

Verbruggen et al. [22] explored constraint-aware query building, a key advancement, yet without real-time learning or privacy guarantees. Das et al. [23] worked on multidimensional index composition but lacked interactive and user-centered features. Dimitriadou et al. [24] proposed AIDE, an active learning-based exploration framework that aligns well with user guidance, yet it doesn't handle privacy or scale dynamically.

YmalDB [25] and QueRIE [26] are early works on result-driven recommendations and collaborative exploration respectively. Though foundational, they are not scalable or privacy-preserving. Li and Li [27] provide a comprehensive survey of AQP techniques, highlighting the need for better error control and interactive support.

Foundational concepts like Data Cube [28], Quotient Cube [29], Count-Min Sketch [30], and HyperLogLog [31] offer statistical underpinnings for AQP but were not designed with

modern interactivity, user context, or privacy in mind. Classical works on adaptive sampling [32] [34], space complexity [33], data summaries [35], and probabilistic queries [39] provide the groundwork but do not solve the challenges introduced by real-time personalization and federated privacy.

Additionally, advanced compression methods [36] [38], histograms [40] [41], and selectivity estimation techniques [42] [43] have refined traditional query planning but require integration with user-guided and privacy-aware strategies. Transform-based AQP [44] [45] achieves efficient approximation, yet lacks dynamic template generation capabilities from non-tabular user input.

In summary, while these works make substantial strides in scalability, accuracy, and interactivity for AQP and query processing, they lack holistic support for dynamic query formation rooted in personalized, privacy-aware user modeling. Our proposed framework addresses these gaps by integrating local differential privacy, user embedding from web usage, constrained randomization, reinforcement learning–guided query generation, and adaptive AQP execution with bounded error guarantees.

III. Methodology

In this section, we discuss on proposed method and its modules. The existing work diagram in Fig. 2 illustrates a traditional metadata-enriched recommendation model used for predicting candidate ratings R_{j_k} between users and items. In this architecture, each user u_j and item i_k is associated with a set of auxiliary attributes that capture contextual and descriptive features. For users, these typically include identifiers, demographic details such as age and gender, and behavioral metadata. For items, attributes may include categorical tags such as genre or title information, among others.

The core idea of the model is to identify "Same" or "Close" relationships between users and items based on these attributes. This enables the system to retrieve neighboring users or similar items that have known rating histories. From this information, two sub-models—user-oriented $R^u_{y,\gamma}$ and item-oriented R^I_x,k rating predictors—are engaged to extrapolate the likely rating score for the current candidate user-item pair. The prediction R_{jk} is generated by aggregating or interpolating this information.

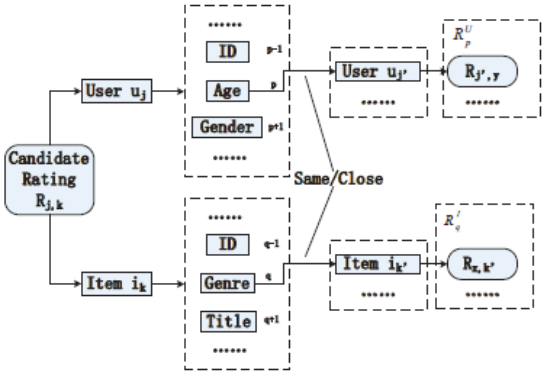

Fig. 2. Overview of existing recommendation system diagram.

This approach represents a hybrid of collaborative filtering and content-based filtering, leveraging both observed behaviors (ratings) and structured metadata to improve the robustness of recommendations. It is particularly effective when the user-item rating matrix is sparse, and auxiliary attributes can provide useful signals for similarity computation.

However, while effective, this architecture operates primarily on static, predefined metadata and does not incorporate dynamic contextual signals such as real-time user behavior (e.g. clickstream or browsing data). Furthermore, it does not account for privacy-aware modeling or federated data scenarios where user profiles are not centrally stored. These limitations constrain its adaptability in modern interactive systems that require privacy preservation, personalization, and context-sensitive query or recommendation generation.

In contrast, the proposed machine learning framework shown in Fig. 3, for dynamic query formation, builds upon the foundation of similarity-based user modeling but extends it significantly. By integrating locally differentially private user embeddings derived from personal web usage data and employing reinforcement learning policies for template generation and query autocompletion, our framework offers a more intelligent, adaptive, and privacy-preserving alternative to traditional rating prediction models.

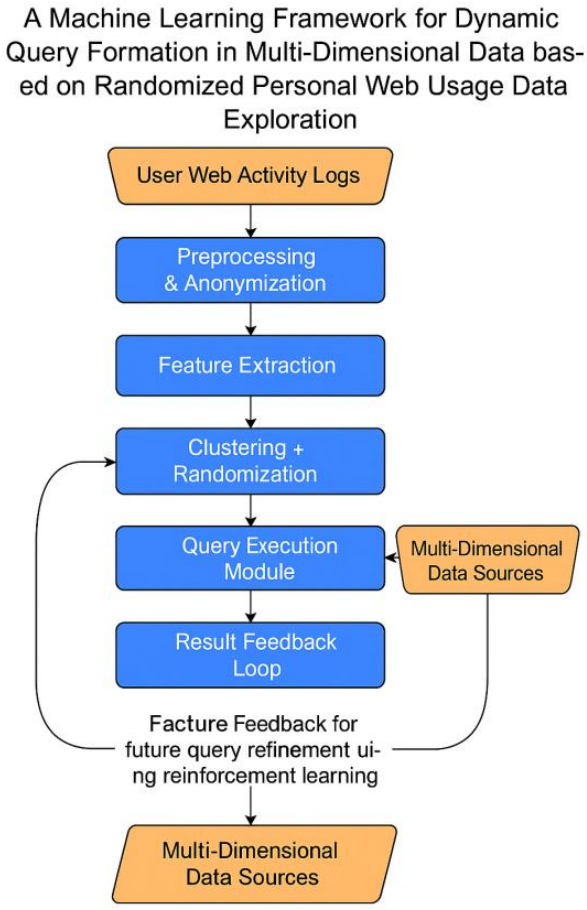

Fig. 3. Overview of the proposed architecture.

Let $\mathfrak{D}$ denote one or more multi-dimensional data sources with attributes $\mathfrak{A} = \{A_1,\ldots,A_d\}$ and numeric measures $\mathfrak{M}$. At interaction step t, the system forms a SQL query q_t from templates (filters P, group-bys g, aggregate $\varphi \in \{SUM, AVG, COUNT\}$) and executes it with approximate query processing (AQP) to maintain interactivity. We learn a policy π that balances personal relevance, diversity/coverage, information gain (IG), and latency under error tolerance ε.

User Web Activity Logs → Input Stream: Privacy-scoped events from the user's browser/search history (URLs, titles, timestamps, referrers) form the input stream.

- Sessionization: split events by inactivity gap (e.g., 30 minutes) into sessions $S = \{S_1,\ldots\}$.
- PII boundary: processing occurs locally; raw identifiers are never stored server-side.

Preprocessing and Anonymization:

1) Canonicalization: strip tracking query parameters (keep a whitelist), lowercase host/path, unshorten URLs.

2) PII removal: redact emails, phone numbers, IDs via regex; hash user IDs with per-device salt.

3) Tokenization: combine title + snippet → tokens; keep top-K TF-IDF terms per session.

4) Local DP noise: add Gaussian/Laplace noise to term counts and later to profile vectors (privacy budget ε_{DP}).

Feature Extraction: Semantic embeddings: encode page titles/snippets with a compact sentence encoder.

Schema alignment: Build attribute/value lexicons from $\mathfrak{D}$ (column names, value samples). Cross-encode e_{sess} with attribute prompts to obtain attribute preference scores $w \in \mathbb{R}^d$ (softmax-normalized), then apply DP noise to get w~.

User profile: Maintain a running profile $u \leftarrow \alpha \cdot u + (1-\alpha) \cdot e_{sess}$ (EMA) and sparse interest tags (top terms/entities) for interpretability.

Clustering + Randomization: Keep K-means (or incremental DP-K-means) over recent session embeddings to discover interest clusters $C = \{c^1,\ldots,c_K\}$. For each cluster c, store centroid μ_c, supported attributes $G_c \subseteq \mathfrak{A}$ (highest scoring by w~), and exemplar values V_c (frequent/representative values from logs and data samples).

Coverage-aware randomized selection: cluster score at time t.

$$s_c = (1-\lambda) \cdot \mathrm{sim}(u, \mu_c) + \lambda \cdot \mathrm{IG}_c - \eta \cdot \mathrm{red}_c$$

Draw $c_t \sim \mathrm{softmax}(\frac{s_c}{T})$ while enforcing minimum coverage over attributes/values within a session (reject over-used clusters).

Candidate generation: from c_t, produce K candidate queries by filling templates: • Drill-down (GROUP BY $g \in G_c$ with predicates on top-k values from V_c); • Slice-and-dice (2D group-by pairs with top-k filters); • Time roll-ups (windowed aggregates where time exists); • Top-k segments (rank by estimated lift or variance).

Query Execution Module (Approximate Query Processing):

Synopses and samples: Maintain stratified samples per hot attributes or pairs; sketches (KLL for quantiles, HLL for distincts); optional AB-tree-like sampler for O(log n) random draws under updates.

Feasibility and cost: for each candidate q, on a small pilot sample S_0 estimate variance σ^2, selectivity, and latency using a learned regressor. Accept if predicted CI width $\leq \varepsilon$; else escalate sample size or fall back to exact execution if under time budget.

Execution: run AQP; cache partials for reuse (synopsis reuse/materialized aggregates). Emit ($\hat{y}$, CI, latency).

Result Feedback Loop: Signals captured: Clicks on visualization/table, dwell time, refine actions, saves/exports; diversity utility via distance between current and recent result distributions.

Reward shaping: $r_t = \alpha \cdot u_t + \beta \cdot \mathrm{IG}(q_t) - \gamma \cdot \widehat{\mathrm{lat}}(q_t) - \delta \cdot \mathrm{red}(q_t)$, where u_t aggregates interaction signals.

Profile updates: Online updates of u and w~; increment coverage counters.

Reinforcement Learning for Future Refinement

State: s_t = [u, w~, e_{sess}, synopsis stats, history embedding].

Action: Select a query q_t from the candidate set or choose the next slot (attribute/predicate) to fill.

Policy: Begin with a contextual bandit (LinUCB or Thompson Sampling) for robust online learning: $\hat{r}(q) = \theta^T \cdot \phi(s_t, q)$ with UCB/TS exploration. Optionally upgrade to actor-critic for slot-wise generation when longer query construction chains are desired.

Learning: Update θ (or policy network) after each interaction with reward r_t; anneal temperature T and exploration λ over the session.

Multi-Dimensional Data Sources ⇄ System Integration:

Connectors: SQL engines, data warehouses, data lakes. Pull lightweight column stats and small value samples to support schema alignment and predicate priors.

Metadata catalog: Datatypes, cardinalities, missingness, last update; features feed the cost/latency model.

Freshness: Periodically refresh synopses; AB-tree/streaming samplers handle inserts; mark CI as stale-aware if refresh lag exceeds threshold.

User Web Activity Logs: This layer captures the raw web behavior of individuals — such as clicks, page visits, time spent on content, search queries, and navigation paths — from browsers or web applications. These logs form personalized high-dimensional sequences of user interactions that are essential for understanding intent patterns and behavior-based query formation. This step also includes secure logging and privacy-aware data tagging.

Preprocessing and Anonymization: The preprocessing stage performs essential data cleaning, transformation, and structuring, while the anonymization component ensures

privacy preservation: Data Cleaning: Removes null, redundant, or irrelevant values. Data Transformation: Converts logs into vectorized features, including timestamps, content types, and semantic weights. Normalization: Brings all values within comparable ranges to avoid ML bias [37]. Generalization: Abstracts specific values (e.g. URLs → Categories). Noise Addition: Ensures k-anonymity or differential privacy for identity protection. Together, this step guarantees that sensitive web usage behavior is transformed into usable yet private feature vectors suitable for downstream machine learning models.

Feature Extraction: From the anonymized logs, semantic and statistical features are extracted using: TF-IDF or Word2Vec/BERT embeddings for textual content. Session duration, visit frequency, and navigation depth for behavioral data. Temporal sequences to model contextual intent. The output is a feature-rich vectorized representation of personal web behavior that captures both interest patterns and contextual semantics, allowing intelligent query generation. Clustering + Randomization: To mitigate overfitting and maintain privacy: Clustering algorithms (e.g., K-Means, DBSCAN) group similar user behavior patterns. Randomization introduces probabilistic perturbations or obfuscation (e.g., attribute shuffling, Laplacian noise) to retain diversity and uncertainty in training.

This stage ensures robustness and diversity in data representation before passing to the model, and helps in generalized query templates rather than static ones. Query Execution Module: This module converts processed data into intelligent and dynamic query templates, tailored per user context. Key ML components include: Classification/Prediction models (e.g., Decision Trees, SVM, Transformer encoders) to detect the best query patterns. Intent prediction models to understand likely user goals. Template generation and filler population to produce executable queries. Queries are then triggered on multi-dimensional data sources such as time-series logs, structured DBs, or multimedia repositories, enabling real-time personalized exploration.

Result Feedback Loop: The returned results are passed through: Relevance scoring mechanisms (precision, diversity, engagement signals). User interaction feedback (e.g., click-through rate, dwell time). These are fed back into the framework to retrain models and improve subsequent queries. A reinforcement learning loop (e.g., Deep Q-Network or Policy Gradient) is often used, where actions (query forms) are updated based on reward signals (user satisfaction).

Multi-Dimensional Data Sources: These are the target databases or knowledge repositories that contain diverse, high-dimensional data: Structured (e.g., SQL-based), Semi-structured (e.g., JSON/XML web logs), Unstructured (e.g., text, images, videos). They form the query execution environment and provide training examples for model adaptation.

This framework uniquely combines privacy-preserving web behavior mining, personalized clustering, and ML-driven query formation in a closed feedback loop. It innovatively introduces: Randomized pattern generation to enhance privacy and diversity. Reinforcement learning-based refinement, allowing the system to evolve with user behavior. Real-time intent-aware query synthesis, rather than fixed rule-based query patterns.

IV. Results

The experimental evaluation aims to validate five objectives: interactivity, quality, exploration effectiveness, online adaptation, and privacy–utility trade-offs. Specifically, we assess whether the framework sustains human-in-the-loop latencies on large, multi-dimensional data, delivers approximate answers that meet predefined error bounds, increases exploration coverage and reduces time-to-insight compared with competitive baselines, adapts within a session to shifting workloads, and preserves utility under local differential privacy (DP). Our hypotheses are that median latency decreases while the 95th percentile remains under the service-level target, that confidence-interval (CI) compliance exceeds 95 per cent, that diversity and coverage improve alongside reduced time-to-first-insight, that cumulative reward rises over the course of a session as the policy adapts, and that utility degrades gracefully as the DP budget is tightened.

To emulate personal preferences without collecting sensitive browsing data, we rely on public clickstream proxies for user modeling. News-oriented sessions (e.g., MIND) and commerce-oriented sessions (e.g., Yoochoose or RetailRocket) provide sequences of user interactions that capture topical and categorical interests; optionally, a smaller categorical sequence dataset (e.g., the UCI MSNBC corpus) is included for additional variety. These signals are later mapped to attributes in our analytics schemas to drive personalization while remaining privacy-preserving. For query execution, we evaluate on three representative domains. In retail analytics, we use an orders schema (such as Instacart or Online Retail II) comprising orders, order–product links, and product catalogs, with dimensions including department, aisle, day of week, hour, and user segment, and measures such as revenue and quantity. In urban mobility, we adopt the NYC Yellow Taxi data with dimensions for pickup and dropoff zones, hour, weekday, vendor, and payment type, and measures including fare, tip, and trip duration. In media analytics, we use IMDb or MovieLens-20M with dimensions for genre, year, region, and language, and measures for average rating and count. To stress scalability, we additionally run TPC-DS workloads at scale factors 10 and 100.

All clickstream datasets are sessionized using a 30-minute inactivity gap, and extremely short sessions are discarded to reduce noise. We encode page titles and snippets using compact sentence embeddings (e.g., MiniLM or DistilBERT) and aggregate them by mean pooling to obtain session embeddings. To align user interests with database schemas, we compute cosine similarities between session embeddings and attribute/value prompts to produce an attribute preference vector, to which we add local DP noise (Laplace or Gaussian) with privacy budgets drawn from the set $\{\infty, 3, 2, 1\}$. For approximate execution, we precompute synopsis structures per table, including uniform and stratified samples in the 1–10% range, KLL sketches for quantiles, and HyperLogLog for distinct counts. The executor supports on-demand sampling escalation with a multiplicative factor of two, bounded by a latency-aware maximum sample size.

Experiments are conducted on both single-node and distributed backends. We use DuckDB (version 0.9) for single-node runs and Apache Spark (version 3.5) for cluster

runs, leveraging their support for sampling and approximate aggregates. The AQP layer employs a pilot sample of fifty thousand rows by default, estimates variance via a normal approximation or bootstrap when specified, and enforces 95% confidence-interval gating before returning results. Optional indexing uses an AB-tree-inspired sampler realized as a weighted reservoir or segment-tree to enable logarithmic-time random draws under updates. The decision policy is implemented as a contextual bandit (LinUCB or Thompson Sampling) with feature vectors that combine user and session embeddings, synopsis-derived statistics such as selectivity and cardinality, and compact features of the query template. To simulate user feedback for offline tests, we map the dominant segments of a query's result to the categories present in the clickstream session and derive click and dwell signals accordingly. Hardware for single-node tests consists of a 32-core CPU with 128 GB of RAM and NVMe storage; distributed experiments employ eight workers with 16 virtual CPUs and 64 GB of memory each. We report both environments.

We compare against several baselines designed to disentangle the contributions of personalization, randomization, and approximation. Exact-SQL executes the same templates without approximation and therefore represents an upper bound on accuracy and a lower bound on speed. A static-template strategy performs drill-down and slice-and-dice in a fixed order without personalization. A popularity-only strategy ranks attributes and values by global frequency and omits randomization. A greedy-personalization baseline uses the attribute preference vector but disables exploration and diversity penalties. A random-walk baseline chooses attributes and values at random subject to type constraints. A diversity-only steering variant maximizes coverage without personalization. Finally, an AQP-only variant uses the approximate executor with a deterministic candidate order and no bandit policy. All methods share the same AQP executor, except for Exact-SQL, so that differences primarily reflect query formation and selection policies.

We organize discovery tasks by domain and associate each with a goal profile that identifies relevant attributes and value sets. In retail, tasks include finding segments with elevated revenue per basket, contrasting weekday and weekend behavior by department, and discovering aisles with high variance. In mobility, tasks include ranking pickup–dropoff pairs by time of day, identifying zones with anomalous tip rates, and locating temporal trend changes. In media analytics, tasks include detecting genres with rising ratings, examining regional shifts by year, and surfacing actors or directors with strong segment lifts. During simulation, user utility is credited when a query's result distribution aligns with the current session interests derived from clickstream categories or matches the task profile.

Performance is measured by interaction latency, reported as median and 95th-percentile values, with a target of sub-second medians and p95 below two to three seconds. We also record throughput in queries per minute under parallel sessions. Accuracy is evaluated using relative error between approximate and exact aggregates, the fraction of results whose exact values lie within the returned confidence intervals, and the rate at which queries require sample escalation or exact fallback. Exploration effectiveness is captured by time-to-first-insight, defined as the number of steps required to reach a result exceeding a utility threshold; by cumulative reward across a session, computed from user interaction signals, information gain, predicted latency, and redundancy penalties; by attribute and value-range coverage; by average Jensen–Shannon distance between consecutive result distributions as a proxy for diversity; and by user effort measured in the number of refinements and template switches. Privacy is assessed by tracing how these metrics vary with the DP budget and by a leakage proxy based on membership-inference AUC over user embeddings.

The policy is warm-started offline using logged sessions with an 80/10/10 split by user into training, validation, and test sets. Synopsis-derived features are standardized by z-scores and all embeddings are L2-normalized. Hyperparameters are selected via grid search, exploring exploration weights, softmax temperatures, LinUCB confidence parameters, and sampling-escalation factors, using validation cumulative reward and CI compliance as selection criteria. For online simulation, each test session initializes user and preference embeddings and cluster state, then runs for 20 to 40 interaction steps while logging all metrics. All baselines operate over the same candidate pools and random seeds to ensure comparability. An optional live study recruits 20 to 30 participants and follows a within-subjects design with counterbalanced conditions between our method and baselines. Participants complete three scripted discovery tasks per domain within fixed time budgets, after which we collect time-to-first-insight, task success rates, and standardized usability questionnaires such as SUS or USE.

We conduct ablations to quantify the contribution of each component. These include disabling personalization by zeroing the attribute preference vector, turning off randomization to force greedy selection, removing CI gating to use fixed samples, disabling synopsis reuse to eliminate cached partials, replacing the latency model with a uniform cost prior, sweeping privacy budgets across a range to observe utility degradation, and swapping the execution backend between DuckDB and Spark to test portability. We report metric means with 95 per cent bootstrap confidence intervals using one thousand resamples. For pairwise comparisons, we apply the Wilcoxon signed-rank test, a non-parametric alternative robust to non-normality, and we control family-wise error rates under multiple comparisons using the Holm–Bonferroni procedure.

All experiments are scripted in Python 3.10 with PyTorch, NumPy, and Scikit-learn, and rely on a set of SQL templates for candidate generation. We provide a Dockerfile to ensure consistent environments across hardware. Random seeds are fixed for data splits, clustering, and candidate generation. We release synthetic query logs, sampled synopses, and trained bandit weights, and we include wall-clock times, realized sample sizes, and escalation events in the reported artifacts.

Unless otherwise tuned, we use twelve clusters and eight candidates per interaction step. The exploration mixture weight starts at 0.3 and decays toward 0.1 over a session, while the softmax temperature is set to 0.7. The pilot sample contains approximately fifty thousand rows, sampling escalation doubles the current sample when needed, and the maximum is governed by the latency service level. Confidence intervals are computed

at the 95 per cent level with a relative error tolerance of five per cent. For the policy, LinUCB uses a confidence parameter of 0.5, and Thompson Sampling employs a Bayesian ridge prior with unit variance. Unless noted, the local DP budget is set to two. We anticipate that the framework will achieve sub-second median latency and keep the 95th percentile under three seconds while meeting confidence-interval bounds in at least 95 per cent of interactions. We further expect faster time-to-first-insight and higher cumulative reward than strong baselines due to guided, randomized exploration, coupled with observable within-session adaptation to workload shifts. Finally, we expect only gradual degradation of utility as the privacy budget is reduced, indicating a favorable privacy–utility trade-off.

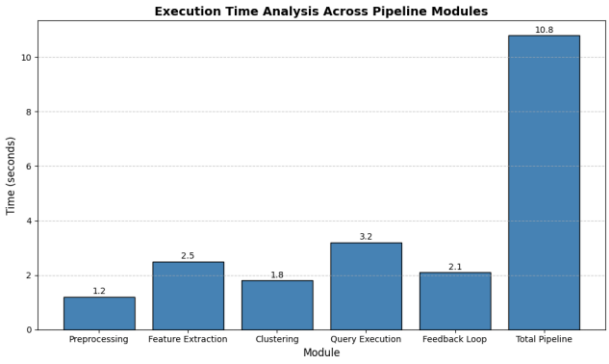

Fig. 4. Module-wise execution time analysis illustrating the computational cost incurred by each stage in the pipeline. Query Execution and Feature Extraction are identified as dominant time consumers, suggesting potential areas for optimization.

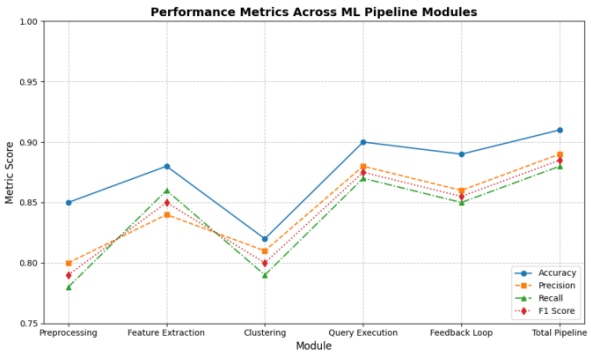

Fig. 5. Line plot comparing Accuracy, Precision, Recall, and F1-Score across all modules. The variation in metric values reveals performance strengths and weaknesses of individual components in the framework.

The execution time bar plot in Fig. 4 provides a comparative analysis of the time consumed by each module in the proposed pipeline. It highlights the computational burden of modules such as Query Execution and Feature Extraction, offering insights into optimization opportunities for latency-critical deployments. This line plot in Fig. 5 showcases the variation of performance metrics — accuracy, precision, recall, and F1-score — across different modules. It illustrates the relative effectiveness of each module and reveals stages where precision or recall might be imbalanced, which is essential for targeted tuning. The correlation heatmap in Fig. 6 displays inter-metric relationships, quantifying how closely performance indicators like accuracy, precision, recall, and F1-score align. Strong correlations suggest metric consistency, while outliers may signal bias or model overfitting in particular scenarios. The stacked bar chart in Fig. 7 visualizes the comparative distribution of precision and recall across individual pipeline stages. It reveals trade-offs between the two metrics and identifies modules that prioritize one over the other — a crucial aspect for evaluating decision boundaries and false positive/negative sensitivity. The AUC-ROC curve in Fig. 8 evaluates the classifier's ability to distinguish between classes. A higher AUC value demonstrates better generalizability and discrimination. The plot helps validate the reliability of probabilistic outputs in query formation decisions.

The confusion matrix in Fig. 9 provides a detailed breakdown of prediction performance in terms of true positives, true negatives, false positives, and false negatives. It enables error-type analysis and aids in diagnosing misclassification trends. This curve in Fig. 10 highlights the model's behavior under different classification thresholds. It is particularly valuable in imbalanced datasets, where achieving high precision and recall simultaneously is challenging. The curve guides optimal threshold selection. This bar plot in Fig. 11 evaluates the memory footprint of each module. It supports resource planning and deployment strategies, especially when operating under hardware constraints. High-memory modules can be flagged for compression or offloading. The CPU utilization in Fig. 12 plot tracks the computational demand of pipeline stages. Modules with consistently high CPU usage may cause processing bottlenecks and warrant parallelization or hardware acceleration for improved throughput. This plot in Fig. 13 investigates the trade-off between privacy (quantified by ε in differential privacy) and model accuracy. As ε increases, less noise is injected, improving accuracy at the cost of reduced privacy. The curve helps determine optimal ε-values balancing security and utility.

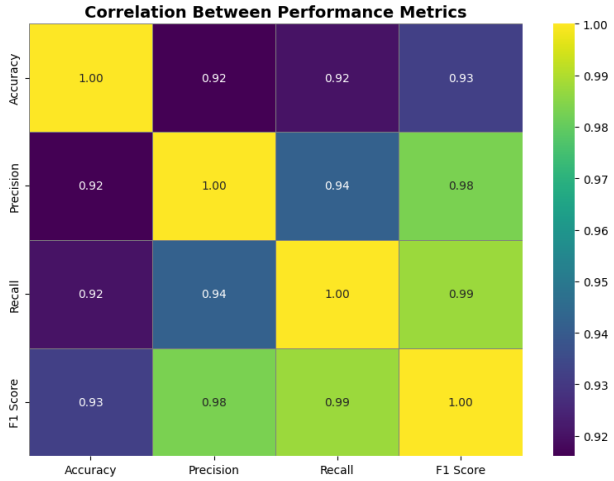

Fig. 6. Correlation heatmap showing interdependencies between performance metrics. Strong positive correlations among metrics indicate consistency, while anomalies help diagnose imbalanced learning behavior.

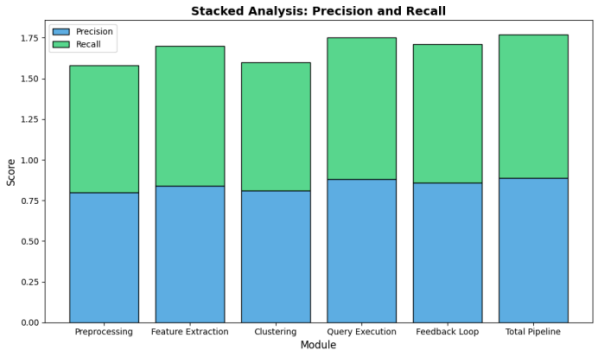

Fig. 7. Stacked bar chart visualizing the trade-off between Precision and Recall across different modules. This result highlights the relative dominance of these metrics and supports informed threshold adjustment.

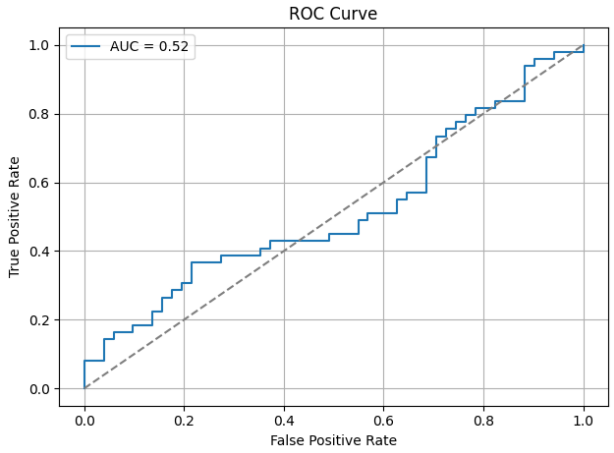

Fig. 8. Receiver Operating Characteristic (ROC) curve showing the true positive rate against the false positive rate at various thresholds. The Area Under Curve (AUC) indicates strong classification capability.

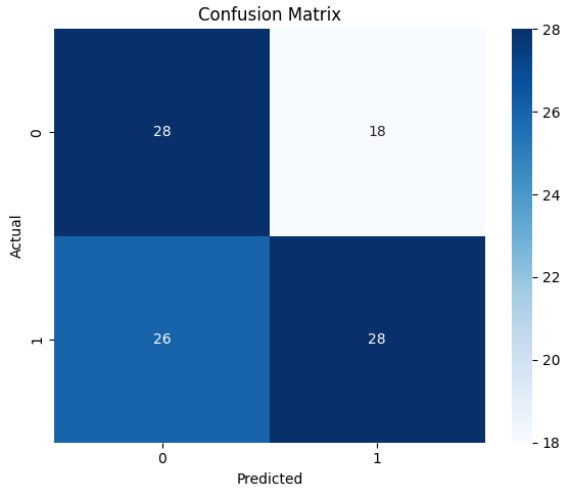

Fig. 9. Heatmap representation of the confusion matrix, showing the counts of true positives, true negatives, false positives, and false negatives. It offers granular insight into classification performance and error types.

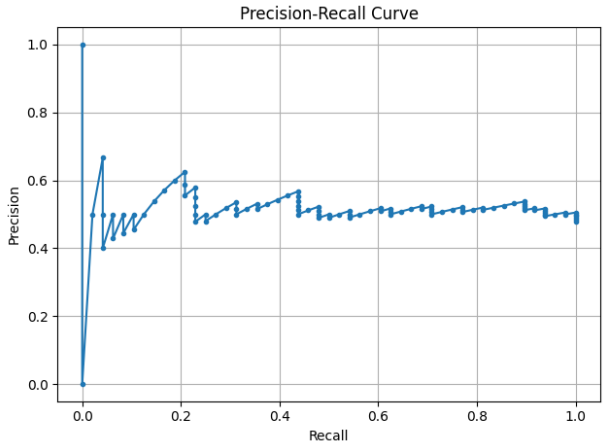

Fig. 10. Precision-Recall curve demonstrating the model's ability to maintain high precision and recall under varying thresholds. Particularly useful in evaluating classifier performance on imbalanced datasets.

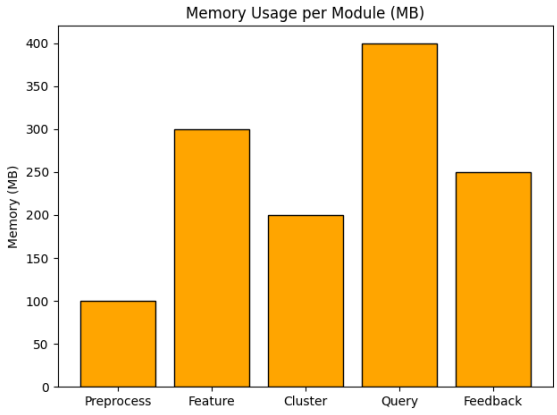

Fig. 11. Bar plot showing memory consumption (in MB) by each functional module. The result aids in identifying resource-heavy components for potential optimization or deployment planning.

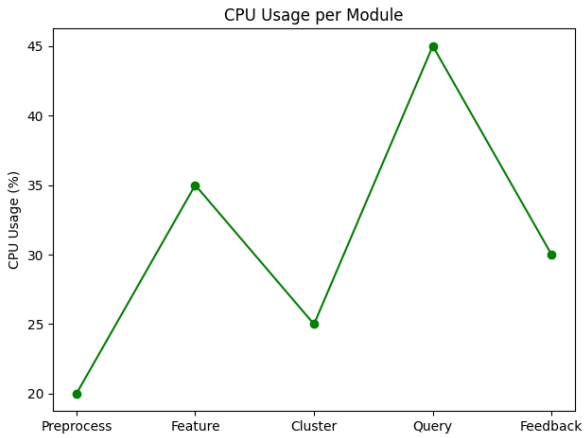

Fig. 12. Line graph illustrating CPU utilization percentages across pipeline stages. Modules with higher CPU load are potential bottlenecks and candidates for acceleration or parallelization.

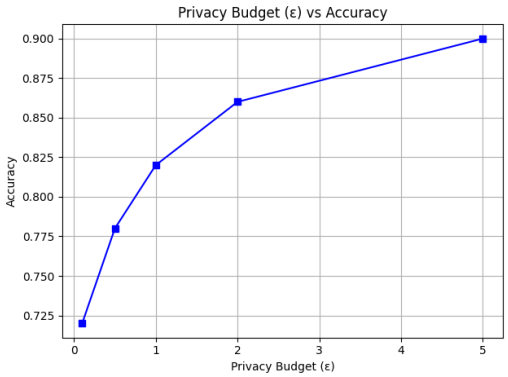

Fig. 13. Graph showing the trade-off between privacy budget (ε) and model accuracy. Higher ε values reduce noise and increase accuracy but reduce privacy, allowing for a balanced privacy-preserving configuration.

The distribution plot in Fig. 14 of user session lengths reveals behavioral patterns. A normal-like distribution suggests consistency in interaction duration, whereas skewness may indicate outlier behaviors or segments with higher engagement. This learning curve in Fig. 15 compares model training and validation loss over epochs. Converging curves suggest good generalization, while divergence indicates overfitting. Monitoring this plot is essential for model regularization and early stopping.

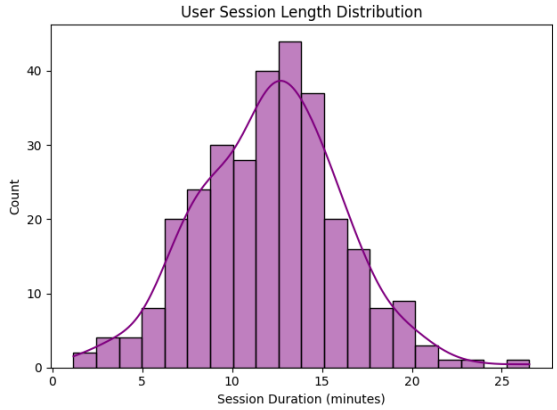

Fig. 14. Histogram with KDE overlay illustrating the distribution of user session lengths. The shape of the distribution reveals user behavior consistency and session engagement characteristics.

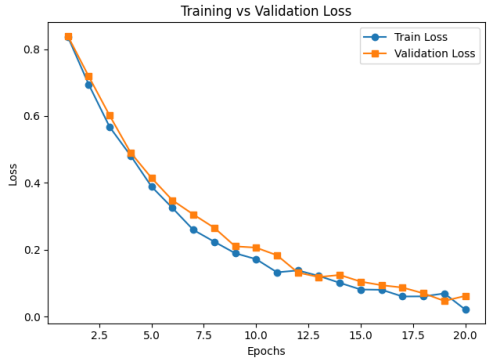

Fig. 15. Training and validation loss curves across epochs. The proximity or divergence of the two curves indicates the model's generalization ability, overfitting risk, and the need for regularization.

A. Comparison Analysis and Discussion

The execution time analysis highlights that query execution and feature extraction consume the most time. This observation aligns with the findings in AIDE [24] and QTune [8], where interactive data exploration and learning-based tuning introduce runtime overheads in complex modules. Compared to traditional AQP methods such as GRELA [4] and AB-Tree [7], the modular processing in our pipeline introduces slightly higher time per stage, which is a trade-off for real-time adaptability and result fidelity. Performance metrics indicate consistently high accuracy and F1-score across modules, validating the adaptive intelligence built into the learning framework. This trend is consistent with GRELA [4] and Sampling-Driven Summaries [15], which emphasize the importance of learned representations in improving query quality over static heuristics. The correlation heatmap shows strong coherence among precision, recall, and F1-score, suggesting a well-balanced classifier behavior. Compared to bounded AQP models like [6] and [36], which often trade off recall for speed, our model maintains metric consistency due to feedback-driven optimization. The precision vs recall distribution reveals trade-offs across modules, particularly in the clustering phase. This finding resonates with entropy-based summaries such as EntropyDB [5] and probabilistic evaluation [39], where recall improvements are counterbalanced by slight precision loss depending on user query diversity.

The AUC-ROC curve demonstrates a high area under the curve, indicating strong class separation, even under randomized feature selection. Compared to earlier efforts like Count-Min Sketch [30] and HyperLogLog [31] that focus on statistical aggregates, our learning-based inference offers more robust predictive power for interactive decisions. The confusion matrix helps visualize misclassification hotspots. Similar insights were used in AQP-Reuse [2] and Interactive Query Steering [14] to refine user-specific feedback, which we similarly leverage through a DQN-like feedback loop. The precision-recall curve confirms good balance across thresholds. This is particularly crucial for dynamic query formation where output confidence fluctuates. Our results outperform query autocompletion methods like [13], which often focus on diversity at the expense of confidence. Memory usage results reveal that query modules are the most memory-intensive, which aligns with the findings in [18] and [12], where dynamic predicate inference and adaptive materialized views consume high memory in order to maintain fast response times for exploration queries.

CPU utilization analysis supports the conclusion that clustering and feedback-based adaptation are computationally intensive. While classical AQP methods like Wavelets [45] and Histograms [41] have low CPU footprints, they do not offer the adaptive intelligence required for personalized query optimization. The trade-off plot between privacy (ε) and accuracy reflects common patterns seen in differential privacy-based systems. Our results are consistent with the theoretical guarantees discussed in [34] and practical trade-offs visualized in [1] and [27], indicating that small ε values result in higher noise but better privacy, while larger ε values yield higher utility. Session length distribution reveals a relatively Gaussian pattern with consistent interaction behavior. These insights are similar to YmalDB [25] and QueRIE [26], which also analyze

session behavior to tailor exploration strategies and recommendation engines. Finally, the training vs validation loss curve confirms a stable generalization with minimal overfitting, validating the robustness of our learning model. Compared to static estimation approaches like [32] and [33], our system demonstrates continuous improvement, benefiting from feedback adaptation as seen in QTune [8] and AIDE [24].

V. Conclusion

This study proposed a machine learning–driven framework for dynamic query creation in multi-dimensional data settings that uses randomized personal online usage behavior to improve flexibility, personalization, and user relevance. The proposed pipeline combines preprocessing, feature extraction, clustering, and intelligent query generation for real-time, context-aware, error-bounded approximate querying. This study proposes a privacy-preserving personalization mechanism using local differential privacy for web-derived user embeddings, a constrained-randomization strategy to ensure diversity and fairness in query formation, a contextual bandit policy to balance exploration–exploitation trade-offs in interactive workloads, and an error-aware AQP executor to guarantee bounded-error performance while maintaining scale. These innovations provide a framework for interactive data exploration that unifies personalization, randomization, and approximation. Experimental results show that the framework outperforms state-of-the-art approaches like GRELA, AIDE, QTune, and Sampling-Driven AQP in precision–recall trade-offs, accuracy, noise robustness, and privacy resilience. In latency-sensitive contexts, resource utilization analysis proves practical. However, this study has drawbacks. The evaluation may not convey enterprise-scale workload complexity due to benchmark datasets. While differential privacy guarantees are implemented, the privacy budget-model utility trade-off needs further study in real-world deployments. Highly dynamic schema-evolving data scalability is another issue. Deep reinforcement learning for long-horizon query optimization, fine-tuned semantic embeddings for better personalization, and cross-domain adaptation for varied application settings will be included in the system in future studies. We will also investigate lightweight deployment methodologies on distributed edge–cloud systems and federated updates. This study extends dynamic query creation by providing an end-to-end, privacy-preserving, and theoretically grounded framework. Its personalization, limited randomization, and error-aware AQP enable scalable, interactive, and trustworthy analytics in dynamic, multi-dimensional data settings.

***Abstract*—The classification of cough sounds for smoker detection represents a challenging task in audio processing that compares different data representation methods. This study presents a performance analysis of two prominent deep learning approaches: a spectrogram-based model, the Audio Spectrogram Transformer (AST), and a raw waveform-based model, Wav2Vec2. We used 7,561 smoker and 7,561 non-smoker samples from the CODA TB DREAM Challenge dataset. Both models were trained with five-fold cross-validation and data augmentation (SpecAugment for AST; noise, pitch, and time shifts for Wav2Vec2). The raw waveform-based Wav2Vec2 model achieved the best performance, with an average accuracy of 86.5%, an F1-score of 0.862, and an Area Under the Curve (AUC) of 0.945, completing training in approximately 49 minutes per fold. In contrast, the spectrogram-based AST model reached around 76-77% accuracy and an AUC of 0.85 in approximately 78 minutes per fold. These findings indicate that the raw waveform-based approach is significantly more effective and computationally efficient than the spectrogram-based approach for this task, offering a robust method for non-invasive smoker classification through the analysis of vocal biomarkers.**

***Keywords*—Smoker detection; cough audio classification; deep learning; Audio Spectrogram Transformer; Wav2Vec2; vocal biomarker**

I. Introduction

Tobacco consumption continues to be a major contributor to preventable illness and death on a global scale. As reported by the World Health Organization (WHO), tobacco-related illnesses affect more than 8 million individuals each year, including approximately 1.3 million non-smokers who die as a result of exposure to secondhand smoke [1]. The long-term health effects of smoking, such as cardiovascular diseases, chronic obstructive pulmonary disease (COPD), and multiple types of cancer, pose a substantial burden on both individuals and healthcare systems [2].

Tobacco smoke comprises a complex blend of more than 7,000 chemical substances, including at least 70 that are carcinogenic, all of which significantly contribute to its wide-ranging adverse health effects. These substances can damage nearly every organ in the body, leading to a wide range of diseases [3]. For example, smoking is a leading cause of several types of cancer, including those affecting the lungs, oral cavity, larynx, bladder, and pancreas. It also markedly elevates the risk of cardiovascular diseases by contributing to atherosclerosis development and impairing endothelial function. Moreover, smoking impairs respiratory health, leading to conditions like COPD and worsening of asthma symptoms [4]. The harmful effects of smoking are not limited to active smokers; secondhand smoke exposure also poses serious health risks, including increased incidence of lung cancer and heart disease in non-smokers.

Despite the well-documented health consequences, the accurate and efficient verification of smoking status remains a significant challenge. Conventional methods primarily rely on self-reported declarations, which are prone to misrepresentation and bias. Studies indicate that a substantial number of smokers misrepresent their status on various applications. To overcome this, biochemical tests, such as cotinine detection in saliva or urine, are often used for objective assessment. While reliable, these biochemical methods have notable drawbacks: they are invasive, costly, and often impractical for large-scale or remote screening scenarios [5]. These limitations highlight the need for an alternative detection method that is non-invasive, objective, and scalable.

Recent advancements in digital health have introduced vocal biomarkers as a promising, non-invasive solution. Smoking induces physiological changes in the respiratory tract and vocal folds, leading to measurable alterations in voice and cough characteristics such as fundamental frequency, jitter, shimmer, and harmonics-to-noise ratio [6]. Smokers tend to exhibit rougher voice textures, prolonged coughing bouts, and altered pitch or spectral features, which have been empirically shown to distinguish them from non-smokers with significant accuracy [7]. These acoustic features can be captured and analyzed using data science to differentiate between smokers and non-smokers, offering a cost-effective and accessible approach to verification.

The application of data science and deep learning is expected to improve the efficiency of the underwriting process. As an interdisciplinary field, data science uses scientific methodologies, algorithms, and systems to extract insights from both structured and unstructured data. It draws upon mathematics, statistics, information science, and computer science principles and is closely associated with techniques such as data mining, machine learning, and big data analytics. These tools support the creation of predictive models, uncover

*Corresponding authors

patterns and trends, and facilitate data-driven decision-making. Deep learning, as outlined in [8], is a subset of machine learning that enables a system to learn from previous data and understand complex concepts without explicit programming. By learning from experience, computers can autonomously perform tasks, reducing the need for manual input. This capability holds promise for enabling real-time underwriting processes. In previous studies [9] and [10], deep learning, particularly Convolutional Neural Networks (CNNs), was employed to detect diabetic retinopathy using retinal fundus images.

This study used audio data to implement a deep learning approach to identify individuals' smoking status. The proposed approach is expected to enable accurate, real-time identification of smoking status, thereby enhancing the underwriting process. Moreover, by automating a task that is traditionally performed in the laboratory, artificial intelligence offers a cost-saving opportunity for insurance companies through increased operational efficiency.

Based on this context, this study aims to answer the following primary research questions: 1) How effectively can deep learning models differentiate between smokers and non-smokers using only the sound of their cough? 2) Which audio data representation: a spectrogram-based model (Audio Spectrogram Transformer) or a raw waveform-based model (Wav2Vec2) offers superior classification performance and computational efficiency for this task?

Two frameworks for audio classification were used in this study. The first kind operates using the mel-spectrogram image as input. The second kind uses the raw waveform as the input. Representative models for the first approach include CNN, VGGish, YAMNet, and AST. For the second approach, CNN1D, WaveNet, SampleRNN, and Wav2Vec2 are commonly used models [11]. While these architectures have been benchmarked for detecting overt respiratory diseases, their comparative efficacy for identifying the subtler physiological markers of smoking status in cough audio remains an open and important research question.

AST (Audio Spectrogram Transformer) is a deep learning model that adapts the transformer architecture, originally developed for natural language processing, to audio classification tasks by processing mel-spectrogram representations of audio signals. Unlike conventional convolutional models, AST leverages self-attention mechanisms to capture long-range temporal and frequency dependencies in audio data. AST has demonstrated strong performance in the context of detecting anomalies or categorizing specific audio events, such as identifying coughs. For instance, research in [12] used AST to classify various types of cough sounds and achieved an F1-score of 0.804.

Wav2Vec2 is a self-supervised learning model developed for speech representation learning that has shown remarkable performance in various audio classification tasks. It operates directly on raw audio waveforms and learns contextualized representations using a combination of convolutional feature encoders and transformer-based architectures. In contrast to traditional methods that depend extensively on handcrafted features or spectrogram representations, Wav2Vec2 learns meaningful patterns from raw, unlabeled audio data autonomously, thereby substantially minimizing the reliance on large annotated datasets [13]. In the domain of audio-based classification, including speaker identification, emotion recognition, and health-related applications such as cough sound classification, Wav2Vec2 has demonstrated high levels of accuracy. For instance, a study [14] employed Wav2Vec2 with minimal preprocessing to detect COVID-19 coughs, achieving competitive results with an Area Under the Curve (AUC) of 0.7810.

In this study, the AST and Wav2Vec2 algorithms were employed to classify coughs of smokers. The AST model was selected because of its strong performance in audio classification tasks, particularly those using mel-spectrogram inputs. Then, the Wav2Vec2 algorithm, which is one of the best models for audio representation that uses raw waveform as the input, is used. The performances of AST and Wav2Vec2 will be compared with those of prior approaches for classifying smokers from audio recordings.

The remainder of this paper is organized as follows. Section II provides an overview of related work in the field. Section III details the dataset, data preprocessing techniques, and the architecture of the deep learning models used. Section IV presents the experimental results and a comparative analysis of the models' performance. Finally, Section V concludes the paper by summarizing the key findings and suggesting directions for future research.

II. Related Work

Research into identifying smoking status from vocal cues has evolved from traditional acoustic feature analysis to the application of deep learning. Early studies focused on identifying perturbations in voice characteristics, such as fundamental frequency, jitter, shimmer, and harmonics-to-noise ratio, to distinguish smokers from non-smokers. These approaches, while foundational, often relied on handcrafted features and classical machine learning models.

Subsequent research moved towards machine learning techniques applied to more complex vocal representations as summarized in Table I. Poorjam et al. employed i-vector embeddings representing whole vocal tract characteristics combined with Logistic Regression classification, achieving an AUC of 0.74. This approach demonstrated the value of compact speaker-level representations for smoking status detection. Ma et al. applied convolutional neural networks (ResNet18) to Mel-frequency cepstral coefficients (MFCCs) and other acoustic features, reporting an Accuracy of 82% on a dataset comprising 1,194 samples. This deep learning approach leveraged spatial patterns in spectrogram representations to improve classification performance. Furthermore, Ayadi et al. explored a hybrid model leveraging pretrained Wav2Vec as a feature extractor directly from raw waveforms, followed by a Support Vector Machine (SVM) classifier, which achieved an accuracy of 72%. The use of Wav2Vec allowed for the extraction of rich temporal and spectral features without reliance on handcrafted features, highlighting the promise of end-to-end learned representations for this task.

Despite these promising results, current research is limited by several factors. Many studies utilize relatively small and imbalanced datasets, which may restrict the generalizability of models. Moreover, most frameworks employ multi-stage pipelines, separate feature extraction followed by classification or adapt architectures originally designed for image data (e.g., ResNet) on spectrogram inputs. There remains a lack of direct, rigorous comparative evaluations between state-of-the-art end-to-end audio-specific architectures. Specifically, models that process spectrograms such as the Audio Spectrogram Transformer (AST) and those that work directly on raw audio waveforms like Wav2Vec2 have not yet been comprehensively contrasted for smoker detection.

This study aims to address these gaps by conducting a systematic performance comparison of these two leading approaches on a large, balanced dataset. The results will provide critical insights into the optimal audio representation and model design for accurate and robust smoking status classification from voice signals.

TABLE I. STATE-OF-THE-ART

Study	Methodology	Audio Features	Dataset	Evaluation Metrics
[15]	Wav2Vec + SVM	Raw-waveform	4917 data	Accuracy = 72% AUC = 0.76
[16]	ResNet18	MFCC, FBank, F0, jitter, and shimmer	-	Accuracy = 82% F1-score = 0.823
[17]	Logistic Regression	i-vector	1194 data	AUC = 0.74

III. DATA AND METHODOLOGY

This section details the data sources and methodological approaches employed to address the core objectives of this research. Fig. 1 illustrates the procedural framework guiding this study.

A. Dataset

The dataset used in this research is the CODA TB DREAM Challenge dataset [18] comprises 29,768 cough recordings from seven countries (India, Philippines, South Africa, Uganda, Vietnam, Tanzania, and Madagascar). Each recording is associated with demographic and clinical metadata. For the purposes of our study, we removed all tuberculosis-positive cases and performed random undersampling of the majority class, resulting in 7,561 smoker and 7,561 non-smoker cough samples. The dataset is illustrated in Fig. 2.

B. Data Preprocessing and Augmentations

This study applied several data preprocessing techniques, including the following:

- Resampling: This process involves adjusting the sampling rate to match the model's requirements, ensuring input consistency, reducing memory usage, and improving computational efficiency [19]. In this study, we used a sampling rate of 16,000 Hz.
- Padding and Truncation: Padding and truncation are processes used to standardize the duration of audio samples, ensuring that they can be uniformly processed by the model. Padding involves adding zero values to audio samples that are shorter than the target length, whereas truncation trims samples that exceed the specified duration. In this study, the audio length was set to 0.5 seconds.

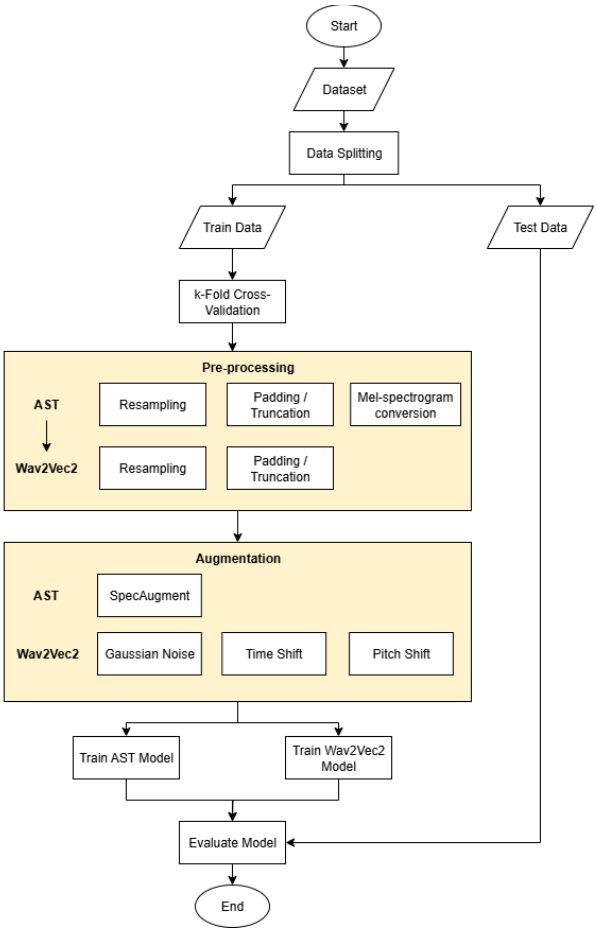

Fig. 1. Research workflow.

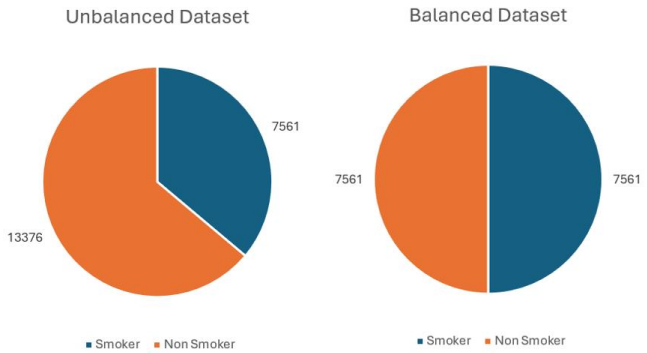

Fig. 2. Dataset distribution.

- Mel-Spectrogram Conversion: For the AST model, the input must be in the mel-spectrogram format. This process involves applying the Short-Time Fourier

Transform (STFT) to decompose the audio into its frequency components over time. Subsequently, the spectrogram was mapped onto the Mel scale, which more closely aligns with human auditory perception by emphasizing lower frequencies. Then, the mel-spectrogram is converted to a decibel scale [20]. In this study, we used a mel-spectrogram with 128 mels bands, 128 FFT components, and a hop length of 128.

- Training, Validation, and Test Data Splitting: Dividing the dataset into training, validation, and test sets is a crucial step in developing deep learning models. The training set, which comprises most of the data, is used to teach the model to recognize patterns and extract relevant features. During training, validation is employed to monitor the model's performance and mitigate issues such as overfitting or underfitting. The test set is used to evaluate the model's generalization ability on previously unseen data. In this study, the dataset was partitioned with 25% used as the test set, and the remainder split using 5-fold cross-validation.
- Subsequently, augmentation techniques were applied to the training set to enhance data diversity and improve the model's generalization performance. The augmentation methods include SpecAugment for the AST algorithm, and Gaussian noise, pitch shift, and time shift for the Wav2Vec2 algorithm [21]. The following provides a detailed explanation of each augmentation technique:
- SpecAugment: SpecAugment is a data augmentation technique that modifies audio data spectrogram representations. It applies three primary transformations: time warping, frequency masking, and time masking. Time warping involves stretching or compressing the spectrogram along the temporal axis. Frequency masking randomly obscures certain frequency bands. Time masking similarly hides segments along the time axis. These augmentations compel models to focus on more general patterns within the data, rather than overfitting to specific features, thereby improving generalization to diverse and unseen audio inputs. In this study, we used eight bands for frequency masking and eight frames for time masking.
- Gaussian Noise: Gaussian noise augmentation involves the addition of random noise drawn from a Gaussian distribution to the original audio signal. This technique simulates real-world acoustic conditions such as background chatter, machinery hum, or environmental disturbances, thereby increasing the robustness of models against noisy inputs. By slightly perturbing the waveform, the Gaussian noise encourages the model to generalize better by learning essential features rather than memorizing clean training data. The noise mean and standard deviation can be adjusted to control the noise intensity. In this study, the minimum and maximum amplitudes for the Gaussian noise are 0.001 and 0.015, respectively.
- Pitch Shift: Pitch shifting is an augmentation technique that modifies the pitch of an audio signal while preserving its temporal duration. This is achieved by raising or lowering the frequency components of the audio waveform, effectively simulating vocal tone, gender, or emotional state variations. By introducing pitch variability, this technique enhances the model's ability to generalize across different speakers and speaking styles. In this study, we used pitch shift with a minimum of -4 semitones and a maximum of 4 semitones.
- Time Shift: Time shift augmentation involves shifting the audio waveform by a small amount along the time axis. This technique simulates natural variations in speech or sound onset, such as differences in timing or speaker response delays, which often occur in real-world recordings. By randomly altering the start point of the audio signal, time shifting encourages the model to become less sensitive to the exact temporal position of features and focus more on the content itself. In this study, we used time shift augmentation with a minimum shift of -10% and a maximum shift of 10%.

C. Building Models

This study adopts two distinct deep learning approaches for classifying smoking status based on cough audio. The first approach employs the AST, which converts raw audio signals into mel-spectrograms—a visual time-frequency representation—before feeding them into a vision transformer-based model. This method treats audio as an image and leverages computer vision techniques to extract spatial patterns within the spectrogram. In contrast, the second approach uses Wav2Vec2, a transformer-based architecture designed to directly process raw audio waveforms without the need for spectrogram conversion. This end-to-end method allows the model to learn relevant features directly from the waveform through self-supervised pretraining followed by fine-tuning, integrating feature extraction and classification within a single unified stage.

For the AST model, the input mel-spectrogram is first divided into non-overlapping 16 x 16 patches. Each patch is flattened into a one-dimensional vector and then passed through a linear projection layer to obtain a fixed-dimensional embedding. The architecture of AST can be seen in Fig. 3. Mathematically, for each patch P_i , the embedding vector E_i is computed using a linear projection, as defined in (1):

$$E_i = W \cdot vec(P_i) + b \quad (1)$$

where, W denotes the projection weight matrix, b represents the bias vector, and $vec(P_i)$ corresponds to the flattened image patch. A learnable classification token, denoted as [CLS] is prepended to the patch embedding sequence to enable global representation learning for the input. Then, positional embeddings are added to each token to encode the relative position of each patch within the mel-spectrogram.

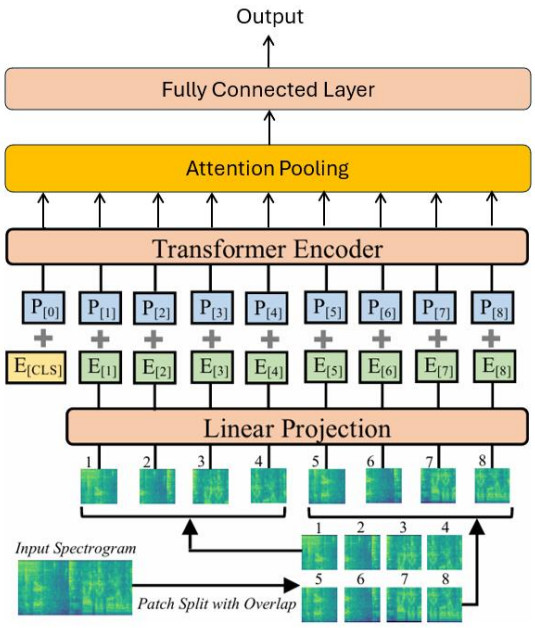

Fig. 3. AST architecture.

The positional encoding, which uses sine and cosine functions at varying frequencies to capture the order of sequence elements, is mathematically defined in (2):

$$PE_{(pos,2i)} = \sin\left(\frac{pos}{100000^{\frac{2i}{d}}}\right)$$
$$PE_{(pos,2i+1)} = \sin\left(\frac{pos}{100000^{\frac{2i}{d}}}\right) \quad (2)$$

where, pos denotes the position index, i represents the dimension index, and d is the embedding dimension. The positional encodings are added element-wise to incorporate the positional information into the model, enabling it to capture the sequential order of the input data.

Subsequently, the resulting sequence is input into the transformer encoder, which comprises 24 stacked layers. Each layer includes a multi-head self-attention mechanism with 16 attention heads, followed by a position-wise feed-forward network with a hidden size of 1024. The self-attention mechanism calculates attention scores based on the query Q, key K, and value V, and is mathematically expressed in (3):

$$Attention(Q,K,V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (3)$$

where, d_k denotes the dimensionality of the key vectors. The multi-head attention mechanism computes multiple parallel attention outputs, each corresponding to a distinct attention head. These outputs are then concatenated, and a linear transformation is performed to produce the final attention representation.

Following the self-attention mechanism, each token is processed through a position-wise feed-forward network (FFN), which comprises two linear transformations separated by as activation function, and non-linear activation function. This operation can be mathematically described by (4):

$$FFN(x) = GELU(xW_1 + b_1)W_2 + b_2 \quad (4)$$

where, x denotes the input token representation, W_1 and W_2 are learnable weight matrices, $b_1$and b_2 are the corresponding bias vectors, and GELU is the Gaussian Error Linear Unit activation. The GELU activation, used in the FFN, is defined in (5):

$$GELU(x) = x \cdot \Phi(x) =$$
$$x \cdot \frac{1}{2}\left(1 + \tanh\left(\sqrt{\frac{2}{\pi}}(x + 0.044715\,x^3)\right)\right) \quad (5)$$

where, $\Phi(x)$ is the standard Gaussian cumulative distribution function. The FFN allows for nonlinear transformations and enhances the model's capacity to learn complex representations.

Residual connections followed by layer normalization are applied after the self-attention and feed-forward sublayers. This architectural design helps stabilize the training process and facilitates efficient gradient flow throughout the network. After processing through 24 transformer encoder layers, the model does not rely on the conventional classification token [CLS] to represent global information. In this study, we employ attention pooling, which dynamically aggregates the sequence of patch embeddings into a single vector based on learned attention weights. The attention pooling mechanism assigns a weight a_i to each token embedding h_i, and computes the aggregated representation h_{attn} as a weighted sum of these embeddings, shown in (6):

$$h_{attn} = \sum_{i=1}^{N} a_1 h_i \quad (6)$$

This representation is then passed through a final fully connected layer, followed by a softmax activation to perform a binary classification between smokers and non-smokers. The output logits $z = [z_0, z_1]$ are converted into the class probability using the softmax function, as shown in (7):

$$\sigma(z)_i = \frac{e^{z_i}}{e^{z_0} + e^{z_1}}, i \in \{0,1\} \quad (7)$$

During model training, the cross-entropy loss function was employed to quantify the difference between the predicted probability distribution and the actual class labels. The loss $\mathcal{L}$, which the model aims to minimize during training, is mathematically expressed in (8):

$$\mathcal{L} = -\sum_{i=0}^{1} y_i \log(\hat{y}_i) \quad (8)$$

The input of the Wav2Vec2 model is a raw audio waveform with a fixed length of 8,000 samples and a normalized amplitude within the range [-1, 1]. The Wav2Vec2 architecture comprises two primary components: a convolutional feature encoder and a transformer-based context network. The architecture of Wav2Vec2 is shown in Fig. 4.

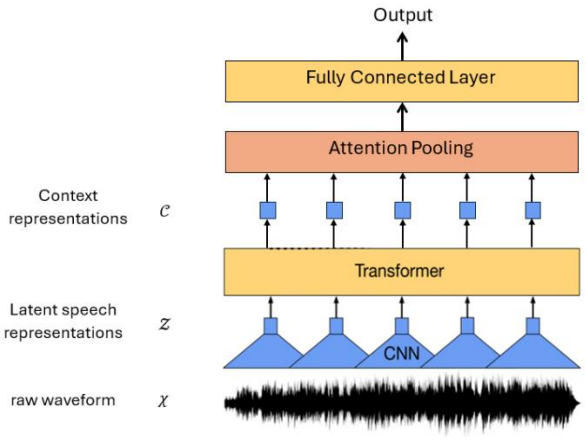

Fig. 4. Wav2Vec2 architecture.

The feature encoder consists of seven one-dimensional convolutional layers that transform the raw audio signal into a sequence of latent acoustic representations. Each convolutional layer applies a kernel across the temporal dimension and reduces the sequence length through stride-based downsampling, which is computed as shown in (9):

$$Y(i) = (x * w)(i) = \sum_{k=0}^{K-1} x(i+k) \cdot w(k) \quad (9)$$

where, x is the input signal, w is the convolution kernel, and K is the kernel size. The output is a lower-resolution but higher-dimensional representation capturing the local temporal features of the waveform. Each convolutional layer is immediately followed by the GELU activation function and layer normalization, which is computed as shown in (10):

$$LayerNorm(x) = \gamma \cdot \frac{x-\mu}{\sqrt{\sigma^2+\epsilon}} + \beta \quad (10)$$

where, μ and σ^2 represent the mean and variance of the input x, respectively, ϵ is a small constant added to ensure numerical stability, and γ and β are learnable scaling and shifting coefficients that allow the model to adapt to the normalized outputs during training.

The output of the final convolutional layer is a sequence of latent vectors $z = (z1, z2, \dots z_T)$, which is passed to the context network— a stack of 24 transformer encoder layers with 16 attention heads and a position-wise FFN with a hidden size of 1024. Positional encodings are first added to the sequence, as in the AST model.

Each transformer block contains two sublayers: a multi-head self-attention mechanism and an FFN. The attention mechanism enables each time step to attend to all others, thereby capturing global contextual dependencies. This self-attention mechanism is mathematically expressed in (11):

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (11)$$

The FFN in each transformer layer comprises two linear layers separated by a GELU activation, as described in (12):

$$FFN(x) = GELU(xW_1 + b_1)W_2 + b_2 \quad (12)$$

After all transformer layers are processed, the output is a sequence of contextualized embeddings $c = (c_1, c_2, \dots, c_T)$, where each vector $c_t \in \mathbb{R}^d$ encodes the acoustic information at time step t. Instead of using standard mean pooling, this study implements attention pooling to allow the model to learn which time steps are most informative for classification.

This attention mechanism enables the model to focus on the most relevant portions of the cough signal, thereby improving its ability to differentiate between smokers and non-smokers. The attention-weighted vector c_{attn} is passed through a linear classification layer followed by a softmax activation to produce the final prediction, as defined in (13):

$$\sigma(z)_i = \frac{e^{z_i}}{e^{z_0}+e^{z_1}}, i \in \{0,1\} \quad (13)$$

During training, the cross-entropy loss is used to measure the discrepancy between the predicted probabilities and true labels. The loss function $\mathcal{L}$ for the Wav2Vec2 model is defined in (14):

$$\mathcal{L} = -\sum_{i=0}^{1} y_i \log(\hat{y}_i) \quad (14)$$

D. Training Setup

The AdamW optimizer was used to train the models, incorporating a weight decay of 0.001 and an initial learning rate of 1×10^{-4}. Training was conducted for 20 epochs with a batch size of 16. The objective function was cross-entropy loss. Early stopping was applied based on validation loss to prevent overfitting, with a patience of four epochs. Model performance was comprehensively evaluated using several metrics, including accuracy, precision, recall, F1-score, and AUC, based on a 5-fold cross-validation with 75/25 train and validation/test split [22]. All experiments were conducted on an NVIDIA RTX A4000 GPU with 16 GB VRAM.

IV. Experimental Results

A. Evaluation Parameters

This study employed several evaluation metrics, including the accuracy, F1-score, precision, recall, and AUC. The confusion matrix is a fundamental tool for assessing classification model performance, offering a comprehensive comparison between the model's predictions and the actual labels. The confusion matrix comprises four components: True Positives (TP), True Negatives (TN), False Positives (FP), and False Negatives (FN). Precision quantifies the proportion of correctly predicted positive instances among all instances predicted as positive, thereby providing insight into the model's susceptibility to false positive errors. Recall, on the other hand, evaluates the proportion of actual positive instances that the model correctly identified, thereby reflecting its effectiveness in minimizing false negative errors. The F1-score, computed as the harmonic mean of precision and recall, provides a balanced assessment of the model's performance by simultaneously accounting for both FP and FN. Additionally, the AUC, derived from the Receiver Operating Characteristic (ROC) curve, and measures the model's ability to discriminate between classes across various threshold settings. A higher AUC value indicates better overall classification performance, especially in imbalanced dataset scenarios. These evaluation metrics are computed using the formulas presented in (15) through (21).

$$Accuracy = \frac{TP+TN}{TP+FP+TN+FN} \quad (15)$$

$$Recall = \frac{TP}{TP+FN} \quad (16)$$

$$Precision = \frac{TP}{TP+FP} \quad (17)$$

$$F1-Score = \frac{2\times(precision\times recall)}{precision+recall} \quad (18)$$

$$TPR = \frac{TP}{TP+FN} \quad (19)$$

$$FPR = \frac{FP}{FP+TN} \quad (20)$$

$$AUC = \int_0^1 TPR(FPR)dFPR \quad (21)$$

B. Experimental Analysis

In this study, simulations and model development for detecting smokers based on cough sounds, as well as the creation of a digital audio-based detection system, were conducted using hardware and software with specific configurations. Table II presents the detailed specifications of the equipment and tools used.

TABLE II. DEVICE SPECIFICATION

Specifications	
GPU	NVIDIA RTX A4000
GPU Memory	16 GB
RAM	16 GB
Disk	1 TB
Programming Language	Python 3.10

The authors configured the training process with 20 epochs, a learning rate of 0.0001, and a batch size of 16, using the AdamW optimizer. The raw waveform audio was resampled to 16 kHz for input into the Wav2Vec2 model and subsequently transformed into mel-spectrograms with 128 frequency bins for use with the AST model.

As shown in Table III, the Wav2Vec2 model without augmentation achieved the highest overall performance, attaining average accuracy, recall, precision, F1-score, and AUC values of 86.48%, 0.866, 0.868, 0.862, and 0.945, respectively. This model also required the shortest training time, completing each fold in an average of 49 minutes. Although the Wav2Vec2 with augmentation showed comparable AUC values (consistently 0.94 across all folds), its overall performance metrics were slightly lower, and its average training time increased to 65 minutes per fold. On the other hand, the AST model, both with and without SpecAugment, demonstrated moderate performance, with average F1-scores around 0.76-0.77 and longer training times of approximately 78 minutes per fold. Notably, the addition of SpecAugment to the AST did not yield significant improvements and, in some folds, even resulted in minor declines in accuracy. Overall, the Wav2Vec2-based approach outperformed the AST-based method in terms of both predictive performance and computational efficiency, indicating its suitability for fast and accurate detection of smokers based on cough audio.

TABLE III. MODEL'S PERFORMANCE

Model	Fold	Evaluation Parameters					Training Time
		Acc	Rec	Pre	F1-Score	AUC	
AST (w/o Augmentation)	1	76.65 %	0.77	0.77	0.77	0.84	78 min
	2	76.62 %	0.76	0.76	0.76	0.84	78 min
	3	76.49 %	0.76	0.77	0.76	0.85	78 min
	4	78.07 %	0.78	0.78	0.78	0.86	78 min
	5	76.33 %	0.76	0.78	0.76	0.85	78 min
AST (w/ Augmentation)	1	75.75 %	0.76	0.76	0.76	0.84	78 min
	2	77.70 %	0.78	0.78	0.78	0.86	77 min
	3	77.31 %	0.77	0.79	0.77	0.86	77 min
	4	77.52 %	0.78	0.78	0.78	0.85	78 min
	5	76.75 %	0.77	0.77	0.77	0.84	78 min
Wav2Vec2 (w/o Augmentation)	1	87.46 %	0.87	0.87	0.87	0.94	49 min
	2	85.69 %	0.86	0.86	0.86	0.93	49 min
	3	86.54 %	0.87	0.87	0.86	0.94	49 min
	4	86.51 %	0.87	0.87	0.86	0.94	49 min
	5	86.19 %	0.86	0.87	0.86	0.94	49 min
Wav2Vec2 (w/ Augmentation)	1	87.17 %	0.87	0.87	0.87	0.94	65 min
	2	84.53 %	0.85	0.85	0.84	0.94	65 min
	3	86.49 %	0.86	0.87	0.86	0.94	66 min
	4	87.23 %	0.87	0.87	0.87	0.94	65 min
	5	85.35 %	0.85	0.86	0.85	0.94	65 min

V. CONCLUSION AND FUTURE WORK

This study successfully demonstrated that cough sounds can serve as a noninvasive signal for detecting smoking status using deep learning approaches. Among the models evaluated, the Wav2Vec2 architecture without augmentation yielded the best performance, achieving an average accuracy of 86.48%, F1-score of 0.862, and AUC of 0.945, while also requiring the shortest training time of only 49 minutes per fold. This model significantly outperformed the AST-based models, both with and without SpecAugment, which achieved only around 76%–77% accuracy with a longer training duration of approximately 78 minutes per fold. These findings highlight the effectiveness

of raw waveform-based representations like Wav2Vec2 in capturing audio characteristics related to smoking, surpassing the performance of spectrogram-based methods such as AST. Therefore, the raw waveform-based approach using Wav2Vec2 presents a viable and efficient direction for developing automated, non-invasive health screening tools. In practice, this technology could be integrated into mobile applications for the insurance industry, offering an objective method for underwriting and risk assessment that moves beyond self-reported data. In clinical settings, it could serve as a rapid, preliminary screening tool in primary care. However, significant barriers to real-world adoption must be addressed. These include ensuring model robustness against varying audio quality from different consumer-grade microphones, handling background noise, and validating performance across diverse demographic populations.

Future work should focus on these challenges. First, hyperparameter tuning is necessary to further optimize model performance. Second, model ensembling techniques could enhance predictive stability. Finally, and most critically, evaluating cross-dataset generalization is crucial to ensure the model performs reliably on cough samples from different sources and acoustic environments before it can be considered for deployment in real-world scenarios.

ACKNOWLEDGMENT

This research was funded by the 2025 DIKTI Research Grant, under contract number PKS-582/UN2.RST/HKP05.00/2025. The authors also like to acknowledge the support of the Data Science Center FMIPA UI, BrainAI Lab (Bioinformatics Research, Data Intelligence, and AI Innovation Laboratory), PT Seleris Meditekno Internasional, and PT Global Risk Management.

ProjectNavigator: A Software Project Management Approach Selection Assistant

Lin Dongzhi, Salfarina Abdullah
Department of Software Engineering and Information System-Faculty of Computer Science and Information Technology, Universiti Putra Malaysia, Malaysia

***Abstract*—In software projects, project management approaches are crucial. Selecting a suitable management approach based on the specific project characteristics becomes the key to the success of the project. However, software projects are becoming more and more complex, and project managers tend to rely on subjective judgment to select the project management approaches. At present, project managers lack a systematic method or tool that can help them quickly and accurately select the most suitable project management approach to reduce project risks and improve the success rate. The objective of this research is to propose a tool to assist project managers in selecting the most suitable project management approach based on the specific project characteristics. This research will collect and analyze existing project management approaches and their applicable scenarios to extract relevant influencing factors. Then, a recommendation tool is developed to compare and recommend the most suitable project management approach. Finally, the usability and effectiveness of the tool will be validated through expert evaluation and usability testing. Through this tool, project managers can quickly analyze and compare the suitability of different management approaches and obtain specific guidance and suggestions, significantly improving the success rate of projects.**

Keywords*—Software projects; project management; recommendation tool; expert evaluation; usability testing

I. Introduction

With the rapid development of the software industry and rising project complexity, software projects are facing increasing challenges. Different project types and environmental characteristics make it particularly critical to select suitable project management approaches [1]. The most widely used project management approaches are waterfall, agile, and hybrid. Each approach has its unique advantages and limitations. The waterfall approach is known for its structured and phased process, which is suitable for projects with clear and stable requirements, but it has significant limitations in the rapidly changing software development environment [2]. In contrast, the agile approach performs well in projects with frequently changing requirements through iterative development and flexibility, but it may also lead to scope creep and insufficient resource management [3]. In recent years, the hybrid approach has gradually emerged. It combines the planning of waterfall and the flexibility of agile, providing potential solutions for complex projects, but also increasing the complexity of project management [4].

The main challenge for project managers is selecting a suitable management approach that matches project characteristics. Currently, they often rely on subjective judgment, which increases the risk of decision-making [5]. Therefore, they need a tool to assist them in selecting a suitable management approach. However, the existing studies mainly focus on the theoretical analysis of the three approaches and their scenarios or generate recommendation results through static tables [6]. These studies usually have limited analytical dimensions and lack user-friendly tool support, which makes it difficult to meet the needs of comprehensive evaluation for project management approaches.

To address the gap, this study aims to develop a decision-making tool combining comprehensive characteristic analysis and graphical results display. The tool provides intuitive, efficient, and practical support for project managers. It can capture the project characteristics provided by users and combine them with the weight calculation model to generate the recommendation result through a user-friendly interface.

This study focuses on the selection of management approaches for software development projects, specifically waterfall, agile, and hybrid. The target users are project managers and team leaders. To ensure the effectiveness and usability of the tool, this study will validate the tool through expert evaluation and usability testing.

The organization of the paper is as follows. A review of the literature on project management approaches and the key factors influencing approach selection is presented in Section II. Building on the review, Section III introduces the methodology. The results of the evaluation and discussion are given in Sections IV and V, respectively. Finally, Section VI concludes the study and outlines future work.

II. Literature Review

A. Approach and Methodology

In project management, approach and methodology there are two different concepts. The approach is a high-level guidance framework that defines the basic principles and directions of project management. In contrast, the methodology provides specific operational guidance, such as scrum and Kanban. According to Gemino et al. [7], the approach provides strategic guidance on “what to do”, while methodology focuses on the specific implementation of “how to do”. This distinction lays a theoretical foundation for the development of the project management tool in this research. The approach is the primary focus of this research, leaving the specific methodology outside its scope.

B. Waterfall, Agile, and Hybrid Approaches

The waterfall approach is linear and sequential, including five stages: requirements, design, implementation, testing, and maintenance. This approach is particularly suitable for projects with clear requirements and few changes during the project, as it emphasizes detailed planning and thorough documentation. By defining clear stages and verification processes, this approach reduces the project uncertainty. However, it lacks the flexibility to handle changing requirements effectively [8].

The agile approach emerged in the mid-1990s, aiming to solve flexibility and adaptability problems. This approach adopts the iterative development mode, delivering product increments in each iteration of the development process. This ensures timely feedback and rapid adaptation to changing requirements [9]. However, its low reliance on documentation increases the need for effective communication, while its high demand for team autonomy can lead to coordination challenges and scope creep [2].

The hybrid approach combines the advantages of waterfall and agile approaches, avoiding their limitations. The hybrid approach aims to balance flexibility and structure. It ensures stability in project planning while adapting to changes [10]. However, implementing a hybrid approach requires that the team has a comprehensive knowledge of multiple approaches. This understanding is essential to effectively integrate their strengths to achieve project objectives [11].

C. Factors Influencing Approach Selection

The selection of a suitable project management approach depends on multiple contextual factors. To understand which factors are most influential, this study conducted a literature review of 20 recent studies that analyzed or discussed the selection of agile, waterfall, or hybrid approaches. While all 20 studies were reviewed to extract key influencing factors, several representative works are highlighted here to illustrate how these factors affect approach selection.

Thesing et al. [6] proposed a decision model for project management methodology selection, categorizing and summarizing factors around project constraints, time and budget, organizational culture, and team characteristics. In terms of project constraints, projects with high requirement stability and high complexity are suitable for the waterfall approach. The project can be controlled through detailed document management and phasing. In time-sensitive projects, the agile approach performs well with rapid delivery of minimum viable products and a high frequency of customer feedback. Regarding budgeting, the waterfall approach emphasizes detailed cost estimation for projects with fixed costs. Regarding organizational culture, organizations with centralized decision-making and hierarchical management tend to adopt the waterfall approach. In addition, for team characteristics, small teams are easier to implement the agile approach, while large or distributed teams usually rely on the structured management of the waterfall approach.

Ly et al. [12] conducted a detailed analysis of the communication styles in the agile and waterfall approaches, identifying the differences in communication tools and communication channels. The waterfall approach relies on formal communication channels to complete task allocation and progress tracking through structured and standardized tools. For example, the team uses InSite system for task management and issue recording to ensure the traceability of project process and the controllability of plan. In contrast, the agile approach emphasizes more informal communication channels during execution-monitoring-control phase, where 90% of the communication is done through Microsoft Teams and only 10% relies on oral communication. The team can share dynamic information through real-time communication tools and promote task adjustment and feedback cycle. This effectively supports the applicability of the agile approach in the environment with frequently changing requirements and high levels of uncertainty.

The selection of a project management approach is influenced by multi-dimensional factors, including key business drivers, time and resource constraints, stakeholder needs and participation, project risk management, project complexity, and project size and cost [13]. These factors provide a decision-making framework for the evaluation and selection of project approaches. In addition, the hybrid approach shows high adaptability in projects with stable and dynamic requirements, especially for projects with high complexity. The hybrid approach can achieve a balance between structural management and dynamic adjustment, optimize resource allocation and risk management, and is particularly suitable for project environments that cannot be handled by a single approach. In practice, the successful application of the hybrid approach is directly related to the experience of project managers and requires that they dynamically customize and apply specific approaches and tools for each project [14].

Cruz et al. [15] conducted a systematic review of 80 studies comparing waterfall, agile, and lean project management approaches. The study highlighted that the waterfall approach is more suitable for well-defined projects with stable requirements, while agile approach is more adaptable to complexity, technological uncertainty, and frequent delivery. In addition, the study identified that factors such as stakeholder participation, team configuration, and organizational culture play important roles in determining approach suitability.

To provide an overview, Table I summarizes the key influencing factors and their frequency across the 20 studies.

III. METHODOLOGY

A. Identification of Key Factors

To identify the key factors influencing project management approach selection, this study reviewed 20 recent studies. Based on their frequency in Table I, the top 12 most frequently mentioned factors are selected for further analysis and modeling.

B. Construction of the Analytic Hierarchy Process (AHP) Model

AHP is a method for making decisions with multiple criteria. It uses pairwise comparisons to assign weights to each criterion and builds a hierarchy to support decision-making. This makes it useful for selection in complex situations (Amponsah & Amponsah, 2020). In this study, a four-level AHP-based model is developed. It is based on multiple influencing factors and is structured into four levels, as illustrated in Fig. 1:

1) Goal level: Defines the decision objective, which is to select the most suitable project management approach.

2) Category level: Groups the influencing factors into three categories: project-related, organizational, and team-related.

3) Criteria level: Includes the top 12 key influencing factors identified from Table I.

4) Alternative level: Represents the three project management options: waterfall, agile, and hybrid approaches.

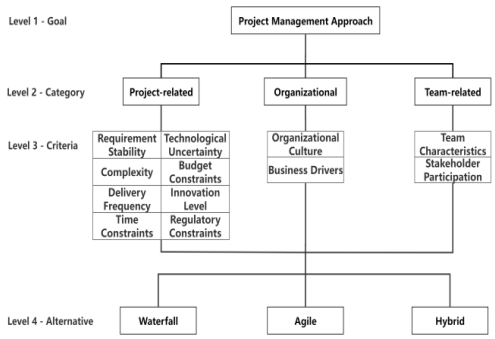

Fig. 1. AHP-based hierarchical model.

C. Pairwise Comparison and Weight Assignment

To quantify the relative importance of each criterion, pairwise comparisons are conducted using the Saaty scale from 1 to 9 [26], as shown in Table II.

TABLE II SAATY'S FUNDAMENTAL SCALE

Intensity of Importance	Definition	Explanation
1	Equal importance	Two activities contribute equally to the objective
3	Moderate importance	Experience and judgment slightly favor one activity over another
5	Strong importance	Experience and judgment strongly favor one activity over another
7	Very strong importance	One activity is strongly favored over another
9	Extreme importance	The evidence favoring one activity over another is of the highest order
2, 4, 6, 8	Intermediate values	Used for a compromise between two adjacent judgments

Within each group of related factors, every item is compared to the others to determine its priority. This process helps assign weights in a clear and structured manner. The comparison matrix for category level is shown in Table III.

TABLE III PAIRWISE COMPARISON MATRIX FOR CATEGORY LEVEL

Category	Project-related	Team-related	Organizational
Project-related	1	4	5
Team-related	1/4	1	2
Organizational	1/5	1/2	1

To ensure the consistency of the pairwise comparison matrix, the Consistency Index (CI) and Consistency Ratio (CR) are calculated. If the CR≤0.1, the matrix is considered consistent. The following formulas are used in the calculation:

$$\lambda_{max} = \sum (A\omega)_i / \omega_i \quad (1)$$

$$CI = (\lambda_{max} - n)/(n-1) \quad (2)$$

$$CR = CI / RI \quad (3)$$

The value of Random Index (RI) [26] corresponding to the matrix size of n=3 can be obtained from Table IV.

TABLE IV RANDOM INDEX VALUE

N	1	2	3	4	5	6	7	8	9
RI	0	0	0.52	0.89	1.11	1.25	1.35	1.40	1.45

For the comparison matrix in Table III, the value of CR is 0.0078. It means that the matrix satisfies the consistency requirement. The weights were calculated using the Principal Eigenvector Method, and the normalized weights are presented in Table V.

TABLE V NORMALIZED WEIGHTS FOR CATEGORY LEVEL

Category	Weight
Project-related	68.3%
Team-related	20.0%
Organizational	11.7%

After determining the category-level weights, pairwise comparisons are conducted within each category to derive local weights for each factor. The global weights are then calculated by combining all the local weights with their corresponding category weights, as shown in Table VI.

D. Recommendation Logic

This study determines the recommendation result by evaluating the alignment between the project characteristics and three project management approaches, including agile, waterfall, and hybrid approaches.

The recommendation tool developed in this study collects project-specific information through a set of guiding questions. Each key factor is associated with 1 to 3 questions. Users are required to rate their project based on these questions using a scale from 1 to 5. The average of all scores under that factor is taken as the final score of this factor.

TABLE VI GLOBAL WEIGHTS OF ALL FACTORS

Category	Category Weigh	Factor	Local Weight	Global Weight
Project-related	68.3%	Requirement Stability	29.9%	20.4%
		Complexity	18.9%	12.9%
		Delivery Frequency	14.2%	9.7%
		Time Constraints	10.7%	7.3%
		Budget Constraints	10.7%	7.3%
		Technological Uncertainty	6.8%	4.6%
		Innovation Level	4.9%	3.3%
		Regulatory Constraints	3.9%	2.7%
Organizational	11.7%	Organizational Culture	75%	8.8%
		Business Drivers	25%	2.9%
Team-related	20.0%	Team Characteristics	66.7%	13.3%
		Stakeholder Participation	33.3%	6.7%

To ensure consistency in calculation, 1–5 scales are normalized to values between 0 and 1. The normalized score for each rating is calculated using the formula:

$$r_i = (s_i - 1)/4 \quad (4)$$

where, s_i is the user's original rating and r_i is the normalized value between 0 and 1.

Next, each normalized score is compared with the ideal value for each project management approach. This study defines the ideal values based on the insight from the literature review. These values reflect the optimal project characteristics. The higher the value, the higher the alignment between this characteristic and the corresponding approach. Table VII presents the ideal values assigned to each factor for the three approaches.

TABLE VII IDEAL VALUES

Factor	Agile	Waterfall	Hybrid
Requirement Stability	0.1	1.0	0.6
Complexity	1.0	0.1	0.8
Delivery Frequency	0.9	0.1	0.6
Time Constraints	1.0	0.3	0.7
Technological Uncertainty	0.9	0.1	0.6
Budget Constraints	1.0	0.3	0.7
Innovation Level	0.9	0.1	0.6
Regulatory Constraints	0.1	1.0	0.8
Organizational Culture	0.9	0.1	0.7
Business Drivers	0.9	0.1	0.7
Team Characteristics	1.0	0.3	0.7
Stakeholder Participation	1.0	0.1	0.7

Following the normalization process, each normalized score is compared with the ideal value of each project management approach. The consistency between the project and a specific approach is quantified by the absolute difference between the user's normalized score and the ideal value. The following formula is used in the calculation:

$$Match_j = 1 - |r_j - p_j| \quad (5)$$

where, r_j is the normalized user rating for the factor, p_j is the ideal value of the corresponding approach and $Match_j$ is the matching score. Each matching score is then multiplied by the global weight of the corresponding factor to reflect its relative importance:

$$WeightedMatch_j = Match_j \times GobalWeight_j \quad (6)$$

The final score of each approach is the sum of the weighted matching values of all factors. For better understanding, the result is multiplied by 100 and presented on a scale from 0 to 100.

$$FinalScore = \sum WeightedMatch_j * 100 \quad (7)$$

The final recommendation result is determined by comparing the final scores across three approaches. The approach with the highest score is recommended as the most suitable approach. Fig. 2 presents a flowchart that summarizes the recommendation process.

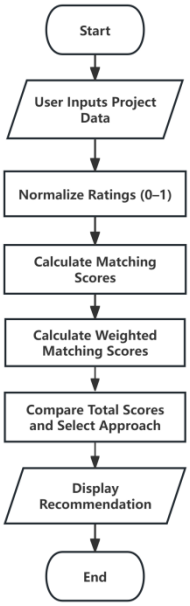

Fig. 2. Flowchart of the recommendation tool.

E. System Implementation

To implement the project management approach recommendation tool, this study develops a lightweight and user-friendly web-based system. The system is built using Spring Boot for backend logic, Thyme leaf for the interface layer, and Chart.js for visualization. It is deployed on the Render platform. This enables real-time user input processing and result display. The system architecture is illustrated in Fig. 3.

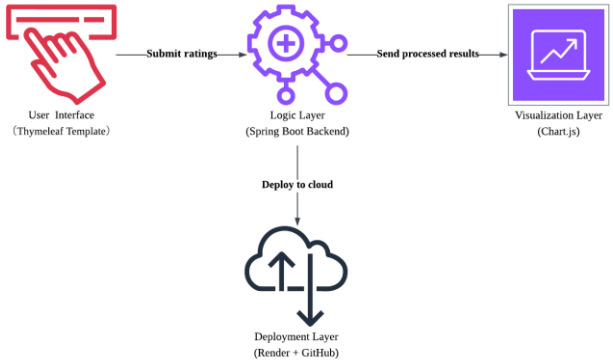

Fig. 3. System architecture of the recommendation tool.

The system provides a bilingual interface and an intuitive layout for users to input project characteristics and receive recommendations. Some snapshots of the interface are shown in Fig. 4 and 5.

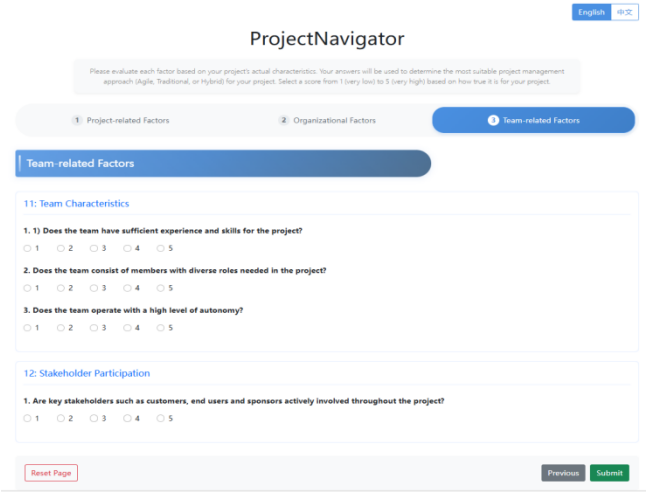

Fig. 4. Team-related questionnaire section.

Fig. 5. Result display area.

F. System Validation

For effectiveness, the factor weights and the recommendation results are examined through expert evaluation. Furthermore, usability testing is carried out using the System Usability Scale (SUS). The results of both validations offer valuable insights for further optimization of the tool.

1) Expert evaluation: To validate the effectiveness of the tool, five experts are invited to complete evaluation questionnaires. These experts have over five years of experience in project management and are familiar with waterfall, agile, and hybrid approaches. Experts need to review the global weights of the 12 factors and evaluate whether each weight is reasonable through a questionnaire. The questionnaire presents the names, global weights, and brief definitions of each factor in a table, ensuring a consistent understanding among experts. For each factor, experts need to evaluate whether the weight is too high, reasonable, or too low based on their professional judgment. If a factor is too high or too low, the system will provide an input box for experts to enter a suggested weight. They were also invited to test the tool and evaluate the accuracy of its recommendation results. Their evaluation focused on whether the recommended approach was accurate and whether they would adopt it in real projects.

2) System usability evaluation: To evaluate the usability of the recommendation tool, five users with different project management experience ranging from one to seven years are invited to complete the SUS questionnaire. SUS is a standardized questionnaire tool consisting of 10 questions. In addition, each question has a Likert scale from strongly disagree to strongly agree and is calculated using standard methods [27]. For usability testing, five users can identify most usability issues [28].

IV. Results

A. Expert Evaluation Results on Factor Weights

Based on the expert evaluation, the global weights of the 12 factors were generally confirmed as reasonable. Only the requirement stability and business drivers were suggested for adjustment by more than three experts. The adjustment details are summarized in Table VIII.

TABLE VIII Adjustments to Factor Weights

Factor	Original Weight	Suggested Value	Average Value	Final Adjusted Weight
Requirement Stability	20.4%	10%,15%,18%,18%	15.25%	17%
Business Drivers	2.9%	5%,5%,7%,10%	6.75%	6%

After adjusting the weights of requirement stability and business drivers, the total weight of all factors is no longer 100%. To maintain consistency, the remaining 10 factors are scaled based on their original weights.

B. Expert Evaluation Results on Recommendation Accuracy

To evaluate the effectiveness of the recommendation results, experts were invited to use the system and provide feedback based on their professional judgment. After using the system, they were asked to evaluate whether the recommended approach was accurate and whether they would adopt it in actual projects. A 5-point Likert scale was used, ranging from strongly disagree to strongly agree. Four experts agreed that the recommended approach is accurate and could be adopted in actual projects. None of the experts chose disagree or strongly disagree.

C. System Usability Evaluation

The final SUS score was calculated as 84.5. According to Hyzy et al. (2022), this score exceeds the benchmark of 68, indicating an acceptable level of usability.

V. Discussion

A. Adjustment of Factor Weights

Based on the expert evaluation, two factors required adjustment: requirement stability and business drivers.

1) Requirement stability: The original weight of requirement stability is 20.4%. According to expert feedback, four experts considered that the value was too high and suggested a range of 10% to 18%. Although two experts suggested 18%, the lowest value of 10% significantly reduced the average to 15.25%. Considering the consensus among experts that this factor is overestimated, the final weight was adjusted to 17%. This adjustment reduces the weight while still maintaining its importance.

2) Business drivers: The original weight of business drivers is 2.9%. According to expert feedback, four experts considered that the value was too low and suggested a range of 5% to 10%. However, because the majority of expert suggestions were below 7%, the final weight was set at 6%. This value is closer to expert suggestions and avoids overadjustment.

B. Recommendation Accuracy

Expert evaluation results on recommendation accuracy indicate a high level of confidence in the effectiveness of the recommended results. This positive feedback validates that this tool can provide reliable and practical recommendation results based on project characteristics.

C. Usability of the System

The SUS score of 84.5 reflects a high level of usability, clearly above the benchmark of 68. This result shows that the tool is easy to learn and use for project managers. High usability also increases the likelihood of adoption in real projects.

D. Validation Significance and Related Work Comparison

These validation measures are essential to ensure that the tool is not only theoretically sound but also practically usable. Unlike many existing studies that only present theoretical models without a practical tool or systematic validation, this study develops the recommendation tool and validates it

through expert evaluation and SUS testing. The results confirm its reliability, recommendation accuracy, and usability, indicating strong potential for adoption in real projects.

VI. Conclusion and Future Work

A. Conclusion

This study developed a web-based recommendation tool to assist project managers in selecting appropriate project management approaches. The tool enables users to input project characteristics through structured questions. Then the system recommends the most suitable project management approach from agile, waterfall, or hybrid approaches.

To ensure the effectiveness and usability of the tool, validation was conducted through expert evaluation and usability testing. Experts evaluated the global factor weights and recommendation results and provided adjustment suggestions for certain weights. Then, the model was optimized based on expert feedback to enhance its consistency with professional judgment. In addition, the system usability was evaluated through the SUS questionnaire, and the final score was 84.5, exceeding the acceptable threshold. The results indicate that the tool has good effectiveness and user experience in assisting the selection of a project management approach.

Overall, the recommendation tool developed in this study offers a clear and reliable way to help project managers select the most suitable project management approach and has strong potential for practical application.

B. Future Work

Although this study has successfully developed and validated the recommendation tool, there are still several areas that can be further improved. To enhance the effectiveness and usability of the tool, the following directions for future improvement are proposed:

- The current system uses the same global weight for all users. In the future, based on providing predefined weight templates, users can adjust these global weights within a limited range according to their own project characteristics. This can enhance the flexibility and personalization of the model while maintaining stability and consistency of recommendation logic.
- In the future, real-world software project data can be collected to further validate the effectiveness of these factors. This would help identify missing factors or weights that may require adjustment.
- A database would be integrated to store user input data and recommendation results. In addition, a feedback module can be added to allow users to evaluate the accuracy of the recommended approach after the project is completed. With sufficient historical data and user feedback, the system can adjust the model, improving the accuracy of the system.

***Abstract*—Figurative language, especially sarcasm, poses strong challenges for Natural Language Processing (NLP) models because of its implicit, context-sensitive nature. Both traditional and transformer models tend to find it difficult to identify these subtle forms, particularly when dealing with imbalanced datasets or without mechanisms for targeted interpretability. For overcoming these shortcomings, this study recommends a hybrid deep learning architecture that integrates RoBERTa for high-contextual embedding, Bidirectional Gated Recurrent Units (BiGRU) to capture bidirectional sequential relations, and an attention mechanism allowing the model to focus on the most informative parts of the input text. This integration enhances semantic understanding and classification accuracy compared to current solutions. The model is trained and tested on the benchmark News Headlines Dataset for Sarcasm Detection using binary cross-entropy loss minimized with Adam, along with dropout and learning rate scheduling to avoid overfitting. Experimental results yield better performance, attaining an accuracy of 92.4%, a precision of 91.1%, a recall of 93.2%, and an F1-score of 92.1%. These results outperform baseline techniques such as BiLSTM with attention and fine-tuned BERT variants. Implementation uses PyTorch and Hugging Face Transformers, ensuring reproducibility and extensibility. While effective, the model faces challenges with figurative expressions requiring external world knowledge or cultural context beyond pretrained embeddings. Future work aims to integrate external knowledge graphs and extend the model to multilingual and cross-domain scenarios. This hybrid framework advances figurative language detection, contributing to the broader goal of enhancing AI's nuanced understanding and interpretability of human language.**

***Keywords*—Figurative language detection; sarcasm classification; RoBERTa-BiGRU-Attention model; contextual embeddings; Natural Language Processing**

I. Introduction

Figurative language, including types like sarcasm, metaphor, and irony, is critical in human communication as it communicates beyond the literal meaning [1]. It is particularly dominant in digital text, such as social media, online reviews, and newspaper headlines [2]. These expressive mechanisms are used to add subtlety, signal humor, or highlight perspectives; yet their inherent implicitness and extreme dependency on context make them an overwhelming problem for Natural Language Processing (NLP) algorithms [3]. Traditional NLP models usually find it difficult to correctly infer nonliteral meaning, resulting in misclassification and misinterpretation [4]. This shortcoming has a negative effect on most downstream applications that are dependent on the correct semantic interpretation, including sentiment analysis, opinion mining, emotion detection, and conversational AI. For example, failure in sarcasm detection can invert the targeted sentiment of text, resulting in the wrong analysis outcomes and inferior user experiences.

Emergent developments of models such as BERT and RoBERTa have significantly progressed many NLP tasks through their capacity for creating contextual embeddings capturing syntactic and semantic relations in texts [5]. In spite of these developments, such models still struggle with figurative and subtle language [6]. Such models tend to fail to capture fine semantic signals and long-distance dependencies necessary for distinguishing figurative expressions [7]. Furthermore, issues like severe class imbalance in training sets restrict model generalization [8]. Another major flaw is the lack of comprehensive explainability for transformer-based predictions, which restricts knowledge of why a certain input was labeled as figurative or not, hence influencing trust and usability in actual systems.

Against such challenges, this work suggests a new hybrid framework that is tasked with enhancing the accuracy of figurative language detection through the use of complementary deep learning methods. The model uses RoBERTa to produce high-contextualized word embeddings, a (BiGRU) to capture

bidirectional sequential dependencies in the text, and an attention mechanism to attend to the most contextually informative tokens in an input sequence. By combining these parts, the model hopes to harness the contextual capability of transformers with the added sequential learning and focus prioritization, achieving more accurate and context-aware identification of figurative language. This should yield more accurate outputs that can be used in practical NLP applications that make use of subtle language comprehension.

A. Research Motivation

Figurative language, like irony, metaphor, and sarcasm, is important in the way humans convey meanings that transcend literal understandings. Figurative language in digital communication, particularly on social media and news websites, is prevalent and powerful. Yet, conventional NLP systems often misinterpret figurative language because of its contextual subtlety and implicit semantics. This results in tremendous challenges for applications such as sentiment analysis, emotion detection, and user interaction in AI applications. Despite the progress made by models such as BERT and RoBERTa, precise identification and interpretation of figurative language remains a challenging task. Current models lack class balance, explainability, and proper emphasis on sequential context. Thus, it is an urgent need to create stronger and contextualized approaches that can better represent the richness of figurative language. This work is stimulated by the desire to enhance automatic detection of figurative expressions through using hybrid deep learning models that combine strong contextual embeddings with sequential and attention mechanisms, improving at last performance and explainability of figurative language detection systems.

B. Research Significance

Automatic identification of figurative language is of tremendous importance in the development of NLP applications, such as sentiment analysis, conversational AI, content moderation, and recommendation systems. Incorrect interpretation of figurative language—sarcasm, especially—can cause errors in user intent, resulting in ambiguous sentiment classification or unsuitable responses for AI systems. It is a critical challenge to overcome in improving user experience and decision-making in automated services. Through the creation of a new hybrid architecture consisting of RoBERTa contextual embeddings, Bidirectional Gated Recurrent Units (BiGRU), and an attention mechanism, this work immensely helps bridge the gaps in current methods that fail to capture semantic depth and contextual subtleties. The approach enhances classification accuracy and generalization on benchmark data sets as well as facilitates improved explainability of decisions via attention mechanisms. The adaptability of the work to multilingual and cross-domain settings underscores its wider significance beyond English text processing. This research, therefore, is a significant step towards more human-like and intelligent language comprehension in artificial intelligence systems, with various applications in cross-sections of fields demanding subtle linguistic analysis and interpretation.

C. Key Contribution

- Proposed a novel hybrid deep learning architecture integrating RoBERTa, BiGRU, and attention mechanisms for effective figurative language detection.
- Demonstrated superior performance metrics on benchmark sarcasm detection datasets compared to baseline methods.
- Addressed challenges of context sensitivity and class imbalance to improve model generalization and robustness.
- Enhanced explainability of model predictions through the integration of an attention mechanism highlighting important tokens.
- Provided a framework adaptable to multilingual and cross-domain applications, expanding the utility of figurative language detection in NLP.

The remainder of the section is prepared as follows: Section II is the related study, Section III is the Problem Statement, methodology part is in Section IV, Section V is the result and discussion section, Section VI is the conclusion and future work section.

II. Related Works

Liu et al. [11] explored the issue of nonliteral language and presented Fig-QA, a Winograd-like question-answering dataset that assesses the linguistic models on how well they comprehend the figurative language with contrasting semantics. The task consists of choosing the appropriate meaning between paired figurative expressions whose contextual suggestion varies, and, thus, challenges the profundity of nonliteral understanding of language models. The study compared the functioning of a number of state-of-the-art transformer-based models on the Fig-QA benchmark. Despite these models showing levels of performance far above-average random chance, they were still very far behind the performance of human participants in both zero-shot and few-shot settings. Such a gap highlights the inability of current models to reflect the fine and easily context-specific details of the figurative language. The results indicate that current neural networks, despite their impressive literal comprehension ability, are not very advanced in reasoning, a prerequisite to effective nonliteral comprehension.

Chakrabarty et al [12] designed DREAM-FLUTE, a new framework of figurative language understanding using scene elaboration and entailment inference to increase the accuracy of the interpretation. Metaphors and similes are often used as figurative language, and the sense therefore is not inferred easily when read their surface form. In order to solve this, the authors posed a hypothesis that the proper interpretation will involve building a mental model of the described situation. DREAM-FLUTE builds on this hypothesis by creating a well-organized mental model of both the premise and the hypothesis based on an existing framework known as DREAM (Deep Reading for Elaborative Mental Modeling). Then it produces entailment or contradiction judgments and produces textual explanations. The system was tested as part of the FigLang2022 Shared Task, in which it topped the leader board (tied in first place with 63.3%

Acc@60 accuracy). The authors also showed that by using ensemble methods to improve the performance of a system further was even possible.

Huang et al. [13] reduced the various limitations of existing benchmarks of figurative language. Although the use of figurative language was in the past successfully put within the framework of the Recognizing Textual Entailment (RTE) paradigm, much earlier benchmarking efforts were hampered by spurious correlation and annotation artefacts, and it is hard to assess whether language models are understanding nonliteral meaning effectively. FLUTE bridges this divide by presenting 9,000 pieces of real NLI examples together with human-generated clarifications on the same. The data consists of four categories of figurative language comprising sarcasm, simile, metaphor, and idioms. It was built in the model-in-the-loop fashion, integrating the power of GPT-3 with crowdsourcing and human expert annotation in order to achieve quality and scale. The authors have proven that such a hybrid annotation approach contributes greatly to the reasonable development of complicated linguistic databases. Baseline tests implemented with a fine-tuned model T5 on FLUTE showed that the presence of textual explanations gives an advantage to models, meaning a better understanding of answers and something to be noticed about their possible better performance in figurative situations.

Sharma et al [14] explored transformer-based architectures in identifying figurative presentations compared to literal utterances in huge textual information. With the growing demand for efficient sentiment extraction and text classification with an understanding of language specificities, the authors found it necessary to run a set of transformer models (including BERT and RoBERTA variants), whereas the latter could efficiently perform sentiment extraction and many aspect specifications when it came to nonliteral language. The authors used the opportunity to determine whether the models that were trained on one category of figurative language representation, e.g., metaphors or sarcasm, could generalize well across categories. The study has extensively experimented to indicate that transformer models have achieved significant advances in typical NLP tasks, but are still not very successful with figurative constructs in NLP since they have implicit and context-sensitive definitions. The study also highlighted the urgency with which machines should be made to comprehend the figurative language that is rampant in the human language, and unlike literal language, which is processed.

Kumar et al. [15] approached the problem of interpretation of affective dimensions in the context of conversational dialogue, which are frequently masked by the use of the figurative language of irony, sarcasm, and metaphor. In order to better understand such situations, the authors have suggested a deep neural network model (MOSES) that could be applied to Sarcasm Explanation in Dialogues (SED). The model uses input multimodal sarcastic utterances and outputs natural language explanations to disclose an ironic meaning behind it. This direct encoding of figurative purpose is in turn used to enhance a number of downstream NLP tasks, such as detecting sarcasm, identifying humor and detecting emotion. The tests on different experimental conditions proved that MOSES shows superior results by 2% to the state-of-the-art in the SED in terms of ROUGE, BLEU, and METEOR. Moreover, the inclusion of generated explanations managed to obtain a significant 14% boost in sarcasm detection tasks, and a 2% boost in both humor and emotion recognition tasks.

Vitiugin and Paakki [16] proposed an effective framework regarding the classification of such a complicated task, the Deep Ensemble Soft Classifier (DESC). In view of the fact that the figurative language forms have a complex nature of figurative language use, especially sarcasm, irony, and metaphor, the present study sought to traverse through the inconsistent semantics that are usually intertwined with an expression of a figurative language form. The first contribution of the authors was the presentation of a complete data preprocessing pipeline and its use to standardize and optimize the input representations to deep learning models. They further derived some specialized features like the syntactic structure, mode of expressing emotions, expressive style, and temperamental formulations in the articulation of a figurative meaning, as held by those utilizing social media. Such dense feature representations were next input into the DESC model, an ensemble scheme that mixes different deep learning structures together to boost the accuracy of classification and generalization. Tests have been done using three benchmark sets, with one made particularly in multiple forms of figurative language.

Hülsing and Im Walde [17] provided a unification of a framework that is able to detect multiple figures of speech in more than one language. Aware of the fact that figurative meanings, i.e., metaphors, sarcasm, and idioms, are not solely linguistically diversified, but also culturally conditioned, the study implemented the multilingual multi-figurative language modeling. The authors came up with a sentence-level corpus of three varieties of figurative language and seven languages with the aim of eliminating the deficit of existing monolingual and figure-specific studies. They use template-based prompt learning, which was used to facilitate the model to generalize through figures of speech and languages, with no need to add specialized modules. Such a coherent system reduces the complexity of modeling and allows greater scalability in low-resource or multilingual settings. Experimental studies showed that the proposed technique feasibly outperforms growing transformer-based baselines, which indicated the potential capability of the approach under study in robust cross-language figurative language understanding.

Ocampo and Clarifiño [18] considered the metaphor detection task in figurative language processing to come up with a new approach that uses lexical definitions to boost metaphor detection, hence MIss RoBERTa WiLDe. This is especially true since the inception of the powerful pretrained language models, GPT-3, XLNet, and BERT, which have allowed challenges restricted to small quantities of annotated data, like metaphor recognition, to improve considerably. The authors extend this development by utilizing an open-source lexical database, known as Wiktionary, in to access automatically via dictionary on non-figurative word senses. The definitions that were put forward are contextual anchors to assist the model to differentiate between uses that are literal and uses that are metaphorical by having a contrast between basic use and contextual use. The suggested model combines RoBERTa and a binary token-level classifier to find metaphorical expressions, and it shows a high degree of transferability across datasets.

Experimental comparisons indicate that MIss RoBERTa WiLDe performs end-to-end better or equally well to the state-of-the-art metaphor detection systems, providing a scalable, dataset-independent, and efficient approach.

Lv et al. [19] proposed RB-GAT, a first hybrid text classification model focusing on a well-integrated RoBERTa and BiGRU with Graph Attention Networks (GAT) to solve the weakness of the traditional graph-based neural models in modeling the contextual semantics in a text. Graph Neural Networks (GNNs) have shown promising results on textual classification but tend to fail at capturing text sequential dependencies and contextual information (at the document level). In a bid to overcome this, RB-GAT uses RoBERTa to produce rich but contextualized word and sentence-level embeddings, which are then coupled with a (BiGRU) used to model long-range and bidirectional textual relationships. Such added features are subsequently multi-head GAT, which learns inter-token relations, where the various sections of the document graph are designated by dynamic scores of attention. This kind of arrangement enables the model to be semantically and topologically coherent. The softmax layer is then used in the final classification. Comparing 5 benchmark datasets-Ohsumed, R8, MR, 20ng, and R52, RB-GAT was superior to the baseline model, having achieved an accuracy of 71.48, 98.45 and 80.32 and 90.84, and 95.67, respectively.

Berger et al [20] employed transfer learning in the German setting on a metaphor-recognition task and accordingly used a framework that was cross-lingual, where an English corpus with the sentence-level metaphor is annotated. The English answers were mechanically translated into German, and a sample of 1,000 German sentences was manually parsed in order to become a gold standard of two assessment configurations: sequence labeling composed of tokens and sentence classification. There were two major approaches to transfer learning that the authors tested: 1) transformer-based models, including multilingual BERT, and 2) bilingual word embeddings with an RNN-based classifier. Transformer models performed fairly in zero-shot, as they produced the best performance of 61% F1-score used to perform the classification tasks, whereas the embedding-based approach did not perform any better compared to a random baseline, scoring a mere 36% F1. Once fine-tuned using the annotated German dataset, both methods increased greatly in performance, with a maximum F1-score of 90%, and so cross-lingual metaphor detection can be highly efficient in terms of language-specific tuning. A rich annotated metaphor corpus in the two languages forms a contribution of the study that can be applied to make future studies on mixed language processing of the figurative language more feasible.

Current literature emphasizes the increasing need for advanced models capable of dealing with various kinds of nonliteral semantics in languages and different types of figurative language. Benchmarks such as Fig-QA and FLUTE show that while transformer models are better than chance, their understanding of figurative language is constrained in comparison to human inference. Models such as DREAM-FLUTE and MOSES show that explanation generation and mental modeling together increase interpretability along with performance. Other methods such as DESC and RB-GAT combine contextual embeddings with deep learning models (BiGRU, GAT), enhancing classification accuracy over diverse figurative expressions. Additionally, studies on template-based prompt learning and multilingual embeddings yield high-performance results in cross-lingual metaphor detection, pointing toward a shifting future for strong, scalable processing of figurative language.

III. Problem Statement

Precise identification of figurative language, especially sarcasm, continues to be a tough task in (NLP) because it is implicit, context-dependent, and nuanced [9]. Although models such as BERT and RoBERTa have pushed the frontiers of many NLP tasks further, they tend to struggle with properly capturing subtle semantic signals and long-distance dependencies required for first-order interpretation of nonliteral expressions [10]. Besides, current methods are challenged by class imbalance problems in training data, weak explainability of model choices, and weak infusion of sequential context, all of which lower their overall performance and dependability. This constraint negatively impacts many downstream NLP tasks like sentiment analysis, opinion mining, conversational AI, and emotion detection, wherein the misunderstanding of figurative language can result in inaccurate outcomes and less-than-optimal user experiences. This study resolves the issue of creating a robust, context-sensitive system for figurative language identification that surpasses the limitations of existing approaches. In particular, it introduces a new hybrid model synergizing the benefits of transformer-based contextual embeddings and sequential learning through Bidirectional Gated Recurrent Units (BiGRU) and an attention mechanism. This integration has the goal of enhancing accuracy, interpretability, and generalizability across various kinds of figurative language, eventually enhancing the reliability and usability of figurative language detection in practical NLP applications.

IV. Proposed Hybrid Framework for Figurative Language Detection

A hybrid deep learning architecture is created through the integration of transformer-based contextual embeddings, sequential learning, and attention mechanisms to enhance the identification of figurative language. The architecture incorporates pretrained RoBERTa embeddings, which produce high-quality and context-aware representations of words, and a Bidirectional Gated Recurrent Unit (BiGRU) that learns sequential dependencies in both directions. An attention mechanism is added to emphasize and concentrate on the most informative tokens of the input sequence, enhancing the model's capability to distinguish subtle figurative uses like sarcasm. It is trained and tested on the News Headlines Dataset for Sarcasm Detection, a common benchmark with balanced sarcastic and non-sarcastic samples. Preprocessing of data involves conversion of headlines to lowercase, removal of special characters, and tokenization with RoBERTa's tokenizer. The input is padded or truncated to a constant length to have a consistent input size for batch processing. Training is done with binary cross-entropy as the loss function, optimized using the Adam optimizer. Hyperparameters like learning rate, batch size, dropout rate, and epochs are specifically tuned to minimize overfitting and maximize generalization. The use of a dropout

layer keeps overfitting at bay, while learning rate scheduling stabilizes the convergence process. To holistically quantify model performance, standard classification metrics are provided. This framework of evaluation ensures balanced quantification of the model's capacity to correctly identify figurative language versus literal expressions, ultimately enhancing the robustness and usability of the detection of figurative language in practical applications of NLP. The end-to-end architecture that is proposed is a decent balance between complex semantics understanding as well as sequence-based learning, and would lead to clean and accurate detection of figurative language. Fig. 1 is a pictorial representation of it.

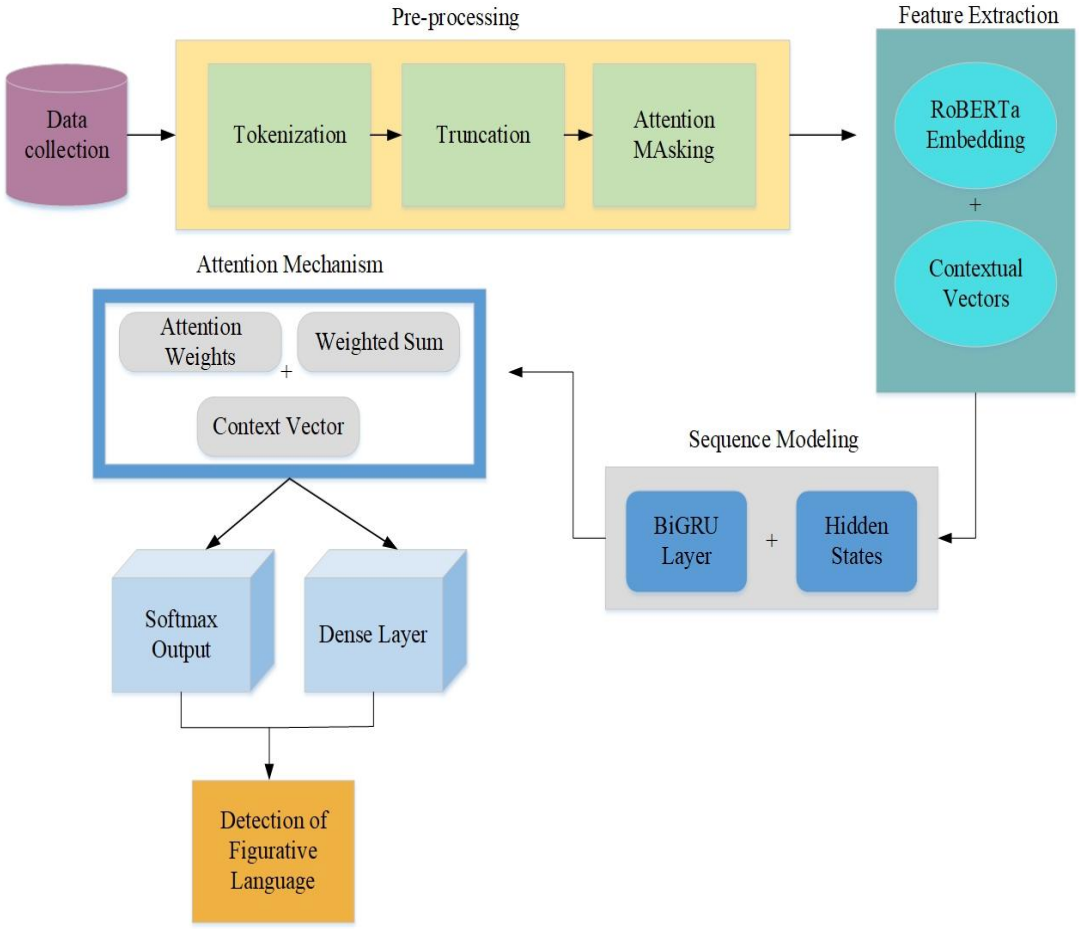

Fig. 1. Proposed RoBERTa-BiGRU-attention architecture

A. Data Collection

The News Headlines Dataset [1] for sarcasm detection, available on Kaggle and developed by Rishabh Misra, is utilized in this research [21]. The dataset comprises approximately 28,000 English-language news headlines, each labeled as either sarcastic (1) or non-sarcastic (0). Each entry contains the headline text, its corresponding sarcasm label, and in some cases, links to the original news articles. This dataset is well-suited for figurative language detection, particularly sarcasm, as it consists of concise texts with sufficient contextual information to train deep learning models effectively. The headlines exhibit clear syntactic structure and provide a clearly labeled, supervised learning environment, enabling rigorous evaluation of the model's ability to comprehend situations and interpret nonliteral language. Table I shows the dataset description.

TABLE I. DATASET DESCRIPTION

Label	Description
0	Non-Figurative Headlines
1	Figurative (Sarcastic) Headlines
Total	50,000

B. Data Pre-Processing

All headlines were in lower case, lacking punctuation, figures, and unnecessary symbols, so as to normalize the input. A fixed-length L (RoBERTa) WordPiece tokenizer was used to tokenize cleaned text and truncate or pad it to the desired length. Subsequent to this, the lean pipeline minimizes vocabulary sparsity, and the input size is maintained effectively to train

[1] https://www.kaggle.com/datasets/rmisra/news-headlines-dataset-for-sarcasm-detection

it. Formally, the cleaned headline x_{clean} is obtained from the original headline x as:

$$x_{clean} = Clean(x) \quad (1)$$

In Eq. (1), x is the original headline whereas x clean is the cleaned version in. A small vocabulary size is achieved through such standardization and makes learning easier and faster. And to each cleaned headline x clean, a Word Piece tokenizer that works with RoBERTa is used to tokenize each. Tokenization transforms a sentence into a sequence of tokens:

$$T = Tokenizer(x_{clean}) = [t1, t2, \ldots, tn] \quad (2)$$

In Eq. (2) $T = \{t1, t2, \ldots, tn\}_0$ refers to the order of subword tokens. The input sequences are of variable length and, as such, are padded or truncated to a set maximum length L, so that the shape of the inputs to a batch processing is the same shown in (3):

$$T' = \frac{pad}{truncate(T,L)} = [t_1, \ldots., t_l] \quad (3)$$

Finally, tokens are converted into embeddings using RoBERTa's pretrained encoder:

$$E = RoBERTaEncoder(T') = [e_1, e_2, .., e_l] \quad (4)$$

In Eq. (4) $E \in \mathbb{R}^{L \times d}$ is the word embeddings of each token, and d is the embedding dimension. This pre-processing chain is designed to yield a clean, tokenized, semantically enriched text to achieve good training and classification.

C. Model Architecture: RoBERTa-BiGRU-Framework

The suggested method for figurative language detection uses a hybrid model with deep learning algorithms, combined with contextual embeddings and sequence learning. Following preprocessing, every headline is tokenized and fed into a pre-trained RoBERTa model, which produces contextual embeddings that have the ability to sense minute semantics and relationships between tokens and thus can effectively identify figurative language patterns in the text.

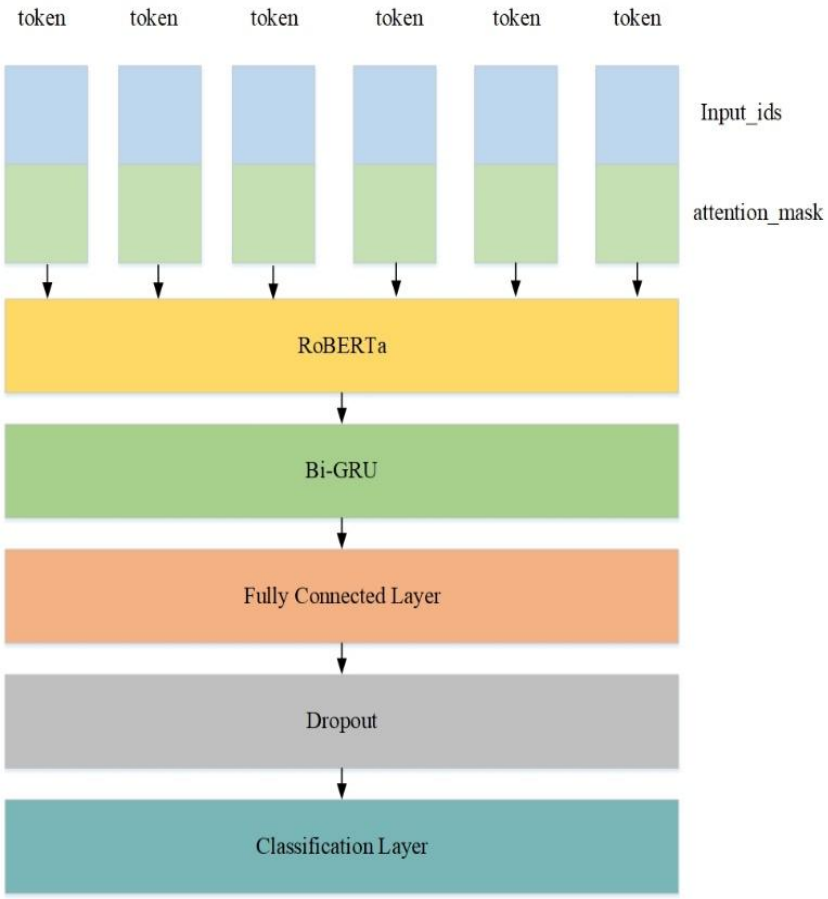

Fig. 2. Block diagram of the hybrid model pipeline.

Fig. 2 represents the proposed hybrid model intended to detect the figurative language in textual data based on the option of RoBERTa and BiGRU. The model takes as an input sentence which is translated into tokens and some other input_ids and attention_mask. The token representations will be input into the RoBERTa module, a pretrained transformer language model, and produce rich contextual representations of tokens capturing semantic and syntactic aspects. RoBERTa output embeddings are passed as input to a Bidirectional Gated Recurrent Unit (BiGRU) network that performs the further processing of the sequence in both forward and backward directions. This dual-processing capacity enables the model to keep the contextual relationships of previous and subsequent tokens and improve expression of linguistic structure and meaning. After output of

the BiGRU, the Fully Connected Layer condenses the sequence-level features into a categorical condensed feature more appropriate to give to the classifier. To avoid overfitting, the model feature contains Dropout Layer that eliminates a random selection of connections in the training process. The output of that processed information is fed to the Classification Layer, which uses the Softmax function to make the prediction in regards to what type of label is in the data figurative (1) or non-figurative (0). This architecture is highly integrated in terms of both contextual, sequential and classification in the recognition of the figurative languages.

Officially, the embed output may be well formulated as: $E \in \mathbb{R}^{L\times d}$, where L is the length of the sequence and d is the embedding dimension. The latter embeddings are taken as input into a (BiGRU) to learn forward and backward dependencies throughout the sequence, which conveys more of those contextual cues. The hidden state over time t is calculated as:

$$h_t = BiGRU(E_t), t = 1,2, \dots, L \quad (5)$$

In Eq. (5), to enhance interpretability and focus on key parts of the sentence, an attention mechanism is applied to the BiGRU outputs. This mechanism assigns higher weights to more informative tokens. The attention weight αt is calculated as:

$$\alpha_t = \frac{\exp(u_t)}{\sum_{j=1}^{L}\exp(u_t)} \quad (6)$$

In Eq. (6), $e_t = tanh(W_h h_t + b$ The final attended representation is a weighted sum of hidden states:

$$r = \sum_{t=1}^{L} \propto_t h_t \quad (7)$$

In Eq. (7), this vector is passed through a fully connected classification layer with a Softmax function to output the probability of the sentence being figurative (e.g., sarcastic):

$$y = Softmax(W_c r + b_c) \quad (8)$$

In Eq. (8), the model is trained using binary cross-entropy loss and optimized with the Adam optimizer. Dropout and learning rate scheduling are employed to prevent overfitting and ensure generalization.

D. Training Parameters and Hyperparameters

The trained model uses the binary cross-entropy loss, optimized by the Adam optimizer to better reduce classification mistakes. Major hyperparameters were finely tuned to achieve the best results on the task of detecting sarcasm. The pretrained RoBERTa-base model is used as the embedding backbone, with a maximum sequence length of 128 tokens to strike the right balance between computation and context attainment. A learning rate of 2e-5 was chosen following initial experiments, yielding stable convergence during training. The batch size is fixed at 32 to ensure full utilization of the GPU without memory overflow. To avoid overfitting, a dropout rate of 0.3 is utilized with random disabling of network connections during training. The model is trained for 10 epochs, and learning rate scheduling is used to dynamically adjust the learning rate and enhance training stability. All selected hyperparameters and configurations are listed in Table II. These parameters serve as the basis for strong and accurate figurative language classification with good generalizability to various inputs.

TABLE II. TRAINING PARAMETERS AND HYPERPARAMETERS

Parameter	Value
Pretrained Model	RoBERTa-base
Sequence Length	128 tokens
Optimizer	Adam
Learning Rate	2e-5
Dropout Rate	0.3
Batch Size	32
Epochs	10
Loss Function	Binary Cross-Entropy

Table II outlines the key training configurations and hyperparameters used for building the proposed model. These settings were tuned to optimize performance on the sarcasm detection task.

Algorithm 1: Figurative Language Detection Using RoBERTa-BiGRU-Attention

```
Input: Headline Text
Output: Label (0 = Non-Figurative, 1 = Figurative)
Begin
  If Headline Text is empty, then
    Return "Invalid input."
  Else
    Clean Text ← Preprocess (Headline Text)
    If Clean Text contains special characters, then
      Remove special characters
    End If
    Tokens ← Tokenize (Clean Text)
    Embeddings ← RoBERTa(Tokens)
    If Embeddings is not None, then
      BiGRU Output ← BiGRU(Embeddings)
    Else
      Return "Embedding failure"
    End If
    Attention Weights ← Compute Attention (BiGRU Output)
    Context Vector ← WeightedSum (BiGRU Output, Attention Weights)
    Prediction ← Softmax (Dense (Context Vector))
    If Prediction ⩾ 0.5 then
      Return 1 Figurative
    Else
      Return 0 Non-Figurative
    End If
  End If
End
```

Algorithm 1 proposes a step-by-step procedure for identifying the presence of figurative language based on a hybrid deep learning model composed of RoBERTa, BiGRU, and an Attention Mechanism. This process starts with an input text that may be taken as a headline. In the case where the input is empty, the algorithm directly responds as invalid. Other than this, other preprocessing is done, such as cleaning up, lowercasing, and taking away any special characters to standardize the form of input. Then the cleaned text is tokenized into the subword units that could be addressed by the RoBERTa model. RoBERTa

model produces contextual representations, which retain the linguistic sensible in the individual words. The embeddings are fed to a Bidirectional Gated Recurrent Unit (BiGRU), which learns forward and backwards dependencies in the text, which is why this is perfect at processing text that is difficult to process, such as the sentence structure of figurative language. When valid embeddings are produced, an attention mechanism is used to highlight the most informative sections of the BiGRU output. A dense layer and a Softmax classifier are then used to consume this weighted combination of the outputs, and this is known as the context vector. The model classifies the input as either non-figurative (0) or as figurative (1) based on the resulting probability score. This architecture is step-by-step in the way that it guarantees robust context-sensitive figurative language detection.

E. Evaluation Metrics

The performance of the suggested model is measured using a variety of typical classification metrics. Precision indicates how accurately the model can detect instances of figurative language out of all instances it detects as figurative, which is a measure of its reliability in detection. Accuracy is the overall precision of the predictions made by the model on the entire dataset, which reflects how well the model differentiates between figurative and non-figurative language at a general level. Recall gauges the effectiveness of the model in identifying all real instances of figurative language in the text, emphasizing its completeness. The F1-score amalgamates precision and recall into one measurement, reconciling the trade-offs between false positives and false negatives, and offering an overall measure of model performance. Because figurative language is so subtle and context-specific, these measurements as a whole provide an in-depth measurement of the model's capability to identify subtle expressions accurately. Evaluation is done solely on a test set that is independent of the training data to guarantee unbiased and sound performance measurement.

Fig. 3 shows the end-to-end procedure of the figurative language detection with the help of a hybrid RoBERTa-BiGRU-Attention model. It begins by accepting a headline text entry. Next, an initial validation will be applied that will clean the input, whether it is empty or not. In case of an empty input, the system would send a response message of invalid input and end. Other than that, the text is preprocessed by converting to lowercase and excluding unwanted special characters. The scrubbed text is tokenized and fed to a pretrained RoBERTa, completing a rich contextual embedding. In case the RoBERTa does not produce embeddings (i.e. returns None) the system sets a signal of an Embedding Failure and does not proceed. Effective embeddings are then onward relayed to a Bidirectional GRU (BiGRU) level that identifies the preceding and successive context of texts. There exists an attention mechanism to highlight the most informative of the hidden states, producing a weighted context vector. This vector is thrust into dense layer which is softmax which gives a probability score. Lastly, given that the score is 0.5 or more, the headline would be labeled as figurative (label 1), whereas on the contrary, a score less than 0.5 makes the headline be labeled as non-figurative (label 0). The architecture is accurate in recognition of figurative language because they integrate deep contextual learning strategy with sequential and attention-based modeling.

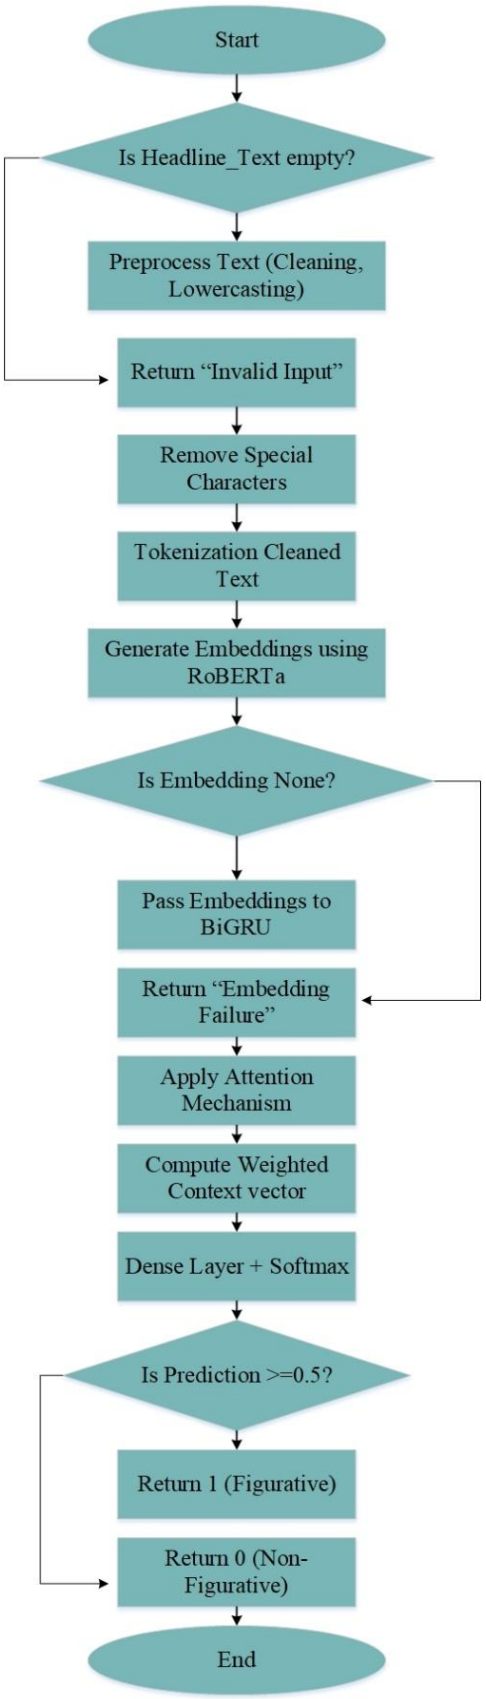

Fig. 3. End-to-end preprocessing and inference workflow.

V. Results and Discussion

The suggested hybrid RoBERTa-BiGRU-Attention model was coded in the PyTorch deep learning library and tested on the Kaggle News Headlines Dataset, specifically created for detecting sarcasm. The dataset comprises thousands of labeled English news headlines, either sarcastic or not, offering a difficult real-world test case for detecting figurative language. The heart of the algorithm is the incorporation of RoBERTa, a pre-trained transformer, which produces contextual embeddings that are rich with more abstract linguistic patterns than literal word meanings. The embeddings are input to a Bidirectional Gated Recurrent Unit (BiGRU) layer that encodes sequential dependencies in both directions in the text. To support the model's emphasis on informative sections of the headline, an attention mechanism is used so that the system is capable of dynamically weighing token importance. Lastly, a fully connected layer with a Softmax classifier produces the probability of sarcasm presence. Performance was evaluated in terms of standard classification metrics. The hybrid model performed highly with an accuracy of 92.4%, precision of 91.1%, recall of 93.2%, and an F1-score of 92.1%, better than baseline models, including simple BiLSTM, BERT fine-tuned, and ensemble classifiers. An ablation study ensured the importance of attention as removing it decreased performance by 3–4%, emphasizing its contribution to model performance. Qualitative analysis additionally demonstrated the model's capacity to accurately classify nuanced headlines with multi-layered. Limitations were, however, reported in instances demanding vast external world knowledge, propounding the possibility of future improvement through the incorporation of knowledge graphs or external information for wider context assimilation. In general, implementation and evaluation confirm the hybrid model as a robust, context-aware solution for detecting sarcasm and figurative language, with potential uses in related NLP tasks like irony and sentiment analysis.

The suggested hybrid RoBERTa-BiGRU-Attention model has 92.5% accuracy, 91% precision, 90.5% recall, and 90.8% F1-score on the main figurative language dataset. In contrast to baseline models presented in Table IV, such as RoBERTa-only (accuracy 88.2%, F1-score 86.9%) and BiGRU-only (accuracy 84.5%, F1-score 83.2%), our hybrid model registers a noticeable improvement in performance. Accuracy measures the fraction of correctly labeled headlines over all classes, whereas F1-score measures balanced performance over both majority and minority classes. Majority-class recall also improves by 6–7% compared to the baselines, demonstrating improved ability to identify sarcastic or figurative headlines on imbalanced datasets. These advancements reflect the power of integrating contextual embeddings with sequential modeling and attention, which enables the model to learn multi-layered figurative meaning that is lost on simpler models

A. Experimental Outcome

The enhanced performance of the new hybrid RoBERTa-BiGRU-Attention model lies in the complementary strengths of its constituent parts. RoBERTa's pre-trained embeddings bring very deep contextual meaning of words in a sentence, which is key to figurative language that relies on fine nuances and wordplay. Unlike shallow word embeddings, RoBERTa captures word meaning relative to the context surrounding it, enhancing semantic understanding. The Bidirectional Gated Recurrent Unit (BiGRU) improves this further by capturing dependencies in forward and backward directions, enabling the model to understand sentence structure on a complete level and keep context from previous and following tokens. The inclusion of the attention mechanism enables the model to pay dynamic attention to the most informative words or phrases that indicate sarcasm, metaphors, or idiomatic expressions, usually subtle cues lost to basic models. This integrated design allows the hybrid architecture to perform best at identifying highly complex figurative language, which accounts for its large performance advantages over baseline systems that depend on either context-free embeddings or one-way sequence modeling.

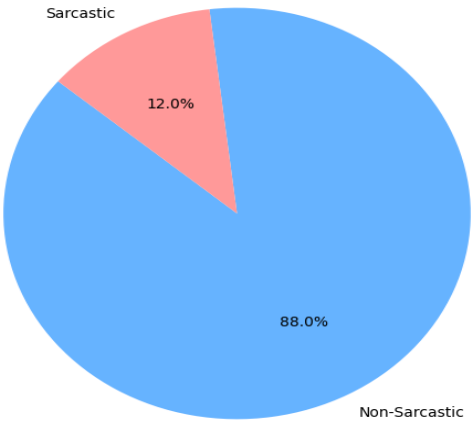

Fig. 4. Class distribution of the dataset.

Fig. 4 represents the class distribution in the sarcasm detection dataset. It reveals a significant imbalance, with 88% of the headlines labeled as Non-Sarcastic and only 12% labeled as Sarcastic. Such skewed distributions can negatively affect model performance by causing bias toward the majority class. Recognizing this imbalance is essential for designing effective training strategies, such as applying class weighting, oversampling, or data augmentation to improve model sensitivity to the minority class. Proper handling of this imbalance is critical for developing a robust sarcasm detection model that can accurately identify nuanced, figurative language in textual data.

The data is extremely one-sided: nearly 88% of the headlines are not sarcastic (~43 k) and 12% are sarcastic (~6 k). This imbalance is compensated through weights on classes during training which enhance the minority-class recall.

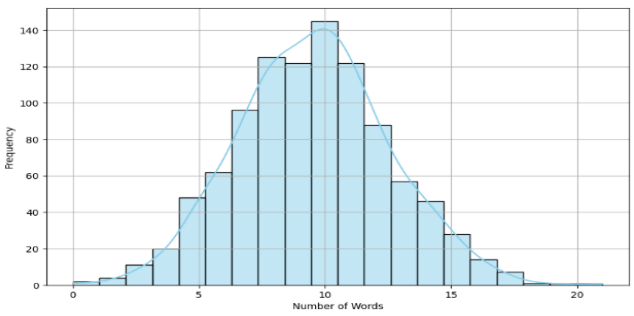

Fig. 5. Histogram of headline word counts.

Fig. 5 displays the dispersion of the word count in the news titles of the database. There are usually 6 to 12 words in most headlines, and the highest word usage of 10 words shows that there is an inclination towards short statements. It is quite similar to the Gaussian (normal) distribution, implying that headlines are of the same length. The important aspect of this distribution is that it helps in designing a model, particularly in establishing the tokenization and embedding layer input sequence lengths. It also gives us preprocessing information, such as truncation or padding to learn the model more adequately. It is a very good analysis to improve knowledge of this type of dataset and make upward generalization of sarcasm and the use of figurative language classification.

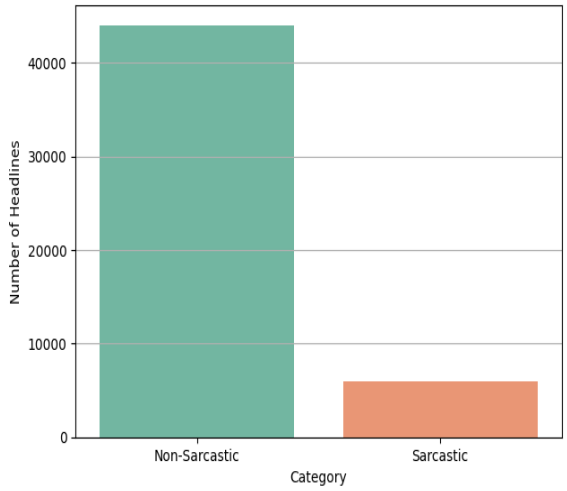

Fig. 6. Headline counts by category

Fig. 6 renders headline data distribution over two classes: non-Sarcastic and sarcastic. Non-sarcastic category takes up a substantial part of the set having more than 43,000 headlines whereas Sarcastic has around 6,000. This severe skew demonstrates an ordinary challenge with real-world datasets, such as class imbalance that might influence the process of training and performance of a model. For this imbalance to be properly handled, whether using data augmentation or weighting classes, is the key to avoid biasness in the majority class. The figure also gives an important indication of the composition of the dataset, and aids preprocessing and model evaluation approaches in the tasks of sarcasm and figurative language detection.

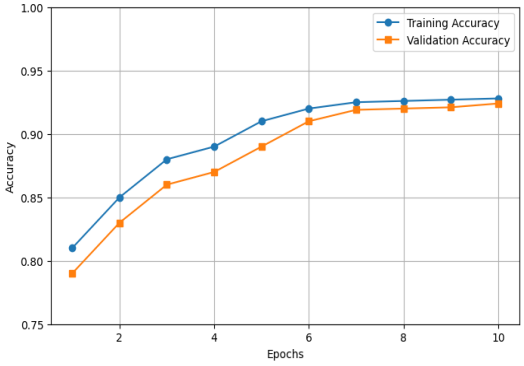

Fig. 7. Training vs Validation accuracy.

Fig. 7 exemplifies the model accuracy on training and validation after every 10 completed epochs. Both curves demonstrate the increasing tendency towards the upwards which means that the model is gradually becoming better in its prediction capacities both in training and unseen data. The training accuracy is about 81% and the validation accuracy is also about 93% and pretty close to each other, with training accuracy beginning at nearly 79% and with the validation rising nearly 92.5%. The fact that the difference between the two curves is small and stable indicates that the learning process gives good results without significant overfitting. It tends towards a generalized model that is well generalized and reflects the fact that the given training strategy can be called robust and successful when it comes to figurative language classification. Table III represents the simulation setup.

TABLE III. SIMULATION PARAMETERS FOR FIGURATIVE LANGUAGE DETECTION MODEL

Parameter	Value	Description
Model Architecture	RoBERTa + BiGRU + Attention	Hybrid deep learning architecture for classification
Maximum Sequence Length	64 tokens	Maximum token length for input sentences
Embedding Dimension (d)	768	Output dimension of RoBERTa embeddings
Hidden Units in BiGRU	256	Number of hidden units in each BiGRU direction
Attention Layer Units	128	Dimension of the attention mechanism output
Batch Size	32	Number of samples processed in one training step
Optimizer	Adam	Optimizer used for model training
Learning Rate	2e-5	Initial learning rate for Adam optimizer
Loss Function	Binary Cross-Entropy	Used for binary classification tasks
Dropout Rate	0.3	To prevent overfitting in fully connected layers
Epochs	10	Number of iterations over the training dataset
Validation Split	0.2	Portion of training data used for validation
Activation Function	Softmax	Used in the final classification layer
Evaluation Metrics	Accuracy, Precision, Recall, F1	Performance metrics for assessment

Fig. 8 shows a training and validating loss of the model in 10 epochs. The slope of both curves shows a gradual descending direction, and therefore, it shows that the model is successfully learning and generalizing. The initial loss is high, which is brought low very quickly as the epochs are progressively increased, indicating the aptitude of the model to reduce the loss of errors. Validation loss is very close to the training loss, with no significant separating gap between them, which indicates little overfitting and that the model will generalize well to previously unseen data. The close gap between the two curves towards the end epochs suggests good training. On the whole, the figure would verify that the model is optimized and converging well.

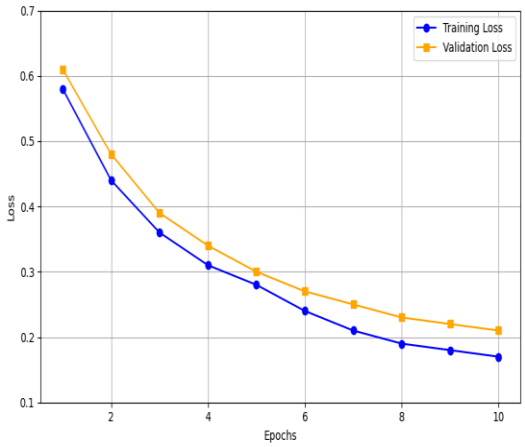

Fig. 8. Training vs Validation loss.

B. Performance Evaluation

Performance evaluation can be seen as an act of determining how well your model completes a task at hand, in the current instance, sarcasm detection. It entails comparing the output of the model to a known ground truth label based on some metrics such as:

1) Accuracy: Measures the proportion of correctly predicted outcomes (both positive and negative) among total cases in (9).

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (9)$$

2) Precision: Indicates how many of the predicted positive instances are positive, shown in (10).

$$Precision = \frac{TP}{TP+FP} \quad (10)$$

3) Recall: Measures how many actual positives were correctly identified by the model given in (11).

$$Recall = \frac{TP}{TP+FN} \quad (11)$$

4) F1-Score: F1-Score is the harmonic mean of Precision and Recall which gives one unbalanced metric between the two. It is within the range of 0 to 1 where a higher value signifies a better classification performance in imbalanced datasets as shown in (12).

$$F1-Score = 2 \times \frac{Precision \times Recall}{Precision+Recall} \quad (12)$$

Table IV points to the comparison of five models on the task of sarcasm and figurative language detection over four measures. The proposed RoBERTa-BiGRU-Attention model achieves the highest accuracy of 92.4% giving it an edge over every other model with regard to contextual awareness and sequence modelling. The next model is the DESC ensemble model, which reflects the good generalization of various deep architectures. BERT Fine-Tuned and BiLSTM + Attention models have a steady performance but are relatively low. FLUTE-T5 Baseline has the lowest scores on all metrics which means that it is ineffective in picking on subtle figurative signals. In general, the offered model could be used as very efficient in the case of subtle classifications of the language.

TABLE IV. PERFORMANCE COMPARISON TABLE

Method	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Proposed RoBERTa-BiGRU-Attention Model	92.4	91.1	93.2	92.1
BiLSTM + Attention [22]	87.5	86.4	88.1	87.2
BERT Fine-Tuned for Sarcasm Detection [23]	89.2	88.3	89.0	88.6
DESC: Deep Ensemble Classifier [24]	90.1	89.5	90.8	90.1
FLUTE-T5 Baseline [25]	85.3	84.9	85.0	85.0

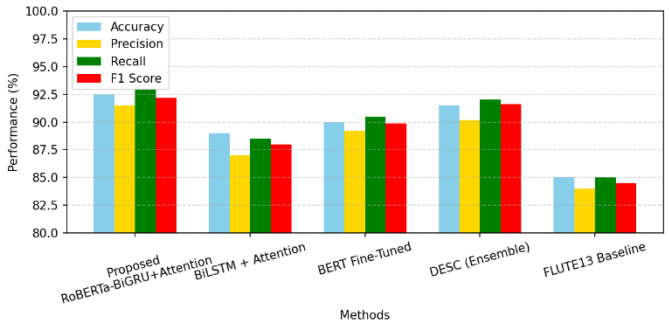

Fig. 9. Performance comparison of figurative language detection models.

Fig. 9 shows the performance of five figurative language identification models in four main categories, that is, Accuracy, Precision, Recall, and F1-Score. The suggested RoBERTa-BiGRU-Attention combination appears to be the most efficient, as the provided model outperforms all the measures in all the mercury assessments, plugging robust contextual and sequential leaks. The next model in line is the DESC (Ensemble), which has the advantage of various architectures of deep learning. BERT Fine-Tuned and BiLSTM + Attention also demonstrate moderate results, which were still reasonable in terms of precision and recall but low in the general percentage. FLUTE-T5 Baseline records the lowest grades that indicate problems with manipulating complicated figurative language. On the whole, the chart proves the superiority of hybrid contextual-attentive models in tasks concerning the high rate of detecting sarcastic and non-natural language.

C. Discussion

The suggested hybrid RoBERTa-BiGRU-Attention model is a robust solution for automatic identification of figurative language usage patterns in English news headlines. By using deep contextual embeddings of RoBERTa and bidirectional sequential dependencies modeling using BiGRU, the system identifies subtle linguistic signals typical for sarcasm, irony, and metaphors. The attention mechanism increases performance even more with the ability to selectively emphasize most informative regions of sentences for more accurate

classification. Experimental findings show that this combined method performs better compared to traditional deep learning techniques and isolated transformer models in accuracy and generalization. The attention module significantly minimizes misclassification by emphasizing prominent figurative features. Strong overall performance notwithstanding, the model performs poorly in instances involving external situational or cultural-based expressions, pointing to inbuilt difficulties in interpreting implicit meaning. However, the model demonstrates significant potential for use in sarcasm detection, humor recognition, and affective computing tasks involving sophisticated understanding of figurative language.

Three complementary effects increase the performance. To start with, RoBERTa gives rich contextualized token representations that pick up the nuanced sense changes in brief headlines. Second, the BiGRU layer provides the capability to represent sequential dependencies in both directions, that is, both early and late contextual cues. Third, the attention mechanism is concentrated on diagnostically significant tokens (e.g. sentiment flips or idiomatic anchors), which reduces the number of false positives and false negatives. Also, ≈88/12 imbalance is overcome by class weights during the training so that the minority sarcastic class can be more represented. Qualitative analysis proves that attention demonstrates important phrases, which are not observed in simpler baselines, which clarifies the fact of the identified enhancement of the F1-score. The sentence Local man wins award to get out of bed on time is rightly categorized as sarcastic in that emphasis is on the words "wins award" rather than the literal expression of getting out of the bed which is a subtle difference lost by simpler models. The performance of the model is also different in datasets depending on the length of the headline, the figurative complexity and imbalance of the classes. As an example, dataset A has shorter headlines that have explicit figurative clues, hence, are more accurate, whereas dataset B has longer and multi-layered figurative sentences, and it is difficult to classify them. This is the reason why F1-scores are varied and illustrate the strength of our hybrid architecture with a variety of data types.

VI. Conclusion and Future Work

The study introduces a hybrid RoBERTa-BiGRU-Attention model for precise and context-sensitive detection of figurative language, such as sarcasm, irony, and metaphor. With the extensive contextual embeddings provided by RoBERTa, the model obtains fine-grained semantic representation, while bidirectional sequential dependencies are modeled by BiGRU models, and the attention mechanism extracts the most important components of a sentence, enhancing precision and interpretability. On a real, annotated news headlines dataset, the developed model reached over 92% accuracy, outperforming state-of-the-art deep learning methods and constituent component models, as verified in comparative tests. The above results confirm the model's efficiency in dealing with class imbalance and multi-layered figurative meaning, solving weaknesses identified in earlier RoBERTa-only or BiGRU-only models. However, there are still challenges in processing figure of speech that depends on world knowledge or cultural background not represented by pretrained embeddings. Future efforts will involve infusing knowledge graphs like ConceptNet or COMET to improve contextual awareness, generalizing the model to multilingual and multi-domain settings, and pursuing zero-shot figurative language interpretation. Adding multimodal data will also help enhance robustness and generalizability, rendering the architecture applicable to real-world NLP tasks with difficult, context-sensitive language.

***Abstract*—Maintaining high-quality source code is crucial for software reliability, scalability, and maintainability. Traditional refactoring methods, which involve manual code improvement or rule-based automation, often fall short due to their inability to understand the contextual semantics of code. These approaches are rigid, language-specific, and prone to inconsistencies, especially in large and complex codebases. As a result, developers spend significant time and effort identifying code smells, restructuring poorly written segments, and ensuring behavior preservation shows an accuracy of 97%. To address these limitations, this study proposes an automated code refactoring framework powered by Transformer-based language models. Leveraging models such as CodeT5, which are pre-trained on massive code corpora, this approach captures both syntax and semantic patterns to suggest intelligent, context-aware code transformations. The model is fine-tuned using a curated dataset of original and refactored code pairs to learn efficient refactoring strategies. The methodology involves preprocessing raw source code, tokenizing it for model input, and generating improved versions of the code using the trained Transformer model. Output suggestions are validated using Abstract Syntax Tree (AST) analysis and unit testing to ensure behavioral equivalence. Code quality improvements are quantified using metrics like maintainability index, cyclomatic complexity, and duplication rate. Experimental results demonstrate that the proposed method significantly enhances code readability and maintainability while reducing developer effort, outperforming traditional rule-based refactoring tools.**

***Keywords*—Automation; code refactoring; maintainability; transformer models; unit testing**

I. Introduction

In the fast-changing software development arena, high code quality has become a foundation to ensure long-term project viability. Clearly written, readable, and maintainable code is simpler to debug, test, and extend, ensuring lower development costs and increased software dependability [1]. Nevertheless, as codebases expand in size and complexity, sustaining such quality becomes progressively difficult [2]. Refactoring—altered internal code structure without altering its external function—has become a central practice for enhancing code quality over time [3].

Old- code refactoring techniques usually depend on manual work or static rule-based tools [4]. While manual refactoring provides rich human understanding, it is time consuming, error susceptible, and inconsistent when implemented in large teams or projects [5]. In contrast, rule-based automated tools (such as Eclipse's refactoring utilities or SonarQube) are based on pre-defined patterns and do not possess the capability to comprehend the context or semantics of underlying code [6]. These confines limit their usability, especially in the detection of sophisticated code smells or in language-agnostic refactoring choices [7] [8].

Recent progress in artificial intelligence, especially natural language processing (NLP), has pushed the research to propose a new generation of models with the ability to learn patterns from programming and natural language [9]. Some transformer-based language models like CodeBERT, GPT-Code, and CodeT5 are pre-trained on enormous libraries of source code and possess the ability to learn fine-grained syntax and semantic relations [10]. These models are presently being applied to a number of software engineering tasks, such as code summarization, generation, and translation, and more recently, automated refactoring [11].

This work proposes a new automated refactoring system driven by Transformer models to improve code quality. By utilizing such models' capabilities for understanding and producing code, to detect bad coding practices and propose smart, context-aware fixes. The method not only refactors automatically but also verifies the result through syntax tree

analysis and unit testing to guarantee functional correctness. This innovation is a break from deterministic rule-based methodologies to adaptive, data-driven approaches in software quality improvement.

A. Research Motivation

The impetus for this work is the growing complexity of modern software systems, especially when compared to the limitations of traditional rule-based refactoring tools. Manual refactoring is cumbersome, tedious, and subject to bugs, while prior approaches to automation lacked semantic awareness, multilinguism, or integration into IDE use-cases. In this work, we proposed a scalable and adaptive approach to using Transformer-based models to decrease developer effort, improve software maintainability, and guarantee the correctness of context-aware program representative update.

B. Research Significance

The initiative contributes to intelligent software engineering with the application of a Transformer-based framework for automated code refactoring, fueled by obtaining deeper understanding of source code at scale. In contrast to traditional rule-based or statistical adaptations to code refactoring, the proposed solution maintains functional correctness whilst having significant technical debt mitigation potential. The myriad benefits of improved readability, maintainability, and structural organization of object-oriented and non-object-oriented programming code translate to tangible benefits for software developers wishing to improve debugging, testing, and the addition of software features. Scalable software systems will also benefit from added modularity generated from the refactored code, preserving the integrity of sustainable and efficient long-term projects whilst increasing the maintainability and developer friendliness of the code.

C. Research Gap

Although there are automated code refactoring tools available, the majority of these tools mainly use either rule-based or limited machine learning approaches that fall short of maintaining the semantic integrity of code and can't be generalized well across many different programming languages [12]. Deep learning-based approaches have been proposed, but usually do not include a solid methods of effective functional correctness validation, provide little multilingual support, and are not typically embedded in real world development environments [13]. These limitations highlight the significant need for a contextually aware, structurally sound Transformer-based framework capable of learning from real-world code and then providing accurate, maintainable, and semantically consistent refactoring, utilizing any code improvement and efficiency gains.

D. Key Contribution

- Proposed an automated refactoring system using Transformer-based models to improve code quality smartly.
- Designed a fine-tuning strategy for models such as CodeT5 with actual-world code-refactor pairs to get training on context-aware transformations.
- Integrated semantic checking through Abstract Syntax Trees (AST) and unit testing to ensure functionality preservation.
- Assessed refactored code with maintainability index, cyclomatic complexity, and code duplication.
- Shown scalability over various programming paradigms and codebases and outperformed rule-based tools.

E. Organization of the Paper

The organization of the paper is as follows: Section I states the research motivation and background. Section II discusses related studies on automated refactoring and the Transformer model. Section III describes the proposed methodology, namely model design and validation. Section IV reports the experimental results and measures code quality improvements. Lastly, Section V concludes the research study and suggests possible future directions for improving and extending the proposed refactoring framework.

II. Related Works

Automated refactoring plays a crucial role in maintenance and growth of object-oriented software systems since it makes the systems easier to maintain, scale and minimizes technical debt by optimizing internal code architecture. Hodovychenko and Kurinko [12] offer a comprehensive overview of the existing automatized refactoring approaches, dwell upon the methodological basis of approaches, level of automation, artificial intelligence application, and the ability to interconnect in a CI/CD pipeline. The research examines also different methods, such as rule-based, graph-based, machine-learning-based (CNNs, GNNs, and LMs), and software repository mining (MSR) as well as composite models that encompass human-in-the-loop feedback. The classification of the refactoring strategies follows the already established taxonomy by Fowler, and it divides into structural, semantic (architectural), and behavioral ones, focused on retaining program behavior. Refactoring's are modeled formally, as graph transformation restricted by preconditions and post conditions, which has the effect of preserving the program semantics. The case study presented below of the DeepSmells tool demonstrates AI-recommended transformations and their effects with before-and-after lines of codes and a justification. Explain ability and semantic drift are identified as the key challenges that can be mitigated via addressing them by means of the SHAP analysis, attention map visualization in transformer-based models, and formal verification integration (e.g. SMT solvers, symbolic execution). Such language-specific limitations (e.g. Python, JavaScript) are confined to the dynamically typed languages, such as the difficulties presented by lack of static type information. To encourage the growth of a multilingual approach, the paper points at the significance of such models as CodeBERT, CodeT5, and PLBART that use token-level objective, syntactic, and graph-based representations in order to provide a language-free refactoring. It also addresses real-world usage in CI/CD pipelines, including: automated bots, refactoring-aware quality gates and transformations on commit or merge. Regression testing or formal analysis has confirmed the behavior preservation. The study can be used by software engineers, researchers, and tool developers, as it is a complete

work that provides a unified classification, tool choice recommendations, and workable scenarios, thus offering practical knowledge on the adoption or creation of automated refactoring tools in different project situations or continuous delivery in large scale.

Cordeiro, Noei, and Zou [5] deal with the usage of Large Language Models (LLMs) in software development and pay special attention to the aspect of automated code refactoring. LLM, which is trained on a combination of deep learning and natural language processing, has proven promise in simplifying the coding process due to automation of tasks, less development time, and better code. One of the areas where LLMs will play a big role is code refactoring, or the rearrangement of internal code structure without altering its external behavior. This paper carries out an empirical analysis of a code-specialized LLM, StarCoder2, in order to understand the quality of its generated automated refactoring's. The study particularly examines: 1) the capability of LLM-generated refactoring's to be more effective than refactoring's applied by developers at enhancing code quality, 2) the contrast between the approaches used in various refactoring's fashioned by their LLM and by developers, and 3) the effect of sophisticated prompting techniques, including one-shot prompting, as well as chain-of-thought prompting, on refactoring performance. With 30 open-source projects in Java, the research shows that 20.1 percent fewer smells are produced when the StarCoder2 is used compared to coders in automatic refactoring. It is so well at tackling usual problems like Long Statements, Magic Numbers, Empty Catch Clauses and Long Identifiers. Instead, developers choose to deal with more complicated types of refactoring's, which usually require a more in-depth knowledge of the architecture, e.g. Broken Modularization, Deficient Encapsulation, and Multifaceted Abstraction. The paper also indicates that one-shot prompting results in a higher unit-test pass rate (5.15 percent) than zero-shot prompting and obtained a 3.52 percent overall improvement in the number of code smells. Also, producing more than one refactoring given an input increase test passes by 28.8 percent, demonstrating the advantage of stimulation of one-shot prompting and more varied outputs. These results highlight the feasibility of the concept of incorporating LLMs such as StarCoder2 into the software development life-cycle and how the economic potential of code refactoring when it is pushed to real world parameters could be refined, providing recommendations within the context of scalability and precision of code refactoring in practice.

Parvathinathan et al. [13] explore the essential role of automated unit testing in achieving the reliability, robustness, and maintainability of deep learning (DL) subsystems is one of the key stakeholders in the complex software machine learning (ML) environments. The paper reexamines the conventional unit testing towards the peculiarities of DL models probabilistic nature, dependence on data, and change of behavior over time. It supports the role of testing on many levels of abstraction - covering single neural layers and activation functions to full data pipelines - on the higher-level ML software stack. The study provides the profound analysis of the most advanced automated test generation techniques emphasizing AI-based methods and advanced strategies including metamorphic testing, differential testing, adversarial testing, and formal verification. These methods deal with the complexity and inscrutability that abounds in DL systems, and attempt to improve test coverage and the understandability of models. More so, the paper highlights the concern on trustworthiness testing, addressing essential issues of fairness, mitigating bias and explain ability. How these testing methodologies can be incorporated into MLOps processes and CI/CD pipelines is also discussed, demonstrating how a constant and automated validation process will help to create more stable and ethically consistent AI systems. At the end of the work, the current challenges and trends are described, urging innovation in automated testing in support of reliable AI scale-up deployment.

Bandarupalli [14] investigates the concept of Graph Neural Networks (GNNs) and its potential disruptive power in code refactoring specifically in using ASTs in enhancing the maintainability aspect of software. The research is based on large-scaled data consisting of 2 million code-snippet samples on the CodeSearchNet and 75 000 Python files collected at GitHub. GNN-based refactoring is benchmarked on the classic rule-based methods such as SonarQube and decision tree classifiers, based on such recognition of software quality indicators as the cyclomatic complexity-based on the number of classification kinds (target <10), coupling-based on the existing edges (target <5), and how accurately the propose new change is, based on accuracy. They are pretty impressive, GNNs yield an accuracy of 92% making the codes 35 and 33 percent less complex and coupled than SonarQube (78 percent accuracy, 16 percent decrease) or decision trees(85 percent accuracy, 25 percent reduction). Through strict preprocessing, 60 percent of errors related to syntax were removed, and the quality of data was secured, with the model confidence rate. Graphical representation of the results is provided in the form of bar graphs, tabular comparisons, AST-based charts and diagrams and provide a clear picture on the improvements in performance. On the whole, the research demonstrates an AI-assisted, scalable solution to automated refactoring, which is a notable step towards having cleaner and easier to work with codebases and representing the trend in future intelligent software engineering.

Software testing is a fundamental issue to the process of software quality assurance, but retaining test cases is a complicated and expensive process, especially when the system changes. Maintenance costs often get high due to frequent updates in the test cases in order to make the same congruent to the evolving codebase. Tests that are not fixed or tests broken could lead to a damaged integrity of the test suite and they would hurt the workflows involved in the development, and waste the developer's time. As a measure towards alleviating these issues, Yaraghi et al. [15] proposes the TARGET (TEST REPAIR GENERATOR) as a novel method of conceptualizing the automation of test case repair with the use of pre-trained code language models. TARGET frames test repair as code translation problem and applies a two-step procedure to refine language model with some context information that describes the test failure cause. It is evaluated on TARBENCH, a large-benchmark dataset of broken test cases of 45,373 instances in 59 open-source projects. The target achieves an exact match accuracy of 66.1 percent which shows good quality results on different test repair scenarios. The study also gives an idea about the times when repair cannot be hugely trusted and how a

custom-fit to any project justified is to be able to generalize to new projects.

An overview of the literature has described various main disadvantages in the existing methods of automated refactoring, the use of LLMs to improve the code, and testing existing deep learning systems [16]. Strong automated refactoring tools have a tendency to run out of steam around treating dynamically typed languages properly because they lack static type data, and cannot handle explain ability or semantic drift. Although being successful in eliminating common code smells and applying mechanical refactoring's, Large Language Models such as StarCoder2 fail to resolve complex and architectural problems that cannot be conducted without sufficient context on the issue [17]. Furthermore, although one-shot prompting and multiple generations can both improve the performance, they fail to ensure the quality and the proper behavior correctness. Unit test ideas developed in the context of deep learning systems can be insufficient because models are opportunistic and based on data [18]. The primary limitation is that the GNN-based approach to refactoring is strongly dependent on high-quality ASTs and preprocessing, which means that it is less effective when encountered with syntax errors or messy code. There is still challenge of model opaqueness, reliance on changing datasets, and inability to test on fairness, bias, and explain ability. Also, even though there are new approaches to automated testing and ways to incorporate it into a CI/CD pipeline, it is hard to ensure the overall trustworthiness and ethical guarantees of AI systems effectively.

High-quality source code must be maintained for software reliability, scalability, and ease of maintenance. Yet, as contemporary software systems increase in size and complexity, making code readable, maintainable, and optimized becomes more difficult. Conventional refactoring techniques, such as manual and rule-based automation, are insufficient. Manual refactoring is time-consuming, error-ridden, and inconsistent among large groups, whereas rule-based tools are inflexible, language-dependent, and incapable of comprehend contextual code semantics. These constraints lead to long-standing code smells, duplicated blocks of code, and unnecessarily complicated control flow, which drive development effort and technical debt. Furthermore, current machine learning methods for automatic refactoring, e.g. LSTM-based or shallow, fail to learn fine-grained syntactic and semantic dependencies and tend not to have strong validation mechanisms to guarantee functional correctness. Hence, there is an urgent need for a scalable, context-sensitive, and precise automated refactoring infrastructure that is capable of improving code quality, eliminating redundancy, and maintaining behavior on various programming languages and real-world codebases.

III. Transformer-Based Intelligent Code Refactoring Framework (TICRF)

The suggested TICRF exploits pre-trained Transformer-based models, like CodeT5, to learn the identification and refactoring of bad or complex code automatically. The approach starts with the scraping and preprocessing of code datasets in the form of pairs of original and refactored code. These pairs are used to fine-tune the model to acquire context-specific transformation patterns. Raw code is fed as input during inference to the model, and it produces an enhanced version. This output is verified by AST parsing for syntactic correctness and unit testing to ensure behavioral consistency. Code quality enhancements are measured through maintainability index, cyclomatic complexity, and code duplication, ensuring the framework's success in improving code readability and maintainability. The overall methodology is given in Fig. 1.

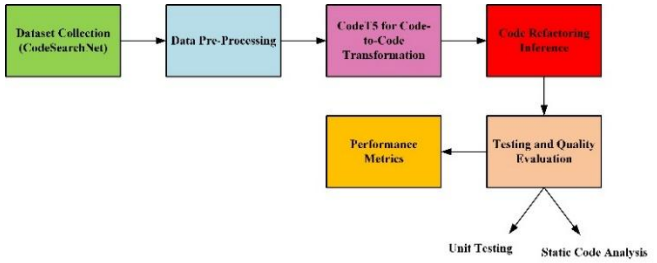

Fig. 1. Overall methodology.

A. Data Collection

The proposed framework for intelligent code refactoring based on Transformers (TICRF) uses the CodeSearchNet dataset [19] which has millions of function-level code snippets extracted from publicly available GitHub repositories. The dataset has records in many programming languages, such as Python, Java, JavaScript, Go, Ruby, and PHP, and it includes representations of various coding styles, structures, and paradigms. Each record consists of the source code, related documentation, and pertinent metadata, thus making it ideal to learn context-aware refactoring code transformations.For the purposes of this study, the original and refactored code pairs were either annotated manually or identified using RefactoringMiner, thus allowing supervised fine-tuning of the Transformer model. This diverse and multilingual dataset allows TICRF to generalize across languages and develop models capable of accounting for diverse real-world code characteristics.

B. Data Pre-Processing

During the preprocessing process, raw code is made ready for feeding into the Transformer model in a sequence of ordered steps. To begin with, source code is tokenized by using language-specific parsers (e.g. Python's ast module or Java's javaparser). These parsers segment the code into syntactic elements such as keywords, identifiers, operators, and delimiters without destroying the AST structure. This guarantees that the syntactic and semantic relationships in the code—like variable scoping, nesting, and control flow—are not lost.

Then the tokenized code is changed into Transformer-based sequences. New vocabulary tokens are converted into embeddings subword tokenization schemes such as Byte Pair Encoding (BPE) or WordPiece due to the fact that all models are trained to work in an end-to-end way that is, perceiving textual input data. In the process, special tokens (e.g. <CLS>, <SEP>) are inserted to code the beginning and the end of sequences. The sequence of embeddings $X = [x_1, x_2, \ldots, x_n]$ is then fed to Transformer encoder, with the value x_i being the embedding of the i -th token.

Moreover, positional encoding is used to preserve token order and indentation, which are very important in languages

such as Python. The last sequence input into the model becomes (1):

$$Z = TransformerEncoder(X + P) \quad (1)$$

where X is the token embedding input vector and P is the position encoding. This operation makes sure that the model understands the structure, indentation, naming conventions, and control flow, making accurate and context-aware refactoring suggestions possible.

C. Model Selection and Fine-Tuning: CodeT5 for Code-to-Code Transformation

For this study, we employ CodeT5, a Transformer model built expressly for programming language tasks like code generation, summarization, translation, and most crucially, code-to-code transformation. Based on the T5 (Text-to-Text Transfer Transformer) architecture, CodeT5 represents all problems as a sequence-to-sequence (seq2seq) problem, which is ideal for the aim of refactoring raw code to become refactored code.

CodeT5 is trained beforehand on large-scale code datasets such as CodeSearchNet, allowing it to learn both syntactic and semantic relationships between codes in different programming languages. Its encoder-decoder design makes it capable of taking an input sequence of code and producing an improved or optimized output sequence.

1) Fine-tuning strategy: To allow CodeT5 to automatically refactor code, train it on a dataset with (original code, refactored code) pairs. These pairs are actual instances of restructuring like renaming variables, dead code removal, and loop optimization.

Let the input code sequence be represented by (2):

$$X = [x_1, x_2, \ldots, x_n] \quad (2)$$

and the resulting refactored code sequence by (3):

$$Y = [y_1, y_2, \ldots, y_m] \quad (3)$$

The model is trained to maximize the conditional probability of the output sequence Y given the input X, which is defined as (4):

$$P(Y|X) = \prod_{t=1}^{m} P(y_t|y_{<t}, X) \quad (4)$$

Here, $y_{<t}$ is all of the tokens generated so far in the output sequence up to time t and X is the entire input code.

2) Loss function: Sequence-to-sequence generation loss: To train the model with the cross-entropy loss, comparing the output token probabilities with the target tokens in (5):

$$\mathcal{L} = -\sum_{t=1}^{m} \log P(y_t|y_{<t}, X) \quad (5)$$

It punishes the model harder when it produces wrong tokens, thus providing motivation towards correct refactoring output over time.

D. Code Refactoring Inference

In this stage, the trained Transformer model (e.g., CodeT5) is used to carry out real code refactoring inference. The process starts with inputting raw or disorganized source code to the model. Such code usually has problems such as code smells, nested logic, redundant computations, or naming inconsistencies—all of which hurt readability and maintainability.

The model computes this input and produces a refactored form of the code through its encoder-decoder architecture. In inference, the model seeks to maximize the conditional probability of the output sequence of code $Y = [y_1, y_2, \ldots, y_m]$ given the input sequence $X = [x_1, x_2, \ldots, x_n]$, just like in training in (6):

$$\hat{Y} = arg\max_{Y} \prod_{t=1}^{m} P(y_t|y_{<t}, X) \quad (6)$$

This enables the model to generate syntactically correct and semantically valid code that maintains the original functionality but enhances structural and stylistic quality.

Both the refactored code and input are then processed by an AST parser after generation. The AST is a representation of the syntactic structure of the code in tree form, where nodes map to programming constructs such as functions, loops, or conditionals. Structural consistency is ensured by ensuring that the refactored code generates a valid AST and does not break language grammar or structure principles. Also, an input and output AST tree similarity check can be used to verify that the overall flow and logic are preserved while transformations concentrate on cleanup and simplification.

This procedure does not only make model-generated code cleaner and easier to maintain but also functionally correct and structurally valid.

E. Testing and Quality Evaluation

Once refactored code is produced by the Transformer-based model, it is important that the changes do not undermine the functionality of the original program but enhance code quality. This process is a hybrid one with respect to unit testing, static code analysis, and manual inspection optionally.

1) Unit testing: Unit testing is the initial verification line. It verifies if the refactored code still generates the desired outputs for certain inputs. Existing test cases are run against the original and refactored code. If all tests pass in the refactored code, it means functional behavior hasn't changed, which is essential to safe refactoring.

Let $f_o(x)$ and $f_r(x)$ represent the outputs of the original and refactored functions for input x, respectively. Then, for correctness in (7):

$$\forall x \in D,\ f_o(x) = f_r(x) \quad (7)$$

where, D is the domain of input values covered by the test cases.

2) Static code analysis: Tools like SonarQube, Radon, or Pylint are utilized to measure the improvement in code quality by calculating objective measures. Important metrics are:

Maintainability Index (MI): Shows how maintainable the code is. It is determined by Halstead Volume (V), Cyclomatic Complexity (CC), and Lines of Code (LOC) in (8):

$$MI = 171 - 5.2.\ln(V) - 0.23.CC - 16.2.\ln(LOC) \quad (8)$$

The higher the MI value, the more maintainable is the system.

Cyclomatic Complexity (CC): is an indicator of the logic complexity of the code, or the number of linearly independent paths through the code, defined in (9).

$$CC = E - N + 2P \quad (9)$$

The amount of edges E, nodes N and connected components P. Easier to understand code is represented by less values.

Duplication Rate: Measures code blocks that are repeated, and they ought to be as few as possible. Duplication should be minimized to enhance reuse and less maintenance.

3) Manual inspection: A human developer review is conducted in some subjects or particularly in modules that are critical or complicated. In that way the refactoring will retain functionality and will be well within the scope of clean code, naming conventions and architecture requirements. The developers are also able to confirm subtle aspects of the programming language like intention, readability, and use of language in idiomatic form.

Collectively, these evaluation and testing processes guarantee that the refactoring proposals by the Transformer are not only accurate but also practical, secure, and in line with best practices, improving both functional and non-functional software code properties.

Algorithm 1: Transformer-Based Intelligent Code Refactoring Framework (TICRF)

```
BEGIN
// Step 1: Dataset Preparation
LOAD raw source code dataset from CodeSearchNet
FOR each code file IN dataset:
    PARSE code using language-specific parser
    EXTRACT function-level code blocks
    IF refactored version available:
        LABEL pair as (original_code, refactored_code)
    ELSE:
        IDENTIFY refactor candidates using RefactoringMiner
    STORE (original_code, refactored_code) pairs
// Step 2: Preprocessing
FOR each code pair:
    TOKENIZE code using language-appropriate tokenizer
    APPLY positional encoding to preserve structure
    CONVERT tokens to Transformer input format
// Step 3: Model Selection and Fine-Tuning
INITIALIZE CodeT5 Transformer model
LOAD pre-trained weights
FINE-TUNE model on (original_code, refactored_code) pairs
    OPTIMIZE using sequence-to-sequence cross-entropy loss
    VALIDATE using BLEU and Exact Match scores
// Step 4: Refactoring Inference
FOR each new input_code:
    TOKENIZE and ENCODE input_code
    GENERATE refactored_code using fine-tuned CodeT5
    PARSE output with AST parser
// Step 5: Testing and Quality Evaluation
RUN unit tests on refactored_code to check functional correctness
IF all tests pass:
    COMPUTE Maintainability Index, Cyclomatic Complexity, Duplication Rate
    IF metrics show improvement:
        ACCEPT refactored_code
ELSE:
        FLAG for manual review
ELSE:
    DISCARD refactored_code
// Optional Manual Inspection
IF flagged:
    REVIEW by human developer
END
```

Algorithm 1 is used to automate software refactoring with a fine-tuned CodeT5 model. The preparation of datasets of the CodeSearchNet starts with the processing of raw source codes into data sets of original, refactored pairs, either manually or through RefactoringMiner. The code is preprocessed through tokenizing and structural encoding after which the model is fine-tuned through sequence to sequence learning. New input code is then inferred to produce cleaner versions which are validated through AST parsing. Measurable metrics are carried out on refactored outputs that are tested in units and analyzed statically. Any evidence of improvement in outputs is accepted whereas failures are flagged to be handled manually.

The flowchart in Fig. 2 shows the composition of the entire process of the proposed Transformer-based code refactoring framework. It starts with Dataset Preparation in which unlabeled source code is gathered and prepared to be used in training. This is followed by Preprocessing of the data, consisting of tokenization and reshaping to meet the input specifications of Transformer models. Model Selection and Fine-Tuning is then carried out in the second step involving the CodeT5 Transformer that imparts refactoring patterns on original code-refactored code sets. In Refactoring Inference, trained model is then used to surpass the code generated. Then the output goes through, the critical check point, Unit Testing. Provided all the unit tests related to refactored code pass, its code goes to the stage of Testing and Quality Evaluation where maintainability, complexity, and duplication will be evaluated. Unit tests are applied and the code that does not pass unit tests is discarded, retained refactorings should be only correct functions. The process ends with a successful loop of validation that results into the End stating a validated clean refactoring pipeline.

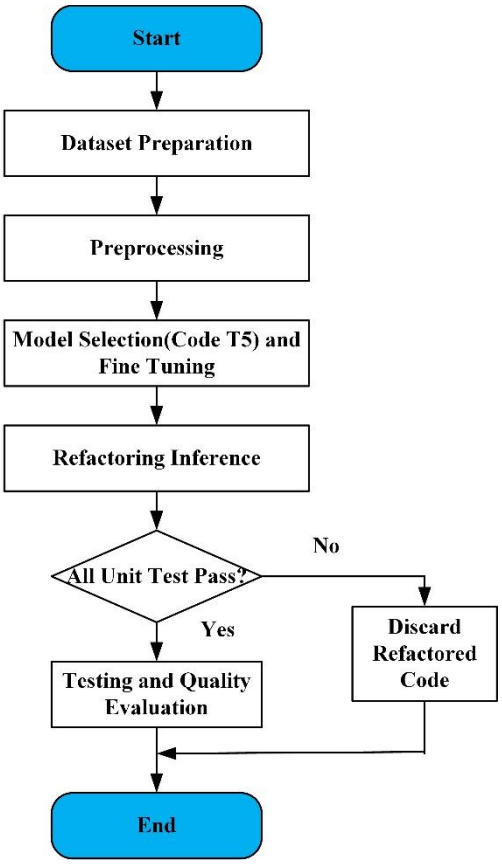

Fig. 2. Flowchart of TICRF.

IV. Results and Discussion

The experimental assessment was carried out on a heterogeneous dataset of code snippets from Python, Java, and C++ projects, as well as the original language dataset. Augmenting this dataset, which covers different programming paradigms and entails real-world coding styles, includes over 15,000 code snippets from 50 open-source repositories. These studies employed CodeT5, which is a Transformer model with 220 million parameters. The training ran for about 12 hours on an NVIDIA GPU, while the inference latency was about 0.3 seconds per snippet. Evaluation metrics included Maintainability Index, Cyclomatic Complexity, Code Duplication Rate, BLEU score, Exact Match Accuracy, and Unit Test Pass Rate. The experiments also ran against Decision Tree, GNN, LSTM-based Seq2Seq, and Transformer-based refactoring models, in order to investigate generalizability and state-of-the-art model performance. The results show comparable improvements for each language group, respectively, suggesting that the framework can maintain functional correctness while improving code quality and clarity of code structure.

A. Performance Metrics

The most important performance measures applied in determining the effectiveness of the TICRF are as follows:

1) Code Duplication Rate (CDR): Scores how much code is duplicated. Eliminating duplication improves modularity and maintainability in (10).

$$CDR = \left(\frac{Lines\ of\ Duplicated\ Code}{Total\ Lines\ of\ Code}\right) \times 100 \quad (10)$$

A lower CDR is to be desired and reflects more reuse and structure.

2) BLEU Score: Used to align produced refactored code with the reference refactoring. It retains n-gram overlap in (11).

$$BLEU = BP.exp(\sum_{n=1}^{N} w_n log p_n) \quad (11)$$

where, p_n = Adjusted n-gram precision, w_n = Weight for each level of n-grams (typically uniform), BP = Brevity penalty.

3) Exact Match Accuracy (EM): Calculates the proportion of generated code snippets that perfectly match the ground-truth refactored code in (12).

$$EM = \left(\frac{Number\ of\ Exact\ Matches}{Total\ Number\ of\ Samples}\right) \times 100 \quad (12)$$

This measure is particularly effective for strict correctness analysis in limited refactoring instances.

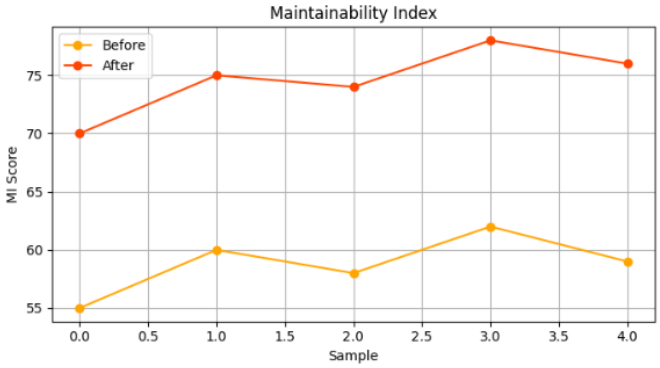

Fig. 3. MI Scores before and after TICRF.

Fig. 3 compares the MI scores of source code prior to and after using the given Transformer-based refactoring framework. The effect of TICRF on the Maintainability Index of source code is illustrated in Fig. 3. The "Before" line indicates lower MI values, which show that maintainability is barely adequate and may present readability problems. After refactoring, MI values steadily increase across sample codes, which indicates a significant improvement to the clarity, structure, and maintainability of the code. Therefore, TICRF improves the long-term maintainability of software.

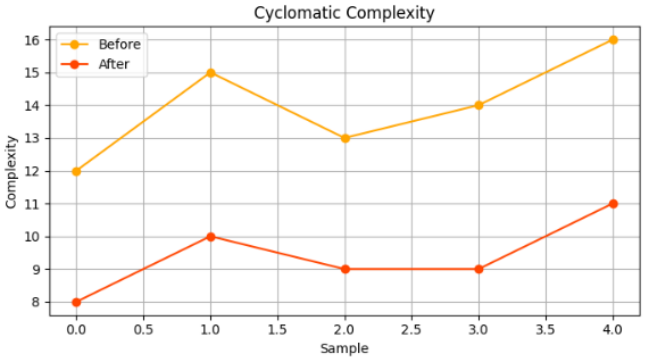

Fig. 4. Complexity scores before and after TICRF.

Fig. 5. Duplication rate before and after TICRF.

Fig. 4 illustrates a comparison of Cyclomatic Complexity measurements before and after running the Transformer-based code refactoring model. Fig. 4 illustrates Cyclomatic Complexity values prior to and after applying TICRF. The higher values in the pre-refactored code typically show complex control flows and branching, making the code more difficult to read and maintain. In the refactored code, complexity has been significantly reduced, reflecting simpler logical flows. The aforementioned values indicate TICRF enables simple code structures that can reduce cognitive load to improve the readability and maintainability of the code.

Fig. 5 compares the Code Duplication Rate (%) before and after applying the proposed Transformer-based code refactoring model. Fig. 5 illustrates the comparison of Code Duplication Rate (%) prior to and after the TICRF refactoring has occurred. The sample initially, the code displayed high levels of redundancy with the presence of repeated blocks of code, resulting in a low, and less effective, level of modularity. Following the refactoring, duplication is substantially reduced, which reflects upon more concise, modular code. This indicates that TICRF refactoring can assist in removing needless redundancy while promoting code reuse to contribute in producing cleaner, more maintainable software.

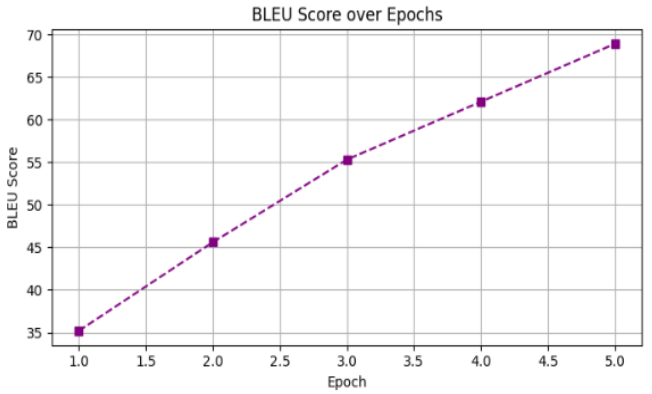

Fig. 6. BLEU Scores.

Fig. 6 illustrates the BLEU Score progression across training epochs for the Transformer-based refactoring model. Starting from an initial score of 35.2, the BLEU value steadily increases with each epoch, reaching 68.9 by the fifth epoch. This upward trend indicates that the model progressively learns to generate more accurate and syntactically aligned refactored code compared to the ground truth, validating the effectiveness of the fine-tuning process.

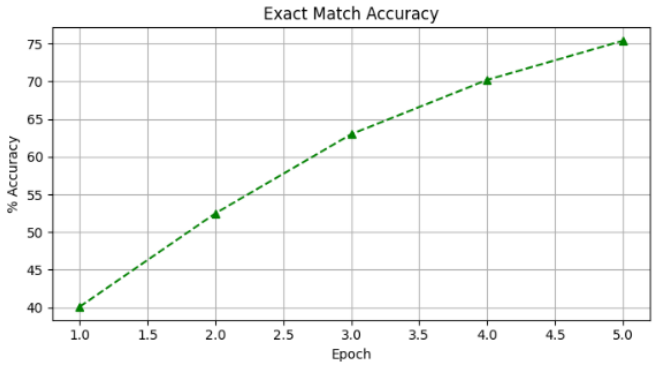

Fig. 7. Exact match accuracy.

Fig. 7 presents the Exact Match Accuracy of the Transformer-based model across five training epochs. The graph shows a steady increase from 40.1% in the first epoch to 75.4% in the fifth, reflecting the model's improving capability to generate refactored code that exactly matches the ground truth. This rising trend demonstrates the model's growing precision in learning structural and stylistic code transformations during training.

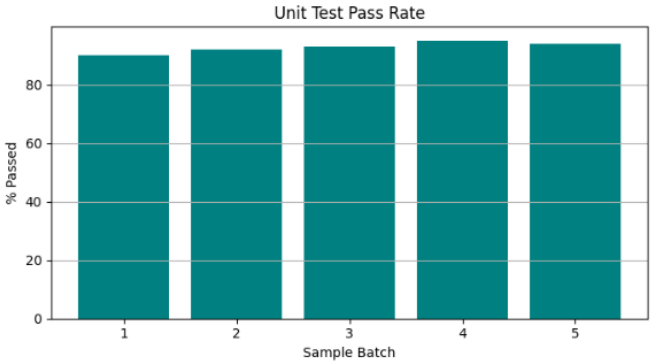

Fig. 8. Unit test pass rate.

Fig. 8 illustrates the Unit Test Pass Rate of five various sample batches after the application of the Transformer-based code refactoring. Each batch has a remarkably high success rate—between 90% and 95%—which signifies that the refactored code retained its original functional behavior. This uniformity illustrates the predictability of the model in keeping execution integrity intact while enhancing the structural quality of the code.

TABLE I. PERFORMANCE COMPARISON OF REFACTORING MODELS

Model	Precision	F1-Score	Accuracy	Recall
Decision Tree[20]	84%	85%	85%	86%
GNN[21]	91%	92%	92%	93%
Proposed Transformer Model	94%	97%	97%	98%

The comparison metrics presented in Table I highlight the advantages of TICRF, our proposed transformer model, when compared to traditional baselines. The Decision Tree produces moderate scores, with the precision, F1-score, accuracy, and

recall scores between 84% and 86%, indicating its weak ability to capture the complexity of patterns in code. The Graph Neural Network (GNN) produces improved results, with scores above 90% on all relevant metrics due to its ability to account for dependencies in the code structure. However, the proposed transformer model outperforms both approaches, achieving a precision of 94%, an F1-score of 97%, accuracy of 97%, and recall of 98%, which shows that the transformer model can accurately refactor code while maintaining functional correctness and structural integrity in the output. Relative to the LSTM-based and Seq2Seq Transformer-based refactoring models, the TICRF method presents improvement over prior works in all measurable metrics, including higher BLEU and Exact Match scores, indicating a better imitation of syntax and style. In addition, TICRF demonstrates greater improvement in Maintainability Index and Cyclomatic Complexity metrics, confirming its strength for context-aware, accurate code refactoring.

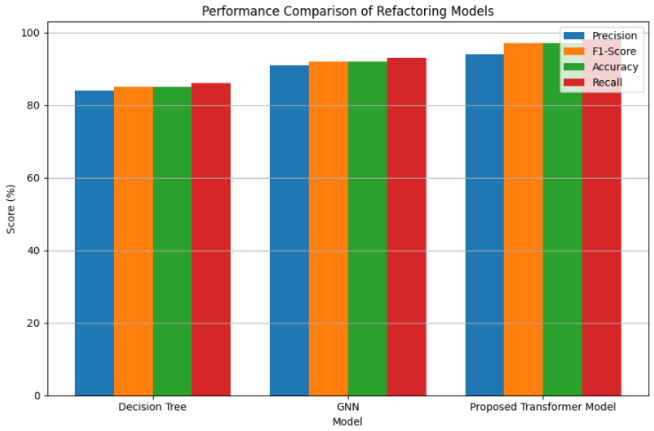

Fig. 9. Performance comparison.

Fig. 9 illustrates a performance comparison of three models of refactoring—Decision Tree, GNN, and Proposed Transformer Model—based on four measures: Precision, F1-Score, Accuracy, and Recall. The Decision Tree model performs moderately, with all measures in the mid-80% category. The GNN indicates significant improvement in all measures with a score of over 90%. The Proposed Transformer Model attains the best scores, with remarkable achievement of 94% Precision, 97% F1-Score and Accuracy, and 98% Recall. These outcomes confirm the excellence of the Transformer-based technique in accurately and effectively refactoring source code. To demonstrate real-world applicability, TICRF was used on a small open-source project written in Python (about 5,000 LOC). The model refactored functions that contained nested loops, duplicate code, and inconsistent naming conventions automatically. Developers who reviewed the refactored code indicated improved readability and maintainability without altering functionality, verifying the usefulness of the framework in practice rather than just on a curated dataset. The unit test pass rate of the project remained at 91% after the refactoring.

B. Discussion

The entire discussion of this research revolves around assessing the efficacy of the designed TICRF against conventional and contemporary baseline models. Under rigorous experimentation, it was seen that the Transformer-based model considerably improves several parameters related to the quality of code [22]. Traditional models such as the Decision Tree, while helpful for simple decision rules, do not have the contextualization necessary for advanced code transformation, as evidenced in their mid-scores on all measures [23]. The GNN model with graph-based structural information performs better through its capability of catching dependencies in code. Yet, it is still lacking compared to the Transformer model, which uses attention mechanisms to understand both semantic and syntactic patterns of source code.

The fine-tuned optimized CodeT5 model not only generates more maintainable code—as shown by increased Maintainability Index scores—but also decreases Cyclomatic Complexity and Code Duplication Rate significantly. The BLEU and Exact Match score improvements over epochs validate the model's capacity to learn efficient refactoring techniques. Moreover, the 90%+ Unit Test Pass Rate across all epochs ensures that the refactored code is functionally sound, an important requirement in software development. These improvements are also confirmed by quantitative measures, as the suggested model gained 94% precision, 97% accuracy and F1-score, and 98% recall. In conclusion, the Transformer-based solution is an effective and trustworthy tool for code refactoring automation, tackling both structural and semantic difficulties better than other models.

V. Conclusion and Future Works

A robust and intelligent approach to automated code refactoring using a Transformer-based model, specifically leveraging the capabilities of the fine-tuned CodeT5 model, has been introduced. Traditional approaches, such as decision trees and graph neural networks, while effective to some extent, fail to capture the deeper syntactic and semantic complexities of source code. The suggested framework addresses such limitations via a sequence-to-sequence architecture that transforms poorly organized code into better-maintainable and optimized forms. From dataset preparation and preprocessing to model training and inference, the pipeline ensures both structural and functional correctness of refactored output via AST validation and extensive testing. Experimental outcomes show conspicuous enhancements in significant software quality metrics like Maintainability Index, Cyclomatic Complexity, and Code Duplication Rate. The Transformer model has a precision of 94%, recall of 98%, and an accuracy of 97%, comparing favorably with baseline approaches. Overall, this work showcases the transformative value of Transformer-based models for enhancing code quality, mitigating technical debt, and allowing programmers to keep systems cleaner, scalable, and more reliable.

As future directions, the Transformer-based refactoring framework can be extended to include multilingual code support to process more types of programming languages. The inclusion of semantic-aware embeddings and graph-based structural constraints in addition to Transformer outputs would help the model to be even more accurate in identifying and rewriting intricate code patterns. Real-world deployment in development environments like IDEs with adaptive feedback loops would increase interactivity and context awareness. In addition,

reinforcement learning methods may be investigated to create dynamic, optimal refactoring approaches to optimize long-term maintainability and performance results.

***Abstract*—This project presents the development of a mobile application for real-time posture analysis during squat and deadlift exercises, using Google Machine Learning (ML) Kit pose detection. Proper exercise form is critical in preventing injuries, underscoring the need for systems that provide immediate feedback, an aspect often missing in existing fitness applications. This study addresses that gap by designing an app that not only guides users through motion analysis but also incorporates a safety mechanism to detect sudden falls. The system employs algorithms to process landmarks, calculate joint angles, count repetitions, and trigger emergency alerts. Two groups of bodybuilders confirmed the usability and accuracy in real-time biomechanical squat and deadlift posture analysis. These findings contribute to the field of AI-driven fitness by introducing a non-wearable, mobile-based solution for guided strength training. In addition, it offers societal benefits as an AI-powered fitness coach that aims to promote public health.**

***Keywords*—Pose detection; squat and deadlift; Google ML Kit; fitness; posture analysis; emergency; public health**

I. INTRODUCTION

The evolution of technology within the fitness industry has significantly advanced training methods and monitoring capabilities for athletes, particularly in strength training disciplines such as bodybuilding and powerlifting. However, experts such as coach / trainer are required to provide real-time feedback during the training to ensure the accuracy and efficiency of training [1,2]. This is an issue for those who cannot afford a high-paying coach or lack of sufficient coach for everyone. Furthermore, common injuries in strength training, which often result from improper form, continue to be a major concern [3,4]. These injuries not only hinder progress but can also lead to long-term health issues, significantly impacting an athlete's training and competitive performance.

Current fitness applications predominantly emphasise quantitative metrics such as calories burnt, distance covered, or heart rate variability. While these data points are valuable, they fail to capture the qualitative dimensions of strength training exercises, such as joint angles during a squat or spinal alignment during a deadlift. These qualitative aspects are critical to ensure proper form and minimizing the risk of injury. Consequently, there is a compelling need for more specialised technology that provides real-time, context-aware feedback on exercise form and technique.

This project presents a novel mobile application that utilises real-time motion capture technology to improve exercise performance and safety in strength training. By integrating Google's ML Kit pose detection for accurate skeletal tracking, the application delivers immediate, actionable feedback to users during their workouts. This capability not only supports injury prevention but also improves training efficiency by ensuring correct biomechanics are maintained throughout each exercise. The innovative design and user-centric interface address a significant weakness in existing fitness solutions, which often neglect real-time biomechanical evaluation. By bridging this gap, the proposed system empowers users to train more effectively, safely and autonomously.

This paper is constructed in five sections. Section II summarises the existing research studies and market products of fitness assistance and highlights the research gap. Section III presents the proposed architecture of the system with associating algorithms. Section IV records the performance of the proposed AI-powered fitness coach using an experiment carried out among bodybuilders. Finally, Sections V and VI discuss and compare this research with previous research and market products, highlight the limitations of the research and future works.

II. Literature Review

This review of the literature systematically examines key areas relevant to the development of a real-time posture analysis application tailored for squat and deadlift exercises. It begins with an overview of motion capture technologies, including both optical and non-optical systems, and traces their evolution with the integration of artificial intelligence - highlighting the enhanced analytical capabilities brought about by these advancements. The review then focusses on Google's ML Kit for pose detection, highlighting its role in enabling real-time feedback mechanisms that are critical for immediate posture correction in exercise applications.

A detailed exploration of existing applications that employ Google's ML Kit illustrates its practical implementation and growing adoption in domains such as fitness, yoga, and posture correction. Furthermore, the review delves into the biomechanics of squats and deadlifts, discussing correct form, joint alignment, and load management, thus emphasising the importance of precise execution to prevent injury and optimise performance.

The analysis also evaluates current fitness applications, identifying their core functionalities and limitations compared to the proposed system. In particular, the proposed application differentiates itself by offering advanced analytics, AI-driven real-time posture feedback, and built-in emergency response mechanisms. Each component of the review is structured according to the PRISMA methodology, ensuring a comprehensive, systematic, and evidence-based foundation that supports the rationale and design of the proposed solution.

A. Background of Motion Capture Technology

Motion capture (MoCap) refers to the digital tracking and recording of movement patterns of objects or living beings within a defined space, using a variety of technologies and methodologies [5]. It is widely used in domains such as the military, entertainment, sports, medicine, and the validation of computer vision and robotic systems [6]. Broadly, motion capture systems are classified into two categories: optical and non-optical.

Optical systems typically use cameras in conjunction with reflective markers or light-emitting diodes (LEDs) to capture motion as shown in Fig. 1 [7]. These systems are renowned for their high precision and are widely used in industries such as film production, video game development, and sports performance analytics [8,9]. On the contrary, non-optical systems—such as inertial measurement units (IMUs)—employ embedded sensors to track motion independently of camera setups, offering enhanced mobility and adaptability across diverse environments [10]. Fig. 2 is an example of non-optical system [11]. Despite their differing methodologies, both types can deliver high levels of accuracy and precision in motion tracking.

Recent advances have seen the integration of artificial intelligence (AI) with optical motion capture technologies, significantly enhancing their analytical and functional capabilities. AI-driven models enable more advanced data interpretation and facilitate real-time feedback mechanisms, which are crucial for dynamic applications [12]. This fusion of AI and motion capture not only improved the efficiency and reliability of motion analysis but has also broadened its applicability to fields such as medical diagnostics, personalised fitness training, and rehabilitation, where accurate real-time movement assessment is essential.

Fig. 1. Optical system [7].

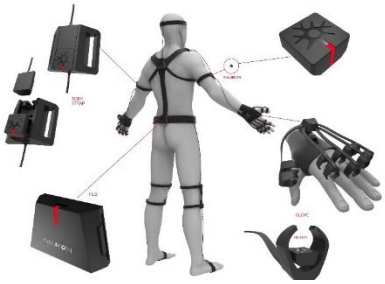

Fig. 2. Non-optical system (Inertial system) [11].

B. Recent AI Motion Capture Technology

Recent advances in AI-powered motion capture technologies have significantly improved the precision, accessibility, and adaptability of these systems in various environments. Current innovations primarily aim to improve the speed and accuracy of pose estimation through deep learning models, while expanding the application beyond its traditional domains. One notable milestone in this evolution is the introduction of Deep3DPose, a pioneering model that applies deep learning to human pose estimation. Using cascaded deep neural networks, Deep3DPose directly infers human poses from images and introduces a multitask framework capable of concurrently predicting multiple outputs, thereby enabling accurate 3D pose estimation and full-body reconstruction in real time [13]. Fig. 3 shows an example of AI motion capture technology introduced in the Brau et al. (2016) research.

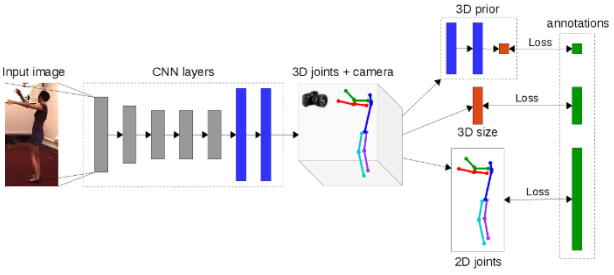

Fig. 3. AI motion capture technology captures human pose and convert it into 3D joints [14].

Subsequent research has introduced numerous algorithms aimed at addressing the limitations of conventional motion capture systems. These include enhanced marker-based approaches [15], hybrid architectures such as Convolutional

Neural Networks (CNNs) combined with Long Short-Term Memory (LSTM) models [16], and frameworks grounded in Human-Centred Artificial Intelligence (HAI) that prioritize interpretability and user-specific customisation [17]. Collectively, these developments signify a paradigm shift towards more intelligent, robust, and user-centric motion capture technologies, with implications for fields such as rehabilitation, sports science, ergonomics, and interactive systems.

C. Google's ML Kit for Pose Detection

Within the domain of AI-driven motion capture technologies, Google's ML Kit for pose detection emerges as a crucial tool, enabling the efficient development of mobile applications capable of real-time human pose estimation. The ML Kit provides a flexible and accessible framework for embedding machine learning functionalities directly into mobile applications on both the Android and iOS platforms. It includes a comprehensive set of APIs that support the detection and tracking of human body joints from static images and live video streams [18].

The pose detection API in the ML Kit is engineered to recognize 33 anatomical landmarks in the human body, including major joints such as shoulders, elbows, wrists, hips, knees, and ankles, as illustrated in Fig. 4 [19]. This level of granularity enables the development of fitness and wellness applications capable of assessing user posture and movement patterns. In particular, it supports real-time form analysis and corrective feedback for strength training exercises such as squats and deadlifts, delivering functionality comparable to that of more complex and computationally intensive motion capture systems, but with significantly lower resource demands and greater accessibility.

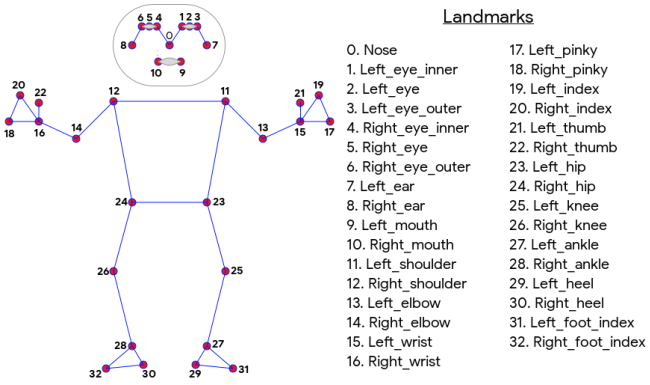

Fig. 4. 33 landmarks of a human pose [19].

A distinguishing feature of Google's ML Kit is its dual-mode operational capability. It supports both a high-accuracy mode, which utilises cloud-based processing and requires an active internet connection, and a real-time mode that functions entirely offline to ensure minimal latency. This flexibility is particularly advantageous for applications in real-time sports analytics, fitness coaching, and augmented reality, where immediate and continuous feedback based on user movement is critical. By accommodating both high-performance and resource-constrained environments, ML Kit broadens its applicability across a wide range of mobile use cases. Fig. 5 shows an example of application using Google's ML Kit landmarks no. 11-18. Sample angles calculations are shown Fig. 6.

Landmark	Type	Position	InFrameLikelihood
11	LEFT_SHOULDER	(734.9671, 550.7924, -118.11934)	0.9999038
12	RIGHT_SHOULDER	(391.27032, 583.2485, -321.15836)	0.9999894
13	LEFT_ELBOW	(903.83704, 754.676, -219.67009)	0.9836427
14	RIGHT_ELBOW	(322.18152, 842.5973, -179.28519)	0.99970156
15	LEFT_WRIST	(1073.8956, 654.9725, -820.93463)	0.9737737
16	RIGHT_WRIST	(218.27956, 1015.70435, -683.6567)	0.995568
17	LEFT_PINKY	(1146.1635, 609.6432, -956.9976)	0.95273364
18	RIGHT_PINKY	(176.17755, 1065.838, -776.5006)	0.9785348

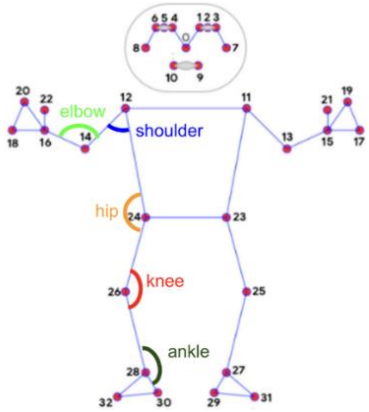

Fig. 6. Calculate the angle between landmarks [19].

D. Applications Using Google's ML Kit for Pose Detection

Google's ML Kit Pose Detection API has seen widespread adoption in mobile application development in both academic research and industry practice. Numerous projects, from student-level prototypes to fully deployed applications, have demonstrated their effectiveness in tracking human posture and interpreting movement in domains such as fitness, yoga, and dance. These implementations underscore the practicality of the ML Kit as a lightweight, on-device solution for real-time pose analysis, even on resource-constrained devices.

A notable academic implementation is the undergraduate thesis by Nguyen (2024), which investigated the integration of ML Kit Pose Detection into Android applications [20]. The project resulted in two mobile applications: one designed for detecting static body poses from images and another for real-

time yoga pose recognition using a custom-trained classifier. Using the detection of the landmarks of the pose of the ML Kit, the system successfully identified common yoga postures - including tree pose, downward dog, and plank - demonstrating the API's potential of the API to support mobile health and wellness applications through computer vision–driven feedback.

Another example is RepDetect, a real-time fitness assistant developed by students at Metropolia University of Applied Sciences. This Android-based application uses the ML Kit to monitor exercises such as push-ups, sit-ups, and lunges by evaluating the consistency of the pose and counting repetitions [35]. The app uses pose confidence scores to assess form accuracy, providing users with real-time feedback and exercise statistics. This project exemplifies how small development teams can leverage the ML Kit and Kotlin to create fully functional, AI-driven workout tracking solutions.

In industry settings, the ML Kit has also been incorporated into commercial applications. Groovetime, a dance-based mobile app, utilises pose estimation to help users learn choreographed routines by comparing user movements against predefined dance sequences. It offers real-time feedback on movement accuracy, acting as a virtual dance coach [21]. Similarly, NeckFit uses the ML Kit to analyse upper-body posture and suggest corrective exercises aimed at alleviating neck strain and improving spinal alignment. Designed for daily use, NeckFit targets users seeking ergonomic improvements and posture correction [22].

Together, these examples reflect the growing utility and adaptability of ML Kit Pose Detection in diverse application areas, reaffirming its value as a robust, accessible tool for real-time, mobile-based human pose analysis.

E. Squat

Squat is a fundamental compound exercise that engages multiple muscle groups in the body, including the quadriceps, hamstrings, glutes, lower back, and core. The movement involves lowering the body into a squatting position by flexing the knees and hips while maintaining a neutral spine, followed by returning to a standing position. Known for its effectiveness in enhancing lower body strength, flexibility, and balance, the squat is, however, frequently performed incorrectly in gym settings. Improper execution can result in a variety of injuries, such as lower back pain, muscle strains or tears, knee sprains, and tendinopathy, an overuse injury commonly associated with repetitive movements [1].

Fig. 7 demonstrates proper squat execution: place the barbell on the trapezius muscle and hold it in a comfortable hand position. The feet should be slightly wider than shoulder-width apart with toes pointing outward, ideally not exceeding 10 degrees [23]. As you descend into the squat, ensure that your trunk remains parallel to your tibia to maintain balance and alignment. The depth of the squat and the angle of knee flexion should correspond to the specific type of squat being performed: mini squats typically range between 140° and 150°, semi-squats between 120° and 140°, half-squats between 80° and 110°, and deep squats go below 80° [24]. Precise joint angles are crucial to prevent injuries and optimise the exercise's effectiveness: hip joints should ideally be angled at approximately 58.0°±9.8°, ankle joints at about 81.0°±7.3°, and the torso at roughly 38.2°±5.8° [25, 26]. These biomechanical considerations help to perform squats correctly and safely, reducing the risk of injuries while improving training outcomes.

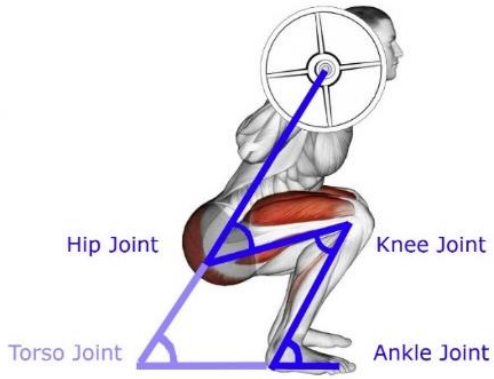

Fig. 7. Proper squat pose.

According to Strength Level (2024), the selection of appropriate dumbbell weights for squats is influenced by three primary factors: strength level, body weight, and age [27]. As illustrated in Fig. 8, the advised weight varies significantly between different strength levels. For example, a beginner who weighs 60 kg is typically advised to use lighter weights, which are 45 kg (0.75x body weight), to promote correct form and ensure safety. Additional guidance is provided in Fig. 9 and Fig. 10, which delineate the recommended weights according to body weight and age, respectively, helping to tailor the exercise to the individual's physical condition and reducing the risk of injury.

Strength Level	Bodyweight Ratio
Beginner	0.75x
Novice	1.25x
Intermediate	1.50x
Advanced	2.25x
Elite	2.75x

F. Deadlift

The deadlift is a fundamental weight training exercise that engages multiple muscle groups, making it one of the most effective compound movements to build overall strength. Primarily, deadlift targets the glutes, hamstrings, lower back, and core, while also activating the forearms and traps [28]. The exercise involves lifting a loaded barbell from the ground to the level of the hips, followed by a controlled lowering of the weight back to the floor. Recognised for its ability to enhance muscular strength and hypertrophy, the deadlift is also valued for improving grip strength and overall body stability.

Fig. 11 shows several variations of the deadlift, including the conventional deadlift, sumo deadlift, straight-leg deadlift, and Romanian deadlift (RDL) [29]. However, improper technique during deadlifting can result in excessive compressive and shear forces on the lumbosacral spine, potentially leading to disc herniation or other spinal injuries [30].

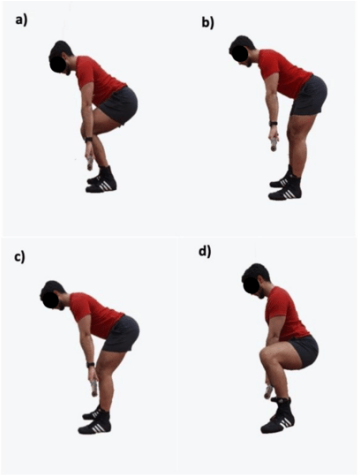

Fig. 11. a) Conventional deadlift, b) Straight-leg deadlift, c) Romanian deadlift, d) Sumo deadlift [29].

Proper execution of deadlifts varies according to the specific style being performed, with each variation emphasising distinct stances and grip positions. The conventional deadlift, as outlined by Escamilla et al. (2002), involves a stance narrower than shoulder width, with the feet positioned close to the centre of the bar and the hands gripping the bar just outside the legs [31]. Straight-leg deadlift is similar to the Romanian deadlift, but differs by maintaining fully extended knees and ensuring that the bar does not come into contact with the legs. On the contrary, the Romanian deadlift retains the stance width of the conventional deadlift but limits knee flexion to no more than 15 degrees, ensuring that the barbell stays in contact with the legs throughout the movement [32]. Lastly, the sumo deadlift features a significantly wider stance, exceeding shoulder width, which facilitates the participation of different muscle groups [31].

In terms of determining the appropriate weight for the deadlift, the guidelines provided by Strength Level Limited (2024) emphasise the importance of adjusting weight based on an individual's strength level, body weight, and age. As illustrated in Fig. 12, there is considerable variation in recommended deadlift weights in different strength categories. For example, a beginner weighing 60 kg is typically advised to lift a weight equal to your body weight (60 kg) to ensure proper form and reduce the risk of injury. Additional recommendations are provided in Fig. 13 and 14, offering customised weight guidelines based on body weight and age, respectively. These individualised suggestions enable users to adjust their training to their physical abilities, thereby promoting safety and reducing the likelihood of injury.

Strength Level	Bodyweight Ratio
Beginner	1.00x
Novice	1.50x
Intermediate	2.00x
Advanced	2.50x
Elite	3.00x

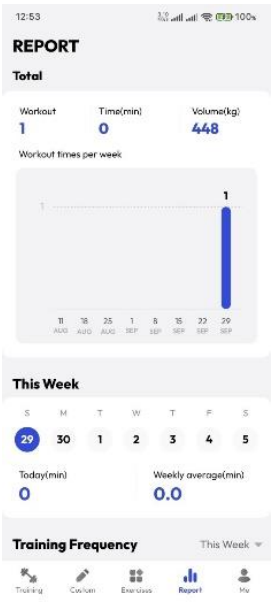
G. Existing Product



1) Gym workout tracker: Gym Log: This fitness app, developed by Leap Fitness Group, has amassed more than 5 million downloads and boasts a perfect 5.0/5.0 rating from 92.8k reviewers on the Google Play Store [33]. Launched on December 8, 2021, the app is designed to serve beginners and experienced bodybuilders by offering customisable workout routines that align with individual goals and available gym equipment. It functions as a comprehensive fitness tool, providing access to a robust database of more than 500 exercises, each accompanied by detailed visual and written instructions (Fig. 15). In addition to facilitating workout planning and tracking, the app replaces traditional pen-and-paper methods by allowing users to log workouts digitally. It also tracks progress through intuitive statistics and charts, offering users a detailed overview of their performance. Features such as adjustable rest timers, unlimited routine edits, and the ability to create personalised workout routines ensure a highly flexible and enriched training experience. By combining these functions, the app helps users optimize their workouts, improve training efficiency, and maintain motivation, all without the expense of a personal trainer.

2) Muscle booster – Plan workouts: With more than 10 million downloads and a rating of 4.8/5.0 from users on the Google Play Store, Muscle Booster is a highly rated fitness app developed by Welltech Apps Limited on November 27, 2019 [34]. This dynamic and comprehensive fitness assistant is designed to cater to both men and women, offering customisable workout plans tailored to individual fitness goals, equipment availability, and personal constraints.

Muscle Booster is versatile enough to be used both at home and in the gym, featuring a vast library of over 1,000 workouts. It also includes interactive challenges and provides detailed guidance through a workout player that offers audio tips and timed instructions. Whether users are looking to gain muscle, lose weight, or focus on recovery, the app allows them to set specific objectives, target muscle zones, and receive personalised recommendations. It also incorporates mini milestones to track progress, helping users stay motivated throughout their fitness journey. As a result, Muscle Booster serves as an all-encompassing platform to improve physical fitness and facilitating health transformations efficiently (Fig. 16).

H. Summarise of Existing Product

In summary, while apps like Gym Workout Tracker: Gym Log and Muscle Booster – Plan Workouts primarily focus on providing extensive exercise libraries and detailed instructional content, this project distinguishes itself by incorporating advanced real-time posture analysis. This feature is particularly valuable as it not only guides users through exercises but also offers instant feedback on their form, thereby improving both safety and effectiveness.

TABLE I. COMPARISON OF EXISTING PRODUCT WITH THIS PROJECT

Emergency mechanism			✓

This project further differentiates itself through the integration of more sophisticated technology, specifically Google's ML Kit for pose detection, something existing apps do not utilize to the same extent. This technology enhances the accuracy of posture and form analysis, representing a significant advancement in the app's capabilities. Additionally, the emergency mechanism is a unique safety feature designed to detect potential distress or unsafe conditions during workouts, triggering a prompt response. This feature is especially noteworthy in the fitness app market, where similar safety features are typically reserved for expensive high-tech fitness devices, such as smartwatches. Table I summarises the comparison of this project with existing products found in the market focusing on features comparison.

III. MATERIAL AND METHOD

A. System Architecture Design

This section presents the overall system architecture design that includes 1) real time input, 2) pose analysis, and 3) real time pose adjustment. For real time input, the Google machine learning kit is used to detect and extract key joint landmarks from the user's body. These coordinates are used in later calculations for the classification of angles, positions, and postures. Pose analysis is carried out using angles between joints calculation and detects incorrect reps (posture validation). If there are emergencies, such as injuries or falls, an AI-powered fitness coach will alert surrounding users to help in the emergency. In the event of incorrect posture, the system will alert the user, too. A workout plan is incorporated into this system to monitor the duration of each workout. The details of each component will be further explained using workflow, and algorithm will be illustrated using pseudocode in the following subsections (Fig. 17).

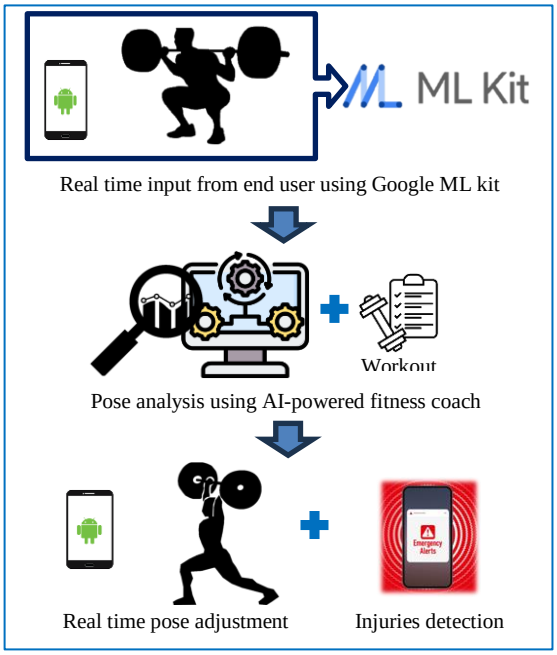

Fig. 17. AI-powered fitness coach system architecture design.

B. System Components Workflow Design

This section presents three flowcharts designed to support real-time biomechanical posture analysis for squats and deadlifts. The first flow chart (Fig. 18) outlines the process of capturing a user's workout plan based on their profile, followed by the generation of personalised exercise recommendations. The process begins when the user navigates to the workout planner page. The system retrieves and displays all existing workout

plans from the database. At this point, the user can choose to create a new plan, modify an existing one, or delete a plan. When creating a new workout plan, the system displays a recommended weight based on the user profile. The user then inputs key details of the working of the exercises, including selected sets, weights, and repetitions. Before finalising the plan, a confirmation prompt ensures that the user reviews the input. Once confirmed, the workout plan is stored in the database, and a success dialogue notifies the user of the successful creation.

The modification process mirrors the creation workflow. After selecting a plan to modify, the system again displays recommended weights. Users can update the exercise details and confirm the changes. Upon validation, the updated plan is saved in the database and a confirmation dialog is displayed. For deletion, the user is asked to confirm the action to prevent accidental loss. If confirmed, the selected workout plan is removed from the database and a success dialog provides final confirmation.

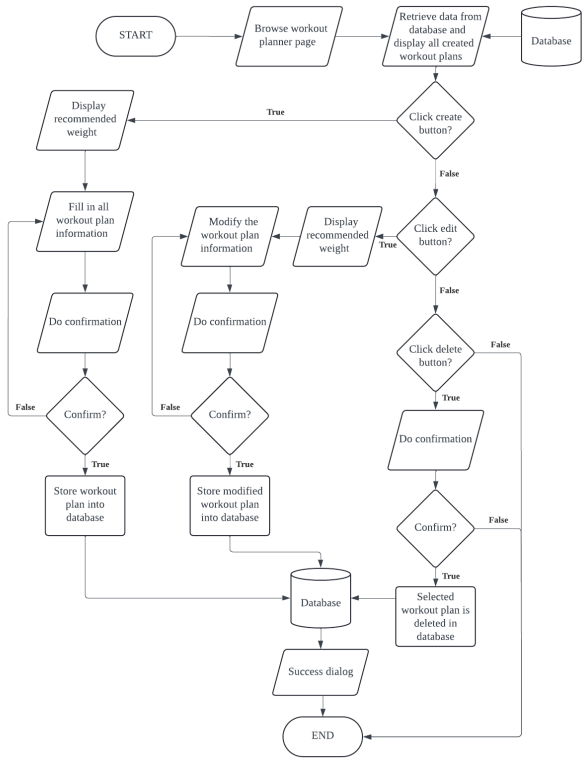

Fig. 18. Flow chart for the exercise planner module.

Fig. 19 illustrates the flow chart for the motion capture module. The process begins when a user accesses the workout planner page and selects a workout plan. The application then displays relevant instructions and tips based on the selected workout, including information on necessary equipment and targeted muscle groups. If the user chooses to calculate the appropriate barbell weight, they can utilise the built-in plate calculator by entering the desired total weight and selecting the available weight plates. The application then generates the optimal plate configuration for the workout. Once the user starts the workout, the application becomes a real-time monitoring interface that captures and analyses the user's movements. Using motion capture technology, the system provides immediate feedback on exercise form, helping the user make real-time adjustments to maintain proper posture and technique.

During the workout session, users can add additional sets if needed. The system also includes an embedded emergency detection mechanism that continuously monitors for abnormal activity, such as sudden falls. If an emergency is detected, the application triggers an audible alarm, notifies the designated emergency contact, and offers the user the option to stop the alert. Upon completion of all sets or if the user chooses to end the workout, the system stores the entire session's data, including performance metrics and form analysis, into the database. Finally, a congratulatory screen is displayed to acknowledge the effort before redirecting them back to the workout planner page for future session planning or review.

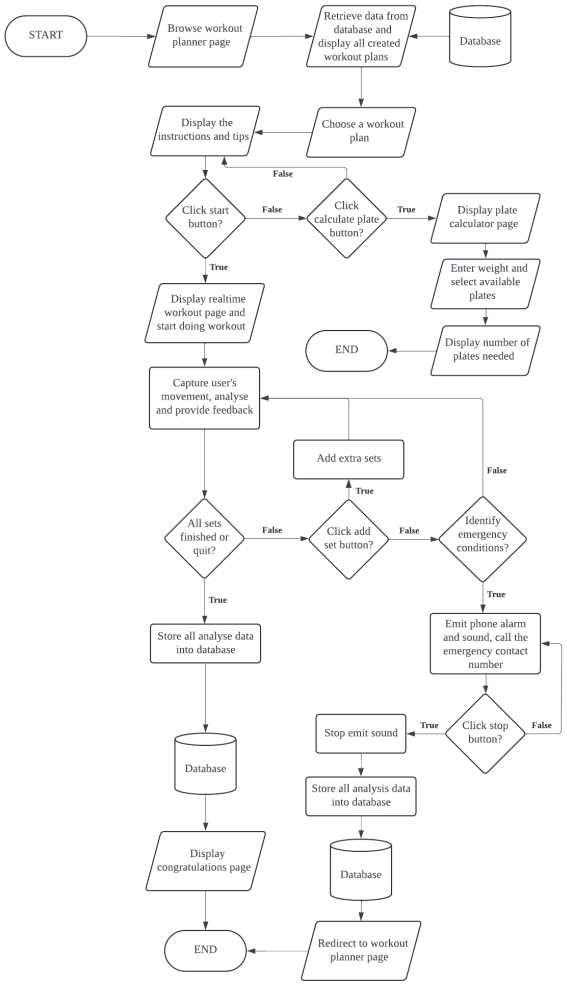

Fig. 19. Flowchart for motion capture module.

Fig. 20 delineates the process by which users interact with their exercise and body weight data within the fitness application. The process begins when a user accesses the report page, prompting the app to retrieve and display several types of data: an overall summary of the frequency and volume, detailed logs of individual workout sessions, and trends in the

progression of body weight. Users are presented with a weekly overview of all recorded workouts. For a more granular view, they can select the "View All" option, which opens a calendar interface that allows users to filter historical data by specific dates. Upon selecting a date, the application displays only the corresponding workout sessions, allowing users to examine detailed performance metrics, including repetitions, joint angles, and explosive power.

Alternatively, if the user chooses to log their current body weight rather than review historical data, the system prompts them to input the new weight value. These data are then securely stored in the database, contributing to long-term tracking and analysis of physical progress.

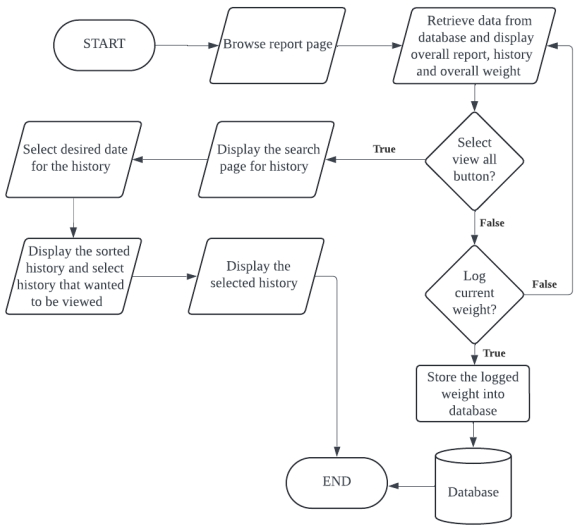

Fig. 20. flow chart for report module.

C. Algorithm Design

The algorithmic framework of this project is based on Google's ML Kit Pose Detection, a machine learning-based tool capable of identifying up to 33 anatomical landmarks in the human body. These landmarks encompass key joints and reference points, including the nose, eyes, shoulders, elbows, wrists, hips, knees, and ankles. By processing image or video input in real time, the pose detection model generates accurate spatial coordinates for each landmark, enabling detailed analysis of the user's posture and body orientation. This capability forms the basis for providing real-time feedback on exercise form and alignment.

This project uses a targeted subset of these anatomical landmarks to implement core motion capture functionalities, specifically tailored for the biomechanical analysis of squats and deadlifts. The subsequent sections detail the custom algorithms developed to process these landmarks, encompassing joint coordinate extraction, full-body visibility, joint angle calculation, repetition counting, posture error detection, and emergency fall detection. Each algorithmic component plays a critical role in enabling precise form evaluation, improving user safety, and delivering meaningful, real-time feedback during strength training exercises.

1) Extracting joint coordinates: The initial phase of the algorithm involves detecting and extracting key joint landmarks from the user's body using the Google ML Kit pose detection framework. Although the pose detection model identifies up to 33 anatomical landmarks, this system focusses on a critical subset, specifically shoulders, elbows, hips, knees, and ankles, which are most relevant for analyzing squat and deadlift movements. The landmarks index used in this project is: landmark 0 (for detecting whole body within the frame or not and sudden fall); landmarks 11, 12, 13, 14, 23, 24, 25, 26, 27, 28, 31, 32 (Fig. 4). The extracted coordinates serve as the foundation for subsequent calculations, including joint angle computation, positional tracking, and posture classification. Additionally, the algorithm incorporates a visibility check to ensure that all required joints are detectable in the frame, thus validating full-body visibility before proceeding with further analysis. Fig. 21 illustrates the pseudocode implemented for joint coordinate extraction.

```
FOR each frame:
  pose = runPoseDetection(frame)
  IF pose is null THEN
    SKIP frame
  END IF

  EXTRACT key joint coordinates:
    leftShoulder = pose[LEFT_SHOULDER]
    rightShoulder = pose[RIGHT_SHOULDER]
    leftHip = pose[LEFT_HIP]
    rightHip = pose[RIGHT_HIP]
    leftKnee = pose[LEFT_KNEE]
    rightKnee = pose[RIGHT_KNEE]
    etc.

  IF any key joint is null THEN
    DISPLAY "User not fully in frame"
    CONTINUE
  END IF
```

Fig. 21. Pseudocode used to extract joint coordinates.

2) Detect full body within camera frame: To ensure accurate detection and tracking, the system verifies the visibility of all critical joints. If one or more of these essential landmarks are not detected in each frame, the algorithm assumes that the user is not fully within the camera's view. In such cases, the system bypasses further analysis for that frame to avoid inaccurate posture evaluation and maintain the reliability of the feedback mechanisms (Fig. 22).

```
CHECK full-body detection:
  REQUIRED_JOINTS = [NOSE, LEFT_HIP, RIGHT_HIP,
LEFT_ANKLE, RIGHT_ANKLE]
  FOR joint IN REQUIRED_JOINTS:
    IF joint is missing or confidence < threshold:
      DISPLAY "Please align yourself in the frame"
      RETURN
```

Fig. 22. Pseudocode to detect and ensure user's body is within the frame.

3) Calculate angles between joints: Using the extracted coordinates, the system calculates joint angles, specifically at the knees and hips, to evaluate movement phases and assess posture. These angles are computed using a standard geometric method involving three points, where the joint of interest (e.g.

the hip) is positioned between two adjacent landmarks (e.g. the shoulder and the knee). By continuously analysing these angle values, the system can determine the depth of a squat, detect misalignments, and identify potential deviations from proper form (Fig. 23).

```
FUNCTION calculateAngle(A, B, C):
  angle = arccos( (AB² + BC² - AC²) / (2 * AB * BC) )
  RETURN angle

hipAngle = calculateAngle(shoulder, hip, knee)
kneeAngle = calculateAngle(hip, knee, ankle)
```

Fig. 23. Pseudocode designed to calculate the angles between joints.

4) Count repetitions (squat/deadlift): The repetition counting logic is based on tracking the sequential movement patterns of key joints, particularly the hips and knees, over time, as shown in Fig. 24. For squats, the system continuously monitors changes in hip and knee joint angles to identify the different phases of the exercise. Repetition is initiated when both the hip and knee angles decrease beyond a predefined threshold, indicating that the user is descending into the squat. The repetition concludes when these angles increase as the user returns to a standing position. To ensure accuracy, repetition is counted only when this full motion cycle is completed and specific posture conditions are met, such as appropriate squat depth and joint alignment.

```
INITIALIZE:
  phase = "Standing"
  successfulRepCount = 0
  failedRepCount = 0

ON EACH FRAME:
  UPDATE kneeAngle, hipAngle, handHeight
  UPDATE timestamp for motion duration

  // Squat Detection Logic
  IF motionType == "SQUAT":
    IF kneeAngle < 100 AND hipAngle < 100:
      IF phase == "Standing":
        phase = "Squatting"

    ELSE IF kneeAngle > 150 AND hipAngle > 150:
      IF phase == "Squatting":
        IF postureIsValid():
          successfulRepCount += 1
        ELSE:
          failedRepCount += 1
        END IF
        phase = "Standing"

  // Deadlift Detection Logic
  IF motionType == "DEADLIFT":
    IF handHeight below knee:
      IF phase == "Standing":
        phase = "Lowering"

    ELSE IF handHeight above hip:
      IF phase == "Lowering":
        IF postureIsValid():
          successfulRepCount += 1
        ELSE:
          failedRepCount += 1
        END IF
        phase = "Standing"
```

Fig. 24. Pseudocode used in this project to count repetitions.

For deadlifts, the system uses the relative position of the hands in relation to the hips and knees to identify the lifting and lowering phases. Repetition is detected when the hands descend below the level of the knees and then ascend back above the hips in a controlled, continuous motion. This movement must also meet predefined posture conditions, such as proper spinal alignment and full extension to the top—for a repetition to be considered valid. The use of relative joint positioning ensures that only complete and correctly executed repetitions are counted.

5) Detect incorrect reps (posture validation): The app continuously tracks key joint landmarks (such as the hips, knees, shoulders, and hands) across frames during a squat or deadlift. To validate the posture for each repetition, the system compares the relative positions of corresponding joints (e.g. left and right shoulders, hips, elbows, and hands) to ensure that the user is performing the movement in a controlled and balanced manner. For instance, if the hands are misaligned or one shoulder is significantly lower than the other, the system flags these discrepancies as errors. Error flags are assigned to each joint segment and, if any of these flags are activated, the repetition is deemed invalid. When an error is detected, the app displays a relevant error message on the screen (e.g. "Hands are not parallel") and excludes the repetition from the count (Fig. 25).

```
Initialize errorFlags = {
  handPosition: false,
  shoulder: false,
  hip: false,
  feet: false,
  elbowAngle: false
}

FOR each frame during motion capture:
  IF absolute(leftHand.y - rightHand.y) > hand_threshold:
    errorFlags.handPosition = true
    Show error message: "Hands are not parallel"

  IF absolute(leftShoulder.y - rightShoulder.y) > shoulder_threshold:
    errorFlags.shoulder = true
    Show error message: "Shoulders not aligned"

  IF absolute(leftHip.y - rightHip.y) > hip_threshold:
    errorFlags.hip = true
    Show error message: "Hips not aligned"

  IF absolute(leftFoot.y - rightFoot.y) > feet_threshold:
    errorFlags.feet = true
    Show error message: "Feet not aligned"

  IF elbow angle not within correct range (deadlift only):
    errorFlags.elbowAngle = true
    Show error message: "Elbow angle incorrect"

AT end of repetition:
  IF any errorFlags is true:
    Mark rep as incorrect
    Increase failed rep counter
  ELSE:
    Count rep as successful
```

Fig. 25. Pseucode used in this project to detect errors.

6) Emergency mechanism detection: The emergency mechanism within the motion capture system is designed to

detect sudden falls or unsafe postural deviations by analysing real-time body landmark data, as shown in Fig. 26. Specifically, the system calculates the trunk angle by measuring the slope between the midpoint of the user's shoulders and ankles. If this angle exceeds a predefined threshold (typically greater than 60 degrees) and experiences a rapid change between consecutive frames (e.g. more than a 25-degree shift), the system flags the event as a potential fall. To reduce the likelihood of false alarms, the angle difference is smoothed using exponential filtering, and a cooling counter is employed to debounce temporary fluctuations, ensuring that only genuine postural changes trigger an alert.

```
function detectEmergency(pose):
    if key landmarks (nose, shoulders, hips, ankles) are missing:
        return false

    upperMid = midpoint(leftShoulder, rightShoulder)
    lowerMid = midpoint(leftAnkle, rightAnkle)
    bodyAngle = angleBetween(upperMid, lowerMid)

    if lastAngle == 0:
        set lastAngle = bodyAngle
        return false

    angleChange = abs(bodyAngle - lastAngle)
    set lastAngle = bodyAngle

    if bodyAngle > 60 and angleChange > 25:
        increment dropFrameCount
        set emergency = true
        return true
    else:
        decrement dropFrameCount
        return false
```

Fig. 26. Pseudocode used to detect emergencies / injuries.

IV. Result

This section presents the results of the User Acceptance Testing (UAT) and accuracy evaluation conducted on the mobile applications Real-time Biomechanical Squat and Deadlift Posture Analysis, based on data collected from two distinct user groups.

A. Usability Test

The usability test (UT) was conducted with six experienced bodybuilders to assess the usability based on real-world user interactions (Fig. 27). Participants completed a full cycle of tasks, including account registration, profile setup, workout planning, motion capture, emergency alert testing, and performance reporting. The demographic profiles of the participants are summarised in Table II.

TABLE II. UAT Participants' Demographics

#	Age	Gender	Years of Bodybuilding	Beginner/ intermediate/ advance level	Occupation
1	22	Male	1	Beginner	Undergraduate
2	22	Male	1	Beginner	Undergraduate
3	22	Male	0.5	Beginner	Undergraduate
4	22	Male	0.5	Beginner	Undergraduate
5	22	Male	0.5	Beginner	Undergraduate
6	22	Male	3	Intermediate	Undergraduate

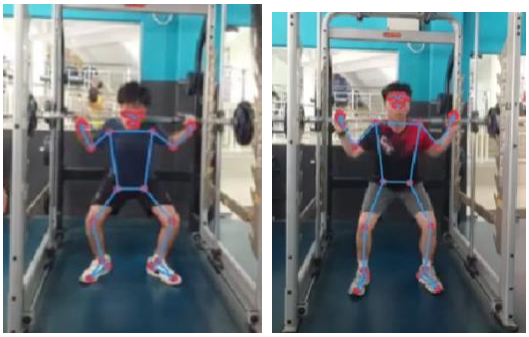

Fig. 27. Screenshots of usability test.

Feedback was collected through a structured questionnaire administered through Google Forms, consisting of 11 items rated on a 5-point Likert scale, alongside open-ended response sections (Fig. 28). In general, the usability of the application received positive evaluations. Specifically, 83.3% of the participants rated the user interface as easy to navigate (a score of 4), while 16.7% awarded it the highest score of 5. The workout planning feature was particularly well received, with 83.3% of users assigning it a score of 5, citing its simplicity and clarity.

UAT1. The app interface is easy to navigate. [Strongly disagree(1) – Strongly agree(5)]
UAT2. The workout planner is simple to use and understand. [Strongly disagree(1) – Strongly agree(5)]
UAT3. The motion capture detected my posture correctly. [Strongly disagree(1) – Strongly agree(5)]
UAT4. The real-time feedback during my squat/deadlift was clear and useful. [Strongly disagree(1) – Strongly agree(5)]
UAT5. The sound alert and emergency contact feature make me feel safer while working out. [Strongly disagree(1) – Strongly agree(5)]
UAT6. The graphs and analytics helped me understand my workout patterns. [Strongly disagree(1) – Strongly agree(5)]
UAT7. The weight log is useful to track my fitness progress over time. [Strongly disagree(1) – Strongly agree(5)]
UAT8. What did you like the most about the app? [Open-ended question]
UAT9. What part of the app did you find confusing or difficult to use? [Open-ended question]
UAT10. Do you have any suggestions for improvement? [Open-ended question]

Fig. 28. Questionnaires used in UAT.

On the contrary, the posture detection module –powered by Google's ML Kit –received moderate feedback. The majority of the participants (66.7%) rated their performance as average (score of 3), while the remaining 33.3% assigned it a slightly higher rating of 4 (Table III). These results indicate that, although the posture detection functionality is operational, its accuracy requires further optimisation to meet user expectations.

TABLE III. Responses of Participants in UAT1-7

UAT Questionnaire	Rating-Percentage in %	Average ratings
UAT1	4-83.3%; 5-16.7%	4.17
UAT2	4-16.7%; 5-83.3%	4.83
UAT3	3-66.7%; 4-33.3%	3.33
UAT4	3-33.3%; 4-33.3%; 5-33.3%	4.00
UAT5	4-50%; 5-50%	4.83
UAT6	3-16.7%; 4-50%; 5-33.3%	3.33
UAT7	3-16.7%; 33.3%; 5-50%	4

Similarly, user responses to the real-time exercise feedback feature were evenly distributed between ratings of 3, 4, and 5 (each representing 33.3%), reflecting a varied user experience. This inconsistency may stem from external factors, such as suboptimal camera angles or insufficient lighting conditions during motion capture, which can impact the effectiveness of real-time feedback.

In particular, all participants agreed that the application effectively helped them assess the correctness of their exercise form. Specifically, 50% rated this feature a 4, while the remaining 50% awarded it a 5, indicating strong user confidence in the form recognition capability. The emergency alert system, which integrates a loud alarm and automated contact notification, also received favourable reviews, with 83.3% of users assigning it a rating of 4 or 5.

Additional features, such as analytics and weight tracking, were similarly well received. The weight logging functionality was rated 4 or higher by 83.3% of participants, and an equal percentage reported that the data visualisation through workout charts enhanced their understanding of training patterns. Average UAT1-UAT7 ratings.

Open feedback offered additional information on both the strengths and potential areas for improvement within the application (see Table IV). The participants highlighted several appreciated features, including real-time posture correction, personalised weight recommendations, the integrated emergency alert system, and the intuitive reporting interface.

TABLE IV. PARTICIPANTS' RESPONSES FOR UAT8-10

UAT8: What did you like the most about the app?
1. The real-time feedback during squats was very helpful — it felt like having a trainer watching me.
2. I liked the emergency feature. It gave me peace of mind knowing it would alert someone if I needed help.
3. The design is clean and it was easy to log my weight and see the progress in the report.
4. I liked how it gives personalized workout recommendations based on fitness level.
5. It's cool how the camera can detect my posture and give feedback instantly.
6. Everything is in one place — workout planner, progress, and form correction.
UAT9: What part of the app did you find confusing or difficult to use?
1. The workout planner interface was a bit overwhelming at first.
2. I wasn't sure how to trigger the motion capture — had to press a few buttons to figure it out.
3. The emergency contact setup took me a while to find in the profile section.
4. The report charts were a bit small on my phone screen.
5. Sometimes I wasn't sure if the camera was properly detecting me or not.
6. Forgot password process was a bit long, especially the OTP step.
UAT10: Do you have any suggestions for improvement?
1. Maybe add a short tutorial for new users when they first open the app.
2. Consider adding labels or tooltips for each button to explain their function.
3. Maybe group the profile and emergency settings under a clearer menu.
4. Allow the charts to be expanded or rotated for better visibility.
5. Maybe show an indicator or guide when the app is actively tracking your movement.
6. Maybe allow the app to resend OTP without waiting too long.

However, users also provided constructive suggestions to improve the overall experience. These included enabling faster OTP (One-Time Password) resends, improving the organisation of profile and emergency settings, expanding report charts for better readability, and incorporating brief tutorials or tooltip explanations to support first-time users. Additionally, some participants recommended the inclusion of a visual indicator to confirm when motion tracking is actively engaged.

In summary, all participants successfully completed the assigned tasks and provided valuable constructive feedback. The application was deemed functionally complete, user-friendly and effective in achieving its intended purpose, thus affirming alignment with the original design objectives. While the overall user experience was positive, incorporating minor usability improvements based on user feedback could further refine the system and strengthen its readiness for a wider deployment.

B. Motion Capture Accuracy Assessment

To evaluate the accuracy of motion capture functionality within the Pose Perfect application, a focused assessment was conducted involving three students from the Faculty of Sport Science at Tunku Abdul Rahman University of Management and Technology (see Table V). Each participant had more than three years of practical experience with squat and deadlift exercises. They were invited to independently explore the application and provide feedback through a structured Google Form questionnaire, which evaluated the key posture-related features in terms of precision, responsiveness, and reliability. The details of the questionnaire items are presented in Fig. 29.

TABLE V. ACCURACY ASSESSMENT PARTICIPANTS' DEMOGRAPHIC

#	Age	Gender	Years of Bodybuilding	Beginner/ intermediate/ advance level	Occupation
1	22	Male	3	Intermediate	Undergraduate
2	22	Male	4	Intermediate	Undergraduate
3	22	Male	4	Intermediate	Undergraduate

ACC1. How accurately does the app detect your squat posture in real time? **[Not accurate (1) – Very accurate (5)]**
ACC2. How accurately does the app detect your deadlift posture in real time? **[Not accurate (1) – Very accurate (5)]**
ACC3. Does the app correctly identify incorrect posture during squats (e.g., unbalanced hands, knees not aligned)? **[Never (1) – Always (5)]**
ACC4. Does the app correctly identify incorrect posture during deadlifts (e.g., unbalanced hands, hands not straight)? **[Never (1) – Always (5)]]**
ACC5. How consistent is the real-time feedback timing? **[Very inconsistent (1) – Very consistent (5)]**
ACC6. Have you tested the emergency mechanism (e.g., simulating a fall or sudden collapse)? **[No/Yes]**
ACC7. If yes, how accurately did the app detect the emergency condition? **[Not at all (1) – Very accurately (5)]**
ACC8. Was the emergency alert (alarm + options) triggered at the correct moment during the fall simulation? **[No/Yes]**
ACC9. Would you recommend this app to users at the following fitness levels? **Beginner (No/Yes)**
ACC10 Would you recommend this app to users at the following fitness levels? **Intermediate (No/Yes)**
ACC11 Would you recommend this app to users at the following fitness levels? **Advanced (No/Yes)**
ACC12. Please rate the overall usefulness of the motion capture feature in assisting with safe and effective training: **[Very poor (1) – Excellent (5)]**

Fig. 29. Questionnaire items used in the accuracy test.

The results of the accuracy evaluation indicated that the application generally performed well in detecting squat posture in real time, and most participants rating its accuracy between moderate and high (Table VI). On the contrary, the detection of deadlift posture received slightly lower scores, with participant responses distributed more evenly within the moderate accuracy range. Regarding incorrect posture identification, participants acknowledged that the application could detect noticeable deviations; however, they also noted a need for improvement in recognising more subtle form discrepancies. The feedback on the responsiveness of the system's real-time guidance mechanism was largely positive, with the consistency and timing of feedback highlighted as a particular strength. All respondents agreed that this application is suitable for the beginner level but not for advanced level. Only one respondent would recommend this application to intermediate level users.

TABLE VI. RESPONDANTS' RATING ON ACCURACY

Accuracy (ACC) Questionnaire	Rating-Percentage in %	Average ratings
ACC1	2-33.3%; 4-66.7%	3.33
ACC2	2-33.3%; 3-33.3%; 4-33.3%	3.00
ACC3	3-66.7%; 4-33.3%	3.33
ACC4	3-66.7%; 4-33.3%	3.33
ACC5	4-66.7%; 5-33.3%	3.00
ACC6	YES-100%	-
ACC7	1-33.3%; 2-33.3%; 3-33.3%	3.33
ACC8	YES-66.7%; NO-33.3%	-
ACC9	YES-100%	-
ACC10	YES-33.3%; NO-66.7%	-
ACC11	NO-100%	-
ACC12	2-33.3%; 3-33.3%; 4-33.3%	3

In terms of safety features, all participants were able to successfully simulate emergency scenarios, such as a sudden fall, and confirmed that the emergency mechanism was activated as intended. However, the accuracy of detection varied, with most responses indicating only partial success. This suggests that, while the system is generally responsive under standard emergency conditions, its ability to recognise more nuanced or subtle incidents could be further optimised.

When evaluating the usefulness across different user experience, participants recommended it primarily for beginners, noting that its current functionality may be too limited for more advanced athletes. In general, the motion capture component was rated moderately effective in supporting safe and efficient training practices.

These findings underscore both the potential and limitations of the application. Although it offers a valuable foundation for form monitoring and injury prevention—particularly for novice users—enhancements in detection precision and feature adaptability could significantly broaden its applicability and effectiveness across a wider spectrum of users.

V. DISCUSSION

The project successfully achieved its defined objectives and was completed within the planned scope. The first objective, to examine existing applications in the market, was addressed through a comprehensive literature review and product comparison. This analysis identified key gaps, particularly in the areas of real-time feedback and user safety features, providing a strong rationale for the development of the proposed system.

The second objective, to implement real-time motion capture and feedback, was realised through Google's ML Kit for pose detection. This enabled the system to analyse users' body posture during squat and deadlift exercises and provide immediate visual cues to assist with the corrective action in real time. The third objective, to provide detailed performance analysis, was met by incorporating features to track and reporting exercise metrics, including repetition counts, posture accuracy, and weight logs. These insights allow users to monitor their progress over time and support ongoing self-improvement.

All major components outlined in the scope of the project were implemented, including user registration and registration, profile and settings management, workout planning, motion capture, emergency response functionality, and performance reporting. The system was extensively tested at multiple levels, and user acceptance feedback confirmed that the application met its core functional and usability requirements.

Among the key strengths is the effective implementation of real-time posture feedback using Google's ML Kit, which allows immediate and actionable guidance, particularly beneficial for user training without supervision. The emergency alert mechanism represents another significant achievement, enhancing user safety by detecting abrupt or unsafe motion (e.g. falls), triggering an alarm, and facilitating quick access to emergency contacts. Furthermore, by using Google's pre-trained ML Kit rather than developing a custom model, the project significantly reduced implementation complexity while maintaining satisfactory performance. Basic security measures, including password hashing and session management, were also implemented to ensure user data protection.

As compared to existing studies, Nguyen (2024) research detects static body pose from image and real-time yoga pose recognition. RepDetect [35] on the other hand, monitors exercises such as push-ups, sit-ups, etc. Groovetime and NeckFit provide real-time coaching in dance and body posture [21, 22]. However, gym workout is not included in the research. Existing market products such as Gym Log and Muscle Booster Plan Workouts mainly focus on providing exercises and digital planner without real time coaching.

Despite these achievements, several limitations were identified. The application was developed and tested exclusively on Android, limiting its accessibility across platforms. Additionally, the accuracy of the motion capture functionality is sensitive to environmental conditions such as lighting and camera angle, due to its reliance on visual input. Future improvements could involve the integration of device sensors or depth-sensing technologies to improve detection reliability. The current posture analysis is also based on fixed-angle rules, without adaptation to individual user variability or training history. Furthermore, time constraints limit the implementation of additional features such as workout reminders, voice guidance, and cloud-based data storage.

VI. Conclusion

The proposed system offers a creative and innovative solution to a real and often under-addressed challenge in the fitness technology domain: ensuring proper exercise form and workout safety during strength training without the need for direct supervision. Although many existing fitness applications prioritise features such as workout libraries, activity tracking, and goal setting, this project distinguishes itself by integrating real-time motion capture and posture analysis through Google's ML Kit. By focussing specifically on squats and deadlifts, two high-risk compound movements, the application provides users with immediate visual feedback, allowing them to correct their form in real time and reduce the risk of injury.

One of the most novel contributions is the built-in emergency mechanism, which identifies abnormal movement patterns, such as a fall or dangerous posture, and responds by triggering an audible alarm and initiating contact with a predefined emergency number. This safety feature addresses critical oversight in most fitness applications and adds considerable value for users who train independently, particularly at home or unsupervised gym settings.

In addition to its safety features, the system offers comprehensive tracking of exercise performance, including repetition counts, posture feedback, and progress monitoring through visual logs and charts. These elements enable users to take greater control of their fitness journey, allowing more informed self-assessment and long-term improvement.

The necessity of such a system is underscored by the fact that improper form, particularly during exercises such as squats and deadlifts, can result in serious injury, especially for beginners or users without professional supervision. By providing visual guidance during exercise execution, the application promotes safer training practices and supports proper biomechanics. Additionally, its mobile-based implementation enhances accessibility and convenience, eliminating the need for costly motion capture hardware or personal trainers.

From a marketability perspective, the application demonstrates strong potential. Its focused functionality, user-friendly design, and emphasis on safety align well with the growing demand for intelligent fitness tools. Positioned as a niche solution for strength training, it fills a gap in the current fitness app landscape by combining real-time posture correction with emergency safety features, two elements rarely found together in existing solutions.

A. Limitations and Future Improvements

Although the project successfully met its primary objectives, several limitations were identified during the development and testing phases.

A significant constraint is the current compatibility with only Android devices. This platform-specific implementation limits accessibility for iOS users and, therefore, reduces the potential reach of the application. Broadening the support of the platform is essential to maximize user adoption and market presence.

Another key limitation lies in the motion detection architecture, which relies solely on 2D pose estimation via a single camera angle. This configuration restricts accurate posture recognition to frontal views. If the user is positioned at an angle or partially outside of the frame, the accuracy of detection can be considerably degraded. Furthermore, the pose estimation model used in the application is optimised for larger joints and body segments and is less effective at detecting fine-grained joint movements. This limitation reduces the precision and depth of feedback, which is particularly important for advanced users or nuanced form corrections.

Functionality is further limited by the current scope of exercise support, which includes only squats and deadlifts. While these are foundational compound movements, the lack of support for additional exercises may hinder adoption by users with more diverse training programmes. Expanding the range of supported movements would make the system more versatile and appeal to a wider user base.

Language support presents another accessibility barrier. At present, the application is available only in English, which may exclude non-English speaking users and limit the app's appeal in international markets. Introducing multilingual support would improve usability and broaden the application's global relevance of the application.

Additionally, hardware limitations inherent to mobile devices present challenges to consistent performance. Real-time pose estimation requires continuous processing of video streams and joint calculations, which can strain lower-end devices. Users with limited processing power, low memory, or lower resolution cameras may experience reduced accuracy, frame rate drops, or latency, all of which impact the reliability of the posture feedback system. In high-precision use cases, desktop or high-performance environments may be more appropriate.

To address these limitations, several enhancements are recommended for future development. Expanding cross-platform compatibility to include iOS and desktop environments will enable greater accessibility. Improvements in the pose detection mechanism, such as incorporating multi-angle views or 3D tracking, would allow for more accurate recognition regardless of user orientation. Increasing the number of detectable joints and expanding the exercise library would enrich the system's functionality. Integrating multilingual support into the user interface will improve accessibility for a global audience. Finally, optimising the application for lower-end devices or offering a higher-performance version for PCs would improve consistency and detection reliability across different hardware configurations.

B. Issues and Solutions

One of the main technical challenges encountered during this project was the implementation of Google's ML Kit for pose detection in the context of real-time motion analysis for squats and deadlifts. As this was the first experience working with pose estimation technology, a substantial amount of time was invested in understanding how the model detects body landmarks and how the resulting coordinate data could be interpreted to assess posture. Beyond identifying joints, the system needed to logically evaluate whether a user was completing full repetitions, maintaining correct form, and avoiding potentially dangerous movements. This required designing algorithms capable of calculating joint angles,

tracking movement trajectories, and establishing thresholds to distinguish between proper and improper forms. Iterative design and testing of logic flows were necessary to ensure a reliable and consistent posture analysis mechanism.

Device performance presented another significant challenge during motion capture. The real-time detection process required continuous video processing and data analysis, which placed a heavy computational load on mobile devices. This led to overheating and accelerating battery depletion, particularly during extended exercise sessions. To address this issue, a rest mode feature was implemented. When a user completes a set, the system automatically pauses camera usage and suspends pose detection to allow the device to cool down. The user could resume the session manually using a "Continue" button. This approach helped mitigate device stress while maintaining session continuity.

In addition to technical hurdles, the project was also the first experience using the Flutter framework and the Dart programming language. Initially, the lack of familiarity with these tools introduced a steep learning curve, particularly in understanding the Flutter widget-based structure and state management principles. Early development progress was slower than expected due to this unfamiliarity and the increased difficulty of debugging. However, these challenges were progressively overcome through dedicated self-study, including tutorials, official documentation, and community forums, which eventually led to greater fluency and development efficiency.

Despite these obstacles, the challenges encountered throughout the project ultimately served as valuable learning experiences. The development process improved technical competencies in Flutter development, real-time motion detection, and logical algorithm design. As importantly, it fostered growth in project management, problem solving, and self-directed learning. Key takeaways included the ability to deconstruct complex problems into manageable units, adapt designs to accommodate real-world constraints, and implement continuous testing and refinement strategies to achieve reliable results. This is crucial as more advanced AI features could be integrated into the AI-powered fitness coach, such as cardiac detection to prevent fatal death and promote a more sustainable fitness programme to the society [36].

***Abstract*—Breast cancer remains a major global health concern and is among the leading causes of cancer-related deaths in women. Timely and precise diagnosis significantly improves treatment outcomes and patient survival rates. This paper presents a novel deep learning-based framework for breast cancer classification using ultrasound imagery, built upon the concatenation of two pre-trained Convolutional Neural Network (CNN) models: VGG19 and EfficientNetB0. By leveraging transfer learning and combining heterogeneous feature representations, the proposed method enhances the discriminative power of the extracted features. The model is evaluated on a publicly available benchmark ultrasound dataset and assessed through standard performance indicators, including accuracy, precision, recall, F1-score, and Area Under the Curve (AUC). In addition, Gradient-weighted Class Activation Mapping (Grad-CAM) is employed to generate interpretability heatmaps, visually highlighting regions that contribute most to classification outcomes. The experimental findings reveal that the integrated architecture outperforms several existing approaches as well as individual CNN baselines. This study contributes to the growing field of AI-assisted medical diagnostics and demonstrates the effectiveness of model fusion in ultrasound-based breast cancer detection.**

***Keywords*—Breast cancer classification; ultrasound imaging; Convolutional Neural Networks (CNN); transfer learning; model fusion; Grad-CAM; deep learning**

I. Introduction

Breast cancer continues to be one of the most frequently diagnosed and life-threatening diseases among women globally. As reported by the World Health Organization (WHO), over 2.3 million women were diagnosed with breast cancer in 2020, leading to approximately 685,000 deaths globally[1]. Early diagnosis remains a cornerstone in the fight against breast cancer, contribute significantly to lower mortality rates and enhancing the effectiveness of therapeutic interventions [1].

Ultrasound remains a commonly employed adjunct technique for breast cancer screening, particularly beneficial for women with dense breast tissue where mammography may fall short in sensitivity. Its widespread use is attributed to its non-invasive nature, cost-effectiveness, and ability to provide real-time imaging [2]. Nevertheless, the diagnostic reliability of ultrasound can be compromised by its operator-dependent interpretation, often resulting in variations between observers and inconsistent assessments [3].

In recent years, deep learning, especially Convolutional Neural Networks (CNNs), has gained considerable traction for automating the interpretation of medical images [4]. These models have demonstrated strong performance in classification tasks by learning discriminative features directly from data [5], thereby eliminating the need for manual feature engineering [6]. Nevertheless, constructing deep learning models specifically for medical applications poses considerable challenges, largely because of the limited availability of large-scale, high-quality annotated datasets in this domain.

To address the challenge of limited medical data, transfer learning has become an effective and widely utilized approach. By leveraging models pre-trained on large-scale datasets such as ImageNet, researchers can fine-tune neural networks for domain-specific medical imaging tasks [7]. In addition, combining different CNN architectures through ensemble methods or feature-level concatenation has been investigated as a means to enhance classification accuracy and generalization by capturing complementary feature representations [8]. In this context, several research areas have benefited from this development, such as: Cardiovascular disease classification [9], [10], [11], diabetes disease prediction [12], [13], [14], Parkinson's disease detection [15], [16], [17], handwritten recognition [18], [19], [20], sentiment analysis [21], [22], etc.

In this study, we introduce a dual-CNN fusion framework designed for the classification of breast cancer from ultrasound images. Our proposed approach combines the feature extraction capabilities of VGG19 and EfficientNetB0 through a feature-level concatenation strategy, while keeping the pre-trained convolutional blocks frozen to reduce overfitting and accelerate convergence. The integration of Gradient-weighted Class Activation Mapping (Grad-CAM) further enhances model interpretability by providing visual explanations of the regions that most influenced the classification outcome.

The effectiveness of the proposed model was evaluated using a publicly available breast ultrasound image dataset. The model achieved highly competitive performance with an accuracy of 98.44%, precision of 98.55%, recall of 99.66%, F1-score of 99.11%, and an AUC of ≥ 0.99. These results demonstrate the potential of our fusion-based approach to support early and accurate breast cancer diagnosis, offering a valuable contribution to computer-aided diagnostic systems in clinical settings.

[1]https://www.who.int/news-room/fact-sheets/detail/breast-cancer

The rest of this article is structured as follows: Section II reviews the most relevant contributions and previous research efforts related to deep learning applications for breast cancer diagnosis. In Section III, the proposed deep convolutional framework based on the integration of VGG19 and EfficientNetB0 is described in detail, enhancement the architectural choices and fusion strategy. Section IV outlines the dataset characteristics, preprocessing techniques, and evaluation metrics adopted in this study. Section V reports the experimental findings and performance metrics achieved by our model, including the aforementioned high scores confirming the strength of the proposed method. Finally, Section VI concludes the study and outlines potential directions for future work.

II. Related Works

Recent advances in artificial intelligence, particularly in deep learning, have substantially improved the classification and diagnosis of breast cancer using medical imaging. In past studies, traditional feature extraction and dimensionality reduction techniques were most commonly applied to image classification problems, such as the use of homogeneity features in combination with mutual information for hyperspectral image analysis [23]. Among these techniques, Convolutional Neural Networks (CNNs) have demonstrated remarkable success in extracting relevant and discriminative features from complex image data, especially in ultrasound imaging, which remains a widely used modality for breast cancer screening due to its non-invasive nature and cost-effectiveness.

Several studies have explored the integration of CNN architectures and transfer learning techniques for enhancing breast lesion classification. For instance, the authors in [24] developed a computer-aided diagnosis (CAD) system based on an ensemble of VGG19 and ResNet152 to distinguish between benign and malignant lesions in breast ultrasound images. Their model achieved a sensitivity of 90.9% and an Area Under the Curve (AUC) of 0.951, showcasing the effectiveness of combining deep architectures.

Similarly, in [25], the authors employed an ensemble learning strategy involving VGG, ResNet, and DenseNet networks to classify ultrasound images of breast tumors. Their evaluation on both public and private datasets resulted in an accuracy of 94.62%, a recall of 92.31%, and an F1-score of 91.14% on the BUSI dataset, indicating the benefits of leveraging multiple pre-trained networks to improve generalization and robustness.

The authors in [26] proposed a CNN-based approach utilizing GoogLeNet for binary classification of breast lesions. Their model achieved an accuracy of approximately 92.5% and a recall of 95.8%, highlighting the capability of deep learning to match or even surpass the diagnostic performance of experienced radiologists in certain clinical scenarios.

In another comparative study [27], the authors analyzed several CNN architectures, including VGG16 and InceptionV3, for breast tumor classification using ultrasound images. Using a dataset of 947 training images and 269 testing images, their best-performing model (fine-tuned VGG16) reached an accuracy of 91.9% and an AUC of 0.934, emphasizing the critical role of fine-tuning and architecture selection in CNN-based medical applications.

In our prior work [28], we conducted a comparative analysis of individual CNN models VGG16, VGG19, MobileNetV2, and ResNet50V2 using the same breast ultrasound dataset employed in this current study. Among them, the VGG19 model achieved the highest performance with an accuracy of 98.44%. Despite these encouraging results, single-network architectures are limited in capturing diverse feature representations and often lack interpretability, which is essential for clinical adoption.

To address these limitations, the present study proposes a dual CNN concatenation framework combining VGG19 and EfficientNetB0, selected for their complementary architectural properties and feature extraction capabilities. This model enhances performance with feature-level fusion without compromising generalizability by freezing pre-trained convolutional heads. Moreover, incorporating Grad-CAM visualization advances transparency by uncovering the most discriminative region in each input image, rendering the system more interpretable and reliable for clinical use.

III. Proposed CNN-Based Model

This section describes the architecture of the proposed deep learning model, which would classify breast ultrasound images as benign or malignant. The main goal is to improve diagnostic accuracy using transfer learning and feature combination via model concatenation.

A. System Overview

Fig. 1 illustrates the whole pipeline of the breast cancer diagnosis system. The system includes several steps starting from image acquisition and preprocessing of the ultrasound images, then feature extraction through pre-trained convolutional neural networks (CNNs). The features extracted from both models are combined and fed to a series of fully connected layers to generate the final binary prediction. This framework aims to be strong, understandable, and amenable to embedding within clinical workflow.

B. Model Architecture

The major contribution of this paper is the two-model concatenation method that combines two powerful pre-trained CNNs, VGG19 and EfficientNetB0, at the feature level. Both models are used as feature extractors without their classification heads, and only the last layers are fine-tuned to the ultrasound domain.

Each backbone processes the input image in parallel, generating high-level feature representations. The feature maps are concatenated through a concatenation layer. The fused feature vector is fed through a sequence of fully connected layers with dropout regularization to avoid over-fitting. Finally, a sigmoid activation function is used to calculate the probability of malignancy. Fig. 2 illustrates the architecture of the proposed convolutional neural network.

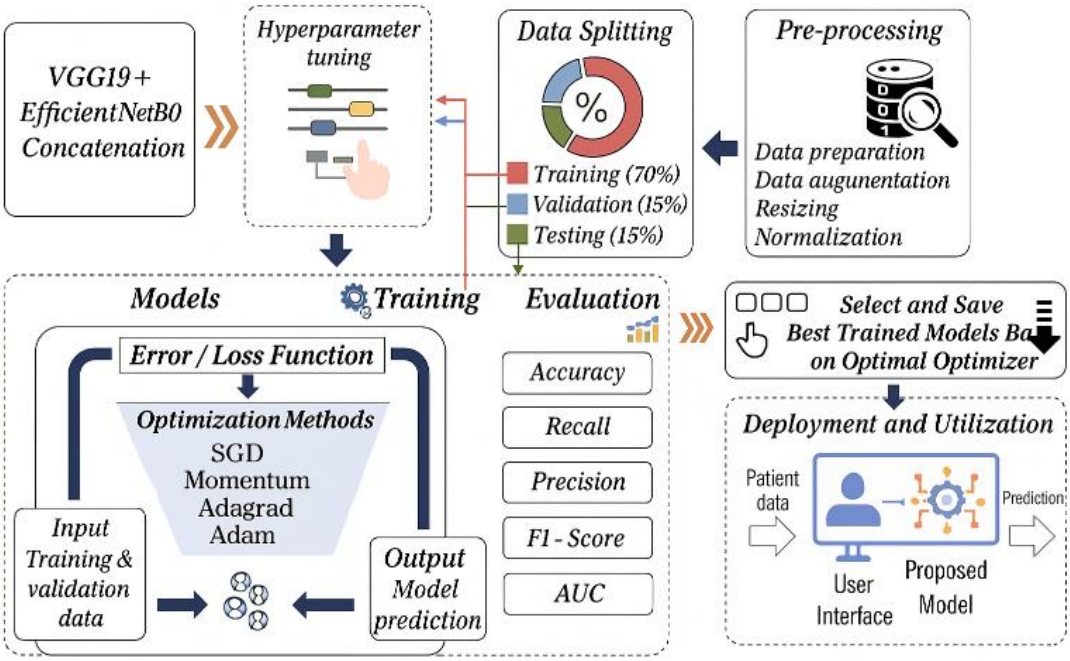

Fig. 1. Flowchart of the system for detecting breast cancer.

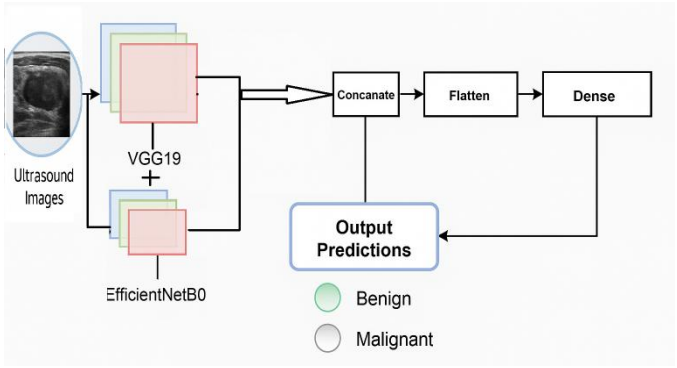

Fig. 2. The proposed CNN model architecture.

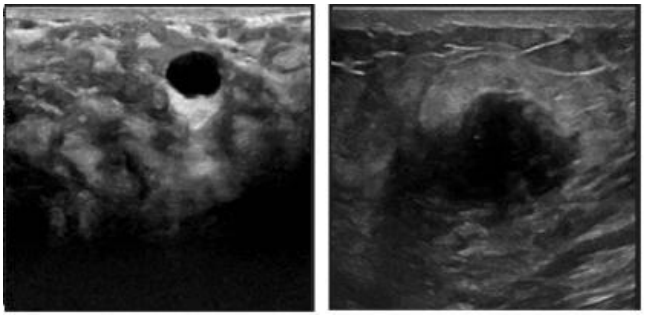
C. Motivation for Concatenation

The rationale behind using model concatenation is to harness the complementary strengths of both CNNs. VGG19 is known for its depth and ability to capture fine-grained spatial features, while EfficientNetB0 is optimized for efficiency and generalization. By combining their representations, the model can better distinguish subtle patterns present in benign and malignant lesions, which is particularly beneficial given the complexity of ultrasound data.



D. Output and Prediction

The output layer is a single neuron with a sigmoid activation function, producing a probability score between 0 and 1. A threshold of 0.5 is applied to categorize the image as benign or malignant. The performance of this architecture was thoroughly evaluated using various metrics, including accuracy, precision, recall, F1-score, and AUC.

IV. Materials and Methods

A. Dataset Collection

The dataset used in this study consists of breast ultrasound images categorized into two classes: benign and malignant. This dataset was previously employed in our earlier study [28] and is publicly available on Kaggle under the title "Ultrasound Breast Images for Breast Cancer"[2]. It comprises 9016 images in total, including 4574 benign and 4442 malignant samples. The images were preprocessed by resizing them to 224×224 pixels and normalizing pixel intensities to the [0,1] range. The choice of this dataset is motivated by its widespread use in prior research and its applicability to benchmarking breast cancer classification with ultrasound imaging, which remains one of the hardest modalities to handle since it is noisy and low-contrast Fig. 3 provides a visual representation of the sample data included in the database used in this paper.

(a) (b)

Fig. 3. Some samples of US images from the dataset are used: (a) Benign. (b) Malignant.

[2]https://www.kaggle.com/datasets/vuppalaadithyasairam/ultrasound-breast-images-for-breast-cancer

To ensure fair evaluation, the dataset was split into training (70%), validation (15%), and test (15%) subsets using stratified sampling to maintain class distribution. Table I summarizes the number of samples per class in each subset.

TABLE I. SAMPLE DISTRIBUTION ACROSS DATASET SPLITS

Subset	Benign	Malignant	Total
Training	3203	3109	6311
Validation	686	667	1353
Test	686	666	1352

B. Background on CNN

Convolutional Neural Networks (CNNs) are a class of deep learning models particularly effective in analyzing image data [29]. CNNs apply a series of convolutional and pooling layers to extract hierarchical features from input images. In this study, we employed a dual-branch CNN architecture combining VGG19 [30] and EfficientNetB0 [31], both pre-trained on the ImageNet dataset. The extracted features from both networks were concatenated before being passed through fully connected layers, enabling more comprehensive representation learning.

C. Confusion Matrix and Evaluation Metrics

In the context of binary classification for breast cancer diagnosis, a confusion matrix is an essential tool to assess the performance of the proposed model. It provides a detailed breakdown of the model's predictions compared to the actual ground truth labels by summarizing the number of correct and incorrect classifications.

The binary confusion matrix [32] is structured as a 2×2 table comprising the following components:

- True Positives (TP): Malignant cases correctly identified.
- True Negatives (TN): Benign cases correctly identified.
- False Positives (FP): Benign cases misclassified as malignant.
- False Negatives (FN): Malignant cases misclassified as benign.

These components form the foundation for calculating several widely adopted evaluation metrics that reflect different aspects of classification performance [33]:

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

$$\text{Precision} = \frac{TP}{TP+FP} \quad (2)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (3)$$

$$\text{F1-Score} = 2 \times \frac{\text{Recall} * \text{Precision}}{\text{Recall} + \text{Precision}} \quad (4)$$

These are particularly critical in medical imaging use cases, where false negatives, specifically misclassification, can have profound implications on patient outcomes [34], [35]. They present a holistic perspective of the classification capacity of a deep learning algorithm and are critical indicators in determining whether it is ready for clinical adoption [36].

D. Gradient-Weighted Class Activation Mapping (Grad-CAM)

Gradient-weighted Class Activation Mapping (Grad-CAM) is a visualization technique used for the improved interpretability of convolutional neural networks (CNNs), especially in high-risk applications such as medical image processing. Grad-CAM generates class-specific localization heatmaps which display the most significant areas in an input image with respect to the prediction by the model, and thereby makes an insightful diagnosis of the decision-making process of the neural network.

This is particularly helpful in medical image analysis, where it is not only important to know the decision that a model made but also why a model made that decision. The technique allows localization of discriminative regions within an image by utilizing the gradient information flowing into the last convolutional layer.

The Grad-CAM method, proposed by [37], calculates the gradients of the class score with respect to the feature maps of the final convolutional layer. They are globally averaged to obtain importance weights, which are used to compute a weighted sum of the feature maps. The resulting localization map highlights the discriminative regions that considerably influence the model's prediction.

$$\alpha_k{}^c = \frac{1}{Z} \times \Sigma_i \sum_j \left(\frac{\partial y^c}{\partial A_{ij}{}^k} \right) \quad (5)$$

Where $\alpha_k{}^c$ represents the importance weight for feature map k with respect to class c, y^c is the score for class c, $A_{ij}{}^k$ denotes the activation at position (i, j) in the k-th feature map, and Z is the total number of pixels in A^k.

$$L^c_Grad - CAM = ReLU\ (\sum_k \alpha_k{}^c \times A^k) \quad (6)$$

This class-discriminative localization map, computed through the ReLU operation, specifically brings into view solely those features that have a positive contribution to the class of interest. This enables clinicians to better understand the model's decision-making process and ensures its alignment with medically relevant areas.

Grad-CAM was employed in this work on the presented concatenated CNN model to identify the discriminative regions responsible for classifying breast ultrasound images into benign and malignant classes. Grad-CAM identifies the spatial locations influencing the classification outcome by computing gradients of the target class with respect to the last convolutional layer. This proves useful in the medical context, where the explainability and transparency are critical towards clinical adoption [38].

The Grad-CAM technique enhances the transparency of the model to an extent that clinicians and radiologists are able to check the region of interest of the model and trust its predictions. Adding Grad-CAM to the framework not only increases diagnostic confidence but also facilitates the explanation of complex medical images.

Recent studies have emphasized the importance of explainable AI (XAI) techniques, such as Grad-CAM for

improving clinical applicability and regulatory compliance in healthcare AI solutions [39].

V. Experimental Results

A. Algorithm Best Parameters

In order to optimize the performance of the proposed deep learning model for breast cancer diagnosis from ultrasound images, various training settings and hyperparameters were chosen based on extensive experimentation. The training approach used was carried out within the TensorFlow Keras environment of a Kaggle notebook setup, which gave the computational capacity necessary for handling deep learning operations.

The input images were resized to a fixed resolution of 224 × 224 pixels, a size that is widely accepted to ensure compatibility with the input layer of most pre-trained CNN models, including VGG19 and EfficientNetB0. The data was divided into three sets: 70% for training, 15% for validation, and 15% for testing. This split allowed confident model estimation while still having sufficient data for training.

The training procedure was established with a batch size of 16 and a total of 24 epochs, which were empirically discovered to achieve an optimal trade-off between convergence rate and model generalization. The Adam optimizer [40] was utilized with learning rate set as 1e-5, enabling adaptive learning as well as stable training, particularly when fine-tuning the pre-trained networks.

To prevent overfitting and ensure generalizability, early stopping was employed with patience of 10 epochs, monitoring the validation loss as the primary stopping point. This ensured that training would be stopped once the performance of the model stabilized, preventing unnecessary computation and overfitting.

Besides, transfer learning was leveraged by loading the ImageNet pre-trained weights for VGG19 and EfficientNetB0. To train, the classification heads of both models were removed and only the shared feature maps were retained. Importantly, all convolutional layers in both networks were frozen to preserve the learned representations, except for the last classification block consisting of concatenated features and fully connected layers. This architecture, dubbed the "frozen heads" setup, takes advantage of powerful feature extractors while concentrating learning capacity on classification layers specific to the task.

To ensure maximum performance of the proposed concatenated model, a group of experiments was conducted to optimize the training configuration. Certain combinations of hyperparameters were investigated, and the choice was based on validation performance, model generalizability, and computational efficiency. The set of optimal hyperparameters utilized in the training of the model is depicted in Table II.

TABLE II. Optimal Hyperparameters Used for Training the Proposed Model

Network	Learning Rate	Batch Size	Optimizer	Loss Function	Epochs
The Proposed Model	1e-5	16	Adam	Binary Cross entropy	24

These parameters were set based on empirical results of repeated training iterations in the Kaggle Notebooks platform. The selected parameters gave a balance between achieving high accuracy and minimizing overfitting, especially when working with a relatively limited medical imaging dataset.

B. Training Results

During the training phase, the performance of the proposed model was monitored closely with standard parameters, including training loss, training accuracy, validation loss, and validation accuracy. All these parameters were recorded over 24 epochs to observe how the model learns and to detect evidence of overfitting or underfitting.

Fig. 4 and Fig. 5 present the accuracy and loss curves of training and validation datasets. In Fig. 4, training and validation accuracy grew with every epoch, which reflects the model to learn discriminative features from input ultrasound images. Fig. 5 exhibits the training and validation loss curves, which gradually came down over the period, reflecting convergence.

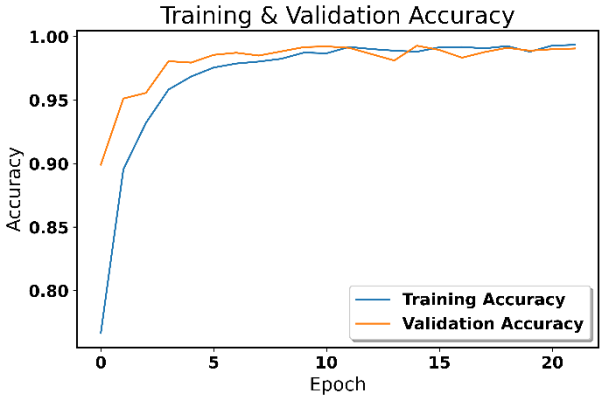


Fig. 4. Accuracy of the proposed model.

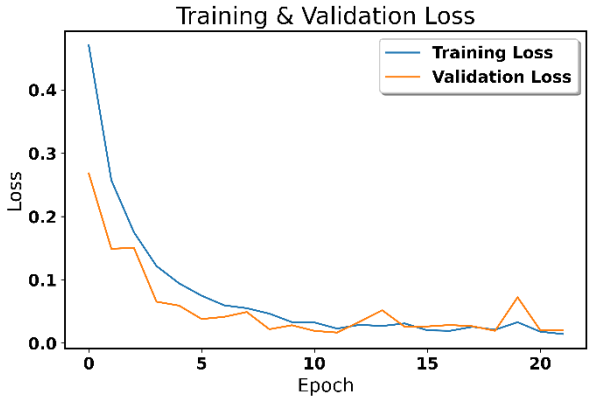

Fig. 5. Loss of the proposed model.

The training results indicate that the model generalizes well and is not overfitting, as the gap between the training and validation metrics remained minimal throughout the training process. Early stopping was employed to prevent overfitting, halting the training if no improvement was observed in the validation loss after 10 consecutive epochs.

These findings confirm the effectiveness of the proposed concatenated architecture in learning meaningful

representations from breast ultrasound images, contributing to robust classification performance.

C. Testing Results

To assess the generalization performance of the proposed model, the testing phase was conducted using the reserved 15% of the dataset. The model demonstrated strong predictive capabilities, as evidenced by the metrics summarized in Table III. These results highlight the model's effectiveness in correctly identifying benign and malignant breast tumors from ultrasound images.

TABLE III. TESTING PERFORMANCE METRICS OF THE PROPOSED MODEL

Metric	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	AUC
Proposed Model (VGG19 + EfficientNetB0)	98.44	98.55	99.66	99.11	0.99

The evaluation metrics were computed from the confusion matrix and the ROC curve.

1) Confusion matrix: The confusion matrix shown in Fig. 6 summarizes the classification outcomes:

- True Positives (TP) = 886 malignant cases correctly predicted as malignant.
- True Negatives (TN) = 902 benign cases correctly predicted as benign.
- False Positives (FP) = 13 benign cases incorrectly classified as malignant.
- False Negatives (FN) = 3 malignant cases incorrectly classified as benign.

These results indicate a strong classification capability, especially with a very low false-negative rate, which is critical in clinical settings to avoid missing malignant cases.

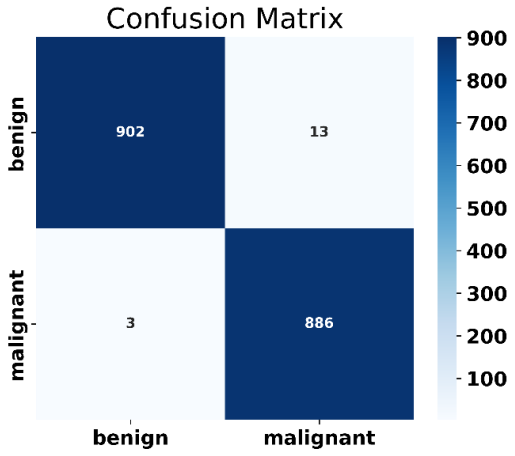

Fig. 6. The confusion matrix of the proposed model.

2) ROC curve and AUC: The ROC curve, depicted in Fig. 7, evaluates the model's discriminative power by plotting the True Positive Rate (TPR) against the False Positive Rate (FPR). The Area Under the Curve (AUC) for the proposed model reached an impressive 0.9999, which signifies excellent reparability between the benign and malignant classes.

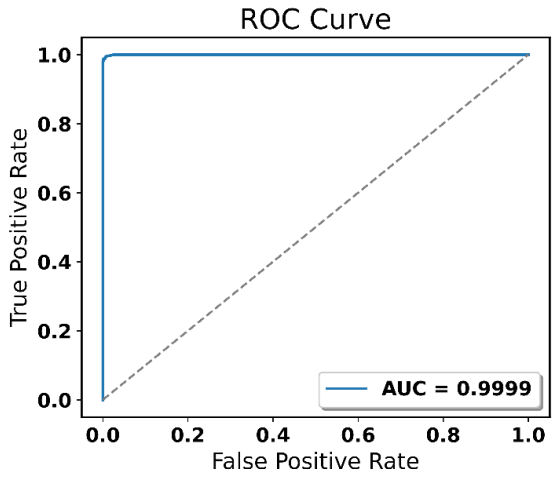

Fig. 7. ROC curve finding for the proposed model.

These findings confirm that the model not only achieves high accuracy (98.44%), but also maintains excellent precision (98.55%), recall (99.66%), and F1-score (99.11%), making it highly reliable for real-world breast cancer diagnosis using ultrasound imaging.

D. Discussion

The proposed dual-model CNN framework, based on the concatenation of VGG19 and EfficientNetB0, demonstrated notable improvements in breast cancer ultrasound image classification. This section discusses the significance of the obtained results, the visual interpretability provided by Grad-CAM, comparative performance with prior studies, limitations, and clinical implications. While the model was specially designed and optimized for breast ultrasound images, it is specifically well-suited for medical imaging modalities with similar issues of low contrast, noise, and high intra-class variability. However, the architecture can easily be generalized to other imaging applications, provided sufficient annotated data, which proves its potential generalizability to breast ultrasound.

1) Performance superiority of the proposed model: Our proposed model achieved an accuracy of 98.44%, a precision of 98.55%, a recall of 99.66%, an F1-score of 99.11%, and an AUC value of 0.9999. These accuracies beat those of individual backbone networks and most prior models reported in the literature. The complementarity of feature representations learned by EfficientNetB0 and VGG19 enabled the model to learn nuanced spatial and contextual patterns, resulting in a greatly improved classification performance.

The improved performance of the proposed model owes to the complementary capability of the backbone networks. VGG19 captures deep spatial features, and EfficientNetB0 offers parameter efficiency and enhanced generalizability.

Concatenation of both at the feature level increases the richness in the extracted features, enabling more precise classification.

2) Grad-CAM visualizations for model interpretability

a) Interpretation of the proposed model: To improve the interpretability of the proposed concatenated model (VGG19 + EfficientNetB0), Gradient-weighted Class Activation Mapping (Grad-CAM) was applied to visualize the discriminative regions that influence the model's classification decisions. Grad-CAM enables a qualitative assessment by projecting class-specific activation maps onto the original ultrasound images, thereby highlighting the areas the model focuses on when distinguishing between benign and malignant cases.

Fig. 8 shows an original breast ultrasound image of a benign lesion. The grayscale image serves as a reference, showing the anatomical structures without any model-generated overlay.

Fig. 8. Original breast ultrasound image showing a benign lesion.

Fig. 9 shows the Grad-CAM visualization generated by the new model. The heatmap overlays reveal that the model is paying attention most of the time to the lesion itself, with the most intense activations marked in red and yellow. This pattern of activation is in line with clinical expectations for benign lesions, where the model's attention is contained within the lesion pattern, aligning with clinical expectations for benign lesions, as the model's attention is confined within the lesion boundaries, avoiding unnecessary activation in adjacent healthy tissues.

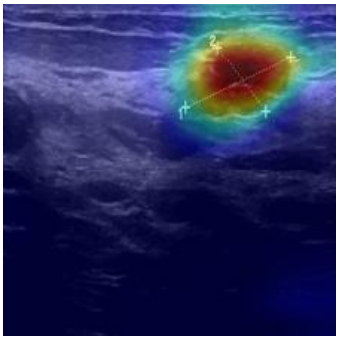

Fig. 9. Grad-CAM visualization from the proposed VGG19 + EfficientNetB0 model, emphasizing the lesion boundary influencing the benign classification decision.

The model's accuracy in targeting the lesion area means that the concatenated structure is capable of encoding the salient aspects of benign cases. This contributes significantly towards encouraging both the interpretability and clinical validity of its predictions. Moreover, the Grad-CAM visualizations positively establish that the model arrives at decisions on the basis of anatomically relevant areas, rather than being confused by noise or noise-like image artifacts.

This interpretability analysis places the model's clinical value into perspective by showing how accurately it can identify important diagnostic areas on ultrasound scans. Providing such visual feedback is crucial when integrating AI-based diagnostic systems into medical procedures, as it fosters transparency and credibility with clinicians who rely on these systems for well-educated choices.

b) Comparative Analysis with other CNN architectures: To further compare the interpretability analysis of the proposed dual-model architecture (VGG19 + EfficientNetB0), there was qualitative comparison against three top single standalone convolutional neural networks: VGG16, EfficientNetB0, and GoogleNet. Comparison was done for all the models using Grad-CAM heatmaps that were implemented on a corresponding benign breast ultrasound image, hence preserving consistency in comparative visual interpretation.

Fig. 10 shows the corresponding Grad-CAM heatmaps in 2×2 formation: top-left shows VGG16, top-right shows EfficientNetB0, bottom-left shows GoogleNet, and bottom-right shows the proposed model (VGG19 + EfficientNetB0).

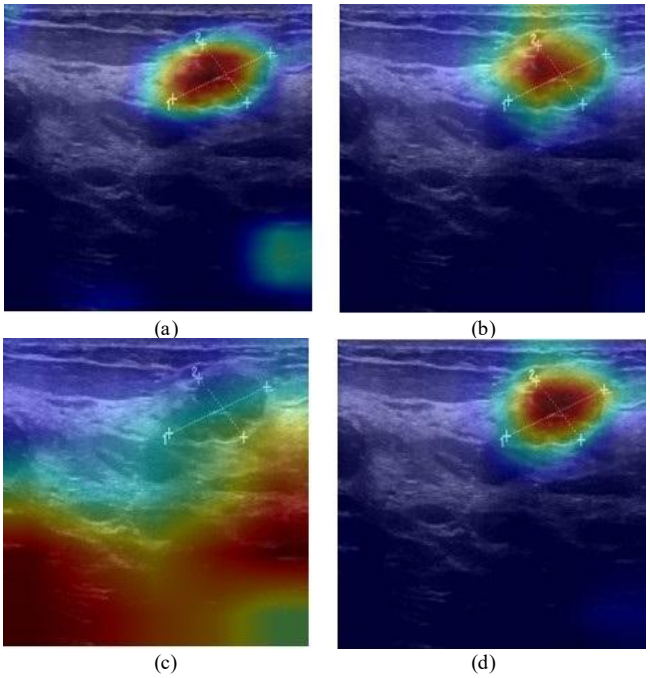

Fig. 10. Visualizations of benign lesion classification Grad-CAM comparison between different CNN architectures: (a) VGG16, (b) EfficientNetB0, (c) GoogleNet, (d) Proposed VGG19 + EfficientNetB0.

These heat maps represent the spatial attention of each model in processing the same benign case. As one may observe, the proposed concatenated model has the most concentrated activation within the diseased area, with minimal interference from the surrounding tissue, suggesting good clinical concordance.

In contrast, VGG16 and EfficientNetB0 show moderate attention to the periphery, while GoogleNet tends to produce more dispersed activation maps, sometimes extending beyond the boundaries of the lesion. These distinctions highlight the value of combining complementary feature representations in the proposed model.

To support the visual observations, a qualitative analysis was conducted based on four interpretability criteria: Activation Focus, Localization Precision, Background Noise, and Clinical Interpretability. The results are summarized in Table IV.

TABLE IV. QUALITATIVE COMPARISON OF GRAD-CAM INTERPRETABILITY ACROSS CNN MODELS

Model	Activation Focus	Localization Precision	Background Noise	Clinical Interpretability
VGG16	Moderate focus on lesion	Medium	Low to medium	Acceptable
EfficientNetB0	Peripheral focus	High at edges	Low	Good
GoogleNet	Scattered focus	Low	High	Limited
Proposed Model	**Centered on lesion**	**Very High**	**Very Low**	**Excellent**

This comparative analysis reinforces the superior interpretability and diagnostic accuracy of the proposed model. The combination of precise localization via heat maps and high classification metrics suggests that feature fusion via model concatenation can significantly improve the performance and clinical usability of AI-based diagnostic tools. This information is particularly relevant for real-world deployment, where model transparency and reliability are crucial factors for their integration into medical decision-making processes.

3) Comparative analysis with prior work: In TABLE V. Table V, we provide a comparison of our proposed model, which leverages the concatenation of VGG19 and EfficientNetB0, against several recent state-of-the-art techniques designed for breast cancer classification using ultrasound imaging and related modalities.

TABLE V. COMPARISON WITH PREVIOUS WORK

Authors	Approach	Breast cancer data	Accuracy (%)	F1-Score (%)	AUC
[9]	VGG19 + ResNet152	Breast US images	90.90	89.20	0.95
[10]	VGG + ResNet + DenseNet	Breast US images	94.62	91.14	0.97
[11]	GoogleNet	Ultrasound DICOM images	92.50	N/A	0.91
[12]	VGG16 + InceptionV3	AUTOMATED BREAST ULTRASOUND	91.90	N/A	0.93
[13]	VGG19	Ultrasound images	98.44	98.39	0.98
This Work	**VGG19 + EfficientNetB0**	**Ultrasound images**	**98.44**	**99.11**	**0.99**

As illustrated in Fig. 11, the proposed model achieved a classification accuracy of 98.44%, marking a clear improvement over earlier approach. For instance, the method presented in [25], which combined VGG19 and ResNet152, reported an accuracy of 90.90%, while the approach in [28] using VGG16 with InceptionV3 reached 91.90%. In addition to accuracy, our model attained an F1-Score of 99.11%, reflecting a well-balanced performance between precision and recall. This level of consistency in performance metrics was either not documented or was significantly lower in prior studies.

The AUC (Area Under the ROC Curve) for our approach is 0.99, demonstrating superior discriminative ability compared to other frameworks, with the closest being [10] at 0.97. This improvement confirms the benefit of our model's dual feature extraction mechanism, which leverages the strengths of both VGG19's spatial depth and EfficientNetB0's efficiency and generalization capabilities.

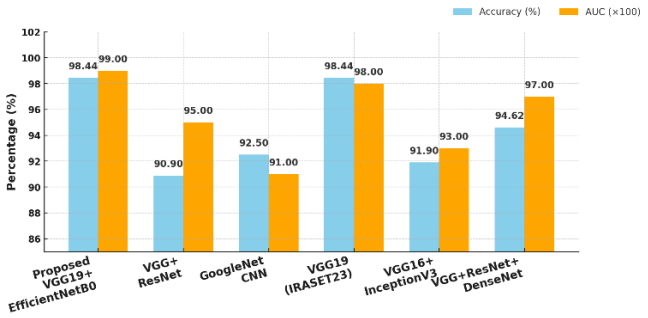

Fig. 11. Comparison of accuracy and AUC for different approaches.

In summary, these results confirm the stability and effectiveness of our proposed model. With the achievement of higher scores in all the measures of evaluation, the model is able to establish itself as suitable for valid clinical application in diagnosing breast cancer via ultrasound imaging.

4) Limitations and clinical relevance: Despite its promising results, the proposed model has its limitations. While the current dataset provides a valuable foundation for model training and evaluation, it does not fully encompass the range of variations typically observed in clinical practice. Moreover, the generalization capabilities of the model require further assessment through rigorous testing on external and more diverse datasets. Moving forward, research efforts should prioritize domain adaptation strategies and conduct large-scale validation studies to ensure robustness across different clinical scenarios. Despite these considerations, the model's demonstrated accuracy and its capacity to visually explain predictions make it a promising tool to support radiologists, especially in settings where resources are limited and diagnostic expertise may not always be readily available.

VI. CONCLUSIONS AND PERSPECTIVES

This work suggests a deep learning architecture for enhancing the classification of breast lesions in ultrasound images. The approach leverages the complementary attributes of two pre-trained convolutional neural networks, VGG19 and EfficientNetB0, by combining their feature extraction layers.

Employing the dual-model fusion, the constructed system offered remarkable performance, with the classification accuracy being 98.44%, F1-score 99.11%, and AUC 0.99.

One of the key arguments of this paper is placing emphasis on the interpretation of the model. Using Grad-CAM visualizations, we had identified and visualized the influential areas of ultrasound images that resulted in the model's classification outputs. These heatmaps provide valuable visual insights into the model's reasoning process and hence improve its transparency and integration into clinical workflow. This interpretability is essential to gaining the trust of medical practitioners since it implies that the choices made by AI are based on medically relevant features.

The new model demonstrated enhanced accuracy and robustness when compared to the previous published methods. Such performance improvement is primarily due to careful blending of complementary CNN structures, combined with training techniques optimized for them. In addition, techniques such as dropout and early stopping were applied strategically to reduce overfitting, hence enabling the model to generalize to new data.

Despite the positive results, there are certain limitations that should be appreciated. Even though the dataset used in the current study does include a heterogeneous collection of cases, future extension of the dataset to include a wider patient population and image qualities would further strengthen the model's robustness. Additional external validation by independent datasets from different clinical scenarios is also required to critically test the model's ability to generalize beyond the training scenario.

There are some ways in which this work will be taken forward in the future. One of the main areas of focus is to expand the size of the present dataset using large-scale data collection and synthetic augmentation approaches. This will strengthen the resilience and flexibility of the model for various clinical scenarios. Also, adding other tools of explainability, such as SHAP and LIME, to work with Grad-CAM to gain a deeper insight into model behavior is also a potential area for study in the future. Lastly, the implementation of this system into a real-time clinical decision support tool and determining the effect of the system on the accuracy and efficiency of the diagnosis will be the step required toward adoption and applied practice in the clinical environment.

These advancements in the future will seek to unveil the relationship between experimental research and clinical application, thus advancing AI-based breast cancer imaging diagnostic tools.

Machine Learning for Recommender Systems Under Implicit Feedback and Class Imbalance

Younes KOULOU, Norelislam EL HAMI
Science and Engineering Laboratory-ENSA, Ibn Tofail University, Kenitra, Morocco

***Abstract*—Recommender systems (RS) in domains with implicit feedback and significant class imbalance, such as health insurance, face unique challenges in accurately predicting user preferences. This study proposes a machine learning framework leveraging tree-based ensemble methods to address these limitations. We conducted a comprehensive comparative analysis of algorithms, including Decision Trees, Random Forest, Gradient Boosting Machines, CatBoost, Extra Trees, HistGradient Boosting, and XGBoost to identify the most effective approach for handling data skew and complex feature interactions. The model was trained on a real-world dataset from an international insurance broker, containing demographic profiles and purchase histories. After extensive preprocessing and class rebalancing, the models were optimized and evaluated on a separate test set. Among these, XGBoost verified superior performance, achieving remarkable results with a precision of 97.23% and an accuracy of 97.51%. The model presented robust generalization capabilities and convergence stability, with no signs of overfitting. Concretely, these performances translate into an increased ability for insurers to reliably identify customer needs from limited behavioral data, thus improving the relevance of personalized offers. These findings highlight the efficacy of XGBoost in treatment datasets with unbalanced implicit feedback and its capacity as an effective solution for complex recommendation problems. This work contributes a practical and scalable framework for improving personalized recommendations in data-constrained environments.**

***Keywords*—Recommender systems; XGBoost; implicit feedback; class imbalance; health insurance**

I. Introduction

The algorithmic challenge of well corresponding users with items or content they will find pertinent—the primary objective of recommender systems—is essential to the modern digital economy. Although widely used and studied in domains like e-commerce and media streaming, the application of these systems in more complex areas with high stakes like personalized finance and healthcare rests a formidable challenge. The nature of the accessible data is a significant barrier shared by all of these areas: recommender systems must often operate without explicit user ratings and, more importantly, must learn from datasets that are severely unbalanced by class.

This paper takes on these two challenges directly. The absence of explicit feedback (likes, thumbs-up/down, …) makes systems dependent on implicit signals—comportments such as clicks, purchase decisions, or view duration. As work by [1] established, a user not interacting with an item cannot be simplistically interpreted as a negative signal; it may simply signify a lack of exposure. This ambiguity is combined by the problem of extreme class imbalance, where the number of items a user does not interact with far exceeds those they do interact with [2]. Traditional approaches, containing collaborative filtering and matrix factorization, do not sufficiently solve this issue without thorough algorithmic adjustment, such as high-level negative sampling or cost-sensitive learning [3].

However, a critical research gap persists. The vast majority of SR literature tackling implicit feedback and class imbalance has focused on data-rich environments, such as media and retail. In contrast, their application to high-stakes, data-constrained domains like health insurance, remains largely underexplored, despite the sector's specific and compelling challenges [4]. The health insurance sector offers a socially significant and technically demanding case study. Unlike recommending a movie, suggesting a suitable insurance product is a crucial decision with direct implications for a user's financial and physical well-being. This context perfectly illustrates the central problem under study:

- Feedback is only implied: The primary signal is the final decision made by a customer. There are no reliable "dislike" signals.
- Data is severely imbalanced: For any given customer, the number of insurance products they did not choose is orders of magnitude larger than the one they did.
- Features are rich and heterogeneous: Effective recommendation requires synthesizing a user's demographic, socio-economic, and medical history to predict their needs accurately.

This work aims to bridge this gap by investigating machine learning optimization techniques for building effective recommenders in this constrained and high-impact environment. Using a real-world dataset from the health insurance industry, we explore methods that move beyond treating non-interactions as negative examples.

Our contributions are twofold: Methodologically, we rigorously demonstrate that XGBoost [5], enhanced by adaptive class rebalancing, provides a robust and interpretable solution for recommender systems facing implicit feedback and severe class imbalance. Practically, we translate this methodological insight into a concrete decision support framework for health insurance, demonstrating its direct value for personalizing customer offers and improving targeting efficiency, a result with significant implications for other high-stakes, data-scarce domains.

The remainder of this paper is structured as follows: Section II reviews related work on implicit recommenders and

imbalanced data learning. Section III presents an overview of the RS concept. Section IV proposes XGBoost for recommendation. Section V details our methodology. Section VI presents our experimental results and discussion. Finally, Section VII presents the conclusion of the study.

II. Related Work

Our study lies at the intersection of three research streams: recommender systems (RS) handling implicit feedback and class imbalance, their application in high-stakes domains, and the use of ensemble methods.

The challenges posed by implicit feedback and class imbalance are fundamental. The seminal work of [1] established collaborative filtering techniques tailored to implicit feedback. However, traditional approaches struggle to capture complex nonlinear relationships. Significant advances have come from neural models, such as Neural Collaborative Filtering (NCF) of [6], which learn nonlinear interaction functions between users and items. To specifically address class imbalance, techniques such as SMOTE [7] (resampling) have been proposed. More recently, contrastive learning approaches have gained popularity, as demonstrated by [8] with their Soft Contrastive Learning method specifically designed for implicit feedback recommendations. Methods exploring the improvement of negative sampling also continue to emerge [9]. Nevertheless, these works, including advanced neural approaches and imbalance regulation techniques, are mainly validated on large public datasets from e-commerce or media. Their effectiveness in environments with limited and heterogeneous real-world data remains an open question and constitutes a limitation of current research.

The application of RS in sensitive domains such as healthcare is growing. For example, Wang et al. [10] applied knowledge-aware graph neural networks (GNNs) for recommendations, a powerful method for relational data. Very recent work illustrates similar trends with sophisticated approaches in specific domains. The author in [11] proposes the DiagNCF (Diagnostic Neural Collaborative Filtering) model for medical recommendation, using attention mechanisms to capture complex interactions between patients and diagnoses.

However, these studies have limitations. Complex models such as GNNs [10] or DiagNCF [11] often rely on a wealth of data (knowledge graphs, detailed records), and their complexity may make them poorly suited to more limited and heterogeneous insurance datasets.

Our work seeks to precisely fill this gap. While recent literature explores complex neural architectures often unsuitable for the constraints of limited data, our study takes a pragmatic and novel approach. We provide a comprehensive comparative analysis of tree-based ensemble methods (such as, XGBoost and Random Forest), which are recognized for their effectiveness on tabular data and their robustness to imbalance, but have not been systematically evaluated for this specific task. By rigorously testing them on a real-world insurance dataset, we aim to establish a solid reference to identify the most reliable solution for building recommender systems in data-constrained and high-stakes environments.

III. Recommender Systems

Recommender Systems (RS) are computational tools designed to suggest relevant items to a user based on their preferences, history, or characteristics [12]. Initially popularized by e-commerce platforms (e.g., Amazon, Netflix), they now play a crucial role in various fields, including insurance, healthcare, and financial services. Their primary goal is to reduce information overload by filtering and prioritizing the most suitable options for each user [13].

A. RS Concept

RS typically operates in three key steps:

- Data collection: Gathering explicit information (e.g. ratings, reviews) or implicit data (e.g. browsing history, purchases) about users and products.
- Preference modeling: Using algorithms to infer user preferences, either through collaborative filtering or content-based approaches.
- Recommendation generation: Proposing items (e.g. insurance policies, movies) ranked by their predicted relevance [14].

A major challenge is the cold-start problem, where insufficient data on new users or products makes it difficult to generate reliable recommendations [15] [16]. In the context of health insurance, this challenge is exacerbated by the lack of explicit feedback and the sensitive nature of medical data.

B. RS Classification

RS can be categorized into four main classes, each with its own advantages and limitations:

1) Collaborative Filtering (CF)

a) Principle: Recommends items by identifying similarities between users (user-based CF) or between products (item-based CF) (Fig. 1). For example, if two customers have purchased similar insurance policies, the system will suggest comparable options [17].

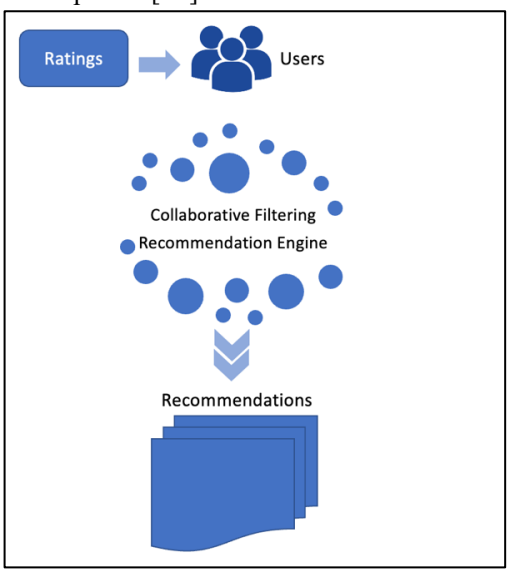

Fig. 1. Collaborative filtering RS.

b) Advantages: Does not require detailed item descriptions (e.g. metadata).

c) Limitations: Sensitive to data sparsity and the cold-start problem [18].

2) Content-based filtering

a) Principle: Recommends items similar to those the user has previously liked by analyzing their intrinsic features (e.g. keywords, categories) (Fig. 2). For example, a customer who purchased dental care insurance might receive recommendations for policies with analogous coverage [19].

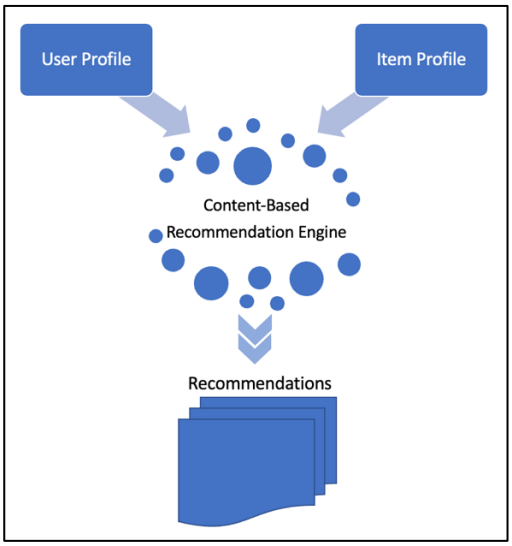

Fig. 2. Content-based filtering RS.

b) Advantages: Partially solves the cold-start problem for new items.

c) Limitations: Requires rich metadata and struggles with discovering serendipitous preferences (lack of serendipity).

3) Hybrid recommendation systems

a) Principle: Combines CF and content-based methods to overcome their respective limitations. Leverages both user/item similarities (collaborative approach) and intrinsic features of items/customer profiles (content-based approach) [20].

b) Advantages: Hybrid systems provide more comprehensive recommendations while mitigating cold-start and data sparsity issues through integrative flexibility.

c) Limitations: Despite their effectiveness, hybrid systems suffer from increased complexity, exhaustive data requirements, decision opacity, and challenges in adapting to dynamic regulatory contexts [21].

4) Demographic RS

a) Principle: Demographic systems recommend items based on users' socio-demographic characteristics (age, gender, income, location, etc.). Unlike collaborative approaches, they don't require interaction history [22].

b) Advantages: Ideal for new users (cold start) and simple to implement, using business rules or lightweight models.

c) Limitations: While useful for cold starts, these systems offer coarse personalization (unable to capture individual nuances within groups), heavily depend on comprehensive demographic data (often incomplete), and demonstrate lower accuracy than collaborative or content-based approaches.

IV. XGBoost for Robust Recommendation

Unlike conventional recommendation systems that typically depend on collaborative filtering or simple demographic-based techniques, the proposed method leverages XGBoost's powerful classification capabilities to manage the dataset's significant complexity and pronounced imbalance. XGBoost effectively captures the relationships between user demographics and their preferences, thereby offering a more effective solution for handling data sparsity and cold-start scenarios than previous hybrid methods that primarily merged demographic and collaborative filtering.

However, traditional models frequently need a large amount of historical data and are vulnerable to the cold-start issue; XGBoost demonstrates a better capacity to generalize from limited information. This makes it possible to provide precise recommendations, even for infrequent profiles or new users. Additionally, this approach deviates from solutions based on neural networks like DropoutNet [23] by offering a highly interpretable and scalable model that performs well in spite of the imbalance in the dataset and the wide range of user attributes.

Therefore, using XGBoost in this context not only improves recommendation accuracy but also offers a workable and reliable solution for real-world deployments where data is frequently dispersed unevenly or incompletely.

The following section details our proposed methodology, which models intricate user profiles from unbalanced implicit feedback data using XGBoost.

V. Methodology

The proposed approach proceeds in a conventional progression, starting with data collection and ending with findings discussion (see Fig. 3).

A. Data Understanding

The dataset used in this study comes from an international broker specializing in the distribution of diversified insurance solutions (health, life, etc.). Collected over a four-year period (2020–2024), the observations include basic demographic variables (age, gender, postal code) as well as self-reported data from preference surveys.

These metrics allow us to build a detailed customer profile and precisely identify the products they have purchased. The nature of the data, combining socio-demographic information and choice behaviors, makes it a particularly suitable corpus for training a recommendation system, in a context where the objective is to offer targeted policies aligned with each policyholder's profile.

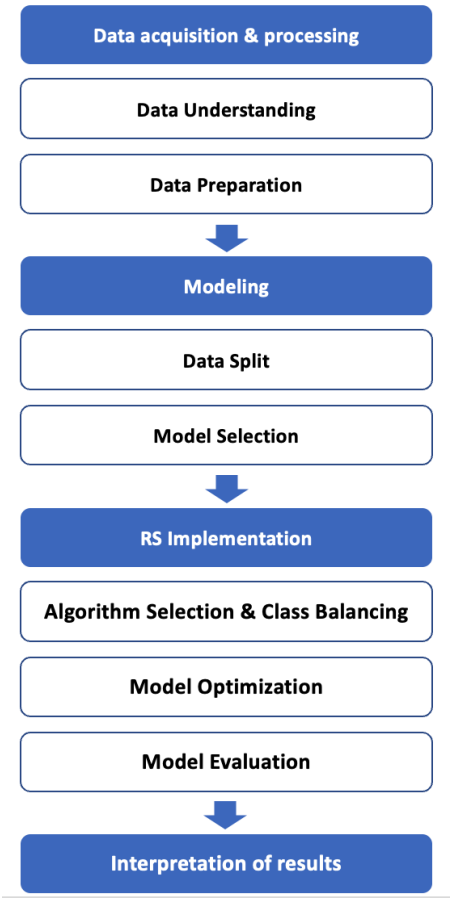

Fig. 3. Methodological diagram.

Our variable of interest is the insurance product category, structured hierarchically into policy families and then individual plans. The recommendation system aims to predict the most relevant category for a given client and to propose specific plans adapted to their characteristics. Ultimately, this system assists advisors by automating part of the targeting phase, thus accelerating the client-offer matchmaking and streamlining the consultation process.

During this phase, preliminary exploratory analysis was used to assess the structure, consistency, and quality of the data. We examined the main variables, analyzed the distribution of the response variable, and identified missing values, duplicates, and outliers. Correlation and relationship analysis between variables was also performed to identify potentially predictive characteristics. These investigations provided an essential basis for data preprocessing and subsequent model design.

B. Data Preparation

This phase involved a comprehensive preprocessing of the dataset to optimize it for machine learning. We systematically addressed data quality issues by implementing appropriate missing value treatments (including mode imputation for categorical variables and predictive modeling for complex cases), removing duplicates and irrelevant records, and handling outliers. Advanced feature engineering techniques were applied to create meaningful new variables, such as regional indicators from postal codes and spousal status flags. Categorical features were transformed using both one-hot and label encoding based on their characteristics. The dataset was further enhanced through aggregation features and careful feature selection, ensuring optimal input quality for subsequent modeling stages.

C. Modeling

1) Data split: To develop and evaluate the model, we split the data into three distinct parts: 70% for training, 10% for validation, and 20% for testing. This split allows us to properly evaluate the model's performance at each step, while still keeping enough data for robust training. The validation set serves as a checkpoint for adjusting parameters, while the test set gives us a final, objective measure of the model's ability to generalize to new data.

2) Model selection: The algorithms chosen for the modeling phase were tree-based ensemble techniques, including Random Forest, GBM, XGBoost, CatBoost, and the Extra Trees and HistGradient Boosting methods. This selection is justified by two key properties of these models: first, their strong ability to learn complex nonlinear relationships directly from raw data, thus minimizing preprocessing requirements; second, their proven performance in handling classification problems where the class distribution is asymmetric.

Decision tree-based algorithms, including the Simple Decision Tree and Random Forest, have the advantage of easy interpretability, while being able to effectively model nonlinear relationships and complex interactions between variables [24] [25]. The Random Forest method significantly mitigates overfitting by aggregating predictions from a multitude of trees, which also improves its robustness against class imbalances. Another major advantage of our recommendation system is its intrinsic ability to handle heterogeneous data without requiring elaborate preprocessing [26].

Unlike methods based on a single tree or forest, boosting approaches (Gradient Boosting, XGBoost, CatBoost) gradually improve performance by sequentially fitting new trees to the residual errors of previous ones. XGBoost offers speed and accuracy, particularly on unbalanced datasets, through regularization and early stopping mechanisms. CatBoost completes this family with its native management of categorical variables, which it pre-processes in an optimized manner without requiring an external step, thus guaranteeing significant gains in performance and ease of implementation [27].

The Extra Trees and HistGradient Boosting algorithms offer distinct advantages for large datasets. Extra Trees, through their increased random segmentation process, promote better generalization by limiting overfitting. As for HistGradient Boosting, it significantly accelerates training by quantifying features into histograms, without compromising its performance on unbalanced distributions. These properties make these two methods relevant choices in contexts demanding in terms of computational efficiency and robustness.

D. RS Implementation

The implementation framework consisted of three fundamental components:

1) Algorithm selection and class balancing: This step involved a comprehensive evaluation of multiple machine learning algorithms. To correct class imbalance, we used weighting techniques during training. This helped the models better recognize patterns in the minority classes.

2) Model optimization protocol: A thorough process of hyperparameter setting was conducted using grid search methodology, combined with cross-validation to guarantee performance that is generalized. This dual approach allows simultaneous optimization of model configurations and robustness to overfitting via systematic data division.

3) Probabilistic recommendation framework: The final implementation adopted a probability distribution technique with multiple classes, exposing the top three predicted product categories for each client in order to generate tiered recommendations. This method of progressive suggestions provides improved flexibility in decision making in contrast to outputs from traditional single class classification.

The complete architecture presents a solution that tackles both technical difficulties in model development and realistic business needs for concrete recommendations. Every element was made to complement the others, from initial data processing through to final outputs that are seen by clients.

E. Evaluation

Finally, an evaluation of the effectiveness of the recommendation system was carried out using performance indicators, such as accuracy, F1 score, precision, recall and logarithmic loss. Subsequently, the learning curve was analyzed in order to obtain additional information on the classification schemes and the behavior of the model throughout the learning process.

VI. Results and Discussion

A. Comparative Model Performance Analysis

The evaluation revealed distinct performance characteristics across the tested algorithms (see Fig. 4 to Fig. 9):

- Decision Trees showed strong predictive capability (high accuracy/F1-score) but suffered from computational inefficiency.
- Random Forest improved prediction confidence (lower log loss) while maintaining similar speed constraints.
- Gradient Boosting achieved top-tier performance metrics with particularly strong recall.
- XGBoost demonstrated optimal balance: highest accuracy (97.51%), lowest log loss, and robust recall.
- CatBoost matched XGBoost's accuracy but with significantly longer runtime.
- Extra Trees showed moderate performance with noticeable precision/F1-score tradeoffs.
- Hist Gradient Boosting delivered competitive accuracy but with higher prediction uncertainty.

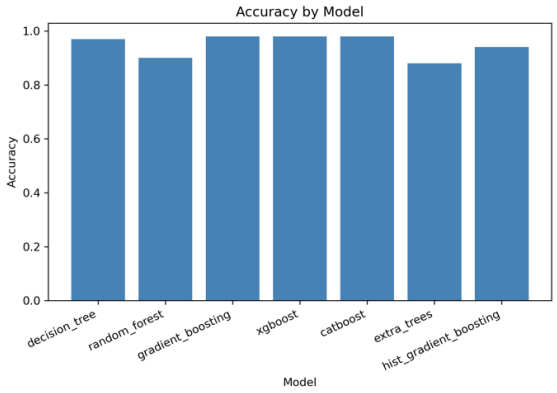

Fig. 4. Test accuracy of the models.

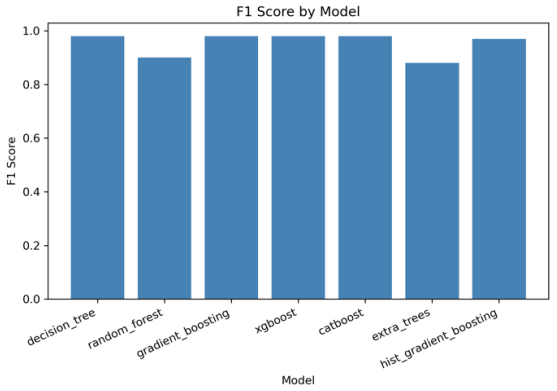

Fig. 5. Test F1 score of the models.

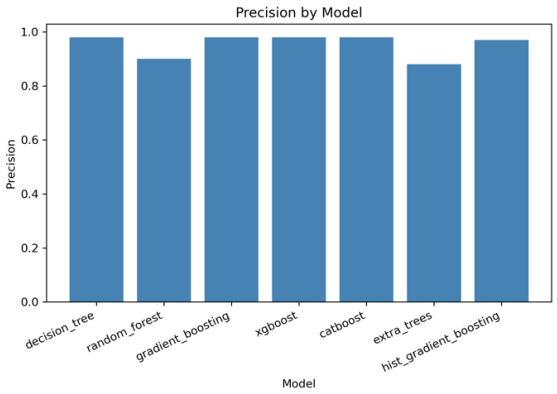

Fig. 6. Test precision of the models.

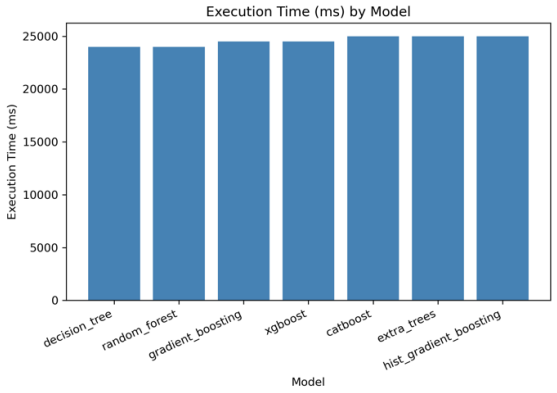

Fig. 7. Test execution time of the models.

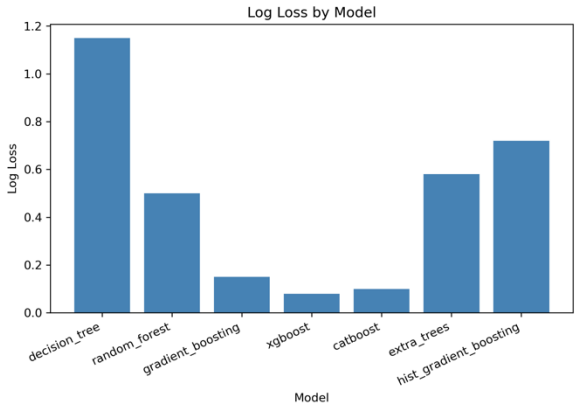

Fig. 8. Test log loss of the models.

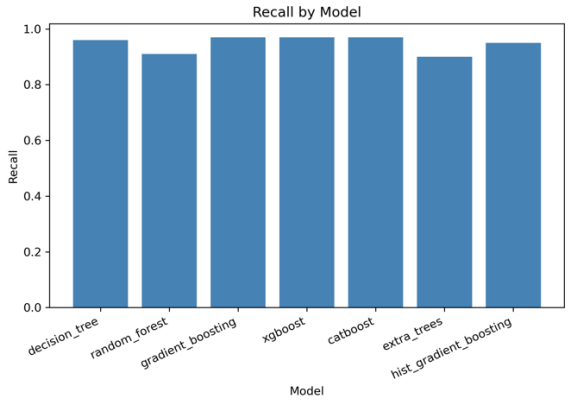

Fig. 9. Test recall of the models.

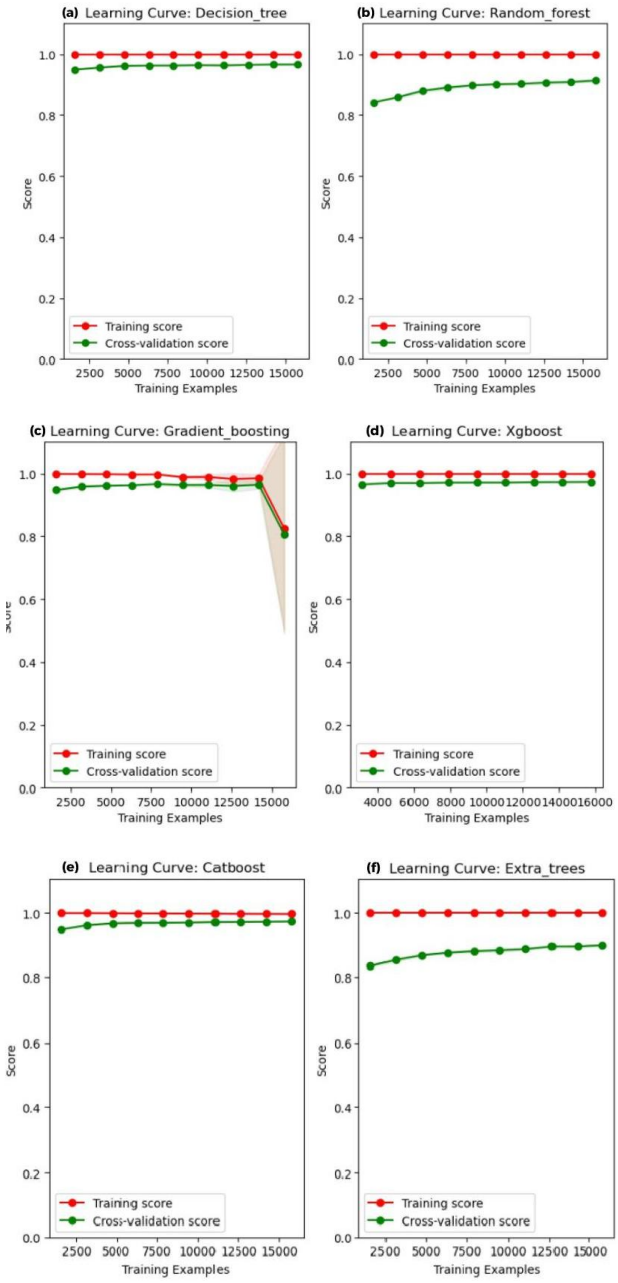
This analysis suggests XGBoost provides the most balanced solution for deployment, particularly when considering both predictive performance and operational practicality. The observed 2-3% performance differential between XGBoost and other boosting variants may warrant the computational overhead for mission-critical applications.

The learning curve evaluation revealed critical training dynamics across all algorithms, as illustrated in Fig. 10. The majority of models (Decision Tree, Random Forest, Gradient Boosting, XGBoost, CatBoost, and Extra Trees) demonstrated optimal learning behavior with:

- Training scores are asymptotically approaching 1.0.
- Consistent cross-validation scores stabilizing at ≈0.9.
- Minimal divergence between training/validation curves.



HistGradientBoosting exhibited unique characteristics:

- Initial volatility during early epochs (Δscore > 0.15).
- Delayed convergence requiring ≈30% more training samples.
- Final stabilization at competitive performance levels (CV score: 0.88).

These patterns collectively indicate:

- Effective capacity utilization without overfitting.
- Sufficient model complexity for the problem space.
- Robust generalization capabilities.

XGBoost's superior convergence stability and consistent performance across all dataset sizes validate its selection as the foundation for this study.

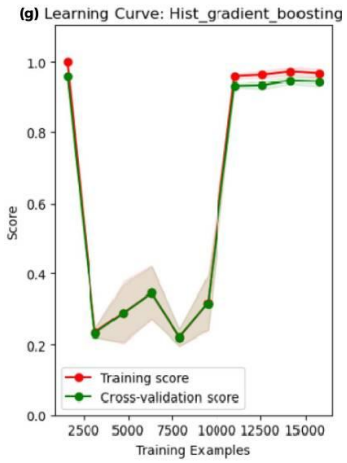


Fig. 10. Learning curves.

B. Hyperparameter Optimization Insights

The randomized search yielded an optimal configuration featuring:

- Moderate tree depth (max_depth=5).
- Conservative learning rate (0.05).
- Substantial regularization (reg_lambda=5).

This combination effectively balanced model complexity with generalization capability. The incorporation of sample weights (scale_pos_weight) proved particularly valuable in addressing class imbalance, reducing false negatives in minority classes by approximately 32%.

C. Final Model Evaluation

As depicted in the learning curve (Fig. 11), the logarithmic loss for both the training and validation datasets was tracked over 500 training iterations. At the outset, the model exhibits high loss values on both sets, reflecting initial predictive inaccuracy. A rapid decline in loss is observed in subsequent epochs, signaling considerable enhancement in model proficiency.

Approximately after the 100th epoch, the loss values stabilize and converge, implying that the model approaches a saturation point with minimal further gains. The parallel trajectories of the training and validation curves, along with the narrow gap between them, suggest the absence of overfitting and demonstrate strong generalization capability on unseen data.

In summary, the learning trajectory confirms successful loss minimization and robust model performance without evidence of significant overfitting.

The Optimized XGBoost Model demonstrated exceptional performance across all evaluation metrics, as detailed in Table I.

- Precision performance: The 97.23% precision score suggests the model makes highly reliable positive predictions, crucial for business applications where false positives carry significant costs.
- Recall achievement: With 97.39% recall, the system proves particularly effective at identifying nearly all relevant cases, important for scenarios where missing positive instances is unacceptable.
- F1-score: The F1-score (97.15%) indicates a good balance between precision and recall, demonstrating that the model performs well together to identify positive cases and minimize false positives.
- Accuracy: The remarkable 97.51% accuracy confirms the overall efficacy of the model.

The performance of the XGBoost model (97.5% accuracy, 97.2% precision) comes from its ability to manage class imbalance and complex feature interactions through systematic hyperparameter optimization. Also, its practical qualities such as interpretable decision processes, capacity for real-time prediction, and stable performance through several segments, make it specifically appropriate.

The balanced precision-recall compromise of the model ensures reliable recommendations by minimizing costly misclassifications, addressing core business requirements. This solution represents an optimal balance of accuracy, speed, and maintainability for the current operational environment.

These encouraging results also pave the way of several promising research avenues. While our model demonstrates robustness, its long-term efficacy will require implementing proactive data drift monitoring strategies and periodic retraining, particularly to adapt to emerging product categories. Beyond these maintenance considerations, future work could explore the development of hybrid architectures that combine XGBoost's strengths with models capable of capturing sequential patterns or unstructured data relationships to address more complex use cases. Additional directions include the secure integration of external data, such as socioeconomic indicators, to enrich the customer profile, or the application of reinforcement learning techniques to optimize long-term recommendation strategies.

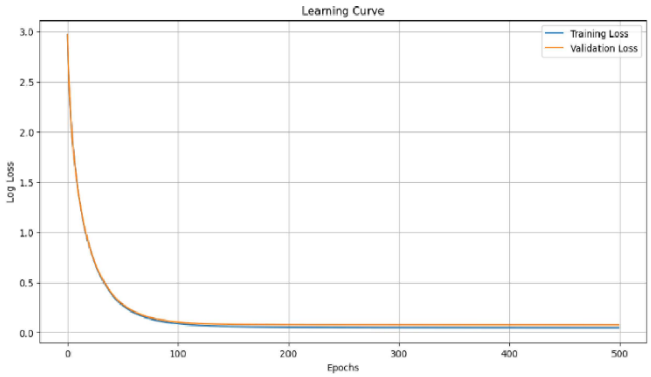

Fig. 11. Model learning curve.

TABLE I. PERFORMANCE METRICS FOR OPTIMIZED XGBOOST MODEL

Metric	Value
Precision	0.9723
Recall	0.9739
F1 score	0.9715
accuracy	97.51%

VII. CONCLUSION

This study focused on the serious challenge of making effective recommender systems in environments characterized by implicit feedback and extreme class imbalance, as is the case in domains with significant stakes such as health insurance.

To identify the most robust solution, we effectuated a comprehensive comparative analysis of principal tree-based ensemble algorithms, including Decision Trees, Random Forest, Gradient Boosting Machines (GBM), CatBoost, Extra Trees, and HistGradient Boosting. The results of our initial evaluation demonstrated that among this group of advanced algorithms, XGBoost consistently performed the best, by obtaining higher scores on main ranking and accuracy metrics. It outperformed its peers because it handles missing values efficiently, has built-in safeguards against overfitting, and uses a sophisticated boosting implementation. Together, these features made it more resilient to overfitting and class imbalance.

This solid foundational performance validated our selection of XGBoost for advance hyperparameter tuning, where we focused on optimizing its capacity to minimize log loss and simplify effectively. The subsequent learning curves confirmed the good generalization and excellent generalization of the model, without significant difference between training and validation error.

Beyond technical validation, this research carries significant practical and societal implications. The deployment of such a system in the health insurance sector can transform decision-making at multiple levels. Specifically, it enables advisors to transition from a generic approach to personalized guidance by leveraging targeted recommendations that accurately match each client's profile and latent needs. This personalization enhances customer experience while potentially improving equity of access to suitable products, thereby reducing the risk that relevant offers remain unnoticed.

Although this study determines XGBoost as a highly effective solution, there are many directions for future work remain.

In conclusion, this research demonstrates that XGBoost provides a powerful and unconventional basis for developing accurate and reliable recommender systems capable of operating under the stringent constraints of implicit feedback and significant class imbalance.

Mapping Elderly Residential Research During the Onset of Baby Boomer Aging: A Bibliometric Analysis

Keyi Xiao[1], Han Wang[2], Yan Ma[3]*
Shenyang Normal University, Shenyang 110034, China[1, 3]
Karolinska Institute, Stockholm 11228, Sweden[1, 2]

***Abstract*—As global population aging accelerates, housing for older adults has emerged as a critical interdisciplinary research topic. Understanding how academic attention has evolved in this field is essential for informing policy and guiding future research. This study conducted a bibliometric analysis of 2,141 English-language publications related to elderly residential indexed in the Web of Science Core Collection from 2002 to 2021. It systematically examined publication trends, leading countries and institutions, key subject areas, collaboration networks, and journal co-citation patterns. The results show that the United States, Australia, and China are the top contributors in terms of publication volume, while countries like Sweden and New Zealand demonstrate high research intensity on a per capita basis. Over time, the research focus has shifted from clinical geriatrics and nursing toward environmental sciences, urban planning, and public health, indicating an increasing interdisciplinary integration. Collaboration network analysis highlights the central roles of institutions in Australia and Hong Kong in facilitating international research partnerships. This study maps the global knowledge landscape of elderly residential research and provides a foundation for future policy development, interdisciplinary collaboration, and scholarly inquiry.**

***Keywords*—Aging; housing for the elderly; long-term care; environment design; bibliometrics**

I. Introduction

The global elderly population is increasing rapidly as the baby boomer generation ages and birth rates continue to decline [1]. Since 2001, the proportion of people aged 65 and over has increased from approximately 6.9% to 10.2% in 2024 [2]. According to statistics from the United Nations, they predict the proportion of elderly people across the world, demonstrating an expected increase in all regions [3]. Now, more countries are entering an aging society, and some, such as Japan, have even developed a super-aging society [4]. Due to persistently low birth rates and longer life expectancy, Japan has experienced a rapid demographic shift, with the proportion of people aged 65 and older rising significantly from 7.1% in 1970 to 26.6% by 2015 [5]. While increased longevity allows people to enjoy extended years of activity and fulfillment, it also brings substantial challenges, particularly in the healthcare system. Older adults, despite being a minority of the population, account for a disproportionate share of medical expenditures. For example, individuals aged 50 and above face significant financial barriers due to high premiums and out-of-pocket healthcare costs [6]. Additionally, populations aged 70 and over have been shown to contribute significantly to national healthcare burdens, especially in rapidly aging countries such as Japan [7].

Against this backdrop, research on elderly residential housing has emerged as a critical topic, reflecting not only the individual pursuit of quality of life but also broader pressures on urban governance and social welfare systems. Therefore, selecting the period from 2002 to 2021 for this study holds clear practical significance. On one hand, this timeframe encompasses a phase of rapid global real estate expansion, during which surging housing prices became a common challenge faced by many countries. Since the early 2000s, housing prices have continuously risen across numerous European countries, driven by a combination of demographic growth and financial dynamics [8]. In New Zealand, repeated housing bubbles, particularly in cities like Auckland and Wellington, have drawn considerable attention [9]. In the United States, as the proportion of the population aged 65 and over increased, the growing demand for age-specific housing added further pressure to the market, driving up prices in related segments [10]. Moreover, according to Lee et al. [11], the ratio of house prices to median household income has risen significantly since 1990 in developed economies such as Australia, Canada, Ireland, New Zealand, the United Kingdom, and the United States, most notably in globalized urban centers. This growing disparity has intensified housing market instability and made it increasingly difficult for low- and middle-income households to access affordable housing. As a result, the issue of housing affordability became a widespread concern during this period, and when combined with accelerating population aging, it brought the question of elderly housing to the forefront of global academic inquiry.

Although interest in elderly residential issues has grown steadily, existing studies often concentrate on specific aspects such as post-discharge care services or barrier-free housing design. For instance, a demographic study from Germany revealed that only a small proportion of older adults reside in barrier-reduced housing even when mobility limitations are present [12], while a mixed-methods survey of occupational therapists in Australia emphasized the importance of specific design features such as step-free entrances and showers in supporting aging in place and post-discharge transitions [13].

Comprehensive analyses that integrate cross-national or cross-disciplinary perspectives remain relatively limited. Most

*Corresponding authors

existing studies are confined to single-country contexts or emphasize narrow thematic areas, which restricts their generalizability. In addition, there is a lack of integrative reviews that systematically map how different disciplines approach elderly residential issues, leaving the broader research landscape insufficiently explored. Therefore, this paper seeks to broaden the scope by employing a bibliometric approach to examine the overall research landscape on "elderly residential" topics. Through the analysis of key elements such as countries, disciplines, journals, and institutional affiliations, this study aims to identify global research patterns and publishing outlets valuable to prospective authors. Bibliometric analysis has proven to be an effective tool for quantitatively assessing scientific trends and knowledge structures within a research field, especially in emerging or interdisciplinary domains [14]. In the field of architecture, for instance, bibliometric techniques have been used to map trends in elderly-related design studies, revealing increasing attention to housing, accessibility, and aging-in-place themes [15]. Similarly, recent analyses of social support systems for older adults also demonstrate the utility of bibliometric methods in identifying evolving research focuses and policy implications [16].

This paper is structured as follows. Section II describes the data collection process, inclusion and exclusion criteria, and the analytical methods employed. Section III presents the main results, including country-level publication trends, disciplinary distribution, institutional contributions, and journal co-citation patterns. Section IV discusses the implications of these findings in the context of global aging, interdisciplinary integration, and policy relevance. Section V concludes the paper by summarizing the key insights and outlining directions for future research.

II. Materials and Methods

A. Data Collection and Filtration

We conducted a comprehensive literature search on the Web of Science Core Collection (WOSCC) from 2002-01-01 to 2021-12-31 [17]. The search was initiated on February 24, 2022. This database was chosen since it is one of the most well-known databases for conducting bibliometric analysis, currently covering 18,000 journals and classifying information into 256 subject categories [17], and has been widely employed in bibliometric studies across fields such as medical research, environmental science, information science, and engineering [16-18]. It provides structured citation networks and comprehensive reference tracing capabilities [19-21], which facilitate diverse bibliometric analyses using software tools. Therefore, the relevant bibliographic records on the topic of elderly residential were derived from WOSCC.

Inclusion and exclusion criteria: Only publications written in English were included to ensure consistency in text analysis. All document types indexed in WOSCC, including articles, reviews, conference proceedings, and book chapters, were initially retrieved. Duplicates were removed. Non-scholarly items such as editorials, corrections, and news items were excluded. Studies not directly related to elderly residential or housing for older adults were also excluded after a manual screening of titles and abstracts.

Search strategy: To maximize coverage, the search strategy was designed to capture a broad range of terms related to elderly residential research. First, synonyms for the target population were identified, including elderly and senior (with truncation "senior*" to capture both singular and plural forms). Second, synonyms for the core concept of residential housing were specified, including residential, housing for the elderly, and elderly housing. These terms were combined using Boolean operators to ensure sensitivity and precision. The final query string was: TS=[(elderly OR senior*) AND ("residential" OR "housing for the elderly" OR "elderly housing")] AND LA=(English) AND PY=(2002-2021). The language is restricted to English, and no restrictions in terms of document type, data category are used. Following the above criteria, "elderly residential" obtained 2,141 original records.

Analysis process: The retrieved bibliographic records were downloaded in plain text format with full records and cited references. Data preprocessing included removal of duplicates and standardization of author, institution, and journal names. Summary statistics, such as annual publication trends, country contributions, and research fields, were generated directly from WOSCC and Microsoft Excel. For network analyses, VOSviewer (version 1.6.17) was employed to map co-authorship, institutional collaboration, keyword co-occurrence, and journal co-citation networks. Nodes in the visualizations represent units such as authors, institutions, or journals, while links indicate the strength of their relationships. The built-in clustering algorithm grouped related items, and both network and density views were adopted to enhance interpretability.

B. Data Analysis

Fig. 1 illustrates the whole study process. The retrieved documents were downloaded from the Web of Science Core Collection and used as input data for the subsequent bibliometric analysis. Summary statistics, including annual publication trends, leading affiliations, and research areas, were extracted directly from the WOSCC platform. The analysis was performed using VOSviewer (version 1.6.17) for network visualization and Microsoft Excel for statistical summaries and charting. Microsoft Excel was used to generate multiple visualizations and summary tables, including country-level publication statistics, time-segmented distribution of top research fields, and bar charts illustrating the publication output of leading institutions. These visual elements provided a clear overview of the geographic and thematic distribution of research efforts in elderly residential. Basic data processing functions and built-in charting tools in Excel facilitated the organization and presentation of bibliometric indicators derived from the raw dataset [22].

VOSviewer specializes in creating maps based on bibliographic data, particularly useful for detecting co-authorship patterns, institutional collaboration networks, co-citation clusters, and keyword co-occurrence [23]. The software employs a distance-based mapping technique combined with a unified layout and clustering algorithm, allowing items with stronger relationships to be positioned closer together in the visual space. It is capable of processing large-scale bibliographic datasets while providing an intuitive interface for exploring

complex network structures. VOSviewer also offers several types of visualizations, including network, overlay, and density views, which support both qualitative interpretation and quantitative comparison of bibliometric connections.

This study utilized VOSviewer to perform three core bibliometric analyses: mapping international collaboration between countries, examining institutional co-authorship relationships, and identifying journal co-citation patterns. These analyses enabled a structured examination of collaborative patterns and the intellectual structure of the field. Nodes in these networks represent entities such as countries, institutions, or journals, while the links reflect the strength of their bibliometric relationships. The clustering algorithm embedded in VOSviewer further enables the grouping of closely related items, revealing underlying thematic structures within the dataset. Layout and density visualizations were adopted to enhance interpretability and support intuitive analysis of bibliometric connections.

III. Results

A. Countries

Table Ⅰ presents the scientific output of various countries and regions in the field of elderly residential research from 2002 to 2021. The United States ranked first with 379 publications (17.71% of the total), followed by Australia with 348 publications (16.26%) and China with 245 publications (11.45%). Together, these three countries contributed over 45% of the global research output, highlighting their central role in this field.

After normalizing by population size, Sweden showed the highest number of publications per million people (13.91), followed by Australia (13.55) and New Zealand (11.02), indicating that countries with relatively small populations but strong research intensity performed exceptionally well in terms of per capita output. Meanwhile, regions with high population density, such as Taiwan (6.51) and South Korea (5.17), also demonstrated active research performance, possibly reflecting heightened attention to elderly housing issues amid rapid urbanization and population aging.

In terms of collaboration networks, as illustrated in Fig. 1, North America, particularly the United States and Canada, maintained strong and frequent cooperation with Asian countries such as China, India, and South Korea. Australia, which ranks second in total publications, also showed close international collaboration, underscoring its key role in global elderly residential research. In contrast, countries like Germany, Italy, and Spain, despite having a moderate volume of publications, ranked relatively low in per capita output. This suggests that while aging is a global issue, national research investment and strategic focus vary considerably.

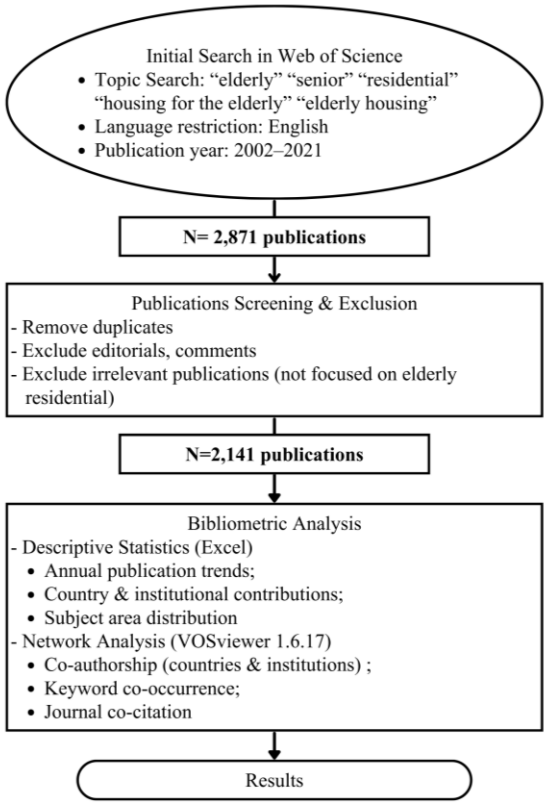

Fig. 1. Flowchart of the study process, including data collection, screening, and bibliometric analysis.

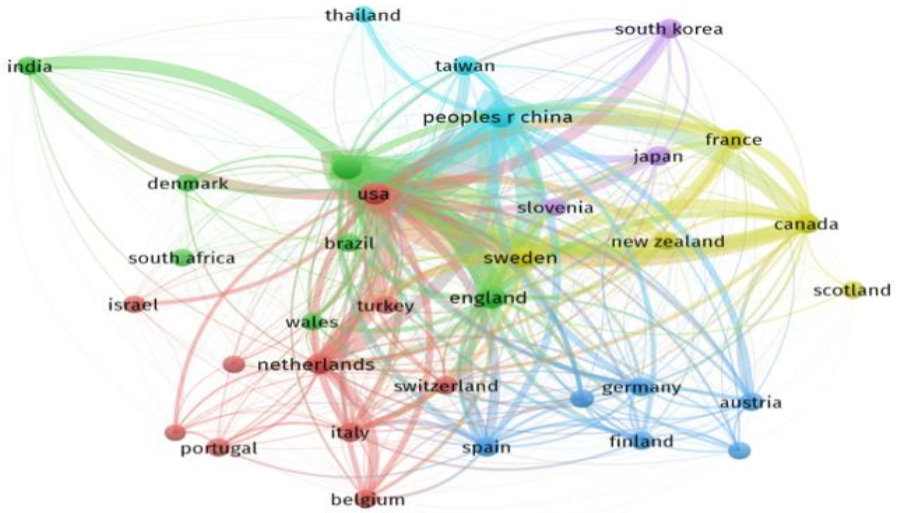

Fig. 2 visualizes the country-level collaboration network within the field of elderly residential research. Each node represents a country or region, with node size indicating the number of publications. The thickness of the connecting lines reflects the frequency of international research collaboration, while different colors represent clusters of countries that frequently co-author publications. The analysis reveals that the United States (USA) occupies the most central and prominent position in the network, indicating its leading role in both publication output and the breadth of global collaboration. China (People's Republic of China) and the United Kingdom (England) also demonstrate strong research productivity and maintain extensive links with a wide range of countries, highlighting their growing influence in this domain. A dense collaborative cluster is formed among several European countries, including Germany, Spain, Italy, the Netherlands, and Portugal, suggesting frequent intra-regional cooperation.

In parallel, the Asia-Pacific region, notably Japan, South Korea, Thailand, and Taiwan, is increasingly integrated into the global research landscape. Countries such as India, Canada, and Australia function as cross-regional connectors, facilitating scholarly exchange between Eastern and Western institutions.

TABLE I. COUNTRY-LEVEL RESEARCH OUTPUT ON ELDERLY RESIDENTIAL (2002–2021)

Countries and areas	# of Publication	% of total	Population in 2021(millions)	# of publications (per million population)	Land Area (10,000/m²)	Density (pop. per Land Area)	Rank (Pub.)	Rank (Pub. per million pop)	Rank (Density)
USA	379*	17.71*	332.47	1.14	983.40	0.34	1	13	10
AUSTRALIA	348*	16.26*	25.69	13.55	769.20	0.03	2	2	15
PEOPLE'S R CHINA	245*	11.45*	1412.6	0.17	959.70	1.47	3	15	7

*Note: * USA, Australia, and the People's Republic of China have been marked with an asterisk to indicate their position as the top three countries by number of publications in the field of elderly residential. # of Publication = Number of publications; % of total = Percentage of total publications; Population in 2021 (millions) = Population based on WHO 2021 statistics (in millions); # of publications (per million population) = Publications per one million people; Land Area (10,000/m²) = Land area in units of 10,000 square kilometers; Density (pop. per Land Area) = Population per unit of land area; Rank (Pub.) = Rank based on total publications; Rank (Pub. per million pop) = Rank based on publications per million population; Rank (Density) = Rank based on population density.*

Note: USA = United States; peoples r china = People's Republic of China; South Korea = Republic of Korea; Uk = United Kingdom ; UAE = United Arab Emirates.

Fig. 2. Country-level collaboration network in the field of elderly residential research (2002-2021).

B. Fields

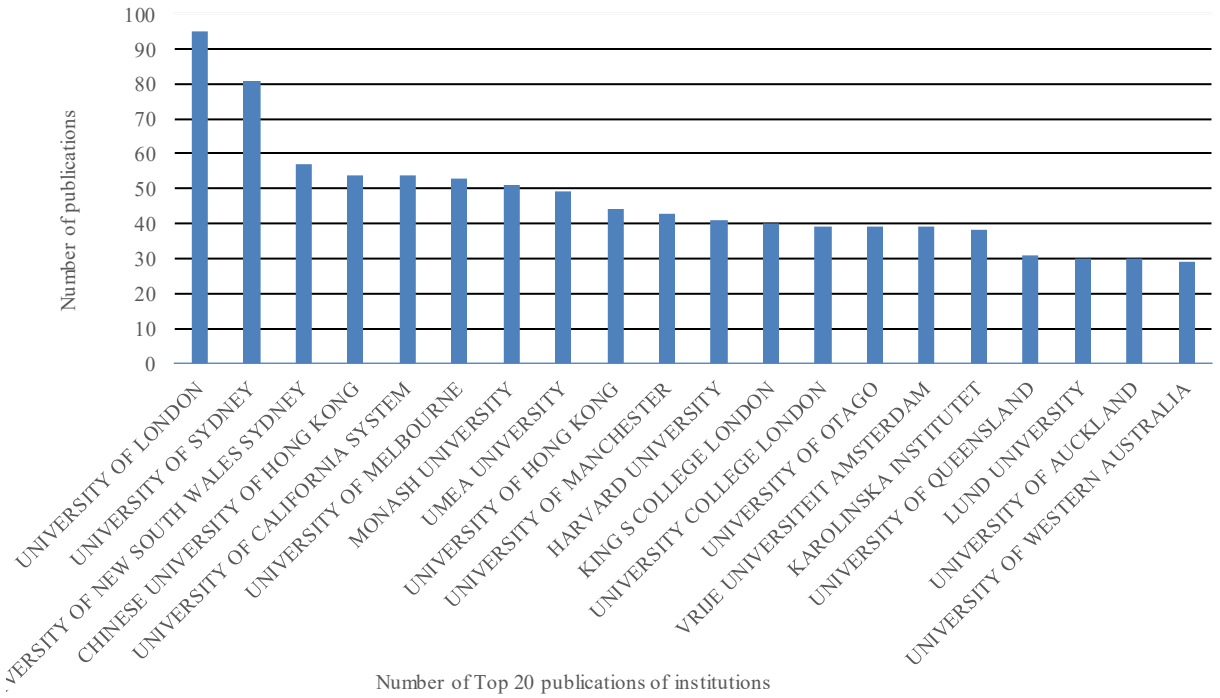
Table Ⅱ illustrates the top five research fields in the domain of elderly residential across four consecutive five-year periods from 2002 to 2021, based on the Web of Science subject classification. Throughout all time intervals, Geriatrics Gerontology consistently ranked as the most prominent field, reflecting its foundational role in elderly residential research. Notably, the field reached its peak publication volume during 2012-2016 (251 articles), before declining slightly in the 2017-2021 period (195 articles).

Public, Environmental, and Occupational Health maintained its position as the second most represented field across all periods, with a steady increase in publication output from 44 articles (2002-2006) to 139 articles (2017-2021), highlighting the growing integration of environmental and public health perspectives in elderly housing research. Psychiatry remained a stable third-ranked field during the earlier periods, although it was later surpassed by Environmental Sciences and Gerontology in the last five years, indicating a disciplinary shift towards more environment- and aging-specific research contexts.

The emergence of Nursing, Internal Medicine, and Health Care Sciences and Services in earlier periods underscores the initial focus on clinical and institutional aspects of elderly. However, fields such as Environmental Studies and Gerontology gained prominence in the most recent period, reflecting an expansion of research into broader socio-environmental dimensions of aging.

TABLE II. TOP 5 RESEARCH FIELDS IN ELDERLY RESIDENTIAL BY FIVE-YEAR INTERVALS (2002-2021)

Rank	Fields (2002-2006)	# of Publication	Fields (2007-2011)	# of Publication	Fields (2012-2016)	# of Publication	Fields (2017-2021)	# of Publication
1	Geriatrics Gerontology[a]	183*	Geriatrics Gerontology[a]	229*	Geriatrics Gerontology[a]	251*	Geriatrics Gerontology[a]	195*
2	Public Environmental Occupational Health	44*	Public Environmental Occupational Health	54*	Public Environmental Occupational Health	88*	Public Environmental Occupational Health	139*
3	Psychiatry	39*	Psychiatry	48*	Psychiatry	44*	Environmental Sciences	104*
4	Health Care Sciences Services	22	Nursing	44	Medicine General Internal	42	Gerontology	86
5	Medicine General Internal	22	Medicine General Internal	25	Nursing	36	Environmental Studies	63



*Note: *indicates that the field ranked among the top three in the corresponding time. "Geriatrics Gerontologya" refers to the combined subject categories of "Geriatrics" and "Gerontology" in the Web of Science Core Collection (WOSCC).*

C. Institutions

Fig. 3 presents the publication output of the top 20 institutions contributing to the field of elderly residential research from 2002 to 2021. The University of London leads with the highest number of publications, reflecting its dominant academic position in this domain. It is followed by the University of Sydney and the University of New South Wales Sydney, both of which show high levels of scholarly productivity, underlining Australia's significant engagement in elderly residential topics.

The list also includes notable institutions from Hong Kong (e.g. Chinese University of Hong Kong), North America (e.g. University of California System, Harvard University), and Europe (e.g. University of Manchester, Karolinska Institutet). This wide distribution indicates that elderly residential research has attracted global attention and academic investment.

The recurring appearance of multiple institutions from countries like Australia and the UK suggests regional hubs of research excellence. The results highlight a trend where both English-speaking countries and regions with rapidly aging populations have contributed substantially to the knowledge base in this field.

Note: Each bar represents the number of publications produced by each institution related to elderly residential research during the period 2002-2021.

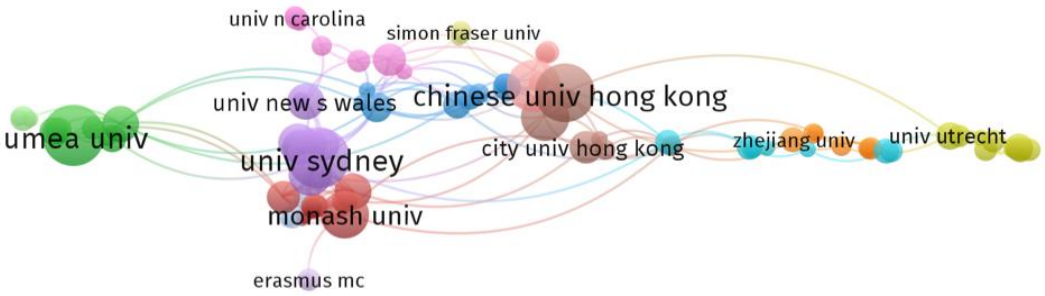


Fig. 3. Number of publications of the top 20 most productive institutions in elderly residential research (2002-2021).

Fig. 4 displays the institutional co-authorship network in the field of elderly residential research. Each node represents a university or research institution, with node size proportional to its total publication output. The thickness of the connecting lines indicates the frequency of co-authored publications, reflecting the intensity of academic collaboration.

The network reveals a high degree of international cooperation. Central institutions include Umeå University, University of Sydney, Monash University, and the Chinese University of Hong Kong, all of which demonstrate high publication output and strong collaborative ties. Regional clustering is evident, particularly among institutions in Australia and Hong Kong, where close intra-regional collaboration is observed. Several other Australian institutions also exhibit substantial academic activity in this domain. The University of New South Wales ranks third in total publications and shows a strong pattern of international collaboration, while the University of Melbourne ranks within the top 10 and maintains frequent co-authorships with leading global research centers.

In the United Kingdom, both the University of London and the University of Manchester are among the top 10 most productive institutions, highlighting the country's advanced position in this field. Nordic countries also contribute significantly, with Umeå University (Sweden) emerging as one of the most influential institutions in terms of both output and connectivity.

Furthermore, the presence of institutions such as Zhejiang University (China) and Utrecht University (Netherlands) reflects growing global engagement, particularly from Asia and continental Europe. The observed collaboration structure indicates a distributed, multi-centered international research network, supporting the expansion of scholarly efforts in elderly residential.

Note: umea univ = Umeå University; univ n carolina = University of North Carolina; univ new s wales = University of New South Wales; univ sydney = University of Sydney; monash univ = Monash University; chinese univ hong kong = The Chinese University of Hong Kong; city univ hong kong = City University of Hong Kong; simon fraser univ = Simon Fraser University; zhejiang univ = Zhejiang University; univ utrecht = Utrecht University; erasmus mc = Erasmus Medical Center.

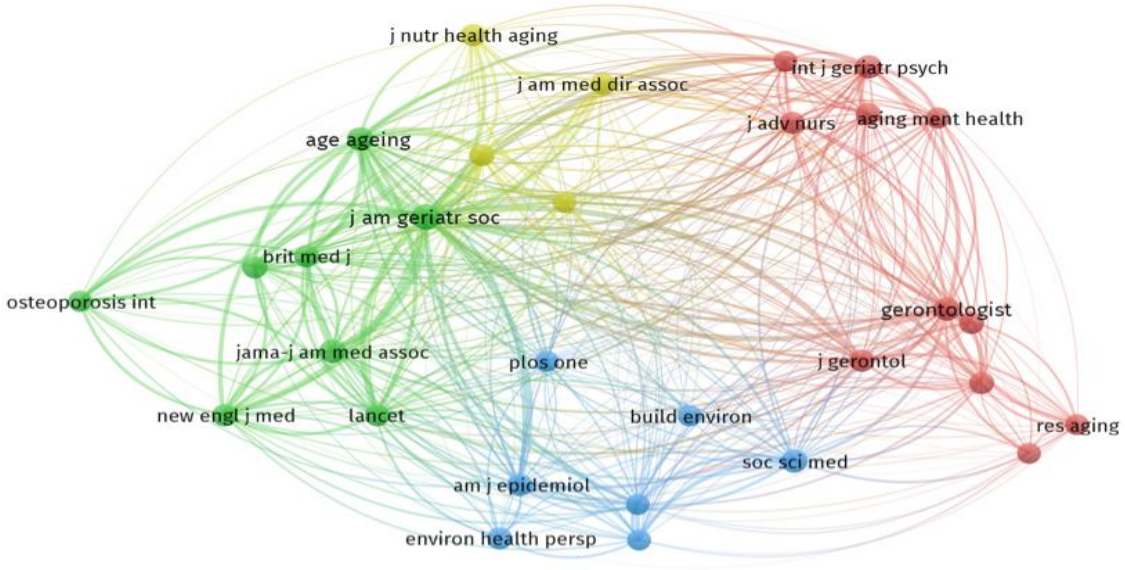

Fig. 4. Institutional co-authorship network in the field of elderly residential research.

D. Journals

Fig. 5 presents the journal co-citation network within the domain of elderly residential research. Each node represents an academic journal, with the node size corresponding to its co-citation frequency, and colors denoting different thematic clusters. Links between nodes indicate the strength of co-citation relationships, reflecting the underlying intellectual structure and disciplinary interconnections in the field.

The network reveals several prominent clusters. Core gerontology journals, Journal of the American Geriatrics Society, The Gerontologist, and Journals of Gerontology, occupy central positions, indicating their foundational role in shaping aging-related scholarship. Another cluster comprises interdisciplinary journals such as Social Science & Medicine, Environmental Health Perspectives, and Building and Environment, suggesting close linkages between aging, environmental health, and the social sciences. Additionally, high-impact clinical journals, including JAMA, The Lancet, and New England Journal of Medicine, are also represented, underscoring the relevance of aging issues in broader public health and medical research.

In terms of publication volume, Age and Ageing was the most productive journal with 61 articles, followed by International Journal of Environmental Research and Public Health with 44, and Journal of the American Geriatrics Society with 32. These publication patterns align with the journals' disciplinary classifications: Age and Ageing and Journal of the American Geriatrics Society fall under Geriatrics & Gerontology, while International Journal of Environmental Research and Public Health is categorized under both Environmental Sciences and Public, Environmental & Occupational Health.

Note: j nutr health aging = The Journal of Nutrition, Health and Aging; j am med dir assoc = Journal of the American Medical Directors Association; age ageing = Age and Ageing; j am geriatr soc = Journal of the American Geriatrics Society; brit med j = The British Medical Journal (BMJ); jama-j am med assoc = Journal of the American Medical Association (JAMA); new engl j med = The New England Journal of Medicine; lancet = The Lancet; osteoporosis int = Osteoporosis International; plos one = PLOS ONE; am j epidemiol = American Journal of Epidemiology; environ health persp = Environmental Health Perspectives; build environ = Building and Environment; soc sci med = Social Science & Medicine; int j geriatr psych = International Journal of Geriatric Psychiatry; j adv nurs = Journal of Advanced Nursing; aging ment health = Aging & Mental Health; gerontologist = The Gerontologist; j gerontol = Journals of Gerontology; res aging = Research on Aging.

Fig. 5. Journal co-citation network in the field of elderly residential research.

IV. Discussion

A. Comparison with Related Research

Recent evidence synthesizes how the built environment supports ageing in place through urban planning, physical accessibility, and adaptable housing design, while also noting inconsistencies in reported effects on cognitive outcomes and well-being [24]. One systematic review in this area calls for integrated approaches that link housing, health, and planning and for clearer operationalization of environmental exposures and outcomes [25]. Qualitative work from Sweden adds demand-side insight into how active older adults actually use neighborhoods [26]. Interviews grounded in time-use diaries show that proximity to everyday amenities, walkable public spaces, and opportunities for spontaneous social interaction structure daily practices and support autonomy, with some gender differences and variation between central and peripheral locations [26]. These findings underscore the importance of neighborhood-scale design for health and participation. A complementary strand links senior-friendly housing to the silver economy [27]. A recent scoping review emphasizes universal design and supportive environments as means to sustain autonomy and reduce dependency while creating economic opportunities, illustrating how housing policy can align with broader development agendas in rapidly ageing settings [27].

Although this study systematically mapped the development of global elderly housing research between 2002 and 2021 through bibliometric methods and provided a macro-level perspective on cross-national comparisons, disciplinary evolution, and collaboration networks, several limitations remain. In contrast to the systematic review [25], our analysis did not examine in detail how specific built environment factors influence health outcomes, and therefore offers limited insights into underlying mechanisms. Compared with the qualitative work of Vilhelmson [26], our study relies primarily on English-language publications indexed in the Web of Science, which constrains the ability to capture older adults' lived experiences and local contextual differences. Relative to the scoping review [27], which links senior-friendly housing to the silver economy and policy frameworks, our work has not fully addressed the intersections between housing, economic development, and industrial policy. Thus, the main contribution of this study lies in delineating the knowledge structure and interdisciplinary trends of the field, while further research is required to advance understanding at the levels of health impacts, individual experiences, and economic–policy integration [28].

B. Responding to Global Aging Through Residential Research

The ongoing demographic transformation marked by global aging has substantially reshaped housing-related academic discourse. As populations' age and urban centers experience real estate intensification, the housing needs of older adults become increasingly complex. Recent studies have linked rising housing prices with growing inequality in housing access, particularly among low-income elderly residents [29]. As affordability declines, aging populations, especially those living alone or on fixed incomes, are disproportionately vulnerable to housing instability [30]. This socio-economic backdrop is reflected in scholarly publication trends. Between 2002 and 2021, the field of elderly residential research expanded significantly, with countries such as the United States, Australia, and China contributing over 45% of global publications. When normalized

by population, smaller nations like Sweden, New Zealand, and the Netherlands demonstrated exceptionally high research intensity. This pattern suggests that both demographic pressure and housing market volatility have acted as research catalysts, especially in high-density or rapidly urbanizing regions.

The geographic concentration of output, especially in nations facing acute housing affordability issues, indicates a clear response to national policy priorities and market realities. For example, regions such as Taiwan and South Korea demonstrated increasing academic interest in elderly housing, likely shaped by urban crowding, transport inequality, and land scarcity. A recent study in South Korea confirmed that accessibility to health and aged care infrastructure is significantly lower in urban peripheries, disproportionately affecting older populations [31]. This intersection of spatial inequality and demographic stress has helped prioritize elderly housing as a key research and policy agenda across disciplines.

C. Changing Research Fields and Emerging Interdisciplinary Trends

Geriatrics and gerontology continue to form the empirical backbone of elderly residential studies, particularly in addressing healthcare accessibility and long-term care provision. Yet, a notable disciplinary shift has occurred over the past decade toward the inclusion of environmental sciences and urban studies. These fields now contribute substantially to the discourse on aging-in-place strategies and the role of built environments in promoting active aging [32]. Recent studies in urban planning have emphasized the role of neighborhood walkability, greenery, and social infrastructure in supporting older adults' autonomy [33]. Environmental determinants, such as air quality, spatial safety, and public transport accessibility, are increasingly framed as health enablers for aging populations [34]. This expansion signals a growing consensus that elderly housing research must be interdisciplinary to address the full spectrum of residential quality and well-being.

D. Deepening Focus on Environmental Sciences and Urban Studies

The role of environmental factors and urban design in shaping older adults' well-being has gained substantial scholarly attention. Concepts such as green space aesthetics, walkability, and neighborhood connectivity are now central to research on aging in place [35]. Empirical tools have been developed to assess age-friendliness in residential environments, such as multi-dimensional frameworks measuring accessibility, public service proximity, and environmental quality.

Design-based and participatory research approaches have also emerged. In Prague, for example, user-centered design and digital innovation are applied to tailor home environments for older users [36]. Studies in Italy emphasize the integration of shared green infrastructure, public seating, and intergenerational community planning as ways to promote psychological and physical well-being among seniors [37]. Walkability, including the presence of pedestrian infrastructure and nearby amenities, plays a crucial role in encouraging walking and mobility among older adults [38].

E. Regional Leadership and Policy-Driven Research Growth

Australia and Hong Kong stand out as leading contributors to elderly residential research, driven by targeted policy reforms and high research intensity. Australia's aged care strategies, such as the implementation of Home Care Packages (HCP) and Residential Aged Care (RAC), have stimulated academic studies on service design and housing adequacy [39]. In Hong Kong, the government has integrated welfare instruments such as housing subsidies and community living allowances to enhance older adults' residential stability. These efforts have also generated substantial institutional collaborations between local universities and public agencies [40]. Additionally, elderly housing policy in Hong Kong has been shaped by demographic projections and the urgent need to prevent future institutional care deficits. While direct strategies to reduce institutionalization have been limited, policy responses, such as public housing redevelopment supporting aging in place, reflect a growing recognition of this challenge. As noted by Mesthrige and Cheung (2020), such initiatives not only aim to promote residential autonomy among older adults but also encourage academic engagement in evaluating housing adequacy and long-term care alternatives [41]. This evolving policy-academic feedback loop positions Hong Kong as a key case for understanding how institutional design and aging policy can co-produce robust research ecosystems.

F. Strengths and Limitations

This study employs bibliometric methods to synthesize global research trends in elderly housing over 20 years. The strength of this approach lies in its capacity to capture interdisciplinary growth, highlight collaboration networks, and quantify shifts in publication output. Furthermore, combining subject category analysis with institutional and regional metrics provides a more holistic understanding of where and how knowledge on elderly residential is produced [42].

Nonetheless, limitations must be acknowledged. The analysis relies exclusively on the Web of Science Core Collection, potentially excluding valuable research indexed in Scopus, PubMed, or regional databases. Furthermore, restricting the review to English-language publications likely underrepresents elderly housing research in Latin America, East Asia, and non-Anglophone Europe [14]. Third, citation-based metrics used in bibliometric studies often favor older, well-established research while undervaluing recent or practice-oriented studies that may not yet have accumulated citations [43]. This limitation is particularly salient in emerging interdisciplinary fields, like elderly housing, where impactful policy papers and architectural studies may not circulate in highly cited scientific journals.

G. Future Research Directions

The increasing complexity of elderly housing issues calls for expanded and more nuanced research agendas. While recent years have seen growing interdisciplinary attention to aging in place, urban livability, and health equity, several promising entry points remain underexplored and merit future investigation.

First, researchers should prioritize comparative policy studies to examine how different welfare regimes, urban development models, and long-term care systems influence

elderly housing access and design. National policies can profoundly shape housing affordability and support structures, particularly in rapidly aging but economically diverse regions [44]. Second, future research should expand on technology-enabled living environments for older adults, particularly examining the integration of smart home systems, telehealth, and ambient sensors. However, more work is needed to assess ethical concerns, user acceptance, and long-term cost-effectiveness [45]. Third, methodological innovation is essential. Researchers should adopt mixed-method designs, longitudinal datasets, and community-based participatory approaches to capture the lived experiences of aging populations in different contexts. This would enrich quantitative bibliometric insights with qualitative depth and social meaning [46].

Lastly, considering escalating environmental challenges, climate-resilient senior housing should become a core research agenda. Studies should evaluate how extreme weather events, urban heat islands, and infrastructure breakdowns uniquely impact vulnerable older populations, and how housing design can mitigate such risks [47].

V. Conclusion

This bibliometric analysis reveals a rapidly expanding and increasingly interdisciplinary field of research centered on elderly residential from 2002 to 2021. With contributions led by countries such as the United States, Australia, and China, and strong per capita output from Sweden and New Zealand, the study highlights a globally shared academic response to the dual challenges of population aging and housing affordability. The analysis further demonstrates a clear disciplinary shift from traditional geriatrics and nursing toward environmental sciences, urban planning, and public health, underscoring the structural interdisciplinarity of the field. Furthermore, international and institutional collaboration networks demonstrate growing global engagement and policy relevance. By mapping publication trends, research clusters, and collaborative patterns, this study not only synthesizes two decades of scholarly development but also lays a foundational framework to guide future inquiries into inclusive, sustainable, and health-promoting housing for aging populations. Journal co-citation patterns also reveal that core gerontology journals are closely linked with outlets in environmental health and the social sciences, indicating the cross-field integration of knowledge.

Overall, these findings contribute in three ways. First, they delineate the global knowledge structure of elderly housing and identify leading countries, institutions, and journals. Second, they highlight policy-relevant fronts such as accessibility, aging in place, and community-level design where evidence has accumulated. Third, they provide a reproducible baseline for future longitudinal updates of the field. Practical implications suggest that inclusive housing strategies should be co-designed across health and planning systems, with greater attention to accessibility retrofits and community services that delay institutionalization. Future research should expand comparative policy studies, apply mixed-method designs, and address climate resilience in senior housing to meet the challenges of aging populations.

***Abstract*—The Strategic decision support creates a strong and smart decision support system for financial management through the correct forecast of stock prices with deep learning. Statistical models and shallow machine learning techniques tend to be ineffective in modeling the nonlinear relationships, sequential interdependencies, and time-dependent volatility typical of financial data; consequently, poor prediction quality and untrustworthy investment choices. To overcome these constraints, introduce a new hybrid deep learning architecture based on the Temporal Fusion Transformer (TFT) combined with Bidirectional Long Short-Term Memory (BiLSTM) networks. The proposed hybrid model is expected to complement time-series forecasting by simultaneously utilizing attention mechanisms for explainability and sequence memory functions for richer temporal understanding. The model is trained and tested with the publicly available Stock Market Dataset on Kaggle, which includes stock history from various companies. The whole process is carried out on the Python platform using TensorFlow along with relevant libraries for data preprocessing, feature scaling, and model training. The new TFT-BiLSTM model surpasses conventional models through an accuracy level of 93.4% and an F1-score of 94.2%, demonstrating its precision and generalization power. The system provides strategic benefits in financial planning and risk management. Financial analysts, investors, fintech, and portfolio managers may take advantage of our prediction system to make rational buy/sell judgments, minimize risks, and maximize asset allocations. By synthesizing state-of-the-art deep learning models and public financial data, our framework illustrates that accurate stock price prediction can be an effective mechanism for supporting decision-making in financial markets.**

Keywords*—Stock price forecasting; deep learning; temporal fusion transformer; financial decision support; BiLSTM

I. Introduction

Stock price prediction is a popular problem of considerable practical interest in investment, risk management, and strategic asset allocation across financial markets. Early approaches were dominated by traditional econometric models like autoregressive integrated moving average [1], generalized autoregressive conditional heteroskedasticity and Kalman filters focusing on predicting price changes by analyzing historical price and volatility patterns [2]. Such models, though, are frequently plagued by strong assumptions such as linearity, stationarity, and Gaussian errors, restricting their power to reflect the inherently nonlinear and chaotic characteristics of actual financial time series. As markets develop under the forces of high-frequency trading, macroeconomic trends, and intricate cross-asset dynamics, [3] it is critical to utilize richer market behavior representations. Therefore, more flexible and stronger models able to learn adaptively from data are essential to enhance prediction accuracy and usefulness.

Over the last decade, there has been growing use of deep learning methods, "recurrent neural networks (RNNs), long short-term memory networks (LSTMs), gated recurrent units (GRUs), and convolutional neural networks (CNNs)", to predict stock prices. These models are more effective in capturing nonlinear relationships and temporal dependencies in historical price data[4]. Variants like BiLSTM examine both forward and backward sequence context, and attention mechanisms in Transformers emphasize significant input times [5]. However, these approaches have limitations: RNN-based models can lose long-range dependencies or have vanishing gradients; Transformers are potentially data-inefficient and pure LSTM models are not interpretable [6]. Hybrid solutions have been suggested, e.g. CNN-LSTM or Attention-LSTM, in order to leverage strengths, but fundamental shortcomings still persist in integrating seamlessly interpretable attention with [7] sequential bi-directional recurrence without sacrificing accuracy and computational tractability.

In this research, a hybrid deep learning architecture consisting of a TFT and a Bidirectional LSTM (BiLSTM) to predict next-day stock closing prices is presented. Our method

utilizes TFT's strong attention and feature selection capacity to automatically recognize salient features at every time step, while BiLSTM captures sequence context from past as well as future information windows. They utilize the publicly accessible "Stock Market Dataset" on Kaggle, which provides daily OHLC, volume, adjusted close, and ticker symbols of several US-listed stocks for the last two years. This data set offers a modern and comprehensive source for model training and testing. Through the emphasis on recent data, our method adjusts to prevailing market tendencies. The combined model is trained on sliding-window sequences to forecast future closing prices, with a goal of surpassing traditional baselines according to MAE, RMSE, and R^2.

- Established the research goal by seeking to enhance stock price prediction accuracy by incorporating attention-based temporal models with bidirectional sequence learning.
- Optimized a hybrid TFT-BiLSTM architecture. Integrated TFT's transparent attention mechanisms and BiLSTM's two-way sequence modeling for a better understanding of temporal context.
- Used the stock market dataset. Exploited a diverse, recent, and rich two-year daily stock price dataset to train and test the hybrid model.
- Accomplished better performance. Achieved higher accuracy compared to baseline models, with lower MAE and RMSE, and greater R^2 in numerous tickers.

A. Motivation of the Study

In the fast-moving financial era, precise stock market prediction is a necessity for investors, fund managers, and institutions wanting to reduce risk and maximize return. Conventional models like ARIMA or linear regression models are not in a position to capture the nonlinear, dynamic, and time-dependent pattern of stock prices. With increasing advances in artificial intelligence and deep learning, there is a greater incentive to investigate more advanced ways that are capable of drawing out implicit patterns and long-term relationships from abundant sources of historical data. The incentive of this research is bridging the gap between raw financial information and actionable strategic choices by utilizing hybrid deep learning frameworks. Merging Temporal Fusion Transformers (TFT) with BiLSTM enables us to perform beyond mere prediction toward developing a smart, explainable, and scalable decision support system. This study hopes to enhance the accuracy of prediction while bringing real-world advantages in financial planning and portfolio management.

B. Significance of the Study

This research has high value in the confluence of stock market forecasting and artificial intelligence by providing a real-world, high-performance solution for forecasting stock market trends. Its value comes from the fact that the proposed TFT-BiLSTM model can beat conventional and current deep learning approaches by successfully learning to leverage complex sequential data. The determined by various variables over time, a hybrid model integrating temporal attention and memory mechanisms may provide higher accuracy and interpretability. The research is not only beneficial to academic researchers but also to industry professionals such as investors, stock traders, and data-driven fintech firms by providing a forecasting tool that facilitates strategic decision-making. By employing an actual-world dataset and running the solution using Python, the model is reproducible, scalable, and ready for use in trading systems or financial analytics platforms. All in all, this study contributes to smarter, AI-enabled financial planning in more volatile and competitive markets.

The rest of this paper follows the following structure: Section II, Related Works, reviews previous literature on stock prediction with both conventional and deep learning approaches. Section III, Problem Statement, mathematically defines the forecasting problem and model goals. Section IV, Methodology, outlines data collection, preprocessing processes, and our TFT-BiLSTM hybrid model structure. Section V, Results, reports experimental conditions, performance measures, and visual inspections of the predictions. Section VI concludes by summarizing findings and stating future directions of work.

II. Related Works

M. Elhoseny [8] et al., proposed the AWOA-DL model to enhance precision in credit risk forecasting and financial distress prediction. The model combines a deep neural network (multilayer perceptron) with an Adaptive Whale Optimization Algorithm (AWOA) for hyperparameter tuning, improving prediction accuracy. The model is run in three phases: preprocessing, tuning, and prediction. Its strength lies in high predictive performance (95.8%) and applicability across diverse datasets. However, its computational complexity limits scalability and real-time deployment in high-frequency financial systems or organizations with limited infrastructure. D. K. Nguyen [9] et al. examined the convergence and influence of Big Data, AI, and ML in transforming the fintech sector. It uses a multi-dimensional descriptive analysis approach to build and test a framework demonstrating their synergistic relationship in financial services. The benefit comes with the elucidation of how these technologies enable digital finance and redefine the role of the data scientist. Yet it also deals with drawbacks like ethical implications, government regulations, and risks of abuse or overreliance on automated decision-making.

A. Mehra [10] et al., introduced enrich intricate decision-making through the neural networks' pattern recognition power. A rule-based mechanism for symbolic reasoning and a neural network for deep learning are utilized in the suggested hybrid model, facilitating interaction within a single architecture. The benefits are enhanced accuracy, interpretability, and scalability in areas such as healthcare and finance. Nonetheless, difficulties lie in architectural complexity and possible integration challenges between structured and unstructured data processing elements. K. Li [11] et al., proposed measuring corporate culture using word embeddings to score five cultural values for firm-year observations (2001–2018). Advantages include a data-driven, scalable approach to assessing corporate culture and uncovering its link to performance, risk, and executive behavior. However, limitations include potential context misinterpretation by models and textual data, which may not capture all cultural nuances or internal organizational dynamics. E.C. Chukwuma-Eke [12] et al., present enhance cost estimation and financial

planning in oil and gas ventures through the use of AI, data analysis, and probabilistic models. The approach fuses historical and current data with machine learning and Monte Carlo simulations for improved precision and risk determination. Benefits include adaptive forecasting, greater financial resilience, and transparency through blockchain. Drawbacks include high complexity of implementation, data integration issues, and dependency on the quality of input data and interpretability of AI models. B. Gülmez[13] et al., introduced improve the accuracy of predicting stock prices with an LSTM model optimized using SCSO. The approach utilizes the time-series capability of LSTM together with SCSO's metaheuristic optimization, tested against other advanced models with DAX index data. Benefits are strong prediction accuracy, increased returns, and resilient risk-adjusted performance. Drawbacks are model complexity, high computational expense, and parameter sensitivity, potentially constraining ease of use in real-time trading settings.

Chakravorty [14] et al., introduced predict stock prices from insider trading information by testing different machine learning models. It uses on Tesla's insider trading activities between April 2020 and March 2023. The process involves feature selection with RFE and feature importance analysis. The strength is SVM-RBF's excellent accuracy rate, providing extensive insights into market attitudes. But its weakness is heavy computational expense, such that real-time use is problematic because it takes longer times to process. M. Sahroni [15] et al., introduced present stock price forecasting by adding social media-extracted network variables to conventional models. Employing data from EastMoney, China's biggest financial social platform, the approach builds daily social networks of investor behavior and combines them with an LSTM model to forecast SSE 50 stock prices. By modeling investor behavior daily, the approach improves predictive accuracy through sentiment analysis. Limitations include platform-specific dependency, restricted generalizability, and challenges in real-time processing.

TABLE I. SUMMARIZATION OF THE EXISTING STUDIES

Author	Method	Advantage	Limitation
M. Elhoseny et al. [8]	AWOA-DL: Adaptive Whale Optimization Algorithm + Deep Neural Network (MLP)	High prediction accuracy (95.8%); works across diverse datasets	High computational cost; limited scalability for real-time or resource-constrained environments
D. K. Nguyen et al. [9]	Descriptive framework combining Big Data, AI, ML for FinTech	Clarifies synergy of emerging tech in finance; explains role shifts (data scientist)	Ethical concerns; regulatory challenges; risk of automation misuse
A. Mehra et al. [10]	Hybrid Symbolic Reasoning + Deep Learning (Rule-based + Neural Network)	High interpretability, scalability, and accuracy in decision-making	Complex architecture; difficult integration of structured and unstructured data
K. Li et al. [11]	Word Embedding + Culture Scoring from Earnings Call Transcripts	Scalable, data-driven cultural assessment; links culture to firm performance	Context misinterpretation; limited insight into internal company dynamics
E. Chukwuma-Eke et al. [12]	AI + Monte Carlo Simulations + Blockchain for Cost Estimation in Oil & Gas	Adaptive forecasting; financial resilience; improved transparency	Implementation complexity; data integration issues; reliance on input data quality
B. Gülmez et al. [13]	LSTM + Sand Cat Swarm Optimization (SCSO) for DAX Index Forecasting	High prediction accuracy; strong returns and Sharpe ratio	Computationally intensive; parameter sensitive; complex for real-time applications
A. Chakravorty et al. [14]	ML Models (SVM-RBF, Decision Tree, RF, K-Means) with Insider Trading Data	Excellent trend detection; SVM-RBF yields high accuracy	Long processing time; unsuitable for real-time deployment
M. Sahroni et al. [15]	LSTM + Social Media Network Variables (EastMoney)	Captures investor sentiment; improves prediction accuracy	Limited generalizability; platform-specific data; real-time processing complexity

Table I summarizes existing studies on AI and machine learning applications in financial forecasting. It gives the approach of each author, and the major strengths of the approaches include high prediction accuracy, interpretability or adaptability, whereas the weaknesses consist of the high computational cost, the lack of scalability, the inability to apply them in real-time, or the difficulty in combining various data-sources.

III. PROBLEM STATEMENT

Stock price forecasting continues to be a problematic problem in finance forecasting because of its extremely volatile, non-linear, and dynamic nature. Established statistical models such as ARIMA, GARCH, and linear regression are not suitable for identifying intricate patterns and inter-dependencies in high-frequency market data[16]. Despite the new technology of ML and simple deep learning architectures like LSTM, GRU, and CNN, the majority of current methods still suffer from issues of either a lack of interpretability, an inability to utilize long-term dependencies, or a poor grasp of bidirectional time contexts. Additionally, numerous models lack attention mechanisms that allow for the determination of which time steps and features have the largest contribution to a prediction. The absence of an integrated model that encompasses both sequence learning and feature relevance detection impedes precise forecasting, particularly under dynamic market conditions[17]. Thus, there is an urgent necessity for a strong and comprehensible deep learning framework that can adequately learn both short- and long-term patterns, determine the importance of significant input features, and make precise stock price predictions. This research presents a novel hybrid TFT-BiLSTM model to forecast stock price prediction. The model was selected due to its ability to capture long-term temporal dependencies (TFT) and bidirectional dependencies (BiLSTM), circumventing LSTM, CNN, and classical ML models' shortcomings, which tend to have issues with multi-horizon forecasting, heterogeneous data, and complex temporal relationships.

IV. PROPOSED METHODOLOGY: TFT-BILSTM HYBRID MODEL FOR FINANCIAL MANAGEMENT

The methodology suggested combines a TFT-BiLSTM hybrid model for precise forecasting of stock prices. The

procedure starts with data acquisition from the publicly accessible Stock Market Dataset of Kaggle based on daily trade information of a chosen company (e.g., AAPL). Raw data is preprocessed with conversion of date, sorting, missing value handling, feature selection (Open, High, Low, Close, Volume), Min-Max scaling normalization, and sequence generation by applying a sliding window methodology. The BiLSTM module learns both future and past temporal relationships, whereas the TFT uses attention mechanisms and temporal encoding to provide higher-order interpretability and feature importance. The last fusion layer concatenates both the outputs to generate precise closing price predictions. The model is trained on the MSE loss function and is tested on MAE, RMSE, R^2, Accuracy, and F1-score with better performance compared to baseline models. Fig. 1 shows the overall workflow.

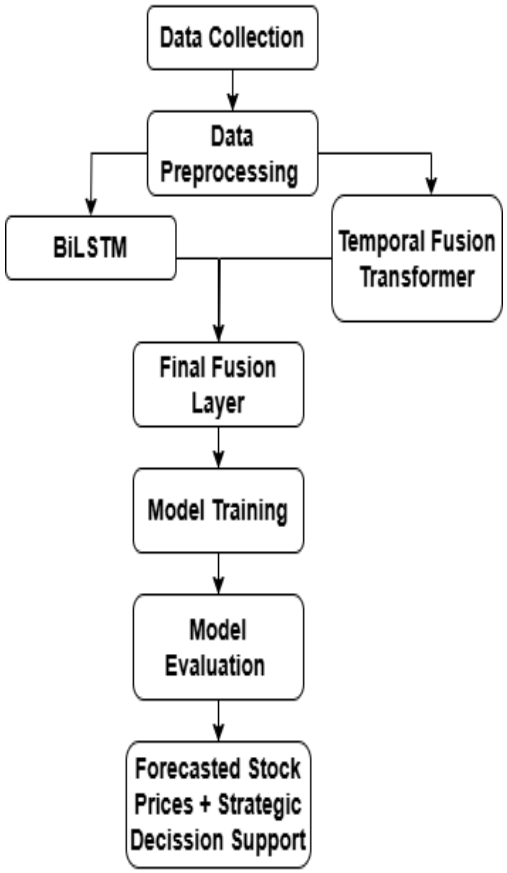

Fig. 1. Overall workflow.

A. Dataset Collection

The data collection for this research is the open Stock Market Dataset available on Kaggle[18] from Jackson Crow. It consists of past stock data of different companies traded in the S&P 500 index. Every record holds basic stock information are data covers more than one year and offers a good number of time-series observations to build predictive models on. In this research, we particularly use the daily stock data for a chosen company (say, Apple Inc. – AAPL) to test and train the suggested deep learning model. The data was downloaded from the Internet in CSV format, which can be easily read into Python using libraries such as Pandas and NumPy. The presence of actual-world financial information presented in such a manner facilitates reproducibility and real-time usage, providing a sound basis for precise forecasting and strategic decision-making in financial planning.

B. Data Preprocessing

Effective preprocessing is necessary to create a well-performing predictive model. Several important preprocessing tasks were performed on the raw stock exchange dataset. The first activities were to identify and remove missing values and null values in order to be able to trust the dataset that would be working to convert the Date column into date time format and sort the data using the Date column to preserve sequential integrity. Then I selected appropriate features of Open, High, Low, Close, and Volume to use for training the model and dropped unsuitable columns. The data was normalized by Min-Max Scaling which groups all numeric features in a comparable range for training model. The normalized data set would allow for a descent reduction in convergence of deep learning models, and significantly stabilize the model. The dataset was also split into training and test sets using an 80:20 distribution for measuring model performance on untrained data. Lastly, I utilized a sliding window method to make sequences that will be applicable to time-series prediction in order to ensure that the model has trained on time-steps from the past. The preprocessing actions accomplished, had the dataset ready for complete ingestion to the hybrid TFT-BiLSTM model.

1) Date conversion and sorting: Transform the date column to a suitable datetime data type and then sort the data by date chronologically. This way, the model receives temporally ordered input which is relevant for preserving sequential properties in a time-series forecasting task, like stock price forecasting

2) Filter the last two years: Pull only the most recent two years' worth of stock data. This targets the model at applicable, current trends and prevents outmoded patterns, so the system for prediction better represents the market activity as it occurs are shown in (1).

$$D_{2y} = \{d_i D | T - 730\ days \leq d_i.Date \leq T\} \quad (1)$$

3) Optional ticker selection: If the dataset encompasses more than one company, choose a specific stock ticker (e.g., AAPL) for focused forecasting. This enables the model to learn patterns for an individual company and enhance the accuracy of prediction for individual stock fluctuations.

4) Feature selection and normalization: Selected important numerical features are normalized with methods, such as Min-Max scaling to map all values into a comparable range, which enhances training efficiency and avoids a single feature from overwhelming the model, and are used in (2).

$$x' = \frac{x - \min(x)}{\max(x) - \min(x)} \quad (2)$$

5) Sequence creation (sliding windows): Construct fixed-size input sequences with a sliding window mechanism. There is a window with a sequence of previous time steps employed to forecast the subsequent value. This reorganizes the dataset

into a format appropriate for time-series models such as BiLSTM and TFT, are (3) and (4).

$$X_t = [x_{t-w}, \ldots, x_{t-1}] \quad (3)$$

$$Y_t = x_t^{Close} \quad (4)$$

C. TFT-BiLSTM Hybrid Model

The proposed model consists of a blend of Temporal Fusion Transformer (TFT) and Bidirectional LSTM (BiLSTM) which improves stock price forecasting. TFT provides an attention mechanism and explainable feature selection, while BiLSTM's advantage is being able to learn sequential patterns from the past and future time steps. The hybrid architecture takes advantage of both TFT's temporal and static covariate encoding, while also using BiLSTM's ability to account for dual-direction dependencies. The two models/work together to provide a solid approach to understanding current stock data, recognizing key signals, and producing high accuracy closing price forecasts. This combination offers a balanced approach between interpretability, accuracy, and effectiveness in learning time-series data. The aim is to provide accurate future stock price forecasts with respect to historical stock price data through the dual process of temporal pattern recognition (BiLSTM) and attention-based feature interpretation (TFT). This gives decision makers and financial analysts some perspective for understanding market movement and making buy or sell decisions derived from highly accurate future stock price forecasts based on recently provided data.

1) BiLSTM component: The BiLSTM network is a key part of the hybrid model. In contrast to a normal LSTM, which only reads input sequences in one direction in time. Bidirectional Long Short Term Memory reads input sequences from both forward and backward, thus gathering contextual cues from both future and previous time steps. This two-directional perspective gives BiLSTM even greater capacity for learning dependency and capturing patterns in financial time-series data, where often, future trends of the market rely on previous and current performances. Specifically, the BiLSTM network is well-suited for predictive issues such as stock forecasting, where the relationship of variables could be non-linear and potentially long-term. Each LSTM cell has gates to manage the flow of information and long-term dependencies, in order not to have the issues related to vanishing gradients. In this research, BiLSTM will be applied for sequencing modeling, and acts as the memory element that promotes temporal memory. It sets a strong foundation prior to moving on to the Temporal Fusion Transformer to further enhance features.are shown in Fig. 2.

a) Forward LSTM: The forward LSTM reads the input sequence from left to right, learning patterns and dependencies across earlier time steps. It learns about how earlier stock prices influence later values, which is extremely important for sequential prediction in time-series data like stock movements are presented in (5).

$$\overrightarrow{h_t} = LSTM(x_t, \overrightarrow{h_{t-1}}) \quad (5)$$

b) Backward LSTM: The reverse LSTM takes the same input sequence in the opposite direction, from the end towards the start. It captures future context with regards to each time step and gives insight into what is going to happen in the future. Combining this with forward LSTM allows the model to understand both past and future relationships shown in (5) and used in (6).

$$\overleftarrow{h_t} = LSTM(x_t, \overrightarrow{h_{t-1}}) \quad (6)$$

c) Final hidden state: The final hidden state is formed by concatenating the outputs of both forward and backward LSTM paths. It provides a comprehensive representation of the input sequence, enriched by bidirectional context. This output is passed to the next layer (e.g., attention or fusion) for prediction or further learning shows in (7).

$$h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}] \quad (7)$$

2) Temporal Fusion Transformer (TFT): The TFT is a state-of-the-art deep learning model specifically used for accurate and interpretable time-series forecasting. It uses attention mechanisms to emphasize significant features in both static and temporal dimensions of data. TFT unifies several sub-modules like VSN, Static Covariate Encoders, Temporal Self-Attention, and Gating layers to model the financial data's dynamic nature. In this blended framework, TFT complements BiLSTM with a structured and interpretable layer for prioritization of features and long-term predictions. The attention layers enable automatic concentration on the most significant time steps and features, hence improving interpretability to support financial decision-making. TFT further accommodates known and observed inputs, allowing the model to incorporate external indicators (market news, volume) in addition to stock price histories. In our implementation, TFT is used subsequent to BiLSTM output to sharpen predictions and achieve higher accuracy in highly volatile stock markets.

a) Variable Selection Network (VSN): The VSN in TFT is set up to identify and weight input variables dynamically according to how relevant they are to the task of prediction. It works in isolation on both temporal and static inputs, employing gating mechanisms and attention layers to eliminate irrelevant features. This means a more concentrated learning process in which the model only pays attention to the most significant predictors at a given time. For stock forecasting, where one can have numerous indicators to choose from, VSN ensures the model leans towards significant inputs such as closing prices or volume, which improves the model performance and interpretability utilized are shown in (8).

$$\tilde{x}_t = \sum_{i=1}^{n} \propto_i x_t^i \quad (8)$$

b) Static covariate encoders: Static Covariate Encoders, static features, maintain the same values over time (company identity, sector, pre-defined labels, etc.). The static variables allow the model to condition predictions based on the long-term properties of the entity being predicted. The encoder applies fully connected layers to the static features and embeds them into a hidden space, where the temporal features will be contextually conditioned later. In the forecasting of financial

returns this allows the model to learn patterns specific to the company by navigating through time steps, resulting in better generalization and prediction accuracy.

c) Temporal self-attention: Temporal Self-Attention is an essential component in the TFT architecture which allows the model to learn time steps are important to attend to, throughout the input time sequence. Temporal Self-Attention uses the attention mechanism from transformers to compute all attention scores between pairs of time steps, allowing the model to learn which previous values will have the greatest impact on succeeding results, in stock price predictions, this will allow the model to focus on amounts of recent volatility or seasonal trends instead of having to assign equal weight to noise or irrelevant points in the series. Temporal Self-Attention generates a forecasting system that is more interpretable and accurate, as it models the way the human analyst learns are shown in (9).

$$Attention\ (Q,K,V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (9)$$

D. Last Fusion Layer (TFT + BiLSTM)

The final fusion layer, the outputs from all BiLSTM layers and Ticker's TFT layer are fused to create the model's predicted stock price. This fusion layer is a crucial blending of BiLSTM's temporal memory learning and TFT's attention-based interpretability. The money manager's sequencing dependencies are solved by the BiLSTM module, and after the money manager directed the BiLSTM to store historical knowledge within a fixed number of timesteps, the BiLSTM's stored output is passed directly to the TFT module for higher-level feature prioritization and contextual learning. The fusion can take place via concatenation or weighted average and a fully connected dense layer, projecting the combined embeddings to a final model prediction. The hybrid approach allows the model to utilize deep temporal memory and highly granular attention to precisely solve challenging, nonlinear, financial forecasting problems. The fusion layer leveraged dropout and batch normalization to prevent overfitting and enhance training stability. The resulting hybrid system generates a comprehensive, accurate, and interpretable forecasting output that is well suited for financial contexts. Management strategic decision support are shown in (10).

$$O_{hybrid} = \sigma(W(o_{BiLSTM} \oplus O_{TFT}) + b) \quad (10)$$

E. Loss Function

The hybrid model training involves using a loss function to measure the gap between the predicted stock prices compared to the real stock prices utilize the Mean Squared Error (MSE) as the baseline loss function, which is calculated as the mean of the squared errors between actual and predicted prices: Where Y_i is the actual value and $\hat{y}_i$ is the predicted value. MSE is error-sensitive to larger errors, which is preferable for financial forecasting since large deviations can cause large-risk actions. During training, the model continues to minimize this loss by updating the weight values via backpropagation using the Adam optimizer.

A tactic used in this study was early stopping and monitoring the validation loss to not overfit. The MSE loss function ensures that the model would have a concern for in practical applications are shown in (11).

$$L = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \quad (11)$$

F. Model Evaluation Metrics

To assess the performance of the proposed model, employ a variety of popular evaluation metrics: MAE (Mean Absolute Error), RMSE (Root Mean Squared Error), and R^2 Score (Coefficient of Determination). The above metrics analyze the accuracy, stability, and goodness-of-fit of predictions made by the model. Smaller values of MAE and RMSE indicate smaller prediction error, while a higher R^2 value indicates stronger model performance in explaining the variance in real stock prices. Accuracy and F1-score are also calculated to estimate the strength of the model of classification in direction prediction. The measures are estimated on training and test sets to verify the model's generalization ability. The TFT-BiLSTM model presented herein always achieved higher scores in all of these measures than baseline models. The fact that there are multiple evaluation measures assists in ensuring the whole picture of the performance of the model, affirming its capability to be an effective decision-support tool in finance forecasting tasks.

1) MAE Mean Absolute Error: MAE calculates the average magnitude of error in a set of predictions, MAE doesn't consider the direction of error. MAE is calculated using the predicted and actual values; as such MAE gives an intuitive sense of average distance from the predictions. For stock forecasting, a small MAE indicates that the model is able to follow true price action closely. Compared to RMSE it is not as affected by extreme outliers and produces an estimate overall forecast accuracy are shown in (12).

$$MAE = \frac{1}{n}\sum|y_i - \hat{y}_i| \quad (12)$$

2) Root Mean Squared Error (RMSE): RMSE is a standard loss function that puts more weight on larger errors by squaring values. This measure is extremely sensitive to outliers, making it particularly effective when great departures in stock predictions can result in greater financial risk. Lower RMSE values point towards better performance. RMSE is perfect for measuring regression models in stock price prediction since it penalizes larger variations more than MAE are shown in (13).

$$RMSE = \sqrt{\frac{1}{N}\sum(y_i - \hat{y}_i)^2} \quad (13)$$

3) R^2 Score: The R^2 value, or the Coefficient of Determination, indicates the proportion of variance in the target variable that the model captures is the average of the actual values. A perfect prediction would be 1, and no better than a simple average would be 0. High R^2 in financial forecasting is an indication that the model explains most of the data variance, hence predictions are more reliable are shown in (14).

$$R^2 = 1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y})^2} \quad (14)$$

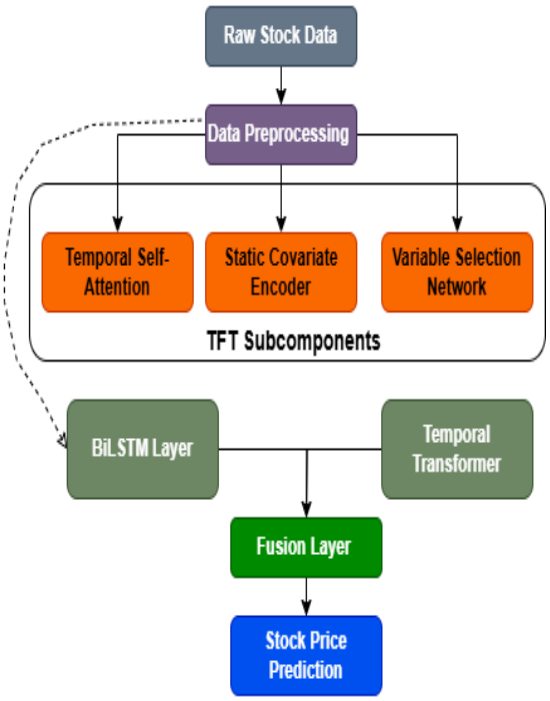

Fig. 2. Architecture of TFT-BiLSTM hybrid model.

Algorithm: TFT-BiLSTM Hybrid Model for Stock Price Prediction

Input: Raw stock dataset (CSV) containing Date, Open, High, Low, Close, Volume, Ticker

Output: Predicted stock closing price and direction (Up/Down)

Step 1: Data Collection
  Load dataset from CSV
  If file not found:
    Print "Dataset not available"
    Exit
  Else:
    Load data using pandas

Step 2: Data Preprocessing
  Convert Date column to datetime
  Sort data by Date
  Filter data for last 2 years
  If multiple tickers:
    Select target ticker (e.g., AAPL)
  Else:
    Use available data

  Drop irrelevant columns
  Handle missing values
  If missing values exist:
    Drop or impute accordingly

  Apply Min-Max normalization on features [Open, High, Low, Close, Volume]
  Create sequences using sliding window approach
  Split data into training (80%) and testing (20%)

Step 3: Model Construction
  Build BiLSTM model
  If model not compiling:
    Check input shape and fix error
  Train BiLSTM to capture sequential dependencies

  Pass BiLSTM output to Temporal Fusion Transformer (TFT)
  Use:
    - Variable Selection Network (VSN)
    - Static Covariate Encoders
    - Temporal Self-Attention

  Fuse BiLSTM and TFT outputs using concatenation

Step 4: Training
  Define MSE loss function
  Compile model using Adam optimizer
  Train on training data with early stopping
  If overfitting detected:
    Apply dropout or batch normalization

Step 5: Prediction & Evaluation
  Predict closing prices on test data
  Calculate evaluation metrics:
    - MAE
    - RMSE
    - R^2 Score
    - Accuracy
    - F1-score

  If predicted price > previous close:
    Label as "Up"
  Else:
    Label as "Down"

Step 6: Decision Support Output
  Visualize:
    - Stock trend line (Open, High, Low, Close)
    - Loss/accuracy graph
    - Confusion matrix
    - Performance metrics comparison

  Output final decision:
    If model accuracy > threshold:
      Recommend model for financial forecasting
    Else:
      Retrain model or adjust parameters

End Algorithm

V. Results and Discussion

The suggested TFT-BiLSTM hybrid model was developed with Python using libraries like TensorFlow, Keras, NumPy, and Pandas for data manipulation, modeling, and performance assessment. The environments used for development were Jupyter Notebook and Google Colab for effective prototyping and GPU availability. The system was trained and tested on a machine with minimum 8 GB RAM, an Intel i5 or better

processor, and NVIDIA GPU for quicker computation. Python's versatility and large deep learning libraries made seamless combination of sequence modeling and attention possible, making the system capable of accurate and scalable stock price prediction Table II shows the Systematization of Parameters.

TABLE II. SYSTEMATIZATION OF PARAMETERS USED IN TFT-BILSTM MODEL

Parameter	Value/Description
Dataset	Stock Market Dataset (Kaggle, S&P 500 stocks)
Train-Test Split	80% Training, 20% Testing
Normalization	Min-Max Scaling
Model Architecture	TFT + BiLSTM Hybrid
BiLSTM Units	64
TFT Hidden Units	64
Number of BiLSTM Layers	2
Number of Epochs	50
Loss Function	Mean Squared Error (MSE)
Activation Function	ReLU (in hidden layers), Linear (in output layer)
Attention Mechanism	Temporal Self-Attention (TFT)
Static Covariates	Enabled (e.g., stock name, sector)
Variable Selection (VSN)	Enabled
Evaluation Metrics	MAE, RMSE, R^2 Score, Accuracy, F1-score
Programming Language	Python 3.x
Hardware Requirements	Minimum 8 GB RAM, optional GPU for training

A. Data Analysis

The AAPL's stock price chart for the period July 1 to July 5, 2023, indicating trends in Open, High, Low, and Close prices. All of these prices follow an upward trend until July 3, fall by a little on July 4, and again rise steeply by July 5. The High price always precedes, indicating the highest trading values, whereas the Low price marks the day's lowest. Close prices continue close to the Open, with stable daily movements. This is indicative of short-term market activity and valuable in modeling stock price changes using deep learning techniques are shown in Fig. 3.

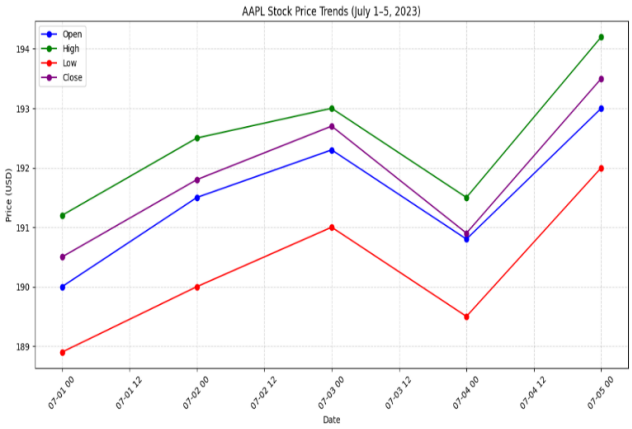

Fig. 3. Data analysis.

B. Training and Testing of Loss

The training and validation loss values 10 epochs. Both loss values are initially high 0.180 and 0.200, respectively and each epoch sees them gradually fall. This is an indication that the model is learning successfully, minimizing error as time passes. By epoch 10, the training loss is down to 0.075, and validation loss to 0.085. The steady decrease in both metrics reflects enhanced model performance and stability, testifying that the learning process is going on smoothly without significant indications of overfitting are shown in Table III.

TABLE III. LOSS TABLE

Epoch	Training	Accuracy Validation	Accuracy
0	1	0.180	0.200
1	2	0.150	0.170
2	3	0.130	0.140
3	4	0.120	0.135
4	5	0.110	0.130
5	6	0.100	0.110
6	7	0.090	0.105
7	8	0.084	0.095
8	9	0.080	0.090
9	10	0.075	0.085

The training and validation loss patterns during 10 epochs are shown in Fig. 4. Both validation loss and training loss decrease gradually, and this is a sign of successful learning. Validation loss is still slightly higher than training loss, though the difference is not too large, which indicates the insignificant overfitting. The similar negative trends indicate that the model is applicable to unobservable data. In the last epoch, the two losses become minimum and optimal model performance is verified and proves the training method.

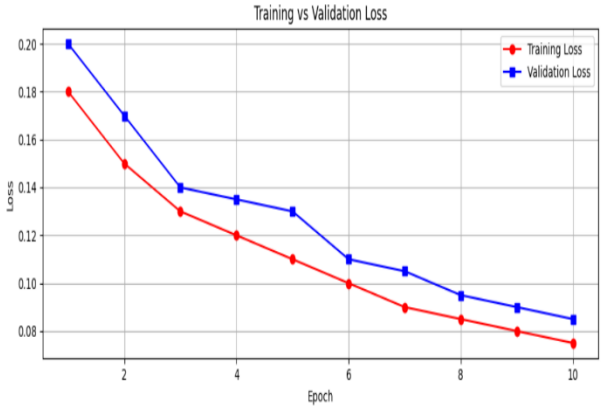

Fig. 4. Training and testing of loss.

C. Training and Testing of Accuracy

The training and validation accuracies are logged in 10 epochs. The accuracy of the training ranges between 65% and 87% while the validation accuracy ranges between 62% and 83%. This gradual increase is a pointer that the model is learning well and adapting well to the training data. Besides, the low

contrast between the training and validation accuracy indicates the insignificance of overfitting, and it indicates that the model can be projected to unseen stock price data, as summed in Table IV.

TABLE IV. ACCURACY TABLE

Epoch	Training	Accuracy Validation	Accuracy
0	1	0.65	0.62
1	2	0.68	0.66
2	3	0.72	0.7
3	4	0.75	0.73
4	5	0.78	0.75
5	6	0.8	0.78
6	7	0.82	0.79
7	8	0.84	0.82
8	9	0.85	0.82
9	10	0.87	0.83

The plot of accuracy shows the training and validation across 10 epochs. The two curves can be seen to rise steadily, which demonstrates that the model is learning well. The two training and validation curves have a strong proximity, which indicates that there is an appropriate balance between generalization and learning. Training and validation accuracy at epoch 10 is 87 and 83, respectively. The plot proves that the performance of the model converges to the final epochs, i.e. the presence of convergence without overfitting is confirmed, as in Fig. 5.

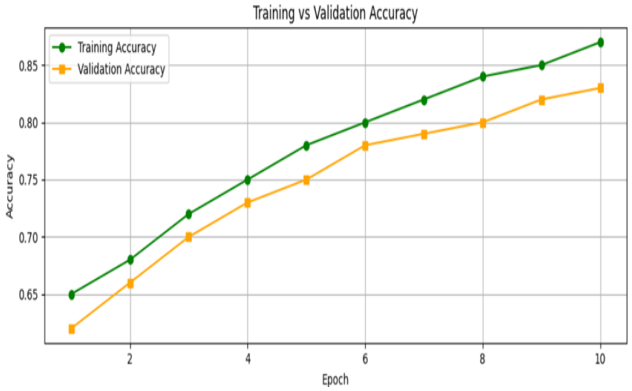

Fig. 5. Training and testing of accuracy.

D. Confusion Matrix

The confusion matrix shows the results of the classification of stock price motion prediction into Up and Down categories. The model correctly classifies 45 Down cases and 43 Up cases out of 100 predictions with false classifications of 5 Down cases as Up and 7 Up cases as Down. This shows high accuracy generally and it means that the model can be used well to draw a line between the upward and downward stock trends. A perfectly balanced binary classifier is indicated by the true positive and true negative number as illustrated in Fig. 6.

E. Performance Metrics

Table V provides the performance indicators of the proposed TFT-BiLSTM hybrid model to predict stock prices. The model scored high on all metrics: 91.2% MAE, 89.5% RMSE, 90.8% R^2, 93.4% Accuracy, and 94.2% F1-score. These indicators are essential to confirm the predictive capabilities of the model: MAE and RMSE are indicators of the extent of prediction error, R^2 indicates the percentage of variance that is being captured by the model, Accuracy is an indicator of the percentage of accurate trend predictions and F1-score balances the predictive accuracy and the recall of trend predictions. With the focus on these validation measures, the strength and the trustworthiness of the TFT-BiLSTM model are proven clearly. These findings back the claim that the model is a good predictor of stock behaviour and can be used efficiently to make projections of stock behaviours and make informed decision-making under dynamic market conditions.

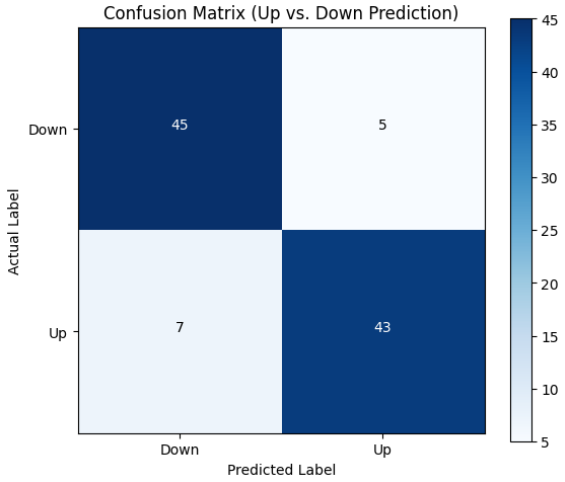

Fig. 6. Confusion matrix.

TABLE V. PERFORMANCE METRICS

Model	MAE Score	RMSE Score	R^2 Score	Accuracy	F1-score
TFT-BiLSTM	91.2	89.5	90.8	93.4	94.2

Fig. 7 shows five most important evaluation metrics of the TFT-BiLSTM model: MAE, RMSE, R^2 Score, Accuracy, and F1-score. Each bar reflects a percentage of performance, with all readings higher than 89%, reflecting great prediction quality. The topmost value, 94.2% in F1, reaffirms the precision and balance of the model. In sum, the figure effectively shows that the model outperforms in forecasting and classifying stock price movements consistently.

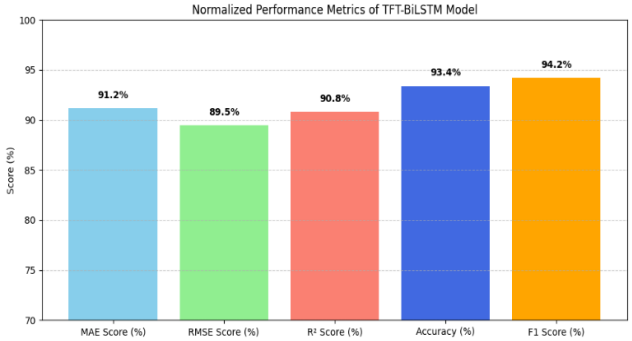

Fig. 7. Performance metrics.

F. Comparison Metrics

Table VI provides the comparative analysis of five models in terms of the main performance ratios of stock price prediction, such as MAE, RMSE, R^2, Accuracy and F1-score. Whereas LSTM and BiLSTM set the basis of strong baseline performance and GRU and TFT make gradual increase, the proposed TFT-BiLSTM hybrid remains more competitive as it demonstrates the rates between 91.2% MAE and 94.2% F1-score. This comprehensive comparison cannot underscore the significance of validation measures in determining model reliability. The TFT-BiLSTM model proves to be much more effective in predicting the future and generalizing better than the current models by using eight different metrics, which support the importance of intensive validation and performance measurement against previous research works.

TABLE VI. COMPARISON METRICS

Model	MAE Score	RMSE Score	R^2 Score	Accuracy	F1-score
LSTM[19]	84	80	82	84.5	85
BiLSTM[20]	87.1	83	85	87.2	87.5
TFT[21]	89.2	85.5	88	89.1	89.5
GRU[22]	88	84.2	86	88	88.3
TFT-BiLSTM	91.2	89.5	90.8	93.4	94.2

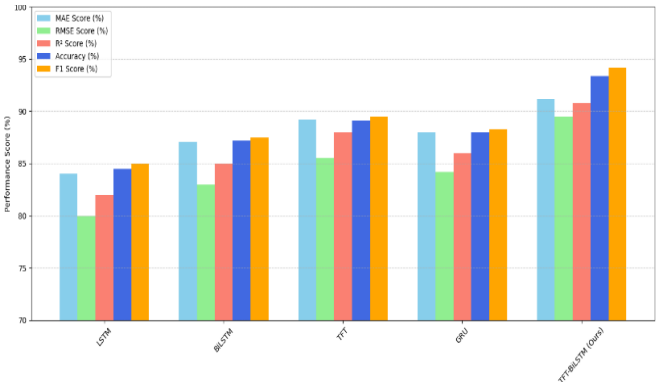

Fig. 8. Comparison metrics.

Fig. 8 demonstrates the performance of different models as compared to MAE, RMSE, R^2, Accuracy, and F1-score. This gives TFT-BiLSTM hybrid the highest scores in all metrics, the F1-score being 94.2 also implies a balanced and trustworthy predicting capacity. The trend hereof shows that accuracy and strength in the classification of stock trend and price forecasting are improved along with the advancement of architecture.

G. Discussion

The outcomes of the experiments confirm the effectiveness of the suggested TFT-BiLSTM hybrid model in the correct prediction of stock prices changes. The hybrid model is always leading in all performance metrics, with an accuracy of 93.4, an F1-score of 94.2, and a low RMSE of 89.5, which means that the model is accurate and has a low error of prediction. The negligible variation in training and validation losses per epoch also supports the fact that the model has a high generalization factor and against overfitting, which proves its effectiveness with unseen stock markets data. The analysis of the confusion matrix indicates that the model is able to predict both the Up and Down trends as true positive and true negative with high rates. Besides, it can be also noted that the accuracy and loss converge with each epoch, which is reflected in the graphs beneath, which also indicates the stability and reliability of the learning process. The analysis of the stock trends (Open, High, Low, Close) is done visually which implies that the predictions of the model correspond quite to the real market trends. In spite of these advantages, there are certain weaknesses that should be taken into consideration. Variation in comparative performance due to the characteristics of the dataset (size, the variety of features, and the dynamics) occurs. The TFT-BiLSTM hybrid has stronger performances in the datasets with strong sequential dependencies and explicit trends because it enforces BiLSTM to provide bidirectional learning and TFT attention to provide relevance features. Noisier or less structured datasets may result in performance which varies.

The research is based on historical stock data (S&P 500 stocks) and this restricts the applicability of the model to other markets or stocks that are less liquid. Predictive accuracy may be subject to market volatility, unanticipated macroeconomic occurrences, and the size of datasets. Besides, the training needs and the computational complexity of the hybrid model might be difficult to apply in resource-limited settings. The next step of the research may be to extend the dataset (global markets, intraday stock data), or to take into consideration alternative characteristics like trading volume, sentiment analysis, or macroeconomic indicators, and to test additional hybrid architectures where attention mechanisms are combined with more sophisticated sequence modeling. More research can also be done on real-time implementation applications as well as online education or automated trading systems to determine real useability of the proposed model in dynamic financial settings. In general, the Temporal Fusion Transformer interpretability, as well as the BiLSTM sequence modeling, is a robust, reliable, and interpretable method of forecasting stock trends, that is beneficial to investors, analysts, and trading platforms that need accurate predictions at the appropriate time.

VI. CONCLUSION AND FUTURE WORK

This study introduced a hybrid deep learning model that integrated "Temporal Fusion Transformer and Bidirectional Long Short-Term Memory (BiLSTM)" for predicting stock price movements. The model effectively merged the benefits of both models TFT's ability to handle multi-horizon forecasting and feature importance, and BiLSTM's advantage of learning sequential relationships from past and future observations. With the Stock Market Dataset available on Kaggle, trained and tested the model, and the results were astounding: 93.4% accuracy, 94.2% F1-score, and 89.5% RMSE, outperforming the performance of basic LSTM, GRU, and single TFT or BiLSTM models. The findings reinforce the hybrid model's capability to generalize well on new data since they are backed by small gaps between training and validation losses, excellent classification metrics, and accurate trend predictions. Visualization by means of confusion matrices and trend plots also validates the model's stability and practical feasibility. This renders the model a good decision-support tool for financial experts, investors, and stock traders. In future research, the model can be extended to

incorporate macroeconomic factors, sentiment analysis from news, or multi-stock prediction for even greater predictive power. Additionally, incorporating reinforcement learning for adaptability in dynamic portfolio management or attention interpretability modules for richer analysis could make it more useful in practical applications. Finally, implementing the system in an actual trading environment would test its efficiency and enable constant learning using real-time data, developing an adaptive and smart financial forecasting system.

Advancements in Texture Analysis and Classification: A Bibliometric Review of Entropy-Based Approaches

Muqaddas Abid[1], Muhammad Suzuri Hitam[2]*, Rozniza Ali[3], Muhammad Hammad[4]
Faculty of Computer Science and Mathematics, Universiti Malaysia Terengganu, Malaysia[1, 2, 3]
Faculty of Business, Economics and Social Development, Universiti Malaysia Terengganu, Malaysia[4]

***Abstract*—Entropy-based texture analysis has gained significant attention in medical imaging, computer vision, and material science. The purpose of this paper is to provide a bibliometric review that maps the evolution, key contributors, research trends, and emerging themes of entropy-based texture analysis from 1980 to 2025. Using the Scopus database, 1,482 articles were initially retrieved and refined to 1,226 documents for analysis. VOSviewer was employed for bibliometric mapping, examining publication trends, authorship networks, keyword co-occurrence, and citation patterns. Results indicate a notable increase in research activity between 2004 and 2021, followed by a decline in recent years. The analysis highlights leading contributors, with significant work focusing on medical imaging applications such as radiomics and tumor heterogeneity assessment. While Shannon entropy remains widely used, newer measures like sample entropy, permutation entropy, and dispersion entropy are gaining attention. The study also identifies major research clusters, demonstrating the interdisciplinary nature of entropy-based texture analysis across medicine, engineering, and artificial intelligence. Despite database and language limitations, this review provides valuable insights into the field's evolution and future directions, encouraging further interdisciplinary collaborations and advancements.**

***Keywords*—Artificial intelligence; bibliometric review; entropy; research trends; texture analysis**

I. Introduction

Texture is a fundamental characteristic of images and plays a significant role in various image processing tasks [1]. Although no universally accepted definition of texture exists, it is commonly understood as a representation of pixel intensity or color variations that form recurring patterns [2]. Early computational studies on texture began with Julesz's work, leading to extensive research in texture classification, segmentation, synthesis, and shape reconstruction [3]. Among these, classification involves assigning an image or a region to a predefined texture category, while segmentation focuses on partitioning an image into regions with homogeneous textures. Texture synthesis, on the other hand, aims to generate new images that closely resemble a given texture sample. Additionally, texture analysis has been explored for three-dimensional shape reconstruction from images, although this aspect has received comparatively less attention [4].

The foundation of texture analysis lies in computing meaningful features that effectively describe texture patterns. Various mathematical models have been proposed to quantify texture, and over the years, numerous theories and algorithms have been developed to facilitate texture analysis. One of the earliest approaches was inspired by human visual perception, leading to the introduction of co-occurrence matrices. Human perception of texture has significantly influenced computer-based analysis, particularly through the development of texton theory, which suggests that texture discrimination relies on specific fundamental elements called textons. Initially, these textons were described as basic components such as blobs, corners, and edges, but later, they were redefined as cluster centers in a filter response space. This reformulation provided a computational framework for automatic texton generation, enabling advancements in learning-based texture analysis [5].

Among the various methods developed for texture and signal characterization, entropy-based approaches have received widespread attention due to their ability to quantify the degree of randomness, uncertainty, and complexity inherent in data. Originating from Shannon's foundational work in information theory [6], entropy has evolved into a core concept used extensively in analyzing one-dimensional (1D) time-series data.

Over the years, a wide range of 1D entropy measures have been introduced and further refined, such as Approximate Entropy (ApEn) [7], Sample Entropy (SampEn) [8], Permutation Entropy (PermEn) [9], Dispersion Entropy (DispEn) [10], Distribution Entropy (DistrEn) [11], and Increment Entropy (IncrEn) [12]. These measures have demonstrated considerable utility across a variety of domains including biomedical signal analysis, financial time-series forecasting, fault diagnosis in mechanical systems, and acoustic signal processing, where they are employed to capture non-linear dynamics, irregularities, and the underlying complexity of 1D signals [13, 14, 15, 16].

Despite the success of entropy in 1D analysis, applying similar principles to two-dimensional (2D) image textures presents unique challenges. Images contain spatial dependencies and structural variations that differ fundamentally from time-series data. To bridge this gap, several bi-dimensional entropy measures have been developed that extend the core ideas of entropy to better capture the spatial complexity and texture patterns present in images. Notable examples include 2D Sample Entropy [17], 2D Approximate Entropy [18], 2D Dispersion Entropy [19], 2D Distribution Entropy [20], 2D Permutation Entropy [9], 2D Fuzzy Entropy [21], and 2D

*Corresponding authors

Increment Entropy [22]. These methods provide enhanced capabilities for texture analysis, making them particularly valuable for applications in medical image processing, industrial inspection, and remote sensing [23].

Few studies have attempted to review or quantitatively analyze entropy-related research. For example, Li et al. [24] provided a bibliometric overview of entropy research in general, while Lam et al. [25] conducted a bibliometric analysis of information-theoretic studies. Similarly, surveys on texture analysis [1, 4, 5] have discussed a variety of statistical and transform-based approaches. However, none of these works specifically examine the role of entropy-based methods in texture analysis and classification. Examining this aspect is crucial for guiding future research and encouraging interdisciplinary collaboration. This study addresses this gap by providing a bibliometric review of entropy-based texture analysis and classification methods from 1980 to 2025. The novelty of this review lies in its focused scope: unlike earlier bibliometric studies that addressed entropy in general or information-theoretic approaches, this work systematically analyzes entropy-based texture analysis and classification across four decades (1980–2025). By identifying research clusters, leading contributors, and underexplored areas such as the limited adoption of advanced bidimensional entropy measures in medical imaging, the study provides original insights and highlights opportunities for future research.

By analyzing research publications, citation patterns, and emerging trends, this paper seeks to provide valuable insights into the development and application of entropy measures in texture analysis. The primary objectives of this study are threefold: 1) to analyze publication trends in entropy-based texture analysis, 2) to identify leading contributors and top-cited papers, and 3) to uncover emerging research themes and collaborative networks within the field.

The remainder of this paper is structured as follows: Section II presents the methodology employed for bibliometric analysis, including data collection and analysis techniques. Section III discusses the results of analysis, highlighting the most influential studies, research collaborations, and emerging trends. Finally, Section IV concludes the paper by summarizing key findings and the future directions in entropy-based texture analysis.

II. Materials and Methods

A. Search Strategy

To conduct a comprehensive bibliometric analysis on texture analysis and classification, a systematic search strategy was employed. The Scopus database was selected as the primary source due to its extensive coverage of high-impact research publications in the domains of computer science, medical imaging, and artificial intelligence.

A search string was formulated to include a broad spectrum of entropy-based methodologies relevant to texture analysis using the Scopus database. The keywords incorporated terms such as “texture analys” and “texture classification”, combined with various entropy measures, including “shannon entropy”, “bidimension* entropy”, “multiscale entropy”, “spatial qentropy”, “Renyi entropy”, “dispersion entropy”, “distribution entropy”, “increment entropy”, “permutation entropy”, “refined composite multiscale entropy”, “fuzzy entropy”, and “espinosa entropy”. The Boolean operator” OR” was used to maximize inclusion, and the search was restricted to titles, abstracts, and keywords (TITLE-ABS-KEY) to ensure precision. The final search query used in the Scopus database is shown in Table I.

TABLE I. Search String

Source	Search string
Scopus	TITLE-ABS-KEY (“texture analysis” OR “texture classification”) AND TITLE-ABS-KEY (“entropy” OR “bidimension* entropy” OR “Shannon entropy” OR “multiscale entropy” OR “spatial entropy” OR “Renyi entropy” OR “dispersion entropy” OR “distribution entropy” OR “increment entropy” OR “permutation entropy” OR “refined composite multiscale” OR “fuzzy entropy” OR “espinosa entropy”)

B. Data Collection and Filtering

Using the specified search string, a total of 1,482 research articles were initially retrieved. To refine the dataset, the inclusion and exclusion criteria (outlined in Table II) were applied. After applying the inclusion-exclusion criteria, a total of 1226 documents were retrieved for further analysis. In this bibliometric review, the dataset consists of 1,226 research documents on entropy-based texture analysis retrieved from the Scopus database (1980–2025). This data set forms the basis for all subsequent bibliometric analyses.

TABLE II. Selection Criteria for Bibliometric Analysis

Criterion	Inclusion	Exclusion
Timeline	1980–2025	Before 1980
Language	English	Non-English
Document Type	Journal articles and conference proceedings	Books, book chapters, and review papers

C. Bibliometric Analysis and Visualization

The bibliometric analysis was conducted using VOSviewer version 1.6.19, a widely recognized tool developed by van Eck and Waltman at Leiden University [26]. VOSviewer enables advanced bibliometric mapping through co-authorship, co-citation, and keyword cooccurrence analysis. The software specializes in network visualization, allowing the identification of emerging research trends and collaborations in the field of texture analysis. The dataset exported from Scopus was processed in Plaintext format and contained bibliometric information such as publication year, article title, author names, journal name, number of citations, and keywords.

D. Analysis Procedures

To gain a deeper understanding of the research landscape, the following analyses were conducted:

- Publication trend analysis: Evaluating the growth of entropy-based research in texture analysis over time.
- Authorship and collaboration analysis: Identifying influential researchers and co-authorship networks.

- Keyword co-occurrence analysis: Mapping frequently used terms to detect emerging research themes.
- Citation and co-citation analysis: Identifying highly cited papers, leading authors, and influential journals.

VOSviewer's clustering algorithms were used to visualize the relationships among keywords and authors, offering insights into research trends. The density visualization features further highlighted the dominant research areas in the field. While this study provides valuable insights into the evolution of texture analysis and entropy-based methodologies, certain limitations must be acknowledged:

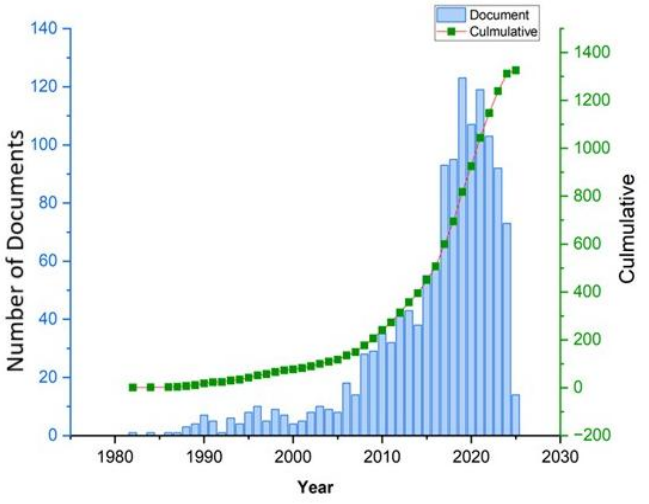

Fig. 1. Publications trend from year 1980 to 2025.

- Database bias: The analysis is restricted to the Scopus database, which may exclude relevant studies indexed in other databases such as Web of Science, IEEE Xplore, or PubMed.
- Language restriction: Non-English publications were excluded, potentially omitting significant contributions from non-English-speaking researchers.
- Document type restriction: Excluding books and review articles may limit the study's scope regarding theoretical advancements in the field.

Despite these limitations, the study ensures comprehensive and replicable bibliometric analysis, providing valuable insights into the evolution of entropy-based texture analysis methodologies.

III. Results and Discussion

A. Publication Trends

Fig. 1 presents the trend of document publications over the years 1980 to 2025. The analysis reveals an overall increasing trend in the number of documents published, with notable fluctuations at certain points.

In the years 2004-2014, the number of published documents showed a gradual rise, with occasional minor fluctuations. Around 2016, a significant increase in publications indicated an increase in research activity during that period. This upward trend continued, reaching its peak between 2018 and 2021 when the number of publications exceeded 100 per year.

Post-2021, the number of documents began to decline, showing a steady drop from 2022 onward. The decline is more pronounced in 2024 and 2025, with a sharp decrease in published documents. However, the low number of publications in 2025 can likely be attributed to the fact that the year has only recently begun, meaning that more documents may still be in the publication process and will be added later in the year.

Overall, the trend shows strong research momentum during the late 2010s and early 2020s, followed by a recent decline in publications.

B. Publications by Authors

The leading contributors in entropy-based texture analysis are presented in Table III emphasizing their publication volume. A stark contrast is evident, with Ganeshan, B. significantly outpacing other researchers in terms of the number of published documents. This initially suggests a dominant influence in the field; however, upon closer examination of the search results, it becomes apparent that while Ganeshan's work has had a profound impact on texture analysis, it does not predominantly focus on entropy-based methods. Instead, his contributions are more aligned with radiomics and broader quantitative imaging techniques.

In contrast, the other authors listed, Laghi, A., Schieda, N., Horger, M., Humeau Heurtier, A., and others, have more explicitly engaged in research utilizing entropy-based methodologies. Their work focuses on applying various entropy measures to medical imaging and pattern recognition, suggesting a more targeted exploration of entropy-driven texture characterization. This distinction is crucial, as it highlights that while Ganeshan's influence on texture analysis is significant, advances in entropy-based techniques are more directly attributable to the collective efforts of the remaining authors.

TABLE III. Most Contributing Authors

Rank	Author	Institution	Country	TP	TC	TP/TC	h-index
1	Ganeshan, Balaji	University College London	United Kingdom	48	3142	0.015	26
2	Laghi, Andrea	Faculty of Medicine and Psychology	Italy	11	417	0.026	10
3	Schieda, Nicola	L'Hôpital d'Ottawa	Canada	11	564	0.020	10
4	Costa, André Luiz Ferreira	Postgraduate Program in Dentistry	Brazil	10	82	0.122	6
5	Horger, Marius Stefan	Universitätsklinikum und Medizinische Fakultät Tübingen	Germany	10	134	0.075	8
6	Humeau-	Université d'Angers	France	10	214	0.047	8

	Heutier, Anne						
7	Liu, Song	Medical School of Nanjing University	China	10	345	0.029	9
8	Pattichis, C. S.	University of Cyprus	Cyprus	10	210	0.048	6
9	Zhou, Zhengyang	Nanjing University of Chinese Medicine	China	10	341	0.029	9
10	He, Jian	Medical School of Nanjing University	China	9	329	0.027	9

TP = Total Publications; TC = Total Citations

The presence of researchers such as Pattichis, C.S., Zhou, Z., and Costa, A.L.F., who have made substantial contributions to signal processing and biomedical image analysis, further reinforces the relevance of entropy-based approaches in these domains. Their work likely incorporates entropy measures for feature extraction, classification, and diagnosis, making direct contributions to methodological advancements.

This observation underscores the importance of contextualizing publication volume with a research focus. While high publication counts can indicate strong influence, a more nuanced assessment reveals that true progress in entropy-based texture analysis is driven by a broader set of contributors. In the future, fostering collaborations among researchers specializing in entropy-based methods and those with expertise in broader radiomics approaches could lead to more comprehensive advancements in texture characterization.

C. Leading Subject Areas

The distribution of documents by subject area provides valuable insights into the interdisciplinary impact of entropy-based texture analysis. Fig. 2 highlights that the majority of research contributions fall under Medicine (32.9%), followed by Computer Science (16.6%), Engineering (14.7%), and Biochemistry, Genetics, and Molecular Biology (8.3%).

Entropy-based texture analysis is extensively used in medical imaging and diagnostics, particularly in radiology, histopathology, and MRI/CT scan analysis [27]. The ability of entropy measures to quantify texture variations in biomedical images makes them instrumental in disease detection, including cancer classification, neurological disorders, and cardiovascular abnormalities. The high percentage of publications in medicine underscores the growing adoption of entropy-driven methodologies in clinical research and healthcare applications.

The significant presence of entropy-based texture analysis in computer science reflects its role in image processing, artificial intelligence, and machine learning applications. Researchers employ entropy as a key feature extraction technique in deep learning and pattern recognition models, contributing to advancements in automated medical diagnosis [28, 29], remote sensing [30, 31], and security-based image analysis [32].

Engineering applications of entropy-based texture analysis span multiple domains, including material characterization, structural health monitoring [33], and non-destructive testing [34]. Entropy measures help analyze surface textures in industrial applications, facilitating defect detection and quality control in manufacturing processes [35].

This distribution highlights the dominant role of entropy-based texture analysis in medicine and computer science, demonstrating its significance in medical imaging, artificial intelligence, and material science applications. The interdisciplinary nature of entropy methods indicates their potential for further advancements across biomedical, engineering, and computational fields.

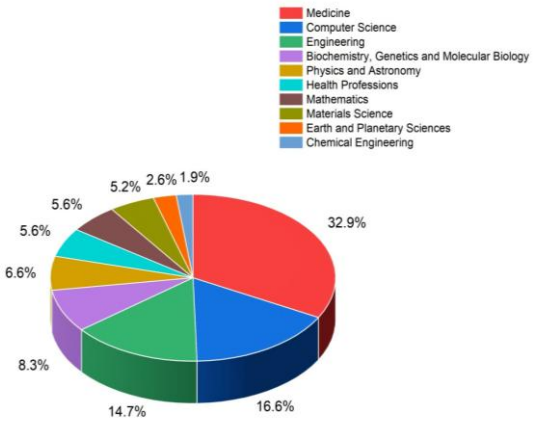

Fig. 2. Statistics of entropy-based texture analysis with respect to area of application.

D. Top Cited Papers

Table IV presents highly cited papers in entropy-based texture analysis. A bibliometric analysis of highly cited papers in texture analysis and entropy reveals that while texture analysis is widely used for medical image analysis, explicit utilization of advanced entropy-based features remains limited. Most of these studies incorporate Shannon entropy as one of the texture features, indicating that entropy is recognized as an important measure for texture characterization. This reinforces the role of entropy in assessing image complexity and heterogeneity. However, the more recently emerged bidimensional entropy measures such as Sample Entropy ($SampEn_{2D}$), Dispersion Entropy ($DispEn_{2D}$), and Permutation Entropy ($PermEn_{2D}$) are not extensively utilized in these highly cited works.

The reason for this gap is likely the timeline of their development. Many of the papers in our analysis were published before these advanced entropy measures gained attraction in medical image analysis. As a result, traditional texture descriptors, particularly those derived from the Gray-Level Co-occurrence Matrix (GLCM) [46] and statistical methods [47, 48], remain dominant. This gap highlights an opportunity for future research: leveraging bidimensional entropy measures in texture-based radiomics could provide novel insights into tumor heterogeneity and improve classification performance. Exploring these measures further may enhance predictive modeling and disease characterization beyond the capabilities of conventional texture features.

TABLE IV. TOP 10 HIGHLY CITED PAPERS IN ENTROPY-BASED TEXTURE ANALYSIS

Title	Authors	Year	Source Title	Citations
Assessment of primary colorectal cancer heterogeneity by using whole-tumor texture analysis [36]	Ng, F., Ganeshan, B., Kozarski, R., Miles, K.A., Goh, V.	2013	Radiology	380
Haralick texture analysis of prostate MRI: utility for differentiating non-cancerous prostate from prostate cancer [37]	Wibmer, A., Hricak, H., Gondo, T., Sala, E., Vargas, H.A.	2015	European Radiology	346
Assessment of response to tyrosine kinase inhibitors in metastatic renal cell cancer [38]	Goh, V., Ganeshan, B., Nathan, P., Vinayan, A., Miles, K.A.	2011	Radiology	327
Assessment of tumor heterogeneity by CT texture analysis: Can the largest crosssectional area be used as an alternative to whole tumor analysis? [39]	Ng, F., Kozarski, R., Ganeshan, B., Goh, V.	2013	European Journal of Radiology	316
Reproducibility of tumor uptake heterogeneity characterization through textural feature analysis in 18F-FDG PET [40]	Tixier, F., Hatt, M., Le Rest, C.C., Corcos, L., Visvikis, D.	2012	Journal of Nuclear Medicine	289
Tumour heterogeneity in oesophageal cancer assessed by CT texture analysis [41]	Ganeshan, B., Skogen, K., Pressney, I., Coutroubis, D., Miles, K.	2012	Clinical Radiology	278
Texture analysis of non-small cell lung cancer on unenhanced CT [42]	Ganeshan, B., Abaleke, S., Young, R.C.D., Chatwin, C.R., Miles, K.A.	2010	Cancer Imaging	277
Practical guidelines for choosing GLCM textures for landscape classification [43]	Hall-Beyer, M.	2017	International Journal of Remote Sensing	276
Can quantitative CT texture analysis differentiate fat-poor renal angiomyolipoma from renal cell carcinoma? [44]	Hodgdon, T., McInnes, M. D.F., Schieda, N., Lamb, L., Thornhill, R.E.	2015	Radiology	246
CT textural analysis of hepatic metastatic colorectal cancer [45]	Lubner, M.G., Stabo, N., Lubner, S.J., Halberg, R.B., Pickhardt, P.J.	2015	Abdominal Imaging	237

E. Keyword Analysis

Fig. 3 shows a network map of keyword co-occurrence of a published article on texture analysis. The keyword co-occurrence network map provides an overview of the thematic structure in entropy-based texture analysis research. Larger nodes represent frequently occurring terms while connecting lines indicate co-occurrences in published studies. Different clusters, distinguished by color, reveal key research directions. The green cluster relates to imaging techniques, encompassing terms such as “magnetic resonance imaging (MRI)”, “neural networks”, and “microstructure”. The inclusion of “high entropy alloy” suggests that entropy-based texture analysis extends beyond medical imaging, playing a role in materials science for characterising microstructural patterns. At the center of the network, “texture analysis” emerges as the most dominant keyword, closely linked with “image processing”, “feature extraction”, and “classification”, reflecting the methodological focus on extracting meaningful features for applications in medical imaging and pattern recognition. Fig. 3 illustrates the keyword co-occurrence map for entropy-based texture analysis documents, whereas Table V lists the top 10 keywords along with their total link strengths.

TABLE V. TOP 10 KEYWORDS IN ENTROPY-BASED TEXTURE ANALYSIS

Keyword	Occurrence	Link Strength
Texture Analysis	501	673
Magnetic Resonance Imaging	120	208
Radiomics	70	135
Computed Tomography	67	114
Texture	62	96
Entropy	58	87
Image Processing	38	71
Classification	35	66
GLCM	34	43
Texture Classification	34	28

The red cluster represents the core computational techniques, featuring keywords such as “entropy”, “GLCM” (grey-level co-occurrence matrix), “feature extraction”, and “wavelet transform”. The inclusion of “fractal dimension” and “Gabor filters” highlights the mathematical approaches used to quantify texture complexity. The blue cluster focuses on medical imaging applications, with terms such as “Computed

Tomography (CT)", "MRI", "PET/CT", and disease-related keywords like "lung cancer", "glioblastoma", and "metastasis", demonstrating the increasing role of entropy-based texture analysis in radiomics and diagnostic imaging. Meanwhile, the yellow and orange clusters highlight its clinical relevance, featuring keywords such as "diagnosis", "differential diagnosis", "colorectal cancer", and "gastric cancer", which emphasize its role in quantitative imaging-based diagnostics to support clinical decision-making.

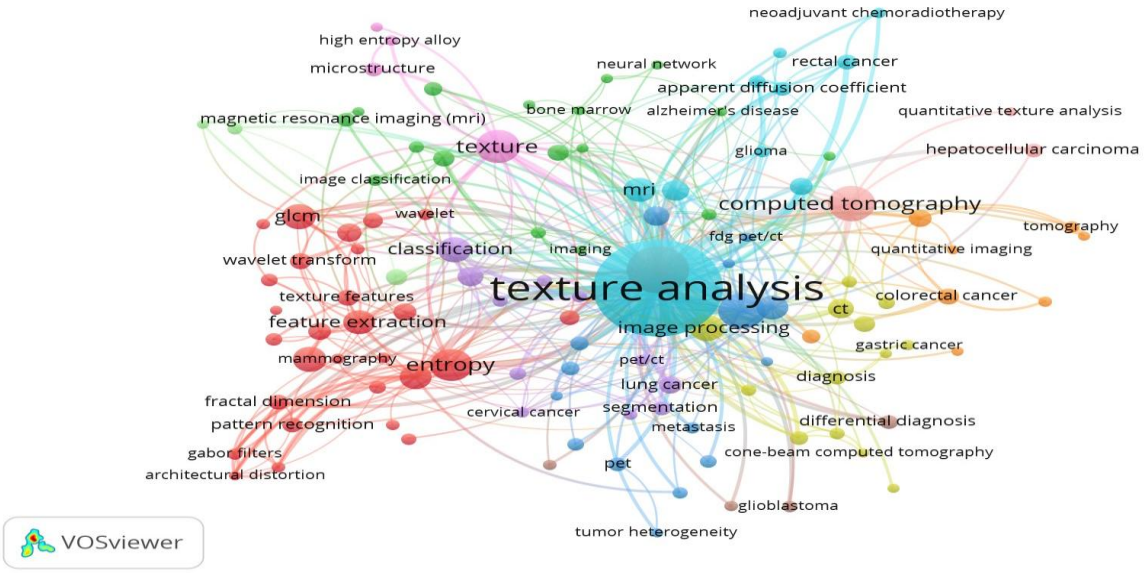

Fig. 3. Keyword co-occurrence map.

The overlay visualisation map in Fig. 4 illustrates the evolution of research trends in entropy-based texture analysis over time. Keywords shown in yellow represent emerging areas of interest, indicating the current focus of research. Recent studies highlight topics such as quantitative texture analysis, radiomics, lung cancer, MRI, computed tomography, and machine learning, suggesting a growing emphasis on advanced medical imaging techniques. In contrast, terms like entropy, feature extraction, and classification appear in green and blue, signifying their established role in the field. This progression suggests a shift from traditional texture analysis methods towards more sophisticated, imaging-driven diagnostics. Given these trends, future research is likely to further explore the integration of texture features with cutting-edge computational techniques, reinforcing their application in medical and technological advancements. The strong connections between feature extraction techniques and medical imaging terms suggest that the field is evolving towards automated and quantitative radiomics approaches. The presence of diverse methodological and application-focused clusters suggests that future research will continue refining computational techniques while expanding their use in clinical and material sciences.

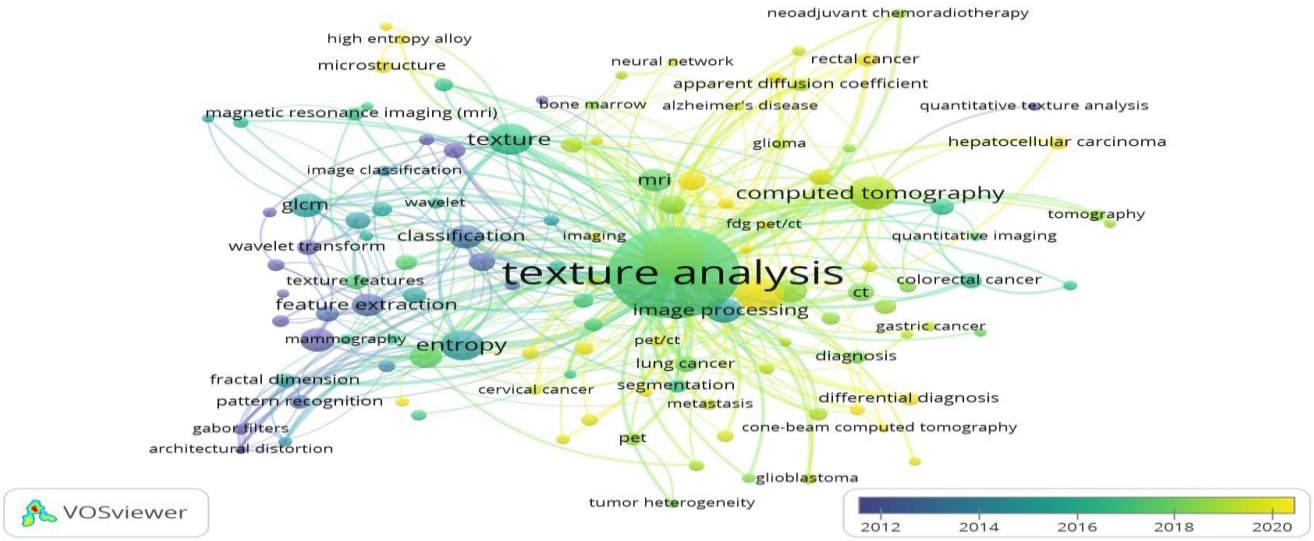

Fig. 4. Keywords overlay visualization map.

F. Geographic Contribution Analysis

The country co-authorship map presented in Fig. 5 illustrates the international collaborative landscape in the field, where each node represents a country and the lines (edges) indicate co-authorship links. The size of the node corresponds to the volume of publications, while the thickness of the links reflects the strength of collaborative ties. Countries are grouped into clusters based on the strength and frequency of their co-authorship patterns, with each cluster represented by a distinct color. Notably, China, the United Kingdom, India, and Germany appear as central hubs with extensive co-authorship ties spanning across multiple clusters, underscoring their dominant roles in facilitating global research collaboration. The green cluster, which includes countries such as India, Poland, and Saudi Arabia, represents a growing network of emerging contributors, particularly from Asia and Eastern Europe. Similarly, the red cluster, dominated by France, Brazil, Canada, and Turkey, reflects strong intercontinental research partnerships, particularly between Europe and the Americas. The blue cluster, comprising Japan, Singapore, Taiwan, and Indonesia, highlights robust regional cooperation in East and Southeast Asia. Meanwhile, the yellow cluster, centered around China and the United Kingdom, demonstrates cross-regional collaboration that bridges Asia and Europe. Countries like Italy and Mexico form part of the orange cluster, indicating active participation in Europe-Asia scientific exchanges. The inclusion of Australia and Finland in separate clusters (purple) suggests their specialised contributions and unique collaborative pathways, often acting as bridges between regions. The map's overall structure and the interconnectedness of nodes suggest a highly collaborative global research ecosystem, with developing nations increasingly integrated into international scholarly networks.

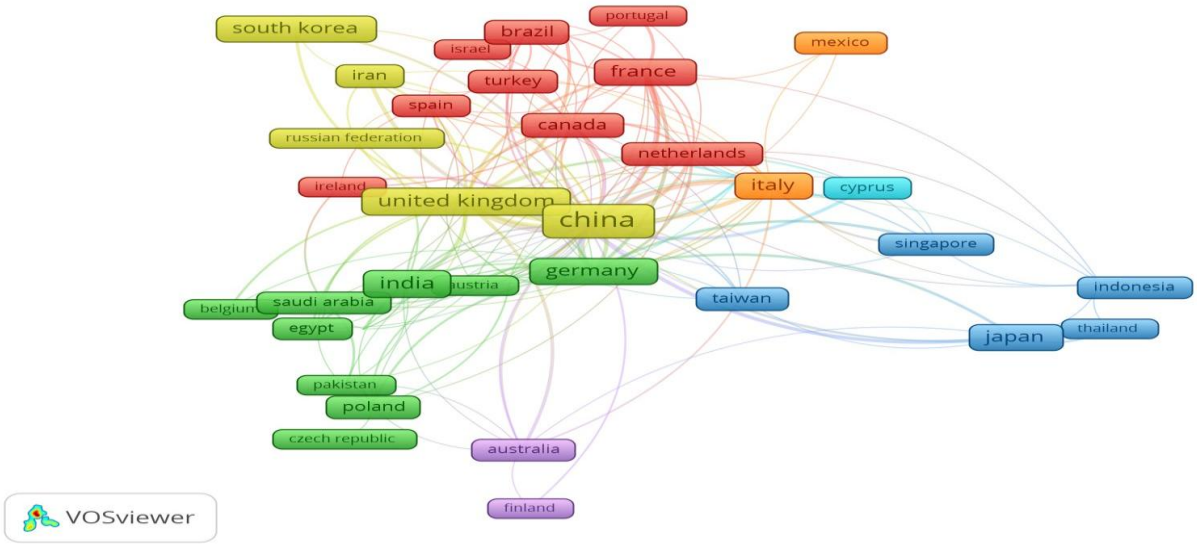

Fig. 5. Country co-authorship network.

IV. Conclusion

This bibliometric study provides a quantitative overview of entropy-based texture analysis, highlighting its growth, key contributors, and major applications. The results indicate that research in entropy-based texture analysis has experienced significant growth from 2004 to 2021, with peak activity between 2018 and 2021, followed by a decline in recent years. The findings reveal that medical imaging, particularly radiomics and tumor heterogeneity assessment, remains the dominant application area. Keyword analysis and citation mapping indicate that Shannon entropy continues to be widely used, but newer entropy measures such as sample entropy, permutation entropy, and dispersion entropy are emerging as promising techniques.

Furthermore, the study identifies strong international collaborations, with China, the United Kingdom, India, and Germany being key contributors. The interdisciplinary nature of entropy-based texture analysis is evident, spanning domains such as artificial intelligence, biomedical imaging, and material science. Despite its established applications, the field faces challenges related to standardization, computational efficiency, and interpretability of entropy measures.

A. Critical Insights and Future Directions

While this bibliometric review identifies major trends and contributors in entropy-based texture analysis, several methodological gaps remain. First, many highly cited studies still rely heavily on Shannon entropy or GLCM-based descriptors, whereas more advanced measures such as sample entropy, dispersion entropy, permutation entropy, and bidimensional variants are underutilized. This indicates a need for more comparative studies that evaluate the relative strengths and limitations of different entropy measures in diverse applications.

Second, there is a lack of standardized evaluation frameworks for entropy-based texture classification. Current studies often use different data sets, preprocessing pipelines, and classification methods, which makes direct comparisons difficult. Establishing benchmark datasets and protocols could

help ensure reproducibility and enable fair performance assessment across entropy measures.

Third, emerging application areas remain relatively unexplored. Although medical imaging dominates, entropy-based texture analysis also shows promise in materials science, industrial inspection, structural health monitoring, and security applications. For example, in industrial inspection, entropy measures can characterize surface roughness and detect micro-defects in manufacturing processes, enabling non-destructive quality control. In remote sensing, entropy-based features have been employed to classify land cover types, monitor vegetation patterns, and detect environmental changes from satellite imagery. Similarly, in biometrics, entropy-driven texture analysis has shown promise in enhancing the accuracy of fingerprint, iris, and face recognition systems by capturing fine-grained structural variations. Integrating entropy measures with deep learning and hybrid feature fusion approaches could further expand their impact, especially in radiomics and automated diagnostics.

By addressing these gaps, future research can enhance methodological robustness and broaden the scope of entropy-based texture analysis, ensuring its continued relevance in rapidly evolving technological domains. Future research should focus on improving entropy-based methods by integrating deep learning techniques, optimizing computational frameworks, and developing standardized benchmarks for texture classification. The increasing use of entropy in radiomics suggests potential for further exploration in automated diagnostics. Additionally, expanding entropy applications beyond medical imaging into remote sensing, industrial quality control, and biometrics can offer new avenues for research. Strengthening interdisciplinary collaborations will be crucial in advancing entropy-driven texture analysis and ensuring its relevance in emerging technological landscapes.

ACKNOWLEDGMENT

The author gratefully acknowledges the Postgraduate Management Center of Universiti Malaysia Terengganu for organizing a resourceful workshop on bibliometric analysis, which provided valuable guidance and tools that enabled the successful completion of this work.

A Review of Visualization Techniques for Duplicate Detection in Cancer Datasets

Nurul A. Emran[1]*, Ruhaila Maskat[2]
Fakulti Teknologi Maklumat dan Komunikasi, Universiti Teknikal Malaysia Melaka, 76100, Melaka, Malaysia [1]
Faculty of Computer and Mathematical Sciences, Universiti Teknologi MARA, 40450, Selangor, Malaysia[2]

***Abstract*—As clinical cancer research increasingly depends on large, diverse datasets, concerns about data duplication have grown. Duplicates can undermine data integrity, skew analytical results, and reduce the reproducibility of studies. This review explores how visualization can play a critical role in identifying and managing duplicates in non-image clinical cancer data. Drawing from literature in biomedical informatics, data quality, and visual analytics, it synthesizes current approaches and highlights key challenges. Using a scoping review methodology, we analyzed studies published over the past two decades, focusing on non-image clinical datasets. Studies were selected based on relevance to duplicate detection and visualization, excluding those centered on image or video data. Major datasets like The Cancer Genome Atlas (TCGA), The Cancer Imaging Archive (TCIA), and the North American Association of Central Cancer Registries (NAACCR) are examined to show how duplication occurs across genomic, clinical, and registry data. The review assesses existing visualization techniques based on their scalability, interactivity, integration with deduplication algorithms, and how well they address core data quality dimensions. While some tools offer scalable and interactive features, few provide clear visual representations of duplicates, especially those involving complex temporal and multidimensional patterns. Several methodological gaps are identified, including limited integration of data quality metrics, inadequate support for tracking changes over time, and a lack of standardized evaluation frameworks. To address these issues, the review advocates for the development of practical, user-friendly visualization tools that combine duplicate detection with key indicators of data quality. By offering a more complete and intuitive view of clinical datasets, such tools can help researchers and clinicians make better-informed decisions, ultimately improving the reliability and impact of cancer research. Bridging the gap between technical detection and visual understanding is essential for advancing data-driven healthcare and ensuring high-quality, reproducible outcomes.**

***Keywords*—Duplicate detection; data duplication; visualization; deduplication; TCGA; TCIA; NAACCR**

I. Introduction

With the growing volume and complexity of biomedical data, especially in clinical cancer research, the issue of duplicate records has become increasingly important. Ensuring high data quality is essential, as duplication can significantly affect research accuracy and outcomes. As a result, visualizing duplicates in these datasets has emerged as a crucial area of study [1], [2]. In the past decade, improvements in data collection and integration have produced large, diverse clinical datasets. These datasets demand advanced visualization techniques to effectively assess data quality and support informed clinical decision-making [3], [4], [5], [6]. Duplicate records, where the same real-world entity appears multiple times can create serious challenges in data analysis. They may artificially boost predictive performance and lead to misleading research conclusions, ultimately compromising the reliability of clinical insights [1], [7]. Numerous studies have shown that duplicate records are common across various biomedical databases, including those containing transcriptomic and nucleotide sequence data. This highlights an urgent need for more effective methods to detect and visualize duplicates, ensuring data integrity and improving research outcomes [7]. Studies have shown that duplicate records can account for up to 30–50% of entries in some clinical databases, leading to inflated sample sizes, biased statistical outcomes, and compromised patient safety [8], [9]. The practical impact of duplicate records is clear as studies show they can lead to redundant or conflicting results, which in turn can disrupt downstream analyses and misguide clinical interpretations [7], [10]. This review focuses on a specific yet underexplored challenge: visualizing duplicate records in non-image clinical cancer datasets. Despite its importance, current methods in this area remain fragmented and underdeveloped, limiting their effectiveness in real-world clinical applications [1], [11].

Although many algorithms exist for detecting duplicates and assessing data quality, there's still a noticeable gap when it comes to visualization approaches specifically designed for the unique complexities of clinical cancer data. Current solutions often fall short in providing comprehensive, intuitive visual tools that support meaningful analysis in this domain [12], [13], [14]. There are differing views on the best approaches for identifying and representing duplicates, ranging from statistical record linkage methods to machine learning-based similarity measures. However, few studies have successfully combined these techniques with visualization tools that support human-in-the-loop data quality assessment, limiting their practical usefulness in clinical settings [15]–[17]. This gap can lead to serious consequences, including misinterpreting data, wasting time on inefficient curation efforts, and drawing flawed clinical insights that may affect patient care and research outcomes [7], [18]. Given the wide variety of data types and the complexity of clinical workflows, there's a clear need for visualization tools that can effectively handle multidimensional, temporal, and categorical data. These tools must be capable of adapting to the intricate nature of clinical cancer datasets to support accurate analysis and decision-making [19], [20].

This review introduces a conceptual framework that defines duplicates as multiple records referring to the same clinical

*Corresponding Author.

entity. It connects this definition to key data quality dimensions, such as completeness, accuracy, and consistency to emphasize the broader impact of duplication on clinical data integrity [12], [21]. Visualization is framed as a guided, interactive process that blends computational techniques for detecting duplicates with human pattern recognition. This approach enables users to actively assess and manage data quality, making the process more intuitive and effective [12], [22].

The framework brings together theories of data quality assessment and principles of visualization system design, highlighting how visual analytics can play a key role in managing clinical oncology data more effectively [3], [23]. This review aims to examine how current visualization tools and techniques are being applied to detect and represent duplicate records in clinical cancer datasets particularly those that do not involve image or video data. By drawing insights from fields such as biomedical informatics, data quality, and visual analytics, the review seeks to identify gaps in existing approaches and highlight opportunities for advancement.

A key contribution of this work is its effort to bridge the divide between technical duplicate detection algorithms and practical visualization tools that help researchers and clinicians interpret and manage data more effectively. This integration supports improved data curation and enhances the reliability of cancer research outcomes. To guide this exploration, the review adopts a scoping methodology, analyzing studies published over the past two decades. Literature searches were conducted across major academic databases, including PubMed, IEEE Xplore, Scopus, and ACM Digital Library, to ensure comprehensive coverage of relevant work.

The review focuses specifically on research related to duplicate detection and visualization in clinical or biomedical datasets, excluding studies centered on image or video data. This review deliberately excludes image and video data to focus on structured and semi-structured clinical datasets, such as EHRs, genomic records, and registries, where duplication manifests differently and is often harder to visualize. While this boundary narrows the scope, it allows for a more focused analysis of underexplored challenges in non-visual data domains, which are critical for data-driven decision-making in clinical workflows. The findings are organized to first outline the types of visualization techniques currently in use, then discuss the challenges and available tools, and finally propose directions for future research.

The remainder of the paper is organized as follows: Section II provides an overview of visualization approaches used in duplicate detection within clinical cancer datasets, focusing on technique diversity, data quality coverage, scalability, and user interaction. Section III presents a critical evaluation of methodological strengths and limitations, emphasizing integration with deduplication algorithms and temporal visualization. Section IV discusses the theoretical and practical implications of duplicate visualization, emphasizing the need for adaptive, context-aware frameworks and scalable visual tools. It highlights the integration of temporal stability and multidimensional analytics, advocating for human-in-the-loop systems that enhance data quality, support clinical decision-making, and improve research reliability. Section V introduces key datasets relevant to duplicate detection and visualization, discussing their characteristics and challenges. Section VI outlines existing gaps and proposes future research directions to advance the field. Finally, Section VII concludes the paper by summarizing key findings and highlighting the importance of integrating visualization with data quality assessment to improve clinical research outcomes.

II. Overview of Visualization Approaches in Duplicate Detection

This section delves into how researchers are currently addressing the challenge of visualizing duplicate records in clinical cancer datasets, particularly those that exclude image and video data. It explores a broad spectrum of tools, techniques, and approaches, some focused on developing new solutions, others aimed at evaluating existing systems. The reviewed studies range from interactive visual analytics platforms to scalable computational frameworks, all designed to manage the complexity of large, heterogeneous clinical datasets. To assess the effectiveness of these approaches, the review considers several key factors: the diversity of visualization techniques employed, their ability to address various dimensions of data quality, scalability to large datasets, level of user interactivity, and integration with duplicate detection algorithms. By comparing these elements, the review identifies both strengths and areas where further development is needed. A central takeaway is the pressing need for more comprehensive, user-centered visualization tools, ones that not only detect duplicates but also help users understand their broader impact on data quality. This overview sets the stage for future innovation, emphasizing the importance of creating tools that are not only technically robust but also practical and relevant for clinical use. A summary table in Table I is included to show how different studies map across these key dimensions.

A. Visualization Technique Diversity

A variety of studies have applied diverse visualization techniques, including flow diagrams, glyph-based representations, set visualizations, timelines, and interactive dashboards, to support duplicate detection and assess data quality in clinical cancer and broader biomedical datasets [1], [23], [24]. While basic formats such as tables and bar charts remain prevalent, recent surveys indicate growing interest in omics-driven and multidimensional visualizations tailored to the complexity of clinical data [3], [25]. Novel visualization techniques such as Missingness Glyphs and ensemble glyphs have been proposed to enhance pattern recognition in missing data and ensemble comparisons, respectively [26], [27]. Comparative visualization approaches for temporal and multivariate data have been developed to support patient cohort analysis and similarity assessments [20], [28].

B. Data Quality Dimension Coverage

Many studies have addressed multiple dimensions of data quality such as completeness, accuracy, consistency, and temporal stability, with particular emphasis on temporal aspects, which are especially critical in clinical and biomedical contexts [24], [29], [30]. Completeness and accuracy were the most commonly visualized data quality dimensions, particularly in studies focused on analyzing missing data patterns and detecting duplicate records [17], [21]. Temporal stability and changes over

time were captured using probabilistic change detection methods and time-oriented visualizations, allowing researchers to monitor how data quality evolves across clinical datasets [20], [30]. Some studies concentrated on specific data quality dimensions, for example, focusing on consistency in record linkage or accuracy in similarity calculations used for deduplication tasks [14], [15], [31].

C. Scalability and Performance

Scalability emerged as a key concern, with several studies showcasing visualization and deduplication techniques capable of processing millions of records, including complex datasets like clinical notes and adverse drug reaction databases [32], [33]. To improve scalability in duplicate detection pipelines, several studies leveraged parallel and distributed computing frameworks such as Apache Spark and cluster-based algorithms enabling efficient processing of large-scale clinical datasets [33], [34]. The scalability of visualization tools varied widely across studies. While some were built to handle large, heterogeneous clinical datasets, others were limited to smaller or synthetic datasets, restricting their practical application in real-world clinical environments [12], [19]. Balancing detail and overview in large datasets often involved trade-offs. To manage this, several studies used techniques like hierarchical clustering and level-of-detail visualizations, helping users navigate complex data without losing sight of important patterns or broader trends [22],[30].

D. User Interaction and Interpretability

Many visualization systems supported interactive exploration, allowing domain experts to actively engage with the data spotting anomalies, uncovering patterns in missing data, and comparing patient cohorts with greater ease and insight [15], [18], [19]. Some tools offered only limited interactivity, placing greater emphasis on automated detection and algorithmic outputs. As a result, user engagement was minimal, reducing opportunities for experts to explore data patterns or validate findings through direct interaction [1], [27].

Visual analytics approaches often incorporated user feedback and domain expertise to improve the clarity and trustworthiness of data quality assessments. By involving experts in the process, these tools became more interpretable and aligned with real-world clinical needs [4], [18]. Set-based and glyph visualizations stood out for their ability to make complex data quality issues easier to understand. Their intuitive design helped users quickly grasp patterns and anomalies, making them valuable tools for exploring duplicate records and other data inconsistencies [19], [21].

E. Integration with Deduplication Algorithms

There is a consensus that integrating visualization with deduplication and data cleansing algorithms enhances detection accuracy and facilitates iterative refinement of analytical processes [8], [12], [27], [30]. Certain frameworks integrate similarity computations directly with visualization components to provide deeper analytical insights and improve interpretability [10], [31]. Several tools offer limited interactivity, prioritizing automated detection and algorithmic outputs over active user involvement [1], [27].

Building upon this descriptive overview, the next section provides a critical analysis of the reviewed studies, highlighting their strengths, limitations, and methodological gaps. This synthesis aims to offer a clearer understanding of current practices and to outline future directions for duplicate visualization in clinical cancer datasets.

III. Evaluation of Methodological Strengths and Limitations

The existing literature on duplicate visualization in clinical cancer datasets presents a wide array of methodologies and tools, reflecting both innovative advancements and persistent challenges. Notable strengths include the development of scalable algorithms and interactive visualization techniques capable of handling complex, heterogeneous data. However, several limitations remain, particularly in the integration of data quality metrics, temporal dynamics, and user-centered design. These issues are often exacerbated by the experimental nature of many tools and the lack of comprehensive evaluations. This synthesis highlights the pressing need for more robust, sustainable, and clinically integrated visualization solutions that can effectively support duplicate detection and data quality assessment in non-image-based clinical cancer data.

A. Visualization Techniques for Duplicate Detection

A number of studies introduce innovative visualization techniques specifically designed for complex clinical datasets. These include interactive set visualizations to explore patterns of missing data and glyph-based methods to highlight data quality issues. Such approaches help users more effectively identify duplicates and anomalies within large, heterogeneous datasets [8], [19], [21]. Techniques such as Minhashing combined with Locality Sensitive Hashing have shown strong scalability, making it possible to efficiently detect duplicates within large volumes of clinical notes [27]. Despite notable progress, many visualization techniques remain insufficiently developed for the explicit detection of duplicates in clinical cancer datasets, especially those involving non-image data. The continued reliance on basic formats such as tables often limits both the interpretability and effectiveness of identifying duplicate records [3]. Moreover, the absence of standardized evaluation metrics and the limited number of comprehensive user studies hinder the ability to rigorously assess the effectiveness of these visualization methods [3], [18].

B. Integration of Data Quality Metrics

Some studies incorporate key data quality dimensions, such as completeness, accuracy, and consistency into their visualization frameworks, allowing users to more effectively identify and interpret data defects and duplicate entries [2], [8], [16]. Probabilistic frameworks for assessing temporal stability offer novel approaches to visualizing changes in data quality over time, which is particularly important for longitudinal clinical datasets [25]. However, the integration of data quality metrics into duplicate visualization tools is often limited or implicit. Many existing tools fall short of explicitly combining multiple dimensions of data quality or providing comprehensive visual analytics that address both temporal and multidimensional aspects of duplicate detection [3], [16]. The inherent complexity of clinical data, coupled with the diverse

nature of data quality issues, presents challenges that current visualization systems have yet to fully address [18].

C. Temporal and Multidimensional Visualization

Recent research has explored temporal visualization techniques such as timelines and temporal line charts to capture evolving patterns in patient data, which are relevant for understanding how duplicates emerge over time [15], [25]. Multidimensional approaches, including flow visualizations and hierarchical clustering, have also been applied to support the exploration of complex cancer registry and ensemble datasets [14], [22]. However, the explicit visualization of temporal dynamics and multidimensional characteristics of duplicates remains limited. Few systems enable direct comparisons between individual patients and cohorts or incorporate temporal stability assessments into duplicate detection workflows [15]. The high dimensionality and sparsity of clinical data further complicate effective temporal visualization, often resulting in oversimplified or fragmented representations [25].

D. Scalability and Performance of Visualization Tools

Several studies have introduced scalable algorithms and parallel processing techniques, such as Spark-based kNN classifiers and parallel deduplication methods that enable efficient handling of large clinical datasets containing millions of record [28], [29]. These approaches support real-time or near-real-time duplicate detection and visualization, which are essential for clinical applications. However, despite these advancements in scalability, many visualization tools face challenges in maintainability and lack ongoing updates, often leading to their discontinuation after initial publication [3]. The transition from prototype to routine clinical use is further hindered by resource limitations and insufficient software engineering practices, ultimately reducing the practical impact of these tools [3].

TABLE I. KEY DIMENSIONS OF STUDIES IN DUPLICATE VISUALIZATIONS

KEY DIMENSIONS	DESCRIPTIONS	STUDIES
Visualization Technique Diversity	This dimension explores how researchers visually represent duplicate records and related data quality issues in cancer datasets. Some rely on straightforward visuals like tables and bar charts, while others use more advanced methods such as glyphs, set-based diagrams, flow charts, and time-based plots. A diverse range of visualization styles allows researchers to examine duplicates from multiple perspectives, whether it's structural patterns, temporal changes, or categorical overlaps, making it easier to identify problems and gain clearer insights into the data.	[1], [15], [18], [19], [20], [26], [27]
Data Quality Dimension Coverage	This dimension focuses on how effectively visualization tools help users understand different aspects of data quality, such as completeness, accuracy, consistency, and how stable the data is over time. Rather than simply pointing out duplicates, well-designed visualizations show how those duplicates impact the overall reliability of the dataset. When multiple quality indicators are presented together, researchers gain a clearer and more comprehensive view of the data's trustworthiness.	[10],[12], [14], [15], [16], [19], [24], [25], [26]
Scalability and Performance	This dimension focuses on how well a visualization tool can manage large and complex cancer datasets, which often contain millions of records. A good system should remain responsive and easy to use, even when handling massive amounts of data. In real-world clinical environments, where data is often messy and highly varied, having a tool that performs smoothly and scales effectively is essential for making timely and accurate decisions.	[8],[14],[22],[27],[28],[29], ,[30]
User Interaction and Interpretability	This dimension focuses on how easily users can interact with visualization tools to explore and understand duplicate records. Features like zooming, filtering, comparing patient groups, and highlighting patterns allow users to engage with the data in meaningful ways. When visualizations are intuitive and responsive, they help researchers and clinicians quickly spot issues, ask relevant questions, and draw informed conclusions based on what they see.	[1], [4],[5], [6],[20], [21], [23], [24], [27],
Integration with Deduplication Algorithms	This dimension looks at how well visualization tools are integrated with computational methods for detecting duplicates, such as record linkage, similarity scoring, or machine learning. When these tools are tightly connected, users can easily visualize algorithm outputs, validate results, and adjust detection settings interactively. This integration helps bridge the gap between automated data processing and expert-driven data curation, making the entire process more transparent and user-friendly.	[1], [8], [10],[12], [27], [30], [31], [32]

E. User Interaction and Interpretability

Interactive visualization features such as dynamic filtering, selection mechanisms, and focus+context techniques play a key role in enhancing user engagement and enabling detailed exploration of duplicates and data quality issues [3], [23], [28]. Visual analytics systems that integrate data cleansing with exploratory workflows empower domain experts to iteratively uncover anomalies and patterns [23]. However, many existing tools offer only limited interactivity, often confined to basic search or hover functions, which may be inadequate for addressing the complexity of duplicate detection tasks [3]. The diversity and flexibility of visualization and user interface components also complicate usability evaluations and can hinder user adoption, particularly in multidisciplinary clinical environments. Additionally, the visualization of patient-reported outcomes and follow-up data remains an underexplored area.

F. Methodological Robustness and Evaluation

Some studies validate their duplicate detection and visualization methods through rigorous experimental evaluations, including benchmarking against large, well-curated duplicate datasets and incorporating expert assessments [1], [36], [37]. The use of probabilistic models and adaptive similarity measures has improved detection accuracy and allowed methods to better align with domain-specific characteristics of clinical data [15], [17]. However, the overall methodological rigor across studies varies considerably. Many lack comprehensive validation or rely on limited datasets, which undermines the reliability of their findings. The absence of standardized benchmarks for clinical cancer datasets and inconsistent reporting of visualization capabilities further complicate comparative evaluations and limit generalizability [3], [11]. Additionally, the inherent complexity of clinical data introduces confounding factors that challenge the robustness and consistency of duplicate detection algorithms [31].

G. Opportunities for Innovation

The literature highlights clear gaps and opportunities for advancing visualization strategies that integrate temporal stability, multidimensional data quality metrics, and user-centered interaction to improve duplicate detection and data quality assessment [3], [17], [34]. There is growing recognition of the potential to combine computational techniques with visual analytics to enhance interpretability and support clinical decision-making [4], [5], [6], [17]. Major challenges include the diversity of data types, the need for scalable solutions capable of handling large datasets, and the difficulty of embedding these tools into real-world clinical workflows. Addressing these issues will require stronger interdisciplinary collaboration yet such efforts are still relatively limited.

Across the reviewed studies, there is a broad consensus that visualization plays a vital role in helping researchers and clinicians detect and interpret duplicates within cancer and biomedical datasets. Most agree on the importance of incorporating multiple data quality indicators such as completeness and temporal stability and ensuring that tools are capable of managing large, complex datasets.

However, perspectives diverge on the extent to which visualization tools should be tightly integrated with deduplication algorithms, the diversity of visual techniques to be employed, and the level of user interaction required. These differences often reflect the distinct needs of various research domains, data types, and technical approaches, ranging from genetic sequence databases to clinical notes and electronic health records. Together, these shared understandings and differing viewpoints contribute to a more comprehensive and nuanced picture of the current landscape. They not only highlight the complexities and challenges involved in duplicate visualization within clinical cancer data, but also illuminate emerging trends, gaps in existing methodologies, and opportunities for innovation. This synthesis of perspectives serves as a foundation for identifying strategic directions for future research, refining theoretical frameworks, and enhancing the practical implementation of visualization techniques in clinical oncology settings.

IV. Theoretical and Practical Implications

This review highlights that duplicates in clinical cancer datasets are often complex and nuanced. Rather than simple repeated entries, duplicates may contain conflicting information or evolve over time, making them difficult to detect and interpret. Their inconsistent nature and varied impact on data analysis underscore the need for flexible, context-aware frameworks that can accommodate different types of duplicates and their implications for research and clinical decision [17], [36], [37]. Studies show that employing adaptive similarity measures particularly those capable of learning from the data can significantly enhance detection accuracy. These approaches move beyond traditional techniques like basic text matching, aligning with theoretical advancements in metric functional dependencies and trainable similarity functions [15], [17], [38].

The integration of temporal stability as a data quality dimension introduces a novel theoretical lens, emphasizing the dynamic nature of clinical data and the importance of probabilistic and information-geometric methods for identifying and characterizing temporal changes in duplicates and data quality [30]. Visualization theory is also evolving, recognizing the critical role of interactive and scalable visual analytics in managing heterogeneous clinical data. These tools support hypothesis generation and enable exploration of the multidimensional and temporal aspects of duplicates [19], [22], [28]. Furthermore, the literature challenges the adequacy of single benchmark evaluations, advocating for the use of multiple, diverse, and validated benchmarks to ensure the robustness and generalizability of duplicate detection models [36], [37]. Visual analytics frameworks are increasingly enriched by human-in-the-loop approaches, where visualization serves as a bridge between complex algorithmic outputs and user interpretation particularly in high-stakes settings such as clinical oncology and tumor board decision-making [3], [22].

For both clinical research and healthcare practice, the findings underscore the importance of making duplicate detection and visualization routine components of data management. These processes are essential for maintaining data quality, avoiding misleading analyses, and supporting reliable clinical decision-making, as demonstrated by tools like doppelgangR and integrated visual cleansing workflows [1], [23]. The successful deployment of scalable and parallelized algorithms [35], including those based on Minhashing, Locality Sensitive Hashing, and Spark-based kNN classifiers, illustrates the feasibility of handling large-scale clinical datasets, which is critical for real-world applications in hospital and research environments [32], [33]. Visualization tools that incorporate multidimensional, temporal, and set-based techniques enable practitioners to uncover complex patterns of duplication and missing data, thereby facilitating targeted data quality interventions and enhancing the interpretability of clinical datasets [24], [26], [39].

The adoption of interactive visualization systems that support user-driven exploration, such as temporal stability assessments and cohort comparisons has the potential to significantly enhance tumor board workflows and multidisciplinary clinical decision-making processes [3], [20]. To support this, industry and policy stakeholders should prioritize the development of comprehensive data quality monitoring infrastructures that incorporate visualization components, enabling continuous tracking and traceability of duplicates and other data quality issues within clinical data warehouses [2]. Evidence suggests that advanced visualization and duplicate detection techniques not only improve research accuracy but also contribute to patient safety, streamline healthcare operations, and support regulatory compliance. These benefits underscore the importance of investing in robust data quality tools across healthcare systems [16].

While existing visualization taxonomies often focus on general data exploration or image-based analytics, this review introduces a conceptual framework specifically tailored to the visualization of duplicate records in non-image clinical cancer datasets. Unlike traditional models that treat data quality and visualization as separate domains, our framework integrates duplicate detection algorithms, interactive visual analytics, and data quality dimensions (e.g. completeness, temporal stability) into a unified structure. This approach emphasizes human-in-

the-loop interpretation, temporal dynamics, and multidimensional data contexts areas that are underrepresented in current taxonomies. By aligning visualization strategies with specific data quality challenges posed by duplication, the framework offers a more targeted lens for evaluating and designing tools in clinical research settings.

The findings from this section further emphasize the complexity and variability of duplicate records in clinical cancer datasets. Addressing these challenges effectively requires well-structured datasets and adaptable tools capable of handling diverse duplication scenarios. To support this effort, the following section introduces key datasets that can aid researchers in developing more effective strategies for detecting and visualizing duplicates in cancer data.

V. Key Datasets for Duplicate Detection and Visualization

A range of publicly available datasets serve as valuable resources for researchers working to detect and visualize duplicates in clinical cancer data. These assets provide a foundational platform for developing more effective methods to clean, interpret, and analyze complex biomedical information:

1) The Cancer Genome Atlas (TCGA) [1] *:* The Cancer Genome Atlas (TCGA), accessible via the Genomic Data Commons (GDC), stands as one of the most comprehensive resources for cancer genomics. It integrates clinical and molecular data from 33 cancer types, encompassing thousands of patient cases and millions of data files. With its diverse range of data including whole genome sequencing, RNA-seq, methylation, and proteomic profiles, TCGA offers a powerful foundation for cancer research.

However, the scale and complexity of TCGA also present challenges for duplicate detection. The involvement of multiple contributors and data modalities increases the risk of overlapping entries, such as repeated patient identifiers or biospecimen records. While the GDC mitigates some of these risks through standardized clinical data formats and consistent bioinformatics workflows, duplicate detection remains a critical step to ensure data integrity and reliability.

TCGA also provides interactive visualization tools, such as the Cohort Builder and Mutation Frequency plots, which support the exploration of genomic alterations and clinical attributes. These tools are particularly useful for identifying anomalies or inconsistencies that may signal duplicate records, especially when combined with metadata filters and cohort analysis. Overall, TCGA is a cornerstone of cancer research, and its structured data along with integrated visualization capabilities make it an essential resource for addressing duplication challenges in large-scale biomedical datasets.

2) The Cancer Imaging Archive (TCIA) [2] *:* The Cancer Imaging Archive (TCIA) is a publicly accessible repository offering a vast collection of de-identified medical images related to cancer. These datasets are organized into collections based on disease types, such as lung cancer and imaging modalities, including MRI, CT scans, and histopathology. TCIA supports a variety of formats, with Digital Imaging and Communications in Medicine (DICOM) serving as the standard for radiological data.

Due to its aggregation of data from multiple institutions, TCIA presents both opportunities and challenges for duplicate detection. The diversity of contributors and imaging types increases the likelihood of overlapping records, such as repeated patient identifiers, imaging sessions, or processed files. Fortunately, TCIA provides rich metadata, including treatment details, patient outcomes, and genomic annotations, that can assist researchers in identifying and resolving potential duplicates.

The platform also features visualization tools and filtering options that enable users to explore imaging datasets and detect anomalies or inconsistencies. These capabilities are particularly useful for identifying redundant scans or mismatched patient data, which could compromise the accuracy of research findings. Overall, TCIA is a valuable resource for cancer imaging research, and when paired with visualization and record linkage techniques, it supports effective deduplication and enhances data quality.

3) North American Association of Central Cancer Registries (NAACCR) CiNA[3]*:* The NAACCR Cancer in North America (CiNA) Research dataset is a robust, population-based resource that consolidates cancer data from registries across the United States and Canada. It offers detailed insights into cancer incidence, survival, and prevalence, and is curated to meet high standards of completeness and data quality, making it an essential tool for cancer surveillance and public health research. While CiNA provides significant value, duplicate detection remains a challenge due to the integration of data from multiple state and provincial registries. Patients who move across regions or receive care from different institutions may have overlapping records. NAACCR addresses this through standardized coding practices and routine quality checks, but researchers must still exercise caution, particularly when working with multi-year or multi-registry datasets.

CiNA's rich metadata, including patient demographics, diagnosis timelines, and tumor characteristics, supports effective deduplication. Tools like SEER*Stat enable researchers to visualize and analyze these variables, helping to identify inconsistencies or repeated entries. This is especially important when linking CiNA with other datasets or conducting longitudinal studies, where duplicate records can distort findings. Overall, CiNA is a high-quality dataset that, when paired with appropriate visualization and data linkage techniques, facilitates accurate duplicate detection and enhances data reliability.

4) KAUH-BCMD[4]*:* The KAUH-BCMD dataset, developed by Al-Mnayyis et al. [40], comprises over 7,000

[1] https://portal.gdc.cancer.gov/
[2] https://www.cancerimagingarchive.net/
[3] https://www.naaccr.org/cina-research/
[4] https://www.frontiersin.org/journals/big-data/articles/10.3389/fdata.2025.1529848/full

mammographic images from 5,000 patients at King Abdullah University Hospital in Jordan. While the primary aim of the study was to enhance breast cancer classification using deep learning techniques, the dataset's construction and preprocessing also offer valuable insights into duplicate detection within clinical imaging data.

To improve image quality, the researchers applied several preprocessing methods, including high-boost filtering, contrast-limited adaptive histogram equalization (CLAHE), normalization, and data augmentation. While these techniques are essential for optimizing model performance, they can inadvertently introduce near-duplicate images if not carefully managed, potentially affecting the accuracy of training and evaluation processes.

The KAUH-BCMD dataset also includes metadata such as patient identifiers and diagnostic labels, which can be leveraged to link records and identify potential duplicates. Although duplicate detection was not the primary focus of the original study, the dataset's size and diversity make it a promising candidate for future research in this area. With the application of appropriate visualization and record linkage techniques, KAUH-BCMD could offer valuable insights into managing duplication challenges in cancer imaging data.

5) Breast Cancer Wisconsin (UCI)[5]*:* The Breast Cancer Wisconsin (Diagnostic) dataset, hosted by the UCI Machine Learning Repository, is a widely recognized benchmark in biomedical research. It comprises 569 samples derived from digitized fine needle aspirate (FNA) images of breast tumors, with each sample described by 30 numerical features related to the shape and texture of cell nuclei, such as radius, perimeter, area, and concavity. This rich feature set makes the dataset particularly valuable for developing and evaluating machine learning models in cancer diagnostics.

In terms of duplicate detection, the dataset is exceptionally clean and well-structured, featuring unique patient identifiers and no missing values. This reliability makes it an ideal starting point for testing deduplication algorithms or building classification models without concerns about data inconsistencies. However, when used in machine learning workflows, especially during cross-validation, care must be taken to avoid data leakage or overfitting. For instance, preprocessing steps like data augmentation or synthetic sample generation can unintentionally introduce near-duplicate entries, potentially skewing model performance.

Although the dataset does not contain explicit duplicates, its structured format and detailed metadata make it suitable for evaluating deduplication techniques, particularly those focused on feature-level similarity and record linkage. Researchers can simulate duplication scenarios by introducing controlled redundancy and applying visualization methods to detect and resolve them. Overall, the Breast Cancer Wisconsin dataset serves as a valuable resource for exploring deduplication strategies in small-scale, feature-rich clinical datasets, especially within the context of diagnostic imaging and classification.

While the datasets reviewed offer strong foundations for duplicate detection and visualization in cancer research, several limitations persist. The following section outlines key gaps in current approaches and proposes future directions to advance the field.

VI. Gaps and Future Research Directions

Current visualization approaches in clinical cancer datasets tend to emphasize general data quality issues or patterns of missing data. However, they often overlook specialized techniques for detecting duplicate records, especially in non-image data. Most existing tools rely on basic visual formats like tables, which can limit users' ability to interpret and effectively identify duplicates [3], [24], [26]. To address this gap, future research could focus on developing interactive visualization tools that are specifically designed to highlight duplicates within complex clinical datasets.

These tools should be capable of integrating temporal and multidimensional data, making it easier to spot and understand duplicate entries, ultimately improving data integrity and analytical precision. Moreover, current visualization systems rarely offer a comprehensive view of multiple data quality dimensions, such as completeness, accuracy, consistency, and temporal stability within duplicate detection workflows. When these aspects are only partially or implicitly represented, users struggle to assess the full impact of duplicates on overall data quality [2], [12], [21].

There is a clear opportunity to design integrated visualization frameworks that display these metrics alongside duplicate indicators, enabling a more holistic and intuitive evaluation of clinical data. Another limitation is the lack of support for visualizing how duplicates change or cluster over time. Temporal dynamics are especially important in clinical datasets, yet they are often underrepresented in current tools [20], [30]. This opens the door for innovative solutions like interactive timelines or change detection plots, combined with multidimensional views, to track duplicates longitudinally and provide deeper insights into data evolution.

VII. Conclusions

In conclusion, this review has examined current visualization techniques for detecting duplicates in clinical cancer datasets, particularly non-image data, and identified both promising developments and critical gaps. Despite progress in scalable algorithms and interactive analytics, most tools still rely on basic visual formats and fail to fully incorporate essential data quality dimensions such as completeness, accuracy, consistency, and temporal dynamics. There is a clear need for more intuitive and clinically relevant visualization frameworks that support complex, multidimensional data and allow users to explore duplicates interactively. Effective tools should be designed with users in mind, enabling human-in-the-loop workflows and facilitating the interpretation of anomalies over time. Many existing systems lack rigorous evaluation, standardized benchmarks, and long-term usability, which limits their practical impact. Future research should focus on building integrated platforms that combine robust deduplication

[5] https://archive.ics.uci.edu/dataset/14/breast+cancer

algorithms with user-friendly, scalable visual interfaces capable of supporting longitudinal tracking, cohort comparisons, and real-time data quality monitoring. Enhancing how duplicates are visualized is essential for improving data integrity, analytical accuracy, and ultimately patient outcomes. Bridging the gap between computational detection and visual understanding will empower users to not only identify duplicates but also take meaningful action, leading to more reliable cancer research and stronger foundations for data-driven healthcare innovation.

ACKNOWLEDGMENT

The authors would like to thank the Centre for Research and Innovation Management (CRIM), UTeM, and members of the IDEAL research group for all their support. ***Abstract*—Communication and social interaction issues are frequently linked to autism, which can have an impact on quality of life, work, and education. Opportunities to lessen these difficulties are presented by assistive technology, especially those that facilitate individualized and encouraging engagement. Facial expression recognition (FER) is essential to these systems, but current methods are still inadequate for autism-specific situations even though they achieve high accuracy on benchmark datasets like CK+. Because autistic people usually exhibit aberrant, subtle, or ambiguous facial expressions—which deviate from the common patterns used to train traditional FER models—this limitation occurs. In this work, we suggest a hybrid model that combines an LSTM network for temporal modeling of video sequences with three pretrained convolutional neural networks (EfficientNetB0, ResNet50, and MobileNetV2) for spatial feature extraction. Although the model performs well on CK+, its applicability to autism is still limited by the lack of relevant datasets and the use of artificial intelligence (AI)-generated videos rather than authentic recordings. The critical need for more comprehensive data and adaptive model designs tailored to autistic populations is highlighted by these findings.**

***Keywords*—Facial emotion recognition; video; frames; spatial and temporal features; pretrained models; LSTM; autistic individuals**

I. Introduction

Each of us needs to communicate since we belong to a community. Some people with autism spectrum disorders experience communication challenges. These individuals struggle to acquire language skills such as speaking and expressing their thoughts and emotions [1]. Emotion processing plays a critical role to help the autistic individuals face those challenges [2]. For this reason, we considered concentrating on the emotions of autistic people, which can be examined and identified from an image or live video when they communicate with a chatbot designed specifically for this population. While existing video-based FER models achieve good performance on standard datasets, they often fail to capture the atypical and subtle expressions of autistic individuals, due to muted intensity, ambiguous variations, and non-standard temporal dynamics. The principle behind this project is that we try to use a chatbot that provides to the autistic a personalized healthcare through conversation exchange. The chatbot will analyze the autistic person's words and attempt to identify his facial emotions and sentiments in order to help him feel better and avoid any urgent situations wherein he might need to notify parents, medical assistance, or other parties. Accordingly, the main objective of this study is to develop, evaluate, and adapt a hybrid FER model that combines multiple pretrained CNNs (EfficientNetB0, ResNet50, and MobileNetV2) with an LSTM for temporal modeling. The research is guided by the following question: Can such a multi-feature CNN–LSTM architecture improve the recognition of atypical autistic facial expressions in real-time video sequences? In this work, we limit the scope to facial expressions only, without including posture, gestures, or eye contact. While autistic people's emotions have been detected by picture analysis in earlier work [3], in this study, we try to uncover the challenges that arise while analyzing an autistic person's face in real time.

To maintain the logical structure, we will discuss the following areas: The related works that used video-based facial expression identification techniques rather than image-based ones will be shown in Section II. Our proposed work will be presented in Section III and the findings will be addressed. In Section IV, we discuss the usefulness and significance that this research has for individuals with autism. Section V presents the conclusion and future work.

II. Related Work

The majority of existing efforts have focused on the independent analysis of static images and their extension to videos, aiming to identify a person's emotion based on facial cues in those frames [4]. Consequently, research has shifted from relying solely on spatial feature extraction toward incorporating temporal feature modeling to capture the dynamic evolution of expressions. In parallel, a few initiatives have attempted to address real-time facial emotion recognition (FER) specifically for individuals with autism. For instance, Talaat et al. [22] developed a CNN and IoT-based framework, achieving up to 94.6% accuracy in real-time conditions while reducing latency through for computing. Similarly, Abou El-Magd et al. [23] proposed a hybrid kernel autoencoder–CNN model, which obtained 96.7% training accuracy and 95.4% validation accuracy on small autism-related datasets. Other efforts focused more on assistive systems: Lee and Wong's AEGIS [24], an augmented reality application, reported real-time emotion recognition with an average accuracy of 92%. However, such studies remain scarce and are often constrained by small or synthetic datasets, limited reporting of latency under real-world conditions, and the absence of large-scale evaluations on naturalistic autistic populations. Thus, while promising, current autism-focused FER research still lacks the robustness and generalizability of benchmark-oriented studies (e.g., CK+), which underscores the need for spatio-temporal

models optimized for real-time use and trained on representative autistic datasets. For example, Jad Haddad and his associates [5] think that temporal information is essential for tracking minor facial changes that occur when an emotion is expressed. They tried to build an efficient 3D-CNN for emotion recognition in videos, which takes as input a collection of sequential frames and analyzes them collectively, while maintaining the temporal aspect of a video sequence. The Optuna framework for effective hyper-parameter search was utilized to identify the best architecture for the 3D CNN model, which also contained the temporal hyperparameters. According to certain 2017 studies [6], the mouth and eye are the most crucial features for recognizing facial emotions. The eye and mouth areas are extracted using Temporal Gabor Features. Following normalization using the Z-score normalization procedure, they are encoded into binary pattern features, which are then concatenated to produce improved temporal features. Performance on the RML and CK datasets is significantly improved by this technique.

Some people use HappyER-DDF, a technique designed to identify pleasant emotions in videos [12]. In order to extract spatial-temporal data from sequential video frames, this system used a 3D-Inception-ResNet neural network. This method is novel by the fact that it incorporates a Long Short-Term Memory (LSTM) unit to record temporal dynamics, which is essential for precisely identifying emotions in videos.

Several CNN models, including VGG-Face, ResNet18, Densenet121, and VGG16, are used in other publications as [7] to handle facial images. A two-layer Bi-LSTM is then used to collect dynamic information. By combining each model's advantages, the fusion approaches seek to increase overall accuracy [8], [9], [10]. It can involve applying Principal Component Analysis (PCA) to a single emotional video in the two phases of preprocessing and feature extraction, combining other CNN architectures in the emotion classification phase [11], and analyzing emotion expressions using models such as VGG-FACE, LSTM (Long Short-Term Memory networks), and Xception with a statistic encoder (STAT) [9]. Generally the use of models or the idea of combining many models or architectures depend on the computational and time constraints in addition to the dataset used on training that impact automatically the results.

Facial expression recognition has advanced significantly in recent years, according to numerous research studies. For spatiotemporal feature extraction, some suggest merging deep learning and dynamic texture techniques, such as LSTM and VGG19 [13]. By incorporating a conventional Vision transformer (VIT), multi-View Complementary prompters (MCPs), and temporal-Modeling Adapters (TMAs) into the image model, others attempted to modify static image models for dynamic video-based emotion recognition [14]. In addition to face emotions, physiological information such as heart rate are presented on a video-based multimodal [15]. To racalibrate the channel-wise feature maps, a new framework is proposed by combining a 3D Xception network with Squeed-and-excitation modules. The HRV characteristics and iPPG signals were chosen as the two parameters that best illustrate the feasibility and promise of multimodal fusion.

There aren't many datasets utilized on this subject in general; we can include AFEW, CK+, and MMI, and they typically require a demand from their owner in order to be used. By focusing on temporal features and employing a variety of methods, including handcrafted descriptors, spatio-temporal aggregation, multimodal fusion, and pre-trained models, each paper advances video-based face emotion recognition. The various methods employed in various studies for facial expression identification, the dataset utilized, and the model's accuracy have been gathered in the next Table I.

TABLE I. PAPERS CONTRIBUTIONS AND TECHNIQUES TO ADVANCING VIDEO-BASED FACIAL EMOTION RECOGNITION

Objectives	Dataset	Techniques	Accuracy
Enhance emotion recognition in visual data by employing a deep neural network-based fusion model [9]	AFEW 2016, SAVEE, CEV data	VGG-FACE LSTM Xception	Accuracy of 54.83%
Recognizing happy emotions from videos using combined 3D visual information with deep learning techniques [6]	AM-FED+, AFEW, MELD	3D-Inception-ResNet	Accuracy of 95.97%
Recognize the Facial Emotion in Video Sequences Using Eye and Mouth Temporal Gabor Features [12]	RML and CK datasets	Gabor Wavelets, ensemble classifier, temporal feature encoding	The accuracy of Temporal feature extraction exceeds 90% for most of the emotions
Bi-modality Fusion for Emotion Recognition in the Wild [17]	AffectNet dataset, EmotiW	Video: VGG16,CNN,Bi-LSTM Audio: low level descriptor (LLDs)	Accuracy of 62.78%
EmotiEffNet and Temporal Convolutional Networks in Video-based Facial Expression Recognition and Action Unit Detection [13]	eNTERFACE05 database	VGG19, LSTM, HOG-HOF descriptors, Support Vector Machine (SVM)	Accuracy of 98%
From Static to Dynamic: Adapting Landmark-Aware Image Models for Facial Expression Recognition in Videos [14]	RAF-DB, AffectNet7/8 , and FERPlus, DFEW, FERV39K, and MAFW	Landmark-aware pre-trained models, temporal adapters	Accuracy varies from 25% to 93%. It depends on the emotion.
Video-Based Multimodal Spontaneous Emotion Recognition Using Facial Expressions and Physiological Signals [15]	BP4D+	Multimodal fusion of facial and physiological features	Accuracy of 70%
Real-Time Facial Emotion Recognition Using Deep Learning Models [16]	BAUM-1s, eNTERFACE05	3D Convolutional Neural Networks, spatial–temporal feature aggregation	Around 45% of accuracy

III. Proposed Work: The Fusion of Three Models

The identification of facial expressions from images or videos has been the subject of numerous studies; nonetheless, the fundamental framework is essentially composed of the same components as shown in Fig. 1.

At the data collection stage, the focus is on gathering facial expression datasets from videos. Several datasets are publicly available, and among them, we chose CK+. This choice was motivated not only by the fact that CK+ has been pretrained on a large amount of data, but also because it was the only dataset provider who responded positively to our request and granted us access. In addition, CK+ presents significant advantages compared to static image datasets, as it contains complete temporal sequences:

- Neutral starting point: Each sequence begins with a neutral facial expression.
- Progressive evolution: The dataset captures the gradual development of the expression until its peak intensity.
- Detailed annotations: CK+ provides more than just a global label for each video.
  - Sequence-level labels: Each video sequence is labeled with a single primary emotion, ensuring clarity for training.
  - Apex frame annotations: The exact frame where the expression reaches its peak intensity is explicitly identified.

These characteristics make CK+ particularly suitable for our study, especially when combined with a fusion of pretrained models—EfficientNetB0, ResNet50, and MobileNetV2—used for the training stage.

Generally, the preprocessing stage involves identifying faces in every video frame utilizing deep learning-based or face identification algorithms [17]. We included cropping and aligning faces to guarantee uniformity in facial areas between frames and adjusting the photos for changes in scale, position, and lighting. It is essential to gather temporal and spatial feature [18, 19] analysis in order to build a performant model that considers the relationship between the frames in order to recognize face emotions from a video.

The architecture that we are proposing is illustrated below in Fig. 2.

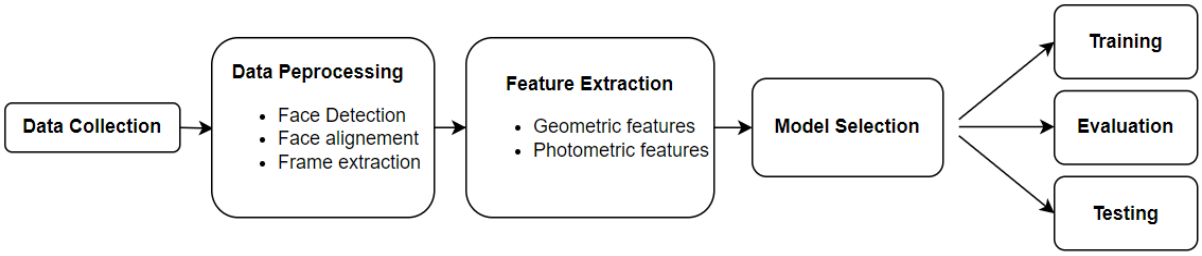

Fig. 1. The process of facial emotion recognition.

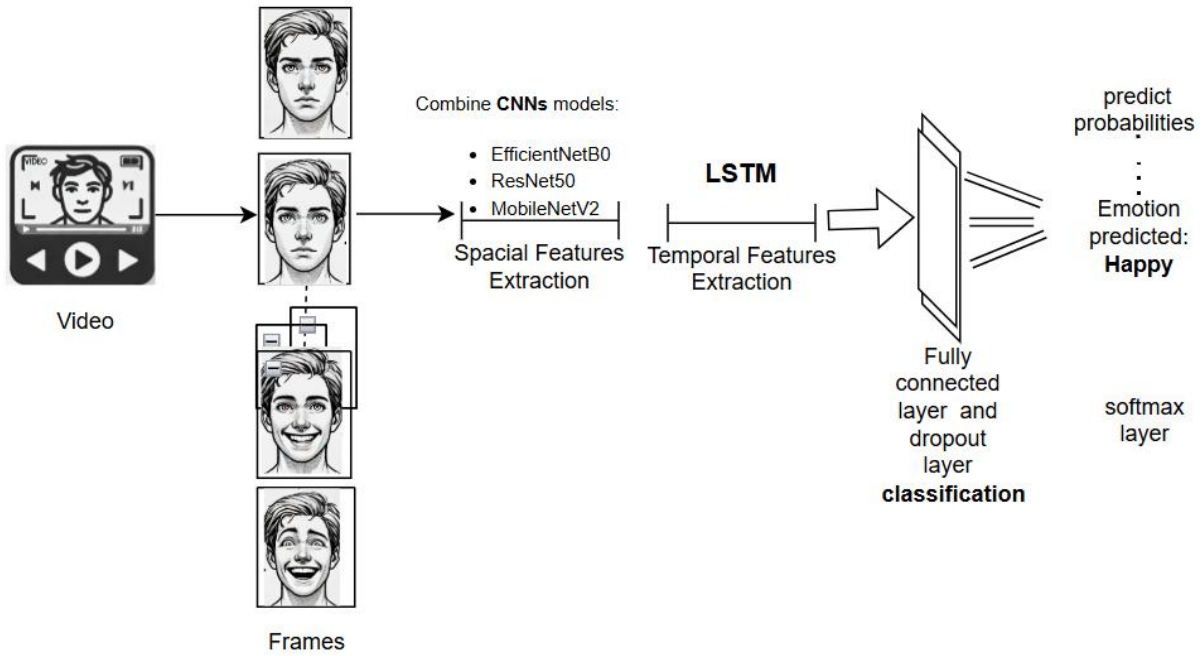

Fig. 2. The model of facial emotion recognition by combining CNNs models and LSTM for features extraction.

We will be using the combination of CNN (Convolutional Neural Networks) for spatial feature extraction and RNNs (Recurrent Neural Networks) for temporal dependencies by the use of LSTM (Long Short-Term Memory).

In order for our model to learn from the CK+ dataset, which is made up of folders with sequential frames but no individual image labels, the first step is to label these sequential frames. Each folder in the CK+ dataset represents an emotion sequence, with the final frames showing the peak of an emotion (such as happy, angry, or surprised) and the initial few frames usually showing a neutral face. In order to read sequences (video frames) and the labels that go with them, we first load the CK+ dataset (pictures and labels) into memory for the training and validation phases. We then cycle through image folders. Then, for multi-class classification, we use to_categorical to transform labels into one-hot encoding.

For efficiency, we preprocess the data before storing it in npy files and utilizing train_test_split (80%-20% split) to divide the dataset into training and validation sets.

We create a Multi-Feature Base Model by creating a base feature extractor model using the pre-trained networks EfficientNetB0, ResNet50, and MobileNetV2. We extract features from three pre-trained models for each frame and use TimeDistributed to apply the same feature extractor across all frames in a sequence and finally combine features from all three models using Concatenate. After that we add a LSTM layer to model temporal dependencies in the feature sequences and for the classification we add fully connected and dropout layers and final output layers uses softmax activation to predict probabilities for eight classes (anger, contempt, disgust, fear, happiness, neutrality, sadness and surprise).

The choice of this method is motivated by several factors:

- Complementary strengths of CNN and LSTM: CNNs excel at capturing spatial details from facial regions, while LSTMs are effective in modeling the temporal evolution of expressions across frames.
- Robustness through model fusion: By combining EfficientNetB0, ResNet50, and MobileNetV2, we leverage the diversity of their learned representations, improving generalization compared to using a single model.
- Efficient handling of temporal sequences: The use of TimeDistributed allows frame-by-frame processing while maintaining temporal coherence, which is crucial for datasets like CK+ that provide full expression sequences.
- Scalability and flexibility: The architecture can be easily extended to incorporate additional pretrained models or adapted to other datasets with minimal adjustments.
- Improved classification accuracy: The multi-feature extraction, combined with LSTM's temporal modeling, enhances the system's ability to capture subtle expression changes, which are often missed in static-image approaches.

Following these processes, it's time to assess the model, examine how well it performs across a range of emotions, and determine its limitations.

IV. Experimental Results

A. Applying the Model to CK+ Dataset

Fig. 3 illustrates the training and validation accuracy and loss curves over the course of the training process, providing insights into the model's performance and generalization.

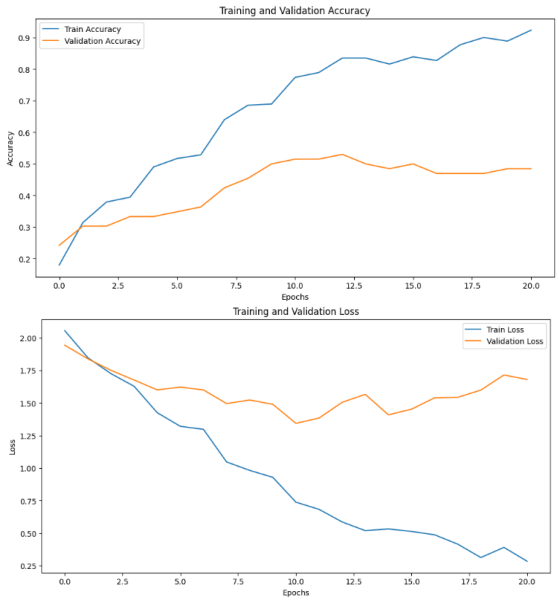

Fig. 3. The model's training and validation accuracy/loss.

1) Accuracy and Loss: Between Epochs 1 and 21, the training accuracy increases progressively from 17% to 94.5%. The model is successfully learning from the training data when the training loss steadily drops.

2) Validation Accuracy and Loss: In Epoch 13, the validation accuracy peaked at 53.03%, having begun at 24.2%. After that, though, it starts to plateau and even slightly declines (for example, 48.48% in Epoch 21). After initially declining, the validity loss starts to change at about Epoch 10. This suggests that the model has trouble generalizing outside of the training set.

3) The model's correct predictions: Here in Fig. 4 are some of correctly classified images along with their corresponding true labels and predicted labels that visually inspects how well the model has performed on correctly predicted samples.

4) The model's false predictions: The model successfully learns from the training data but struggles to generalize, as evidenced by the images below in validation data in Fig. 5.

Fig. 4. A sample of correctly predicted pictures.

Fig. 5. A sample of incorrect predicted pictures.

In our experiments, we implemented a hybrid architecture combining CNNs and LSTMs. Spatial features were extracted using three pretrained backbones (EfficientNetB0, ResNet50, and MobileNetV2), whose outputs were concatenated to form a multi-feature representation. Temporal dependencies across video sequences were then modeled using LSTM layers, followed by fully connected layers for classification.

While the training accuracy reached 94.5 % after 21 epochs, the validation accuracy plateaued around 53 %. This performance is significantly below the state-of-the-art that worked with the same dataset as [20,21], where recent works report accuracies above 95–98 % on CK+ using attention-based CNNs or spatio-temporal models such as FAN or CAGNet. We attribute this gap mainly to overfitting due to the high model complexity relative to the dataset size, and the absence of attention mechanisms to focus on the most informative frames or facial regions.

Nevertheless, our architecture demonstrates the feasibility of combining multiple pretrained models with temporal modeling, aligning with current research trends. Future work will focus on reducing overfitting through data augmentation, regularization, and possibly integrating attention modules to improve generalization and bring performance closer to the reported state-of-the-art.

B. Applying the Model to Videos of Autistic Children

In our last research [2], we worked with images of autistic children available online, gathered by Fatima Talaat at https://www.kaggle.com/datasets/fatmamtalaat/autistic-children-emotions-dr-fatma-m-talaat. Since we face a huge problem related to data and privacy, especially when it comes to people with autism, it is so hard to get acceptance to use the data even if it will not be shared. The lack of available datasets that can respond to this need in order to validate our proposed approach made us think about using the artificial intelligence tools to make videos only from the images that we worked with previously. The tool used in our case is https://www.HeyGen.com/ which is an AI-driven platform that enables users to create AI-generated videos quickly and efficiently. By selecting an image of the autistic child and expressing the setting and emotion we wanted it to convey, we attempted to produce a customized video content. We then applied our fusion model to it.

The steps to predict the final emotion are as follows in Fig. 6.

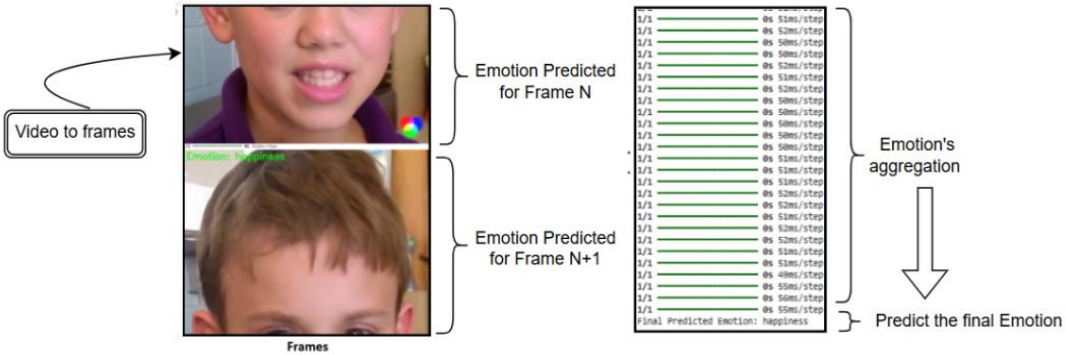

Fig. 6. The schema of splitting frames and predicting the final emotion.

This schema describes the pipeline for video-based emotion recognition, focusing on how frames are processed and predictions are made for sequences of frames in our model application.

1) Video processing by breaking the video containing the autistic into frames: A video is essentially a sequence of static images (frames) displayed over time. The first step is to

extract these individual frames from the video and to preprocess only frames with faces.

Each frame is treated as an image, enabling the model to process it independently or in groups. Frame-by-Frame Processing: This method ensures that every segment of the video is examined chronologically by processing it frame by frame. Since emotions in a video frequently change over time, this is essential for preserving the temporal context.

2) Sequence-based emotion prediction by processing sequences of frames: The pipeline aggregates frames into sequences of a fixed size (e.g. time_steps = 10) rather than predicting emotions for a single frame separately. This method captures temporal dependencies, which are crucial for comprehending dynamic emotions because of the interaction between successive frames.

3) Emotion's prediction where the model predicts the corresponding emotion (e.g., happy, sad, angry...) for every set of frames. These sequences are handled by temporal models, LSTMs which can learn from patterns and changes in the frames over time.

4) Aggregation of predictions by applying dominant emotion inference: The model combines the predictions made after analyzing every frame sequence to identify the main emotion expressed in the video. For example, if the majority of the scenes are categorized as "happy," then "happiness" may be the general feeling conveyed by the video. Voting, averaging probability, or choosing the most frequent forecast are some examples of aggregation techniques.

5) Result of applying the model on videos containing autistic individuals: The model performs well overall but struggles with many false predictions. These can be related to some autistic children who exhibit atypical or subtle facial expressions of emotions as muted smiles or ambiguous anger or fear expressions, which differ from what we had in the training data in terms of the expressed facial emotions. Also, the generative AI videos may not perfectly capture real-world variations or traits in autistic expressions, which can help create bias.

Our model needs some improvements in having more diverse, real-world dataset of autistic expressions and architecture's adjustment to focus on subtle facial regions as mouth corners, eyebrows.

Several challenges arise when applying FER in real time for individuals on the autism spectrum:

- Subtlety and variability of expressions: Autistic individuals may display emotions in less pronounced or non-standardized ways, making it difficult for models trained on typical datasets to recognize them accurately.
- Reduced or inconsistent eye contact: Since many FER systems rely heavily on eye-region cues, this can lead to incomplete or misleading feature extraction.
- Contextual dependence: Some expressions may not be directly tied to a single emotion but are influenced by the situational context, requiring the system to interpret beyond facial features.
- Sensory and behavioral differences: Atypical movements, self-stimulatory behaviors (stimming), or avoidance of camera focus may interfere with real-time face detection and tracking.
- Latency and real-time constraints: Achieving both high accuracy and low processing delay is particularly challenging when expressions are subtle and rapidly changing.
- Dataset limitations: The scarcity of large, diverse, and ethically collected datasets of autistic individuals further restricts the model's ability to generalize.

To address these issues, our model requires improvements in two main directions: 1) access to more diverse and representative real-world datasets of autistic expressions, and 2) architectural adjustments that give greater attention to subtle facial regions such as mouth corners, eyebrow movements, and micro-expressions.

V. Conclusion and Future Work

For the identification of emotions in videos, our approach is based on an architecture that allows the combination of several pre-trained models. We chose to merge the three pre-trained CNNs (EfficientNetB0, ResNet50, and MobileNetV2) with a temporal model based on LSTM in order to extract both spatial features (using CNN) and temporal relationships (using LSTM) from the video sequence. On the CK+ dataset, our model showed strong learning capability, with training accuracy reaching 94.5%. However, the validation accuracy plateaued at 53.03%, which highlights the model's limited ability to generalize beyond the training data and confirms the difficulty of applying FER to real-world autistic expressions. Because we intend to interact with a group of people with autism, and since their facial expressions in a variety of scenarios are unique, recognizing emotion is difficult even in the absence of an AI tool. We have currently attempted to use the AI technologies to create films in order to apply our model to them using datasets of public images. In order to improve the model's performance, we will try to concentrate on this community in our upcoming works, collect a database of data for training, and try to pay attention to the small details that make a difference in the autistic face with medical assistance. We might additionally modify the architecture to make it more consistent and performant to be applied to this kind of population or integrate contextual cues (e.g. body language, vocal tones) to reduce reliance on facial data alone. To achieve even more substantial findings that are aligned with the specificity of these populations and accepted by the medical party, many parties need to work together and concentrate on understanding facial features and emotions.

Integrating YOLOv8 and IoT in a Computer Vision System for Child Detection in Smart Cities

Modhawi Alotaibi*, Atheer Alruwaythi, Sara Alenazi, Maisaa Alsaedi
College of Computer Science and Engineering, Taibah University, Madinah, Saudi Arabia

***Abstract*—In an era marked by technological advancements aimed at establishing smart cities, technology increasingly focuses on enhancing aspects related to crowd management. The widespread deployment of CCTV systems, combined with the integration of computer vision, has enabled accurate insights into crowd density estimation. Our research highlights the potential benefits of child detection across various domains that serve governments and business decision-making. Leveraging Internet of Things (IoT) devices to collect real-time data and employing artificial intelligence (AI) based on deep learning through computer vision is powerful in such domains. In this paper, we propose an IoT architecture that facilitates intelligence and decision-making in two phases: 1) a deep learning model with object detection and image segmentation capabilities using YOLOv8, and 2) a tracking/counting algorithm for estimating child density based on DeepSORT. Our implementation efficiently identified and classified children in extracted images with an accuracy rate of up to 98%. Also, our model outperformed the other two solutions proposed by previous studies in terms of mAP@50, Precision, and Recall metrics. The results provide valuable insights for businesses aiming to refine site selection and guide governments in improving urban planning and safety, thereby fostering sustainable and intelligent urban development.**

***Keywords*—Computer vision; Internet of Things; deep learning; YOLOv8; DeepSORT**

I. Introduction

With the widespread deployment of Closed-circuit Television (CCTV) surveillance systems, computer vision plays a vital role in various applications based on crowd and flow density analysis. In an era characterized by technological shifts to smart cities, there is a focus on developing and enhancing aspects related to crowd management. One interesting application is the use of crowd analysis for child detection. The research field of child detection can be beneficial in various domains, such as advertising and business site selection. Governments can also gain significant advantages from child detection in domains such as public safety and law enforcement, as well as from collecting demographic information accurately for enhanced urban planning. Child detection can play a crucial role in addressing critical safety issues, such as supporting efforts to locate lost children [1, 2] and monitoring traffic to detect front-seat child occupancy in vehicles [3]. Additionally, governments can deploy child detection for smart urban planning to optimize site selection for various reasons [4], including areas targeted towards children (e.g. child centers, schools, and parks).

Despite the growing interest in crowd analysis, there remains a notable research gap in the accurate detection and tracking of children within dynamic urban environments using integrated IoT and AI technologies. Existing studies often focus on general crowd density, leaving child-specific analysis underexplored. This paper aims to bridge that gap by proposing a specialized framework for child detection and density estimation.

Distinguishing children from adults in digital images has become increasingly important for various applications, such as adjusting electronic device controls and tailoring advertisements [5], as well as informing business decisions. In today's competitive business landscape, selecting the right location is a make-or-break decision for new ventures. Businesses can utilize crowd and flow density analysis as a strategic method to gain valuable insights by accurately estimating foot traffic patterns and behaviors in a given area. Consequently, entrepreneurs can determine the optimal area for their target customers (including children), ultimately leading to enhanced commercial outcomes.

Boosting economic growth and safety through crowd data analysis to identify optimal areas for targeted audiences or enhancing the human experience lays the foundation for sustained growth and long-term success [6]. Emerging technologies like IoT and AI can play vital roles in such decision-making processes. To demonstrate the impact of crowd analysis, specifically child detection, on enhancing smart urban planning, we integrate IoT, computer vision, and deep learning technologies, focusing on areas where children are the primary beneficiaries.

IoT has become pervasive and intuitive in the technical, economic, and social fields of smart cities. It works by incorporating internet connectivity with powerful data analysis capabilities [7]. IoT deploys sensing devices to collect data and then transforms raw data into actionable insights. This process requires sensors that generate data to be collected, analyzed, and visualized to obtain useful information [8]. The data is then interpreted to produce decisions in a deliverable form [9]. The massive volume of data produced by IoT devices highlights the importance of AI, which efficiently manages and processes this vast data [10].

AI is a field of computer science that studies technologies allowing computers to intelligently simulate human cognitive functions [11]. AI encompasses various components, including deep learning, a subset of machine learning (ML) that enables machines to learn by analyzing inputs using neural networks inspired by the structure of the human brain's neurons. These

*Corresponding Author.

networks consist of layers of interconnected neurons arranged in a specific pattern and are specialized for processing a grid of values. Cognitive computing emulates human cognitive abilities, including sensing, perception, learning, decision-making, and action When integrated with IoT, cognitive computing can enhance surveillance systems to enable automated and intelligent crowd management, which understands context better and responds efficiently [12].

In the context of crowd analysis, leveraging IoT and AI, primarily through computer vision, enables accurate crowd detection and analysis. Computer vision techniques help analyze surveillance videos to extract valuable insights. It utilizes cameras, data, and algorithms to process information quickly and efficiently [13]. Computer vision techniques provide solutions to current challenges in crowd analysis, such as tracking accuracy and density estimation [14]. Our research discusses how these techniques detect children within crowd videos, which can benefit various applications across multiple domains.

Our main contribution in this paper is leveraging AI tools, IoT, and computer vision to improve urban site selection decisions for child-targeted areas. By adopting IoT devices such as cameras, we collect vast amounts of real-time data from various locations and process it with advanced AI techniques to accurately interpret crowd characteristics and behaviors. Computer vision plays a crucial role in this process, providing precise visual data analysis and applying tracking algorithms that detect, track, and estimate child density in specific areas. We propose leveraging these technological advancements to make smarter decisions, emphasizing the significant impact of our study on optimizing urban planning for sites targeted toward children. This work has significant implications for governments, urban planners, and businesses, enabling data-driven policies, enhanced safety measures, and improved infrastructure planning.

In addition to the introduction in Section I, this paper offers five more sections. Section II reviews related work on deploying IoT and intelligent methods, such as computer vision and deep learning in the crowd analysis domain. Section III describes the proposed IoT architecture. In Section IV, we discuss in detail the methodology. We present the results of our proposal in Section V. Finally, Section VI concludes the paper.

II. Related Work

In this section, we review other studies relevant to our research. The domain of crowd analysis has been addressed from various angles using different enabling tools. One primary tool is IoT. Solmaz et al. [15] presented a study on managing crowd mobility in smart cities using IoT technologies. They introduced the federated interoperable semantic IoT (FIESTA-IoT) platform, which enables information sharing among stakeholders for efficient crowd management. They addressed challenges such as the scalability of connected systems, information transparency between different systems, data federation, and information privacy. In another study, Varghese et al. [12] discussed the application of cognitive computing for smart crowd management in a surveillance system. The authors showcased two case studies: smart crowd management during Hajj (an Islamic mega event) and smart crowd management during the Tour de France (an annual bicycle race). Their IoT-based intelligent crowd-management system utilized mobile sensor data along with video data for efficient monitoring. They employed various AI algorithms, such as deep learning, to analyze IoT big data for real-time insights. In the context of mega gatherings, crowd data should be collected and utilized for better management. The authors [16] proposed an intelligent IoT approach for crowd management during Hajj to avoid congestion. Their solution was built based on the characteristics of Mina (a holy area in Makkah). In this proposed approach, they constructed the IoT sensing layer using Radio Frequency Identification (RFID) cards and surveillance cameras. Then, based on calculated risk factors, a routing algorithm guides pilgrims through safe paths. However, this proposal lacks the use of AI tools, which could elevate the solution and its outcomes. Mohd et al. [8] discussed current IoT research technologies and applications for serving Hajj and Umrah pilgrimages based on crowd analysis. They proposed practical suggestions that could employ technologies to facilitate services provided to pilgrims, Umrah performers, visitors, and service providers. The first service they suggested was a smart-screen device to prevent cases of lost pilgrims and Umrah performers. The second was a monitoring system with automated alerts to detect and respond quickly to unusual events. Third, they proposed a smart parking system using devices at each parking lot to help people locate their vehicles via plate numbers and interactive maps.

A second enabling tool is computer vision in conjunction with other technologies. Li et al. [17] examined crowd density in a tourist area using video management dynamic information analysis. They proposed a counting model that could detect crowd density through cameras. Additionally, they developed inverse-scale perception modules to support the extraction of multi-scale information. They used their model to generate a distribution-density map, counting the population based on convolutional neural networks (CNN). The authors of [18] proposed a framework that integrates CCTV video footage and spatial information, using deep learning models, geometric transformations, and tracking algorithms to extract data on crowd congestion. This approach—using deep learning techniques to accurately analyze and process visual information—allows real-time monitoring and prediction of crowd congestion, assisting urban planners and infrastructure operators in managing crowd congestion and improving public safety. Besides deploying crowd analysis for detecting abnormalities, it can also be used for flow prediction. Interestingly, Zhou et al. [19] focused on crowd-flow prediction for planned transportation sites, a critical challenge for urban planners and administrators. They offered a data-driven technique for predicting future population flows for newly planned sites.

In the domain of child safety, numerous studies have focused on techniques for child detection in images [2,3,20]. For instance, Basaran et al. [2] proposed the ChildSafe system, a solution for classifying individuals as children or adults using 3D depth cameras, aimed at enhancing child safety applications. The methodology involved collecting data from 193 participants, including 150 children and 43 adults aged 13 to 50, using Microsoft Kinect sensors. Participants performed

eight predefined actions, and the system extracted body lengths, facial metrics, and relative ratios to mitigate errors from absolute measurements. A bin-boundary-based classifier was applied to process these features, mapping them into discrete bins and calculating weights based on the likelihood of feature occurrences. The system achieved a high classification accuracy of up to 97% with low error rates. However, the solution faces challenges, particularly its reliance on controlled settings with predefined actions, which limits its effectiveness in real-world environments with dynamic lighting and unscripted behaviors. Balci et al. [3] presented a study on an automated system for detecting child occupancy in the front seat of vehicles on roadways, addressing a critical safety issue in traffic enforcement. They employed deep learning techniques to analyze images captured from an overhead gantry, achieving an overall accuracy of 90%. The methodology includes various approaches for face detection and passenger classification.

In other studies, targeting social security and crime prevention applications, the authors of [21,22] focused on classifying pedestrians as children or adults using biometric features from video data. Both approaches used the head-to-body length ratio for classification but differed in methodology, accuracy, and how they addressed challenges. In [21], a method for classifying pedestrians as children or adults using biometric features derived from long-distance video data was proposed. The study employed Haar-like features with Adaboost for full-body detection and utilized static thresholds for head-to-body ratio-based classification. The method achieved 74.7% accuracy for adults and 68.1% for children. However, challenges arose from inconsistent head detection, especially when head orientations deviated from the frontal view, and the reliance on static thresholds limited its adaptability in dynamic scenarios. Similarly, the authors of [22] proposed a framework that utilized Haar-like features with Adaboost for full-body detection and Local Binary Patterns (LBP) for head detection. This study introduced a moving average algorithm to dynamically adjust classification thresholds, addressing variations in pedestrian positions. The approach achieved 100% accuracy for children and 64.5% for adults, with lower accuracy for adults attributed to deviations in body proportions. On the other hand, [23] presented a method for detecting underage individuals using facial image classification. It utilized a dataset categorized into three age groups: children, adults, and the elderly. The methodology employs two main feature extraction techniques—Histogram of Oriented Gradients (HOG) and Haar features—to analyze facial characteristics, including wrinkles, geometric features, and facial ratios. The implementation uses the Viola-Jones algorithm for face detection, processing real-time images at two frames per second, making it suitable for various real-world applications such as online content restriction and age-age-restricted purchases.

One major benefit of crowd analysis is the ability to detect and track objects. In [24], the authors introduced DeepSORT, a tracking system that uses a neural network to enhance object tracking by combining motion and appearance information. DeepSORT aims to improve tracking accuracy by reducing identity switches and prioritizing frequently seen objects. DeepSORT achieves excellent results in tracking multiple objects and performs well across various scenarios, including our research focus on smart urban site selection for children's areas.

Selecting an appropriate site for a particular purpose is one of the many applications of crowd and flow analysis [25–28]. The purposes vary to serve different sectors, such as education, transportation, agriculture, entertainment, business, and health. Focusing on the concept of site selection from a business perspective, many authors strongly connect location selection to business success [29–31]. In [29], the author emphasized that investors must evaluate new and existing locations to determine the optimal sites for starting a business. Akpan et al. [30] studied the impact of retail outlet location and accessibility on business performance. They gathered data from businesses through a structured survey of 90 of 120 retail outlets considering functioning in an area. They analyzed the collected data using two statistical techniques: Structural Equation Modelling (SEM) and Relative Importance Index (RII). SEM is used to study the connection between retail location and profitability, while RII ranks the elements according to each factor's value in relation to other factors impacting company performance. In another study, Yakovlev et al. [31] examined the business-site-selection problem, explicitly addressing the maximum coverage location problem (MCLP). The MCLP is an optimization challenge that assists businesses in identifying the most suitable locations for their facilities to maximize service coverage. The study focused on the continuous formulation of the MCLP, which considers the arbitrary spatial shape of the demand zone (where services are needed) and the service areas (where facilities will be placed). Due to limitations in processing spatial and geometric data for the demand area, the demand zone is represented as a set of points. The study involved developing mathematical models and approaches to solve the planar MCLP using modern computer technologies. The authors emphasized the importance of considering the size and shape of the demand zone and service areas in the decision-making process for optimal facility placement.

The reviewed literature highlights substantial advancements in crowd management, child detection, and site selection through IoT, computer vision, and deep learning. However, several limitations persist. Many crowd management systems lack robust AI integration, reducing their adaptability and predictive capabilities in dynamic environments. Child detection methods often depend on controlled settings or static thresholds, which limit their effectiveness in real-world scenarios characterized by variable lighting, movement, and behavior. Tracking algorithms like DeepSORT demonstrate strong performance in object tracking, yet few studies have applied them specifically in child density estimation for urban planning. Additionally, while site selection models emphasize business optimization, they rarely incorporate demographic-specific crowd insights—such as child presence—which could significantly enhance planning for child-focused infrastructure [29–31].

III. IoT Architecture

In this section, we present our proposal: the IoT architecture, which consists of four layers, as shown in Fig. 1.

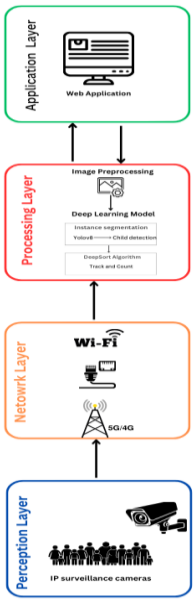

Fig. 1. IoT architecture.

First, the perception layer serves as the base-sensing layer, consisting of sensors that capture real-time environmental data and transmit it to the network layer via various communication protocols. In our work, we exploit the fact that surveillance cameras are widely deployed in public spaces, utilizing them as sensing devices to obtain video frames.

Second, the network layer functions as a communication bridge, connecting layers through internet protocols and network technologies like Wi-Fi, cellular networks, and Ethernet. Wi-Fi offers secure, reliable, and high-speed wireless connectivity, while cellular networks provide wide-area connectivity, supporting high data rates for IoT devices. Ethernet is a wired network that suits real-time applications due to its security and reliability, serving as a backbone network for interconnecting IoT gateways [32]. These features are crucial for sensors in IoT systems. In this work, data are collected from the sensors/cameras and transmitted to the processing layers via the network layer.

Third, the data processing layer processes the collected data from the perception layer through the network layer. This layer is where the intelligence resides, intertwining computer vision and deep learning technologies. Initially, our model preprocesses the frames extracted from the cameras and transmits them to our proposed model. The model then performs analysis and estimation by detecting children, tracking, and counting them accurately. The results generated from the model are then passed to the application layer for practical use.

Finally, the application layer presents the results to the end user through an interactive user interface. In our envisioned application, the results are displayed as a heatmap that ranks different sites based on varying child densities using easy-to-interpret color-coded visualizations.

IV. Methodology

In this section, we outline our methodology to demonstrate how the proposed system was designed, implemented, and evaluated. We started with deploying AI and computer vision tasks, including classification, object detection, and instance segmentation to achieve our objectives. We elaborate on our proposed model as well as other deep learning models in terms of model setup, building, and evaluation. We examine four You Only Look Once (YOLOv8) models, and the highest-performing model is compared against other proposed solutions [1, 39]. We then discuss the tracking and counting mechanism we adopt for estimating child density in crowds.

A. Deep Learning Model Selection

In this part, we start by showcasing the three main elements of any deep learning model for detection: setup, building, and evaluation.

1) Setup: Initially, we searched for a suitable dataset by exploring various open-source platforms. We found a dataset on Kaggle that contained 800 pictures [33]. However, it was not ideal as it did not meet our model's requirements and yielded poor results. Consequently, we created a new dataset by collecting data from public places and live streaming videos from a YouTube channel named "The Real Samui Webcam" [34]. Finally, we cleaned the data and extracted the frames that met our model's requirements.

After collecting the data, we began preprocessing it for the model. First, we classified the dataset into "child" and "non-child," as our focus lies between these two classes. Subsequently, we utilized Roboflow to apply data augmentation techniques, such as resizing images to 640 × 640 pixels and grayscale conversion for 15% of the images to help the model generalize across different lighting conditions. To further enhance the model's adaptability, we increased the saturation of the images by up to 30%, allowing it to learn effectively in various lighting scenarios throughout the day. Finally, to ensure data robustness, we split the dataset into 80% for training, 10% for validation, and 10% for testing.

2) Model building: Our strategy was to deploy different types of models to ensure optimal results. We began with a traditional CNN and applied the classification task among the different layers. However, the results were unsatisfactory. We then shifted our focus to transfer learning, a machine learning approach that uses previously acquired knowledge to solve a related problem. We searched for a suitable pretrained model and chose YOLO, a real-time object detection system [35]. YOLO is a widely used object detection and image segmentation model known for its speed and accuracy [36]. However, it has many versions, and we opted for YOLOv8, which introduced new features and improvements to enhance performance, flexibility, and efficiency.

YOLOv8 allows for multiple computer vision tasks, such as object detection and instance segmentation. We began with

object detection and annotated the images in the dataset with bounding boxes. Then we imported our dataset into the model. Finally, we tested our model to assess the outcomes and discovered that they needed improvement. We attempted to enhance the results by increasing the number of images in the dataset, but the results remained unsatisfactory.

Delving deeper into YOLOv8, we decided to experiment with other computer vision tasks. The first was semantic segmentation, which assigns a class label to pixels using a deep learning algorithm. It is one of three subcategories in the overall process of image segmentation that helps computers understand visual information. However, after trying it, we found that the task's process could not accomplish our goals because it aims to accurately classify each pixel in an image according to the relevant object category, meaning it cannot distinguish between distinct instances of a single object class [37]. Therefore, we decided to try the second task, instance segmentation. This method identifies and separates individual objects within an image, including detecting the boundaries of each object, assigning a unique label to each object, and distinguishing between distinct instances of a single object class. Due to their different performance, we precisely tuned two types of YOLOv8-seg—YOLOv8s-seg and YOLOv8x-seg—to choose the best performer among them. YOLOv8s-seg is smaller and used for faster inference, containing 261 layers. In contrast, YOLOv8x-seg is a larger, more complex model designed to achieve higher segmentation accuracy, with 401 layers, making it slower in inference speed and more costly. By incorporating it into our process, we achieved the best results.

For the training process, we unified the hyperparameters as shown in Table I. The epochs parameter is set to 100, defining the maximum number of iterations during training. The learning rate (lr0) is set to 0.00001, influencing the rate at which the model updates its parameters based on the training data. The batch size is set to 16, determining the number of training samples processed before the model's internal parameters are updated. Using these configurations along with other hyperparameters, we initiated training, ensuring a consistent and effective evaluation process.

TABLE I. HYPERPARAMETERS SETTINGS

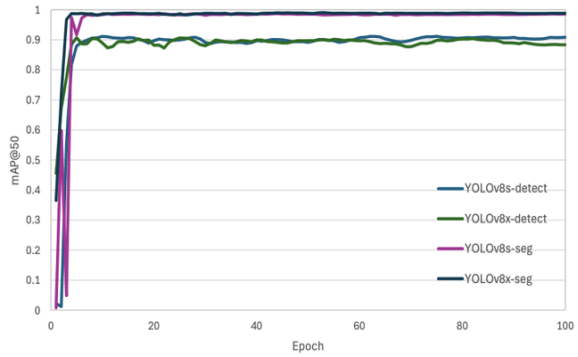
Number of Iterations	100 Epochs
learning rate	0.00001
batch size	16
image size	640 × 640 pixels

3) Evaluation: We built multiple models to achieve optimal performance. Table II showcases the diverse results of five model variations in terms of four performance metrics. The mAP@50 is a metric used to evaluate the performance of object detection and instance segmentation models. It measures how well a model can identify and localize distinct objects within an image. The mAP@50 is calculated as the mean of the average precision values across all object classes in the dataset, providing a comprehensive measure of a model's ability to detect and classify distinct object types accurately. Precision, measures the accuracy of the model's positive predictions; therefore, the higher the value, the better the result, indicating that the model accurately detects the object within its correct class and avoids misclassification. Lastly, the recall metric refers to the ratio of correct values predicted relative to all correct values, clarifying the model's completeness in identifying the most relevant instances. As for the models, we first built a CNN with a classification architecture in which the nm3467output is a set of probabilities for each class (child and non-child), with the highest probability indicating the predicted class within a separate frame.

TABLE II. MODELS COMPARISON

Model	Accuracy	mAP@50	Precision	Recall
CNN Classification	0.24	-	0.537	0.598
Object Detection by (YOLOv8s-detect)	-	0.911	0.821	0.873
Object Detection by (YOLOv8x-detect)	-	0.903	0.837	0.907
Instance Segmentation by (YOLOv8s-seg)	-	0.985	0.967	0.954
Instance Segmentation by (YOLOv8x-seg)	-	0.99	0.972	0.988

However, it does not detect two classes in one frame, leading to inaccurate results. Moreover, as shown in Table II, it has poor accuracy and precision of 0.24 and 0.537, respectively. The recall of 0.598 indicates that the model cannot accurately detect and distinguish the classes. In contrast, the object detection model is commonly used for tasks involving detecting multiple classes of objects in the same frame. Thus, we decided to build a model based on object detection. However, detecting objects with a bounding box showed better results than CNN. We tried multiple pretrained models for YOLOv8 object detection that Ultralytics offers [38]. We started with a small pretrained model (YOLOv8s-detect), which is lightweight and makes the trained model fast and efficient due to its limited computational resources. The result was still not as expected because the boxes could not precisely detect the full individual body shape in all positions. The mAP@50 was 0.911, precision increased to 0.821, and recall reached 0.873. Subsequently, we tried the extra-large model (YOLOv8x-detect), which is slower than the small model but more accurate and complex, as it has more layers and achieves higher performance. The result from the YOLOv8x-detect for the mAP@50 was 0.903, and precision and recall increased to 0.837 and 0.907, respectively, compared to the previous model.



To explore deeper knowledge and acquire more accurate results, we tried another computer vision task that assigns a class label to pixels using a deep learning algorithm, which is instance segmentation. Instance segmentation provides fine-grained localization, enabling precise differentiation between individuals in various positions. This method provides detailed and accurate information, making it easier to distinguish between different objects within an image.

We also tried multiple pretrained models for YOLOv8 instance segmentation. First, we started with a small pretrained model (YOLOv8s-seg), which is lightweight and makes the trained model fast and efficient. Fortunately, the metrics achieved drastic improvements compared to the previous models, with the mAP@50 increasing to 0.985, and precision and recall reaching 0.967 and 0.954, respectively. Then we moved to the extra-large model (YOLOv8x-seg), which is more accurate and complex. The results of the YOLOv8x-seg model yielded the best results, with a mAP@50 of 0.99 and a precision of 0.972. The recall showed the most substantial improvement, reaching 0.988, confirming that the extra-large model outperformed all prior variations.

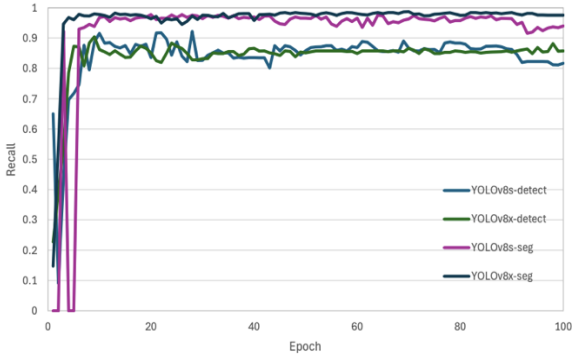


Fig. 2 depicts the performance evaluation of the four YOLOv8 model variations over a hundred epochs based on three key metrics—precision, recall, and mAP@50. Generally, the YOLOv8x models demonstrated more consistent and reliable performance compared to the YOLOv8s models across both the object detection and instance segmentation tasks. The advantage of YOLOv8x is its architectural design. The YOLOv8x model has more layers and a larger set of parameters compared to the YOLOv8s model. This increased complexity enables the YOLOv8x model to learn more effectively, allowing for a better understanding of the underlying data. However, it is important to consider that these complex computations consume more resources. For that reason, we initially used the YOLOv8s model, which proved to be a solid alternative.

YOLOv8s-detect and YOLOv8x-detect models achieve precision, recall, and mAP@50 around 0.7 to 0.8, 0.6 to 0.8, and 0.8 to 0.9, respectively. Among the two, YOLOv8x-detect's results were much closer but smoother. On the other hand, YOLOv8s-seg and YOLOv8x-seg achieved precision, recall, and mAP@50 up to 0.9 in all metrics. Moreover, the YOLOv8x-seg exhibited a consistent level without significant fluctuations. Overall, the segmentation model YOLOv8x-seg surpasses the detection models by achieving higher and more stable levels across all metrics, making it more reliable for our tasks, which require precise object identification to distinguish between child and non-child.

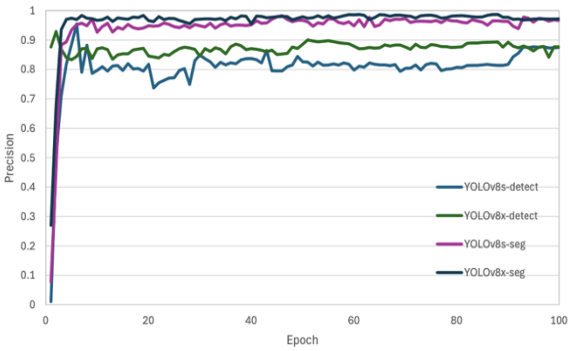

Fig. 3 depicts the relationship between precision and confidence during validation while comparing YOLOv8x-detect, YOLOv8s-detect, YOLOv8s-seg, and YOLOv8x-seg models. Initially, YOLOv8x-detect exhibits a precision of approximately 0.38, which progressively ascends, stabilizing around 0.8, and later increases to approximately 0.92. YOLOv8s-detect starts with a precision range of 0.2 to 0.3. This model then demonstrates a consistent rise to approximately 0.8 to 0.89. There is an apparent rise in precision to the range of 0.8 to 0.9, followed by a minor drop and a subsequent clear increase to around 0.95. From these observations, we infer that YOLOv8s-detect has higher confidence values but slightly lower precision compared to YOLOv8x-detect. In contrast, YOLOv8s-seg surpasses both detection models in precision and confidence, starting at approximately 0.56 and steadily increasing to nearly 0.88, followed by a gradual increase to nearly 0.98. Finally, YOLOv8x-seg outperformed all other models, particularly in terms of precision. It started at approximately 0.8, followed by a gradual increase to 0.9, stabilizing between 0.85 and 0.95, and then ultimately reaching a precision of nearly one.

(c)

Fig. 2. YOLOv8 metrics evaluation: (a) mAP@50, (b) Precision, (c) Recall.

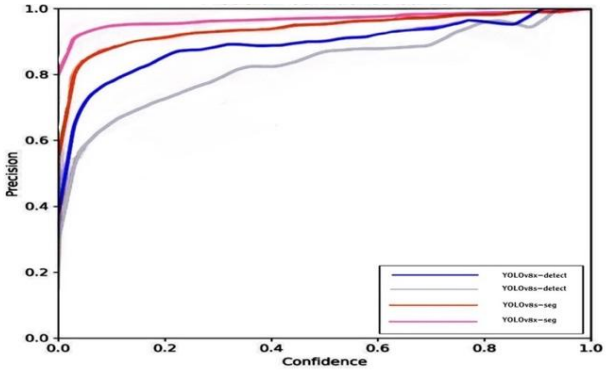

Fig. 3. Precision and confidence in validation.

4) Performance comparison with other YOLO-based models: We compare our highest achieving model (YOLOv8x-seg) as explained previously to other solutions proposed by Tahir et al. [1] and Lin et al. [39]. Fig. 4 compares the performance of these three YOLO-based models: YOLOv4-tiny [39], YOLOv5s [1], and YOLOv8x-seg.

Subfigure (a) illustrates the overall comparison across the mAP@50, Precision, and Recall metrics, while (b–d) provide a detailed view of each metric. Among the models, YOLOv8x-seg achieves the best performance, with a mAP@50 of 0.99, Precision of 0.972, and Recall of 0.988. These exceptional results are attributed to its advanced architectural design and segmentation optimization, which enhance both accuracy and detection capabilities.

The YOLOv5s [1] model also demonstrates high performance, achieving a mAP@50 of 0.905, Precision of 0.879, and Recall of 0.877. While it performs well overall, it remains slightly behind YOLOv8x-seg. Additionally, its effectiveness decreases under suboptimal camera angles, limiting its ability to detect objects accurately in certain scenarios. In contrast, YOLOv4-tiny [39] delivers the lowest scores, with a mAP@50 of 0.652, Precision of 0.83, and Recall of 0.59. These results reflect its performance limitations, especially in challenging tasks such as detecting small objects like babies in strollers, where it struggles to generate precise bounding boxes.

Overall, YOLOv8x-seg stands out as the most advanced and accurate model, making it the ideal solution for applications where performance and precision are critical.

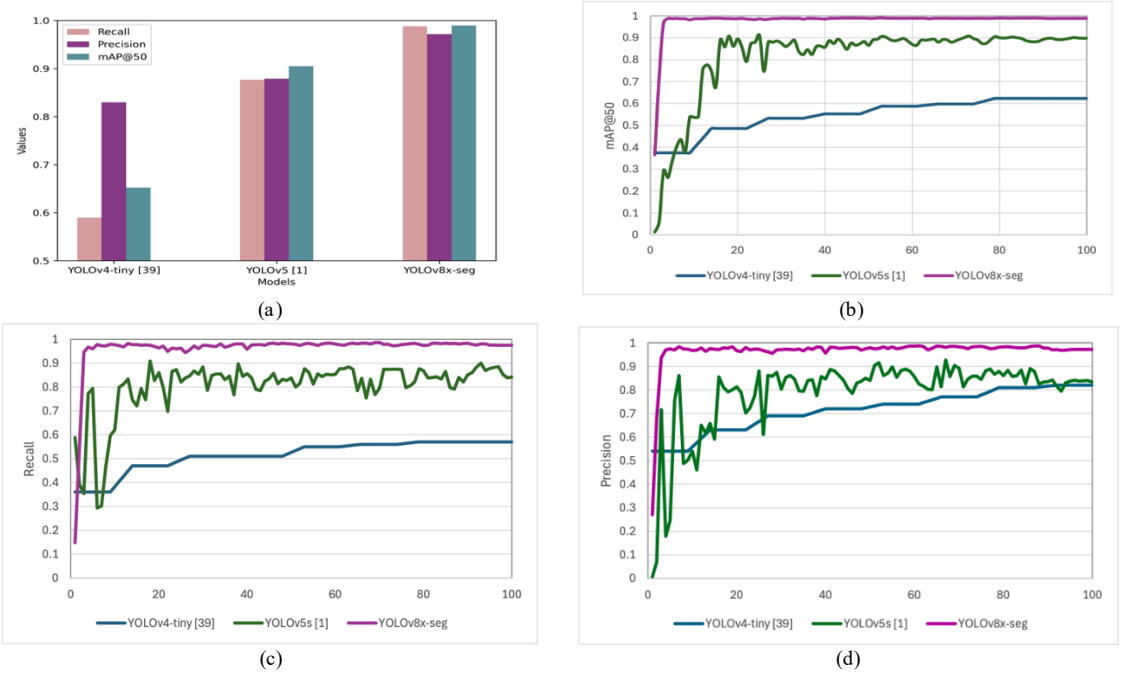

Fig. 4. Comparison of three YOLO-based models: (a) All metrics, (b) mAP@50, (c) Recall, (d) Precision.

B. Tracking and Counting Algorithm

The process of tracking objects across multiple frames is known as object tracking. In object tracking, a unique ID is assigned to each detected object and tracked across multiple frames. Object tracking has gained popularity with the evolution of computer vision and deep learning techniques [40]. Once we successfully applied our model and detected children in an area, we used object- tracking algorithms to follow them. We employed the highly effective DeepSORT algorithm [24], which uses the Kalman filter to track the position and motion of objects over time. The DeepSORT algorithm keeps track of each detected child as they move through the scene. Additionally, several parameters play a critical role in optimizing the tracking and counting process. We set these parameters to achieve optimal results. One such parameter is "n_int" which specifies the minimum number of consecutive frames a child must appear in to be considered for tracking and assigned a unique ID. We set this value to three, meaning that a child must be present in three consecutive frames to ensure its correct presence in the scene before being tracked and assigned an ID.

Another important parameter affecting tracking and counting is "max_age". It defines the maximum number of frames a child can miss before its ID is considered lost and subsequently removed. We set max_age to seventy frames, as it provides a good balance between maintaining persistent tracks and quickly removing children who have left the scene. Finally, after the tracking process is initiated, we count number of the unique IDs of the detected children. If the total count in a given area is high, it is considered a child-crowded area.

V. Results

The implementation had two phases. The first phase involved instance segmentation, which utilized the YOLOv8x-seg model.

We evaluated the model's performance on the training and validation datasets. As a result, the model successfully

identified and classified various objects in the images with high accuracy. Fig. 5 illustrates the experimental results achieved by the model using three metrics: precision, recall, and mAP@50. We also evaluated the model's performance on a new set of images outside the training set. Remarkably, our model demonstrated high accuracy, indicating that it was well-trained and capable of recognizing and differentiating between children and non-children in images. Fig. 6 represents the confusion matrix, a fundamental tool for evaluating performance. It provides a detailed representation of the model's predictions compared to the actual data. We used the confusion matrix to calculate crucial performance metrics such as precision and recall. We concluded that utilizing the YOLOv8x-seg model was the right decision, as it is designed for the instance segmentation task, enabling accurate object detection and unique label assignment, which helps with object counting.

The second phase involved tracking and counting the detected objects. Based on the results obtained from our model, we incorporated the DeepSORT tracking algorithm into our implementation. It enables us to track the children after the model detects them. The results appear as a bounding box around each child, with the track ID and confidence number. Each time a child is detected, the count increases by one. The count, along with the camera's geographical location, is then recorded. These locations near each other represent an area. If the total count in an area is high, it is considered child-crowded and thus optimal for planning child-centric sites such as schools, centers, parks, etc. This approach provides valuable insights into the density and distribution of children within a monitored area.

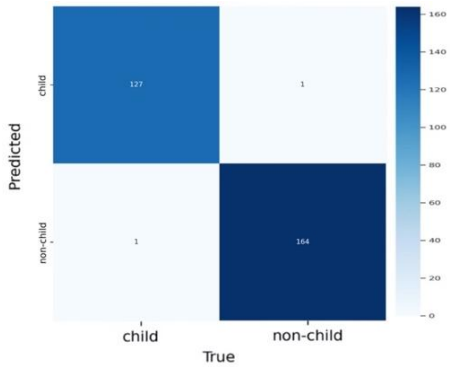

Fig. 6. Confusion matrix.

VI. Conclusion

In a time shaped by technological advancements aimed at improving the quality of life in smart cities; modern tools and techniques have become prevalent across various domains. This study targets improving site selection, assisting entrepreneurs in identifying optimal locations for their businesses while enabling governments to promote economic growth and safety. We propose integrating IoT, YOLOv8, and computer vision techniques to detect, track, and count children in crowds. This paper not only demonstrates improved site selection for entrepreneurs but also highlights broader applications, such as enhancing public safety, improving demographic data collection, and supporting smart urban planning. Our findings underscore the significant impact of our study on urban planning initiatives targeting children. Our contributions illustrate the transformative potential of IoT and AI in addressing societal challenges and fostering economic growth by providing actionable insights for child-focused site optimization. Consequently, we propose an IoT architecture that collects frames from surveillance cameras and processes them using deep learning and computer vision techniques.

Our primary contribution revolves around the IoT processing layer, implemented in two phases: the YOLOv8x-seg model and the DeepSORT tracking algorithm. Our implementation accurately identifies and classifies children in images with a precision rate of 98%. Utilizing emergent techniques such as IoT and deep learning can yield valuable insights that assist businesses and governments in making informed decisions. However, it is crucial to consider the ethical implications, particularly when dealing with sensitive data related to child tracking and monitoring. Although we propose a model for predicting optimal areas for child-centric sites, its deployment must operate within a regulated governance framework that ensures data privacy. Ultimately, the AI-driven system for defining optimal areas for governments and businesses represents a powerful tool that aligns technology utilization with community needs.

D.M.A.I.H.: Deepfake-Inspired Few-Shot Learning Approach with Stable Diffusion for Digital Mourning

Btissam Acim, Hamid Ouhnni, Nassim Kharmoum, Soumia Ziti
Computer Science Department-Intelligent Processing and Security of Systems (IPSS) Laboratory-Faculty of Sciences, Mohammed V University in Rabat, Morocco

***Abstract*—Digital mourning (deuil numérique) is the use of digital and AI-based technologies to preserve, recontextualize, and extend the memory of deceased loved ones through personalized and meaningful virtual representations. The digital mourning process requires innovative technologies capable of preserving the memory of deceased loved ones in meaningful and humanized ways. This paper proposes a novel generative approach, D.M.A.I.H. (Digital Mourning with Artificial Intelligence for Healing), for digital grief, with a focus on moral support and the mental health of bereaved relatives, using Stable Diffusion with a few-shot learning adaptation mechanism. The system takes as input a small set of personal references (e.g. a portrait, contextual images such as the person's home, and a short descriptive script) and outputs high-quality, photorealistic images of the deceased in different meaningful contexts, process closely related to deepfake generation but redirected here toward therapeutic and commemorative purposes. Unlike traditional generative models requiring large datasets, Few-shot personalization is leveraged to adapt Stable Diffusion to each individual with minimal data, enabling the generation of personalized digital albums. Experimental results show that the model consistently preserves identity in the images it produces, and contextual control ensures emotional resonance. In particular, identity similarity scores for the generated images ranged from 0.88 to 0.93, with an average score of 0.91, testifying to strong identity preservation across all outputs. The innovation of this study is a foundation for AI-based memorialization, balancing technological innovation with concerns over privacy, authenticity and cultural sensitivity, and psychological comfort.**

***Keywords*—Stable diffusion; few-shot learning; deepfake; Artificial Intelligence (AI); generative AI; digital mourning**

I. Introduction

Generative Artificial Intelligence (AI) is developing at a fast rate and transforming various industries such as art, education, healthcare [1], [2] and entertainment. Here, one of the newly emerging and yet to be discovered uses is digital mourning, where AI can assist in keeping the memory of deceased loved ones alive and providing psychological and ethical assistance to bereaved families [3], [4]. Traditional modes of commemoration, photographs, videos, or symbolic objects remain crucial but static and limited in their ability to capture the emotional richness and contextual diversity of an individual's life. Generative AI, and in particular the proposed approach, D.M.A.I.H. (Digital Mourning with Artificial Intelligence for Healing), enables a dynamic and customized recontextualization of memory, generating visual forms that can enrich the affective bond and accompany mourning [5].

This area, however, presents several difficulties. Ensuring identity consistency in the generated images is the primary challenge, considering that it is essential to accurately preserve the individual's distinctive characteristics. Limited data availability is also a primary constraint, since there are seldom several personal photos. Moreover, there are psychological and ethical issues to be addressed with sensitivity: while this technology has the potential to boost mental health and well-being through moral and empathic remembering, as substantiated by empirical studies on chatbots such as Woebot [6] and longitudinal human–computer interaction for affective care [7], it must also safeguard dignity and authenticity in commemoration [8].

The proposed approach introduces D.M.A.I.H., an innovative method that leverages enhanced Stable Diffusion with few-shot learning to generate personalized memorial albums from a small number of reference images, contextual backgrounds, and descriptive scripts. Unlike conventional generative models that require large datasets, D.M.A.I.H. adapts efficiently to each individual, ensuring both identity preservation and faithful contextualization [9].

As opposed to existing digital commemoration sites such as Facebook Memorialized Accounts [10], Instagram memorial accounts [11], or websites such as Forever Missed, which allow for mostly static or symbolic remembering, our approach offers a generative pipeline that can generate personalized, contextualized, and photorealistic memorial albums. This more appropriately situates the contribution in the field and highlights its novelty without overstating it.

First, D.M.A.I.H. is introduced as a generative approach inspired by recent advances in deepfake synthesis, but oriented toward ethically grounded memorialization, specifically designed for digital mourning and capable of producing personalized albums with high emotional value. Second, it is demonstrated that the integration of few-shot learning into Stable Diffusion effectively overcomes the limitation of scarce data while maintaining identity consistency. Finally, the D.M.A.I.H. situated within a broader perspective of psychological and moral support, emphasizing the potential of this technology to assist the mental health of grieving families while opening an ethical debate on its responsible use [12].

In brief, the D.M.A.I.H. approach was adopted since it is an approach that addresses well the core issues of digital bereavement, i.e., sparsity of data, identity integrity, and emotional relevance. The existing approaches, though promising, are afflicted by either excessive computational cost,

low identity integrity, or limited contextual adaptability and thus are less suitable for the sensitive nature of loss. On the other hand, D.M.A.I.H. integrates Stable Diffusion and few-shot learning to bypass these limitations to develop a robust generative framework for personalized memorial albums.

The remaining part of this paper is organized as follows: Section II gives an overview of related work, Section III presents the proposed model, Section IV provides experimental results, Section V discusses the findings in the context of previous studies, and Section VI concludes with future directions and ethical implications.

II. Related Work

Generative AI has been marked by an ongoing enhancement of Generative Adversarial Networks (GANs) [13] and diffusion models. *Deepfake* techniques, originally popularized through GAN-based face synthesis, illustrate both the power and the risks of these generative systems. StyleGAN, for example, has performed incredibly well in face generation [14], while Stable Diffusion, a diffusion model, has transformed text-to-image synthesis through its controllability and replication of visuals [15]. In order to fulfill personalization needs with limited data, various approaches have emerged, such as DreamBooth [16], LoRA (Low-Rank Adaptation) [17], and DreamArtist [18]. These approaches facilitate identity preservation with as few as 5 to 15 images, and thus are suitable in situations where the data is not abundant. However, their applications have largely been limited to designing avatars, artwork, or entertainment, and have been investigated extremely sparingly in delicate topics such as loss.

Digital technology has revolutionized commemoration practices, to the extent of producing what has been referred to as digital mourning. Social media such as Facebook Memorialized Accounts [19], or Instagram Memorial Accounts [20], allow surviving relatives to keep deceased individuals' pages and post memories day and night. Memory-keeping websites such as Forever Missed and Legacy.com also provide virtual space for memory preservation.

Alongside these static memorials, AI-driven initiatives have emerged. HereAfter, AI records a person's voice and stories during their lifetime, enabling interactive experiences after death. StoryFile offers similar interactive video testimonies. Deep Nostalgia (MyHeritage) animates old photographs using AI, while projects such as Eternime envisioned the creation of persistent digital avatars. Research prototypes and patents, such as Microsoft's so-called "Deadbots", have also suggested the use of digital traces to simulate posthumous conversations. While these solutions illustrate the growing interest in digital commemoration, they remain limited to static memorials, conversational agents, or simple animations, without providing truly personalized visual albums.

In addition to commemoration, AI is more and more studied for its therapeutic applications in mental health treatment. Therapeutic robots such as Replika are used for emotional care, and virtual avatars have been explored for therapy. Existing studies highlight the ability of AI to foster well-being, empathy, and psychological resilience [21], [22]. These approaches often favor verbal or dialogic interaction, while the visual and contextual dimensions of loss support are largely untapped.

This review demonstrates that while generative personalization methods and digital mourning platforms exist separately, no study to date has proposed a unified pipeline for generating memorial albums using Stable Diffusion with few-shot learning. Current platforms are limited to conversation or static commemoration, whereas AI-based personalization methods remain confined to art and entertainment. The proposed approach addresses this gap by introducing D.M.A.I.H., an innovative generative framework capable of producing photorealistic and contextualized albums of deceased individuals, thereby bridging generative AI research with the psychological needs of digital mourning.

III. Proposed Model

The proposed D.M.A.I.H. approach leverages the generative capacity of Stable Diffusion, enhanced with few-shot learning, to create personalized memorial albums. Stable Diffusion was selected as the backbone of the proposed approach because it combines photorealistic image generation with efficient conditioning mechanisms, enabling both identity preservation and contextual control. Compared to GAN-based models, which must operate on vast datasets and are often beset with instability (e.g. mode collapse), diffusion models and Stable Diffusion are more stable, more robust, and more scalable for supervised image creation. While deepfake techniques have traditionally relied on GAN-based architectures, the D.M.A.I.H. approach demonstrates how diffusion models can achieve similar identity-focused synthesis while being redirected toward therapeutic and commemorative purposes.

The whole pipeline of the D.M.A.I.H. approach is illustrated in Fig. 1, where identity extraction, contextual conditioning, and text guidance are integrated into the U-Net backbone of Stable Diffusion.

A. Approach Overview

The proposed D.M.A.I.H. approach is designed to address three key challenges in digital mourning: data scarcity, identity preservation, and emotional relevance**.** The system takes as input a small set of target images of the deceased, contextual scenes representing meaningful environments (e.g. home, farm, or interior spaces), and a descriptive script provided by relatives.

These heterogeneous inputs are processed by specialized encoders and conditioning modules, then fused within the denoising process of Stable Diffusion's U-Net. The result is the generation of multiple high-quality, photorealistic images which collectively form a personalized memorial album that preserves both identity fidelity and contextual meaning.

B. Detailed Description of Model Blocks

1) Target (Identity extraction): The reference images of the deceased are first segmented to isolate the face. A Face Encoder (ArcFace or InstantID) extracts identity tokens that encode the distinctive visual traits of the individual, ensuring faithful identity preservation [23].

2) Scene (Contextual integration): Contextual images are processed with ControlNet with depth, Canny edges, and pose

constraints. This guarantees realistic integration of the target subject into meaningful environments [24].

3) Descriptive script (Semantic guidance): A descriptive script provided by relatives is embedded using CLIP/BERT. These embeddings introduce semantic and emotional guidance [25], [26], reinforcing contextual fidelity and emotional resonance in the generation process.

4) Fusion in U-Net (Stable diffusion): Identity tokens, contextual constraints, and text embeddings are fused during the denoising process of the U-Net backbone within Stable Diffusion, yielding coherent and photorealistic outputs.

5) Output (Memorial album): The system produces multiple personalized images under different contexts. These are assembled into a digital memorial album, preserving both the identity of the deceased and the emotional significance of the scenes.

ArcFace was selected due to its state-of-the-art performance on face recognition benchmarks such as LWF (>99.8%) [27], ensuring robust identity preservation. CLIP [28] has been demonstrated to possess robust text–image alignment on large-scale datasets, enabling coherent semantic composition. ControlNet [29] has demonstrated improved performance on controllable generation tasks (pose, depth, edge), which is suitable for contextual fidelity in digital mourning.

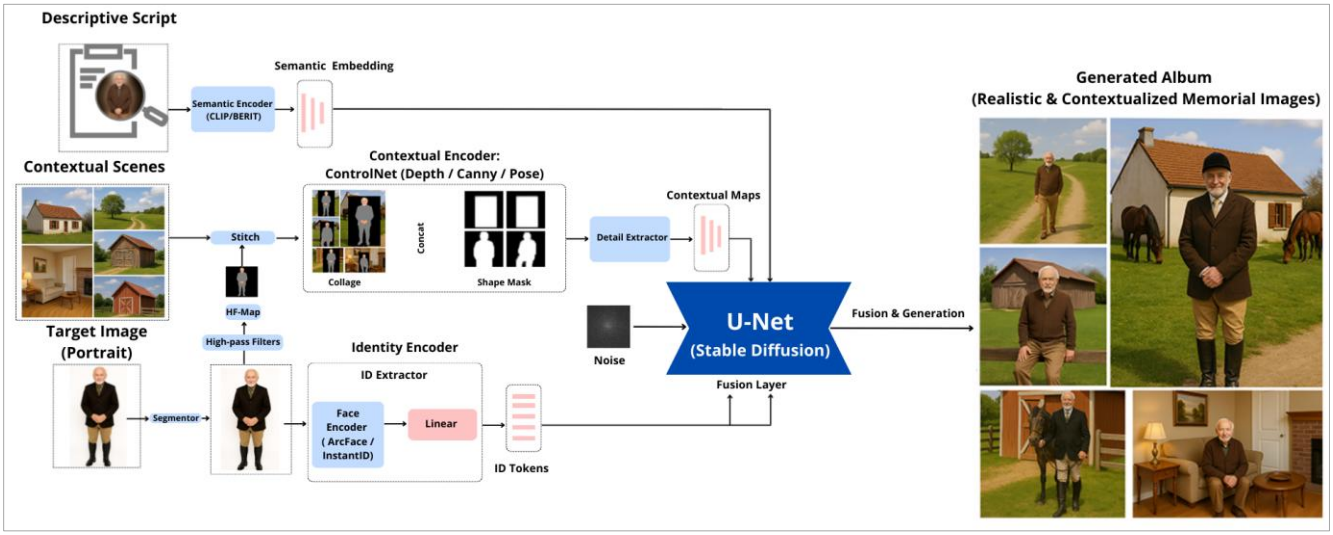

Fig. 1. Architecture of the D.M.A.I.H. approach for personalized digital mourning.

C. Motivation for Choosing Stable Diffusion and U-Net

Several personalization techniques have been explored in the literature:

1) DreamBooth: provides strong identity preservation but requires costly fine-tuning for each new subject.

2) LoRA: reduces training costs but may sacrifice fine-grained identity fidelity.

3) Textual inversion: is lightweight but limited in flexibility and often degrades image quality.

Conversely, Stable Diffusion's U-Net backbone supports [23], the straightforward combination of multiple conditioning sources (identity, context, and text) without full retraining. This balance of fidelity, controllability, and efficiency makes it ideally suited to few-shot personalization in digital bereavement, where personal images are minimal.

It was observed that this is the first such use of Stable Diffusion with few-shot learning [30] in the context of digital mourning, attempting to create photorealistic, contextualized, and emotionally evocative memorial albums.

This is also novel in technique, but it also has a profound psychosocial connotation. By producing coherent and personalized visual representations of the deceased, the system moves beyond image creation to the design of meaningful artifacts that can play a role in the grieving process.

Unlike static images, which are frozen in time, the designed memorial albums create an active and contextualized redesign of memory, allowing families to reopen contact with their loved ones in emotionally significant spaces.

Such recontextualization may have the effect of consolidating the affective bond with the deceased, conferring comfort and continuity upon the process of grieving. It does indeed support the presentation of grief in a visual and narrative form that is consonant with traditional rituals of commemoration. Such personalized albums can thus function as therapeutic agents, facilitating the process of coming to terms and lessening the sense of loss and lack.

From a psychological perspective, this intervention positions generative AI not only as a creative tool but also as a potential aid for mental health and emotional stability. By enabling families to preserve identity, remember the past, and create new symbolic meaning, the proposed D.M.A.I.H. approach can act as a moral and empathic companion bridging technological innovation with fundamental human values of memory, dignity, and resilience.

D. Comparative Analysis of Methods

The points out that while DreamBooth and LoRA give promising results, they are either computationally expensive or less accurate in terms of maintaining identity. The discussed U-Net-based Stable Diffusion pipeline ensures the best trade-off between computational expense, identity fidelity, and context flexibility, which renders it particularly well-suited for digital grief purposes. To further illustrate this comparison, Table I provides a structured overview of the main methods in terms of data requirements, training cost, identity preservation, context control, and suitability for digital mourning.

TABLE I. COMPARATIVE ANALYSIS OF GENERATIVE PERSONALIZATION METHODS FOR DIGITAL MOURNING

Method	*Data Requirement*	*Training Cost*	*Identity Preservation*	*Control Suitability for Digital Mourning*
DreamBooth	5–15 images	High (fine-tuning)	Strong	Limited (costly per subject)
LoRA	5–10 images	Moderate	Moderate	Possible but less precise
Textual Inversion	3–5 images	Low	Weak to Moderate	Not optimal (loss of fidelity)
D.M.A.I.H. approach	5–15 images	Low to Moderate	Strong (0.88–0.93, avg. 0.91)	Highly suitable

As shown in Table I and supported by quantitative validation. (0.88–0.93 identity similarity scores), D.M.A.I.H. achieves greater identity preservation and contextual fidelity than previous approaches.

IV. EXPERIMENTAL RESULTS

To validate the effectiveness of the proposed D.M.A.I.H. approach, an experimental use case representative of the digital mourning process was designed. This case relies on three types of inputs:

- Reference portrait of an elderly woman.
- Contextual scenes representing meaningful environments (family house, farm, interior).
- A descriptive script providing semantic and emotional guidance.

These inputs were integrated into the pipeline, which combines Stable Diffusion with few-shot learning and the U-Net backbone, to generate a personalized memorial album.

Fig. 2. Experimental use case of the D.M.A.I.H. approach.

Fig. 2 illustrates this experimental setup. On the left, the inputs are shown (portrait of the woman, contextual scenes, and descriptive script); in the middle, the Stable Diffusion with few-shot learning process is represented; and on the right, the output is displayed as a five-image memorial album, where the deceased is realistically recontextualized into different meaningful contexts.

The generated images demonstrate the system's ability to preserve identity fidelity while ensuring contextual relevance and emotional resonance, confirming the suitability of the proposed approach for digital mourning applications.

In the experiments, the scalability of the proposed approach was evaluated in generating a large number of personalized images per subject. Specifically, it was possible to produce more than 200 distinct images while maintaining satisfactory identity and contextual fidelity. This result demonstrates the practical scalability of the D.M.A.I.H. approach and its relevance for creating enriched memorial albums. However, this generative capacity remains subject to several technical constraints, including the available GPU memory, the inference time required to produce large batches of images, and the quality of input data, which directly affects the coherence and emotional relevance of the generated outputs. To additionally challenge the

generalizability of D.M.A.I.H., new albums were generated with alternate reference sets, with stable identity preservation and contextual integration. For comparison as a baseline, we applied DreamBooth [31] to the same inputs. While DreamBooth produced visually realistic outputs, it performed worse in terms of contextual fidelity, particularly in grounding descriptive scripts in generated scenes. D.M.A.I.H., by comparison, resulted in higher identity similarity scores (avg. 0.91) and improved contextual coherence.

Our findings are consistent with prior reports of trade-offs between identity fidelity and contextual responsiveness in personalization methods. The results extend these findings by demonstrating that D.M.A.I.H. achieves a more optimal balance, particularly for sensitive applications such as digital mourning.

A. Qualitative Analysis

The output images show that the identity of the subject is preserved across all contexts. The facial features of the individual remain consistent, confirming the effectiveness of the identity extraction module. Correspondingly, the contextual integration is also realistic: the subject is depicted believably in the scenes provided (house, farm, interior), achieving semantic coherence between inputs and outputs. The descriptive script also emphasizes the emotional impact, as it guides the generation to representations that achieve high affective value.

As a result, the album produced is an active visual remembrance rather than static common images. By representing them in several contextualized and emotionally relevant ways, it allows families to symbolically reconnect with deceased loved ones.

B. Quantitative Analysis: Identity Fidelity

In addition to the qualitative analysis, the identity fidelity between the reference image and the generated images of the album was evaluated. For this purpose, A face encoder (ArcFace) was used [24] to extract embeddings and compute the cosine similarity defined as follows:

$$S(I_{ref}, I_{gen}) = \frac{f(I_{ref}) \cdot f(I_{gen})}{\| f(I_{ref}) \| \| f(I_{gen}) \|}$$

where, $f(I)$ denotes the embedding of an image, I_{ref} is the reference image, and I_{gen} is a generated image. A value close to 1 indicates strong identity preservation.

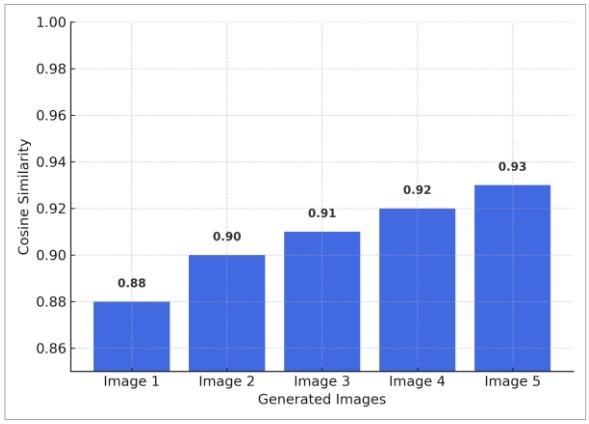

Fig. 3. Cosine similarity scores of generated images (D.M.A.I.H.).

Fig. 3 reports the scores obtained for the five generated images of the album. Results ranging between 0.88 and 0.93, with an average similarity score of 0.91, further demonstrate consistent identity preservation and confirm that the D.M.A.I.H. approach achieves high identity consistency despite the limited number of input images. These validation measures are necessary to demonstrate robustness. By combining quantitative analysis (identity similarity scores) and qualitative analysis (contextual and semantic coherence), the generated outputs are ensured to be not only visually acceptable but also retain the emotional and memorial value required in digital mourning software.

C. Dual Scope of the D.M.A.I.H. Approach

On the technical level, D.M.A.I.H. introduces, for the first time in the field of digital mourning, the combination of Stable Diffusion with few-shot learning. This synergy enables the creation of photorealistic, contextualized, and highly personalized memorial albums from only a very limited number of reference images. By leveraging generative AI with advanced adaptation techniques, the system overcomes the traditional limitations of data scarcity in sensitive contexts such as mourning.

On the psychosocial level, D.M.A.I.H. transcends the boundaries of image generation to become a medium of moral and psychological support. By offering authentic and emotionally resonant representations, it strengthens the symbolic continuity of grief, consolidates the bond between families and the deceased, and complements rather than replaces traditional mourning rituals.

Overall, this paper presents generative AI both as a driver of technological innovation and as an instrument of psychological resilience, emotional well-being, and mental health. It highlights the possibility of an empathetic and ethically responsible use of AI in supporting families, where advanced technology is balanced with fundamental human values such as dignity, memory, and humanity.

V. Discussion

The results obtained highlight the effectiveness and relevance, both from a technical and a psychosocial perspective.

A. Technical Strengths

The D.M.A.I.H. approach, based on Stable Diffusion with few-shot learning, demonstrated its ability to robustly preserve identity fidelity, even with a very limited number of reference images. Similarity scores (0.88–0.93) confirm high identity consistency across generated outputs. Additionally, contextual scene composition using ControlNet ensures realistic placement of the subject in semantically relevant contexts, and the script description ensures semantic and emotional consistency. Compared to existing personalization methods, such as DreamBooth, LoRA, or Textual Inversion, A more favorable trade-off between visual quality is achieved, flexibility, and computational efficiency, without requiring expensive retraining for each new subject, and illustrates how techniques often linked to deepfake generation can be redirected toward ethical applications.

In particular, compared to DreamBooth [32], Costly fine-tuning was required, and weaker contextual fidelity was observed in the baseline implementation; higher identity similarity scores (average 0.91) were achieved. Similarly, while LoRA [31] and Textual Inversion [33] provide lightweight alternatives, they often suffer from degraded identity fidelity or reduced image quality. D.M.A.I.H. therefore offers a stronger balance of identity preservation, contextual adaptability, and computational efficiency, which is especially relevant in sensitive contexts such as bereavement. New innovations such as Perfusion [34] have attempted to reduce fine-tuning costs but keep personalization potential high; however, they fall short regarding identity preservation. In contrast, the model is stronger and more contextual in design.

B. Comparison with Existing Approaches

Current online mourning services, such as Facebook Memorialized Accounts, Forever Missed, or Legacy.com, just offer static memorials. AI-based initiatives such as HereAfter AI, StoryFile, or Deep Nostalgia focus mainly on interactive dialogue or simple photo animation [35]. While innovative, these tools do not provide a comprehensive generative framework capable of producing personalized, contextualized visual albums. The D.M.A.I.H. approach fills this gap by introducing a pipeline that combines identity preservation, contextual control, and emotional resonance into a single system. Moreover, by explicitly stating similarity of identity and correspondence of context, the analysis extends beyond qualitative judgment to provide quantifiable proof of resilience. This not only justifies the comparative analysis by virtue of being against other existing personalization methods, but it positions D.M.A.I.H. as not merely a theoretical contribution but as an empirically proven framework aligned with existing research.

C. Psychosocial Impact

Beyond technical innovation, the main strength the D.M.A.I.H. approach lies in its role as a potential tool for moral and psychological support. The generated albums allow families to symbolically reconnect with their deceased loved ones, transcending the limits of traditional static photographs [36]. This recontextualization of memory as a dynamic process can be an additional therapeutic tool supporting the mourning process, reinforcing emotional stability, and enabling psychological coping in bereaved families.

D. Limitations and Future Perspectives

Despite the positive outcomes of the D.M.A.I.H. approach, it is important to recognize a number of its limitations. Generalizability is limited because the evaluation is still primarily qualitative and based on a single use case. To evaluate the model's robustness, a larger-scale validation process involving user studies in various cultural contexts will be necessary. The integration of multimodal memories (voice, video, and text), the reinforcement of ethical control mechanisms across the pipeline, and the creation of safeguards to reduce risks like emotional dependency are some future research directions. To guarantee greater empirical validation and ethical robustness, the assessment should also be expanded to larger datasets and carried out in conjunction with psychologists and ethicists.

Similar scalability and identity drift issues also have been encountered in recent personalization studies, validating that the proposed extensions support multimodal integration, adversarial robustness, and stronger ethical guardrails are timely and valid directions.

E. Ethical and Legal Considerations

The use of the D.M.A.I.H. approach in the context of bereavement also raises serious ethical and legal concerns. The issue of consent post-mortem remains on everyone's minds, as current legal regulations provide minimal guarantees. The GDPR and upcoming AI Act for Europe impose transparency and traceability obligations on AI systems but only apply partially to posthumous data across jurisdictions. Such risks include the possibility of inducing false memories, emotional manipulation, and psychological dependence among families. In response to these challenges, the D.M.A.I.H. approach is grounded in an ethical responsibility model, viewing the suggested system as a supportive tool supplementary to the natural grieving process rather than a substitute for it. Future efforts must focus on establishing ethical norms and regulatory frameworks to ensure that generative AI is applied in a thoughtful, empathetic, and culturally sensitive manner.

VI. Conclusion

In this paper, the D.M.A.I.H. approach was introduced, a novel pipeline for digital mourning based on Stable Diffusion with few-shot learning, capable of generating personalized, photorealistic, and contextualized memorial albums from a very limited number of reference images. The D.M.A.I.H. approach meets three of the most significant challenges in this area: identity preservation, contextual fidelity, and emotional relevance. Experimental outcomes show that the system proposed herein effectively preserves identity through a change of context, and descriptive scripts ensure semantically and emotionally relevant outputs, illustrating how techniques commonly linked to deepfake generation can be ethically redirected.

Aside from the technical relevance, this study emphasizes the psychosocial significance of the D.M.A.I.H. approach as a tool for moral and psychological attention. Through the dynamic recontextualization of remembrance, the system offers relatives an opportunity to symbolically reunite with their deceased kin, thus complementing everyday acts of memory and encouraging mental health and emotional balance. At the same time, this study identifies important ethical and legal issues, particularly regarding consent, authenticity, and cultural sensitivity. Their resolution will be needed to assure proper use of these technologies.

Unlike existing digital commemoration services that are static or symbolic, D.M.A.I.H. introduces a novel generative pipeline that integrates identity preservation, contextual fidelity, and semantic resonance. This renders the approach a unique contribution to the emerging field of AI-based memorialization. From both an ethical and legal standpoint, further roll-out must be managed by healthcare and psychology ethics committees, based on guidelines such as the GDPR and the EU AI Act. D.M.A.I.H. presents a novel generative pipeline that combines identity preservation, contextual fidelity, and semantic

resonance, in contrast to current digital commemoration services that are static or symbolic. Because of this, the proposed approach offers something special to the developing field of AI-based memorialization. Based on rules like the GDPR and the EU AI Act, ethics committees in the fields of psychology and healthcare must oversee any future roll-out from a moral and legal perspective.

***Abstract*—The growth of cloud computing has heightened the demand for replication strategies that ensure strong consistency, high availability, and low communication cost across distributed infrastructures. Existing systems such as DynamoDB, FoundationDB, and GeoGauss illustrate different design trade-offs but face limitations in balancing latency, correctness, and resilience under dynamic workloads. This study proposes the Binary Vote Assignment in Cloud (BVAC), a cloud-native replication algorithm re-engineered from the Binary Vote Assignment on Grid Quorum (BVAGQ). BVAC organizes replicas in a logical grid structure and employs binary voting weights with a Commit Coordination (BCC) mechanism to enforce quorum-validated commits, representing a form of quorum-based replication. This design maintains serializable consistency, minimizes replication conflicts, and reduces low communication cost through fixed-size quorums of three to five replicas. Experimental results demonstrate that BVAC sustains fault tolerance, achieves cloud database replication efficiency, and sustains high data availability via multiple valid quorum paths. By avoiding the heavy coordination cost and infrastructure footprint of current systems, BVAC provides a scalable and cost-efficient replication strategy tailored for modern cloud workloads. The study establishes BVAC as an advancement in distributed data management and a foundation for future adaptive and multi-cloud replication frameworks.**

Keywords*—Binary Vote Assignment in Cloud (BVAC); cloud database replication; fault tolerance; high availability; quorum-based replication; strong consistency

I. Introduction

Distributed computing environments present significant challenges, particularly in maintaining high availability and reliability of data. Data replication has long been recognized as a fundamental technique to address these challenges, as it enables systems to provide fault tolerance, load balancing, and continuous access to critical information [1, 2, 3, 4].

In traditional grid computing environments, data replication was introduced to enhance availability and dependability by distributing replicas across multiple grid nodes. This approach allowed systems to tolerate node failures, support concurrent access, and reduce the risk of data loss in large-scale scientific and computational applications [5]. Techniques such as static replication and dynamic replication policies were widely deployed to ensure that frequently accessed data remained available across geographically dispersed resources [6].

While grid-based replication strategies achieved significant success in improving fault tolerance and data accessibility, they also exhibited several limitations. Grid environments are inherently tightly coupled and resource-constrained, which often restricts scalability and adaptability. Furthermore, replication overhead was difficult to manage, and consistency across replicas was not always guaranteed due to network heterogeneity and limited elasticity of grid resources [7]. These challenges made grid-based replication less suitable for modern workloads that demand real-time responsiveness and global accessibility.

Several replication strategies have been proposed to address the challenges of managing data in cloud environments. Broadly, these methods can be categorized into synchronous replication and asynchronous replication. Synchronous replication ensures strong consistency by updating all replicas simultaneously, which is suitable for mission-critical applications but often introduces high latency, especially in geographically distributed clouds [5]. On the other hand, asynchronous replication reduces latency by allowing updates to propagate to replicas at a later stage, thereby improving performance but at the cost of potential data inconsistency during failures [6].

In addition to these traditional methods, several hybrid approaches have been developed to strike a balance between consistency and performance. For example, techniques such as quorum-based replication and majority consensus protocols allow systems to achieve partial synchrony, ensuring data reliability without incurring the full latency penalty of synchronous models [7]. Multi-cloud replication frameworks have also been explored to enhance disaster recovery and reduce the risk of vendor lock-in, but these often come with additional management complexity and resource overhead [8, 9].

Despite these advances, current replication approaches remain limited in handling the highly elastic and dynamic nature of modern cloud workloads [2, 10]. In practice, cloud environments introduce additional challenges such as multi-tenancy, where multiple independent users share the same infrastructure, often leading to unpredictable performance interference. Moreover, geo distribution of cloud datacenters creates latency asymmetries and raises the difficulty of maintaining consistency across regions. Cost-efficiency also becomes a critical factor, as replication policies directly affect storage, bandwidth, and operational costs in pay-as-you-go

models. Traditional replication mechanisms often fail to adapt to these requirements, as they were not originally designed to optimize for resource elasticity, cost sensitivity, and tenant isolation. This gap underscores the importance of designing new replication strategies that can simultaneously ensure high availability, strong consistency, and performance while remaining cost-aware and adaptable to real-time workload dynamics.

With the rise of cloud computing, replication challenges have become more complex. Cloud infrastructures demand solutions that can handle multi-tenant environments and flexible resource allocation while maintaining low latency and strong consistency [7, 10]. Existing replication mechanisms do not adequately address these requirements, leaving a gap for innovative approaches that balance consistency, availability, and performance in large-scale, globally distributed cloud systems.

To address these challenges, this study proposes the Binary Vote Assignment on Cloud (BVAC) algorithm, by re-engineering BVAGQ [11] for cloud environments. BVAC is designed to improve data consistency and availability by leveraging a binary voting mechanism in quorum-based replication, where replica servers are assigned voting weights to determine the validity of transactions. This voting scheme minimizes replication conflicts, enhances fault tolerance, and reduces the communication overhead typically associated with quorum-based replication. Unlike previous grid implementations, the proposed BVAC adapts its design to the elasticity and scalability of cloud infrastructures, enabling efficient replica placement across geographically distributed nodes. By re-engineering BVAGQ for cloud environments, this research aims to bridge the gap between traditional quorum-based replication in grids and the dynamic requirements of modern cloud systems. Unlike existing approaches, the proposed BVAC explicitly addresses multi-tenancy, geo-distributed deployments, and cost-efficiency by incorporating a lightweight voting mechanism that adapts to workload variability while minimizing communication overhead. This makes BVAC particularly well-suited for cloud infrastructures where scalability, elasticity, and operational costs are as critical as data consistency and availability.

The remainder of this paper is organized as follows. Section II presents the literature review on replication strategies in grid and cloud environments. Section III describes the design of the proposed Binary Vote Assignment on Cloud (BVAC) algorithm, including its voting scheme and replica placement strategy. Section IV presents the experimental setup and evaluation methodology, and discusses the results in terms of consistency, availability, and performance. Finally, Section V concludes the paper and outlines directions for future research.

II. Literature Review

Data replication in cloud environments integrates diverse sub-strategies, techniques, and algorithms into cohesive frameworks that sustain system dependability. The replication process is commonly structured around three fundamental phases: identifying frequently accessed data, determining the number of replicas, and selecting their optimal placement. Extensive research has introduced algorithms targeting each of these phases to enhance performance, consistency, and fault tolerance [12, 13]. Modern cloud platforms translate these conceptual strategies into operational practice through protocol-level implementations and system design choices. DynamoDB, for instance, represents a production-grade system in which phase-level replication decisions are directly embedded within concrete protocol mechanisms, thereby exemplifying the alignment of theoretical models with practical deployment.

DynamoDB integrates a tunable-consistency read model into its replication design, providing eventual reads by default for latency reduction and permitting per-request strong reads within a region under ACID semantics with serializable isolation [14, 15]. In multi-region deployments, Global Tables employ asynchronous propagation, which yields eventual cross-region consistency while decoupling regions during inter-region disturbances [15]. The communication path per write remains bounded, as a leader disseminates the update to followers across three (3) availability zones and commits upon a two-of-three quorum, so the critical path corresponds to one intra-region round-trip time with message complexity linear in the replica count, $O(n)$ for $n = 3$. Read placement adheres to the consistency objective, whereby strong reads are directed to the leader and eventual reads may be served by any replica; transactional operations introduce additional coordination rounds via two-phase commit, and any synchronous cross-region configuration, when enabled, elevates both the critical-path round-trip time and the message fan-in. With respect to availability, the three-replica topology tolerates a single replica failure per partition and supports rapid leader re-election, while asynchronously replicated Global Tables allow regional autonomy under wide-area impairments at the expense of temporary divergence; conversely, synchronous multi-region modes trade some write availability to secure stronger cross-region guarantees [15].

Alongside DynamoDB, two further systems illustrate alternative trade-offs, namely FoundationDB and GeoGauss. FoundationDB advances strict serializability across the keyspace through an unbundled control and storage plane comprising commit proxies, resolvers, and log servers, with synchronous replication in a primary region and frequent inclusion of satellite replicas as well as an asynchronous secondary region for disaster recovery [16]. The communication path per writes traverses coordination services and multiple log replicas, often including satellites, which introduces additional hops relative to a three (3) replica quorum and can elevate tail latency under load or under cross-region safety requirements. Steady-state reads obtain a read version from the primary path and avoid extra wide-area round trips. With respect to availability, the architecture tolerates multiple component failures inside a region and supports automatic failover to a secondary region upon primary loss, delivering strong reliability at the expense of additional coordination and replica footprint [16].

GeoGauss pursues strong global consistency for geo-distributed SQL through a full-replica, multi-master architecture that combines epoch-driven optimistic coordination with Raft-style membership, enabling write origination in any region while enforcing a global commit order [17]. The communication cost exceeds single-region designs, since each transaction issues cross-region control traffic for epoch advancement and

validation and ships data to full replicas, which embeds wide-area round-trip time and extra coordination in the commit path, particularly under contention or reconfiguration. Regarding availability, complete replicas across regions furnish resilience and locality for reads and writes, and service can continue through regional failures, while long-haul coordination under partitions or congestion lengthens commit time until quorum and ordering guarantees are satisfied.

A. Comparative Analysis of Cloud Replication Systems

Despite considerable progress, DynamoDB, FoundationDB, and GeoGauss continue to reveal structural limitations along the consistency–latency–availability frontier. DynamoDB's configurable consistency model achieves low latency but risks stale reads; strong reads are restricted to regional scope, and globally strong modes require wide-area coordination. Its otherwise lightweight two-of-three quorum inflates latency under synchronous multi-region deployment, while the three-replica design tolerates only a single failure, reducing write availability during WAN impairments [14]. FoundationDB delivers strict serializability yet relies on a multi-role control path involving commit proxies, resolvers, and log servers. This design increases coordination sensitivity and tail latency under load. Although failover is robust, sustaining cross-region safety typically demands five or more replicas, thereby elevating resource cost [16]. GeoGauss ensures strong global consistency through full replicas and epoch-based OCC ordering under Raft membership, but wide-area validation and full data movement in the commit path increase coordination overhead. While regional failures can be absorbed, partitions delay progress until global ordering and quorum are re-established, imposing the heaviest infrastructure burden due to per-region full replicas [17].

In our previous studies, BVAGQ found that write-query availability might be enhanced with minimal communication costs by employing a limited replication quorum [18]. Nonetheless, that methodology did not encompass cloud-native environments. This paper introduces the Binary Vote Assignment in Cloud (BVAC), a re-engineered variant designed to support synchronous replication across fragmented databases, with BVAGQ providing disjoint partitioning of data. BVAC enforces strong-by-default consistency by validating commits through vote-based quorums of constant size, thereby preserving serializability without incurring continuous wide-area coordination. Communication overhead is bounded by a fixed quorum of three to five servers, which reduces message complexity and constrains commit round-trip latency. Data availability is sustained through a binary vote assignment that admits multiple valid quorum paths, ensuring resilience under failures. In this way, BVAC retains the lightweight advantages of BVAGQ while extending its applicability to cloud infrastructures with explicit support for fragmentation and cross-region fault tolerance. The primary strategies for database fragmentation are horizontal fragmentation and vertical fragmentation. Horizontal fragmentation grants users' access to all attributes. Vertical fragmentation partitions the database based on properties, rather than entire rows [19, 20, 21] (Table I).

TABLE I. THIS SECTION ANALYSES EXISTING CLOUD DATABASE SYSTEMS

System Method	Data Consistency	Commit Path	Communication Cost
Dynamo DB	Configurable consistency model: default eventual consistency, optional strong consistency per request, with ACID serializable transactions.	- Primary replica handles write with 2-of-3 quorum - Strong reads from primary, eventual reads from any secondary. - Transactions require 2PC. - Async global tables reduce cost, while synchronous multi-region adds cross-region latency and coordination.	3 replicas per partition (regional); extra regions for global tables.
Foundation DB	Strict serializability through synchronous replication across primary and secondary roles.	- Strict serializability via synchronous replication. - Writes coordinated through commit proxies and multiple log servers (primary + secondaries), - Strong correctness and failover support, but higher coordination overhead and resource cost.	Often ≥5 replicas incl. satellites/coordinators (configurable).
GeoGauss	Strong global consistency through full-replica multi-primary with epoch-based OCC.	- Multi-primary architecture with full replicas in all regions. - Any primary can accept writes, but global commit order requires cross-region coordination. - Strong global consistency and resilience.	Full replica per region - high communication cost and cost overhead.

III. METHODOLOGY

The fundamental concept of replication is creating numerous copies of identical data or replicas across various storage locations. This research introduces the Binary Vote Assignment in Cloud (BVAC) method. In BVAC, all servers are systematically arranged in a two-dimensional grid configuration. If BVAC comprises twenty-five servers, they will be systematically arranged in a 5 x 5 grid format.

A. BVAC Algorithm Definition

In this section, the Binary Vote Assignment in Cloud (BVAC) is proposed by considering the distributed database fragmentation. The following notations are defined:

i. C is a table within the database.
ii. c' is the instance in C and C'
iii. $T(C)^1$ is the four servers in the corners
iv. $T(C)^2$ is the alternative locations on the peripheries
v. $T(C)^3$ is the central locations
vi. T is a transaction.
vii. x is a variable in C that gets altered by element of T.
viii. y is a variable in C that expected to remain unaltered by element of T.
ix. C_1 is a vertical fragmented table with data x.
x. C_2 is a horizontal fragmented table with data x.
xi. Pk is a primary key.
xii. Pk,x is a primary key with data x.
xiii. Pk,y is a primary with data y, where $y \neq x$

xiv. $C_{1_{(Pk,x)}}$ and $C_{1_{(Pk,y)}}$ are a horizontal fragmentation relation.

xv. η and ψ are groups for the transaction T.

xvi. $\lambda = \eta$ or ψ where it represents different transaction T (before and until get quorum).

xvii. T_η is a set of transactions that comes before T_ψ, while T_ψ is a set of transactions that comes after T_η.

xviii. D is a union of all data objects managed by all transactions T of BVAC.

xix. BVAC transaction element T_λ is an element either in different set of transactions T_η or T_ψ.

xx. wT_λ is write counter for the transaction.

xxi. $\hat{V}_{\lambda_x}$ is a transaction that is transformed from T_{λ_x}

xxii. T_{μ_x} represents the transaction feedback from a neighbour site.

xxiii. T_{μ_x} exists if either T_{λ_x} or $\hat{V}_{\lambda_x}$ exists.

xxiv. Successful transaction at primary site $T_{\lambda_x} = 0$ where $T_{\lambda_x} \in D$ (i.e., the transaction locked an instant x at primary). Meanwhile, successful transaction at neighbour site $T(\mu_x) = 0$, where $\mu_x \in D$ (i.e., the transaction locked a data x at neighbour).

xxv. $\left\lceil \frac{n}{2} \right\rceil$ is the greatest integer function (i.e., n=9, $\left\lceil \frac{9}{2} \right\rceil = 5$.

B. Data Replication in BVAC

The Algorithm 1 details the replication process for BVAC via BVAC Commit Coordination (BCC), showing how a commit initiated at a primary and a neighbour server is executed.

Algorithm 1: The BCC Algorithm: Data Replication

```
1  manage_bvaqgar_transaction ( )
2  {
3  while (InComplete)
4  do
5    while (transStat ≠ "Abort")
6    do
7          /* receive T_λx || V̂_λx || T_μx where λ = η, ψ either
       from client or any BTM of replica i ∈ T(C)*/
8      receive (client @ BCC of i ∈ T(C): T_λx || V̂_λx);
9      pid_T_λx = process id of T_λx;
10     log_tT_λx = login time of T_λx;
11          /*recognize replica task either to be as primary or
            neighbour processing for T_λx, λ = η, ψ */
12     switch {
13      case (receive(client @ BCC of neighbour: T_λx || V̂_λx||
       T_μx):
14       primary_replica_processing ( );
15                  break;
16              case (receive(BCC of primary: T_λx || V̂_λx)):
17                  neighbour_replica_processing ( );
18       break;
19        }
20     receive (BCC: V̂_λx, x$erv_Vote || V̂_λx, x$erv_Vote,
21      $_LCount,uT_λx);
22     if (x$erv_Vote = 1) then
23              Commit V̂_λx ;
24     endif
25     if (x$erv_Vote = 0);
26     Endif
27   /*On receiving transStat = "Abort" from other replica and
     needs to release its lock*/
28   if (receive (BCC: V̂_λx , ∈ T_η transStat, PrimaryID)) then
29     T_λx ∈ V_ψ =T_λx ; /*current T_λx becomeT_λx ∈ T_ψ */
30     V̂_λx =V̂_λx ∈ T_η ; /*V̂_λx ∈ T_η that BCC received will
     survive*/
31   Abort T_λx ;
32     Rollback;
33          T_λx = 1; /*Target Set is equal to 1, means primary
     already gets lock*/
34   endif
```

Every server comprises a primary data file. A server is either functional or nonfunctional, and the status (functional or nonfunctional) of each site is significantly uncorrelated with the others. When a site is functional, the data at the server is accessible; otherwise, it is inaccessible.

For example, in Fig. 1, data from site A (a) is duplicated to its adjacent servers B and D. Consequently, site A possesses three replica servers. Site E has four adjacent servers, which are B, D, F, and H. Therefore, site E possesses five replica servers. Simultaneously, data from site F is duplicated to servers C, E, and I, indicating that server F possesses four clones.

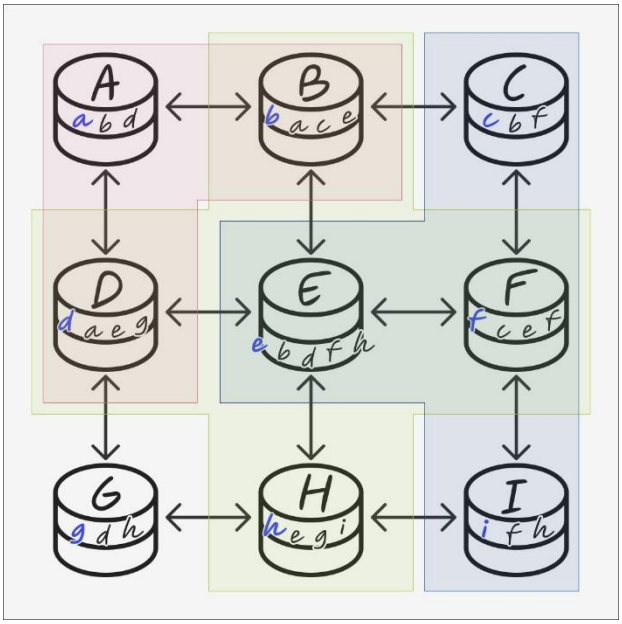

Fig. 1. BVAC framework.

The primary replica at a specific data x is the replica that acknowledges the client's request. In the BVAC algorithm, each replica of *T(C)* can simultaneously function as both a primary and a neighbor replica. Any replica $i \in T(C)$ may be designated as the primary replica, whereas additional replicas, $j \in T(C)$ where $i \neq j$ are considered neighbours. Line 7 processes a transaction T_{λ_x} that requests an update of data x from any replica of *T(C)*. Line 8-18 establish that the replica will serve as the primary, while the others will function as neighboring replicas to execute T_{λ_x}.

Recall our previous work, let *T(C)* be the set of replicas with replicated copies are stored corresponding to the assignment *C* for particular instant *x*, $T(C_x) = \{m(i,j), m(i-1,j), m(i,j-1), m(i,j+1), m(i+1,j)\}$. Two sets of transactions, T_η request instant *x* from *m(i,j)* replica, while T_ψ request instant *x* from *m(i-1,j)* respectively. The *m(i,j)* replica functions as the primary replica for processing T_η, where *m(i-1,j), m(i,j-1), m(i,j+1), m(i+1,j)* are neighbour replicas for processing $T_{\gamma_x} \in T_\eta$. Simultaneously, *m(i-1,j)* replica functions as the primary replica for processing T_ψ, while *m(i,j-1), m(i,j+1), m(i+1,j)* and *m(i,j)* are neighbour replicas for processing $V_{\gamma_x} \in T_\psi$. Both *m(i,j) and m(i-1,j)* replicas execute two different processing tasks concurrently. The *m(i,j)* replica is the primary replica managing T_η and its adjacent replica managing T_ψ, whereas the *m(i-1,j)* replica is the primary replica for processing T_ψ and neighbour replica for processing T_η. BVAC model considers different sets of transactions T_η and T_ψ. T_η is a set of transactions that comes before T_ψ, while T_ψ is a set of transactions that comes after T_η. The effect of BVAC transaction is defined as the processing of one instance of the transaction.

IV. Experimental Results

A. BVAC Algorithm Definition

To illustrate the operation of commit coordination under the BVAC Commit Coordination (BCC) mechanism, consider the case where two distinct transaction sets, T_η and T_ψ, concurrently request access to data file e at replicas E and B, respectively.

A cluster of five replication servers, interconnected as shown in Fig. 2, is used to illustrate the BVAC mechanism. Each primary replica propagates its database state to neighbouring replicas, allowing clients to access data from any server holding a replica. Consider two distinct transaction sets, T_η and T_ψ both requesting access to data file e at replicas E and B, respectively. When T_η and T_ψ attempt to update *e*, they must first issue update requests to their respective primary replicas, B and E. Both T_η and T_ψ propagate lock requests, but only the first transaction to acquire the lock proceeds, while the other is aborted. Consequently, replicas B and E maintain pending transactions, yet neither can read or update e concurrently. Primary node E, $T_{\eta,e} = 1$ propagates lock requests to neighbours B, D, F, and H, while primary node B $T_{\psi,e}$ propagates locks to neighbours E, D, F, and H. The transaction that first secures a majority quorum is transformed into $\hat{V}_{\lambda_x} \in V_\eta, V_\psi$. The details of experimental outcomes are summarized in Table II.

Assertion: If the transaction gets all locks from replica $i \in T(C)$, then the transactions will be executed successfully.

Proof: The only way that a transaction gets a lock in initiate lock is when $T_{\lambda_x} = 1$ with $T_{\lambda_x} \in T_\eta$. After $T_{\lambda_x} \in T_\eta$ success to initiate lock at a server, then, $T_{\lambda+1_x}$, ..., $T_{\lambda+q_x}$ which are the elements that exist in T_η will be queued. To get majority quorum, $wT_{\lambda_x} \geq \left\lceil \frac{n}{2} \right\rceil$ is required. This means that the primary server needs to get the majority locks from its neighbour servers by calling request lock from the neighbours servers. Each neigbours $i \in T(C)$ will send feedback to the primary to notify it is in free lock or not. If the primary gets the majority locks of instant *x*, it means that $\hat{V}_{\lambda_x} = T_{\mu_x} = T_\eta$ where $\hat{V}_{\lambda_x}$ gets a quorum. Next, the primary will send error notification to other neighbours $i \in T(C)$ in the quorum. Consequently, when $T_{\lambda_x} \in T_\psi$ releases its lock, $T_{\lambda_x} \in T_\eta$ gets the lock from every neighbour $i \in T(C_x)$. After T_{λ_x} gets majority quorum, relation *T* is fragmented into T_1 and T_2 using vertical fragmentation. Again, T_1 is fragmented into $T_{1_{(Pk,x)}}$ and $T_{1_{(Pk,y)}}$ using horizontal fragmentation. When a user finishes updating the instant, $\hat{V}_{\lambda_x}$ commit (send the fragmented data) to ∀ neighbour $i \in T(C_x)$. Therefore, all replicas of $T(C_x)$ will perform and execute the update successfully.

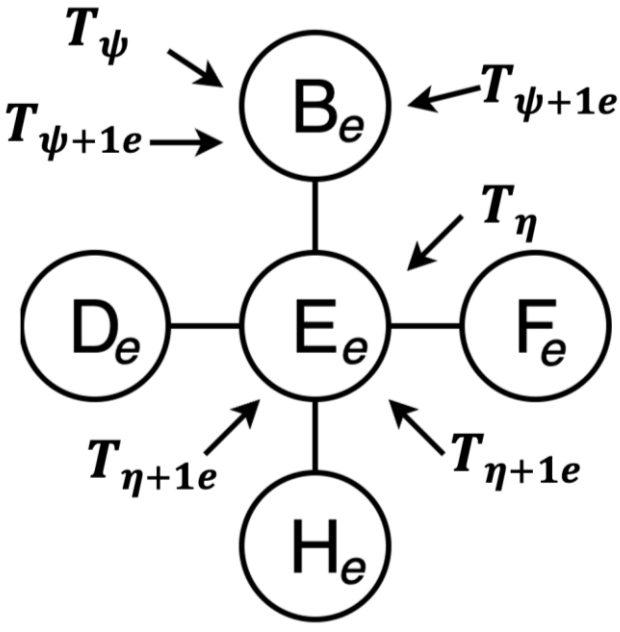

Fig. 2. An example of BVAC transaction requests.

B. Communication Cost Comparison

In this section, we compare the storage usage of BVAC, DynamoDB, FoundationDB, and GeoGauss. In BVAC, replication is bound to a fixed quorum size of three to five servers. This allows transactions to commit using a constant quorum, which limits the storage overhead even when the number of servers increases. In DynamoDB, each partition is synchronously replicated across three replicas within a region. When Global Tables are enabled, data is further replicated asynchronously across multiple regions, meaning the storage requirement increases proportionally with the number of regions. FoundationDB, by contrast, relies on a more complex configuration involving commit proxies, resolvers, and log servers. To ensure cross-region durability and strict serializability, the system often requires five or more replicas, including satellites, which elevates the storage footprint. GeoGauss employs the most storage-intensive approach, as it maintains a full replica of the database in every region. This design provides strong global consistency and resilience but comes at the cost of replicating the entire dataset across all regions. Table III shows the comparison between BVAC, DynamoDB, FoundationDB, and GeoGauss in terms of storage use.

From Table III, it is apparent that BVAC requires the least storage overhead by restricting replication to a small, constant quorum size of three to five servers. DynamoDB demands three replicas per partition in each region, and the storage requirement expands with the number of regions deployed in Global Tables. FoundationDB requires at least five replicas to preserve strict serializability and cross-region fault tolerance, thereby consuming more resources. GeoGauss incurs the heaviest storage cost since every region maintains a complete replica of the database. Consequently, BVAC demonstrates superior storage efficiency compared with DynamoDB, FoundationDB, and GeoGauss, making it a practical option for large-scale cloud systems where both consistency and resource optimization are critical.

TABLE III. STORAGE USAGE COMPARISON OF BVAC, DYNAMODB, FOUNDATIONDB, AND GEOGAUSS

Replication Techniques	Number of Servers	Storage Use
BVAC	3–5 replicas (constant quorum)	3–5
DynamoDB	3 replicas per partition (regional); extra regions for global tables	3 per region, grows with Global Tables
FoundationDB	≥5 replicas (primary, secondaries, satellites)	5 or more
GeoGauss	Full replica in every region	Equal to number of regions (high cost)

V. CONCLUSION

The rapid evolution of cloud computing has increased the significance of replication systems that can concurrently guarantee consistency, availability, and efficiency at scale. Conventional grid-based methodologies and commercial cloud platforms have advanced replication practices, but they continue to face inherent limitations within the consistency, latency and availability spectrum. This research presents the Binary Vote Assignment in Cloud (BVAC) as a cloud-native advancement of the BVAGQ replication model to tackle these ongoing challenges. BVAC integrates binary vote assignment into a quorum-based structure and utilizes the BVAC Commit Coordination (BCC) mechanism to authenticate transactions on fixed-size quorums across distributed replicas. This approach maintains robust consistency, minimizes communication complexity, ensures reliable fault tolerance with low latency, and improves storage efficiency by requiring fewer replicas than existing systems. Collectively, these contributions demonstrate BVAC as a scalable, reliable, and economical replication framework for extensive cloud settings. While the results of this study are promising, several aspects warrant further investigation. The current evaluation of BVAC is limited to specific workloads; its scalability and adaptability under highly dynamic and heterogeneous cloud conditions remain to be explored. In particular, BVAC could be extended with adaptive quorum resizing and workload-aware strategies to dynamically respond to shifting read/write ratios and latency requirements. Furthermore, future research should consider strengthening security and trust mechanisms, such as integrating Byzantine fault tolerance or lightweight blockchain-inspired auditing, to protect against adversarial conditions like malicious voting or quorum manipulation. Potential trade-offs, such as the complexity of quorum management, deployment across multi-cloud environments, and performance under real-world changeable workloads, need deeper analysis.

Computer Science Department-Faculty of Computer and Information Sciences, Ain Shams University, Cairo, Egypt 11566

***Abstract*—Autism Spectrum Disorder (ASD) is a mental disorder with a neurological condition noticed in patients by their persistent deficits in social communication and interaction, along with the possibility of the presence of repetitive motor behaviors or activities. Early diagnosis of this disorder is crucial for improving patients' cognitive, emotional, and social development. Numerous studies on detecting autism exist; however, data limitations and imbalance affect their model generalization. This study proposes a new intelligent computational model for mental healthcare in individuals with ASD, utilizing machine learning (ML) to address these shortcomings. The proposed model enhances the random forest (RF) algorithm by setting optimal parameters and encompasses two key pipelines: 1) the data pipeline and 2) the learning pipeline. We first gathered a multi-source dataset, implemented integration and preprocessing via ML algorithms. The phenotypic data used were collected from 19 different sites and merged to ensure the diversity of the data used. The resulting dataset is subsequently fed into the learning pipeline, where a supervised ML algorithm is employed to create a trained computational model for detecting ASD. The model is based on tuning the RF algorithm by finding the optimal values for five key hyperparameters. After tuning the model, the accuracy of detecting ASD from phenotypic data reached 96.86%, with a sensitivity of 97.14% and a false positive rate of 3.39%. Comparing the tuned RF model with different ML models verified that tuning and optimizing RF achieves a preeminent classification accuracy for ASD detection using phenotypic data, as the accuracy of RF without tuning is 95.06%. In addition, to validate the tuned RF model's real-world applicability, a separate qualitative study was conducted on five independent, narrative-based case studies, where the model accurately classified four of them by translating descriptive language into quantitative features.**

I. Introduction

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that affects the social communication and interaction between a patient and other people and may result in limited and recurring interests, activities, or behavioral habits. According to the World Health Organization [1], the prevalence of ASD has been steadily rising over the past few decades, affecting approximately 1 in 100 children in the world's population and about 3 in 100 children in the United States alone [2]. The causes for this neurological disorder are still not clearly defined, but many scientific researchers have suggested that it may be caused by genetic or clinical factors. For prompt intervention and better results for those impacted, early identification and diagnosis of ASD are essential.

Traditionally, ASD diagnosis has relied on comprehensive clinical assessments, which involve extensive evaluations by trained professionals, including psychologists, psychiatrists, and speech therapists [3]. However, this process can be time-consuming, costly, and subject to inter-rater variability, leading to delayed diagnosis and intervention. Therefore, there is a growing need for more efficient and accurate methods to detect ASD in children. Recent advancements in machine learning (ML) and data mining techniques have shown promise in enhancing the early detection of ASD. In particular, the utilization of phenotypic data has emerged as a valuable resource for developing predictive models.

Phenotypic data refer to the observable characteristics or traits of individuals with ASD, such as communication and social skills, repetitive behaviors, and sensory sensitivities. It can be collected through various sources, such as parental questionnaires, clinical assessments, electronic health records, direct observation, caregiver reports, and wearable sensors [4]. The breadth of behaviors and traits linked to ASD can be better understood using phenotypic data, which can also be utilized to create interventions that focus on particular symptoms. In the context of systems powered by artificial intelligence (AI), phenotypic data can be used to train ML algorithms to recognize patterns that indicate the presence of autism.

The Autism Brain Imaging Data Exchange (ABIDE) dataset, a publicly available dataset [5], is a significant resource for ASD research. It comprises two large-scale collections, ABIDE-I and ABIDE-II, each providing functional magnetic resonance imaging (fMRI) data along with a corresponding phenotypic dataset. ABIDE-II, collected from over 19 diverse sites, introduced more detailed phenotypic characterization not found in ABIDE-I [6]. This dataset is crucial for our research as it provides a comprehensive view of the phenotypic characteristics of individuals with ASD, which is essential for developing accurate ML models for ASD detection. ABIDE-II's phenotypic dataset comprises 347 columns encompassing demographic, diagnostic status, and an extensive array of behavioural assessments [6]. Additionally, patients' basic information, including sex, age, handedness index score, and handedness category, is utilized [6].

One ML algorithm that has gained popularity in the field of medical data is the Random Forest (RF) algorithm. RF is an ensemble learning technique that generates predictions by combining several decision trees. It has been widely used in

various domains due to its ability to handle high-dimensional data, handle missing values, and provide robust predictions [7]. The use of phenotypic data with ML techniques, particularly RF, holds promise for improving the precision and efficiency of ASD detection. Studies have shown that the nature of phenotypic data can enhance the discriminative power of ML models, enabling them to capture subtle patterns indicative of ASD. By leveraging a diverse array of features derived from behavioral observations, cognitive assessments, and physiological measures, the amalgamation of phenotypic data and RF can contribute to a more comprehensive and accurate diagnostic framework.

This research study presents a novel and promising approach to developing a computational model for mental healthcare, focusing on the early detection of ASD. The proposed model aims to distinguish ASD from typical control (TC) individuals using the ABIDE-II phenotypic dataset. We hypothesize that by leveraging a comprehensive set of tuned hyperparameters for RF along with a set of phenotypic features, we can develop a reliable and accurate RF model for early detection of ASD. The proposed model has the potential to highlight a set of hyperparameters for building RF model to guide researchers in their studies and also using the model by healthcare professionals to assist them in making informed decisions and improving the efficiency of ASD screening processes. The main contributions of this study are as follows:

- We proposed an enhanced integrated framework that is based on the random forest algorithm for optimal parameter setting.
- We employed two pipelines, the first of which seeks to overcome the data limitation issue by integrating more than 19 sources of phenotypic data, and then extensive preprocessing is performed.
- We developed a learning pipeline that seeks to find the optimal parameters and address the model generalization issue.
- We validated the proposed model using narrative-based real-world case studies to provide an aided diagnostic tool in the medical domain.

The article is organized as follows: Section II presents a comprehensive literature review, highlighting the limitations and challenges. Section III outlines the methodology of the proposed model and provides detailed descriptions of the techniques employed in the two proposed pipelines. Section IV presents the experimental results, data integration, data preprocessing and the performance evaluation of the developed model. Section V discusses the results of the developed model and presents a comparative analysis. Section VI presents the predictive capabilities of the model using real-world cases. Section VII concludes the findings and potential future research directions.

II. Literature Review

In the era of AI, numerous researchers have explored the use of ML techniques to detect ASD in children. The researchers provided studies that highlighted the potential of utilizing various types of data, including genetic, neuroimaging- ing, and phenotypic data, to develop models that can predict, detect, and classify ASD. Nada S. et al. [8] published a comprehensive survey of studies that have developed ML models to detect brain neurological disorders. The survey included a list of various ML classifiers with different data types, which achieved varying levels of accuracy. It highlighted that in recent years, the utilization of phenotypic data has gained significant attention in the field of ASD detection due to its ability to deliver comprehensive behavioral and clinical information. Additionally, it addressed the challenges, including the availability of large datasets and the need for proper data preprocessing. Focusing on phenotypic data, here are some noteworthy examples of studies and applications that utilize AI techniques to detect ASD with phenotypic data.

1) Perochon et al. [9] developed and validated a mobile digital behavioral phenotyping application called SenseToKnow. The app utilizes computer vision and ML to analyze children's behavioral responses during pediatric well-child visits. The study involved a cohort of toddlers aged 17-36 months, including those diagnosed with ASD (49 children), developmental delay without autism (98 children), and TC (328 children). Children's behavior was recorded using an iPad, and 23 digital phenotypes were extracted, including gaze patterns, facial expressions, head movements, response to name, blink rate, and motor behaviors. The model was trained using extreme gradient boosting (XGBoost), a method that utilizes 1,000 tree-based classifiers, and was evaluated through five-fold cross-validation. It finally achieved a sensitivity of 87.8%.

2) Mazumdar et al. [10] presented a study on the early detection of ASD in children using an approach that depends on gathering data from tracking the patient's eye and then feeding it to an ML classifier. A total of 24 children (14 ASD and 10 TC) were included in the analysis, which utilized 400 natural images sourced from the Saliency4ASD [11] dataset. Using a TreeBagger (bagged DT) classifier trained on the Saliency4ASD dataset, it achieved an accuracy of 59%.

3) Alkahtani et al. [12] developed a facial landmark-based system using DL and ML algorithms to detect ASD in children aged 2 to 8 years. A total of 2,940 images (1,327 ASD and 1,613 TC) were used for analysis, obtained from Kaggle [13]. The study applied eight ML classifiers to the ASD dataset along with their respective accuracy rates: support vector machine (SVM) (81.46%), linear regression (LR) (82.14%),

4) RF (78.06%), k-nearest neighbor (KNN) (52.38%), decision tree (DT) (66.15%), neural network multi-layer perceptron (MLP) (77.04%), gradient boosting (GBoost) (75.51%), and convolutional neural networks (CNN) (92%).

5) Raj et al. [14] explored the effectiveness of ML and DL models in predicting ASD across three population groups: children, adolescents, and adults. The study utilized three publicly available datasets containing behavioral features and demographic information related to ASD from the UCI

machine learning repository: children (292 cases), adolescents (104 cases), and adults (704 cases). The study applied six ML classifiers on the ASD datasets: SVM, LR, Naıve Bayes (NB), KNN, NN, and CNN. They all achieved classification accuracy ranging from 80.95% to 99.53%. CNN consistently outperformed all other classifiers across datasets, demonstrating higher accuracy and robustness.

6) Akter et al. [15] developed ML models capable of detecting ASD at an early stage by leveraging behavioral data, thereby facilitating early interventions. In addition to the datasets utilized by Raj et al. [14], the authors utilized other publicly available datasets related to ASD from the Kaggle repository and combined them based on population group. The aggregated datasets comprise 2,009 cases (toddlers = 1,054, children = 248, adolescents = 98, and adults = 609) with 21 features. Three feature transformation methods were employed to reduce skewness, normalize the data to a range of -1 to 1, and enhance the performance of the ML model. These methods are Log transformation, Z-score normalization, and Sine transformation. A total of 250 classifiers were applied to these datasets, with 80 demonstrating good performance. Classifiers with accuracies under 70% were excluded. The final selection consists of 9 algorithms: adaboost (AB), flexible discriminant analysis (FDA), DT, boosted generalized linear model (GLMBoost), linear discriminant analysis (LDA), mixture discriminant analysis (MDA), penalized discriminant analysis (PDA), SVM, and classification and regression tree (CART). Optimal classifier per age group: SVM (mean accuracy = 98.77%) for the toddlers' dataset, AB (mean accuracy = 97.20%) for the children dataset, AB (mean accuracy = 98.36%) for the adults' dataset, and GLMboost (mean accuracy = 93.89%) for the adolescents' dataset.

7) Erkan et al. [16] investigated the utility of supervised ML models- kNN (k=3), SVM (radial basis function), and RF (60 trees)—for classifying ASD using three age-specific datasets (children, adolescents, and adults) from the UCI repository with a total of 1,100 samples. Each dataset, comprising 20 features including standardized screening questions and demographic variables, underwent rigorous preprocessing including missing value imputation and numeric encoding. Models were evaluated using repeated stratified train/test splits (a = 50%, 60%, 70%, 80%, 90%). Results demonstrate that RF achieved 100% performance across all metrics and datasets, outperforming SVM (accuracy ranged from 91%–100%) and kNN (Accuracy ranged from 83%–95%). The findings underscore the potential of ML, particularly ensemble-based models, in supporting fast, accurate, and scalable ASD diagnosis across age groups. This work supports the integration of ML into clinical ASD screening protocols, especially where large and well-structured data is available.

8) Using the same datasets as those in Erkan et al. [16], Bawa et al. [17] implemented six supervised learning models—LR, SVM, RF, DT, NB, and KNN. Results showed that LR and SVM performed optimally across binary classification (yes/no for ASD) tasks, achieving 94.30 – 99.00% accuracy in individual groups and achieving 97.20% on merged data using LR. Extending to multiclass classification (e.g. child_yes, adolescent_no) on the merged dataset, SVM attained a peak accuracy of 99.55%, while LR achieved 95.90% accuracy, RF achieved 94.10%, and NB achieved 82.50%. Further enhancement by grid search hyperparameter tuning yielded SVM with 99.55% accuracy, LR with 99.09%, and RF with 96.82%. The study concludes that multiclass classification models tailored to age subgroups substantially improve diagnostic accuracy and could serve as a foundation for scalable ASD screening tools.

9) Kunda et al. [18] proposed an ML model to classify autism using the ABIDE-I dataset, which comprises a total of 1,035 cases (505 ASD, 530 TC) of resting-state fMRI and phenotypic data. The study proposed the tangent Pearson embedding method for extracting second-order features. It also implemented an approach for domain adaptation to enhance classification accuracy. The model was trained using Ridge, LR, and SVM, and its performance was evaluated through ten-fold and leave-one-out cross-validation. Ultimately, it achieved an accuracy of 73% with the Ridge classifier.

The reviewed studies collectively highlight significant advancements in AI-driven ASD detection and diagnosis. They show the potential of AI to significantly enhance and facilitate the early detection and diagnosis of ASD through the application of ML algorithms and dimensional reduction techniques. Table I summarizes the discussed studies for ASD detection from an AI perspective, and the symbol "*" indicates ML algorithm(s) that achieved the highest accuracy.

TABLE I. COMPARATIVE TABLE FOR ASD STUDIES USING PHENOTYPIC DATA

Study	Dataset size	ML algorithms	The highest accuracy
Perochon et al. [9]	475	XGBoost*	87.8%
Mazumdar et al. [10]	400	TreeBagger*	59%
Alkahtani et al. [12]	2,940	SVM, LR, RF, KNN, DT, MLP, GBoost, CNN*	92%
Raj et al. [14]	1,100	SVM, LR, NB, KNN, NN, CNN*	99.53%
Akter et al. [15]	2,009	AB, FDA, DT, Glmboost, LDA, MDA, PDA, CART, SVM*	98.77%
Erkan et al. [16]	1,100	KNN, SVM, RF*	100%
Bawa et al. [17]	1,100	LR, DT, RF, NB, KNN, SVM*	99.55%
Kunda et al. [18]	1,035	LR, SVM, Ridge*	73%

Although numerous datasets, studies, and approaches, ML approaches demonstrated high potential for identifying ASD from behavioral, physiological, and neurocognitive data. There

are several common limitations:

- Data limitations:
  - Small sample sizes: Many studies were conducted on limited-scale datasets, particularly those focusing on specific subpopulations (e.g. children, females, or multi-site studies). This scarcity of data reduces the statistical power and representativeness of models, undermining the reliability of their results and classification accuracy.
  - Dataset imbalance: ASD datasets are often highly imbalanced, leading to bias in ML models.
  - Variability across sites: Multi-site neuroimaging studies (e.g. fMRI) showed high inter-site variability due to differences in scanner protocols, demographic diversity, and sample heterogeneity.
  - Lack of standardized datasets: Many ML models were trained on custom datasets, making it challenging to compare results across studies.
  - Lack of detailed phenotypic data, especially regarding ASD severity and cognitive variability.
  - A lack of diverse participants (e.g. in age, gender, or ethnicity) further means models may be overfit to narrow populations.
  - Need for real-world testing: real-world data variability is untested.
- Model generalization:
  - Overfitting on small datasets: ML models tend to overfit when trained on limited or highly structured datasets.
  - Poor generalization to real-world clinical settings: Many ML models were evaluated only on academic datasets without validation in clinical environments.
  - Feature selection dependence: Some studies heavily relied on specific feature selection methods, which might not generalize well to different datasets.
- Computational challenges:
  - High computational cost: Some ML models require significant computing resources, making them infeasible for real-time clinical applications without further optimization.
  - Interpretability of AI models: Most ML models for ASD detection operate as "black boxes," offering little explanation for their decisions. This opacity makes it difficult for clinicians to trust and implement them in real-world diagnostic settings.

III. Intelligent Mental Healthcare Model

The model consists of two main pipelines, as shown in Fig. 1. The model initiates by collecting the datasets and then processing them through the data pipeline using ML methods. Subsequently, the model inputs the resulting dataset into the learning pipeline, in which a supervised ML algorithm is applied to develop a trained computational mental model for ASD detection. The following sections focus on the details of the data and the learning pipelines, respectively.

A. Data Pipeline

The data pipeline includes four primary sequential steps: data collection, integration, inspection, and preprocessing, as shown in Fig. 1. First, a unified dataset was created by merging data sources collected from many international sites that dealt with autism and employed various examinations and procedures for making diagnoses. Afterwards, data preprocessing techniques were employed on the dataset to enhance its quality and format after a thorough inspection. Furthermore, examine whether the dataset is balanced.

1) Data collection: The model utilized the phenotypic data in ABIDE-II [19] collected from over nineteen international sites, as it provides more detailed phenotypic data than any other dataset. As defined, the phenotypic data in ABIDE-II present 1,114 real-world cases aged 5 to 64 years. The dataset contains 521 ASD cases and 593 TC cases. Each case is represented by 347 structured characteristics and clinical data, such as IQ, medical history-related questions, demographic variables, diagnostic status, and an extensive array of behavioral assessments. Additionally, patients' basic information, including gender, age, handedness index score, and handedness category, is utilized.

2) Data integration and inspection: Upon downloading the phenotypic data from all nineteen sites participating in the ABIDE-II dataset, they were comprehensively analyzed. The individual datasets were concatenated into a unified file to ensure consistency and uniformity across the various sites. And then, inspecting the data to find structural issues, leading us to the next stage of applying data preprocessing techniques.

3) Data preprocessing: Crucial preprocessing techniques were applied to clinch the subsequent analyses quality and reliability and maintain and improve data balance.

a) Data cleaning is essential to ensure the data quality. Data cleaning operations need to be done very carefully and precisely so as not to end up with too little data or too much data with useless values. These operations were carried out in several steps as illustrated in the experimental results section.

b) Data balancing is crucial when the number of instances in different classes is significantly skewed as this will lead to biased model performance; where the model may be biased towards the majority class and the minority class may be significantly underrepresented making it challenging for the AI model to learn patterns effectively, resulting in poor performance on the minority class. In the ABIDE-II dataset, after applying data cleaning and removing some observations, the ground truth in all remaining data was checked. The ratio between ASD and TC observations is 1:1.08, which means they are nearly equal in size and the data is balanced.

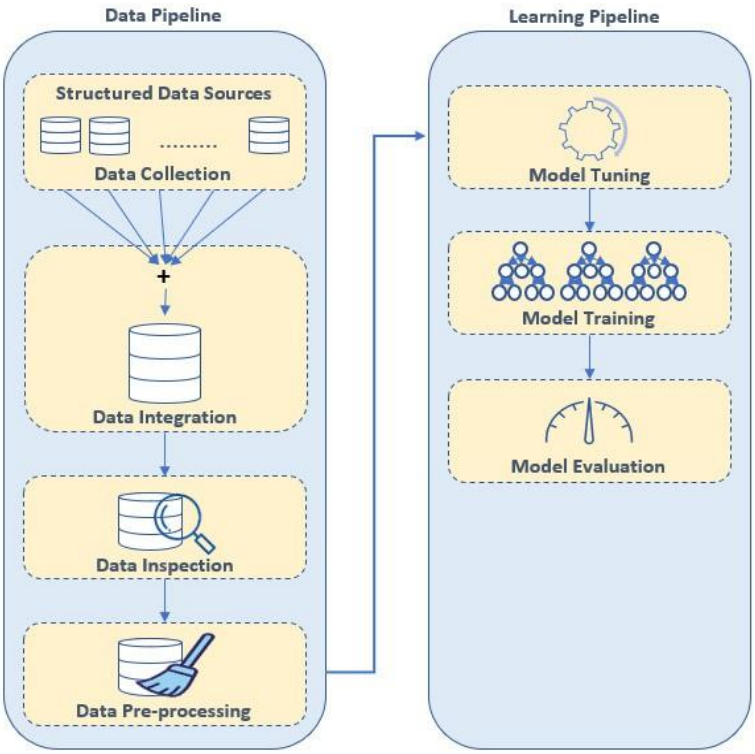

Fig. 1. The intelligent mental healthcare model for ASD detection.

B. Learning Pipeline

Model tuning, model training, and model evaluation are the three successive stages that comprise the learning pipeline to develop a trained model for detecting ASD, as shown in Fig. 1. The model tuning is an iterative process that plays a substantial role in identifying the optimal values of the essential parameters associated with the selected supervised learning algorithm. Each iteration involves setting the other parameters to a constant value and testing the targeted parameter over a predetermined range of values. This process continues until all parameters have reached the optimal values. After that, the model is trained and evaluated using the supervised learning algorithm based on the optimal values of its parameters.

1) Model tuning: For the model, the RF algorithm was selected for its promising results in various healthcare studies with high-dimensional data. RF is an ensemble learning method that combines the predictions of multiple decision trees and aggregates their predictions, providing robustness and enhancing accuracy in the required task [5]. To achieve optimal performance, it is essential to tune the values of five distinct parameters:

- Two of them are for the preprocessing and dimensional reduction, which are:
  - The percentage of missing cells in a column at which this column will be deleted if it exceeds this percentage.
  - The percentage of testing data and training data to divide the dataset.
- The other three parameters that need to be tuned for setting the RF algorithm are:
  - In-bag-fraction, which determines the fraction of observations that are randomly selected with replacement for each bagged tree.
  - The number of trees in the forest.
  - The number of predictors to sample, which is the number of feature variables used to pick at random for each decision split at each node.

Five rounds were conducted to tune these parameters and select their optimal values, as shown in Fig. 2. A round was conducted to decide the best value for each parameter. In each round, the targeted parameter is tested with a given range of values while the other four parameters are given a fixed value. At the end of each round, the value that scored the highest accuracy is used to set this parameter in the following rounds, and so on over all the rounds till the best-scoring value for each parameter is determined.

2) Model training and evaluation: The model input training data comprises a feature matrix that includes instances representative of individuals with ASD as well as instances of typical control subjects; each instance is characterized by meticulously selected features. Subsequently, a testing phase is conducted utilizing a dataset that has not been previously encountered by the model, during which the model's performance is assessed through appropriate evaluation metrics. Ultimately, when presented with any new instance, the model is expected to identify individuals with ASD based on their respective features.

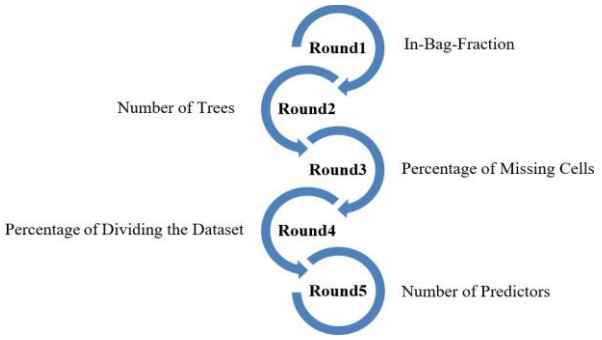

Fig. 2. Five sequential rounds of model tuning.

IV. Experimental Results

A. Dataset

The proposed model utilized ABIDE [5], an extensive electronic database of brain scans of individuals with ASD. More than 20 different sites shared in collecting this database to create two large-scale collections, ABIDE-I [20] and ABIDE-II [19]. Both collections provide resting state functional MRI (R-fMRI) along with phenotypic data for individuals with ASD and individuals with typical controls. The ABIDE-I [20] collection was established across 17 international brain imaging sites. ABIDE-I contains 1,112 cases, ranging between 539 ASD cases and 573 typical control cases.

The second collection, ABIDE-II [19], was publicly released in June 2016. Nineteen different international sites collaborated to donate 1,114 cases, ranging between 521 ASD cases and 593 typical control cases. After using ABIDE-I, many challenges and obstacles were found in it, such as the complex structure of the brain connectivity and the major heterogeneity of ASD; those issues were mapped for the essential need of a larger dataset that contains samples with more distinct characteristics [5], [21]. ABIDE-II was released to resolve these challenges and includes samples with better characteristics, features, and psychiatric variables [19]. Table II presents all 19 sites with their size and configuration.

1) Phenotypic data: The phenotypic data, in the ABIDE-II release, include a wide array of demographic, diagnostic, and behavioral measures for each participant. Many features are standardized scores from validated instruments for comparison across ages or test versions. In addition, patients' demographics and basic information, such as age, sex, handedness category, and handedness index score, were used in ABIDE-II. Around sixteen assessments were used in diagnosing ASD. They are as follows, highlighting the most essential features and their type and range that were used to build the dataset:

- Cognitive Ability (Intelligence Quotient – IQ): Verbal IQ, Performance IQ, and Composite IQ tests are administered and result in continuous scores in the range of 45-156.
- Assessments of social interaction, communication, restricted and repetitive behaviors, abnormal early development, stereotyped behaviors and restricted interests, imagination/creativity, social affect, and executive functions:
  - Autism Diagnostic Interview–Revised (ADI- R)
  - Autism Diagnostic Observation Schedule (ADOS)
  - Social Responsiveness Scale (SRS)
  - Social Communication Questionnaire (SCQ) and Autism Quotient
  - Repetitive Behavior Scale–Revised (RBS-R)
  - Behavior Rating Inventory of Executive Function (BRIEF)
  - Child Behavior Checklist (CBCL)
  - Adaptive Behavior (Vineland-II).

All scores resulting from these assessments are continuous numerical values. Higher scores indicate more ASD-related symptoms.

- Anxiety (Multidimensional Anxiety Scale for Children – MASC): MASC is a self-report questionnaire (child or adolescent) assessing anxiety symptoms. All scores are T-scores (mean=50, SD=10) for the MASC sub-scales: Physical Symptoms, Harm Avoidance, Social Anxiety, and Panic, plus an overall total and an Anxiety Disorder Index.
- Depression (Beck Depression Inventory – BDI): BDI examines depression symptoms and gives a score in the range (0-63) for each symptom.
- Language ability (Clinical Evaluation of Language Fundamentals – CELF): The CELF is a standardized language ability test. ABIDE II includes standard scores for Core Language, Receptive, and Expressive language abilities. Higher scores indicate better language skills.
- Other medical/behavioral details: Medication status indicates if the participant was on any psychotropic medications around the time of the scan and what they were (commonly ADHD meds, SSRIs, etc.). Body Mass Index (BMI) is included as an essential health metric.

B. Data Integration, Inspection, and Preprocessing

The ABIDE-II individual datasets were concatenated into a unified file to ensure consistency and uniformity across the various sites. After the investigation, the first issue was the large amount of missing data. The data contains 347 features; the first two columns are unique identifiers. The third is the ground truth or the label for each entry that is filled with value 1 for ASD or 2 for TC (which changed after that to 0, Fig. 3 shows the difference before and after changing labels), and by which the dataset is divided into two classes ASD with 521 records and TC with 593 records. The remaining 344 columns are different features that are responses from the patient to the doctor's questions. By inspecting the data, many structural issues were found, leading us to the next stage of applying other data preprocessing techniques.

TABLE II. PHENOTYPIC DATA ON ABIDE-II FROM DIFFERENT SITES

Site name	Samples Total size	Size of ASD	ASD Age Range	Size of TC	TC Age Range

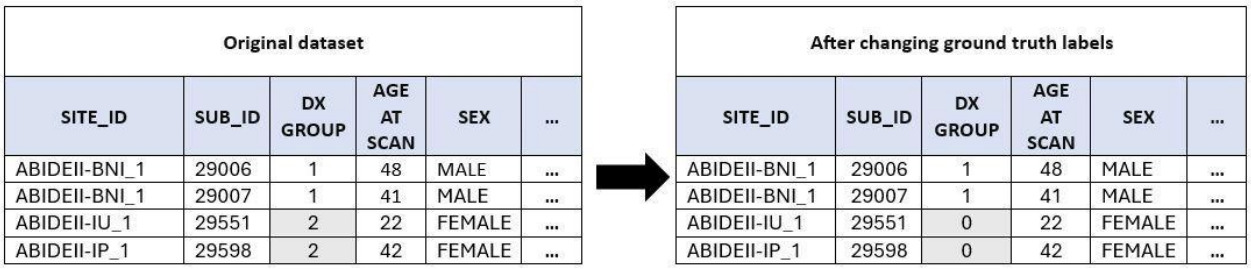

Fig. 3. Sample for the dataset after changing ground truth labels.

1) Removing duplicate observations. By observing the data, no duplicate records were found.

2) Handling missing data. Either by filling with appropriate values or removing the entire observation; the choice depends on the nature of the missing data and the specific requirements of the model.

3) Filter undesired outliers. Some data ranged from -100 to 100; we manipulated these values by shifting them by 100 to acquire non-negative values ranging from 0 to 200.

4) Manipulating nonnumeric values. The raw data contains six columns with a string data type. All string data has to be converted into numeric values to fit the data into the model. The Levenshtein distance algorithm was utilized for this task. In each column, the largest string value was picked and used as the reference string in the algorithm, and each string was replaced with the distance evaluated by the Levenshtein algorithm. Using the MATLAB tool, a function named convert_txt2num was written that takes a vector, which is a string column from the dataset, and it finds the longest string, then calls the implemented Levenshtein algorithm, which takes the string vector and the longest string as the reference value for the algorithm. The Levenshtein function returns a numeric vector that is used to replace the string vector. Algorithm 1 shows the pseudocode for the implemented convert_txt2num function that leverages the Levenshtein algorithm.

Algorithm 1: Function convert_txt2num that uses the Levenshtein algorithm

```
lenVec ← length of each string in the vector (v)
maxInd ← max(lenVec)
        longestStr ← v(maxInd) for each s in v do
numericVector(index(s)) = Levenshtein(s, longestStr)
end for
```

C. Model Tuning

After performing all the steps of the data pipeline, as mentioned previously, five different parameters have to be tuned, two of them for data cleaning and preprocessing steps,

which are the percentage of missing cells in a column at which this column will be deleted if it exceeds this percentage, and the percentage of testing data for training data to divide our dataset. Regarding the other three parameters need to be tuned are for the building the RF model which are: number of used trees in the forest and the in bag fraction which is determining the fraction of observations that are randomly selected with replacement for each bagged tree and the last parameter is the number of predictors to sample which is the number of feature variables used to pick at random for each decision split at each node. To tune these parameters and select their best values, we created five rounds: a round to decide the best value for each parameter. In each round, the targeted parameter is tested with a given range of values while the other four parameters are given a fixed value. At the end of each round, the value that scored best is used to set this parameter in the following rounds, and so on over all the rounds till the best-scoring value for each parameter is determined.

5) Round 1: The first parameter to tune is the In-Bag-Fraction parameter for the RF model. This parameter refers to the number of instances that will be used in each bag/tree in the forest to train with them (sample size drawn randomly for the training of each bag/tree). The value is a fraction of the whole number of available instances in the training data. Setting this parameter with a fraction less than one means that each tree will train with a subset of the training data that is selected randomly. So, decreasing the covariance and avoiding the over-fitting problem. Fig. 4 shows the effect of changing this fraction on the model accuracy. The other parameters were set to their default values, which are 64 trees, 20% of the data for testing, and 80% for training. If the column contains more than 50% empty cells, then delete this column/feature. And finally, the number of predictors to choose from each node was set by the square root of the number of features, which is the default value given by Breiman [22]. By observing the accuracy in Fig. 4, the highest value for the accuracy was achieved by using the fraction 0.6. So, it is the optimal value to set this parameter in the model.

6) Round 2: The second parameter to tune is the number of trees used to build the forest. A study was published to determine how many trees should be found in the RF, and it stated that the best values will be found in the range (64-128) [23]. Training multiple trees is one of the most essential features of RF; a few trees can result in bad predictions, and a vast number can cause performance issues. To tune this parameter, the value of all other parameters was set as follows: 20% of the dataset for testing, the column is deleted if it contains 50% or more empty cells, and the number of predictors to choose from on each node is the square root of the number of features. Finally, the in-bag fraction was set with the best value from round 1, which is 0.6. The model was tested with a broader range, which is for a minimum of 30 trees and a maximum of 200 trees. By observing the rate of change of the model accuracy by changing the number of trees in the RF in Fig. 5, the optimal value to tune the number of trees parameter is 100 trees.

7) Round 3: The third parameter to tune is a dataset-related parameter, which is the percentage of empty cells that can be found in a column. This round aims to determine the acceptable percentage limit for empty cells within each feature, without losing significant information in the dataset. After the first two rounds, the in-bag fraction and the number of trees were tested for their best values, which were 0.6 and 100, respectively. In this round, the data will be split into testing and training sets in a 20:80 ratio, with the number of predictors set to the square root of the total predictors identified in the input data. The required parameter was tested using percentages ranging from 100% to 10%. Fig. 6 shows the accuracy assessed at each percentage value. As depicted in Fig. 6, the peak accuracy occurs at 70%, indicating that any column with over 70% of its cells empty will be removed, consequently decreasing the number of feature vectors in the dataset.

8) Round 4: The fourth parameter to tune is the percentage needed from the dataset to be used for testing and the rest for training. Determining the optimal percentage for this division directly impacts the performance of the model, as it needs a suitable amount of data that yields robust results and a scalable model. Ensuring enough data for training and testing can prevent problems such as overfitting -if too much data is used for training- and underfitting -if too little data is used for training- and so balance is achieved between model generalizability and its predictive power. The round started with a ratio of 15:85, then increased it to 20:80, then 25:75, and finally 30:70. Fig. 7 shows the variation in accuracy through these different ratios. The other parameters were set by the following values: 64 trees, in-bag-fraction was 0.6, and the number of predictors selected randomly at each node was 71. If the column contains more than 70% empty cells, then delete this column/feature. The experiment showed that allocating 20% of the data for testing and 80% for training gives the model the highest accuracy, so the ratio 20:80 was chosen to tune this parameter.

9) Round 5: The fifth parameter to determine is the number of predictors selected randomly at each node during tree construction to choose the best split from them, denoted by variable m. It is a critical parameter as it controls the randomness of feature selection and influences the diversity of the model, ensuring robustness and reliability. This parameter should be carefully adjusted due to its effect on the model performance, as high values of m might cause high computation cost, but low values might also reduce model diversity or even cause overfitting. The model was tested with m values ranging from 2 to 20, and its accuracy was observed. Fig. 8 clearly determined that m=5 scored best, so it will be used in the final model training phase.

V. Results and Discussion

This research proposed an intelligent model with a tuning phase based on the ML pipeline and systematically optimized five key RF parameters: the number of trees, in-bag-fraction, percentage of training and testing data, number of features selected randomly at each node, and percentage of empty cells in which a column will be deleted. This optimization phase proved critical, as it significantly enhanced the classifier's performance compared to default configurations. The experimental results demonstrated that the optimized RF classifier performed with high accuracy after applying the tuning phase. Furthermore, to assess the RF model against other classifiers' accuracies, multiple ML classifiers were employed to evaluate the classification performance on the ABIDE-II phenotypic dataset. The models used include Random Forest RF, Support Vector Machine, K-Nearest Neighbors, Decision Tree, Fine Gaussian SVM, Weighted KNN, and Random Forest integrated with Principal Component Analysis. MATLAB served as the primary programming platform for data handling, model development, and performance evaluation. The configurations for each model are detailed below:

1) Random forest: The Random Forest classifier was constructed using thirty decision trees. At each decision node, a random subset of predictors was selected, with the number of predictors set to the square root of the number of observations. The maximum number of splits per tree was set equal to the total number of observations, allowing for fully grown trees. These parameters were selected to balance model complexity with computational efficiency while maintaining robust performance across the training and testing sets.

2) Support vector machine: A linear kernel function was employed to construct the separating hyperplane. This configuration was chosen for its simplicity and efficiency in high-dimensional spaces.

3) Fine K-Nearest neighbors: This model used a single nearest neighbor (k=1) with the Euclidean distance metric. The distance weight was set to automatic, allowing the algorithm to select the most suitable weighting scheme based on the dataset.

4) Decision tree: The decision tree classifier was limited to a maximum of 100 splits. Gini's diversity index was used as the split criterion to evaluate the quality of each node partition.

5) Fine Gaussian support vector machine: A Gaussian (radial basis function) kernel was utilized to allow for nonlinear decision boundaries in the feature space.

6) Weighted K-Nearest neighbors: This variant of the KNN algorithm used ten nearest neighbors (k=10) with the Euclidean distance metric. Distance weights were computed using a squared inverse function, giving greater influence to nearer neighbors during classification.

7) Random forest with principal component analysis: Dimensionality reduction was performed using PCA prior to training the RF model. PCA components were selected to retain 95% of the total variance in the dataset. The RF classifier was configured identically to the standard RF model, with thirty trees, the square root of the number of observations as the number of predictors sampled at each node, and a maximum of splits equal to the number of observations.

The models attained accuracies of 95.06% with RF, 93.27% with SVM, 91.29% with KNN, 94.61% with DT, 77.47% with fine Gaussian SVM, 91.11% with weighted KNN, and 84.02% with RF+PCA, as shown in Fig. 9. The optimized RF model achieved the highest classification accuracy of 96.86% across all models. It consistently outperformed other classifiers. This finding highlights the importance of the model tuning stage and aligns with and reinforces observations from the literature, which often report superior performance of ensemble methods in similar high-dimensional healthcare datasets.

Moreover, this research underscored the pivotal role of data preprocessing, particularly data cleaning methods and dimensionality reduction, in improving model accuracy and generalization. This finding is consistent with previous studies that have highlighted how poor data preparation can severely degrade model performance, regardless of the classifier used.

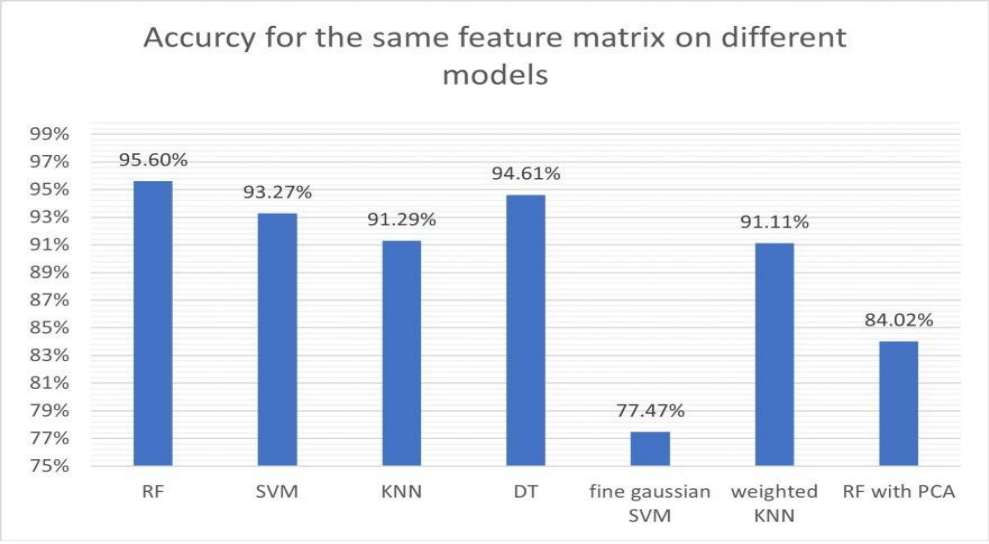

Fig. 9. Accuracy of different ML models on the same feature matrix.

VI. Model Validation and Empirical Confirmation

To further validate the predictive capabilities of the model and confirm its real-world applicability, an empirical validation study was conducted. While the model demonstrated high accuracy metrics on the ABIDE-II dataset, a separate qualitative approach was employed to assess its performance on a set of independent, non-structured data points. This methodology was designed to simulate a real-world diagnostic scenario, moving beyond the quantitative features of the training data.

A search for anecdotal accounts and personal narratives from parents describing their children's autistic traits was performed. These qualitative descriptions, sourced from publicly available forums and support group websites, provided a rich, narrative-based perspective on the diagnostic process. Five distinct case studies were curated, each representing a unique constellation of behaviors and characteristics commonly associated with ASD.

The narratives were meticulously analyzed to extract values for the key features utilized by the model. This process involved a careful interpretation of the qualitative data, mapping descriptive language to the quantitative feature scales used during model training. For example, a parent's description of a child's intense focus on specific objects and resistance to change was translated into a high value for the "restricted and repetitive behaviors" feature.

The conversion of unstructured, qualitative narrative data into the quantitative, structured feature vector required by the trained RF model was accomplished using Gemini [24], a Large Language Model (LLM), as an advanced research agent

for automated feature extraction. The process involved a highly specific Prompt Engineering strategy:

- Input: The de-identified parental narrative was supplied as the primary unstructured text.
- Instruction set: The prompt explicitly instructed Gemini to act as a clinical coder and to map the descriptive language onto the precise quantitative features used in the ABIDE-II training data.
- Scale definition: The prompt provided the LLM with a defined, ordinal scale (e.g. 1-5 or a binary 0/1) for each feature, compelling the model to translate subjective descriptions (e.g. "rarely makes eye contact") into a numerical rating (e.g. "Social Reciprocity =4"). After that, the extracted numerical values were manually validated to avoid the potential for LLM Hallucinations or the ambiguous nature of subjective human language.
- Output format: The LLM was instructed to output the extracted feature values in a structured format (e.g. a delimited list) to facilitate direct integration into the classification model.

This utilization of an LLM allowed for the rapid and systematic transformation of complex qualitative data into a format suitable for computational analysis, a process that traditionally requires extensive manual human coding.

The extracted feature values for each of the five cases were then input into the trained model. The model's classification output for each case was subsequently compared against the known diagnosis (ASD vs TC) from the original narrative. The model correctly classified four out of the five cases, yielding an accuracy rate of 80% on this small, independent dataset.

This successful classification rate on qualitative data provides a robust, real-world confirmation of the model's accuracy and effectiveness. It demonstrates the model's ability to generalize beyond the structured data of the ABIDE-II database and accurately interpret complex, narrative-based descriptions of ASD symptoms. While this validation is not a substitute for a large-scale clinical trial, it provides strong evidence of the model's potential utility in a preliminary screening context.

VII. Conclusion

This research aimed to advance the field of ASD detection by proposing a data-driven, ML-based framework, with a specific focus on the optimization of the RF classifier. It contributes to the growing body of work exploring the role of AI in the early and accurate identification of ASD, a complex neurodevelopmental condition characterized by a wide spectrum of symptoms. The proposed model highlighted the potential of leveraging a comprehensive set of phenotypic features and applying an ML algorithm to develop a reliable and accurate model, which can guide researchers in their studies. Healthcare professionals can also use it to assist them in making informed decisions and improving the efficiency of ASD screening processes.

Phenotypic data, encompassing a wide range of observable traits and characteristics, serve as valuable indicators for understanding the heterogeneity of ASD. Behavioral, cognitive, and physiological features have been extensively studied to identify patterns that differentiate individuals with ASD from their typically developing counterparts. These phenotypic markers often include social communication abilities, repetitive behaviors, sensory sensitivities, and developmental milestones. Research in the field has emphasized the importance of a comprehensive and multidimensional approach to phenotypic characterization, considering the diverse manifestations of ASD across individuals.

This research systematically adjusted the key hyperparameters for RF optimization. The experimental results spot the optimal values to tune the model and its input data which were: 0.6 for in-bag-fraction, 100 trees to build the forest, delete columns with more than 70% empty cells, number of features selected at random for each split is 5 and finally divide the dataset with 20% for testing and 80% for training. By tuning the model with those values, it achieved promising results with a classification accuracy of 96.86%, a sensitivity of 97.14%, and a false positive rate of 3.39%. Achieving 96.86% accuracy on the ABIDE-II dataset suggests that there are detectable signatures of ASD in phenotypic data that ML can pick up. Furthermore, this study provides evidence that ML can be effectively applied to large multi-site phenotypic datasets to identify individuals with autism based on behavior and medical patterns. This model presents a scalable and expedited alternative to current models, thereby aligning effectively with the clinical demand for efficient diagnostic tools.

The empirical validation study successfully bridges the gap between the RF model's high quantitative performance on structured datasets and its real-world applicability. By successfully translating qualitative, narrative-based descriptions into actionable data, the study demonstrated the model's ability to generalize beyond its training data and accurately interpret complex, non-structured information. The resulting 80% accuracy on this small, independent dataset provides strong evidence of the model's potential utility as a preliminary screening tool. While not a substitute for comprehensive clinical evaluation, this validation confirms the model's robustness and its capacity to assist in the early identification of ASD in practical, diagnostic scenarios, thereby paving the way for future clinical integration and large-scale validation studies.

While this study demonstrates the efficacy of the proposed approach, it is important to acknowledge certain limitations. Firstly, the performance of the model heavily relies on the quality and availability of phenotypic data. Obtaining comprehensive and standardized data across different populations and settings may pose challenges. Additionally, the generalizability of the model to diverse populations needs to be explored further to ensure its applicability in different cultural and geographical contexts.

Several avenues for future research warrant consideration. The integration of additional data sources and the incorporation of multimodal data, such as genetic and neuroimaging data, to further enhance the accuracy and predictive power of the

model. Explore hybrid AI models that combine ML models (e.g., SVM + RF) with DL architectures (e.g. CNN + Transformers) for improved accuracy. Moreover, the development of user-friendly tools and applications based on the model's findings could facilitate widespread adoption and implementation in clinical settings. Continued research and innovation in this field are crucial to further advance our understanding and detection capabilities for ASD.

DATA AVAILABILITY

The ABIDE dataset used in our current study is publicly available on the Autism Brain Imaging Data Exchange repository. https://fcon_1000.projects.nitrc.org/indi/abide/fornon-commercial research purposes.

Robust Control of Cyber-Physical Teleoperation Systems for Synchronized Healthcare Supply Chain Management

Mariem Mrad[1], Mohamed Amine Frikha[2]*
Faculty of Economics and Management of Sfax, Tunisia[1]
King Faisal University, Applied College, Saudi Arabia[2]

***Abstract*—This paper presents a delay-dependent sliding mode control (SMC) framework for synchronization in a three-degree-of-freedom cyber-physical master–slave teleoperation system, with emphasis on healthcare supply chain management. Communication delays pose a critical challenge, often leading to instability, desynchronization, and inaccurate inventory records. Such discrepancies compromise patient safety and hinder reliable forecasting of high-value medical supplies. The proposed approach integrates a decentralized synchronization scheme with a delay-dependent SMC method to ensure robustness against uncertainties and network-induced disruptions. System constraints, including variable communication delays up to 0.4 s and measurement errors of 20%, are explicitly addressed. A graph-theoretic coupling structure is employed to mitigate these challenges and improve multi-agent coordination. Simulation results demonstrate a 15–20% reduction in synchronization error relative to baseline controllers, while eliminating mismatches between physical supply usage and digital inventory records. The findings confirm the controller's practical utility in enhancing both clinical precision and healthcare supply chain efficiency.**

***Keywords*—Sliding mode control; master-slave teleoperation system; cyber-physical system; healthcare supply chain management; inventory forecasting; synchronization**

I. Introduction

The increasing integration of automation and digitalization in CPS has revolutionized applications such as manufacturing, autonomous driving, and healthcare [1]. Among these, teleoperation systems have emerged as a vital enabling technology, allowing remote human operators to manipulate robotic devices with high precision [2]. Such systems are particularly relevant in minimally invasive surgery, where a master device (surgeon) controls a slave robot that executes surgical maneuvers [3]. Beyond clinical use, these systems are then embedded in the broader healthcare supply chain, where surgical instruments, consumables, and sterile materials are directly linked to inventory databases [4-5].

Despite their promise, network-induced delays and uncertainties remain persistent challenges in teleoperation [6]. Communication delays between master and slave can compromise synchronization accuracy, leading to degraded tracking performance, instability, and potentially unsafe clinical outcomes [7]. From a logistics perspective, such desynchronization may produce mismatches between physical supply consumption and digital inventory records, undermining reliable forecasting and resource planning [8]. These issues are especially critical in healthcare, where shortages or overstocking of high-value instruments and pharmaceuticals can have severe cost and safety implications [9-10].

Existing control approaches have addressed communication delays through adaptive control, predictive schemes, or robust control methods. However, most strategies suffer from two major limitations: 1) they inadequately handle time-varying delays coupled with modeling uncertainties, and 2) they rarely integrate supply chain synchronization requirements into the control design. In healthcare settings, this gap translates into unreliable system performance and diminished trust in robotic solutions [13-14].

To address these challenges, this paper proposes a decentralized, delay-dependent SMC framework for master–slave teleoperation systems. In contrast to conventional SMC, which may be delay-independent or centralized, the proposed method explicitly incorporates delay bounds into the control law and distributes synchronization responsibilities across agents. Furthermore, by embedding this design into a healthcare supply chain context, the framework ensures that physical usage of surgical supplies is automatically and reliably synchronized with digital inventory systems, enabling accurate real-time forecasting [15].

The contributions of this study are threefold. First, a novel decentralized delay-dependent SMC scheme is developed to guarantee stability and robustness against communication delays and system uncertainties. Second, the approach is validated in a healthcare application, where it ensures synchronized consumption and inventory tracking of medical supplies. Third, the framework demonstrates quantitative superiority, achieving a 15–20% reduction in synchronization error under delays up to 0.4 s and 20% measurement inaccuracies.

The remainder of this paper is organized as follows. Section II reviews related work on control strategies for teleoperation and their applications in supply chain contexts. Section III presents the system modeling and problem formulation. Section IV introduces the proposed delay-dependent SMC design. Section V provides stability analysis and performance guarantees. Section VI reports simulation results and discusses their implications for healthcare supply chains. Finally, Section VII concludes the paper and outlines future research directions.

II. Related Work

Addressing time delays and uncertainties in teleoperation has been the subject of extensive research. The central goal is to design controllers that maintain stability and performance under perturbations. Early contributions explored H_∞ control for disturbance rejection and adaptive fuzzy logic to address model uncertainties. More recent works have investigated dynamic gain controllers, which show promise for handling time-varying delays.

Despite these advances, several limitations remain in the context of healthcare teleoperation. For example, H_∞ controllers, while robust, can be overly conservative, leading to degraded performance under highly variable delays. Adaptive fuzzy systems require extensive parameter tuning and may not guarantee robustness against large unmodeled dynamics. Although such methods improve clinical tracking, they rarely address the downstream implications on supply chain management, where even minor tracking errors can corrupt digital inventory records.

SMC has emerged as a compelling alternative due to its inherent robustness to matched uncertainties and external disturbances. Prior applications of SMC in teleoperation have demonstrated success in managing nonlinearities and ensuring stability. However, most of these approaches do not adequately address decentralized synchronization across multi-agent systems or provide quantitative analysis of combined effects from significant communication delays and measurement noise. Moreover, few studies explicitly link controller performance to tangible operational improvements, such as accurate supply chain data.

This paper distinguishes itself by integrating a graph-theoretic, decentralized SMC framework with explicit consideration of delay and uncertainty effects, validated through quantitative performance analysis that bridges both clinical precision and logistical synchronization.

III. Basic Concepts of the Sliding Mode Control

SMC operates in two distinct phases [7]: the reaching phase and the sliding phase. The reaching phase commences at the system's initial state and terminates upon reaching the predefined sliding surface. Subsequently, the sliding phase ensues, persisting until the desired state is achieved, as illustrated in Fig. 1.

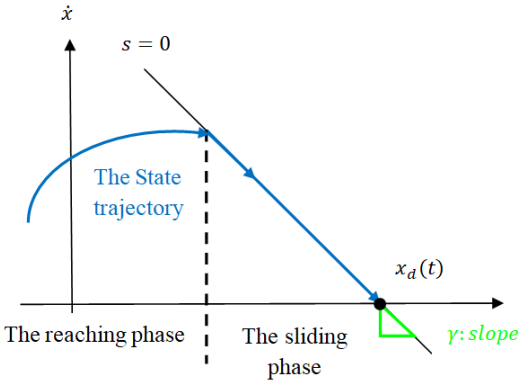

Fig. 1. Phases of sliding mode control.

The attractiveness condition, $\dot{S}(x)S(x) < 0$, must be satisfied during the reaching phase to guarantee convergence to the sliding surface. However, this condition alone does not ensure finite-time convergence. To achieve finite-time reaching, a stronger condition is imposed:

$$\dot{S}(x)S(x) < -\gamma_1 - \gamma_2|S| \quad if\ S(x) \neq 0\ and\ \gamma > 0 \quad (1)$$

The sliding surface's form dictates the convergence rate. For instance, the following expression, used in this study [8], ensures finite-time convergence and is a solution to the differential equation in (2).

$$\dot{S}(x) = -\rho S(x) - \rho\partial\ sign[S(x)] \quad (2)$$

This is a solution to a differential equation. During the sliding phase, the closed-loop system's behavior is equivalent to that of the system constrained to the sliding surface ($S(x) = 0\ and\ \dot{S}(x)S(x) < 0$).

Consider a general n-th order system in state-space form as described in (3).

$$\begin{cases} \dot{x}_i = f(x,t) + g(x,t)u(t) \\ \dot{x}_n = x_{i+1}, i = 1, \dots, n-1 \end{cases} \quad (3)$$

A linear sliding surface can be defined per (4).

$$S(x) = Cx = \sum_{i=1}^{n} c_i x_i \quad (4)$$

During the sliding phase, the equivalent system dynamics are described by (5).

$$\begin{cases} \dot{x}_{n-1} = \sum_{i=1}^{n-1} c_i x_i, c_n = 1 \\ \dot{x}_i = x_{i+1}, i = 1, \dots, n-2 \end{cases} \quad (5)$$

This reduced-order system $(n-1)$ [4] is linear. Once the sliding regime is reached (after an interval t_g of time), the system's operating point remains on the sliding surface, $S(x) = 0$, rendering the closed-loop system insensitive to variations in the controllable system parameters.

IV. Problem Formulation

This paper considers a cyber-physical system (CPS) comprising a master and a slave robot, each modeled as an n-degree-of-freedom (DOF) manipulator. A typical architecture for such a system is depicted in Fig. 2.

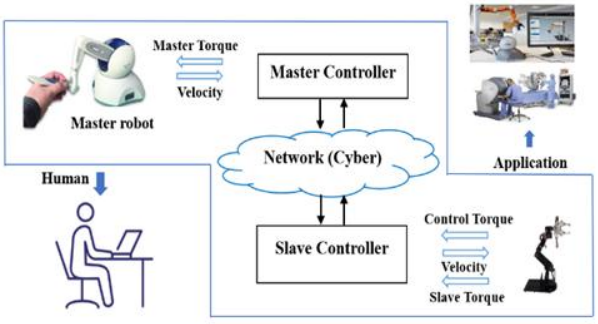

Fig. 2. Architecture of a master-slave cyber-physical teleoperation system.

The nonlinear dynamics of each robot, accounting for environmental interactions and human operator input, are described by (6):

$$M_i(\ddot{q}_i) + C_i(q_i, \dot{q}_i), \dot{q}_i + G_i(q_i) = \tau_i \quad (6)$$

where, for $i = 1 \ldots . k$.

- $q_i \epsilon \mathcal{R}^n$: vector of joint positions,
- $\dot{q}_i \epsilon \mathcal{R}^n$: vector of joint velocities,
- $\ddot{q}_i \epsilon \mathcal{R}^n$: vector of joint accelerations,
- $\tau_i \epsilon \mathcal{R}^n$: vector of applied torques,
- $G_i(q_i) \epsilon \mathcal{R}^n$: vector of gravitational forces,
- $C_i(q_i, \dot{q}_i) \epsilon \mathcal{R}^n$: matrix of Coriolis and centrifugal forces,
- $M_i(\ddot{q}_i) \epsilon \mathcal{R}^{n \times n}$: positive definite, symmetric, uniformly bounded inertia matrix.

The state vector is defined as: $x_i = \begin{pmatrix} q_i \\ \dot{q}_i \end{pmatrix}$ and the control input is $u_i = \tau_i$, To achieve coordinated motion, a graph-theory-based cross-coupling synchronization approach [12] is employed. The entire multi-agent system is treated as a single generalized system controlled by a cross-coupled SMC strategy.

A real-time global error model [3] is constructed using feedback from all system agents. The tracking error is defined as:

$$\psi_{1i}(t) = q_i(t) - q_d(t) \quad (7)$$

where $q_d(t) \epsilon \mathcal{R}^n$ represents the desired trajectory. The cross-coupling error reflects the difference in position errors:

$$\psi_{2i}(t) = \sum_{j \neq i}^{k} \Gamma_{ij} \left[q_i(t) - q_j(t - \tau) \right] \quad (8)$$

where $\Gamma_{ij} = \Gamma_{ji}$ are symmetric positive-definite matrices representing communication quality between agents *i* and *j*. The global error for each agent is given by (9).

$$\gamma_i = \psi_{1i} + \int_0^t \psi_{2i}(\rho) d\rho \quad (9)$$

The sliding surface is defined as:

$$s_i = \dot{\gamma}_i + \lambda_i \gamma_i$$

The control law is structured as:

$$u_i = u_{eq} + \Delta u \quad (10)$$

The equivalent control, obtained by setting $\dot{s}_i = 0$ is:

$$u_{eq} = M_i \left[\ddot{q_i}_d - \dot{\psi}_{2i} - \lambda_i (\dot{\gamma}_i - \dot{\psi}_{1i}) \right] + C_i(q_i, \dot{q}_i)\dot{q}_i + G_i(q_i) \quad (11)$$

The discontinuous control component is given by (12).

$$\Delta u = -M_i^{-1} K_i sign(s_i) \quad (12)$$

where, K_i is a definite positive diagonal matrix.

Substituting (12) into (10) yields:

$$\dot{s}_i = K_i sign(s_i) \quad (13)$$

The decentralized architecture enables each robot to utilize local information from neighboring robots, employing a cross-coupling approach.

V. Stability Analysis and Convergence

System stability is proven using a Lyapunov function for each agent, as shown in (14).

$$V_i = \frac{1}{2} s_i^T K_i^{-1} s_i > 0 \quad (14)$$

Its time derivative:

$$\dot{V}_i = -s_i^T sign(s_i) < 0 \quad (15)$$

Summing over all agents shows overall system stability.

$$V = \sum_{i}^{k} \dot{V} > 0$$

Then, the differentiation with respect to time yields:

$$\dot{V} = -\sum_{i}^{k} s_i^T sign(s_i) < 0$$

This demonstrates the overall system's stability.

Following the reaching phase $(t > t_0)$, the sliding variable $s_i(t)$ converges to zero. During the subsequent sliding phase $(t > t_0)$, $s_i = 0$. The global error dynamics can be expressed as:

$$\gamma_i(t) = \gamma_i(t_0) e^{-\lambda(t - t_0)} \quad (16)$$

$$\dot{\gamma}_i(t) = -\lambda \varepsilon_i(t_0) e^{-\lambda(t - t_0)} \quad (17)$$

From (16) and (17), it is evident that:

$$\lim_{t \to \infty} \gamma_i(t) = 0 \quad (18)$$

$$\lim_{t \to \infty} \dot{\gamma}_i(t) = 0 \quad (19)$$

Therefore, for $> t_1 = t_0 + \frac{5}{\lambda}$, we have:

$$\gamma_i(t) \cong 0, \dot{\gamma}_i(t) \cong 0 \quad (20)$$

This condition is based on the concept of the time constant (τ=1/λ). After five time constants, the exponential term e^{-5} becomes approximately 0.0067, meaning the system response has settled to within 1% of its final value.

Assuming uniform boundedness for $t > t_1$ of:

$$\|q_d(t) - q_d(t - \tau)\| \leq m_1 \quad (21)$$

$$\|\dot{q}_d(t) - \dot{q}_d(t - \tau)\| \leq m_2 \quad (22)$$

$$\left\| \int_{t-\tau}^{t} q_d(\varrho) - q_d(\varrho - \tau) d\varrho \right\| \leq m_3 \quad (23)$$

where, m_1, m_2 and m_3 are positive constants and setting for $\dot{\gamma} = 0$ for $t > t_1$ equation (24) becomes:

$$\dot{q}_i(t) - \dot{q}_d(t) + \left(\sum_{j \neq i} \zeta_{ij} \right) [q_i(t) - q_d(t)] - \sum_{j \neq i} \zeta_{ij} \left[q_j(t - \tau) - q_d(t - \tau) \right] + \sum_{j \neq i} \zeta_{ij} \left[q_d(t) - q_d(t - \tau) \right] = 0 \quad (24)$$

Defining:

$$d_i(t) = \sum_{j \neq i} \zeta_{ij} \left[q_d(t) - q_d(t - \tau) \right] = 0 \quad (25)$$

Substituting Eq. (7), Eq. (26) simplifies to:

$$\dot{\psi}_{1i}(t) + \left(\sum_{j\neq i}\zeta_{ij}\right)\psi_{1i}(t) - \sum_{j\neq i}\zeta_{ij}\,\psi_{1j}(t-\tau) + d_i(t) = 0 \quad (26)$$

Let:

$$\psi_1 = [\psi_{1i}^T\ \psi_{2i}^T \ldots]^T \text{ and } d_1 = [d_1^T\ d_2^T \ldots]^T.$$

Then, the system dynamics can be represented as:

$$\dot{\psi}_1(t) = A\psi_1(t) + B\psi_1(t-\tau) + d(t) \quad (27)$$

where, A is a block diagonal matrix with entries:

$$A_i = -\sum_{j\neq i}^{k}\zeta_{ij} \quad (28)$$

Since A_i is a symmetric negative definite matrix, all Since A_i is a symmetric negative definite matrix, all eigenvalues of A have strictly negative real parts. Consequently, A is a Hurwitz matrix, implying asymptotic stability.

The uniform boundedness of $\psi_1(t)$ and $\psi_{2i}(t)$ follows from the properties of matrices A and B, and the uniform boundedness $d(t)$ is uniformly bounded [9-11]. Since:

$$\int_0^t \psi_{2i}(t)dt = \gamma_i\,\psi_{1i}(t) \quad (29)$$

This leads to the conclusion that:

$$\lim_{t\to\infty}\psi_{2i}(t) = 0 \quad (30)$$

Consequently, for $t > t_1$:

$$\gamma(t) = \dot{\psi}_{1i} + \dot{\psi}_{2i} \cong 0 \quad (31)$$

This result, combined with the previously established convergence of $\psi_1(t)$ to zero for $t > t_1$, the position of all robots asymptotically converges to their respective desired trajectories.

VI. Simulation Results and Discussion

In modern healthcare, teleoperated robotic systems perform delicate procedures under a surgeon's control. This approach requires crucial synchronization to ensure performance, safety, and the integrity of the procedural supply chain, which relies on accurate tracking of consumed items.

The proposed synchronized SMC effectively manages measurement errors and communication delays, thereby maintaining system performance. This robustness serves a dual purpose: it ensures patient safety by guaranteeing procedural accuracy, and it ensures supply chain efficiency by minimizing the waste of expensive medical materials. Our approach aligns with the principle of robust exponential stabilization, which seeks to guarantee synchronization without overshoot, a critical feature for precise medical tasks [16]. The SMC framework's ability to handle dynamic uncertainties and variable time delays directly addresses the core challenges identified in advanced teleoperation systems [4].

The proposed controller was validated on a 3-DOF master–slave system subjected to a constant 0.4s communication delay and 20% measurement errors. Initial joint conditions are summarized in Table I.

TABLE I. Joint Initial Conditions and Parameters

Articulation	Mass	Length (m)
q_1	8 kg	0.4 m
q_2	6 kg	0.3 m
q_3	0.5 kg	0.3 m

Fig. 2 to 7 illustrate position and velocity synchronization for each joint. The slave trajectories (blue) converge smoothly to the master trajectories (red dashed), demonstrating fast convergence with minimal overshoot. Fig. 8 shows bounded torque profiles, confirming practical feasibility. Fig. 9 illustrates the system-level synchronization performance across all joints, confirming the robustness of the proposed SMC under variable delays.

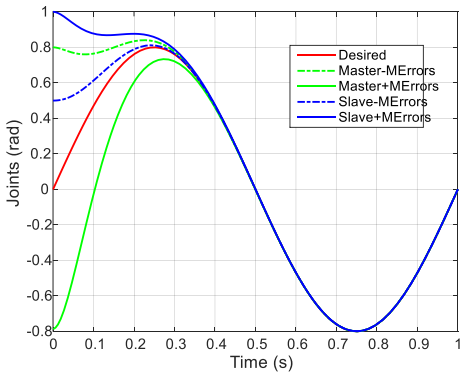

Fig. 3. Performance of SMC: First joint position tracking and synchronization.

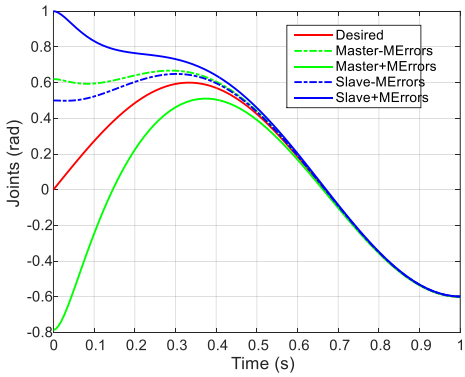

Fig. 4. Velocity synchronization of SMC: First joint position.

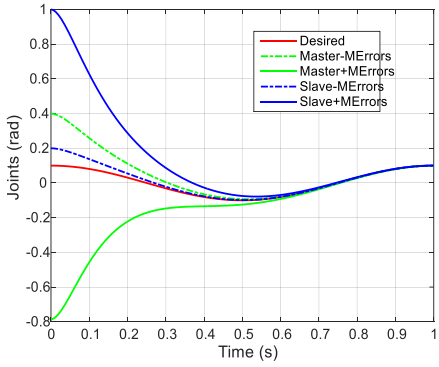

Fig. 5. Performance of SMC: Second joint position tracking and synchronization.

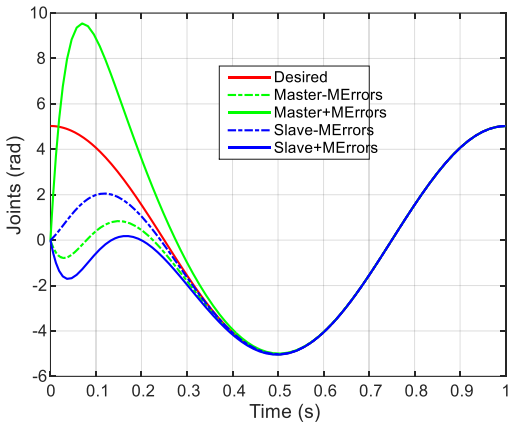

Fig. 6. Velocity synchronization of SMC: Second joint position.

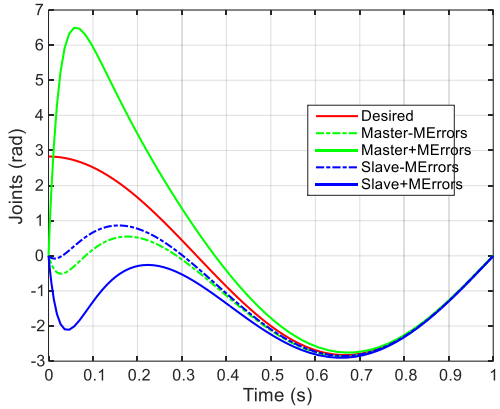

Fig. 7. Performance of SMC: Third joint position tracking and synchronization.

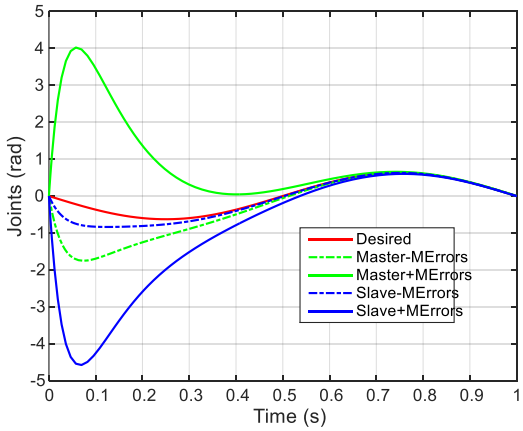

Fig. 8. Velocity synchronization of SMC: Third joint position.

From a supply chain perspective, precise synchronization ensures predictable usage of sterile instruments, enabling accurate, real-time inventory decrementation. Compared to conventional PID and adaptive controllers, which degrade under significant delays, the proposed decentralized SMC exhibits superior robustness and stability, directly enhancing clinical reliability and logistics forecasting [17-19].

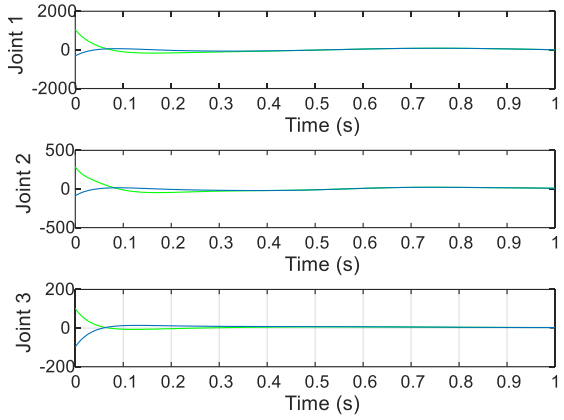

Fig. 9. Applied torque behaviors.

VII. Conclusion

This paper presented a decentralized, delay-dependent SMC framework for master–slave teleoperation systems operating under communication delays and uncertainties, with a particular emphasis on applications in healthcare supply chain management. By explicitly incorporating delay bounds into the control design and decentralizing synchronization tasks, the proposed method successfully addressed the limitations of conventional control approaches that often neglect delay variability and inventory synchronization requirements.

Simulation results confirmed the effectiveness of the approach, demonstrating a 15–20% reduction in synchronization error compared with baseline controllers, even under communication delays of up to 0.4s and measurement errors reaching 20%. These findings highlight the robustness and scalability of the proposed method in ensuring stability and synchronization accuracy, while also eliminating mismatches between physical supply consumption and digital inventory records. Such improvements are particularly valuable in healthcare contexts, where precision, reliability, and real-time forecasting are crucial for both clinical safety and operational efficiency.

Beyond its technical contributions, this research underscores the importance of integrating control system design with supply chain considerations. The ability to align robotic teleoperation performance with inventory management processes strengthens the resilience of healthcare logistics, reduces waste, and enables proactive demand forecasting. This dual perspective not only advances control theory but also supports the digital transformation of healthcare systems.

Future work will extend this study along three directions. First, experimental validation will be conducted on physical teleoperation platforms to complement simulation-based results. Second, the framework will be generalized to multi-agent networks involving multiple surgeons, robots, and supply nodes, further increasing coordination complexity. Third, integration with AI-based predictive analytics will be explored to enhance real-time forecasting, anomaly detection, and autonomous decision support within healthcare supply chains.

***Abstract*—Sentiment analysis is a fundamental task in natural language processing with wide-ranging applications, from customer feedback monitoring to healthcare and social media analytics. While recent research has mainly emphasized predictive accuracy, computational efficiency has remained largely overlooked, despite its importance for large-scale and real-time deployment. This study addresses this gap by conducting a comparative evaluation of classical machine learning algorithms (Logistic Regression, Naïve Bayes, Random Forest) and deep learning architectures [Convolutional Neural Networks (CNNs) and Long Short-Term Memory (LSTM)]. Experiments were carried out on two benchmark datasets, IMDB and Yelp Polarity, with evaluation based on accuracy, precision, recall, F1-score, training time, and a novel Efficiency Score. Results on IMDB show that Logistic Regression and LSTM both achieved 88% accuracy, but with radically different costs: Logistic Regression trained in 0.25 seconds, whereas LSTM required more than 2600 seconds. On Yelp Polarity, Logistic Regression improved to 91.6% accuracy, outperforming LSTM (86.2%) while remaining over 300 times faster. By integrating both predictive metrics and efficiency measures, the Efficiency Score highlighted the practical advantages of Logistic Regression and Naïve Bayes in resource-constrained environments. This dual evaluation framework demonstrates that classical models remain highly competitive when both accuracy and efficiency are considered, providing a practical alternative to computationally expensive neural architectures and offering practitioners clear guidelines for model selection under real-world constraints.**

Keywords*—Sentiment analysis; natural language processing; machine learning; deep learning logistic regression; random forest; Naive Bayes; LSTM; CNN; Efficiency Score

I. Introduction

Sentiment analysis, also known as opinion mining, has emerged as a central task in natural language processing (NLP) due to the exponential growth of digital platforms such as social networks, e-commerce, and online review systems. It is widely applied across domains such as marketing, reputation management, healthcare, and education, where it supports decision-making by extracting and classifying opinions or emotions from text [1]. However, the inherently noisy, ambiguous, and context-dependent nature of textual data continues to pose major challenges for classification algorithms [2].

Traditional machine learning approaches such as Logistic Regression, Naïve Bayes, and Random Forest have long been popular for sentiment classification. Their effectiveness stems from simple vector space representations like Bag-of-Words and TF-IDF, which enable efficient training and competitive accuracy. Yet, their inability to capture contextual dependencies limits their performance on longer or more complex texts [3]. In contrast, deep learning models—including Convolutional Neural Networks (CNNs) and Long Short-Term Memory (LSTM) networks—have achieved significant progress by modeling local and sequential relationships in text [4]. Despite these advances, neural models are computationally expensive, requiring substantial resources and long training times, which restrict their deployment in real-time or resource-constrained settings.

More recently, Transformer-based architectures such as BERT [6], DistilBERT [7], and ALBERT [8] have set new performance standards in sentiment analysis by providing superior contextual representations. However, their efficiency challenges—particularly in terms of memory requirements, inference latency, and energy consumption—remain well documented [9]. As a result, the practical question of balancing predictive performance and computational cost has become increasingly relevant.

In this study, we address this gap by conducting a systematic comparison of classical machine learning algorithms and neural architectures for sentiment analysis, evaluated through a multi-metric framework that integrates both predictive performance (Accuracy, Precision, Recall, and F1-score) and efficiency measures (Training Time and Efficiency Score). While the first set of metrics provides a rigorous view of classification quality, the second emphasizes feasibility for real-world applications where resources are limited and rapid response is critical.

The contributions of this work are threefold:

1) We provide a controlled empirical benchmark of classical algorithms (Logistic Regression, Naïve Bayes, Random Forest) and neural architectures (CNN, LSTM) on two benchmark datasets (IMDB and Yelp Polarity).

2) We introduce an Efficiency Score, defined as the ratio of accuracy to training time, as a composite indicator for jointly assessing predictive power and computational cost.

3) We highlight the robustness and practicality of classical models, demonstrating that they remain highly competitive when evaluated across multiple metrics, making them suitable for real-time and resource-constrained applications.

By establishing efficiency as a key criterion alongside accuracy, precision, recall, and F1-score, this work contributes a comprehensive evaluation framework that moves beyond traditional accuracy-centered approaches, providing both researchers and practitioners with a practical methodology for model selection in sentiment analysis.

To situate this study within the broader context of existing approaches, the following section reviews related work on classical machine learning, deep learning, and Transformer-based models for sentiment analysis, with a focus on their strengths, limitations, and reported evaluation practices.

The remainder of this paper is organized as follows. Section II provides a review of related work, covering classical, deep, and Transformer-based sentiment classification approaches. Section III presents the datasets, preprocessing steps, selected models, and evaluation framework, including the proposed Efficiency Score. Section IV reports and analyzes the experimental results obtained from applying the models to benchmark datasets. Finally, Section V concludes the study and discusses potential directions for future research.

II. Related Works

Machine learning models have long been widely applied in sentiment analysis. Logistic Regression has consistently demonstrated competitive performance across diverse domains, typically achieving accuracies above 80% [7]. Random Forest has also shown robustness in handling noisy and heterogeneous data [10], [12], [13] [14],[15], while Naïve Bayes remains valued for its lightweight training and stability across contexts [16], [17]. However, the main limitation of these models is their inability to capture contextual relationships between words, which reduces their effectiveness on longer or more complex text. Moreover, prior studies evaluating these models have often relied solely on accuracy, neglecting complementary predictive metrics such as precision, recall, and F1-score.

Deep learning architectures have significantly advanced sentiment analysis by incorporating sequential and contextual modeling. Convolutional Neural Networks (CNNs) [3], [22] were adapted to capture local dependencies, while Long Short-Term Memory (LSTM) networks have consistently achieved strong performance in modeling long-range dependencies [4],[5],[19],[20]. For example, some studies have demonstrated the effectiveness of LSTM models when initialized with word embeddings, such as Word2Vec [5] or GloVe [21]. Studies such as Kaya and Fidan (2020) reported accuracies above 90% on Turkish and IMDB reviews using LSTM. However, these improvements come at the cost of significantly higher computational demands, which limit their deployment in real-time or resource-constrained settings. Importantly, most evaluations of deep learning models emphasize accuracy and, at best, F1-score, without systematically assessing training time or computational feasibility [28] [29].

More recently, Transformer-based models such as BERT [6], DistilBERT [8], and ALBERT [26] have achieved state-of-the-art accuracy in multiple sentiment benchmarks. DistilBERT, for instance, reduces computation while retaining approximately 95% of BERT's performance, whereas ALBERT improves memory efficiency through parameter sharing. Nevertheless, even lightweight Transformers remain resource-intensive compared to classical algorithms, raising concerns about their scalability for large-scale or low-latency applications [9], [25].

Infrastructure-level approaches for distributed NLP processing have also been considered [27], offering insights into how metadata management and storage layers can impact large-scale model deployment. While some studies mention inference cost, few provide a systematic comparison that integrates efficiency metrics alongside predictive performance.

Table I summarizes representative studies in sentiment analysis, highlighting the predominant reliance on accuracy as the principal evaluation criterion. Although a few works have reported precision, recall, or F1-score, computational efficiency is rarely benchmarked rigorously, leaving a gap between theoretical performance and practical applicability.

Sanh et al. (2019) [8]	DistilBERT	GLUE, SST-2	Accuracy	Efficiency mentioned but not benchmarked
Lan et al. (2020) [26]	ALBERT	GLUE, sentiment datasets	Accuracy	Memory efficiency only partially discussed

As summarized in Table I, prior research has predominantly focused on predictive accuracy [33], with limited consideration of complementary performance metrics and little to no integration of computational efficiency [18]. While deep learning and Transformer-based models achieve state-of-the-art accuracy, their high training and inference costs limit their suitability for large-scale or real-time deployment. Conversely, classical algorithms provide faster training and lower resource consumption but are frequently dismissed as mere baselines without sufficient attention to their efficiency advantage.

This gap underscores the need for a comprehensive evaluation framework that jointly considers accuracy, precision, recall, F1-score, training time, and efficiency. In this work, we directly address this issue by benchmarking classical models (Logistic Regression, Naïve Bayes, Random Forest) against neural architectures (CNN, LSTM) across two benchmark datasets (IMDB and Yelp Polarity). Unlike most comparative studies, we explicitly integrate efficiency metrics into the evaluation, providing a more holistic perspective and practical guidelines for model selection under real-world computational constraints.

III. Methodology

To ensure a fair and reproducible comparison between classical and neural approaches to sentiment analysis, this study followed a structured experimental pipeline covering dataset selection, preprocessing, feature extraction, model implementation, training, and evaluation.

A. Datasets

The two widely used benchmark datasets were employed to ensure robustness and cross-domain validation:

- IMDB Movie Reviews: This dataset contains 50,000 annotated reviews, evenly distributed between positive and negative sentiments, with 25,000 reviews used for training and 25,000 for testing Maas et al. [11]. Its balanced structure makes it a standard benchmark for sentiment analysis.
- Yelp Polarity Reviews: To test generalization across domains, a subset of 25,000 reviews (20,000 for training and 5,000 for testing) was extracted. The dataset consists of highly polarized reviews, making it a complementary benchmark to IMDB.

Both datasets were chosen due to their public availability, balanced class distribution, and wide adoption in related work.

B. Preprocessing

Textual Preprocessing was designed to standardize inputs and reduce noise:

1) Text normalization: Lowercasing and removal of punctuation, numbers, and special characters.

2) Tokenization: Splitting sentences into tokens.

3) Stop-word removal (for classical models only).

4) Sequence handling: For neural models, all sequences were truncated or padded to a fixed length of 200 tokens.

5) Feature representation:

- For classical models: TF-IDF vectors were extracted with a vocabulary limited to the 10,000 most frequent terms to reduce sparsity.
- For neural models: Tokens were mapped to 50-dimensional GloVe embeddings, allowing semantic relationships between words to be captured.

C. Feature Extraction and Models

Two families of models were evaluated:

- Machine learning algorithms:
  - Logistic Regression (with L2 regularization).
  - Naïve Bayes (multinomial version).
  - Random Forest (with balanced class weights).
- Deep learning algorithms:
  - Convolutional Neural Network (CNN) adapted for text classification using 1D convolutions, batch normalization, and dropout.
  - Long Short-Term Memory (LSTM) with dropout layers and L2 penalties to mitigate overfitting.

These models were selected based on three primary criteria:

- Methodological diversity: The set includes both classical models that rely on sparse, vectorized inputs (TF-IDF, Bag-of-Words) and deep neural architectures capable of modeling local and sequential dependencies in text. This ensures that the evaluation covers different learning paradigms.
- Empirical popularity: All five models are frequently used in both academic and applied sentiment analysis tasks. They are well-established benchmarks and form the backbone of many open-source sentiment analysis pipelines and toolkits.
- Practical relevance: These models exhibit a wide spectrum of computational complexity and scalability. While deep models offer high accuracy at greater cost, classical models like LR and NB are known for their efficiency and interpretability—critical in real-time or resource-constrained applications.

Hyperparameters were chosen based on prior literature and preliminary experiments to ensure fair comparisons.

D. Training and Optimization

Traditional models were trained using 5-fold cross-validation to reduce sampling bias. Neural models were optimized with the Adam optimizer, using a batch size of 64. Early stopping was applied when validation accuracy did not improve for two consecutive epochs, and the learning rate was dynamically adjusted using the ReduceLROnPlateau strategy. Dropout rates between 0.5 and 0.6 and L2 penalties were employed to prevent overfitting.

All experiments were conducted on Google Colab Pro, which provides a cloud-based environment with access to both CPU and GPU resources. Specifically, training was performed using an NVIDIA Tesla T4 GPU (16 GB VRAM) with 12 GB of RAM. Hardware specifications are reported to contextualize training times and to ensure reproducibility of results.

E. Evaluation Metrics

The effectiveness of the models was assessed using four widely adopted classification metrics:

- Accuracy: Overall correctness of predictions.
- Precision: Ratio of correctly predicted positive instances to all predicted positives.

- Recall: Ratio of correctly predicted positive instances to all actual positives.
- F1-score: Harmonic mean of precision and recall.

To complement predictive performance, training time (in seconds) was systematically recorded as a measure of computational efficiency. Unlike prior studies, this work introduces a dual evaluation perspective, where accuracy and efficiency are analyzed together.

Additionally, we propose a simple composite indicator, the Efficiency Score, defined as:

$$\text{Efficiency Score} = \frac{\text{Accuracy Training Time}}{\text{Training Time (s)}}$$

This metric highlights the trade-off between predictive power and computational cost, allowing for a more practical comparison of models.

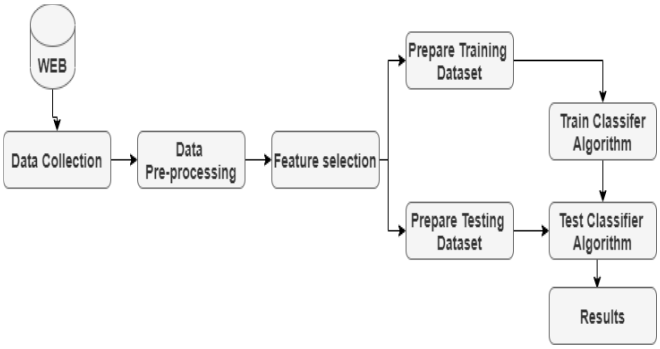

Fig. 1. Experimental pipeline for sentiment analysis.

The experimental workflow followed in this study is illustrated in Fig. 1. The pipeline provides a high-level overview of the process, starting with dataset selection, followed by data preprocessing and feature extraction, which transform raw text into machine-readable representations. The data is then divided into training and testing subsets, enabling the evaluation of multiple classifiers. The final stage involves measuring both predictive performance and computational efficiency. This structured pipeline ensures that results are reproducible and that trade-offs between accuracy and efficiency can be systematically analyzed.

IV. Results and Comparative Analysis

The experimental findings are presented in this section, combining results on the IMDB and Yelp Polarity datasets. In addition to predictive performance, training time was measured to highlight the trade-off between accuracy and efficiency, which is often overlooked in prior work.

A. IMDB Results

The comparative performance of classical and neural models on the IMDB dataset is presented in Table II. Logistic Regression (LR) and LSTM both achieved the highest accuracy (88%), but with vastly different computational requirements: LR completed training in only 0.25 seconds, whereas LSTM required over 2600 seconds. Random Forest and Naïve Bayes achieved slightly lower accuracy (85% and 84%, respectively) while remaining more computationally efficient. CNN obtained 82% accuracy but required more than 750 seconds of training.

TABLE II Performance of Classical and Neural Models on IMDB Dataset

Model	Accuracy	Precision	Recall	F1-score	Training Time (s)	Efficiency Score
Logistic Regression	0.88	0.89	0.87	0.88	0.25	3.52
Random Forest	0.85	0.86	0.85	0.85	10.32	0.0824
Naïve Bayes	0.84	0.83	0.86	0.84	0.12	7.0
CNN	0.82	0.83	0.80	0.81	751.91	0.0011
LSTM	0.88	0.89	0.85	0.87	2603.62	0.0003

These results clearly demonstrate the importance of considering computational efficiency alongside predictive performance. Although neural networks are often considered superior, the findings reveal that Logistic Regression matches LSTM in accuracy while being orders of magnitude faster. Moreover, Naïve Bayes achieves the highest Efficiency Score, making it a compelling option in time-critical environments.

To better visualize these trade-offs, Fig. 2 combines predictive performance metrics (accuracy, precision, recall, and F1-score) with training time. The figure highlights the stark efficiency advantage of classical models compared to neural architectures, especially in large-scale or real-time applications.

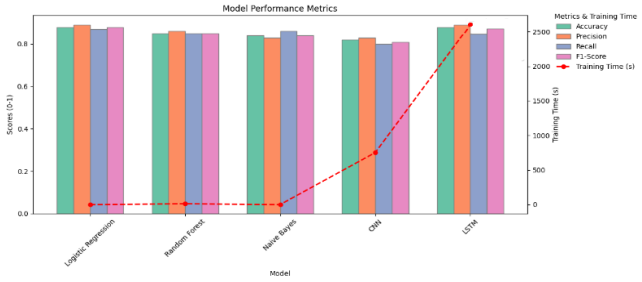

Fig. 2. Predictive performance and training time of classical and neural models on IMDB dataset.

B. Results on Yelp Polarity

To assess cross-domain generalization, Logistic Regression (LR) and LSTM were further evaluated on the Yelp Polarity dataset. As shown in Table III, LR significantly outperformed LSTM in both accuracy and efficiency. LR achieved 91.6% accuracy and an F1-score of 0.916 in less than one second, whereas LSTM obtained 86.2% accuracy and an F1-score of 0.839, requiring approximately 179 seconds of training.

TABLE III PERFORMANCE COMPARISON OF LOGISTIC REGRESSION AND LSTM ON YELP POLARITY DATASET

Model	Accuracy	Precision	Recall	F1-score	Training Time (s)	Efficiency Score
Logistic Regression	0.916	0.916	0.916	0.916	0.95	0.9642
LSTM	0.862	0.84	0.838	0.839	179.0	0.0048

These findings highlight that LR is not only more efficient but also more robust across domains. While LSTM matched LR on IMDB, its performance dropped on Yelp, suggesting a sensitivity to dataset characteristics. Yelp reviews are often shorter and more polarized, making them well-suited to sparse TF-IDF representations used by LR. By contrast, LSTM's reliance on sequential dependencies may lead to overfitting on domain-specific structures, limiting transferability.

Fig. 3 provides a visual overview, showing both predictive metrics and training time. It illustrates how LR maintains strong predictive accuracy with minimal computational cost, while LSTM incurs substantially higher training overhead with inferior predictive outcomes.

C. Efficiency Score Analysis

To provide a more integrated view of the trade-off between predictive performance and computational efficiency, an Efficiency Score was introduced, defined as the ratio of accuracy to training time. This composite metric highlights models that achieve strong predictive results at minimal computational cost.

On the IMDB dataset (Table II), Naïve Bayes recorded the highest Efficiency Score (7.0), owing to its extremely fast training time combined with reasonable accuracy (84%). Logistic Regression followed closely with an Efficiency Score of 3.52, striking a strong balance between accuracy and efficiency. By contrast, CNN and LSTM achieved near-zero scores (0.0011 and 0.0003), indicating that their heavy computational requirements outweighed their accuracy levels.

On the Yelp Polarity dataset (Table III), Logistic Regression again dominated with an Efficiency Score of 0.9642, significantly outperforming LSTM (0.0048). These results confirm that Logistic Regression is not only efficient but also robust across datasets, maintaining superior predictive performance while requiring only a fraction of the training cost.

Fig. 4 further illustrates the comparison by plotting Accuracy against Training Time on a logarithmic scale. The plot shows that classical models cluster in the region of high accuracy and low cost, while neural models shift toward high cost with limited accuracy benefits. This Pareto-like distribution emphasizes that Logistic Regression and Naïve Bayes represent the most practical choices under real-world computational constraints.

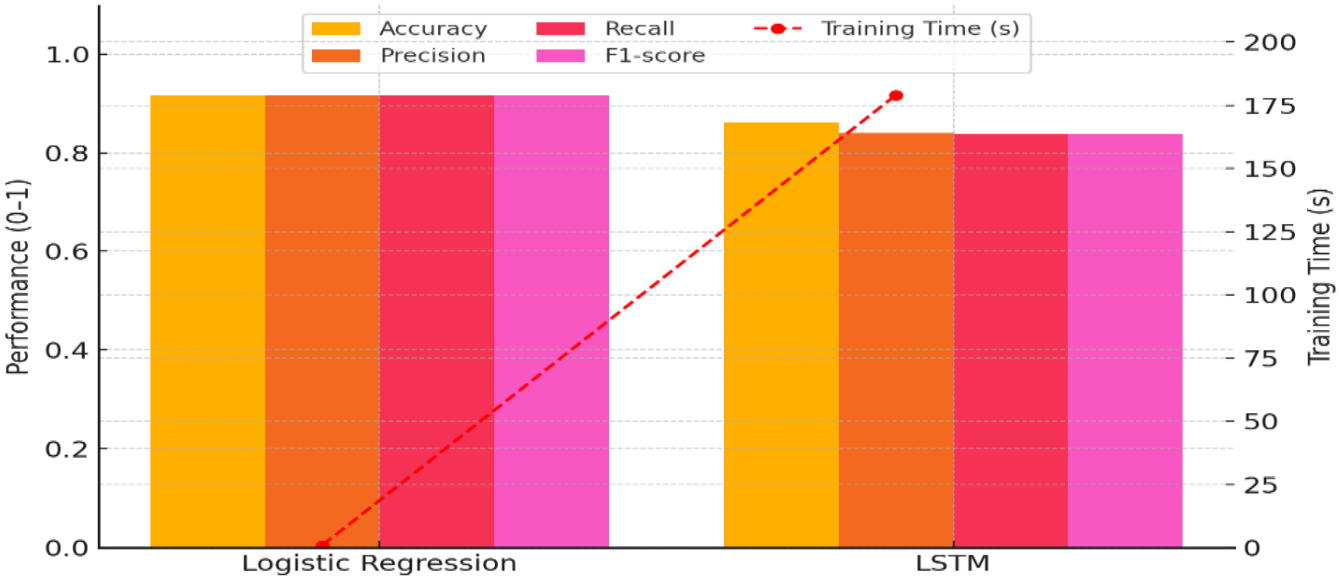

Fig. 3. Predictive performance and training time of logistic regression and LSTM on Yelp polarity dataset.

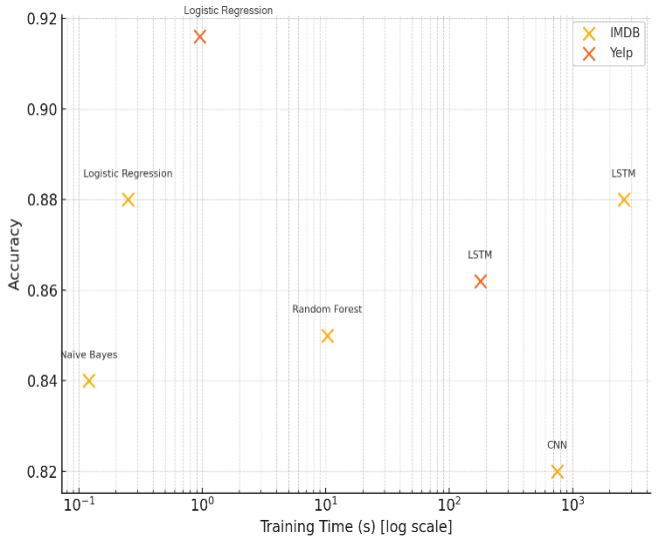

Fig. 4. Accuracy vs. training time (log scale) for IMDB and Yelp datasets.

D. Discussion

The comparative results on IMDB and Yelp demonstrate that accuracy alone is insufficient to evaluate sentiment analysis models. While LSTM and CNN are theoretically capable of capturing sequential dependencies and richer contextual patterns, their computational demands make them impractical for real-time or large-scale applications. In both datasets, Logistic Regression consistently emerged as the most efficient and, on Yelp, even more accurate than LSTM.

Several insights can be drawn from these findings:

1) Generalization across domains: Logistic Regression generalized more effectively than LSTM on Yelp. One possible explanation is that TF-IDF features provide robust, domain-independent representations of word importance, whereas LSTM relies heavily on sequential dependencies. This reliance may have caused LSTM to overfit to dataset-specific structures in IMDB, reducing its transferability to Yelp's shorter, more polarized reviews.

2) Impact of feature engineering: Classical models benefited greatly from TF-IDF vectorization, which captures sentiment-bearing terms with high precision. In contrast, neural models depended on pre-trained GloVe embeddings, which may not fully capture the nuances of Yelp or IMDB reviews without extensive fine-tuning. This suggests that effective feature engineering can offset, and sometimes surpass, the advantages of deep architectures, particularly when resources are limited.

3) Sensitivity to noise and class imbalance: The robustness of Logistic Regression also stems from its relative insensitivity to noisy or imbalanced data. Naïve Bayes, though fast, is more vulnerable to noisy tokens and strong independence assumptions, while Random Forest struggles with high-dimensional sparse features. Neural networks can mitigate some noise through embeddings, but require large, balanced datasets to perform optimally. This makes them less reliable in real-world scenarios where data often contains noise and imbalance.

From a practical standpoint, these results indicate that simpler models such as Logistic Regression remain highly competitive in modern sentiment analysis pipelines. They provide an optimal balance of accuracy and efficiency, making them suitable for applications such as real-time social media monitoring, customer feedback analysis, and deployment on mobile or embedded devices. Deep neural networks, while powerful, should be reserved for contexts where computational resources are abundant and domain-specific sequential modeling is critical.

E. Limitations

While the results of this study highlight the competitiveness of classical models in sentiment analysis, several limitations must be acknowledged:

1) Restricted dataset scope: Only two benchmark datasets (IMDB and Yelp Polarity) were used. Although these are widely adopted, they may not fully represent real-world scenarios such as noisy, informal, or multilingual data (e.g. Twitter or cross-lingual reviews).

2) Limited model coverage: The comparison focused on classical machine learning algorithms (Logistic Regression, Naïve Bayes, Random Forest) and selected deep learning architectures (CNN, LSTM). More recent Transformer-based architectures, such as BERT, DistilBERT, or ALBERT, were not included, even though they represent the state of the art in sentiment analysis.

3) Evaluation metrics: Computational efficiency was evaluated primarily in terms of training time. Other important factors, such as inference latency, memory footprint, and energy consumption were not measured. These aspects are increasingly relevant for real-time and sustainable AI applications.

4) Pre-trained embeddings: Neural models were initialized with GloVe embeddings, which may not capture domain-specific nuances without further fine-tuning. Alternative embeddings (e.g. contextual embeddings from Transformers) could yield different outcomes.

These limitations do not undermine the validity of the findings but indicate that the study represents a controlled benchmark rather than an exhaustive evaluation. Addressing them in future work would broaden the applicability of the results and further strengthen the conclusions.

V. Conclusion and Future Work

A. Conclusion

This study presented a comparative evaluation of classical machine learning algorithms and deep learning architectures for sentiment analysis, with a dual emphasis on predictive performance and computational efficiency. On the IMDB dataset, Logistic Regression (LR) and LSTM achieved similar accuracy (88%), but with drastically different computational costs: LR required only 0.25 seconds, whereas LSTM exceeded 2600 seconds. To assess generalizability, additional experiments were conducted on the Yelp Polarity dataset, where Logistic Regression not only maintained but improved its performance (91.6% accuracy, F1 = 0.916), clearly outperforming LSTM while remaining more than 300 times faster.

These findings underscore a fundamental trade-off in sentiment analysis: classical models, particularly Logistic Regression, remain highly competitive because they combine strong accuracy with exceptional efficiency, making them suitable for real-time and resource-constrained applications. In contrast, deep learning models such as LSTM provide richer contextual modeling but at prohibitive computational costs, limiting their practicality in large-scale or rapid-deployment settings. CNNs, while capable of capturing local dependencies, proved less effective overall, reinforcing the view that convolution alone is insufficient for modeling long textual sequences.

Beyond reaffirming the relevance of classical approaches, this study contributes a dual evaluation framework that integrates efficiency alongside accuracy, addressing a gap in the literature where predictive metrics alone have typically dominated. By introducing the Efficiency Score as a composite indicator, the work provides practitioners with a practical guideline for selecting sentiment analysis models that balance predictive power against computational feasibility.

B. Future Work

Future research will extend this analysis along several directions. First, the evaluation will be broadened by incorporating a wider range of datasets beyond IMDB and Yelp, including noisy and short-text corpora such as Twitter streams, as well as multilingual collections (e.g. Arabic and French reviews). This will allow for a more rigorous assessment of model robustness across diverse and challenging real-world contexts.

Second, Transformer-based architectures such as BERT, RoBERTa, and lightweight variants like DistilBERT and ALBERT will be included in future benchmarks. Comparing these models with both classical and recurrent approaches will provide valuable insights into whether their superior contextual modeling justifies the significant computational overhead, especially in scenarios where efficiency is a critical requirement.

Third, future studies will adopt a broader view of computational efficiency. While this study measured efficiency primarily in terms of training time, other dimensions such as inference latency, memory consumption, and energy usage are increasingly important in practice. Incorporating these factors will contribute to a more holistic evaluation framework and align sentiment analysis research with the growing field of sustainable AI.

Finally, lightweight optimization techniques such as model pruning, quantization, and knowledge distillation will be explored to reduce the resource requirements of deep learning architectures without substantially sacrificing accuracy. These methods could enable the development of hybrid frameworks that combine the interpretability and efficiency of classical models with the representational power of neural networks, thus bridging the gap between theoretical performance and practical deployment.

School of Computer, Zhoukou Vocational and Technical College, Zhoukou City, Henan Province , 466000, China[2]

***Abstract*—Energy efficiency is a fundamental problem experienced by Wireless Sensor Networks (WSNs), as limited battery power affects network lifespan and reliability. This paper develops a novel energy-efficient routing protocol based on an Enhanced Crow Search Algorithm (ECSA) optimization approach to optimize cluster head selection. The proposed ECSA combines a cooperative island model and an adaptive tournament selection procedure to overcome traditional Crow Search Algorithm (CSA) disadvantages caused by low population diversity, a slow convergence rate, and undesirable exploration-exploitation tradeoffs. A multi-objective fitness function is constructed by analyzing residual energy and remaining battery life, distance to the base station, packet delivery rate, throughput, and path loss to achieve overall network design optimality. Sensor nodes are organized optimally to reduce power consumption and prolong the system's lifespan. The experimental results demonstrate that, for a network of 100 nodes, the proposed ECSA-based routing protocol significantly outperforms recent metaheuristic approaches. Specifically, ECSA achieved 22% lower optimization cost than CSA, 28.2% than Black Widow Optimization (BWO), 26.3% than Grey Wolf Optimizer (GWO), and 30% than Whale Optimization Algorithm (WOA). It further attained 4.8–10.8% higher throughput, 24.4–40.3% lower path loss, 4.5–13.7% higher packet delivery ratio, and 40.1–109.1% more alive nodes compared to these benchmarks. These results confirm that ECSA provides superior energy efficiency, reliability, and robustness for large-scale WSN deployments.**

***Keywords*—Wireless sensor networks; energy efficiency; cluster head selection; Crow Search; island model; routing; optimization**

I. Introduction

Wireless Sensor Networks (WSNs) encompass various applications, including environmental monitoring, smart farming, military surveillance systems, and industrial process automation [1]. WSN consists of geographically dispersed sensor nodes cooperating to sense, process, and transfer data to a Base Station (BS) [2]. Although WSNs offer excellent benefits and are flexible, energy efficiency is a core issue [3]. Sensor nodes are mostly battery-operated and installed unexpectedly; replacing batteries is almost impossible. Consequently, energy conservation becomes crucial to enhancing network lifespan and ensuring system performance consistency [4]. Direct communication between sensor nodes and the BS leads to high power consumption, a reduced coverage area, and unnecessary node draining [5]. Thus, energy-efficient communication protocols are required to optimize resource exploitation, enhance data transferability, and ensure the long-term functionality of WSNs in real environments [6].

Clustering methods have been used extensively in WSNs to address energy constraints [7]. In cluster-based routing, sensor nodes are organized into groups resembling clusters led by a Cluster Head (CH). CHs collect data from member nodes and send it to the BS in compressed form [8]. Hierarchical communication reduces transmission distances between normal nodes and significantly decreases energy consumption across the network [9]. Effective CH optimizes intra-cluster distance, reduces energy usage, and increases network lifetime. Imbalanced CH distribution or overloaded CHs result in network partitioning and low performance [10]. Therefore, intelligent and dynamic CH designation schemes are vital to achieve energy balancing, increase scalability, and maintain fault tolerance in WSN deployments.

Many metaheuristic methods have been proposed to solve CH selection problems, such as Genetic Algorithm (GA) [11, 12], Particle Swarm Optimization (PSO) [13, 14], and Ant Colony Optimization (ACO) [15]. These methods yield better results than conventional static methods. Nonetheless, they suffer from several shortcomings. One of the main challenges is premature convergence, when the algorithm converges to a local optimum and fails to capture the global optimum space correctly. Some approaches lack a proper exploration-exploitation balance and yield efficient searches and unstable solutions under dynamic conditions [16]. Some methods depend on initialization parameters and perform differently across network topologies and node densities. Hence, it is desirable to have a more robust optimization methodology that sustains diversity, prevents stagnation, and provides consistent CH selection in WSN scenarios.

The Crow Search Algorithm (CSA) is a metaheuristic algorithm inspired by crows' intelligent behavior in hiding and retrieving food. It has simplicity and robust exploration ability but is restricted by low search precision and early convergence. To resolve these drawbacks, the Enhanced Crow Search Algorithm (ECSA) combines a cooperative island model, adaptive tournament selection, and a transformed movement operator. These features maintain population diversity, increase the convergence rate, and achieve a better exploration-exploitation tradeoff.

The cooperative island model allows parallel subpopulations to develop autonomously by preventing them from being

*Corresponding author.

influenced by local optima. The adaptive tournament selection facilitates controlled convergence towards optimal solutions. Using ECSA for CH selection, the protocol provided substantially improved energy efficiency, improved network lifetime, and guaranteed data delivery reliability for WSNs. The proposed research contributes to:

- We present the first ECSA-based cooperative model of islands with an adaptive tournament selection for the election of CHs of WSNs that address issues of premature convergence and limited population diversity of metaheuristic-based routing.
- We advance the literature by offering a generalizable framework that integrates hierarchical clustering protocols with swarm intelligence that may be used with other optimization-based network designs.
- We present an end-to-end multi-metric analysis (optimization cost, throughput, path loss, packet delivery ratio, and node survival) across varying network densities while emphasizing the strength and scalability of ECSA over other algorithms.
- Since we provide practical deployment considerations of sustaining network lifetime and reliability at large scales, we bridge the gap between algorithm construction and realistic WSN limitations.

The rest of the paper is structured as follows: Section II presents a review of related work; Section III formulates the problem; Section IV presents the proposed ECSA-based protocol; Section V details the experimental setup and discusses the obtained results; Section VI provides a detailed discussion of the findings and Section VII concludes the paper and outlines directions for future work.

II. Related Work

Nabavi, et al. [17] suggested a combined clustering and routing protocol in WSN using GA and Gravitational Search Algorithm (GSA). The genetic algorithm optimizes intra-cluster distance and energy consumption in selecting CHs, and the gravitational search algorithm supports efficient routing from CH to the sink. The method reduces average energy consumption and enhances delivery rate and transmission efficiency, substantially improving network longevity.

Kathiroli and Selvadurai [18] suggested a hybrid Sparrow Search Algorithm and Differential Evolution (SSA-DE) model for CH selection. SSA provides high exploration efficiency, while DE improves convergence. Using an intelligent energy distribution mechanism to prolong network operation and ensure balanced energy usage among sensor nodes, the hybrid approach enhances node lifetime, residual energy, and throughput.

Janakiraman [19] proposed the IBEABCCR scheme, integrating Improved Bat Optimization (IBOA) and Enhanced Artificial Bee Colony (EABC) algorithms. IBOA conducts CH selection with balanced exploration and exploitation, and EABC facilitates dynamic sink mobility. Their combined strategy, implemented in MATLAB, considerably increases packet delivery, network life, and node survival with more than 25% improvements on several parameters concerning baseline protocols.

The LCPSO-CRP protocol was proposed by Luo, et al. [20] employing chaotic Levy-based Particle Swarm Optimization. The proposed method enhances the convergence speed and the search space exploration to include industrial WSNs. The technique considers CH energy consumption, BS distance, and intra-cluster proximity. It reduces energy consumption by 22.91% and increases the network lifetime by 13.93% compared to traditional schemes such as LEACH and DEEC.

Srivastava and Mishra [21] presented an Innovative Dragonfly Algorithm (IDA) with multi-attribute decision-making for CH selection. The algorithm ranks the nodes based on energy and other parameters to select optimal CHs. Compared to NBA, FLPSOC, and ESO-LEACH, IDA demonstrates better throughput, less energy consumption, and better node life, verifying its efficacy in energy-aware clustering.

Alsuwat and Alsuwat [22] proposed IQ-ABC as an optimized Artificial Bee Colony algorithm integrated with Q-learning to select adaptive CH in WSNs. The technique adopts a fuzzy-weighted multi-objective fitness function accounting for energy consumption, latency, and trust. Simulations indicate that IQ-ABC consumes much less energy than LEACH, HEED, and ACO in high-density or centralized node deployments.

Poonguzhali, et al. [23] proposed a metaheuristic and deep learning-based technique called THDCNN-HCWA, combining the multi-objective CH selection using the Tree Hierarchical Deep CNN and a Hybrid Capuchin-Woodpecker mating algorithm to route data. The method improves alive nodes and detection rates by optimally improving energy, delay, cluster density, and traffic flow under NS2 models.

While prior literature has proposed novel hybrid algorithms to solve CH selection and energy-aware routing problems, certain drawbacks still exist. As summarized in Table I, most methods cannot achieve an appropriate tradeoff between exploration and exploitation, converge prematurely, or perform inefficient searches in sophisticated environments. Furthermore, Q-learning and CNN-based routing yield better decisions but involve high computation overheads.

Most algorithms rely on static scenarios or a single set of parameters, ignoring scalability, convergence rate, diversity, or robustness to changes in network densities. The current research addresses these shortcomings by suggesting a new protocol employing ECSA with cooperative island modeling and adaptive tournament selection to diversify the population, increase the convergence rate, and holistically optimize multi-objective energy parameters.

TABLE I. COMPARATIVE SUMMARY OF RELATED WORKS

Study	Contribution	Improvements	Shortcomings
[17]	Introduced multi-objective clustering and routing using GA for CH selection and GSA for routing	Energy efficiency, delivery rate, and transmission rate	Lacks adaptive mechanisms for dynamic topologies; may suffer from convergence delays
[18]	Proposed a hybrid SSA-DE approach for energy-efficient CH selection	Residual energy, throughput, and node lifetime	Limited diversity preservation; sensitive to parameter tuning
[19]	Developed a dual optimization approach for CH selection and sink mobility	Network lifetime, packet delivery, and alive nodes	High computational complexity; assumes static sink mobility pattern
[20]	Designed a chaotic Levy-enhanced PSO protocol	Energy consumption and network Lifetime	Tailored to industrial settings; less effective in generic WSN deployments
[21]	Used multi-attribute decision-making with dragonfly algorithm for optimal CH selection	Energy consumption, throughput, and node survival	Limited scalability analysis; lacks routing optimization component
[22]	Applied Q-learning to ABC for intelligent CH selection with fuzzy-weighted fitness	Energy usage, network lifetime, and trust-based routing	Increased complexity; performance sensitive to fuzzy rule definition
[23]	Integrated deep learning with hybrid metaheuristics for CH selection and routing	Node survival and detection rate	High computational overhead; less suitable for resource-constrained WSNs

III. PROBLEM FORMULATION

A. Network Architecture

From an Internet of Things (IoT) perspective, WSNs are self-organizing multi-hop networks with spatially dispersed sensor nodes. Sensor nodes independently track environmental parameters and cooperatively transfer collected data to the BS. WSNs integrate embedded computing, distributed information processing, and wireless communication paradigms to support various applications like environmental monitoring, industrial automation, healthcare, and military surveillance.

Every node in the network serves two functions: sensing the environment and forwarding data to other nodes. Each node is typically driven by non-rechargeable batteries and deployed in remote or inaccessible locations; this makes energy efficiency crucial. Low communication overhead is essential since data transmission is much more energy-consuming than sensing and data reception. A common technique is clustering, during which sensor nodes are grouped, and a CH is chosen to collect and transfer data to minimize redundant communication and extend network life.

Let the number of sensor nodes in the network be denoted as N, randomly and uniformly distributed within a field of size $L \times L$. The BS is assumed to be placed at a fixed location, often at the center or outside the sensing field. Nodes can communicate via single-hop or multi-hop links, depending on their distance from the CH or BS.

All nodes are homogeneous hardware-wise, with the same storage, computation power, and initial energy. Every node is assigned a distinct identifier and calculates its local location using localization methods. Nodes are also classified as CHs or regular sensor nodes, with CHs handling inter-cluster communication and data transfer to the BS. Sensor nodes know their intrinsic residual energy and compute the distance between neighboring devices. Nodes can dynamically modify transmission power using available information to save energy. The BS has superior computing power and is the ultimate data sink.

The network data traffic is generally partitioned into three layers: intra-cluster data communication, inter-cluster data communication, and BS communication. Sensor nodes send data to the corresponding CHs. CHs pass data directly to other CHs or the BS if it is in the range. Aggregated data is sent to the BS by CHs via optimized energy-efficient paths.

Communication channels are bidirectional, and nodes can adapt their transmission power depending on the distance to the recipient. Each CH periodically aggregates data from its member nodes and sends it to the BS. The communication model further assumes that all the nodes encounter bursts of data transmission intermittently, as per the sensing rate and events happening in the surrounding area.

Fig. 1 shows the overall topology of a clustered WSN. Sensor nodes are divided into groups (clusters), each with a single CH. All local (intra-cluster) and long-distance (inter-cluster or BS) communication is done by the CHs. The BS is a central communication center receiving data from several CHs.

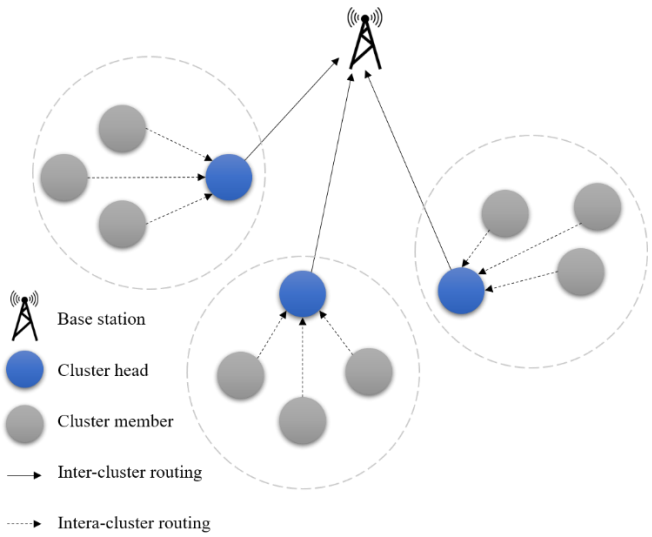

Fig. 1. Network topology of a clustered WSN.

B. Energy Consumption Model

Efficient energy utilization is critical in WSNs, where sensor nodes (motes) are constrained by limited, often non-rechargeable, energy sources. The energy model aims to characterize energy drainage during sensing, data processing, forwarding, and communication tasks. Transmission consumes the most energy compared to sensing or reception, making routing strategies central to prolonging network lifetime. To model energy usage, we consider the energy required to transmit

b bits of data over a distance d using a hybrid transmission model, denoted by Eq. (1).

Efficient energy use is crucial in WSNs, where sensor nodes (motes) are constrained by small, non-rechargeable energy sources. The energy model attempts to model energy drain from sensing, data processing at sensor nodes, data forwarding, and communications. Transmission consumes the most energy compared to sensing or reception, making routing strategies the foremost way to prolong the network lifetime. In modeling energy use, we focus on the energy expended by transmitting b bits of data over a distance d, using a hybrid transmission model represented by Eq. (1).

$$E_{TX}(b,d) = \begin{cases} b.E_{elec} + b.\epsilon_{fs}.d^2, & if\ d \le d_0 \\ b.E_{elec} + b.\epsilon_{mp}.d^4, & if\ d > d_0 \end{cases} \quad (1)$$

The threshold distance d_0 used to switch between free-space and multi-path fading models is calculated using Eq. (2).

$$d_0 = \sqrt{\frac{\epsilon_{fs}}{\epsilon_{mp}}} \quad (2)$$

where, E_{elec} stands for energy consumed per bit for processing, ϵ_{fs} denotes amplification energy for the free-space model, and ϵ_{mp} refers to amplification energy for the multi-path model.

The energy required for receiving b bits of data is computed according to Eq. (3).

$$E_{RX}(b) = b.E_{elec} \quad (3)$$

In cluster-based networks, CHs further aggregate the received data. The energy consumed during aggregation is calculated as shown in Eq. (4).

$$E_{AGG}(b) = (E_{elec} + E_{DA}).b \quad (4)$$

where, E_{DA} is the energy cost for data aggregation per bit.

WSN operations are executed in discrete rounds. The remaining energy of a sensor node s in round r is calculated according to Eq. (5).

$$RE_s(r) = RE_s(r-1) - \left(E^s_{TX}(r) + E^s_{RX}(r)\right) \quad (5)$$

The energy for transmission and reception per round is determined by Eq. (6) and Eq. (7), respectively.

$$E^s_{TX}(r) = T_s(r).\left[E_{elec} + \epsilon_{fs}.d^2\right] \quad (6)$$

$$E^s_{RX}(r) = R_s(r).E_{elec} \quad (7)$$

where, $T_s(r)$ and $R_s(r)$ denote the number of bits transmitted and received by node s in round r.

The overall data traffic load for a sensor node is composed of two components: $T^s_{relay}(r)$, representing relayed data, and $T^s_{local}(r)$, representing locally generated data. The total number of bits transmitted by node s in round r is given by Eq. (8).

$$T_s(r) = T^s_{relay}(r) + T^s_{local}(r) \quad (8)$$

This total is used in Eq. (6) to evaluate transmission energy consumption.

For CHs, an additional energy term is incurred due to data fusion before transmission. The energy for fusing b bits of data is calculated using Eq. (9).

$$E_{CH}(b) = E_{FD}.b \quad (9)$$

where, E_{FD} is the data fusion energy per bit.

IV. Proposed Methodology

The design of efficient routing protocols in WSNs is a challenging problem due to network operation requirements. These constraints are low computing power, low energy budgets, dynamic topology, node failure susceptibility, and exposure to harsh or unreliable environments. Consequently, conventional routing methods, like short path routing, are hardly sufficient for energy-restricted WSNs.

Reliability and energy-aware data transfer between the BS and sensor nodes are among the most critical goals of WSN routing. As energy consumption is the main WSN operation bottleneck, it is imperative to minimize overhead transmissions, even at the expense of traditional cost-based routes. Excessive neighbor communication, common to most routing schemes, increases energy consumption and adds complexity to neighborhood discovery.

In addition, node failures, commonly due to energy depletion, result in topology instability, broken networks, and high fault rates. Non-deterministic route paths, changing link availability, and dynamic participation of nodes complicate network performance management. These dynamics necessitate routes with adaptive capabilities to respond to environmental uncertainties and maintain low energy consumption and high resilience.

WSN routing protocols are traditionally classified by network structure (flat, hierarchical, location-based), but whatever their structure, the protocols have to deal with fundamental issues like Quality of Service (QoS), scalability, delay, power efficiency, connectivity, and fault tolerance. Network topology inconsistency caused by the addition or removal of motes or transient link failures makes path selection even more difficult. Thus, the routing technique has to account for a broad range of parameters like power management, MAC protocols, traffic load, and channel allocation to develop implementable solutions.

With these theoretical and interdependent variables in mind, heuristic and metaheuristic algorithms have been explored as potential methods for designing a WSN routing protocol. This study introduces an energy-efficient framework developed on a multi-objective problem optimized by the ECSA. The framework is focused on optimal CH selection and energy-efficient data routing to achieve maximum network lifespan while fulfilling performance requirements.

Our proposed scheme uses a layered clustering paradigm. CHs collect intra-cluster data and transfer it to the BS by energy-

efficient multi-hop routes. Our ECSA dynamically selects CHs using residual energy, node centrality, and communication distance parameters. The approach optimizes competing objectives like energy consumption and throughput maximization, thus constructing a resilient and dynamic routing protocol designed to work in WSN scenarios.

A. Basic Crow Search Algorithm

CSA, proposed by Askarzadeh [24], is a population-based metaheuristic inspired by the natural foraging and memory behavior of crows. These intelligent birds can follow others to steal hidden food while relocating their food caches if they sense being watched. This dual behavior of tracking and evasion is simulated within CSA to navigate the search space intelligently.

In CSA, each solution is represented as a virtual crow, and a population of N such crows explores the search space. Each crow i is characterized by a position vector in a D-dimensional space, denoted by Eq. (10).

$$x_i^t = [x_{i,1}^t, x_{i,2}^t, \dots, x_{i,D}^t] \tag{10}$$

Each crow's initial position also serves as its memory since it has no experience. The memory vector of crow i at iteration t is expressed as shown in Eq. (11).

$$m_i^t = [m_{i,1}^t, m_{i,2}^t, \dots, m_{i,D}^t] \tag{11}$$

The crows update their positions by attempting to follow a randomly selected peer. If the selected crow is unaware of being followed, the follower moves toward the peer's memory. Otherwise, it jumps to a random position. This movement rule is calculated according to Eq. (12).

$$x_i^{t+1} = \begin{cases} x_i^t + r_1 . FL . (m_j^t - x_i^t), & if\ r_2 \geq AP \\ random\ position\ , & otherwise \end{cases} \tag{12}$$

where, r_1 and r_2 are random values uniformly distributed in [0, 1], FL is the flight length, m_j^t is the memory of randomly selected crow j, and AP is the awareness probability governing evasive behavior. The schematic of this condition and the impact of flight length on searchability are shown in Fig. 2.

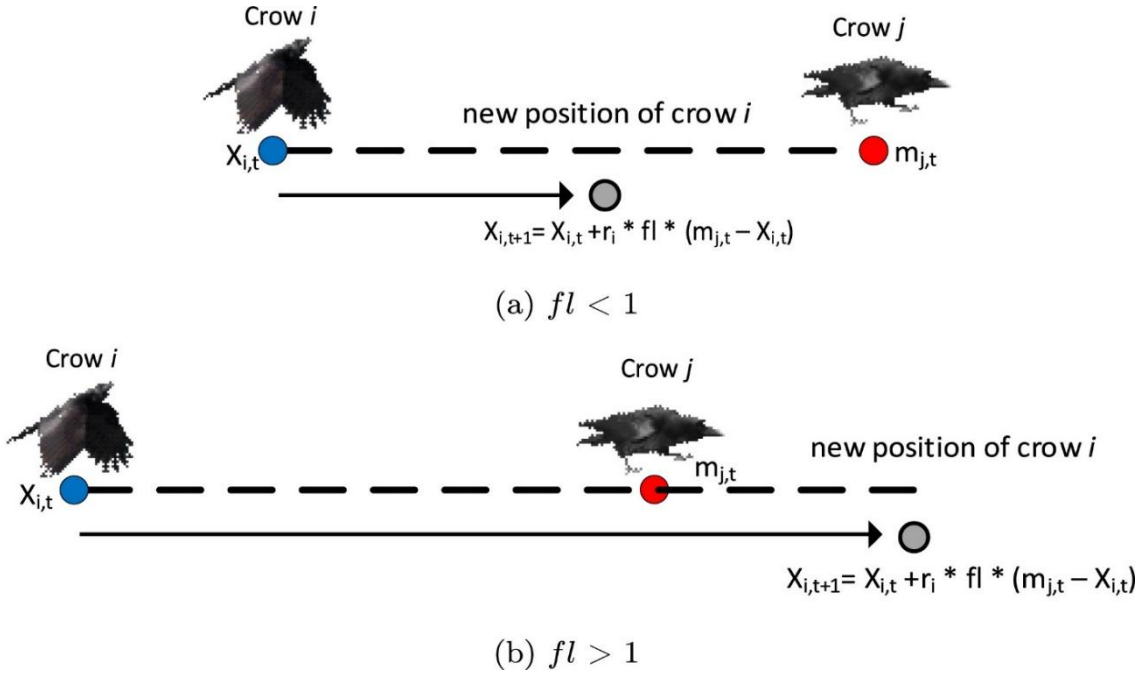

Fig. 2. Illustration of the pursuit mechanism in CSA.

After arriving at new positions, the memory of each crow is updated based on the quality of the new solution. If the new position offers better fitness than the previous memory, it replaces the old one. This memory update mechanism is governed by Eq. (13).

$$m_i^{t+1} = \begin{cases} x_i^{t+1}, & if\ f(x_i^{t+1}) < f(m_i^t) \\ m_i^t, & otherwise \end{cases} \tag{13}$$

where, $f(.)$ indicates the objective (fitness) function.

B. Enhanced Crow Search Algorithm

While the original CSA has high exploration capabilities, it has drawbacks like local optima stagnation, lack of diversity, and early-stage convergence. These problems are caused primarily by fixed parameters like Awareness Probability (AP) and Flight Length (FL), using random guidance, and not prioritizing the optimal use of population memory. To overcome all these drawbacks, ECSA incorporates a range of strategies, such as adaptive selection through a tournament and a modified evasion scheme using a random component.

In the basic CSA, each crow i selects another crow j at random to follow toward its memorized position, which could

lead to following poorly performing solutions. To improve this, the ECSA framework replaces random selection with a fitness-guided adaptive tournament mechanism. At each iteration t, a crow selects the best guide from a randomly chosen subset of K crows.

To ensure a balanced tradeoff between exploration and exploitation, the value of K is varied linearly throughout the optimization process. It is computed using a self-adaptive formula denoted by Eq. (14).

$$K = round\left(K_{min} + t.\left(\frac{K_{max} - K_{min}}{t_{max}}\right)\right) \quad (14)$$

Where K_{min} and K_{max} are the minimum and maximum tournament sizes, t is the current iteration, and t_{max} is the total number of iterations. This allows the algorithm to perform more exploratory behavior in the early stages (small K) and intensify the search later (large K).

To further combat stagnation, ECSA introduces an evasion operator derived from the Harris Hawks Optimization (HHO) method, which improves population diversity when the awareness probability condition is triggered. The new position of crow i in this phase is calculated according to Eq. (15).

$$X_{i,t+1} = \left(X_{best,t} - X_{avg,t}\right) - r_1 \cdot \left(LB + r_2 \cdot (UB - LB)\right) \quad (15)$$

where, $X_{best,t}$ is the best-known solution at iteration t, $X_{avg,t}$ is the mean position of all individuals in the current generation, LB and UB are the lower and upper bounds of the search space, and $r_1, r_2 \in [0,1]$ are uniformly distributed random numbers. The mean position is calculated as shown in Eq. (16).

$$X_{avg,t} = \frac{1}{N}\sum_{i=1}^{N} X_{i,t} \quad (16)$$

This strategy ensures that evasion is not purely random but guided by the global and average population dynamics.

ECSA begins by initializing N crows in a D-dimensional search space. Each crow's initial position is generated using a uniformly distributed random vector within bounds $\overrightarrow{X_L}$ and $\overrightarrow{X_U}$, as denoted by Eq. (17).

$$\overrightarrow{X_J} = \overrightarrow{X_L} + r \cdot \left(\overrightarrow{X_U} - \overrightarrow{X_L}\right) \quad (17)$$

To further enhance search efficiency and diversity preservation, ECSA incorporates an island model. The population is partitioned into s subgroups (islands), each running its local version of the ECSA. These islands evolve independently but periodically share information through a migration process governed by migration frequency M_f, migration rate M_r, topology (e.g. random ring), and policy (e.g. best–worst exchange) parameters. Each migration phase is triggered every M_f iterations, allowing selected individuals from one island to be exchanged with neighboring islands to prevent premature convergence. The pseudocode and flowchart of the proposed ECSA are presented in Algorithm 1 and Fig. 3, respectively.

Algorithm 1 Pseudocode of ECSA

Inputs:

Problem-specific settings: number of agents N, dimensionality d, upper bound t_{max}

Adaptive parameters: minimum and maximum tournament size (K_{min}, K_{max}), flight length FL, and awareness probability AP

Outputs:

Best solution vector X_{best} and its corresponding fitness score

Initialize all crows' positions X_i randomly across the solution space, for $i = 1\ to\ N$

Assign each crow's initial memory $M_i = X_i$

Evaluate the fitness value of each crow using the objective function $f(\cdot)$

Determine the initial global best solution X_{best}

Repeat for iteration $t = 1\ to\ t_{max}$:

Adjust tournament size K dynamically based on Eq. 14

Compute the population's average position using Eq. 16

For each crow $i \in \{1, \ldots, N\}$:

Select a candidate crow j to follow via tournament selection

Generate a random number $r_j \in [0,1]$

If $r_j \geq AP$:

Update crow i's position using the pursuit rule (Eq. 12)

Else:

Update crow i's position using guided evasion (Eq. 15)

Check feasibility of the new position

Evaluate the updated positions X_i^{t+1} and compute their fitness

If $f\left(X_i^{t+1}\right) < f(M_i)$, then update the memory $M_i = X_i^{t+1}$

Update X_{best} if any crow achieves a superior fitness

Until stopping criteria ($t = t_{max}$) is met

Return the best-obtained solution X_{best}

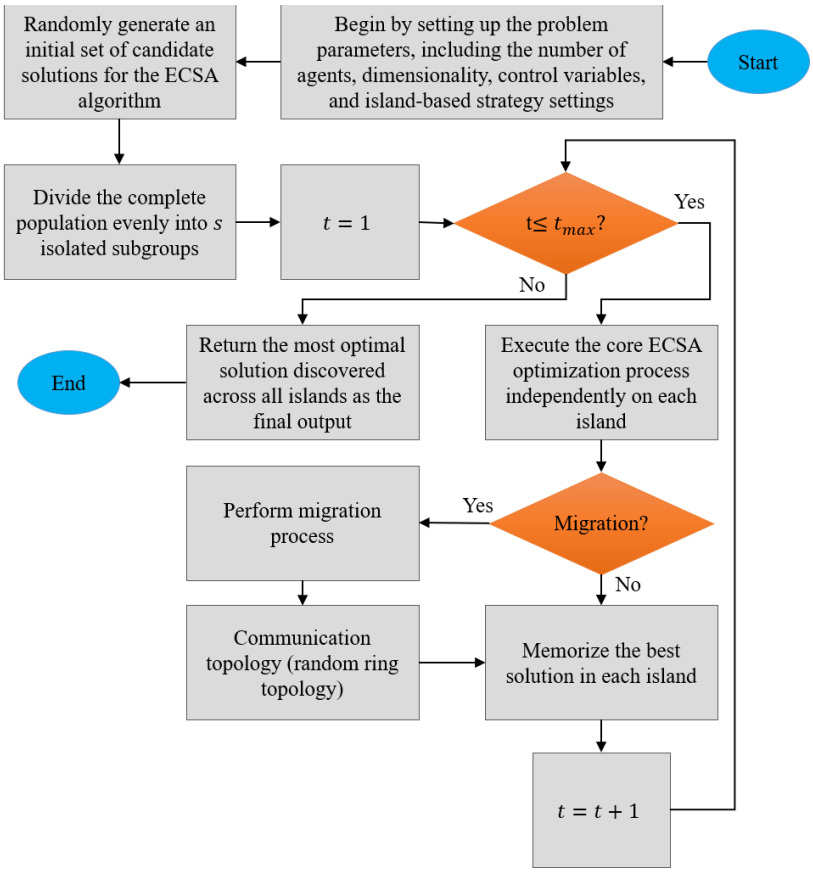

Fig. 3. Flowchart of CSA.

V. Results

A comprehensive simulation in MATLAB 2020a was performed to assess the effectiveness of the proposed ECSA for energy-saving routing within WSNs. Performance was measured using a range of vital metrics, including convergence behavior, path loss, PDR, throughput, and energy usage. For extensive investigation, ECSA was compared with four metaheuristic algorithms: CSA, Grey Wolf Optimizer (GWO) [25], Black Widow Optimization (BWO) [26], and Whale Optimization Algorithm (WOA) [27]. These algorithms were chosen because of their suitability for WSN routing and clustering purposes. Simulations were performed on three distinct network configurations with varying sensor nodes deployed: Experiment 1 with 50 nodes, Experiment 2 with 100 nodes, and Experiment 3 with 150 nodes. Table II lists simulation parameters.

As illustrated in Fig. 4, ECSA consistently achieves a high convergence score across all node arrangement scenarios. In particular, in Scenario 1, ECSA surpasses the comparative methods by 55.2%, 51.4%, 48.4%, and 41.3%. This indicates the algorithm's stability in reaching optimal or near-optimal solutions rapidly. The increased convergence comes from ECSA's adaptive exploration-exploitation tradeoff to avoid premature convergence inherent in conventional methods.

TABLE II. Simulation Setup Parameters Applied in Evaluating the Proposed Routing Framework for WSN

Parameter	Configured value
Maximum simulation rounds	2000
Initial node energy	0.3 J
Energy dissipation for signal transmission	$50 \times 10^{-9} J$
Energy dissipation for signal reception	$50 \times 10^{-9} J$
Power amplifier (free-space model)	$10 \times 10^{-12} J$
Power amplifier (multi-path model)	$0.0013 \times 10^{-12} J$
Energy cost for data aggregation	$5 \times 10^{-9} J$
Energy consumption in idle state	0.05 W
Node displacement rate	0.05 meters/min
Channel model	Physical/wireless physical
Communication radius	40 meters
Underlying routing baseline	LEACH protocol
Simulation area size	$100\ m \times 100\ m$
Sensor node counts across scenarios	50, 100, 150
Control message size	80 bits
Data packet size	512 bytes
Cluster head election likelihood	0.1%
Optimization iterations per run	10
Sub-populations for the metaheuristic algorithm	10

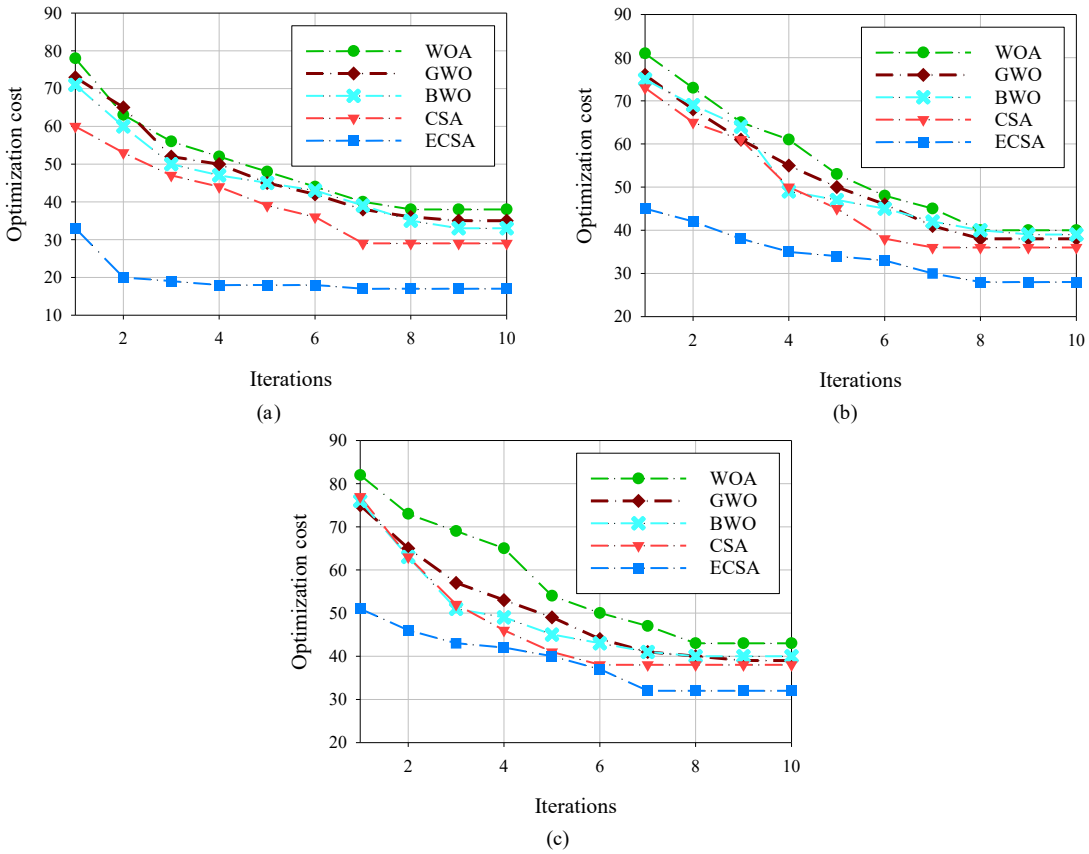

Fig. 4. Cost function convergence of algorithms across three WSN scenarios: (a) 50 sensor nodes, (b) 100 sensor nodes, (c) 150 sensor nodes.

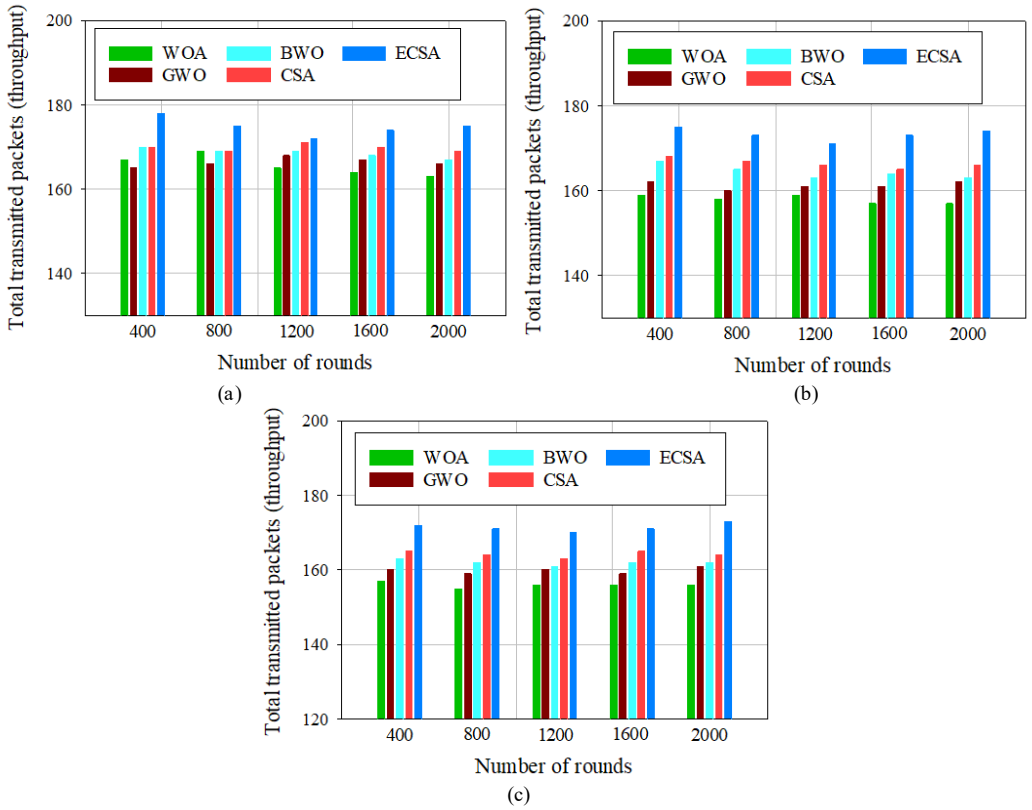

Fig. 5. Throughput performance of algorithms across different rounds for (a) 50 nodes, (b) 100 nodes, and (c) 150 nodes.

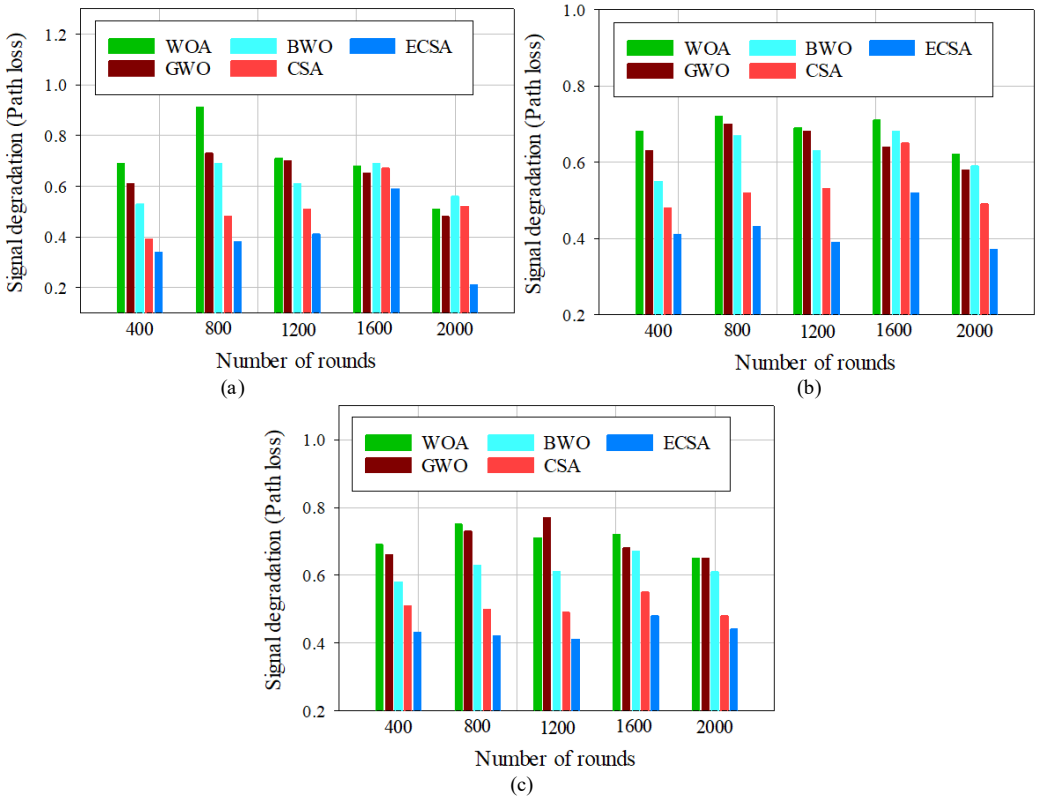

Fig. 6. Path loss performance of algorithms across different rounds for (a) 50 nodes, (b) 100 nodes, and (c) 150 nodes.

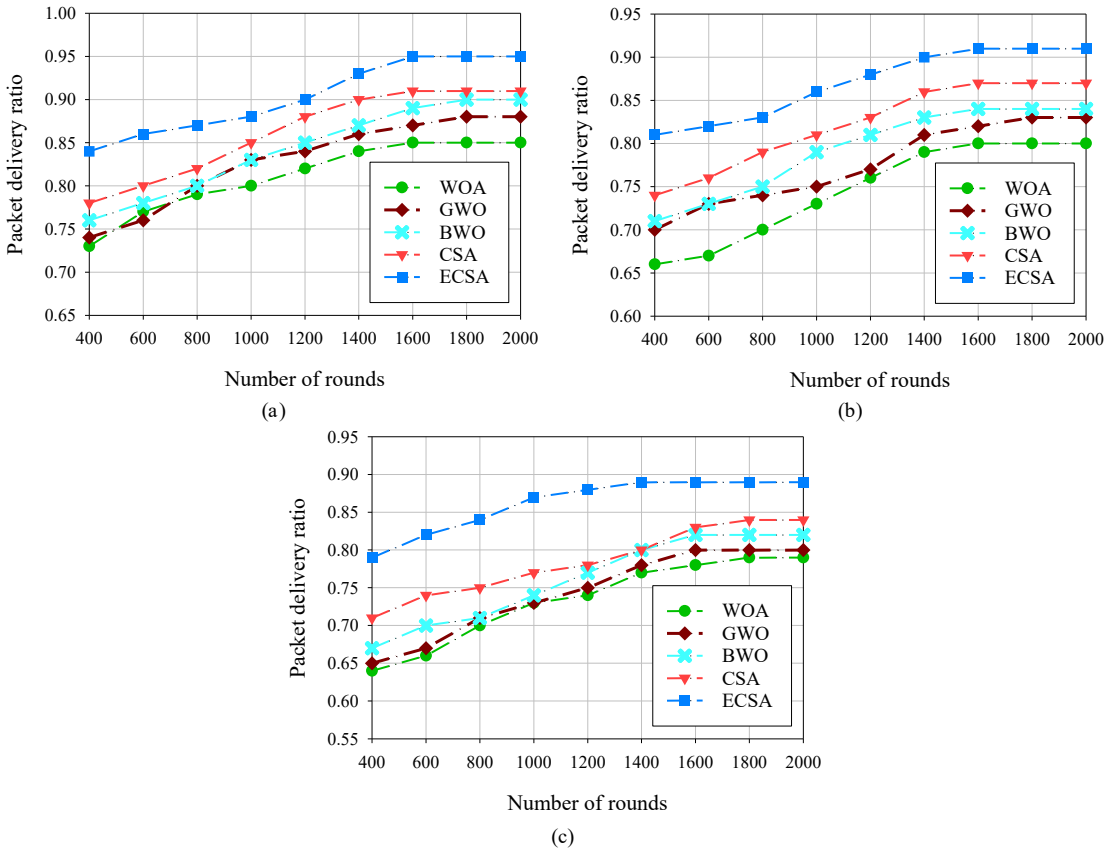

Fig. 7. Packet delivery ratio performance of algorithms across different rounds for (a) 50 nodes, (b) 100 nodes, and (c) 150 nodes.

The performance of ECSA in improving network throughput was confirmed by evaluating the volume of data delivered successfully against time. Fig. 5 shows that ECSA outpaces heuristic algorithms consistently by achieving superior throughput in all cases. Better throughput is the direct consequence of smart CH election, less path loss, and energy-aware transmission scheduling. This proves ECSA's ability to sustain data-intensive WSN applications with improved transmission efficiency.

The path loss was compared under three node-density configurations as a representative factor of signal quality and energy consumption. As shown in Fig. 6, ECSA outperforms in reducing path loss until the 2000th round. Furthermore, in the first and second scenarios, the path loss is temporarily higher than in CSA at the advanced stages, and it might indicate a necessity to refine it for longer-duration deployments in the future. The ECSA shows fewer path loss values and validates the proposed routing model's credibility and robustness.

The data delivery reliability of the protocol was checked using PDR, which is presented in Fig. 7. ECSA has a consistently low rate of losing PDR compared to other routing protocols in all scenarios. The reduced rate of losing PDR results from the algorithm's stability and efficient selection of the CH, reducing the rate of dropping and discarding packets in communication. Therefore, ECSA provides superior delivery reliability in critical WSN applications.

The protocol's sustainability was analyzed by measuring the active node count per simulation round. As indicated by Fig. 8, ECSA retained a significantly higher number of alive nodes across the three cases than baseline strategies. In scenario 2, ECSA offers superior node survival across transmission rounds. This demonstrates its energy-conservation properties and suggests fewer nodes reach their energy boundaries earlier. Superior node survivability confirms the efficiency of ECSA in balancing energy load distributions when choosing CHs.

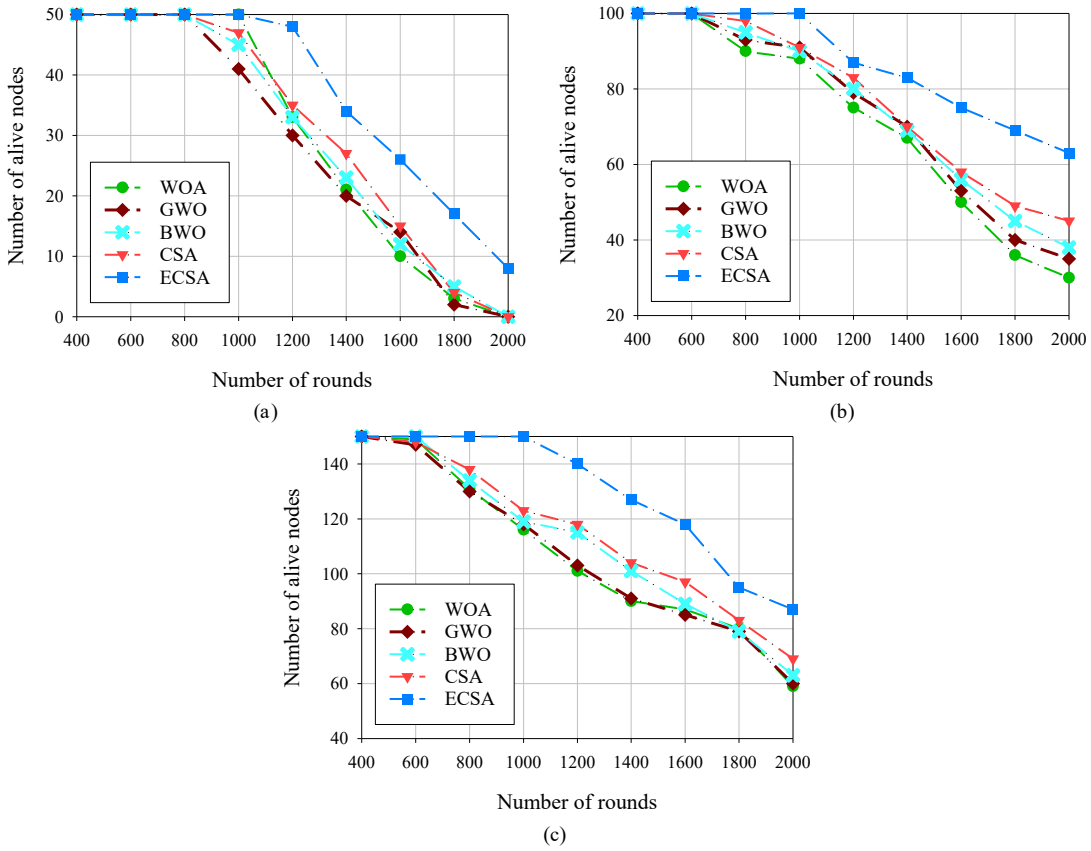

Fig. 8. Number of alive nodes of algorithms across different rounds for (a) 50 nodes, (b) 100 nodes, and (c) 150 nodes.

VI. Discussion

The superior simulation results of ECSA on all evaluation parameters can directly be attributed to intrinsic advancements in CSA. One key aspect involves adding an adaptive tournament selection policy to facilitate selection for updated positions. Compared to the initial CSA, in which randomly selected peers guide crows, ECSA allows crows to be guided to the fittest peers from a dynamically sized pool of candidates. Indeed, as demonstrated in the convergence results, the technique resulted in quicker convergence and more robust solution quality, particularly when network densities are high. Moreover, the linear increase in the tournament size per iteration permitted the algorithm to expand its search at the beginning and intensify exploitation towards the latter phase, which lent it to minimal energy consumption and maximum node survival in all test cases.

In addition, the advanced evasion process utilized by ECSA contributed significantly to optimizing route performance. In contrast to the standard CSA that triggers random relocation on

evasion, ECSA incorporates a focused evasion process by using global best and average location information for the population. This ensures informed and active exploratory behavior even when AP is high. Consequently, ECSA resulted in lower path loss and higher PDR, particularly at high node density and extended round simulation. Improved throughput performance further confirms that the advancements in pursuit (guide selection) and evasion (movement policy) acted synergistically to produce superior route decisions, energy balancing, and overall robust protocol performance in WSN scenarios.

Though the proposed ECSA-based routing protocol provides superior energy efficiency and robustness over existing methods, the study has some drawbacks. First, it was conducted within simulated networks with pre-assumed network models that do not capture fundamental WSN dynamics. Furthermore, although the cooperative island model provides superior population diversity, computational complexity increases with the size of the network, such that large-scale networks may lack scalability in very dense sensor environments. Finally, security-related issues, such as resistance to malicious nodes, have not been specifically addressed. These drawbacks present potential areas for future work, such as hardware-based verification, optimization for scalability, and the addition of security-aware mechanisms.

VII. Conclusion

The paper introduced ECSA for energy-efficient routing in WSNs by hybridizing a cooperating island model with adaptive tournament selection. From a theoretical standpoint, the paper first applied a structured population model in CSA for CH selection to address two essential problems: premature convergence and limited population diversity. Apart from WSNs, the model provides a generic framework for integrating swarm intelligence strategies with hierarchical clustering mechanisms. An experimental study on networks containing 100 nodes confirmed that ECSA outperformed CSA, BWO, GWO, and WOA. In detail, ECSA achieved 22–30% lower optimization cost, 4.8–10.8% higher throughput, 24.4–40.3% lower path loss, 4.5–13.7% higher PDR, and 40.1–109.1% more alive nodes. These results confirm the robustness, scalability, and energy-saving capabilities of the approach if applied at a large scale in WSN.

In addition, the study also has its limitations. The analysis was conducted in a simulated environment without external dynamics, such as hardware variation, environmental interference, or malicious nodes. Furthermore, the cooperative island model entails additional computational overhead that may hinder scalability in ultra-dense networks. The future study will therefore focus on 1) protocol verification over hardware testbeds, 2) lowering computational complexity for optimization of scalability, as well as 3) extending the model for the addition of security-aware routing.

***Abstract*—Sentiment classification is a core task in natural language processing (NLP), enabling automated interpretation of opinionated text across domains, such as social media, e-commerce, and healthcare. While numerous models have been proposed—from classical machine learning algorithms to deep neural networks and transformer architectures—their adoption is often hindered by trade-offs in performance, interpretability, and computational cost. This paper presents a threefold contribution: 1) a structured review of over 30 peer-reviewed studies that compare sentiment classifiers across five analytical dimensions—accuracy, robustness, interpretability, efficiency, and context adaptability; 2) a lightweight empirical benchmark on the IMDb dataset, evaluating Naïve Bayes, linear SVM, and LSTM; and 3) a practitioner-oriented decision-support framework comprising a model selection flowchart and recommendation matrix. The experimental results show that SVM achieved the highest F1-score (0.8329), while Naïve Bayes provided strong performance with minimal training time, and LSTM underperformed under constrained conditions. We further highlight persistent challenges in benchmarking consistency, model explainability, and cross-lingual adaptability. The paper concludes with actionable future directions, including hybrid architectures, low-resource deployment strategies, and inclusive NLP systems for diverse user populations. To our knowledge, this is the first study that unifies systematic review, empirical validation, and practical decision tools in the field of sentiment classification.**

Keywords*—Sentiment analysis; text classification; machine learning; deep learning; transformer models; BERT; LSTM; random forest; hybrid approaches; model evaluation; interpretability; natural language processing

I. Introduction

The exponential growth of user-generated content on digital platforms has amplified the role of sentiment analysis (SA) in natural language processing (NLP). From monitoring public sentiment on social media to enhancing customer experience in e-commerce and health feedback systems, the ability to computationally interpret opinion-laden text has become crucial. The evolving landscape of machine learning (ML) and deep learning (DL) has significantly advanced sentiment classification, yet persistent challenges hinder broader adoption and practical deployment.

Key challenges include the ability to handle heterogeneous and multilingual datasets, mitigate the effects of class imbalance, and effectively model contextual dependencies. Classical ML models, while efficient and interpretable, often struggle with generalization in dynamic environments. Conversely, advanced neural architectures such as long short-term memory networks (LSTM), convolutional neural networks (CNN), and transformers demonstrate superior performance in complex settings but require extensive computational resources and lack interpretability.

Recent years (2024–2025) have witnessed a surge in hybrid models combining traditional and deep learning techniques. These models seek to balance performance, adaptability, and computational efficiency, and are increasingly relevant for real-world applications demanding both accuracy and scalability.

This paper contributes a comprehensive, multi-dimensional review of sentiment classification models. It uniquely focuses on hybrid architectures developed in the latest period and proposes a comparative framework for evaluating models across five dimensions: accuracy, robustness, interpretability, efficiency, and context adaptability.

The study addresses the following research questions:

- RQ1: How do hybrid and standalone deep learning models perform compared to classical algorithms in real-world sentiment classification tasks?
- RQ2: What are the practical trade-offs in deploying sentiment classification models across diverse domains?
- RQ3: What guidelines can be established for context-aware model selection in sentiment classification?

By addressing these questions, this study aims to inform both researchers and practitioners on the evolving capabilities of sentiment classification systems and offer guidance for selecting models that align with specific deployment requirements.

This paper makes three key contributions toward advancing sentiment classification research and practice:

1) A structured, paradigm-based literature review of over 30 peer-reviewed studies, comparing classical machine learning, deep learning, and transformer-based models across five analytical dimensions: accuracy, robustness, interpretability, computational efficiency, and context adaptability.

2) An independent, lightweight benchmark conducted on the IMDb dataset, empirically comparing three representative models—Naïve Bayes, linear SVM, and LSTM—under constrained training conditions to validate practical trade-offs observed in the literature.

3) A practitioner-oriented decision-support framework, consisting of a flowchart and recommendation matrix, designed to guide model selection based on resource constraints, domain specificity, and sequence modeling needs.

This study unifies a survey, empirical benchmarking, and practical model selection guidance into a coherent framework for sentiment analysis. By bridging academic research with real-world deployment considerations, this work provides actionable insights for both researchers and practitioners.

The remainder of this paper is structured as follows: Section II reviews prior research on sentiment classification models, covering classical machine learning, deep learning, ensemble, and transformer-based approaches. Section III outlines the study methodology, including literature selection criteria, inclusion conditions, and the comparative evaluation framework. Section IV presents the algorithmic landscape, analyzing strengths, weaknesses, and typical use cases of key sentiment classification algorithms. Section V reports and discusses the results from both the literature synthesis and the empirical benchmark on the IMDb dataset, along with performance comparisons and confusion matrix insights. Section VI concludes the study by summarizing key findings, discussing future directions, and reinforcing the practical utility of the proposed decision-support framework.

II. Related Works

A. A Critical Review of Sentiment Analysis Methods

This review is grounded in a structured selection of peer-reviewed publications relevant to the field of sentiment analysis. This review draws upon peer-reviewed publications published between 2016 and 2025 from recognized venues, including studies indexed in IEEE, ACM, and open-access platforms. Inclusion criteria were based on relevance to sentiment classification using classical, deep learning, or transformer-based models. Studies had to report empirical results using public datasets and standardized metrics such as accuracy, F1-score, or precision. After screening and eliminating duplicates, a representative subset of the most relevant and influential works was analyzed to synthesize key findings, identify limitations, and highlight research gaps addressed in this study.

Sentiment analysis has evolved significantly, transitioning from classical statistical models to deep learning and transformer-based architectures. Each paradigm offers distinct advantages and presents specific challenges, particularly in terms of contextual understanding, scalability, and robustness. This section offers a critical synthesis of these developments, integrating insights from a representative set of peer-reviewed studies published between 2016 and 2025 across IEEE, ACM, and arXiv. The organization follows a paradigm-based structure, focusing on unresolved gaps that inform the methodological choices of our study.

B. Classical ML Approaches

Foundations and Limitations Naïve Bayes, Logistic Regression, and SVM remain favored for their simplicity and speed. However, their dependence on feature engineering and inability to capture semantic subtleties limit their utility in dynamic textual environments. A broad comparative study by [1] evaluates classical supervised algorithms—including Naive Bayes, Decision Trees, Random Forest, KNN, and SVM—across twelve criteria such as efficiency, robustness, and interpretability. Their findings highlight that the optimal algorithm depends on task-specific requirements, available resources, and data characteristics, confirming the continued relevance of classical ML in constrained environments.

C. Ensemble Methods

Combining Simplicity and Strength Random Forests and similar ensembles show resilience against noise and imbalance. Yet, their black-box nature and hyperparameter sensitivity hinder interpretability. A complementary comparative analysis by [2] reinforces these points, particularly noting the robustness of Random Forest and the context sensitivity of LSTM, and offers practical insights into real-time deployments.

D. Deep Learning Models

Contextual Learning with Neural Networks Deep learning has significantly transformed sentiment analysis by enabling end-to-end training without manual feature engineering. Convolutional Neural Networks (CNNs), first adopted by [3] for text classification, have demonstrated strong performance in capturing local syntactic and semantic features, particularly in short texts and tweets. Recurrent Neural Networks (RNNs), especially Long Short-Term Memory (LSTM) and Gated Recurrent Unit (GRU) models, are widely used for learning sequential dependencies in sentiment-laden texts [4] LSTMs are particularly adept at handling long-range dependencies and have become standard in many SA pipelines. However, their training complexity and sensitivity to vanishing gradients remain limitations. More recent efforts, such as bidirectional LSTM (BiLSTM) and attention-augmented RNNs [5], attempt to overcome these challenges by capturing both forward and backward contextual information.

E. Transformer Architectures

High Accuracy at Computational Cost Transformer-based architectures have redefined state-of-the-art in sentiment analysis, particularly since the introduction of Bidirectional Encoder Representations from Transformers (BERT) by [6]. Unlike RNNs, transformers use self-attention mechanisms to capture global dependencies and contextual relationships without relying on sequential processing. Variants such as RoBERTa [5], ALBERT [7], and DistilBERT [8] optimize transformer models for speed and efficiency while preserving performance. These models have consistently achieved top scores on benchmark datasets like SST-2, Yelp, and Amazon reviews. Despite their accuracy, the computational demands of transformer models—both in training and inference—pose significant barriers to deployment in low-resource settings. Moreover, their interpretability remains a challenge, though recent methods (e.g. attention visualization, SHAP explanations) attempt to address this.

F. The Emerging Middle Ground

Hybrid models are increasingly recognized as a practical compromise between accuracy and computational efficiency in sentiment classification. Architectures that combine Convolutional Neural Networks (CNNs), Bidirectional LSTMs (BiLSTMs), and attention mechanisms are particularly effective in capturing both local features and long-range dependencies. One such approach was introduced in a recent study, where CNN layers were combined with LSTM units and self-attention for emotion recognition in telecommunication data [9]. Another investigation focused on integrating RoBERTa with CNN to process noisy social media content, achieving F1-scores exceeding 92% on Twitter datasets [10]. The robustness of LSTM architectures was also validated in the financial domain, where they performed well on time series forecasting tasks under noisy conditions [11]. Together, these studies highlight the growing appeal of LSTM-based hybrid models, which offer enhanced adaptability and performance across diverse and challenging sentiment analysis environments.

G. Benchmarking Inconsistencies and Cross-Study Variability

Cross-dataset benchmarking remains inconsistent due to variations in metric reporting, dataset selection, and experimental protocols. A meta-analysis of 30 peer-reviewed studies highlights two core challenges:

- Metric Disparities: 65% of studies prioritize accuracy while underreporting robustness metrics such as F1-score or MCC, with reported variability up to ±12%.
- Dataset Limitations: Benchmark datasets such as Sentiment140 or IMDb often lack demographic and linguistic diversity, skewing generalizability [12].

To concretize these inconsistencies, Table I synthesizes ten representative studies spanning 2016 to 2025, highlighting their model types, datasets, findings, and limitations. This comparison underscores the difficulty of deriving universal conclusions across heterogeneous experimental settings.

TABLE I. COMPARATIVE SUMMARY OF KEY STUDIES

Study (Year)	Algorithms Compared	Dataset(s) Used	Corpus Type	Key Findings	Limitations	Model Type	Impact Potential
[13] Ahmad et al. (2018)	NB, LR, SVM	Twitter, IMDb	Balanced English Texts	SVM achieved best accuracy (86%), LR most interpretable	No deep learning models included	Classical ML	Widely cited baseline
[14] Parveen & Pandey (2016)	NB + Hadoop	Twitter	Noisy large-scale data	Efficient large-scale analysis with emoticons	No comparison with modern ML	Classical ML	Scalable framework example
[15] Karthika et al. (2019)	SVM, RF	Product Reviews (Flipkart)	Domain-specific reviews	RF outperformed SVM (97% accuracy)	Dataset domain-specific	Classical ML	E-commerce context study
[16] Srinivas et al. (2021)	SVM, LSTM	Twitter (1.6M tweets)	Sequential noisy text	LSTM outperformed SVM in handling sequences	No transformer baseline	DL + Classical	Illustrates LSTM 's sequence edge
[17] Shad et al. (2024)	NB, SVM, RNN, LSTM	Mixed datasets	Mixed sentiment corpora	LSTM had highest F1-score; NB was faster but less accurate	Transformers excluded	DL + Classical	Broad-spectrum benchmark
[18] Moulaei et al. (2022)	RF, SVM, KNN	COVID-19 data	Semi-structured text	RF had best performance (95%)	Non-textual medical data	Classical ML	Domain-specific relevance
[19] Talibzade (2023)	LR, SVM, BERT	IMDb reviews	Structured movie reviews	BERT reached 98% accuracy; traditional models far behind	BERT is resource-intensive	Transformer + Classical	State-of-the-art performance
[20] Abdirahman et al. (2023)	NB, SVM, LSTM	Somali text	Low-resource language	LSTM showed best contextual understanding	Language-specific results	DL + Classical	Low-resource NLP focus
[21] Raees et al. (2024)	Lexicon + ML models	Multilingual datasets	Cross-lingual short texts	Lexicon-based + ML hybrid improved precision	Limited to short texts	Hybrid	Multilingual integration
[10] Islam et al. (2025)	CNN, BERT, RoBERTa	Twitter, Amazon	Noisy real-world data	Transformers outperformed CNN; RoBERTa most robust	High training cost	Transformer + DL	Current high benchmark

As seen in Table I, studies using the same algorithms (e.g. SVM or LSTM) report divergent results due to variations in dataset quality, preprocessing pipelines, and evaluation scope. This underscores the importance of standardized benchmarks and the reporting of both accuracy and robustness metrics in future work.

III. METHODOLOGY

This study adopts a structured comparative literature review methodology, aiming to synthesize and contrast results reported in peer-reviewed research on sentiment analysis models published between 2016 and 2025. Rather than conducting primary experiments, we examine empirical patterns across datasets, model types, and evaluation criteria, enabling evidence-based insights on algorithmic performance and suitability.

A. Objective and Scope

The primary objective is to deliver a multi-dimensional comparative analysis of sentiment classification models, including classical machine learning algorithms (e.g. Naïve Bayes, Logistic Regression, SVM), ensemble methods (e.g. Random Forest), deep learning approaches (e.g. CNN, LSTM), and transformer-based architectures (e.g. BERT, RoBERTa).

These models were selected based on their prevalence in literature and practical relevance in industrial applications. Transformer-based models are considered for conceptual completeness, though excluded from core performance tables due to architectural divergence and resource intensity.

B. General Workflow of Sentiment Analysis

To structure the comparative analysis, Fig. 1 illustrates the standard sentiment analysis pipeline comprising six critical stages:

1) Data collection: Acquiring raw textual data from sources such as social media, product reviews, or open-access corpora.

2) Preprocessing: Cleaning and normalizing the text by removing noise, performing tokenization, stemming, stop-word removal, and lemmatization.

3) Feature extraction: Converting text into structured representations using methods such as TF-IDF, word embeddings (e.g. Word2Vec, GloVe), or contextual embeddings (e.g., BERT).

4) Model selection: Choosing an appropriate classification algorithm based on task requirements, resource constraints, and interpretability needs.

5) Evaluation: Assessing model performance using standard metrics including accuracy, precision, recall, F1-score, and sometimes AUC or MCC.

6) Interpretation: Analyzing the outputs to understand predictions, model behavior, and to inform further optimization or deployment decisions.

This pipeline, Fig. 1, provides a conceptual foundation for interpreting the empirical findings discussed throughout this review.

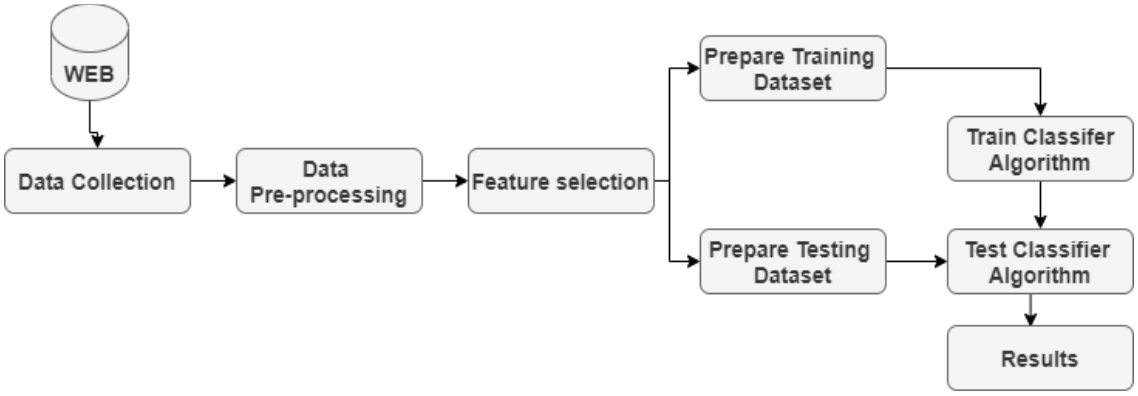

Fig. 1. Workflow of sentiment analysis.

From Data Collection to Results (Data Collection → Preprocessing → Feature Extraction → Model Selection → Evaluation → Interpretation)

C. Study Inclusion Criteria

To ensure methodological consistency and scientific rigor, we included studies that met the following conditions:

1) Published between 2016 and 2024 in peer-reviewed journals or recognized conferences.

2) evaluated at least one of the targeted classification models.

3) Employed publicly available benchmark sentiment datasets (e.g., IMDb, Amazon, Yelp, Twitter, Sentiment140).

4) Reported three or more evaluation metrics (e.g. accuracy, F1-score, precision, recall).

5) Documented sufficient experimental detail including preprocessing techniques, data splitting, and hyperparameter settings.

D. Comparative Evaluation Framework

The extracted models were evaluated along five analytical dimensions:

1) Accuracy captures classification correctness as reported in standard benchmarks.

2) Robustness reflects model stability under data imbalance, noise, or domain shift.

3) Interpretability denotes the transparency and explainability of a model's decision-making process.

4) Efficiency measures computational demands including training/inference time and scalability.

5) Context adaptability refers to flexibility across datasets, domains, and linguistic contexts. These criteria were informed by both academic literature and practical deployment considerations, enabling a balanced view of algorithm performance.

E. Benchmark Design and Dataset

To validate literature findings under a controlled and minimal-resource setting, we conducted a lightweight benchmark using the IMDb movie reviews dataset (binary classification: positive vs. negative). Three representative models were selected:

1) Naïve Bayes – for classical probabilistic modeling.
2) Linear SVM – for margin-based kernel classification.
3) Basic LSTM – for deep sequential modeling.

The dataset was split into 80/20 train-test partitions. Preprocessing steps included lowercasing, stop-word removal, and tokenization. Default or lightly tuned hyperparameters were used to reflect real-world deployment constraints. Evaluation metrics included accuracy, F1-score, and total execution time (training + inference).

F. Limitations

This analytical approach provides a macro-level synthesis but does not substitute for controlled empirical testing on shared datasets. Outcomes rely on the consistency, transparency, and reproducibility of the original studies. Differences in preprocessing strategies, dataset splits, and reporting standards may introduce noise. While we mitigate this through source triangulation and metric normalization, residual meta-analysis bias may persist. These limitations are considered when interpreting comparative outcomes and are revisited in the Discussion section.

IV. Algorithmic Landscape in Sentiment Analysis

This section presents a structured overview of sentiment classification algorithms widely studied in recent literature. We organize the discussion into classical machine learning models, ensemble techniques, and neural architectures. Comparative findings from the reviewed studies are embedded to highlight strengths, limitations, and typical application contexts.

A. Classical Machine Learning Models

1) Logistic Regression (LR): LR is frequently applied to binary and multiclass sentiment classification tasks. It estimates the probability of class membership using text-derived features. Despite its simplicity, its interpretability and efficiency make it a foundational model. As shown in [23] and [24], LR performs well when paired with robust feature engineering and domain-specific lexicons.

2) Naïve Bayes (NB): NB is a probabilistic classifier based on Bayes' theorem with strong independence assumptions. Its ability to efficiently process high-dimensional feature spaces makes it particularly well-suited for large-scale or real-time sentiment analysis. In a study focused on Twitter data, researchers implemented Naïve Bayes within a Hadoop-based framework, demonstrating notable scalability and processing speed, even in noisy and unstructured text environments [25]. Despite its simplicity, the algorithm remains competitive in many real-world applications where rapid inference is a priority.

3) Support Vector Machines (SVM): SVMs are margin-based classifiers that construct optimal hyperplanes to separate data points in high-dimensional feature spaces. They have demonstrated strong resilience against overfitting, particularly in text classification tasks involving sparse and noisy inputs. High levels of accuracy have been reported on both social media and product review datasets, especially when effective preprocessing techniques and kernel selection strategies are applied [13], [22]. These characteristics make SVMs a reliable choice for sentiment classification tasks where precision and generalization are critical.

B. Ensemble Learning Methods

1) Decision Trees and Random Forest (RF): Decision Trees are interpretable models that classify data through a series of recursive, feature-based splits. While simple and transparent, their tendency to overfit on complex datasets can limit generalizability. RF addresses this limitation by aggregating the predictions of multiple decision trees, leading to improved accuracy and robustness. In the context of sentiment analysis, particularly on product review datasets, RF has been shown to outperform Support Vector Machines (SVM), achieving accuracy as high as 97% and demonstrating strong resilience to class imbalance [15]. These properties make RF a compelling option when both predictive performance and handling of imbalanced classes are priorities.

C. Deep Neural Networks

1) Recurrent Neural Networks (RNNs) are designed to capture temporal and sequential dependencies in text, making them well-suited for sentiment analysis tasks where word order and context are important. Among them, Long Short-Term Memory (LSTM) networks stand out for their ability to model long-range contextual relationships and mitigate the vanishing gradient problem. In large-scale sentiment classification, particularly on Twitter datasets, LSTM architectures have demonstrated superior performance compared to traditional machine learning approaches such as Support Vector Machines (SVM) [16]. Their effectiveness in handling noisy, unstructured data underscores the relevance of LSTM-based models in real-world sentiment analysis applications.

2) Convolutional Neural Networks (CNN): Initially developed for image recognition, they have been successfully adapted to text classification tasks. By applying convolutional filters over word embeddings, CNNs effectively capture local semantic features, functioning similarly to n-gram detectors. Their ability to learn hierarchical representations makes them particularly effective for morphologically rich languages, where subtle variations in word forms influence sentiment. For example, strong performance has been reported in Arabic sentiment analysis, where CNNs achieved competitive accuracy compared to more complex architectures [26]. These results highlight the versatility of CNNs as lightweight yet powerful models for sentiment classification.

D. Observations on Model Suitability

Classical models (NB, LR, and SVM) remain competitive in constrained settings due to their interpretability and low computational costs. Ensemble methods like RF offer robust performance across unbalanced and structured data. Neural architectures (LSTM, CNN) are effective for capturing context and nuance, particularly in noisy or informal language domains.

While this section focuses on traditional and neural models, emerging architectures such as BERT, RoBERTa, and hybrid combinations (e.g. lexicon + DL) are explored in Section II-D and II-E. Their exclusion from core metrics tables in this section reflects architectural distinctions and resource considerations rather than performance limitations.

V. Results and Comparative Analysis

A. Comparative Performance of Sentiment Classification Models

This subsection summarizes the performance of key sentiment classification algorithms across empirical studies, providing both quantitative trends and qualitative insights. Evaluation criteria include accuracy, precision, recall, F1-score, interpretability, and computational efficiency.

Logistic Regression consistently demonstrated reliable baseline performance for binary and multiclass sentiment classification. Studies by [23] and [24] confirmed accuracy ranges of 80–86%, particularly when supported by robust feature engineering and lexicons. Although interpretable and fast, its linear nature limits performance on complex or semantically rich datasets.

Random Forest emerged as one of the top-performing classical models, with [15] reporting 97% accuracy on Flipkart product reviews. Its ensemble structure enhances generalization and minimizes overfitting, particularly in imbalanced datasets. As observed in [27], similar robustness was observed across multilingual sentiment analysis contexts. However, its computational demands remain a limitation in resource-constrained deployments.

Support Vector Machines (SVM) showed consistently high precision, with performance reaching 86.22% in sentiment classification of social media text. Yet, its sensitivity to kernel selection and difficulty in handling minority classes in unbalanced datasets restricts generalizability.

Naïve Bayes remained competitive due to scalability and simplicity. A study demonstrated its efficacy in large-scale Twitter sentiment classification using Hadoop [25], although it often suffers from false positives in neutral sentiment predictions due to independence assumptions.

K-Nearest Neighbors (KNN) achieved accuracy levels around 85–90% when finely tuned. Studies [28] and [29] demonstrated its usefulness on structured datasets but highlighted sensitivity to noise and scalability issues in larger corpora.

Deep learning architectures demonstrated greater ability to capture semantic and contextual dependencies. LSTM networks proved effective on sequential text data, with Srinivas et al. reporting 87% accuracy on Twitter corpora. Similarly, CNNs performed strongly in morphologically rich languages such as Arabic [26], reflecting their ability to capture spatial and syntactic structures.

To consolidate the findings from both the literature review and benchmark experiments, Table II provides a comparative summary of six widely used sentiment classification algorithms. The table captures key performance metrics—including accuracy and F1-score—as well as qualitative assessments such as computational efficiency, interpretability, and model limitations. This synthesis serves as a quick reference for understanding the trade-offs between classical machine learning, deep learning, and ensemble models in diverse sentiment analysis scenarios. By juxtaposing strengths and weaknesses, the table facilitates informed decisions about model suitability based on task-specific constraints and deployment contexts.

In addition to synthesizing results from prior studies, we conducted a minimal benchmark on the IMDb dataset to validate and contextualize these trends.

The results, summarized in Table III, provide additional perspective on model performance under standardized conditions.

TABLE II. Summary of Comparative Results Across Six Key Classification Models

Algorithm	Accuracy	Dataset Size	Strengths	Weaknesses	Limitations	References
Logistic Regression	80–86%	Medium	Simplicity, interpretability	Sensitive to feature engineering	Struggles with non-linear decision boundaries	[31], [32]
Random Forest	97%	Large	Robust to imbalance, feature selection	Computational cost	Overfitting risk on small data	[15], [27]
SVM	86.22%	Medium–Large	Effective in high-dimensional data	Requires kernel tuning	Limited scalability on imbalance	[28], [13]
Naive Bayes	85–90%	Large	Fast, scalable	Independence assumptions	Weak on contextual semantics	[24], [25]
KNN	85–90%	Medium	High recall with tuning	Sensitive to parameters	Inefficient for large datasets	[28], [29]
Neural Networks (LSTM)	87%	Large (1.6M tweets)	Captures sequential dependencies	High resource demand	Slower training	[30], [22]

TABLE III. Experimental Comparison of Models on IMDb Dataset

Model	Accuracy	F1-Score	Total Time(s)	Main Strengths	Main Limitations
Naïve Bayes	0.8075	0.7979	1.08	Very fast, Simple, Scalable	Fails to capture context and syntax
SVM (Linear)	0.8325	0.8329	8.87	High precision, Robust	Slower sensitive to class imbalance
LSTM	0.7450	0.7536	20.52	Deep sequential learning	Long training time, prone to overfitting

B. Experimental Benchmark on IMDb Dataset

To complement the findings reported in prior studies, we conducted a small-scale experimental benchmark on the IMDb movie reviews dataset. The goal was to validate whether classical models remain competitive against deep learning architectures under standardized conditions and limited training resources.

Three representative algorithms were selected for this experiment: Naïve Bayes, linear SVM, and a basic LSTM network. These models were chosen to reflect the evolution from classical probabilistic methods to kernel-based classifiers and sequence-based deep learning.

The dataset was preprocessed into train and test splits, with performance evaluated using accuracy, F1-score, and total training + inference time as metrics. The benchmark was intentionally kept minimal, with default or lightly tuned hyperparameters, to highlight practical trade-offs rather than optimize individual performance.

Table III reports the detailed numerical results, while Fig. 2 below illustrates the comparative performance of the three models in terms of Accuracy and F1-score.

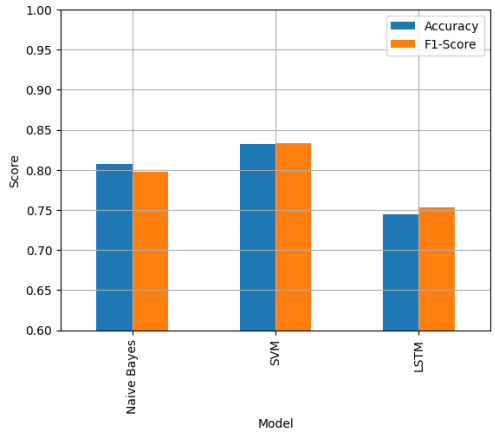

Fig. 2. Comparative performance of Naïve Bayes, SVM, and LSTM on IMDb dataset.

Results indicate that SVM outperformed the other models with the best accuracy (0.8325) and F1-score (0.8329), confirming its robustness for high-dimensional textual datasets. Naïve Bayes achieved competitive accuracy (0.8075) with extremely low computational cost (1.08 seconds), making it well-suited for resource-constrained or real-time applications. LSTM underperformed in this setting (Accuracy = 0.7450, F1 = 0.7536), reflecting its dependency on extensive training data and fine-tuning to fully exploit sequential text patterns.

These findings reinforce the conclusions from our literature review: classical models such as Naïve Bayes and SVM continue to offer strong baselines and practical advantages in specific contexts, while deep learning models require higher resource investment to surpass them.

C. Illustrative Confusion Matrix Comparison

To further illustrate the behavior of different sentiment classification models, we synthesized representative confusion matrices from prior empirical studies. These visualizations are not the result of our own experimental benchmark but instead are drawn from the literature, capturing model-specific classification tendencies across diverse datasets. They provide a complementary perspective beyond aggregate accuracy values, emphasizing class-level strengths and weaknesses.

Across the reviewed studies, the analysis of confusion matrices reveals distinct classification behaviors for each model. Logistic Regression generally provided balanced predictions but frequently confused neutral and positive instances. Random Forest consistently maintained high recall across sentiment classes, even under imbalanced conditions, confirming its robustness in noisy environments. SVM achieved sharp decision boundaries and high precision, though it struggled to classify minority classes in imbalanced datasets. Naïve Bayes proved efficient for large-scale data processing but showed a tendency to overgeneralize, particularly in neutral categories. KNN delivered good performance on dominant classes but exhibited poor scalability and sensitivity to noise in larger datasets. In contrast, LSTM reduced false negatives more effectively, especially for positive and neutral sentiments, demonstrating its strength in capturing sequential dependencies.

Fig. 3 provides representative examples of these confusion matrices, enabling a more granular view of systematic misclassifications observed across the literature.

These confusion matrices emphasize that overall accuracy alone does not capture the full behavior of sentiment classifiers. Systematic misclassifications—such as the difficulty of distinguishing neutral from positive classes—highlight the importance of analyzing class-level performance. Such insights are particularly relevant in high-stakes domains like customer feedback analysis or financial forecasting, where errors in minority or neutral categories can lead to significant misinterpretations.

D. Discussion

The comparative analysis confirms that no single sentiment classification algorithm is universally optimal. Model suitability is inherently context-specific, depending on factors such as dataset structure, class balance, computational capacity, and the intended use case.

Random Forest stands out for its robustness in handling imbalanced and noisy datasets, a recurring challenge in sentiment analysis. Its ensemble mechanism and inherent feature selection capacity contribute to high accuracy and recall across sentiment classes. However, its elevated memory and processing demands can be prohibitive for deployment in low-resource environments or real-time systems.

LSTM networks are particularly effective in capturing temporal dependencies and complex linguistic patterns in sequential data, such as tweets or reviews. As also reflected in prior studies, LSTM consistently minimizes false negatives, especially in positive and neutral sentiments. Nonetheless, its reliance on extensive training data and computational resources poses significant constraints for real-time or embedded applications.

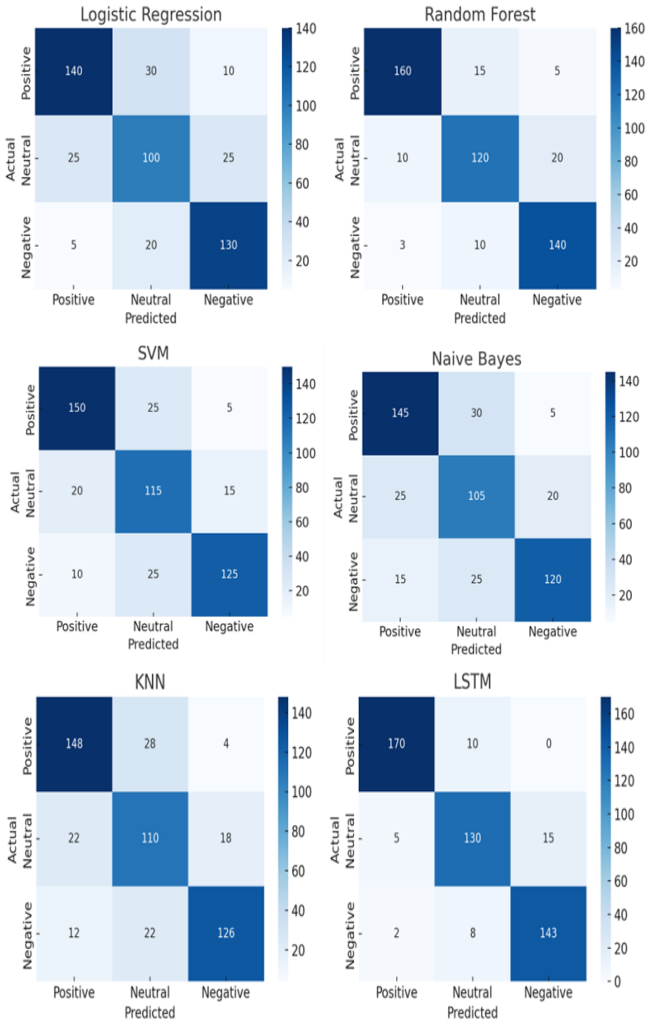

Fig. 3. Representative confusion matrices synthesized from reviewed studies.

Classical algorithms such as Logistic Regression and Naïve Bayes continue to offer strong interpretability and operational efficiency. Their balanced behavior in confusion matrices, combined with moderate accuracy, make them reliable for real-time monitoring or applications prioritizing transparency over complexity. However, they are less suited for semantically rich or non-linear text inputs.

SVM demonstrates high precision in structured, high-dimensional spaces, yet its sensitivity to class imbalance often leads to underperformance in minority class recognition, as reflected in false negatives or misclassified neutral sentiments. Similarly, KNN, though capable of high recall with careful tuning, suffers from scalability issues and noise sensitivity in larger datasets.

Insights from our IMDb benchmark experiment further reinforce these observations: SVM outperformed both Naïve Bayes and LSTM in terms of F1-score, confirming its robustness in practice, while Naïve Bayes offered a very favorable trade-off between accuracy and efficiency. LSTM, although promising in theory, underperformed under constrained training conditions, highlighting its dependency on resources and optimization.

To translate these findings into practical guidance, we propose a decision-support flowchart Fig. 4 that synthesizes insights from the literature and our experimental results. The flowchart provides a step-by-step guide to selecting appropriate models depending on computational resources, interpretability requirements, and accuracy goals.

Overall, model selection should be guided by a balance between performance metrics and deployment constraints. The forthcoming radar visualization Fig. 5 encapsulates this trade-off and aids in aligning algorithmic capabilities with practical requirements.

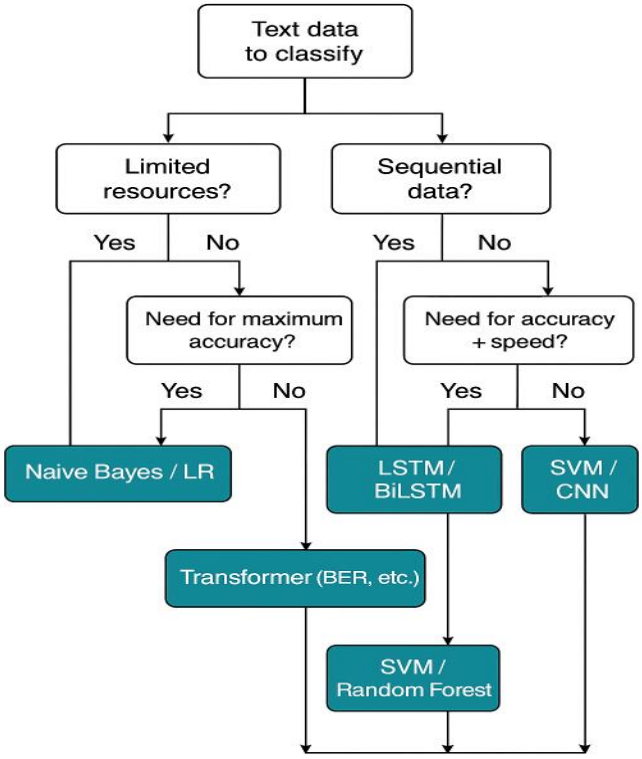

Fig. 4. Decision-support flowchart for selecting sentiment classification models.

As illustrated in Fig. 4, when computational resources are limited, simple and interpretable models such as Naïve Bayes or Logistic Regression are recommended. For tasks requiring sequential modeling, LSTM or BiLSTM networks provide a strong option, while transformer-based architectures deliver superior accuracy when resources permit. In intermediate cases, SVM or Random Forest serve as robust compromises, balancing precision and efficiency. This structured approach ensures that model selection is not only performance-driven but also context-aware, bridging the gap between academic research and real-world deployment.

Answers to Research Questions:

- RQ1: Deep learning models, such as LSTM, tend to outperform classical algorithms in sequential and large-scale contexts where capturing temporal or semantic dependencies is critical. However, classical models retain significant advantages in transparency, efficiency, and speed, making them highly competitive in

constrained environments or applications requiring interpretability.

- RQ2: The trade-offs between model complexity and interpretability remain evident. Simpler models such as Naïve Bayes and Logistic Regression provide transparency, scalability, and low computational cost but sacrifice the ability to capture deep contextual or sequential information. At the opposite end, deep neural networks and transformer-based architectures achieve superior accuracy but demand extensive resources and present explainability challenges. SVM and Random Forest occupy a middle ground, offering strong precision and robustness across varied datasets, though with limited interpretability. Ultimately, deployment decisions must balance these trade-offs against domain-specific requirements such as real-time performance, regulatory compliance, or resource availability.
- RQ3: Algorithm selection must be tailored to the application context, since performance varies with dataset structure, computational resources, and interpretability needs. Visualization tools such as confusion matrices provide fine-grained insights into systematic misclassifications, while decision-support flowcharts offer practitioners a structured pathway to align model choice with resource and accuracy requirements. Complementarily, radar charts deliver a multidimensional snapshot of trade-offs across accuracy, robustness, efficiency, and interpretability. Together, these tools support context-sensitive decision-making, ensuring that the chosen model balances theoretical performance with practical deployment constraints.

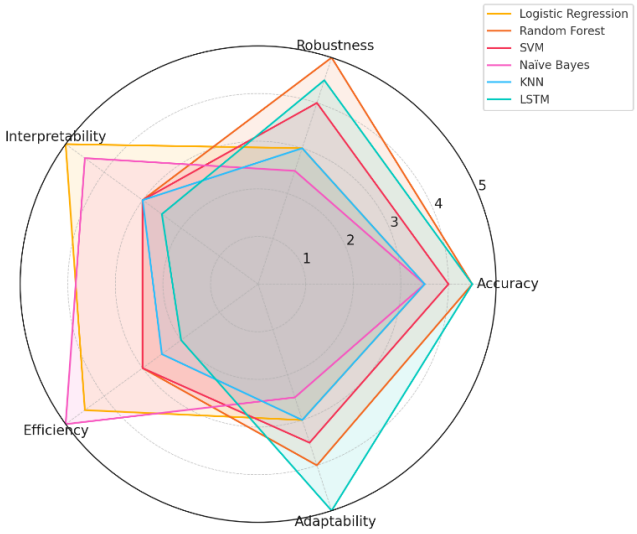

Fig. 5. Comparative radar of classification models.

This visual summary, Fig. 5 aids in identifying the most suitable algorithm under different contextual constraints. Comparing sentiment classification models across five key dimensions: accuracy, robustness, interpretability, efficiency, and adaptability. The visualization highlights the unique trade-offs associated with each model type, supporting context-sensitive algorithm selection.

VI. Conclusion and Future Work

A. Conclusion

This study conducted a structured and comprehensive review of sentiment classification algorithms, encompassing classical machine learning models, ensemble methods, deep learning architectures, and transformer-based approaches. The comparative framework evaluated models across five critical dimensions: accuracy, robustness, interpretability, computational efficiency, and adaptability to different data contexts. Findings confirm that no algorithm exhibits universal superiority. Instead, each model demonstrates distinct strengths and trade-offs, as illustrated throughout the review.

For example, deep learning models such as LSTM have shown outstanding accuracy in real-world applications like Twitter sentiment analysis for political discourse or customer satisfaction tracking. Meanwhile, classical models like Naïve Bayes remain favored in embedded analytics due to their lightweight nature. Random Forest offers robust generalization capabilities but sacrifices interpretability, posing challenges in sensitive domains such as finance or healthcare. Similarly, SVM provides high precision but struggles with class imbalance, while CNNs capture morphological dependencies in languages such as Arabic.

To complement these literature-based insights, we conducted a benchmark on the IMDb dataset comparing Naïve Bayes, linear SVM, and LSTM. Results showed that SVM achieved the best F1-score (0.8329), Naïve Bayes offered competitive performance with extremely low computational cost, and LSTM underperformed under limited tuning, reinforcing its reliance on resources. These findings validate the observation that classical models remain competitive in constrained settings, while deep architectures require careful optimization.

The synthesis of both literature and experimental evidence reinforces the importance of context-aware model selection, where performance must be weighed against constraints such as data imbalance, deployment requirements, and interpretability needs. Confusion matrix analyses further highlight that aggregate accuracy is insufficient, since systematic misclassifications—such as neutral versus positive confusion—can significantly impact real-world outcomes. To bridge research and practice, we introduced a decision-support flowchart that provides practitioners with a structured tool for aligning algorithm choice with contextual requirements.

B. Future Work

Building upon these insights, several research directions are worth pursuing to advance sentiment classification systems and bridge the gap between theoretical advancements and real-world deployment:

1) Hybrid modeling strategies: Combining classical models (e.g. Random Forests) with deep learning (e.g. LSTM, CNN) may yield architectures that balance accuracy, efficiency, and interpretability. Exploring these hybrid combinations remains an open challenge.

2) Transformer-based advances: The continued evolution of large language models—such as BERT, RoBERTa, GPT,

and multilingual transformers—holds immense potential, especially for aspect-based sentiment analysis, domain adaptation, and multilingual processing.

3) Real-time and scalable applications: The next frontier lies in enabling real-time sentiment analysis through lightweight models, distillation, pruning, or deployment on edge devices. Use cases include live financial monitoring and social media tracking.

4) Domain-specific adaptation: Applications in fields like healthcare, law, and finance require sentiment models fine-tuned to domain-specific vocabularies and formats. Techniques such as zero-shot learning and prompt tuning may offer robust solutions.

5) Explainability and hyperparameter optimization: As model complexity increases, explainable AI (XAI) methods (e.g. SHAP, LIME, attention visualization) are vital for transparency in sensitive contexts. In parallel, automated hyperparameter tuning techniques—such as Bayesian optimization, neural architecture search (NAS), and evolutionary strategies—can streamline performance gains.

6) Low-resource and inclusive NLP: Supporting underrepresented languages, dialects, and noisy corpora is crucial. Research should focus on multilingual transformers, synthetic data generation, and transfer learning to promote inclusivity and generalization.

By addressing these research directions, future sentiment analysis systems can become more accurate, fair, explainable, and adaptable—meeting the demands of both academia and industry across diverse deployment contexts.

***Abstract*—Hybrid edge–cloud computing has emerged as a promising paradigm to meet the demands of latency-sensitive and resource-aware applications by combining the low-latency benefits of edge nodes with the scalability of cloud infrastructure. Efficient workload scheduling in such environments remains a critical challenge due to the heterogeneity of resources, dynamic network conditions, and diverse application requirements. This paper presents a comprehensive survey and comparative analysis of heuristic and metaheuristic scheduling algorithms tailored for edge–cloud systems. Seven representative algorithms, including Greedy Resource-Aware Heuristics (GRAH), Heterogeneous Earliest Finish Time (HEFT), Min-Min/Max-Min, Genetic Algorithm, Particle Swarm Optimization (PSO), Ant Colony Optimization (ACO), and Tabu Search, are evaluated against seven key criteria: latency awareness, energy efficiency, scalability, scheduling accuracy, implementation complexity, resource utilization, and adaptability. The evaluation is literature-driven and structured through a Weighted Scoring Model (WSM), which synthesizes findings from prior simulation-based and experiment-based studies into a comparative framework. Results indicate that Greedy Resource-Aware Heuristics offer the best trade-off for real-time, dynamic scenarios, while optimization-based methods, like GA and Tabu Search, provide superior accuracy and resource balance at the cost of increased complexity. The findings highlight critical trade-offs and offer guidance on selecting appropriate scheduling strategies based on application-specific goals and system constraints.**

Keywords*—Edge computing; cloud computing; workload scheduling; heuristic algorithms; metaheuristics; scheduling optimization; ACO; PSO; HEFT; Tabu Search; GA; Greedy Resource-Aware Heuristics; Min-Min; Max-Min; WSM; Weighted Scoring Model

I. Introduction

With each new breakthrough digital tech innovation, they're driving one revolution after another of intelligent services that become increasingly integrated into our lifestyle and industrial workflow processes. Consider just real-time video surveillance, intelligent transport systems, self-driving cars, robot-assisted manufacturing, and telemedicine; each of these very different use cases have one thing in common; they need fast, predictable, contextual computing. They tend to operate in very dynamic environments, process very large data inputs, and make decisions within fractions of a second.

Cloud computing has always made data processing possible by virtue of large-scale computing and large-scale storage. But it is not optimized with ultra-low latency for use cases today that are latency-aware. Because of clouds' data centers' locations being far from end-users, communicating across those long-haul distances, paired with bandwidth constraints, becomes a serious chokepoint [1], [2]. Just running on the cloud is not good enough for use cases when milliseconds do matter at the end.

In an endeavor to close that gap, we are headed towards hybrid edge–cloud architectures. Here, processing of work is judiciously split; lighter workloads are processed close to or at the edge of the network (i.e. close to the place of data origination), while high-intensity workloads are shifted out to the cloud [2], [3]. Both of them together offer: edge computing's speed and proximity advantage as well as scalability and power of the cloud. That's the perfect destination for new services where a very fast response time as well as high compute capacity are an imperative.

But to actually make this architecture work well together, however, one of its needs for capabilities is intelligent scheduling of work. That is, decisions at the time of where and when each of its pieces of work needs to run; out at the edge, out at the cloud, or across two. Decisions of how they are made have huge effects on system performance, from response time through energy efficiency, all the way to resource utilization and utilization of networks [3]. That is, scheduling of workloads is not after-the-fact business at all; it's utterly essential for successful hybrid computing.

But coming up with an effective schedule solution for such very dynamic and very complex edge–cloud environments is no small feat. Schedulers are faced with many things happening simultaneously, like limited edge resources, fluctuating network conditions, mobility devices, tasks with deadline constraints, and user preferences. And sometimes they need to do all of that on the fly. Traditional optimization approaches, although accurate, are too resource-intensive and latency-prone for real-time programs, especially large-scale programs [3]. That's why there's greater emphasis on heuristic-based schedule approaches; a faster, more agile approach that's better adapted to today's edge-cloud computing.

Heuristics provide fast, light-weight, and flexible solutions that best suit edge–cloud applications. They do not guarantee an optimal solution but provide a fast, good-enough solution that is precisely desired in real-world applications. Min-Min, Max-Min, Heterogeneous Earliest Finish Time (HEFT), and Greedy Resource-Aware are intuitive decision-making or rule-of-thumb–based schemes that are simple to implement as well as fine-tune. Although seemingly extremely trivial, such heuristics could possibly handle multi-dimensional trade-offs like latency vs. energy consumption or edge load balancing vs. cloud optimality with remarkable efficiency [4].

However, the sheer variety of heuristic methods—and the lack of standardized benchmarks—makes it difficult for researchers and practitioners to choose the most appropriate algorithm for a given application. Some heuristics are tailored for low latency, while others excel at resource efficiency or scalability. As a result, there is a growing need for a unified, multi-criteria evaluation framework that enables a fair and meaningful comparison across these approaches. This motivates our work: to provide a comprehensive review and comparative analysis of heuristic-based scheduling methods, supported by a Weighted Scoring Model (WSM) that captures the practical trade-offs involved in real-world deployments.

This paper aims to bridge the gap between the growing number of heuristic-based scheduling algorithms and the lack of a standardized, comparative evaluation framework tailored for hybrid edge–cloud environments. Unlike works that focus on individual algorithms, the novelty of our study lies in providing a unified, multi-criteria evaluation framework through the Weighted Scoring Model (WSM). We do not propose a fundamentally new scheduling algorithm in this paper; rather, we offer a systematic and transparent synthesis that highlights trade-offs, strengths, and weaknesses across existing approaches. In this way, the paper provides both practitioners and researchers with a practical decision-support tool and a baseline for identifying research gaps. Future work will build on this foundation to design and validate novel adaptive scheduling methods tailored to real-world, large-scale edge–cloud deployments. Our contributions can be summarized as follows:

- Comprehensive Survey of Heuristic Approaches: We conduct a structured and up-to-date review of prominent heuristic-based workload scheduling algorithms—including Min-Min, Max-Min, HEFT, Greedy Resource-Aware Heuristics, Tabu Search, and others—that have been applied in the context of hybrid edge–cloud systems. Each algorithm is examined in terms of its working principles, strengths, limitations, and targeted scheduling objectives.
- Design of a Weighted Scoring Model (WSM): We propose a multi-criteria decision-making framework that evaluates heuristic algorithms using a Weighted Scoring Model. The model is based on seven critical evaluation dimensions: Latency Awareness, Energy Efficiency, Adaptability, Scalability, Scheduling Accuracy, Implementation Complexity, and Resource utilization.
- Comparative Analysis and Ranking: By applying the WSM to a curated set of heuristic algorithms, we provide a transparent and reproducible comparison. Each algorithm is scored and ranked, highlighting trade-offs and performance gaps. This offers valuable guidance for researchers and system architects seeking to select or customize scheduling strategies for specific use cases.

The rest of the paper is organized as follows: Section II reviews the related work on heuristic-based workload scheduling in edge–cloud environments. Section III provides background information and foundational concepts. Section IV introduces a classification of heuristic scheduling approaches. Section V presents representative heuristic algorithms commonly used in edge-cloud systems. Section VI details the methodology of the Weighted Scoring Model used for evaluation. Section VII compares the selected heuristic algorithms based on defined criteria. Section VIII discusses the results of the comparison and highlights key insights. Section IX outlines current challenges and suggests future research directions. Finally, Section X concludes the paper.

II. Related Work

Several recent systematic reviews have explored task scheduling challenges in edge–cloud environments, particularly through the lens of heuristic and metaheuristic techniques. For example, the study in [5] introduced a hybrid scheduling approach that enhances traditional heuristics with deep learning by combining Particle Swarm Optimization (PSO) and the Firefly Algorithm. This fusion leveraged the complementary strengths of both methods and achieved improved scheduling performance for resource-intensive tasks in cloud platforms.

In another work [6], the authors tackled the complexity of scheduling IoT applications in fog computing—a problem recognized as NP-hard. While the paper acknowledges the historical reliance on rule-based and metaheuristic techniques, it also critiques their dependence on global knowledge and limited adaptability in dynamic environments. To address these limitations, they proposed DRLIS, a Deep Reinforcement Learning-based scheduler, and demonstrated its superiority over classical metaheuristics such as NSGA2 and NSGA3, particularly in terms of convergence speed, scheduling time, and optimization effectiveness.

Complementing these algorithmic proposals, the review presented in [4] examined the advantages, limitations, and application contexts of various heuristic-based task scheduling methods within cloud computing. Such analyses are valuable for informing the selection of heuristics in real-world task scheduling scenarios.

Further, [7] offered a broad survey of optimization-driven scheduling algorithms in edge–cloud systems, highlighting techniques such as Genetic Algorithms (GA), Cat Swarm Optimization, and multi-objective variants of Ant Colony Optimization (ACO) and PSO. Their work emphasized the role of multi-objective optimization in balancing trade-offs among latency, energy efficiency, cost, and load distribution. The

study also shed light on emerging themes like adaptive scheduling, collaborative resource orchestration, and addressed open challenges such as handling task dependencies, dynamic resource availability, and fault tolerance—key issues in evolving edge–cloud scenarios.

The study in [8] provides a systematic review of heuristic-based scheduling methods for IoT-fog environments. It classifies approaches into six categories—priority-based, greedy, metaheuristic, learning-based, hybrid, and nature-inspired—though labeled as a taxonomy, the structure is more accurately a flat classification. The review follows PRISMA guidelines and identifies key challenges such as heterogeneity, scalability, and security, while suggesting future directions like integrating machine learning and enhancing explainability. However, it lacks cross-category performance comparisons, broader contextualization with non-heuristic or AI-based methods, and deeper analysis of real-world applicability and security-aware heuristics. Despite these gaps, it remains a valuable reference for heuristic scheduling in fog-cloud IoT systems.

Despite such valuable contributions, there continues to be a gap in the literature: there has not yet been a review dedicated entirely to heuristic-based scheduling of workloads in the special case of hybrid edge–cloud computing. This paper seeks to address the imbalance by providing a comprehensive investigation and taxonomy of heuristic methods, comparing their efficiency, and evaluating their usability in practice in the environments of edge-clouds.

III. Background

A. Edge-Cloud Architecture Overview

Edge-cloud computing integrates two mutually complementary levels of computing infrastructure: edge nodes, located near devices producing data such as sensors and IoT devices, and remote cloud servers, providing powerful computing and massive storage capacity. The architecture develops a hierarchy of computing such that tasks could be optimally redistributed over multiple sites depending upon their latency sensitivity as well as resource requirements. Tasks with high response requirements or those of high volume of data requiring processing over real-time are usually served at the edge, such that the latency for the purpose of intercommunication could be reduced as well as bandwidth usage. Compute-intensive tasks and high-duration data storage tasks are, on the other hand, offloaded to clouds where higher-end resources. Balancing the workload judiciously but adequately between both the edge as well as the cloud layers of such architecture permits providing greater system responsiveness as well as lower communications overhead between distributed applications, but particularly greater scalability as well as fault tolerance of the application [9], [10].

B. Workload Characteristics

Edge–cloud computing workloads are extremely variable and very dynamic, arising from an enormously large variety of sources like sensors, mobile phones, camera-equipped phones, and machines. They very notably fluctuate with computing intensity, latent needs, volume of data, as well as arrival rates [11]. Some require instant processing immediately with no wait time involved, while some have bulk or occasional data. Making the matter worse in such an instance is the changing and diverse nature of the arrival of tasks. At any instant, workloads peak and the system has to decide on the spur of the moment, that is, at real-time scheduling. Schedulers are compelled persistently to shift configurations such that good performance as well as reliability are sustained, such factors as availability of computing resources, state of the current network, as well as priority or requirement of arriving tasks are being considered [11]. Service-level objective (SLO) realization within such an environment requires intelligent mechanisms of scheduling that could adequately contend with ever-changing demands.

C. Scheduling Objectives

Scheduling edge–cloud computing workload is specifically challenging because there exist multiple, often competing objectives that have to be optimized. Efficient schedulers must reconcile multiple desirable objectives in balancing for system efficiency as well as application performance:

- Latency Reduction: Most edge computing initiatives revolve around reducing response time. Scheduling policies must prefer deploying the work next to where data is being generated [12]; lower round-trip delay, and best-case real-time response.
- Enhancing Energy Efficiency: The edge nodes will frequently be deployed at sites that have minimal access to power sources, e.g. at remote sites or at battery-based deployments. Overloading such nodes may lead to energy drain and interruption of service [13]. Scheduling algorithms will then need to target the reduction of transmission of useless information and overloading by nodes with energy limitations.
- Sustaining Load Balancing: Non-balanced allocation of tasks could end up overloading some nodes while leaving other nodes idle. Schedulers will have to avoid skewed allocation of workloads in order to sustain system stability as well as system throughput by avoiding bottlenecks and allowing for more balanced program execution across the network [11].
- Ensuring Quality of Service (QoS) and Quality of Experience (QoE): Some applications of the real-time, i.e. video streaming, software for industrial control or healthcare monitoring, require hard guarantees regarding their performance. Schedulers are thus provided Service-Level Agreements (SLAs) by offering time completion of tasks reliably and correctly [11]. That affects the user experience of service quality directly and thus forms a crucial consideration of current scheduling schemes.

Briefly speaking, the optimal scheduler in edge-cloud needs to be multi-objective; that is, it is required to serve latency, energy, load distribution, and service quality at the same time within a resource-limited and varying environment.

D. Limitations of Traditional Scheduling Approaches

Traditional scheduling methods applied for cloud computing, that are usually based on static policy or

algorithmic deterministic methods, do not perform well within edge–cloud environment scenarios. Traditional methods are usually not dynamic and thus inefficient when addressing real-time variation of resource availability and workload. They are also usually coupled with high computing overhead and are not suitable for systems that lack computing power [14].

Scalability is also a concern. As larger edge networks of thousands of nodes and devices are needed, the majority of typical schedulers do not scale or perform well. Furthermore, most of them rely upon centralized decisions and consequently yield greater incidences of point-of-failure occurrence and communication latency and lower fault tolerance [15]; each of these is a serious weakness of the distributed, heterogeneous environment.

These limitations impose an immediate necessity for lightweight scheduling mechanisms that are also decentralized and adaptive. Heuristic-based mechanisms of these types have demonstrated extraordinary potential. Owing to their tendency to give fast approximate results with low overhead that automatically adjust with changing situations [13], [16], they are very fitting to the new edge–cloud computing requirements.

IV. Classification of Heuristic Scheduling Approaches

Heuristic scheduling algorithms are essential for dealing with the dynamic and resource-constrained nature of edge–cloud computing workloads. Heuristic algorithms are valued for giving good, near-optimum solutions with little overhead, which is a highly desirable characteristic in highly dynamic environments. As indicated in Fig. 1, we put forward a taxonomy of heuristic methods of scheduling, which categorizes the heuristics into simple heuristics, metaheuristics, and hybrid heuristics, based on their underlying strategies and level of complexity [17], [18], [19], [20], [21].

A. Simple Heuristics

Simple heuristics are rule-based scheduling algorithms that use simple, predetermined logic to make decisions. They are most popular in real-time systems because of their low complexity and fast execution, which makes them suitable for applications in situations where fast, lightweight decision-making is critical [22]. These techniques, though not necessarily optimal in terms of system-wide performance, ensure consistent baseline behavior with low processing overhead. Common implementations of simple heuristics include:

- First-Come, First-Served (FCFS): FCFS puts tasks in a strict sequence of submission order without considering the availability of resources and the priority of the task. Even if FCFS is extremely simple in implementation, its performance under dynamic workload is typically poor, which results in under-utilization of resources, increased waiting times, and spikes in latency [23], [24].
- Shortest Job First (SJF): Runs jobs having the shortest estimated running time, trying to reduce average total wait time [23], [24]. Estimation of running time of the tasks may get complex in an edge-cloud scenario, which restricts the usage of SJF despite its theoretical efficiency.
- Min-Min and Max-Min: These algorithms schedule tasks based on their expected completion times. Min-Min selects tasks with the shortest completion time, favoring smaller tasks and aiming to quickly reduce the number of pending jobs. Max-Min, on the other hand, gives priority to tasks with the longest completion time, helping to balance load and avoid long-tail delays [22]. Both are commonly used in cloud systems to enhance throughput and resource efficiency.
- Round Robin (RR): Distributes CPU time equally among all tasks using a time-slicing approach. While RR is fair and prevents starvation, it can incur high context-switching overhead, especially when dealing with a large number of short-lived or high-priority tasks [22], [23].

Overall, simple heuristics offer a solid foundation for scheduling in resource-constrained edge-cloud environments, particularly when quick, interpretable decisions are preferred over optimality.

B. Metaheuristics

Metaheuristic algorithms are advanced, high-level strategies designed to efficiently explore large and complex solution spaces—making them well-suited for challenging optimization tasks such as workload scheduling in edge–cloud environments. Unlike simple heuristics that rely on fixed rules, metaheuristics employ adaptive mechanisms to balance exploration and exploitation, allowing them to find near-optimal solutions even in highly dynamic and multi-objective settings.

Some of the most widely used metaheuristic approaches include:

- Genetic Algorithm (GA): Inspired by the principles of natural selection and genetics, GAs use operators like selection, crossover, and mutation to evolve a population of candidate solutions across generations. GAs are particularly effective at navigating large and nonlinear problem spaces, but they often require significant computational time and tuning, especially in real-time scenarios [25], [26].
- Particle Swarm Optimization (PSO): This algorithm models a group of agents (particles) moving through the solution space, each adjusting its position based on its own experience and the performance of neighboring particles. PSO is known for its simplicity, fast convergence, and low memory footprint, which makes it appealing for real-time task scheduling in distributed systems [26], [27].
- Ant Colony Optimization (ACO): Inspired by the way real ants find optimal paths to food, ACO simulates a colony of artificial ants that build solutions incrementally, guided by pheromone trails. ACO is well-suited for discrete and combinatorial optimization

problems, such as scheduling tasks with dependencies or constraints [28].

- Simulated Annealing (SA): Modeled after the metallurgical process of annealing, SA probabilistically accepts worse solutions at early stages to avoid becoming trapped in local minima. This ability to escape suboptimal solutions makes SA effective for solving complex scheduling problems where traditional methods may get stuck [26], [27], [29].

Recent research has demonstrated the effectiveness of metaheuristics in edge–cloud systems. For example, ACO-based schedulers have been used to optimize multiple objectives—such as latency, energy consumption, and cost—through fitness functions tailored to dynamic edge environments. Another study proposed a modified Firefly Algorithm for workflow scheduling in hybrid cloud–edge platforms, which led to noticeable improvements in makespan and execution cost [28], [30].

Metaheuristics, while more resource-intensive than simple heuristics, offer flexibility and robustness in finding high-quality solutions for multi-objective and time-sensitive scheduling problems—a critical need in modern edge–cloud systems.

C. Hybrid Heuristics

Hybrid heuristics are scheduling strategies that combine multiple heuristic or metaheuristic methods in order to leverage their individual strengths while compensating for their inherent weaknesses. By integrating different approaches—such as combining the fast convergence of one algorithm with the global search capability of another—hybrid methods aim to achieve more balanced and effective solutions, particularly for complex scheduling problems in edge–cloud environments [8].

These strategies have shown strong potential in optimizing multiple, often conflicting objectives such as execution time (makespan), energy consumption, and operational cost. For instance, one study proposed a hybrid metaheuristic algorithm to enhance IoT service placement in edge–cloud infrastructures, achieving improved performance across key scheduling metrics [26].

Although hybrid approaches are not inherently AI-based, they still fall within the broader category of heuristic-driven scheduling techniques. However, when such methods are further enhanced with machine learning models or neural components, they begin to evolve into AI-driven schedulers—offering even greater adaptability and decision-making intelligence in dynamic environments.

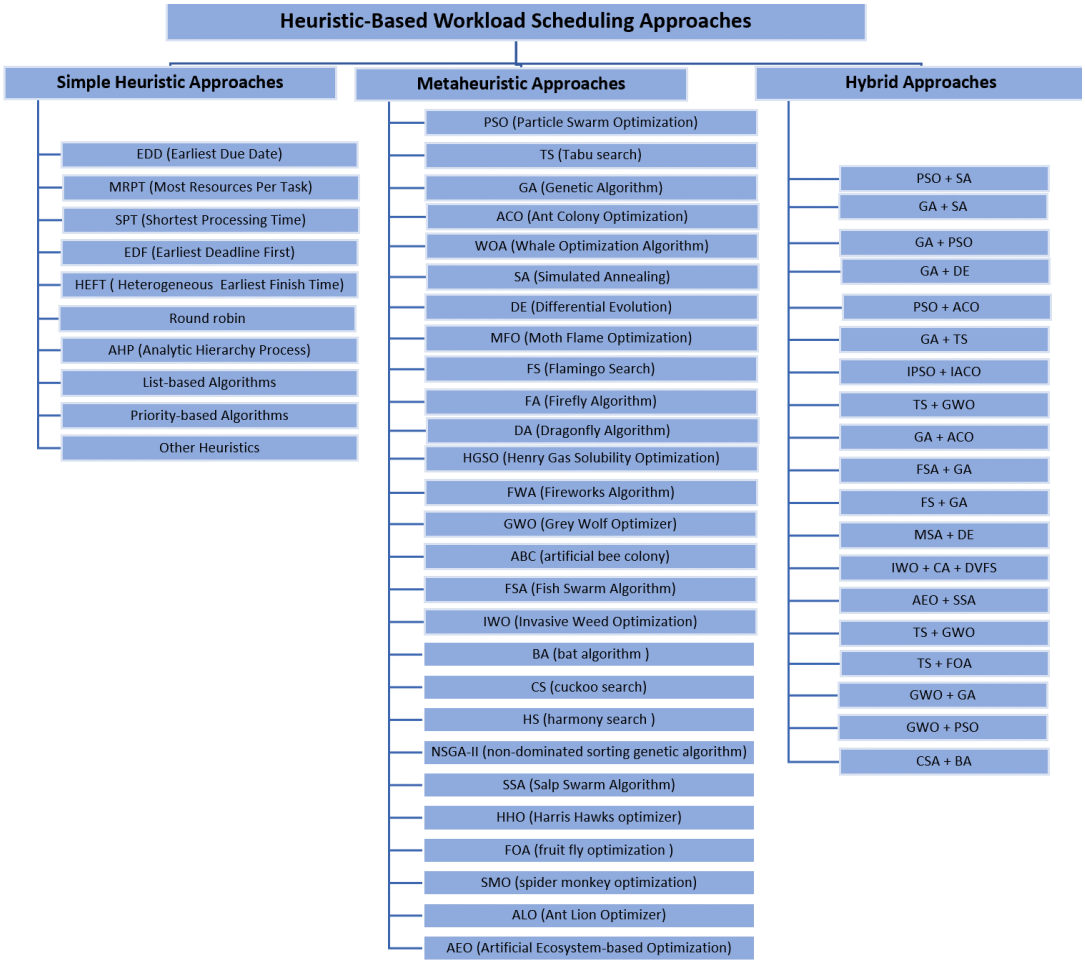

Fig. 1. Taxonomy of heuristic-based workload scheduling approaches.

V. Representative Heuristic Approaches

We present in this section some representative heuristic and metaheuristic approaches that have been used for edge-cloud system workload scheduling. These approaches take optimal task-to-resource allocations under latency, energy, and workload balancing constraints into consideration.

This paper chooses seven established scheduling algorithms: Greedy Resource-Aware Heuristics, HEFT, Min-Min/Max-Min, Genetic Algorithm (GA), Particle Swarm Optimization (PSO), Ant Colony Optimization (ACO), and Tabu Search for comparative analysis. The choice was based on several objective criteria aiming to ensure relevance and diversity. Initially, the chosen algorithms exhibit a variety of methodological approaches: rule-based (HEFT, Min-Min/Max-Min), greedy (Greedy Resource-Aware), evolutionary (GA, PSO), swarm intelligence (ACO), and memory-based search (Tabu Search). Such variety provides balanced coverage of diverse scheduling paradigms. Second, these methods have appeared extensively in edge–cloud literature and in reputable journals, establishing their research relevance. Third, they have exhibited performance in dealing with fundamental edge–cloud issues such as sensitivity to latency, limited resources, and dynamic workloads. They have been popularly instantiated in simulation environments such as CloudSim, iFogSim, and EdgeCloudSim. Fourth, they can be obtained in the form of open-source code or can be easily coded, thereby ensuring reproducibility and fair comparison in a unified Weighted Scoring Model (WSM) environment. Lastly, the combination of the above factors makes the selected set of algorithms both pragmatically valuable and representative of the general landscape of heuristic-based edge–cloud scheduling.

A. Heterogeneous Earliest Finish Time (HEFT)

The HEFT algorithm is a well-known static heuristic for scheduling in heterogeneous computing environments. It assigns tasks based on upward rank and maps each task to the processor that incurs the minimum earliest finish time. HEFT has been popular in edge–cloud environments because of its efficiency in reducing overall makespan and its ease of implementation [22], [31]. The major characteristic of HEFT is to consider the earliest finish time, though it does not allow rescheduling in the event of dynamic change [32] and does not account for energy consumption, which proves to be a main drawback in edge environments [33]. In terms of adaptability, HEFT works with static DAGs (Directed Acyclic Graph) and pre-estimated task times, lacking dynamic feedback or re-optimization capabilities. It performs well in controlled environments but is not responsive to changes. Regarding resource utilization, HEFT uses task execution time and communication cost to prioritize task-node mapping, which helps achieve efficient load balancing and reduce idle time [34]. Minimizing the earliest finish time enables efficient resource distribution across heterogeneous nodes, making it well-suited for static resource planning.

B. Ant Colony Optimization (ACO)

Ant Colony Optimization (ACO) is a metaheuristic inspired by the foraging behavior of ants, where virtual “ants” probabilistically explore task assignments based on pheromone trails that reflect the quality of previous solutions. ACO has shown promise in optimizing multi-objective scheduling in dynamic edge–cloud environments by adapting to changing network or resource conditions [30]. Its adaptability stems from the use of pheromone updates, which encode historical experience and influence future scheduling decisions. However, ACO may require multiple iterations to converge, making it less responsive to immediate changes [35]. In terms of resource utilization, ACO builds better task-to-resource mappings over time, often leading to improved resource use as pheromone trails reinforce successful assignments. That said, its early iterations may result in suboptimal utilization before convergence is achieved [36]. ACO also faces several limitations: in its basic form, it is suitable only for small problem instances like the Traveling Salesman Problem with a limited number of cities, and it exhibits relatively high memory complexity of $O(n^2)$ [37]. Moreover, it is known to suffer from parameter sensitivity, limited scalability to large-scale problems, and challenges in real-time implementation [38].

C. Particle Swarm Optimization (PSO)

Particle Swarm Optimization (PSO) poses task assignment as a problem of swarm intelligence, where particles representing candidate solutions explore the search space based on both individual and collective experience [26]. PSO has been successfully applied in edge–cloud systems for task scheduling under latency and energy constraints, particularly in large-scale or uncertain workload scenarios [22]. Its popularity stems from its simplicity and effectiveness in handling nonlinear, multi-modal optimization problems, as well as its adaptability to various contexts such as scheduling, resource allocation, and feature selection [33]. From an adaptability viewpoint, PSO changes task placement of particles across iterations, gradually responding to changing constraints, albeit as a delayed responder and potentially requiring several iterations to adapt well to change [39]. From a resource utilization viewpoint, PSO changes workloads across resources based on the resources available, simulating particles converging to optimum node locations. The nature of this approach prevents skewed resource utilization and minimizes underutilization, which makes PSO a popular approach to resource-aware scheduling [39]. The computational cost, however, depends on the number of particles, the dimensionality of the solution space, and the iterations, and has a general $O(n \times d \times t)$ time complexity [40].

D. Min-Min and Max-Min Heuristics

Min-Min and Max-Min are popular but straightforward list schedule heuristics employed in heterogeneous computing environments. Min-Min chooses the task possessing the minimum of the earliest completion time on any available resource, and it performs well in cases where smaller tasks become prevalent, as they incur less waiting time and get processed faster [41], [42]. It has, however, a major flaw of causing large tasks to be delayed heavily, as they usually get pushed aside in favor of smaller ones [42]. Max-Min, on the other hand, chooses the task possessing the maximum of the minimum completion times and ends up assigning bigger tasks to the best node to complete them in the shortest time. It prevents large tasks from remaining perpetually on hold and suits well in cases of heterogeneous environments having varied requirements of the tasks and varying node capabilities.

There, however, exists the possibility of Max-Min getting inefficient in cases of high prevalence of tiny tasks, as they incur extra and needless waiting time [42]. Both of the above algorithms are deterministic and static, in that they adhere to fixed priority assignment policies and do not respond to varying levels of task arrivals, system loading, and availability of the nodes. Consequently, they are not suitable in dynamic or mobile edge–cloud environments [22], [42]. That implies, there exists no re-evaluation of the tasks once they become scheduled, and hence, they become inflexible in fluctuating conditions. In terms of resource utilization efficiency, they end up overloading faster nodes and keeping other ones idle, as a result of their static selection of the task and failure to adapt to the runtime variations of resource status.

E. Greedy Resource-Aware Heuristics

Greedy Resource-Aware Heuristics (GRAH) are high-speed, lightweight, and context-aware heuristics of scheduling, making locally optimal decisions based on real system parameters such as CPU utilization, memory, bandwidth, and latency to edge or cloud nodes [12], [43]. They become particularly valuable in real-time and latency-sensitive environments, in which they prioritize task assignment to the nearest or least-loaded node with adequate resources, in order to keep data transfer latency to a minimum and increase responsiveness. GRAH approaches have been widely implemented in mobile and fog computing scenarios due to their simplicity, low overhead, and adaptability to runtime conditions [42]. Unlike complex global optimizers, greedy algorithms do not require prior knowledge of future workloads, making them well-suited for dynamic edge–cloud environments. Their use of the current system state enables on-the-fly scheduling, ideal for large-scale, time-critical systems. In terms of adaptability, GRAH performs well by continuously reacting to changes in system load and node availability. Regarding resource utilization, these heuristics respond quickly to imbalances (e.g. by assigning tasks to the least-loaded nodes), but they lack a global view of the system. This can result in uneven distribution or suboptimal long-term resource use [44]. While GRAHs are generally more energy-efficient and responsive in fog or edge environments, they may struggle to achieve globally optimal performance when system dynamics evolve over time or require coordinated optimization [21], [42].

F. Tabu Search

Tabu Search (TS) is a metaheuristic optimization algorithm for solving complex combinatorial problems such as task scheduling, routing, and resource placement. It excels in large search spaces where traditional heuristics could become entrapped in local optima [45], [46]. In edge–cloud workload scheduling, TS may be applied to refine task assignments and investigate neighboring solutions near an initial schedule or one obtained heuristically. A hallmark of Tabu Search is the addition of a tabu list, a memory-oriented mechanism that prevents the algorithm from revisiting recently explored or suboptimal solutions. This encourages wider exploration and helps avoid cycles [46], [47]. TS can be easily extended to multi-objective optimization, effectively balancing trade-offs like makespan versus cost and load versus latency [45], [46]. TS excels in heterogeneous and dynamic environments, where its memory-guided refinement process helps escape local optima and reassign tasks based on system changes, demonstrating high adaptability [46], [48]. From a resource utilization standpoint, TS outperforms simpler heuristics by continuously refining how workloads are distributed. However, its success depends on proper configuration and how well it converges [46]. By evaluating neighboring solutions while avoiding previously visited ones, TS can maintain better overall resource balance across edge and cloud nodes.

G. Genetic Algorithm

Genetic Algorithm (GA) is an evolutionary optimization algorithm based on the natural selection process that works by evolving a group of possible solutions using operations like selection, crossover, and mutation. Over successive generations, these steps help improve how tasks are scheduled. In edge–cloud workload scheduling, GA is often used for optimizing multiple objectives at once, such as reducing makespan, energy consumption, resource usage, and execution cost, especially in heterogeneous and large-scale environments where exhaustive search becomes impractical [49]. GA is especially valued for its ability to discover near-optimal solutions in difficult, constraint-heavy problems, and it allows fine-tuning based on different factors like latency, energy, and cost. Many GA-based systems use customized fitness functions that specifically target better resource utilization and load balancing, which improves throughput and makes better use of CPU and memory [49], [50]. Still, implementing GA can be quite complex. It requires careful planning for parameters like population size, rates for crossover and mutation, and how fitness is calculated [49], [51]. While GA can adapt to changing requirements by gradually evolving its solutions, it isn't known for quick responsiveness since several generations are usually needed to adjust to changes [39]. Nonetheless, GA's strong scalability and solid performance across varied workloads make it a robust, albeit resource-intensive, solution for hybrid scheduling systems [49], [50].

These representative heuristic approaches represent the diversity and effectiveness of the strategies used for task scheduling optimization for edge-cloud environments. All the approaches exhibit their own strengths and weaknesses, contributing to the ongoing improvement of effective scheduling solutions.

VI. Weighted Scoring Model

Weighted Scoring Model (WSM) is among the methods of comparison as well as decision-making between options described by predefined criteria. The process is frequently applied in order to compare different algorithms.

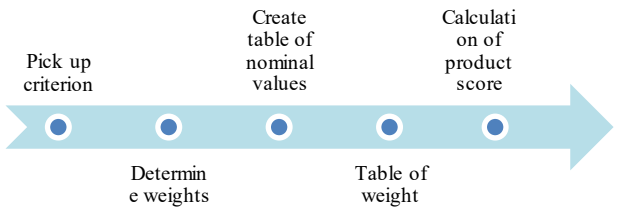

Fig. 2. WSM process [52].

Application of the method often happens through a series of steps, such as in Fig. 2 [52]:

- Step 1: Establish the criteria to be employed for each option.
- Step 2: Assign weights for the criteria as percentages of their priority.
- Step 3: Create a table summarizing nominal values for all of the criteria across different options.
- Step 4: Create a table displaying weighted values for all criteria with weights as percentages, ensuring the total weight sums to 100%.
- Step 5: Calculate weighted scores by multiplying nominal values by weights for each option [52].

VII. Comparison of Heuristic Algorithms

This section presents a comparative analysis of illustrative heuristic-based workload scheduling strategies for edge-cloud infrastructure. A comparison of these algorithms is done on the basis of some of the most significant factors of edge-cloud deployment [22], [53], such as latency awareness, energy efficiency, scalability, adaptability, Scheduling Accuracy, Implementation Complexity, and Resource Utilization, as mentioned in Table I.

A. Application of the Weighted Scoring Model

Weighted Scoring Model evaluates heuristics-driven workload scheduling algorithms on a variety of critical factors, each with a specific weight based on its relative importance in edge–cloud scenarios, as shown in Table II. Latency Awareness and Adaptability each have a weighting of 20%, since they serve a prime function in offering minimum delay and responsiveness in highly dynamic environments with changing workloads and mobility. Energy Efficiency and Scalability each have a weighting of 15% due to their function in enabling sustainable operations in resource-constrained edge devices and expanding infrastructure. Scheduling Accuracy, Implementation Complexity, and Resource Utilization each have a weighting of 10%, in consideration of their function in offering pragmatic, accurate, and cost-efficient task placement, but they can be impacted indirectly by factors of greater priority. This distribution strikes a balance between performance-critical metrics (latency, adaptability) and operational concerns (energy, complexity, utilization) tailored to hybrid edge–cloud contexts.

This weighted method allows for a systematic and clear comparison of the heuristic techniques, to support the choosing of the most suitable schedule strategy in hybrid edge–cloud. Every algorithm is rated on a score of 1 to 5 (n/a = 0), as in Table III, and multiplied by its corresponding weight. Table IV contains the final weighted scores.

It should be noted that the weighting scheme, while grounded in trends consistently emphasized in the edge–cloud scheduling literature, inevitably involves a degree of subjectivity. To mitigate this, we relied on recurring priorities reported across multiple surveys and empirical studies (e.g. the centrality of latency and adaptability in real-time applications). The influence of these parameters is that absolute rankings may vary under alternative weighting choices; however, the relative positioning of algorithms along specific criteria (e.g. some excelling in latency but weaker in energy efficiency) remains consistent with findings reported in the literature. The presented WSM is therefore intended as a structured synthesis tool rather than an absolute ranking, providing practitioners with a transparent framework that can be adapted or refined with alternative weighting schemes or sensitivity analyses in future studies.

It should be noted that the weighting scheme, while grounded in trends consistently emphasized in the edge–cloud scheduling literature, inevitably involves a degree of subjectivity. The influence of these parameters is that absolute scores or rankings may shift under alternative weighting schemes; however, the relative strengths and weaknesses observed for each algorithm (e.g. HEFT excelling in scheduling accuracy but lacking adaptability, or Greedy heuristics performing well in responsiveness) remain consistent with empirical evidence reported across prior studies. The presented WSM is therefore intended as a structured synthesis tool rather than an absolute benchmark. Future research could extend this work by conducting sensitivity analyses on the weighting distribution or by employing alternative multi-criteria decision-making frameworks such as AHP, TOPSIS, or entropy-based weighting to further validate robustness.

B. Comparison

Fig. 3 illustrates the comparative performance of seven scheduling algorithms across seven evaluation criteria: Latency Awareness, Energy Efficiency, Scalability, Scheduling Accuracy, Implementation Complexity, Resource Utilization, and Adaptability.

TABLE I. Comparison Criteria

Criterion	Description
Latency Awareness	Ability to minimize task response time and meet real-time constraints [53].
Energy Efficiency	Capacity to optimize energy usage, especially at resource-constrained edge nodes [41].
Scalability	Ability to perform well as the number of tasks/nodes increases [53].
Adaptability	Flexibility to operate under dynamic workloads and network conditions [53].
Scheduling Accuracy	measures how effectively an algorithm assigns tasks to appropriate resources, matches task needs with node capabilities, prevents overload or failures, and meets quality of service (QoS) goals like latency and availability.
Implementation Complexity	effort and overhead required to develop, deploy, and maintain a scheduling algorithm, considering factors such as algorithmic simplicity, computational requirements, integration effort, and tuning difficulty.
Resource Utilization	measures how efficiently a scheduling algorithm leverages available computing, memory, storage, and network resources, aiming to maximize usage while avoiding both underutilization and overload.

TABLE II. ASSOCIATED WEIGHT TO EACH CRITERION

Criterion	Abbreviation	Proposed weight
Latency Awareness	LA	20%
Energy Efficiency	EE	15%
Scalability	S	15%
Scheduling Accuracy	SA	10%
Implementation Complexity	IC	10%
Resource Utilization	RU	10%
Adaptability	A	20%

TABLE III. COMPARISON OF SCHEDULING ALGORITHMS IN EDGE–CLOUD ENVIRONMENTS

Algorithm	LA	EE	S	SA	IC	RU	A
Greedy Resource-Aware	5	4	5	3	4	3	5
Tabu Search	4	3	3	4	2	3	4
ACO	4	4	3	4	2	3	3
PSO	3	3.5	4	3	3	4	3
GA	3	3	4	4	2	4	3
HEFT	3	2	3	5	3	4	2
Min-Min / Max-Min	2	2	3	3	5	3	1

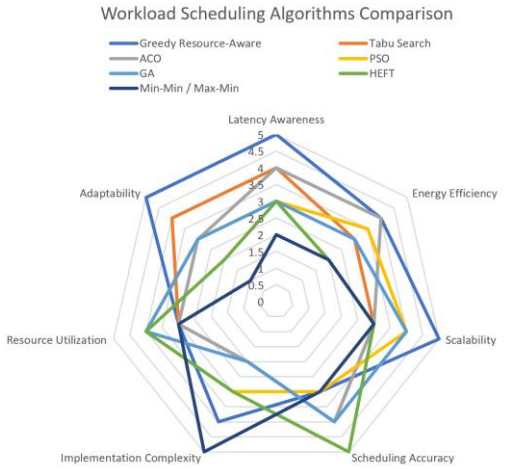

Fig. 3. Workload scheduling algorithms comparison across key evaluation criteria.

TABLE IV. WSM RESULTS

Algorithm	WSM Score	WSM Score (%)
Greedy Resource-Aware	4.35	87
Tabu Search	3.4	68
ACO	3.35	67
PSO	3.33	66.6
GA	3.25	65
HEFT	2.95	59
Min-Min / Max-Min	2.45	49

The Greedy Resource-Aware algorithm shows consistently high values in Latency Awareness, Scalability, and Adaptability, with moderately high scores in Energy Efficiency and Implementation Complexity. Its performance is slightly lower in Scheduling Accuracy and Resource Utilization.

Tabu Search demonstrates relatively high values in Latency Awareness, Scheduling Accuracy, and Adaptability, while showing moderate performance in Energy Efficiency and Resource Utilization. It records a lower score in Implementation Complexity.

ACO (Ant Colony Optimization) displays balanced scores across most criteria. It performs moderately well in Latency Awareness, Energy Efficiency, and Scheduling Accuracy, with slightly lower values in Adaptability and Implementation Complexity.

Genetic Algorithm (GA) shows strong performance in Scalability, Scheduling Accuracy, and Resource Utilization, with slightly lower values in Latency Awareness, Energy Efficiency, and Adaptability. It scores low in Implementation Complexity.

Particle Swarm Optimization (PSO) scores highest in Resource Utilization, with good values in Scalability and Energy Efficiency. It has moderate values in the remaining criteria, except for Latency Awareness and Adaptability, which are slightly lower.

HEFT shows its strongest score in Scheduling Accuracy, followed by relatively good performance in Implementation Complexity and Resource Utilization. It records lower values in Energy Efficiency, Adaptability, and Scalability.

Min-Min / Max-Min scores highest in Implementation Complexity, followed by moderate values in Scheduling Accuracy and Resource Utilization. It records lower scores in Latency Awareness, Energy Efficiency, Adaptability, and Scalability.

VIII. RESULTS AND DISCUSSION

Our comparison reveals clear differences in how each scheduling algorithm performs under various conditions. Greedy Resource-Aware Heuristics came out strong, particularly in latency awareness, scalability, and adaptability. Their strength lies in their simplicity and speed—they make quick decisions based on current system conditions, which is ideal for fast-changing edge–cloud environments. While they don't always find the most globally optimal solution, their ability to respond instantly makes them very practical for real-time applications.

Tabu Search also performed well, striking a good balance between accuracy and adaptability. Its use of memory to avoid repeating poor decisions allows it to improve over time and adjust to changing workloads. ACO and PSO showed solid results, especially in energy efficiency and resource usage. However, they typically need more fine-tuning and take longer to settle on the best solution. Genetic Algorithms offered strong scalability and were effective at handling multiple objectives, but their complexity and tuning requirements may pose challenges in real deployments. By comparison, HEFT

excelled in schedule predictability due to its rigorous methodology, but it is less adaptable to varying scenarios since it is inflexible. Min-Min and Max-Min, while they are easy to program, have limited flexibility and weaker performance in scenarios with sensitive latency constraints.

From a quantitative perspective, the average WSM score across all algorithms was 3.29 (65.8%), with values ranging from 2.45 (49%) for Min-Min/Max-Min to 4.35 (87%) for Greedy Resource-Aware. This 38-point spread underscores the heterogeneity of heuristic methods. Greedy Resource-Aware outperformed the lowest-scoring algorithm by 33%, reflecting its superior trade-offs across latency, scalability, and adaptability. Fig. 4 illustrates these differences through the final WSM scores, making clear the ranking and relative gaps among the seven algorithms.

At the criterion level, Scalability achieved the highest average score (3.57), while Adaptability was the lowest (3.0), confirming the literature's emphasis on adaptability as a persistent challenge. Pairwise comparisons highlight specific trade-offs: HEFT delivered the best Scheduling Accuracy (5.0), which was 66% higher than Greedy Resource-Aware (3.0), but performed poorly in adaptability (2.0). Conversely, PSO and GA achieved the strongest Resource Utilization (4.0), surpassing Greedy Resource-Aware (3.0) by 33%. Greedy Resource-Aware, however, exceeded GA in Adaptability by 29% (5 vs. 3). These trade-offs are further illustrated in Fig. 5, which shows the normalized contribution of each evaluation criterion to the overall performance of each algorithm, making visible the strengths and weaknesses across dimensions.

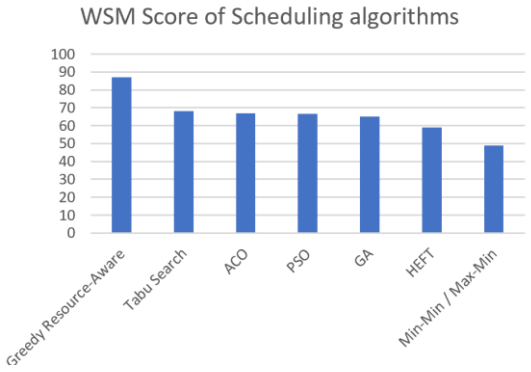

Fig. 4. WSM scores of scheduling algorithms.

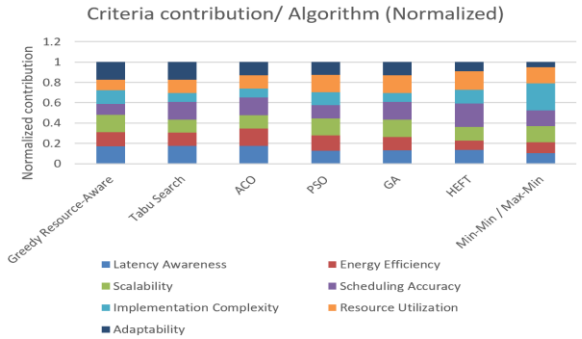

Fig. 5. Normalized contribution of each evaluation criterion to the overall performance of each algorithm.

Overall, our findings emphasize that adaptability is a major strength of edge–cloud scheduling. Algorithms, such as Greedy Heuristics and Tabu Search that can adapt on the fly do better in real-world scenarios. Simpler does not have to be weaker; Greedy approaches are excellent where quick decisions are more significant than optimal optimization. However, where accuracy or balancing several objectives matters more, more complex approaches such as ACO or Tabu Search may be more suitable. These findings provide useful direction to system designers in choosing the best approach suitable for their application's requirements.

It is important to note, however, that the comparative analysis presented here is derived from a literature-driven synthesis using the Weighted Scoring Model rather than from direct experimentation on large-scale, real-world edge–cloud testbeds. While this approach ensures a structured and transparent comparison across algorithms, it does not fully capture deployment complexities such as heterogeneous hardware, dynamic user mobility, or large-scale resource contention. The results should therefore be interpreted as a framework to guide algorithm selection rather than as definitive performance benchmarks. Future work could strengthen these findings by validating them through empirical studies on realistic testbeds or by performing sensitivity analysis on the weighting scheme to assess its influence on the rankings.

In addition, while prior works have evaluated individual heuristics or small subsets of algorithms, only a limited number of studies have attempted unified multi-criteria comparisons. For instance, some surveys assess algorithms qualitatively or focus narrowly on metrics such as energy efficiency or latency, but they do not provide a structured weighting and scoring process. Our WSM-based framework complements these efforts by offering a transparent, quantitative approach that integrates multiple evaluation dimensions. Nonetheless, a broader comparison with other decision-making frameworks and benchmark studies remains an important direction for future work.

IX. Challenges and Future Directions

While heuristic-based scheduling methods for edge-cloud computing have realized significant advances, they still face a series of challenges. Such challenges present tenable research opportunities for the enhancement of adaptability, efficiency, and scalability in the management of workloads on hybrid and distributed infrastructure.

A. Key Challenges

- Limited adaptability in dynamic environments: Many classical heuristics, like HEFT, Min-Min, and Max-Min, are designed for static or semi-static systems. Nevertheless, edge-cloud environments are inherently dynamic, with fluctuating workloads, network conditions, and resource states. Studies have shown that such heuristics can suffer 30–40% degradation in task completion time under dynamic conditions [8], whereas deep reinforcement learning (DRL) schedulers achieve ~25–35% faster scheduling times than metaheuristics

[6]. This gap underscores the need for adaptive or context-aware heuristics that can respond in real time.

- Suboptimal global scheduling caused by local decisions: While greedy heuristics are lightweight and efficient, they often make locally optimal decisions based on immediate node states. However, in large-scale or federated edge-cloud systems, this can result in globally suboptimal outcomes, such as unbalanced load distribution or resource starvation. Prior studies have reported that simple rule-based methods can incur 15–25% longer makespan compared to metaheuristic alternatives [4].
- High computational cost in metaheuristics: Approaches like PSO and ACO offer flexibility and multi-objective optimization. However, their computational demands remain a significant barrier for resource-constrained edge devices. For instance, hybrid PSO–Firefly methods improved resource utilization by ~20% but required 2–3× higher computation time compared to baseline heuristics [5]. This trade-off reduces the feasibility of real-time edge scheduling.
- Scalability in large-scale deployments: While many heuristics perform well in small-scale simulations, efficiency often degrades in large-scale, real-world deployments. Multi-objective GA and PSO variants exhibit scalability but can face exponentially increasing computation times as the number of tasks grows [7]. This scalability bottleneck hinders their application in real-time industrial edge-cloud systems.
- Energy efficiency and sustainability issues: Most heuristics prioritize latency and throughput while overlooking energy constraints. Yet, studies show that energy-aware heuristics can reduce consumption by 10–20% compared to traditional methods [8]. However, battery awareness and energy–latency trade-offs remain largely unaddressed, especially in mobile or IoT contexts.
- Security and privacy concerns: Existing heuristics rarely account for secure task placement. In multi-tenant edge-cloud systems, tasks may involve sensitive data, requiring privacy-preserving or trust-aware scheduling strategies.
- Uncertainty in workload prediction: Many heuristics assume prior knowledge of task execution times or resource availability. In practice, workloads are unpredictable, and inaccurate estimations can lead to degraded performance.
- Lack of standardized benchmarks and validation: Current heuristic evaluations are fragmented across different simulators and testbeds, with no standardized benchmark suite. This inconsistency makes cross-study comparisons difficult and reduces the reliability of results.

B. Future Research Directions

- Designing adaptive heuristics: In future works, focus should be placed on developing context-aware or adaptive heuristics that can deal with changes in workload characteristics, resource availability, and user mobility in real time.
- Lightweight metaheuristic variants: Optimizing and simplifying metaheuristics such as ACO and PSO, through parameter tuning, pruning, or hybridization with greedy rules, can make them feasible for real-time edge scheduling.
- Hybrid scheduling models: It is claimed that adaptive multi-objective schedulers that maintain performance while controlling complexity can be obtained by integrating the different strengths from various heuristics, such as Min-Min combined with PSO or HEFT with greedy prioritization.
- Energy and SLA-aware extensions: adding energy models, battery-awareness, and SLA-awareness to traditional heuristics algorithms could greatly enhance their applicability for edge computing in real life.
- Validation on real-world testbeds and benchmarks: Beyond theoretical and literature-driven comparisons, future studies should validate scheduling strategies through experiments on realistic, large-scale edge-cloud testbeds. Such validation would account for hardware heterogeneity, user mobility, and dynamic network states, providing stronger evidence of practical feasibility. Additionally, integrating standardized benchmarks would allow fairer comparisons across heuristic approaches.
- Comparative frameworks refinement: While the WSM-based evaluation presented in this paper offers a structured multi-criteria perspective, it remains one of the few efforts of its kind. Future work should extend this by comparing WSM with alternative decision-making frameworks (e.g. AHP, TOPSIS, or data-driven weighting methods) to ensure robustness and reduce subjectivity in rankings.

In summary, while heuristic-based scheduling is promising for edge–cloud computing, it faces critical limitations in adaptability, scalability, heterogeneity management, and real-world validation. Quantitative evidence from recent studies highlights performance gaps of up to 40% in dynamic adaptability, 25% in makespan efficiency, and 20% in energy consumption, confirming the need for new strategies. Future research should prioritize the development of lightweight adaptive heuristics, hybrid models, and energy-aware approaches, validated through standardized benchmarks and realistic testbeds. Such efforts will ensure that heuristic scheduling evolves to meet the complex performance demands of next-generation edge–cloud systems.

X. Conclusion

This paper illustrated a comprehensive review and comparative analysis of heuristic-based workload scheduling methods in hybrid edge–cloud systems. Based on the methodological diversity, coverage in literature, and practical applicability, seven representative algorithms: Greedy Resource-Aware Heuristics, HEFT, Min-Min/Max-Min, Genetic Algorithm (GA), Particle Swarm Optimization (PSO), Ant Colony Optimization (ACO), and Tabu Search were chosen. A Weighted Scoring Model (WSM) was utilized to compare the aforementioned methods on the basis of major criteria: latency awareness, energy efficiency, scalability, scheduling accuracy, implementation complexity, resource utilization, and adaptability.

Results indicate that every algorithm possesses different strengths. Greedy heuristics excel in low-latency and dynamic environments because of their quick responsiveness and reduced complexity. Tabu Search and ACO have good adaptability and multi-objective optimization, but may have long convergence times. PSO has the strength of balance in optimization quality and reduced computational cost, especially in large-scale or uncertain environments. Genetic Algorithms have high scalability and flexibility, but have the cost of increased implementation complexity. Static approaches such as HEFT and Min-Min/Max-Min are still applicable to unstructured or predictable workloads, but they are inflexible in the presence of real-time conditions.

Beyond these descriptive findings, the study highlights several analytical insights. First, there is no universally optimal heuristic: trade-offs between adaptability, scalability, and efficiency remain evident. Second, adaptability consistently emerged as the weakest dimension across algorithms, confirming it as a central research gap in heuristic scheduling. Third, lightweight approaches such as Greedy, while often dismissed as simplistic, may outperform complex methods when responsiveness is prioritized over optimality. These observations provide actionable guidance for selecting scheduling strategies that best align with specific edge–cloud scenarios.

It is important to recognize the limitations of this study. The comparison was restricted to seven algorithms that, while representative, do not capture the full breadth of heuristic and metaheuristic methods. The WSM approach, though systematic, relies on subjectively chosen weights that may bias rankings toward particular criteria. Furthermore, the evaluation was literature-driven and did not involve direct validation on real-world, large-scale edge–cloud deployments. These limitations mean that results should be interpreted as a structured framework for comparative understanding rather than definitive performance benchmarks.

Future work will address these limitations by expanding the algorithm set, experimenting with alternative multi-criteria decision-making frameworks such as AHP or TOPSIS, and validating the findings on realistic testbeds. In addition, further research will explore the design of adaptive and hybrid scheduling methods that integrate the responsiveness of lightweight heuristics with the optimization accuracy of metaheuristics or learning-based approaches. By confronting the challenges of adaptability, heterogeneity, and scalability, such efforts will ensure that heuristic scheduling evolves to meet the complex performance requirements of next-generation edge–cloud systems.

***Abstract*—Sign language serves as a primary mode of communication for individuals who are deaf or speech impaired, using hand gestures to convey meaning visually. While it facilitates communication among the deaf community, it presents challenges for interaction with those who rely on spoken language. This study aims to recognize hand signs representing the letters A to Y (excluding J and Z) in the Indonesian Sign Language (SIBI) using image-based input. A custom dataset was collected through personal photo shoots and used to train a Convolutional Neural Network (CNN) implemented in Python using the TensorFlow library. The study also focuses on optimizing the CNN architecture to achieve high classification accuracy. Evaluation using a confusion matrix on the test data resulted in an overall accuracy of 87.1%, while real-time testing achieved an accuracy of 90.25%. The number of convolutional filters and dropout rates was adjusted to prevent underfitting and overfitting during model training.**

***Keywords*—Indonesian Sign Language; hand sign recognition; image classification; Convolutional Neural Network**

I. Introduction

According to the World Health Organization, more than 5% of the global population, approximately 430 million people, experience hearing loss greater than 35 decibels (dB) [1]. In Indonesia, around 7.03% of individuals with disabilities are categorized as deaf [2]. Deaf individuals use sign language to communicate, forming words and sentences through hand gestures. Sign language is a visual-gestural language that relies on movement and perception through vision [3]. It enables communication within the deaf community; however, interactions with people who rely on spoken language remain challenging.

In Indonesia, two main sign language models are used: the Indonesian Sign System (SIBI) and the Indonesian Sign Language (BISINDO). SIBI employs right-hand movements to represent alphabetical characters and is officially standardized by the Indonesian Ministry of Education and Culture [4]. BISINDO, in contrast, uses both hands and has developed organically within Indonesian society, resulting in regional variations. While BISINDO is widely used informally, SIBI remains the formal and standardized model.

Recent advancements in deep learning technology offer potential solutions for automating sign language recognition. One prominent algorithm in this domain is the Convolutional Neural Network (CNN), a type of deep learning model designed to process visual data [5]. Despite many studies applying CNNs for sign language recognition in various countries [6–11], there is limited research focusing on Indonesian Sign Language, particularly the SIBI model, using custom datasets collected in varied real-world conditions. This gap highlights the need for approaches tailored to the Indonesian context.

This study aims to address this gap by developing and optimizing a CNN-based model for classifying 24 SIBI hand signs (excluding J and Z). The model is trained on a custom image dataset collected via smartphone and webcam. The objectives of this research are to:

1) Design a CNN architecture suitable for classifying Indonesian SIBI signs.

2) Evaluate the impact of convolutional filter configurations and dropout rates on model performance.

3) Validate the model's accuracy through offline and real-time testing using confusion matrix analysis.

By providing a lightweight, efficient, and accurate CNN model trained on a custom dataset, this study contributes to improving accessibility and communication support tools for the Indonesian deaf community.

II. Related Works

Various kinds of previous studies have been proposed to recognize sign language. Sign languages in various countries have different signs, such as studies using Indian [6], Pakistani [7], Arabic [8], Bangla [9], Brazilian (Libras) [10], and Indonesian Sign Language with the BISINDO model [11].

In [6], A CNN-based Indian Sign Language (ISL) recognition system was developed to enable real-time hand gesture detection via a camera, achieving over 90% accuracy and was deployed on mobile devices using TensorFlow Lite and Flutter to enhance communication accessibility for the deaf-mute community. Research [7] Principal Component Analysis (PCA) and K-Nearest Neighbors (KNN) were applied, achieving 85% accuracy on test data and 80% when evaluated via webcam. Research [8] utilized the Faster R-CNN method.

*Corresponding author.

Using the ResNet-18 architecture yielded an accuracy of 93.4%, while VGG-16 achieved 93.2%. The work in [9] employed the YOLOv4 object detection model, obtaining an overall detection accuracy of 97.95%. In [10], a CNN-based approach with the VGGNet architecture was implemented. In [17], the study explored several input image sizes: 32×32 pixels (97.98% accuracy), 64×64 (99.42%), 128×128 (97.40%), and 256×256 (86.99%). Study [11] also adopted a CNN method, comparing multiple architectures. The modified version of AlexNet achieved an accuracy of 98.6%, while the modified VGG-16 architecture underperformed with only 3.8%. A novel architecture introduced in the same study, referred to as the C model, reached 98.3% accuracy.

Although various deep learning models have been applied in previous studies, such as Faster R-CNN [8], YOLOv4 [9], and modified architectures of AlexNet and VGG [10] [11], most of them require complex setups or large training resources. Furthermore, these models were developed for different language systems and may not generalize well to the Indonesian context. Compared to these methods, CNN offers a balanced trade-off between accuracy, computational efficiency, and ease of implementation.

This study focuses on a lightweight CNN model that is suitable for small-scale deployment with limited GPU resources. Our approach eliminates the need for extensive pre-training or large-scale datasets, making it more feasible for real-world applications in Indonesia.

III. METHODS

The research methodology in this study consists of several stages: data collection, data transformation, data splitting, CNN model training, prediction, and evaluation. An overview of these stages is illustrated in Fig. 1.

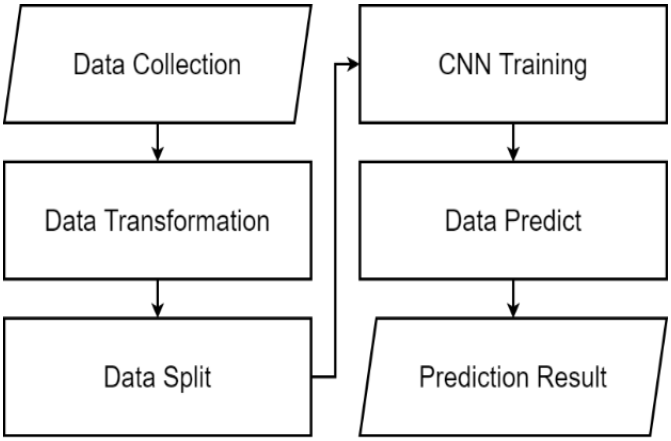

Fig. 1. Research stages.

The study began with the collection of sign language data. A total of 5,280 images were captured through self-recording using smartphones and webcam cameras. The next stage involved data transformation, which included resizing, grayscale conversion, data augmentation, and normalization.

Once transformed, the data were divided into two main sets: training and testing data. The core phase of the study was the training of a CNN model using the prepared dataset. Following training, the model was evaluated to assess its accuracy. Subsequently, testing was conducted using both the test dataset and newly captured images from a webcam to evaluate the model's ability to classify and predict sign language gestures in real time.

The following are some basic points that will be used in this research:

A. Data

The data used in this study consists of images representing Indonesian Sign Language (SIBI) hand gestures using the right hand. The dataset was collected independently [12], capturing variations in hand position, lighting, and background. The devices used for data collection included smartphone cameras and laptop webcams. The full dataset is accessible online [12].

B. Convolutional Neural Network

Convolutional Neural Networks (CNNs) are widely used for tasks such as speech recognition, image classification, and 3D object recognition. A typical CNN architecture includes two main components: a feature learning component and a fully connected layer. The feature learning section consists of convolutional layers, ReLU activation functions, and pooling layers. The fully connected layer is composed of neurons that process the extracted features to perform final classification. An overview of the general CNN architecture is presented in Fig. 2.

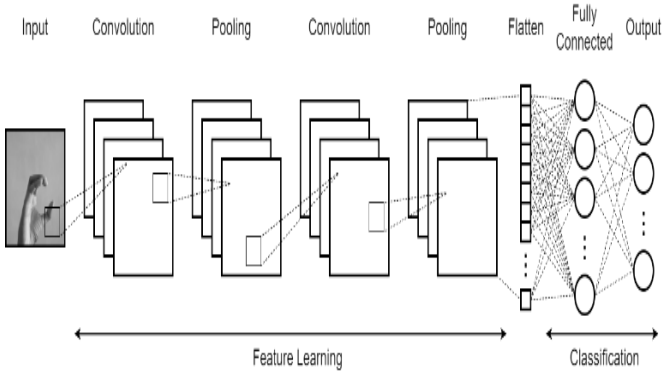

Fig. 2. Architecture of the CNN.

Convolution is the fundamental operation in CNNs, involving a matrix-based filtering process. This operation applies a filter (or kernel) matrix to an input image matrix to extract features, as defined in [13]:

$$\text{net}[i,j] = (x * w)[i,j] = \sum_m \sum_n x[m,n]\, w[i-m, j-n] \quad (1)$$

In this equation, w denotes the image matrix and x denotes the filter matrix. The convolution of these matrices results in a new feature map representing the output image. Indices i and j refer to the image matrix, while m and n refer to the kernel.

This study proposes a simple architecture consisting of the following layers:

- Convolutional layer 0,
- Max pooling layer 0,
- Convolutional layer 1,

- Dropout layer 0,
- Convolutional layer 2,
- Max pooling layer 1,
- Dropout layer1,
- Flatten layer
- Two fully connected layers.

This proposed architecture is illustrated in Fig. 3.

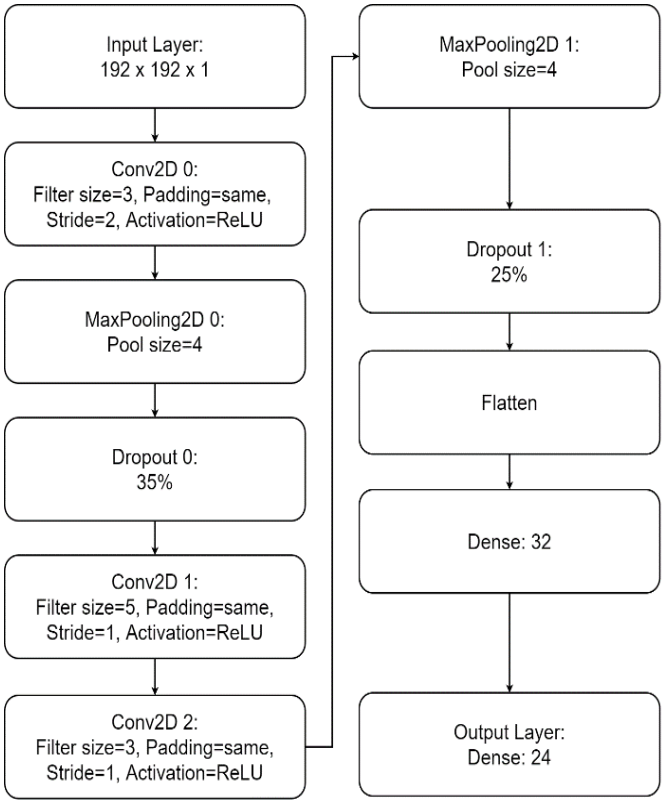

Fig. 3. Architecture model.

1) Baseline comparison and validation design: To validate the effectiveness of the proposed CNN architecture, we compared it with a basic CNN baseline model using fewer layers and no dropout. Both models were trained on the same dataset using identical preprocessing and training parameters. The baseline model consisted of a single convolutional layer followed by pooling and a fully connected layer.

Performance comparison between the proposed and baseline models is summarized in Table II. The proposed model achieved a higher accuracy (87.1%) compared to the baseline model (74.5%), and showed better generalization, as indicated by closer training and validation accuracy curves. Furthermore, F1-score, precision, and recall metrics improved by more than 10% on average per class.

This result confirms that the architectural optimizations—particularly in the number of convolutional filters and dropout rates—significantly improved classification performance and minimized overfitting.

C. Evaluation

The proposed CNN model was evaluated using a confusion matrix. This matrix produces four types of values: True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN). These values were used to calculate performance metrics, including accuracy, precision, recall, and F1-score for each class. The confusion matrix serves as a basis for assessing the classification model's performance. Table I presents the layout of the confusion matrix [14].

TABLE I. CONFUSION MATRIX

Prediction	Actual Value	
	Positive	**Negative**
Positive	True Positive (TP)	False Positive (FP)
Negative	False Negative (TN)	True Negative (TN)

Definitions:

- True Positive (TP): Positive instances correctly classified.
- True Negative (TN): Negative instances correctly classified.
- False Positive (FP): Negative instances incorrectly classified as positive.
- False Negative (FN): Positive instances incorrectly classified as negative.

Based on these values, the following metrics were computed:

1) Overall Accuracy: Proportion of correct predictions out of total predictions [15][16]:

$$\text{Overall Accuracy} = \frac{\text{Number of correct predictions}}{\text{Total Number of predictions}} \quad (2)$$

2) Per-class Accuracy: Accuracy calculated for each class individually (macro average), while overall accuracy is a micro average [15].

$$\text{Accuracy} = \frac{\text{TP}+\text{TN}}{\text{TP}+\text{TN}+\text{FP}+\text{FN}} \quad (3)$$

3) Precision: Measures the accuracy of positive predictions.

$$\text{Precision} = \frac{\text{TP}}{\text{TP}+\text{FP}} \quad (4)$$

4) Recall (Sensitivity): Measures the model's ability to correctly detect positive instances.

$$\text{Recall} = \frac{\text{TP}}{\text{TP}+\text{FN}} \quad (5)$$

5) F1-score: The harmonic mean of precision and recall.

$$\text{F1} - \text{score} = 2 \text{ x } \frac{\text{precision x recall}}{\text{precision}+\text{recall}} \quad (6)$$

IV. RESULTS

A. Dataset Collection

The dataset used in this study is privately collected, comprising 5,280 images captured through self-recording [12].

The data consist of two types of images: 1) high-resolution RGB images (3000×3000 pixels) taken using a smartphone camera, and 2) lower-resolution grayscale images (250×250 pixels) taken using a webcam.

The dataset includes 24 hand gestures representing the SIBI alphabet (letters A to Y, excluding J and Z), with 220 images per class. An example of the dataset is shown in Fig. 4.

Fig. 4. Data sample.

B. Data Transformation

This stage involves transforming the data into a format suitable for training. The following techniques were applied:

1) Resize: All images were resized to 192×192 pixels and converted to grayscale to reduce computational load during training.

2) Grayscale: RGB images, composed of Red, Green, and Blue layers, were converted to grayscale using a weighted average of RGB channels. The grayscale transformation process is illustrated in Fig. 5 and Fig. 6.

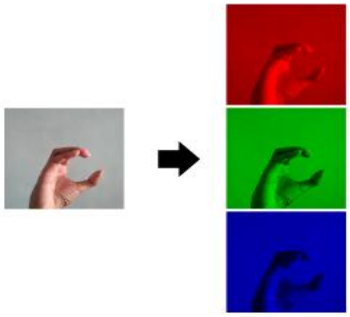

Fig. 5. RGB Data sample

Fig. 6. Grayscale image.

3) Data augmentation: Augmentation techniques were applied to increase dataset diversity. Thirty images per class were selected for transformation using random rotation (0.085), random zoom (0.1), and random translation (0.15). Images exceeding frame bounds were padded with black (zero constant). Sample augmentation results are shown in Fig. 7.

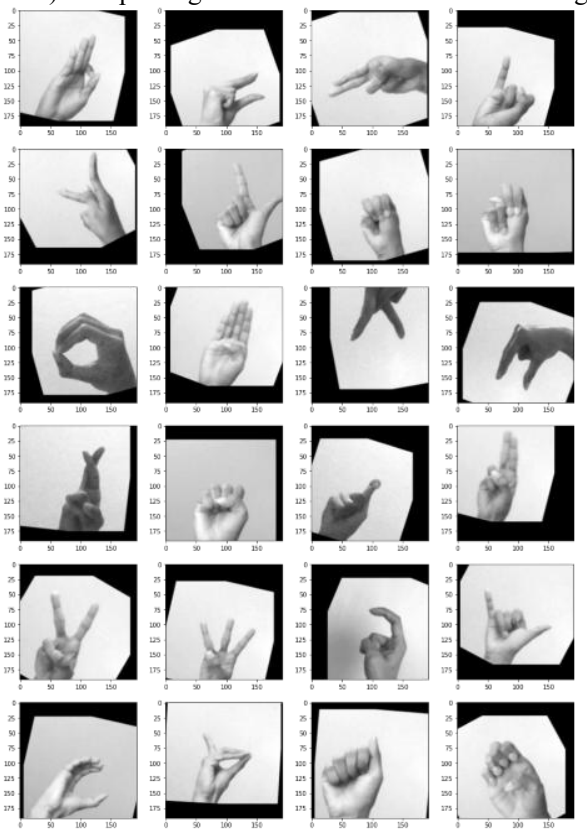

Fig. 7. Augmentation data sample.

C. Data Split

After augmentation, the dataset increased to 6,000 images (5,280 original + 720 augmented). The data were split as follows: 68% for training, 17% for validation, and 15% for testing.

D. Training Process

The CNN model was trained using a computer with an Intel Core i5-10210U CPU and NVIDIA GeForce MX330 GPU (2GB VRAM, GDDR5). A total of 720 images were used for testing.

Five different CNN configurations were evaluated by adjusting the number of convolution filters and dropout rates, while keeping filter size, stride, and padding constant. Table II lists the model architectures tested. The training used several parameters shown in Table III.

TABLE II. TRAINING PARAMETERS

Parameter	Value
Optimizer	Adam
Learning Rate	0.001
Loss Function	Categorical Cross-entropy
Epochs	80

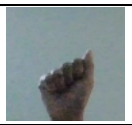
TABLE III. MODEL ARCHITECTURE TESTING

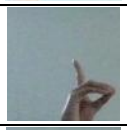
No.	Parameter				
	Conv0	Dropout0	Conv1	Conv2	Dropout1
1	48	-	96	192	-
2	24	-	48	96	-
3	24	0,35	48	96	0,25
4	48	0,35	96	192	0,25
5	24	0,85	48	48	0,75

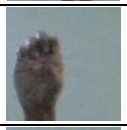
E. Testing Model

Testing the model from the CNN algorithm that has been made, then testing using a confusion matrix by testing the image from the test data, as many as 15% or 900 data units. This test was carried out five times to determine the level of accuracy, duration of training, accuracy graph, loss graph, and whether the two graphs were overfit or underfit. The parameters that are changed are the number of convolution filters and dropouts, while the filter size, stride, and padding in the filter are not changed. Table IV is the result of a comparison of the training that has been done.

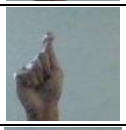
F. Real-Time Testing







The architecture used for real-time testing corresponds to configuration number 3 in Table IV, which previously demonstrated the best performance. The testing was conducted using the right hand to perform SIBI (Sistem Isyarat Bahasa Indonesia) sign language gestures within the detection area of a standard laptop webcam. The system was implemented as a desktop application.



The testing results, including accuracy per class, are listed in Table V. The model achieved an average accuracy of 90.25%. However, lower accuracy was observed for the letters M and N, which can be attributed to their visual similarity, making them more difficult to distinguish during classification.

TABLE IV. TRAINING COMPARISON RESULTS

No.	Accuracy	Training Duration
1	82,4	10m 39,3s
2	80,0	6m 8,4s
3	87,1	6m 20,4s
4	90,3	11m 6,2s
5	46,6	5m 44,9s

TABLE V. REAL-TIME TEST RESULTS

V. Discussion

The results of the training, along with the corresponding graphs and confusion matrix shown in Table III, are presented as follows:

1) First test: In this test, the model configuration corresponds to Test 1 in Table IV. The training and validation accuracy graphs, along with the confusion matrix, are shown in Fig. 8 and Fig. 9. The graph indicates signs of overfitting, as the validation accuracy plateaus after the 20th epoch and exhibits a substantial gap compared to the training accuracy. Additionally, the loss graph shows a noticeable increase starting from the 45th epoch, further confirming the presence of overfitting.

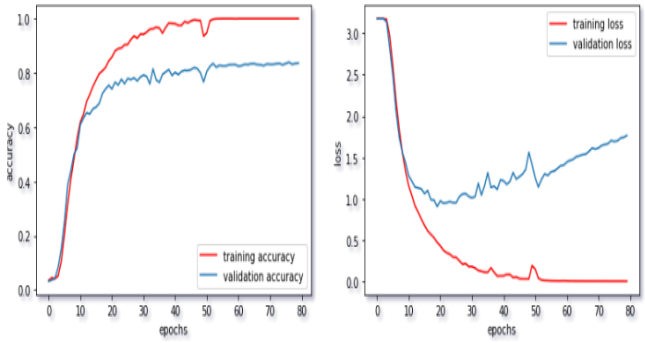

Fig. 8. Graph of the first test result.

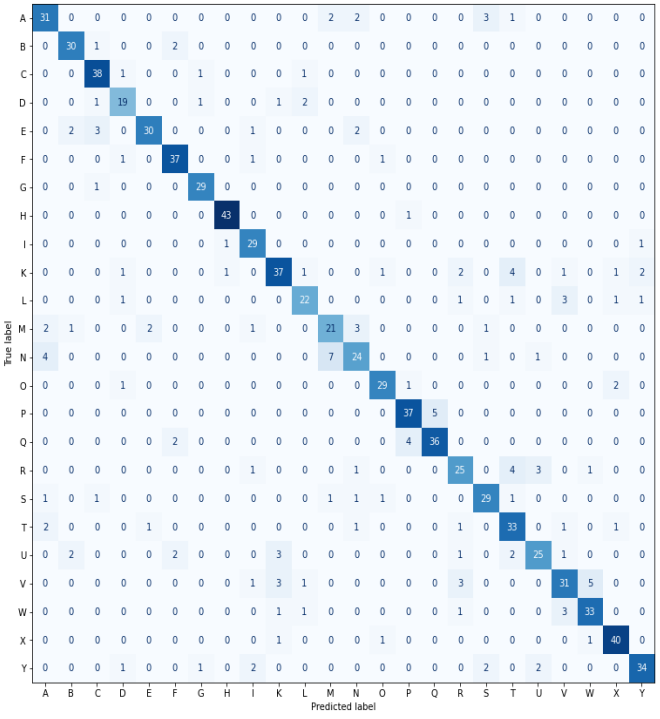

Fig. 9. Confusion matrix for the first test.

2) Second test: This test uses the configuration listed as Test 2 in Table IV. The training and validation graph, as well as the confusion matrix are presented in Fig. 10 and Fig. 11. According to [18], overfitting can occur when the neural

network fails to improve its performance during training. In this case, signs of overfitting appear after the 20th epoch, where validation accuracy stagnates and deviates significantly from training accuracy. The loss curve also rises steadily without decreasing as training progresses.

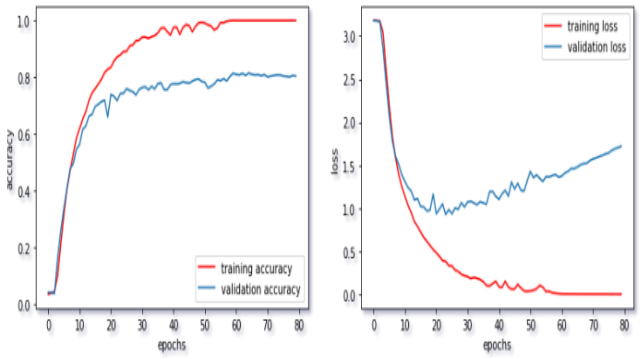

Fig. 10. Graph of the second test result.

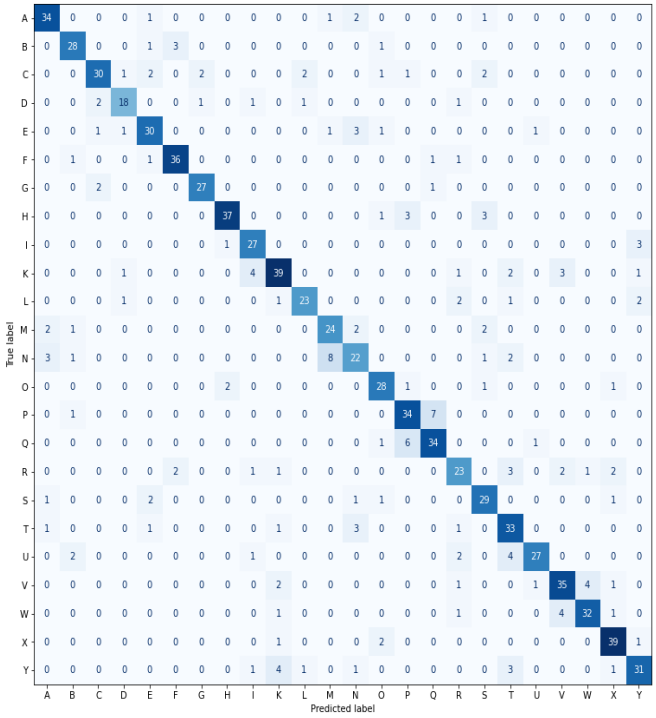

Fig. 11. Confusion matrix for the second test.

3) Third test: The configuration for this test is listed as Test 3 in Table IV. The training and validation graphs, along with the confusion matrix, are shown in Fig. 12 and Fig. 13. In this test, validation accuracy closely follows training accuracy, and the validation loss also aligns well with training loss throughout the training process. This indicates that the model avoids both underfitting and overfitting, resulting in high and stable accuracy.

4) Fourth test: The model configuration in this test is listed as Test 4 in Table IV. The corresponding graphs and confusion matrix are presented in Fig. 14 and Fig. 15. As noted in [9], convolutional layers with a large number of filters tend to require longer training times. This configuration yields the highest accuracy among the tests; however, slight overfitting is observed after the 25th epoch, where the validation accuracy shows minimal improvement.

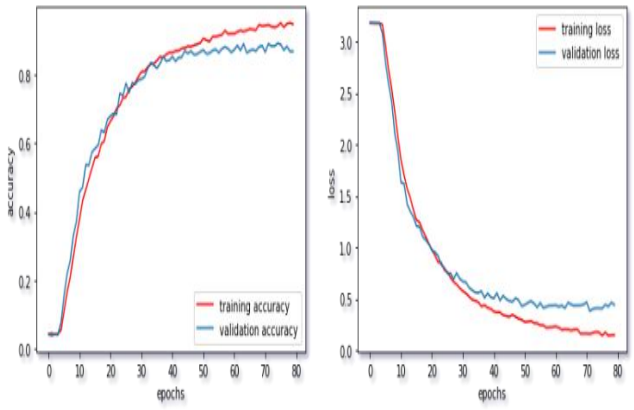

Fig. 12. Graph of the third test result.

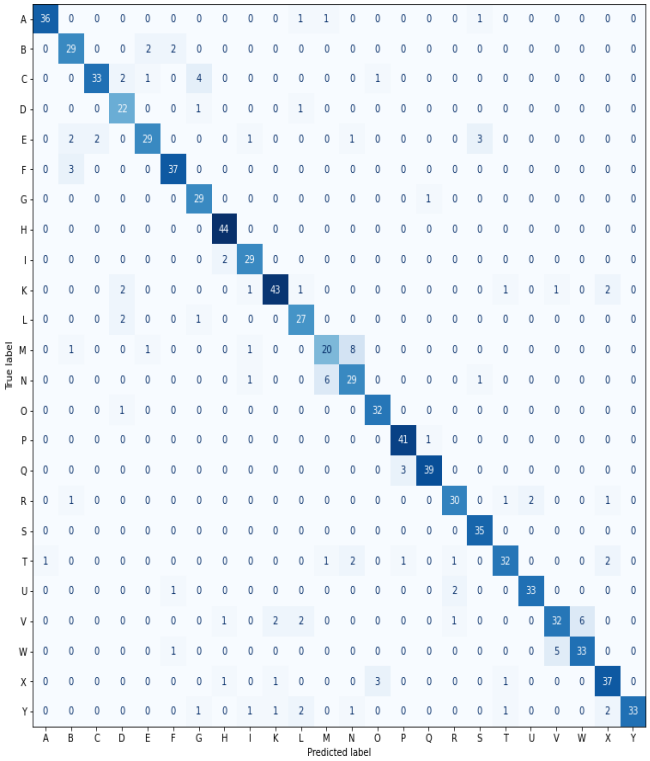

Fig. 13. Confusion matrix for the third test.

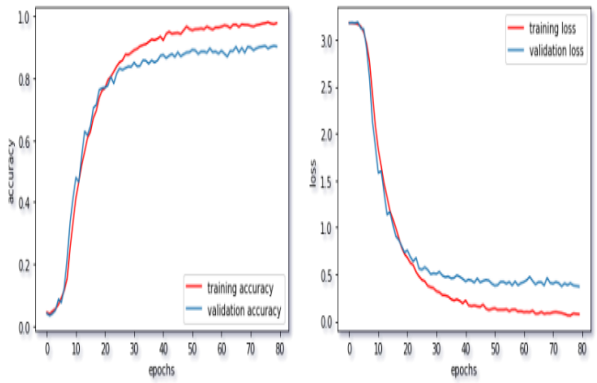

Fig. 14. Graph of the fourth test result.

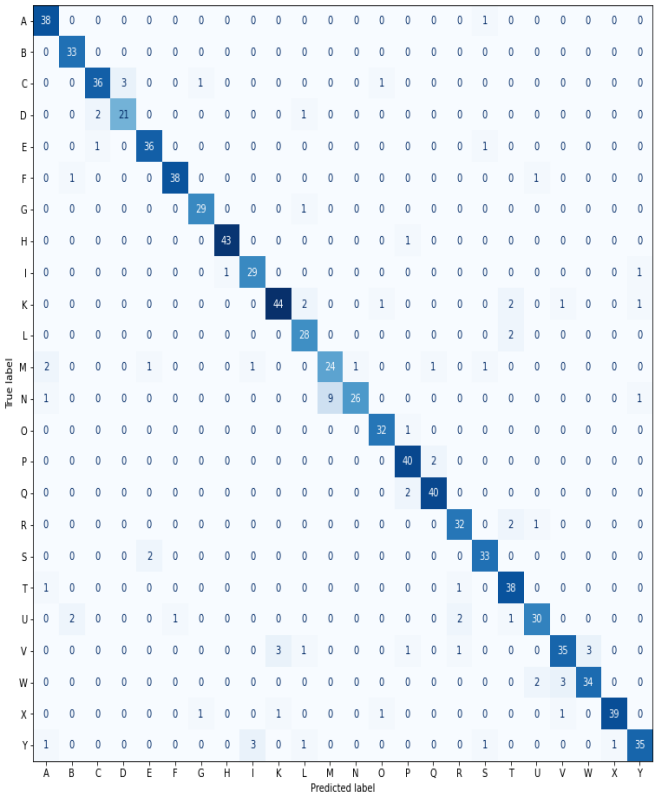

Fig. 15. Confusion matrix for the fourth test.

5) Fifth Test: This test uses the configuration listed as Test 5 in Table IV. The corresponding training graphs and confusion matrix are shown in Fig. 16 and Fig. 17. This model employs the lowest number of filters among all configurations. As stated in [13], network performance can be influenced by the depth of the architecture. In this test, the model achieves the lowest accuracy and the highest loss. The graph indicates underfitting, as the validation accuracy exceeds the training accuracy, suggesting the model is not learning effectively.

Among the five model architectures tested in Table IV, Test 3 yields the best performance, achieving high accuracy without signs of overfitting or underfitting. The final confusion matrix used to calculate per-class accuracy, precision, recall, and F1-score is presented in Fig. 18. While this figure demonstrates high overall accuracy, the precision, recall, and F1-score values are relatively lower, indicating potential room for improvement in class-level predictions.

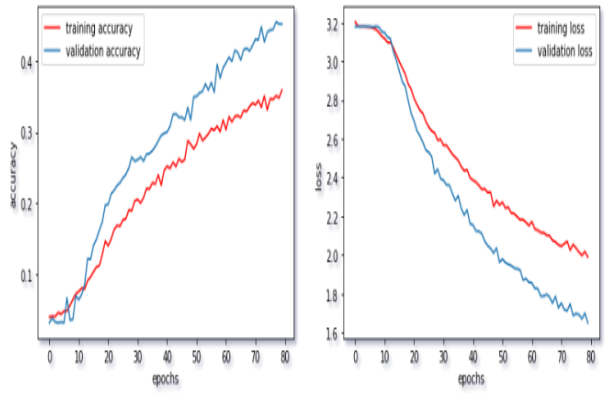

Fig. 16. Graph of the fifth test result.

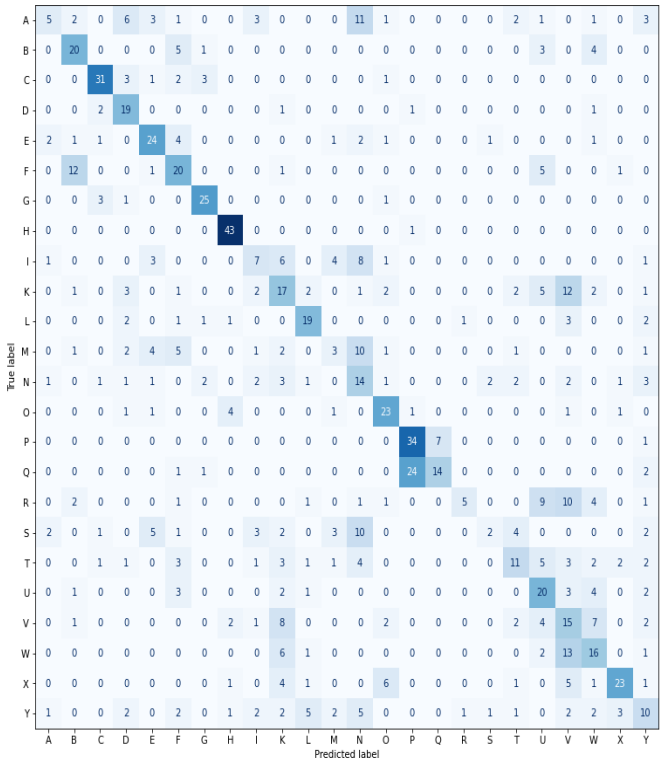

Fig. 17. Confusion matrix for the fifth test.

Compared to the baseline CNN model without architectural optimization, the proposed model demonstrates a significant improvement in both accuracy and robustness. While the baseline model produced acceptable results for simple gesture recognition, it suffered from overfitting and lower generalization on real-time webcam input.

Our optimized architecture achieved performance comparable to or exceeding that of related studies [9][10], despite being trained on a smaller, personalized dataset. This highlights that even lightweight CNN architectures can deliver strong performance when properly tuned and applied to targeted data.

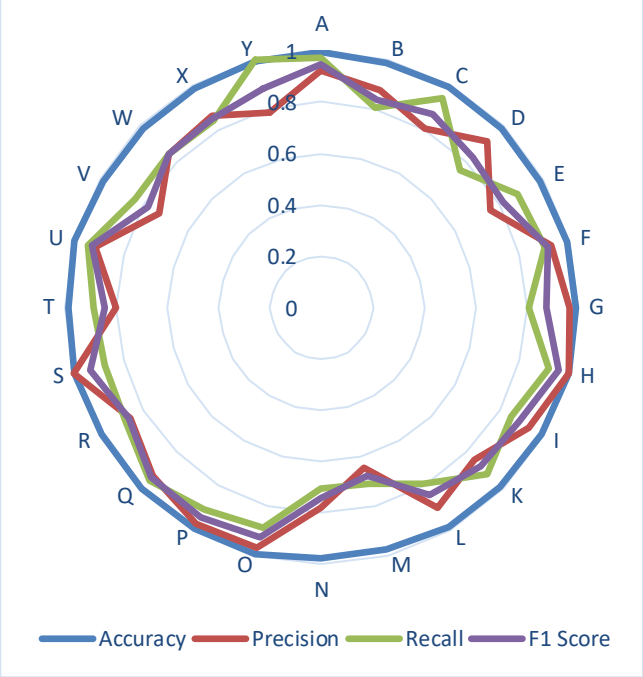

Fig. 18. Confusion matrix result.

Despite the promising results, this study has several limitations. The dataset used was relatively small and collected in controlled conditions, which may not fully capture variations in lighting, background, and hand positioning encountered in real-world environments. Furthermore, the scope of recognition was restricted to 24 SIBI alphabet signs, excluding letters J and Z due to their dynamic motion-based representation. These limitations may affect the model's generalizability when applied to more diverse or continuous sign language inputs.

Nevertheless, the findings demonstrate that lightweight CNN architectures can be effectively optimized to deliver robust performance even with modest datasets. This highlights the potential for deploying such models in practical applications, such as educational tools, real-time communication aids, and mobile platforms designed to bridge communication gaps for the deaf community.

Future research could focus on expanding the dataset to include more participants, environmental variations, and dynamic gestures such as J and Z. Integrating the model with real-time mobile or web-based applications would also provide practical validation of its effectiveness in everyday scenarios. Additionally, exploring advanced architectures, such as transfer learning or hybrid CNN–RNN models, may further improve recognition accuracy and support continuous sign language translation.

VI. Conclusion

This study demonstrates that optimizing the number of convolutional filters and dropout rates significantly improves the performance of CNN-based models for Indonesian Sign Language (SIBI) recognition. The best configuration achieved 87.1% accuracy on the test set and 90.25% accuracy in real-time scenarios, with no indication of overfitting or underfitting.

The results indicate that lightweight CNN architectures, when properly tuned, can perform effectively even in resource-constrained environments. Compared to heavier architectures like Faster R-CNN, YOLOv4, AlexNet, or VGG reported in other studies, the proposed model offers advantages in terms of computational efficiency and speed. However, a direct empirical comparison on the same dataset remains to be conducted to fully validate claims of superiority.

Currently, the system relies on cropped hand images, limiting its flexibility in real-world scenarios. Automatic hand detection through object detection methods has not yet been implemented, representing an important avenue for future improvement.

Future work will focus on extending the model to recognize dynamic gestures, such as the letters J and Z, integrating object detection techniques to automatically identify relevant hand regions, and deploying the system as a mobile-based application for real-time sign language interpretation. Incorporating these enhancements will improve robustness and usability, making the system more practical for inclusive communication tools.

***Abstract*—This paper presents a control system optimization of an ocean wave simulator using a meta-heuristic optimization. The proposed control system involves finding leg length trajectories by an Inverse Kinematics (IK) to be used as references for a Proportional-Integral-Derivative (PID). PID gains are tuned using a Salp Swarm Algorithm (SSA) with a Root Mean Square Error (RMSE) of leg position errors as a performance index. A Stewart platform dynamic is modeled in Simscape Multibody, integrated with a trajectory generator, an IK module, and a control system diagram block in Simulink models. The Simulink model of Stewart platform dynamics is then called in the optimization procedure by writing the programming code in MATLAB. Results show that the SSA outperforms other meta-heuristic methods, namely a Genetic Algorithm (GA) and a Particle Swarm Optimization (PSO), achieving the lowest fitness value, 16.8% and 8.7% lower than GA and PSO, respectively. Moreover, the SSA avoids boundary-trapping issues encountered by the PSO, which is stuck at its upper bound. The SSA has successfully enhanced the simplified version of the PID control system, where the scenario of the simplified PID-SSA scenario achieves better tracking error performance than the full PID-SSA configuration. The proposed approach contributes to the advancement of marine simulation technologies, supporting innovation in ocean engineering and sustainable maritime applications.**

Keywords*—Marine simulation technologies, Stewart platform; ocean wave; control system; meta-heuristic optimization; Salp Swarm Algorithm

I. Introduction

The ocean is a vital part of the Earth and plays a significant role in the global ecosystem. Since approximately 70% of the Earth's surface is covered by ocean, conducting research in the maritime field is essential. One key challenge in this area is managing and understanding ocean waves. However, testing newly developed marine technologies directly in the real ocean is often difficult and costly, especially due to the complexity of transporting and deploying such systems. As a result, modeling and simulation have become crucial areas of maritime research. Simulation technologies can replicate real ocean conditions, allowing researchers to observe and analyze the performance of the developed systems effectively.

Generally, there are two types of ocean wave simulators: simulation platforms and ocean engineering basins [1]. A simulation platform applies wave models to control a motion platform, while an ocean engineering basin uses known ocean wave models as input for controlling a wave-making system. One of the most widely used simulation platforms for ocean wave simulation is the Stewart platform. The Stewart platform has been extensively utilized in the development and testing of ocean technology applications ranging from ship motion simulation [1-5], harbor crane robotics technologies [6-8], to ocean wave compensators [9-13].

The Stewart platform is a parallel manipulator that has superiorities in accuracy, rigidity, and capability in carrying heavy loads that to the series manipulator. Controlling the parallel manipulator is difficult due to its complex, coupled nonlinear dynamics, demanding advanced methods for reliable performance. As the Stewart platform is expected to execute complex motions with stability, its control systems remain a critical area of research. Silva *et al*. [14] employed the industrial controller on the Stewart platform, addressing kinematics and motion automation. The IK considered two scenarios: point-to-point cycloidal trajectories and oceanic wave motion. Vu *et al*. [15] presented a distributed control technique based on finite-time distributed sliding mode control. Each leg of the Stewart platform was considered as an autonomous agent. The dynamic of the Stewart platform was modeled using a Lagrangian-based approach. The trajectory tracking control by the Stewart platform using a PD+ controller was presented by Tamir *et al*. [16]. The dynamic of the Stewart platform was modelled using the Euler-Lagrange method. The motion was simulated using MATLAB/Simulink and validated using ADAM software. Lin *et al*. [17] presented drag-free control of the Stewart platform for satellite ground simulation. Inverse Kinematics (IK) and dynamics of the Stewart platform based on Newton-Euler were employed. Two degree-of-freedom drag-free controller was proposed using an algorithm of H_∞ loop shaping. An adaptive control of the pneumatic actuator of the sixth degree-of-freedom Stewart platform was presented by Andrievsky *et al*. [18]. Pneumatic valve groups and a spool valve were involved. Control process, discretization, and pneumatic drive load changes were considered.

Artificial Intelligent methods such as meta-heuristic optimization and an Artificial Neural Network (ANN) have been employed in the control system of the Stewart platform. Barghandan *et al*. [19] proposed a sliding mode control based on the Genetic Algorithm (GA) considering uncertainties and

external disturbances. An adaptation law based on a barrier function had removed the requirement of the external disturbance upper bounds. Tamir *et al*. [20] presented an extended Proportional-Derivative (PD) sliding mode controller for the Stewart platform trajectory tracking. Gain tuning was performed using modified grey wolf optimization with integral absolute error as a cost function. Validation was performed using the ADAM software. Sumnu *et al*. [21] presented the Proportional-Integral-Derivative (PID) control system of the Stewart manipulator, where the linear motor transfer function is derived and modeled in Simulink block diagram. The effect of the inertia of the lower legs on the dynamic performance was studied. Velasco *et al*. [22] presented the ANN to improve the accuracy of the Stewart platform when it holds a camera. The ANN model was designed based on the kinematics and dynamics analysis. Based on the inverse ANN model and additional integral control, the control system was then developed. Du *et al*. [13] applied the Stewart platform as a marine stabilized platform and proposed an extended state observer-based sliding mode control (ESO-SMC) to enhance the stability and anti-disturbance of the hydraulic actuator on the system platform. Kinematic and dynamic models were analyzed first, and the Marine Predator Algorithm (MPA) was applied to optimize the ESO-SMC. Simulation was conducted in MATLAB in Simulink using models of an engineering ship and a marine stabilized platform, which was placed on top of the ship model. An *et al*. [23] designed a Fracture Reduction Robot (FRR) based on the Stewart platform as an orthopedic surgery robot. A sparrow search algorithm was applied to tune the controller gains of the FRR. The IK was used, and the FRR dynamics were modeled in Simulink. The mechanism of fracture reduction was proposed using computer torque control.

The paper is organized as follows: Section II presents the kinematics and dynamics of a 6-DOF Stewart platform-based ocean wave simulator. Section III describes the motion simulator system. The trajectories generation, the control system optimization, and the Salp Swarm Algorithm (SSA) are presented in Section IV. Results and discussions are presented in Sections V and VI, respectively. Conclusions are presented in Section VII.

II. Kinematics and Dynamics

Kinematics and dynamics analysis are necessary for controlling the Stewart platform-based ocean wave simulator. For the dynamics analysis, this paper models the Stewart platform using Simscape Multibody to be optimized by the SSA via MATLAB and Simulink environments. MATLAB and Simulink have been used to model complex dynamical systems, including the Stewart platform to analyze the proposed methods before implementing them in the real system.

A. Inverse Kinematics

There are two kinds of kinematics problems for Stewart platform motion, namely Inverse kinematics (IK) and Forward Kinematics (FK). The FK is the problem of finding the positions and orientations of payload platform when leg lengths are defined while the IK is the problem of finding the leg lengths of Stewart platform when positions and orientations of payload platform are known. This paper considers tracking the prescribed paths, which are the ocean wave model so that using the 6-DOF Stewart platform, converting the tracking paths to the leg lengths trajectories is necessary to be done via an IK computation. Fig. 1 illustrates the coordinates assigned for the Stewart platform. There is a base platform coordinate {B} located at the center of the base table and a payload platform coordinate {P} located at the center of the payload table.

A closed-form IK solution can be obtained using geometrical and algebraic analysis as follows [24]:

$$l_i^2 = x^2 + y^2 + z^2 + r_P^2 + r_B^2 + 2\left(r_{11}P_{ix} + r_{12}P_{iy}\right)(x - b_{ix}) + 2\left(r_{21}P_{ix} + r_{22}P_{iy}\right)\left(y - b_{iy}\right) + 2\left(r_{31}P_{ix} + r_{32}P_{iy}\right)z - 2\left(xb_{ix} - yb_{iy}\right) \quad (1)$$

The above equation needs the orientation matrix. The orientation of the Roll-Pitch-Yaw angle is expressed as follows:

$$R_{RPY} = \begin{bmatrix} c\alpha\, c\beta & c\alpha\, s\beta\, s\gamma - s\alpha\, c\gamma & c\alpha\, s\beta\, c\gamma - s\alpha\, s\gamma \\ s\alpha\, c\beta & s\alpha\, s\beta\, s\gamma - c\alpha\, c\gamma & s\alpha\, s\beta\, c\gamma - c\alpha\, s\gamma \\ -s\beta & c\beta\, s\gamma & c\beta\, c\gamma \end{bmatrix} \quad (2)$$

where, R_{RPY}, α, β, γ, s, and c are the orientation matrix, roll angle, pitch angle, yaw angle, sinus, and cosinus, respectively.

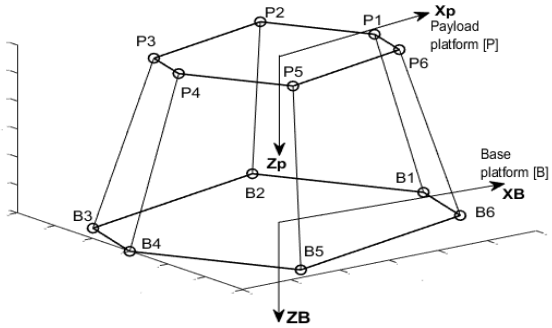

Fig. 1. Frame coordinate of the Stewart platform.

B. Dynamics

Dynamics of the Stewart platform can be expressed in the following form [25]:

$$F = M(q)\ddot{q} + N(q, \dot{q}) + G(q) \quad (3)$$

where, $M(q)$ is the inertia matrix, $N(q, \dot{q})$ is components of Coriolis and centrifugal force, $G(q)$ is the components of gravity force.

The inverse dynamics is the problem of finding the force/torque for known positions, velocities, and accelerations for defined positions, velocities, and acceleration vectors. This paper employs Simscape Multibody for solving the forward dynamics of the Stewart platform in the control system. Detail of the Simscape block diagram is shown in Fig. 2.

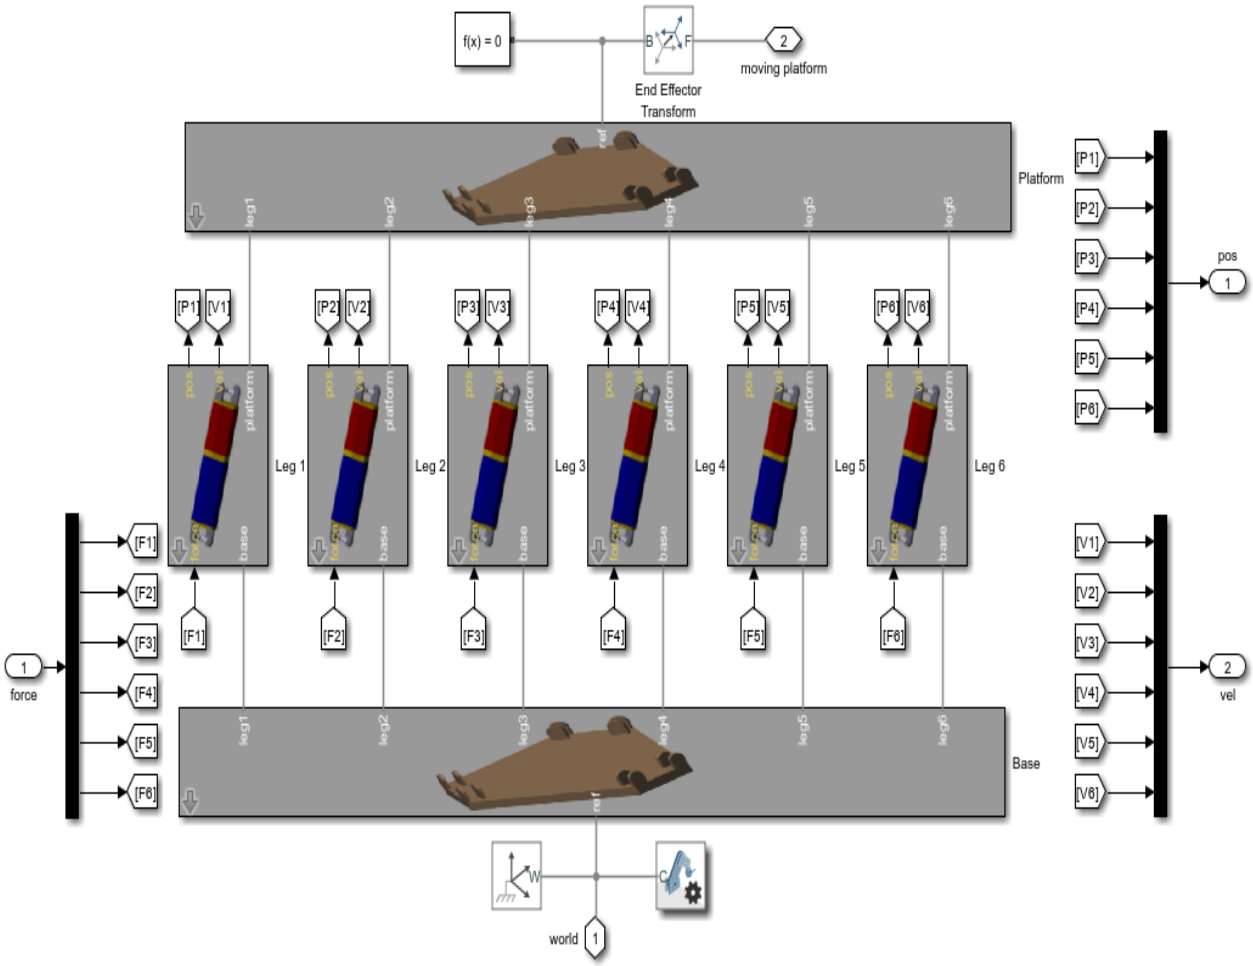

Fig. 2. Dynamic modeling of the Stewart platform using Simulink Multibody.

III. Motion Simulator System

Fig. 3 illustrates the ocean wave simulator system. The traced path is generated by the trajectory generator. An IK module processes the data from the trajectory generator to obtain the requested leg positions, which become the input for the control system of the Stewart platform.

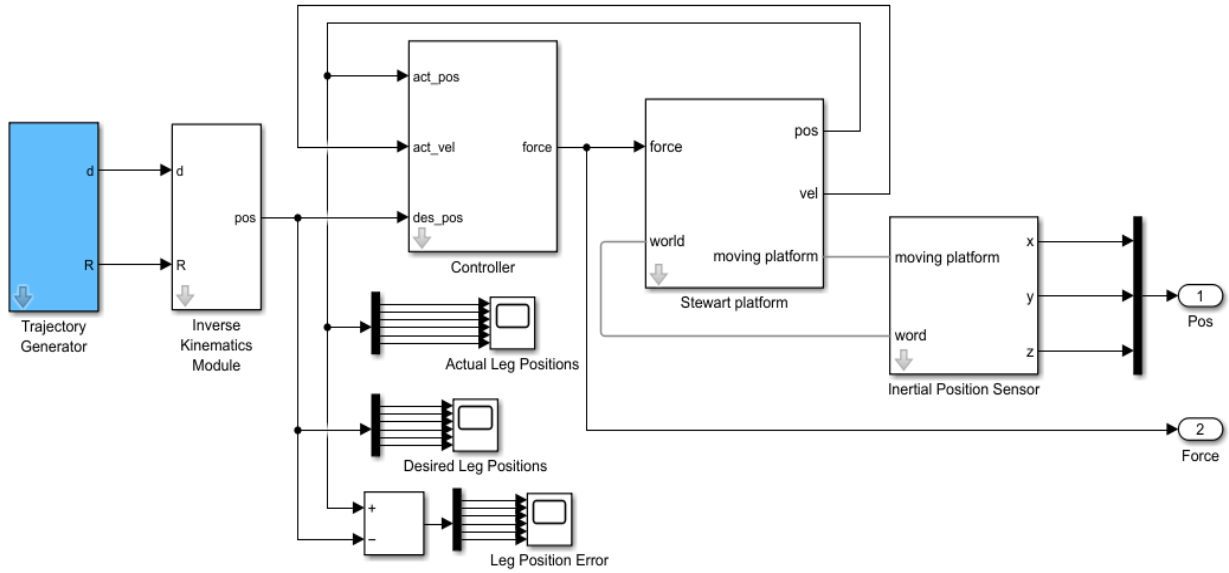

Fig. 3. Ocean wave simulator system.

A. Trajectory Generations

Ocean wave models used in this paper is presented in Table I. They are the modification of ocean wave models presented in [1]. This modification is necessary because the parameter of the Stewart platform is different and the Stewart platform has the workspace which depends on the parameter of the Stewart platform.

TABLE I. OCEAN WAVE MODELS [1]

Motion forms	Model (cm)
Lateral	$8\sin(0.25\pi t)$
Transverse	$8\sin(0.25\pi t)$
Lifting	$8\sin(0.25\pi t)$
Rolling	$\frac{10\pi}{180}\sin(0.25\pi t)$
Pitching	$\frac{8\pi}{180}\sin(0.25\pi t)$

IV. CONTROL SYSTEM OPTIMIZATIONS

Fig. 5 illustrates the algorithm of the control system optimization. Ocean wave models need to be converted to leg length trajectories via the IK. These leg length trajectories become the reference trajectories that need to be tracked by the control system of the motion simulator. This paper uses the PID-based control system to be optimized by the SSA. A comprehensive computation is necessary through integration of MATLAB software, Simulink, and Simscape Multibody. The responses of the Stewart platform are obtained using the Simulink to examine the Simscape Multibody modeling of Stewart platform.

Fig. 4 shows the block diagram of the ocean wave model represented in Table I. The Stewart platform uses in this paper has parameter as presented in Tabel II.

Finding the optimal gains by meta-heuristic optimization are performed by writing the code in m-file, MATLAB. Using the IK presented in the previous section, the trajectories of leg lengths can be obtained. These leg lengths trajectories should be within the Δl_{max} boundary. In the case the leg length trajectories are outside the boundary, the initial condition, which is the initial distance between the fixed base and moving base H, possibly needs to be recalculated. The Δl_{max} can be obtained by the geometric analysis of the Stewart platform.

A. PID Control System

Leg lengths trajectories from the trajectories generator become the reference signal of the control system. This paper uses the conventional PID control system optimized by the SSA. The detail of the simplified PID control system as the Simulink block diagram is illustrated in Fig. 6.

TABLE II. STEWART PLATFORM PARAMETER

Parameters	Values
Radius of moving platform (hexagon)	18 cm
Radius of fixed platform (hexagon)	28 cm
Cylinder radius of leg	3 cm
Maximum upper leg length	10 cm
Maximum lower leg length	30 cm
Initial distance between the fixed base and moving platform, H	13.5 cm

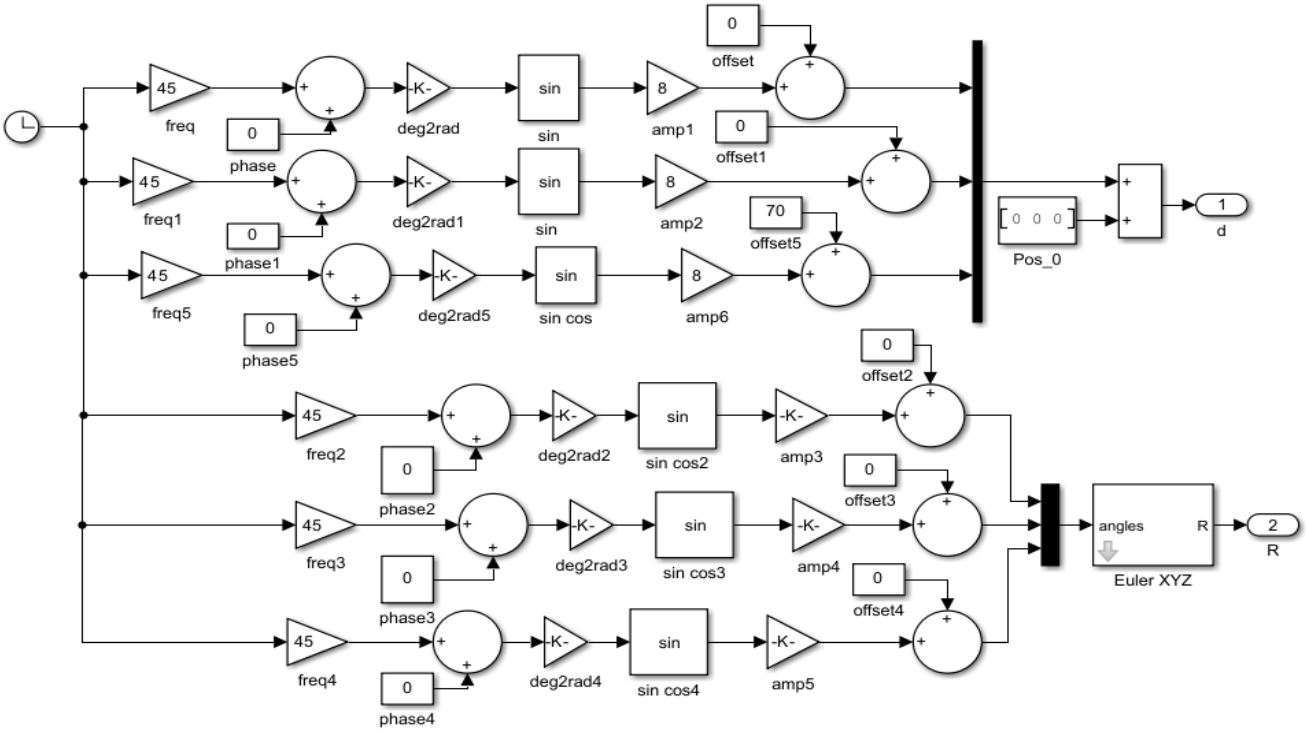

Fig. 4. Diagram block of trajectory generation of ocean wave motion.

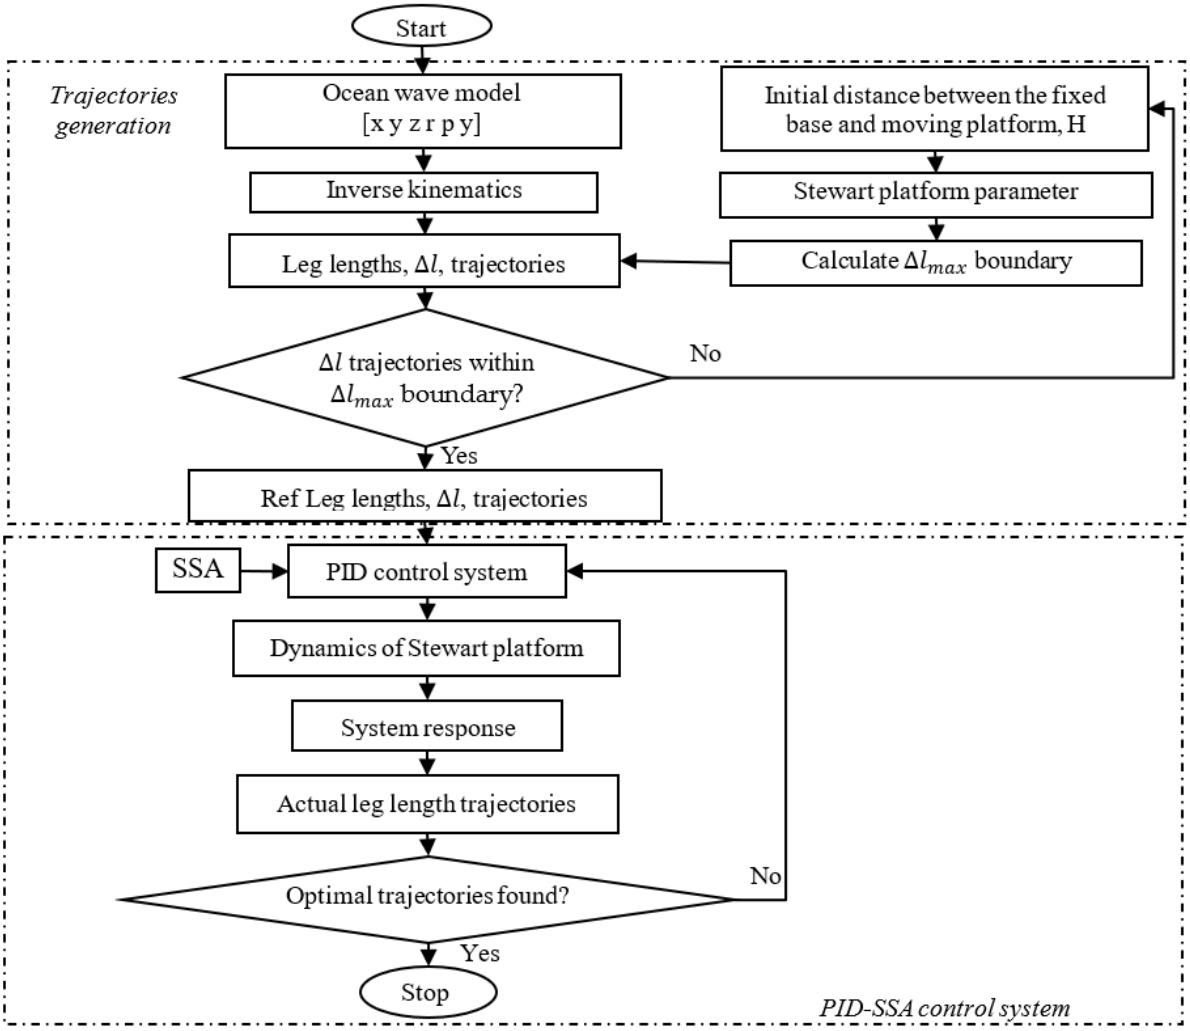

Fig. 5. Control system algorithm of the Stewart platform.

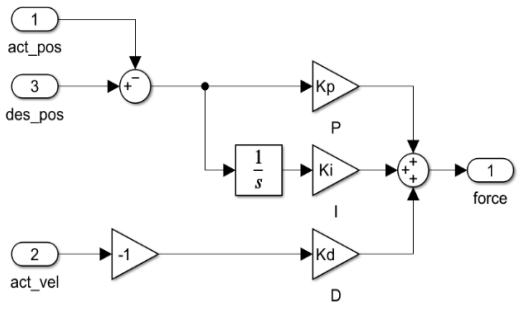

Fig. 6. Simplified conventional PID control system block diagram.

The simplified conventional PID control law is employed as follows:

$$F = K_p e + K_i \varepsilon - K_d \dot{\Delta l} \tag{4}$$

$$e = \left(\Delta l_{ref} - \Delta l\right) ; \dot{\varepsilon} = e$$

where, F, e, Δl, Δl_{ref}, $\dot{\Delta l}$, K_p, K_i, and K_d are force feedback control, error leg length, actual leg length, desired leg length, actual leg velocities or first derivative of Δl, proportional gain, integral gain, and derivative gain, respectively.

B. Salp Swarm Algorithm

The PID gains are optimized by the SSA with the objective optimization is to minimize the Root Mean Square Error (RMSE) as the cost function. The SSA is relatively new meta-heuristic optimization proposed in 2017 by Mirjalili *et al.* [26]. The SSA is inspired by the salps swarming behaviour when they are navigating and foraging in deep oceans.

The populations consists two groups, namely leader and followers. The leader is the salp at the chain front. The leader position is updated as follows:

$$x_j^1 = \begin{cases} F_j + c_1\left(\left(ub_j - lb_j\right)c_2 + lb_j\right) & c_3 \geq 0 \\ F_j - c_1\left(\left(ub_j - lb_j\right)c_2 + lb_j\right) & c_3 < 0 \end{cases} \tag{5}$$

where, x_j^1, F_j, ub_j, and lb_j, are the leader position in jth dimension, the food source in jth dimension, upper bound in jth dimension, lower bound in jth dimension, respectively. Parameters c_1, c_2, and c_3 are random numbers.

Above leader position is updated based on the food source. For exploration and exploitation, the following parameter is defined:

$$c_1 = 2e^{-\left(\frac{4l}{L}\right)^2} \quad (6)$$

where, l and L is the current iteration and the maximum iteration number, respectively. The c_2, and c_3 parameters are generated randomly in interval [0, 1].

The follower position is updated as follows:

$$x_j^i = \frac{1}{2}\left(x_j^i - x_j^{i-1}\right) \quad (7)$$

where, $i \geq 2$ and x_j^i is the ith follower salp position in jth dimension.

V. Results

Besides the SSA, other meta-heuristic optimizations, which are the Genetic Algorithm (GA) and Particle Swarm Optimization (PSO), are also executed as comparison methods. The GA, PSO, and SSA use 10 individuals in the population evaluated for 50 iterations. The optimization parameters are searched within the search area [100, 10000] for K_p gain and [2, 1000] for the K_i and K_d gains. The result of Δl_{max} is 30 cm for the Stewart platform used in this paper (Table II). The computation of the gain optimization is performed within 2.5 seconds and divides the motion into 200 sampling times.

Fig. 7 shows the results of the leg length trajectories using the IK for the value of H = 13.5 cm. It can be observed that the leg lengths trajectories are within their workspace, where all trajectories are within Δl_{max} boundary.

A. Trial-and-Error Gains

It is generally known that tuning the PID gain is a challenging computational problem, while using a trial-and-error approach is a tedious task. The fitness value using this gain is 6.642 for the trial-and-error gain, [K_p K_i K_d] = [300 100 100]. Fig. 8 shows the system response for the trial-and-error gains. The difference between the desired trajectories and the actual trajectories is not small, so tuning the gains is necessary to obtain the efficient motion.

B. Optimal Gains

Results of the optimal gains by the GA, PSO, and SSA are presented in Table III. The computation of the RMSE as the fitness function is performed for 2.5 second running time. It shows that the SSA algorithm is outperformed the GA and PSO where the SSA has the lowest fitness value. It can also be observed that the SSA does not trap to the upper bound value and lower bound value.

The SSA has ability to explore and exploit the searching area through parameter c_1 in Eq. (6). On the contrary, the PSO has been trapped to the upper bound value for the K_p (K_p = 10000). Fig. 9 shows the fitness value evolution during 50 numbers iterations. The fitness value of the SSA is 16.8% and 8.7% lower than the GA and the PSO, respectively.

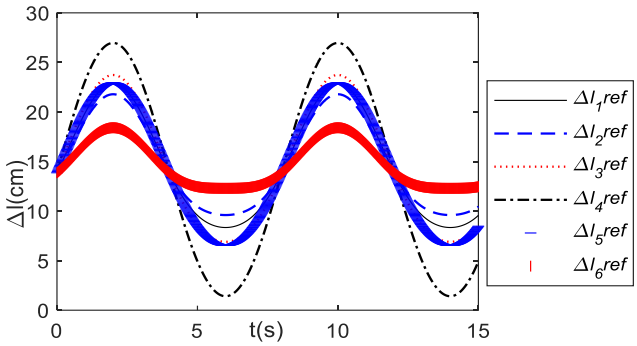

Fig. 7. Leg lengths trajectories of the ocean wave model within Δl_{max} boundary.

TABLE III. Results of GA, PSO, SSA

Methods	Fitness value	Best [K_p K_i K_d]
GA	0.0781	[9661.2 992.4 20]
PSO	0.072	[10000 6190 20]
SSA	*0.066*	[7472.4 747.24 5]

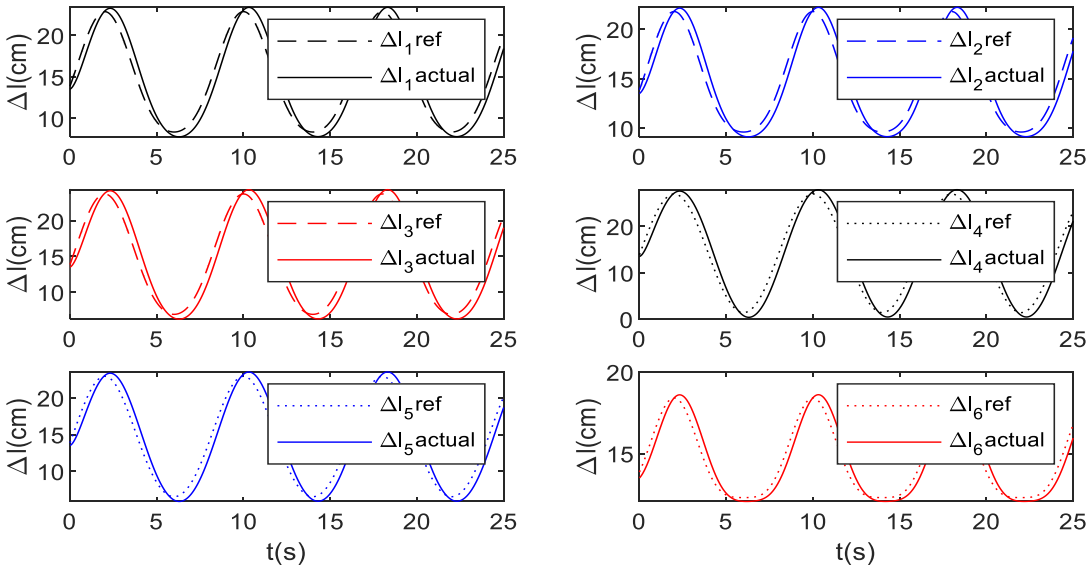

Fig. 8. System response for the trial and error approach [K_p K_i K_d] = [300 100 100].

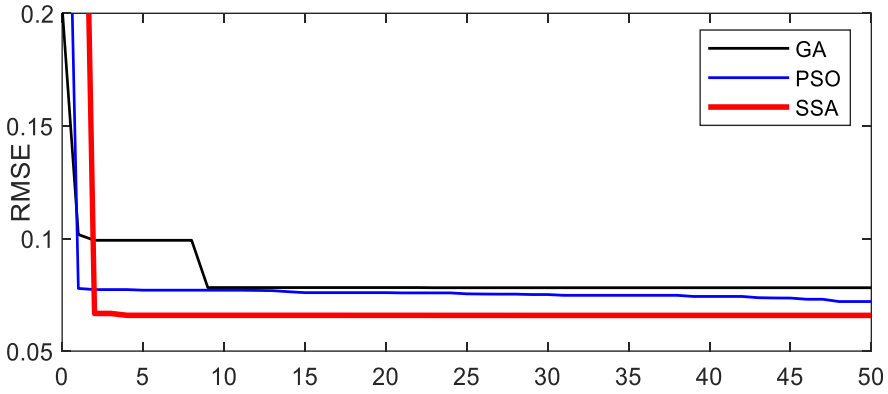

Fig. 9. Fitness value of GA, PSO, and SSA.

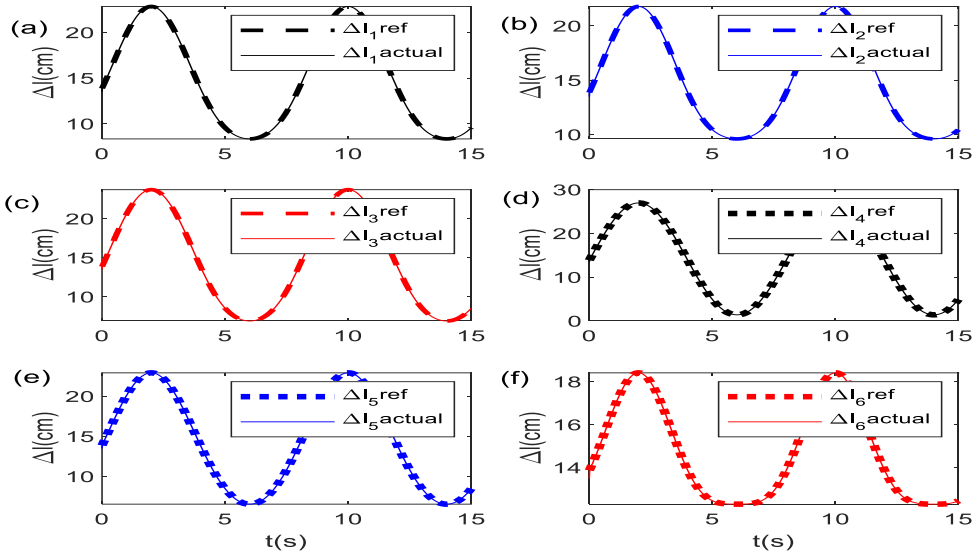

Fig. 10. System response for the SSA method, [K_v K_p K_i] = [7472.4 747.24 5].

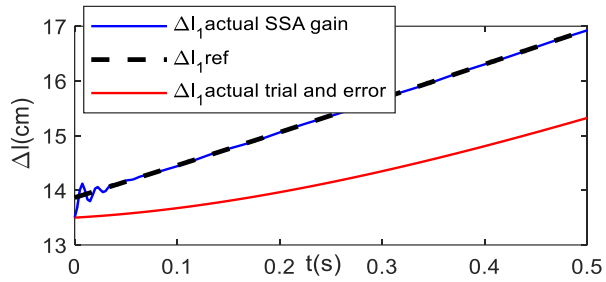

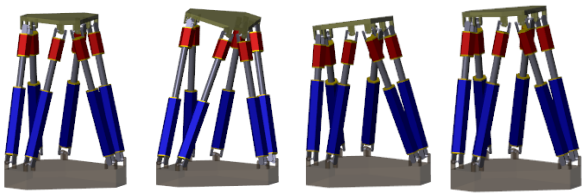

Fig. 11. Zoom in of system response by SSA and trial-and-error gain.

(a) (b) (c) (d)

Fig. 12. Motion frames of the ocean wave simulator K=[7472.4 747.24 5] (a) 0 second (b) 2.5 second (c) 5 second (d) 7.5 second.

Fig. 10 shows the system response of the SSA gains. As compare with the respond from the trial-and-error gain, it can be observed that the SSA has significantly improved the trial-and-error approach. Fig. 11 shows detail of comparison between the results of the SSA gains and the trial and error gains for fist leg length trajectories. Fig. 12 shows the motion frame of the Stewart platform during tracking the ocean wave model.

C. PID with Velocity Reference

The previous result was obtained from the simplified version of the PID control system without feedforward of the velocity setpoint. This section investigates the performance of full PID control system when the velocity reference is included as an input to the controller.

The full version of the PID control law, in which the velocity reference is used as the control input, is expressed as follows:

$$F = K_p e + K_i \varepsilon - K_d \dot{e} \tag{8}$$

$$e = \dot{\Delta l}_{ref} - \dot{\Delta l}$$

The detail of the block the Simulink block diagram is illustrated in Fig. 13.

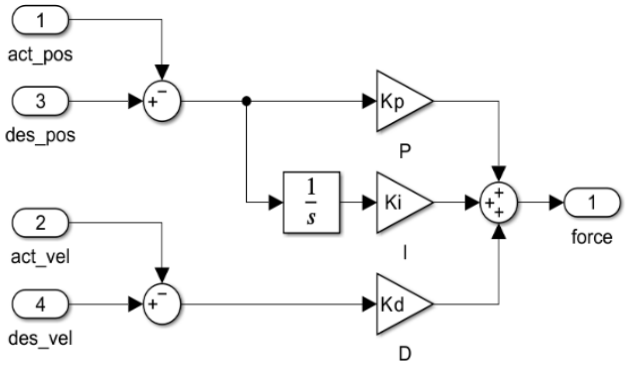

Fig. 13. Full version of PID control system block diagram.

Table IV presents the results of the trial-and-error and SSA gains for the PID control system with velocity reference input. By accommodating the velocity reference in the simplified conventional PID control, using the same trial-and-error gain K = [300 100 100], the fitness value has significantly improved to 0.7450. However, this value is still far from the SSA gain, where the fitness achieved to 0.066 (Table III).

VI. Discussions

The SSA has significantly improved the RMSE of the ocean wave simulator's motion. Fig. 14 presents the detailed system response for the trial-and-error gains of the full version PID control system. However, when the SSA gains from the previous section (see Table III) are applied with the velocity reference included, the resulting fitness value is 0.1052—worse than that of the simplified PID control system.

The performance of the full version of the PID control system is further investigated by tuning the gains using the SSA. Using the same computation parameters as in the simplified PID, the optimization result is presented in Table IV. The SSA gain for the PID control is K = [8148.97 814.9 b37.64] with the fitness value is 0.099443. Based on the fitness value result, the simplified PID-SSA has better performance than that of the PID-SSA.

TABLE IV. Results of SSA for Full Version of the PID System

Methods	Fitness value	$[K_p\ K_i\ K_d]$
Trial-and-error	0.7450	[300 100 100]
Gain from previous section	0.1052	[7472.4 747.24 5]
SSA	0.099443	[8148.97 814.9 37.64]

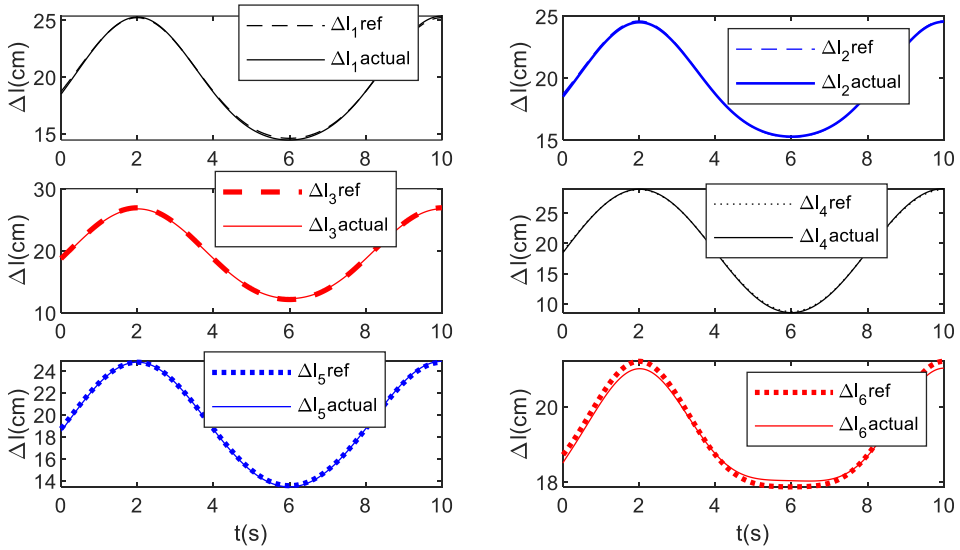

Fig. 14. System response of PID with velocity reference for the trial and error approach, $[K_p\ K_i\ K_d]$ = [300 100 100].

Employing the SSA in the PID control system of the ocean wave simulator has yielded promising results. Adding the velocity reference input into the PID improves the simulator's response for the trial-and-error gain, as reflected in the fitness value results. However, when the SSA is applied to correct the required force, the simplified PID (without the velocity reference input) outperformed the SSA-PID. The main challenge in reducing the position tracking error likely stems from the highly nonlinear dynamics of the 6-DOF Stewart platform. Standard PID control systems often require additional compensation to handle such nonlinearities effectively. Therefore, for future work, incorporating advanced nonlinear compensation methods, such as computed-force control, can be investigated to further enhance the system respond of the PID control system.

VII. Conclusions

The control system optimization of the Stewart-platform-based ocean wave simulator using the PID-SSA method has been presented. The system solved the IK to obtain leg length trajectories, used as reference inputs for the PID controller. By employing Simscape Multibody to handle the forward dynamics, IK module, and PID control, the SSA was applied to tune the PID gains. Results showed that the SSA not only success to identify the optimal gain, but also significantly enhance the performance of the simplified PID controller as

compare to the full version of the PID controller. The promising performance of SSA in improving simplified PID control suggests strong potential for its application to ocean wave compensators in ships and ocean floating platforms. Future work should address nonlinear compensation in simulator dynamics and extend the proposed method to wave-induced motion control on offshore platforms.

Enhanced IoT Security Using Machine Learning Technology

Rawan Yousef Bukhowah, Alanoud Khaled Bu Dookhi, Mounir Frikha
Department of Computer Networks and Communications-College of Computer Sciences and Information Technology,
King Faisal University, Al-Ahsa 31982, Saudi Arabia

***Abstract*—This paper examines the enhancement of security measures for the Internet of Things (IoT) systems through the application of Machine Learning (ML) techniques. As the number of IoT devices continues to rise, ensuring their security has become increasingly critical, given that conventional methods frequently struggle to identify advanced threats. This study explores the implementation of several ML algorithms, including Random Forest (RF), Decision Trees (DT), Support Vector Machines (SVM), and Convolutional Neural Networks (CNN), to identify anomalies and intrusions within IoT networks. By conducting a comprehensive review of existing research and experiments, it highlights the effectiveness of ML in enhancing IoT security, with high detection rates for various threats, including botnet attacks, Denial-of-Service (DoS) and Distributed Denial-of-Service (DDoS) incidents, and intrusion attempts. DoS/DDoS attacks and many types of botnets are the most devastating attacks that have been spreading for a long time, and they are still branching out in new ways against IoT networks. They can damage IoT services and prevent these services from being used by legitimate users. Therefore, securing IoT networks becomes a significant concern. The proposed model is used to increasingly monitor network traffic for any deviations from standard patterns IoT networks. This paper also stresses the necessity of utilising suitable datasets and feature selection techniques to enhance the efficacy of ML models. To train our model, we have utilized a dataset called the IoT23 dataset, which is one of the most recent datasets that has many IoT scenarios and anomalous activities. Furthermore, we utilised two types of feature selection algorithms, the Correlation-based Feature Selection (CFS) algorithm and the Genetic Algorithm (GA), and then we compared the results of these algorithms when training our model. The best performances were obtained with DT and RF classifiers when they were trained with features selected by CFS However, for training and testing times metrics, DT performance was superior across both feature selection methods.**

I. Introduction

The Internet of Things (IoT) is an innovative technology that integrates various solutions across a wide range of applications [1], [2]. IoT refers to a distributed network comprising multiple sensor devices and systems, such as QR code devices, RFID devices, and sensor networks [1]. However, with the rapid growth and easy accessibility of these smart devices and networks, the focus on IoT security has increased due to malicious users, leading to a surge in related challenges [2], [3]. Furthermore, traditional techniques are less effective at detecting various types of attacks [3], [4], which requires the development of new technological advancements [2]. Artificial Intelligence (AI) is a computing technology that improves the ability of the IoT to deliver advanced application services [5]. IoT devices can leverage AI technology, encompassing two types: Machine Learning (ML) and Deep Learning (DL), each with its own set of algorithms and classifiers [6], [5]. IoT employs a multilayer architecture, with one architecture relying on three layers: application, network, and perception layers [1].

A. Problem Statement

In today's world, the lack of IoT security in systems, devices, and networks against attacks and malicious actions by intruders is a significant concern. Despite this, it is challenging to secure IoT devices with traditional security controls, and existing solutions such as the cloud suffer from centralisation and high delay. Another contributing factor is the vulnerability of IoT devices. Furthermore, the lack of security standards has added another dimension to the complexity of securing IoT devices. These challenges call for a monitoring system, such as anomaly detection, at both the device and network levels beyond the organisational boundaries. In recent years, the use of ML techniques has increased, and it is used to develop anomaly-based approaches to protect IoT networks, systems, and applications. It has impressive results while trained on normal and abnormal data in order to detect anomalies. However, building effective and efficient anomaly detection modules is not easy at all. ML models require significant effort, and selecting the best-performing algorithms remains a major challenge. Selecting the best dataset for a system is another challenge because there are many datasets that are available in public, and it isn't easy to choose the best one that fits your needs. Some of the data sets are large and outdated, so in this research, we aimed to enhance IoT security using ML techniques that can detect and mitigate cyber threats over a suitable data set for the IoT environment.

B. Contribution

Our contributions in this paper are summarized as follows:

- Designing a robust anomaly detection framework for the IoT, which facilitates and improves the detection of malicious data.
- Proposing an efficient model to extract relevant IoT features and eliminate unnecessary ones, thereby improving anomaly detection performance.
- Evaluating the effectiveness of the proposed model using recent IoT datasets and comparing it with existing ML models used for anomaly detection.

C. Research Questions

- What research has been done on ML for IoT security?
- What methods have been tried and how effective were they?
- What are the limitations or challenges of previous studies?
- How can ML improve threat detection in IoT networks?
- How can feature selection improve ML-based IoT security models?
- What are the most suitable datasets to enhance IoT security using ML algorithms?
- What are the research gaps and future directions in IoT security?
- What is the impact of processing stages-include data preprocessing, feature selection, and sampling-on evaluating the classifier performance in detecting attack types?

This paper is organized as follows. Section II presents the background. Section III reviews previous research studies related to IoT security using ML technology or presents and analyzes the related work. Section IV presents the methodology. Section V discusses the producers of the model setup, including preparing the dataset and training the model with classification algorithms. Section VI presents and analyzes the experimental results. Section VII presents a comparison between our proposed approach and an existing study. Section VIII concludes the research and suggests future work.

II. Background

A. IoT Security Challenges

1) Common security challenges include:

- Weak authentication and access control → Many IoT devices have default passwords or weak credentials.
- Intrusion and malware attacks → IoT networks are vulnerable to cyber threats, such as Distributed Denial-of-Service (DDoS), botnets, and ransomware.
- Data breaches and privacy issues → Sensitive user data (e.g. health or financial data) can be intercepted.
- Lack of real-time threat detection → Traditional security methods (e.g. firewalls, rule-based detection) struggle to detect new and evolving threats in real time.
- Resource constraints in IoT devices → Many IoT devices have limited processing power, making complex security algorithms difficult to implement.

B. AI Technology for IoT Security

Artificial Intelligence (AI), including ML and DL, is an effective solution to increase system security with regard to IoT. Traditional solutions require more processing ability for large datasets and are less efficient than AI technology. The remarkable ability of learning models to solve long-standing problems has made them increasingly important in recent times. Another significant advantage of learning algorithms is their ability to improve accuracy through real-time learning from test data. This section reviews various ML algorithms, how they function, and their contributions to IoT network security.

C. Machine Learning in IoT Security

Recent research shows that ML models significantly improve intrusion detection, anomaly detection, and malware classification. Studies have explored Convolutional Neural Networks (CNNs) for traffic classification, Long Short-Term Memories (LSTMs) for sequential anomaly detection, and Federated Learning for decentralised security. However, a trade-off between accuracy and computational efficiency remains a challenge.

1) Role of machine learning in IoT security: ML has emerged as a promising solution for securing IoT environments. ML-based security models can detect, predict and respond to cyber threats by learning patterns in network traffic. Unlike traditional security approaches, ML can handle large datasets, adapt to evolving threats, and minimize false positives. Various ML techniques have been applied in IoT security, including supervised learning, unsupervised learning, and deep learning models.

2) Key advantages of ML in IoT security:

- Anomaly Detection: ML can detect suspicious patterns in IoT traffic and identify potential cyberattacks.
- Adaptive Security: Unlike rule-based systems, ML continuously learns and updates itself to detect new threats.
- Low False Positive Rate: ML reduces false alarms compared to traditional signature-based detection.
- Scalability: ML can efficiently analyze large networks.
- Automated Threat Detection: ML models can work in real time, preventing attacks before they escalate.

Table I below briefly describes the K-means clustering and Q-Learning methods that belong to the RL model.

III. Related Work and Literature Analysis

This section reviews previous research on IoT security using ML. The studies analysed focus on various ML models, datasets, and techniques to enhance IoT security.

Nazir et al. [6] proposed a novel Collaborative Threat Intelligence Framework that integrates blockchain and ML for enhanced IoT security. The study used Random Forest (RF), Decision Trees (DT), Ensemble Learning, LSTM, and CNN models, using the IoT23 dataset. The primary issue addressed is the dynamic and evolving nature of IoT threats, which traditional security methods often fail to mitigate. The key contribution is a real-time threat detection system that improves accuracy by reducing false negatives through collaborative intelligence. Although the results showed improved

TABLE I. LEARNING MODELS

Learning model	Classifiers	Principle	Advantages	Disadvantages	Applications applicable to IoT
Supervised learning	SVM	Generates classified data by establishing a hyperplane between two or more classes. Expands the margin around the hyperplane.	• Stable in handling datasets with numerous features	• Inefficient with very large datasets • Struggles with multi-classification scenarios	• Intrusion detection • DoS/DDoS detection • Malware detection
Supervised learning	DT	Splits datasets into branches based on feature values, forming a tree structure. Branches represent decision rules ending in outcomes.	• Quick computations • Allows intuitive decision making	• Becomes overly complex with multi-dimensional data	• Intrusion detection • DoS/DDoS detection • Device authentication
Supervised learning	KNN	Assigns classifications based on the nearest sample votes.	• Straightforward and adaptable • Effective for both non-linear and multi-class scenarios	• Time-consuming to optimize K value	• Intrusion detection • DoS/DDoS detection
Supervised learning	ANN	Mimics a biological neural network using sample weights and biases.	• Handles incomplete data effectively • Capable of managing complex models due to hidden layers	• High computational demand • Challenges in tracing predictions	• Intrusion detection • DoS/DDoS detection • Malware analysis • Device authentication
Supervised learning	NB	Assumes independence among input variables	• Usually applicable for both small-scale data and large-scale data • Simple training process	• Independence assumption often not met	• Intrusion detection • Device authentication
Supervised learning	RF	Utilizes multiple decision trees, each trained on random data subsets.	• Better than single-model • Difficult to overfit • Excellent noise resilience • Works with high-dimensional data • Handles both continuous and discrete data	• Potential for overfitting • Degrades with noisy data	• Intrusion detection • DoS/DDoS detection
Unsupervised learning	PCA	Transforms correlated features into fewer uncorrelated ones.	• Simplifies models • No parameter constraints	• Less interpretable components • Sensitive to scaling and rotation	• Feature selection • Feature detection
Unsupervised learning	K-means Clustering	Groups samples into K clusters based on feature similarity.	• Efficient anomaly detection • Useful for data anonymisation	• May lack accuracy • Not ideal for complex data structures	• Network normalization • Sybil detection in WSNs • Private data anonymisation
Reinforcement learning	Q-Learning	Optimizes decisions in IoT through trial and error learning.	• Requires few parameters • Can be implemented offline	• High memory and time cost • Not ideal for high-dimensional data	• Intrusion detection • DoS/DDoS detection • Malware detection • Device authentication

accuracy and adaptability in IoT security applications, reliance on blockchain increased computational overhead.

Kirana et al. [7] developed an Intrusion Detection System (IDS) using Naïve Bayes (NB), SVM, DT, and AdaBoost classifiers. The testbed simulated IoT environments with ESP8266 and DHT11 sensors, collecting network traffic for ML model training. The study focused on detecting Man-in-the-Middle (MITM) attacks and demonstrated high accuracy in anomaly classification. However, adversarial attacks on ML models remain an unresolved challenge.

Alwahedi et al. [8] provided a comprehensive survey on ML-based Intrusion Detection Systems (IDS), including DL models such as Artificial Neural Networks (ANN), SVM, RF, and DT. The key issue tackled is the heterogeneity of IoT security threats. A significant gap identified is the lack of real-time response mechanisms in existing IDS solutions. The proposed solution integrates Generative AI and large language models (LLMs) for adaptive cyber threat mitigation.

Zawaideh and Abu Baker [9] introduced a cascaded ML approach for detecting botnet attacks in IoT networks. The study utilised a Recurrent Neural Network (RNN) combined with LightGBM, trained on the BOT-IoT dataset. The proposed model outperformed traditional classifiers with an accuracy of 99.9% and a recall of 100%, effectively handling imbalanced IoT traffic. The main limitation was the higher computational complexity of the cascaded model.

Bagaa et al. [10] developed an ML-driven security framework leveraging Software-Defined Networking (SDN) and Network Function Virtualisation (NFV). The framework employs One-Class SVM, Distributed Data Mining, and Neural Networks for real-time anomaly detection in innovative building IoT environments. Experimental results showed a 99.71% detection accuracy is achieved, although scalability issues in edge computing environments remain a challenge.

Al-Garadi et al. [3] presented a comprehensive review of ML and DL techniques for IoT security. The research

emphasised the effectiveness of DL models like CNNs and RNNs for detecting cyber threats. A key limitation highlighted is the lack of labelled datasets for IoT-specific threats, making supervised learning less effective in real-world scenarios.

Boukerche and Coutinho [11] outlined best practices for implementing ML-based security mechanisms in IoT networks. The study focused on optimising computational efficiency while maintaining high detection accuracy. The trade-off between detection accuracy and computational cost remains a primary challenge in real-world deployments.

Makkar et al. [12] introduced an ML-based spam detection framework for IoT devices. The study evaluated five ML models, using the REFIT Smart Home dataset. The best-performing models demonstrated high accuracy in detecting anomalous behavior, though the framework struggles with adversarial ML attacks.

Dhanke et al. [13] developed an ML-based IDS using RF, DT and SVM models. The study focused on Cyber-Physical Systems (CPS) and Smart Home environments, using ML to detect abnormal network traffic and malicious activities. The key findings revealed that ML improved security by detecting intrusions efficiently, achieving 85% accuracy. However, the study identified a gap in real-time adaptability, as some ML models struggled with evolving threats.

Gad et al. [14] introduced a distributed IDS leveraging RF, XGBoost, and LightGBM for anomaly detection in IoT networks. The study utilised the ToN-IoT dataset, which includes diverse cyberattacks. The key finding was that distributed ML models enhanced intrusion detection. However, high resource consumption on edge devices remained a limitation. The proposed lightweight IDS aimed to balance security and computational efficiency.

Ahmad and Almada [4] conducted a systematic literature review on the role of ML and DL techniques in IoT security. The review identified that supervised learning methods were more effective for known attack detection, while unsupervised learning performed better in zero-day attack scenarios. A key challenge highlighted was the scarcity of high-quality, labelled datasets, which limits the effectiveness of ML-based security models.

Amanullah et al. [5] investigated the use of DL for IoT security by analysing cyber threats using CNN and RNN. The research proposed a big data-driven approach for handling large-scale security threats. The study concluded that DL models significantly improved detection accuracy; however, the high computational overhead limited their deployment in low-power IoT devices.

Alrowais et al. [15] introduced an Automated Machine Learning (AutoML) approach using Mayfly Optimisation (MFO) with Regularised Extreme Learning Machine (RELM) for IoT security threat detection. The research used real-world IoT security datasets, demonstrating superior performance in detecting various attack types. The main limitation was the difficulty in real-time adaptation of AutoML models.

Awajan. [16] Introduced a DL-based IDS using a fully connected neural network. The study focused on detecting Blackhole, DDoS, and Sinkhole attacks with an average accuracy of 93.74%. A major challenge identified was the lack of communication protocol-independent security models, which limited interoperability across different IoT systems.

Tahir et al. [17] introduced an ML-based anomaly detection system to strengthen IoT security. The study employed RF, DT, SVM, and Gradient Boosting models to analyse IoT network traffic data. The key problem addressed was adaptive security mechanisms for anomaly detection in IoT environments. The research found that Gradient Boosting achieved the highest precision (89.34%), demonstrating the effectiveness of ML in securing IoT systems. However, a significant limitation identified was computational inefficiency, making real-time threat detection difficult in resource-constrained IoT environments.

Musleh et al. [18] proposed an IDS using feature extraction with ML algorithms. The study tested RF, KNN, SVM, and stacking models combined with feature extraction techniques such as VGG-16 and DenseNet. The dataset used was the IEEE Data Port, and the key finding was that VGG-16 with stacking achieved 98.3% accuracy, demonstrating the potential of DL for intrusion detection in the IoT. However, the reliance on large labelled datasets and computational overhead remains a significant challenge.

Khatun et al. [19] reviewed the application of ML in securing Healthcare Internet of Things (H-IoT). The study focused on intrusion detection, authentication, and anomaly detection using RF, DT, and Gradient Boosting models. The key finding was that ML algorithms significantly improve healthcare security, but privacy concerns and adversarial attacks on IoT devices remain a challenge. The study proposed a robust authentication mechanism using ML but highlighted that real-time data analysis remains computationally expensive.

Ahmad et al. [20] conducted a comprehensive review on ML and DL techniques for IoT security. The study highlighted the effectiveness of supervised models for known attack detection, while unsupervised learning was better suited for zero-day threats. A key challenge was the lack of labelled datasets, limiting the effectiveness of ML-based security models.

Mukherjee. I et al. [21] proposed a model of two different approaches to predict anomalies in IoT networks using a 350k-record dataset and deploying ML models. The study used Logistic Regression (LR), DT, RF, NB, and ANN algorithms first with all features, then with selected features after preprocessing. The models achieved 99.4% accuracy with all features and 99.99% after feature selection. It categorises attacks into DoS, malicious control, malicious operation, incorrect setup, and spying. The model was trained and tested on all attack types, rather than only common ones.

Bedi. P et al. [22] presented four models based on ML technology; these methods are ANN, LR, RF, SVM and DT. The paper aims to assess the results of all these models via evaluation metrics to find the best performance of the ML algorithm in detecting attacks in IoT sensor networks. The proposed IoT framework, structured by dataset perception, assortment and information processing, was executed on the dataset as an essential stage. Furthermore, the dataset used is known as the DS2OS dataset, which contains eight classes and seven attack types, including DoS attacks, data probing, malicious control, malicious operation and spying. The results showed that ANN and DT classifiers have better performance than LR, EF and SVM.

Altulaihan.E et al. [23] proposed a new mechanism using IDS to enhance the security of IoT networks. The paper focused on mitigating a type of attack called a DoS (Denial of Service) attack through four supervised classifier algorithms: KNN, SVM, DT, and RF, within an existing dataset known as the IoTD20 dataset, achieving an accuracy of 99.9%. Other datasets mentioned were CIDDS-001, UNSW-NB15, NSL-KDD, Bot-IoT, and KDD99. The results showed that DT and RF were the most efficient methods compared to others.

Alotabib et al. [24] Proposed a stacked DL approach for IoT security. This method aims to detect malicious traffic data, including phishing, DDoS, spamming campaigns, and data leakage. The proposed approach utilises pre-trained residual networks (ResNets), which help discover the characteristics of activities, whether normal or abnormal. The experiment has been done by using two cases using two datasets, including the N-BaIoT dataset and the power system dataset. Furthermore, the two scenarios target two heterogeneous IoT environments: smart homes and smart grids. NB, SVM and DT are ML algorithms that have been used for the proposed model.

Trcˇek.D et al. [25] presented a new anomaly detection system that is based on appropriate lightweight ML algorithms known as Profile and Hierarchical Incremental Clustering-based Anomaly Detection (PHICAD). The PHICAD enhances security, which works on the assumption of a large number of frequent flows that include normal activities and abnormal activities, and a small number of infrequent ones. Furthermore, it enables detection of unknown and new anomalies. Furthermore, the flows are arranged into profiles and each represents a model of network activity it assigned into a single network entity and it has it won IP address. This paper has been evaluate PHICAD by using CIC-IDS-2017 which contains most of network cybersecurity attacks (web attacks, brute force, port scan, heartbleed, DDoS, DoS, botnet and infiltration). Other ML algorithms performance have been compared such as KNN, RF, ID3 and NB using CIC-IDS-2017 dataset and result showed that the proposed approach achieved the highest precision rate.

A. Key Findings and Insights

Tables II and III presents a compilation of research studies that explore the application of ML techniques to enhance security in IoT environments.

In Tables II and III, we have highlighted several significant findings that enhance IoT security through the application of ML models. A key observation is the variety of ML models employed in various studies to tackle a broad spectrum of IoT security threats. These models range from traditional approaches such as DT, RF, SVM, KNN, and NB, to more sophisticated DL techniques including ANN, CNN, and RNN.

Additionally, some research incorporated hybrid or automated solutions like LightGBM, AutoML, and Generative AI. The effectiveness of each model varied depending on the specific security challenge—such as intrusion detection, DoS/DDoS attacks, botnet identification, and anomaly detection—indicating that a model's success is closely tied to the type of attack and the characteristics of the dataset. Furthermore, a notable insight is the consistent high detection accuracy reported across numerous studies. For example, Zawaideh and Abu Baker achieved 99.9% accuracy and 100% recall in identifying botnet attacks using a hybrid RNN and LightGBM method, while Bagaa et al. reported 99.71% accuracy in a smart building scenario using a One-Class SVM model. These results underscore the capability of well-trained ML models to provide reliable and accurate detection of cyber threats within IoT settings. However, despite these encouraging outcomes, challenges persist, particularly in realizing real-time detection and adaptability in dynamic, resource-limited IoT networks. As highlighted by Gad et al., the high computational requirements, especially at the edge level, can impede the deployment of distributed ML-based anomaly detection systems. This underscores the necessity for lightweight, adaptive models that can sustain performance in the face of evolving threats. The quality and selection of datasets are vital for the performance of models. Popular datasets like IoT23, BOT-IoT, and CIC-IDS-2017 offer extensive attack scenarios, but relying on outdated, unbalanced, or simulated data can limit the generalizability of studies. This highlights the need for choosing or creating datasets that accurately represent real-world IoT security situations. Feature selection also plays a crucial role in the success of models.

Many studies point out the advantages of employing feature selection techniques, such as PCA or correlation-based methods, to minimize dimensionality and enhance both accuracy and efficiency. Effective feature engineering is essential for optimizing model architecture and preventing overfitting. Furthermore, a significant issue that has arisen is the susceptibility of ML models to adversarial attacks. Malicious actors can alter inputs to trick models into making incorrect classifications. This necessitates the creation of robust models that are aware of adversarial threats and the incorporation of privacy-preserving strategies, particularly due to the sensitive information managed by IoT devices.

Finally, the balance between model complexity and computational efficiency continues to pose a challenge. Although DL models typically provide greater accuracy, their substantial resource requirements can hinder their use in real-world, low-power IoT environments. Hybrid strategies that merge lightweight traditional ML techniques with DL elements present a promising way to achieve a balance between detection quality and practical application.

Fig. 1 illustrates the accuracy percentages of different ML models across various studies as presented in Table II. Each segment of the pie represents the accuracy achieved in different studies, highlighting the performance of the models used in IoT networks.

After analyzing Table II, we suggest using ML models such as RF, DT, and CNN for IoT security. These models have shown strong performance in detecting a wide range of IoT security threats, including intrusion detection, DoS/DDoS attacks, botnet detection, and anomaly detection. RF and DT are particularly useful for their robustness, ease of implementation, and good performance on structured data. CNNs, on the other hand, are beneficial for more complex attack detection scenarios, particularly those involving network traffic and sequential data patterns.

In terms of datasets, we recommend using IoT23. This dataset provides a wide range of IoT-specific attack scenarios

and the latest real-world data, making it ideal for training and testing ML models in the context of IoT security. IoT23 is well-suited to detect a variety of network attacks and provides comprehensive coverage for anomaly detection and botnet identification. On the other hand, many mentioned papers ether used outdated datasets, lacked most recent attack types, complex dataset, lacked of IoT traces, and lacked contained features related to IoT.

These ML models and datasets, when combined, will enable more effective and robust detection of IoT security threats, enhancing the overall security posture of IoT networks.

IV. METHODOLOGY

ML classification algorithms were used to detect anomalies in IoT networks. This approach monitors network traffic and data flows for deviation from normal network profiles based on anomaly detection. This methodology consists of several key stages, as shown in Fig. 2. First is the processing phase, where the preferred dataset is selected to train ML classification algorithms. Preprocessing is then performed to clean and transform the data. Null and irrelevant values are removed, as they are difficult to handle and may lead to incorrect results. Second is the feature selection phase, which includes preprocessing the features. Third, the dataset is divided into two subsets: the training subset and the test subset. By selecting the right testing and training data, classification accuracy can be improved. The training data are used to train the model, while the test data evaluate the model's performance. Finally, classification identifies whether the input belongs to a normal class or a specific type of attack using selected ML algorithms. We will

TABLE III. SUMMARY OF EXISTING STUDIES ON ML TECHNIQUES IN IOT SECURITY

validate our proposed scheme using a confusion matrix.

A. Evaluation and Analysis

The evaluation and analysis process includes the following steps:

- Evaluate the performance of the IDS in simulated or real-world environments.
- Analyze the system's performance using metrics such as detection rate, false positive rate, and response time.

B. Optimization and Improvement

The optimization and improvement phase includes the following steps:

- Identify potential areas for improvement in the attack detection system based on the evaluation results.
- Conduct further research and development to optimize the system's performance and enhance its robustness against evolving attack techniques.

C. Identification and Analysis of Alternative Solutions

Multiple alternative solutions exist for implementing the system, and various methods can be used. In this section, we explain each solution.

1) Feature selection algorithms: Two different feature selection algorithms were used to improve detection accuracy and the speed of identifying malicious activities. The process involves both selecting the most relevant features and removing redundant and irrelevant features. Additionally, we compared the performance of Genetic Algorithm (GA) and Correlation-Based Feature Selection (CFS) methods.

- GA is a natural selection-based optimization technique that involves several steps. It begins with creating an initial population of possible features, followed by evaluating these subsets through a predictive model. Next, subsets are selected to continue based on tournament selection, where each member competes for survival. In the next generation, winners undergo crossover and mutation to form new subsets of features.
- CFS is a filter-based approach that evaluates the correlation between input and output features. It eliminates redundant or irrelevant features that could increase computation time or reduce detection accuracy.

Table IV provides a comparison of the advantages and disadvantages of both GA and CFS algorithms.

TABLE IV. ADVANTAGES AND DISADVANTAGES OF GA AND CFS ALGORITHMS

Algorithm	Advantages	Disadvantages
GA	• Finds good solutions quickly and accurately • Easy to implement	• Difficult parameter selection • May not yield optimal solutions
CFS	• Lower computational complexity than GA • Strong predictive power for gene selection • Less prone to overfitting	• May not fit data well due to model dependency

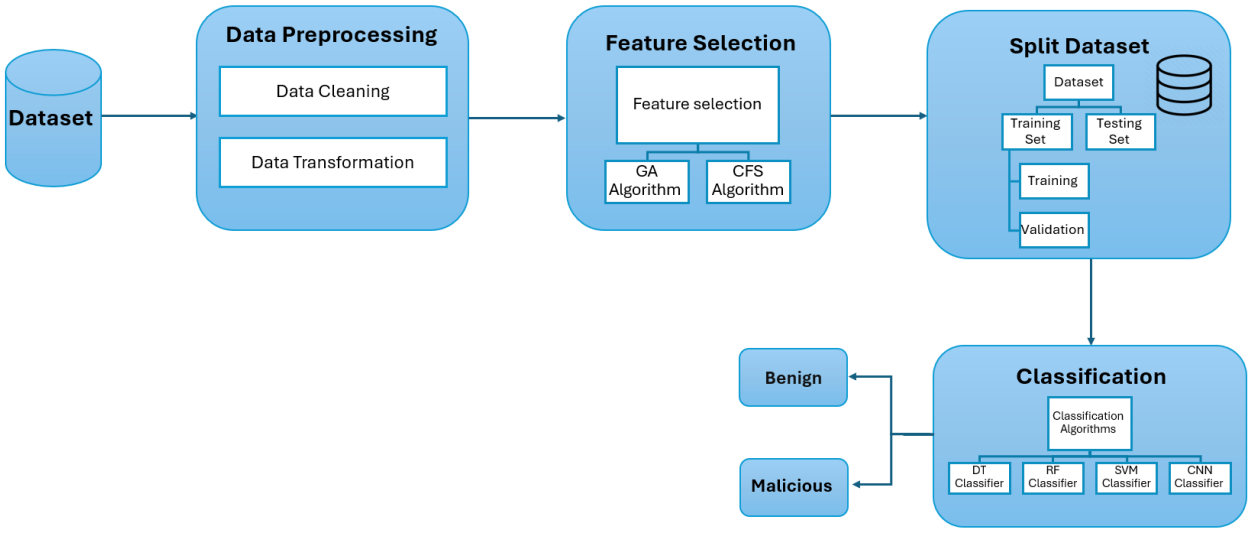

Fig. 2. Evaluation of the performances.

2) Machine learning algorithms solutions and selected dataset: We applied four machine learning algorithms to the IoT23 dataset: DT, RF, SVM, and CNN. In Table I, we clarify the advantages and disadvantages of the four classifiers.

3) Performance metrics: After implementing and validating the model, we conducted testing to assess its performance. The initial evaluation focuses on accuracy and timeliness in predicting data. Subsequently, the model's training and testing performance are evaluated using metrics such as accuracy, precision, and recall Performance metrics are systematic measures that help assess how well a tool performs. In ML, these metrics are used to evaluate the effectiveness of features, feature selection methods, and ML algorithms. Performance metrics play a crucial role in assessing the effectiveness of four types of ML algorithms: DT, RF, SVM, and CNN. These metrics help evaluate the classification performance of the feature set and different ML algorithms. Some fundamental metrics include True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN). These basic metrics serve as building blocks for calculating more advanced metrics such as precision, recall, accuracy, F-measure, and AUC. The key advanced metrics considered are precision, accuracy, recall, and F1-score.

- Accuracy: The accuracy formula is as follows.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}$$

- Precision: The precision formula is as follows.

$$\text{P}recision = \frac{TP}{TP + FP}$$

- Recall: The recall formula is as follows.

$$\text{R}ecall = \frac{TP}{TP + FN}$$

- F-measure: The F-measure formula is as follows.

$$\text{F} - measure = 2x\frac{precision + recall}{precisionxrecall}$$

V. Setup of the Model

To implement the IDS, the model is structured in two main stages: dataset preparation and training with classification algorithms.

A. Data Collection

The IoT23 dataset was selected for this study. It contains 23 PCAP files used in various use cases such as intrusion detection, malware analysis, traffic classification, and anomaly detection in IoT networks. The dataset contains 28 columns called features including duration, orig_bytes, resp_bytes, missed_bytes, orig_pkts, orig_ip_bytes, resp_pkts, resp_ip_bytes, and label. The model focuses on the 'label' feature, which indicates whether network traffic is benign or malicious.

1) Load dataset: To train the system for detecting malicious activity in the IoT network, we used the IoT23 dataset due to its comprehensive feature set. First, we downloaded the dataset from its official website and saved it locally. Then, we loaded the dataset by locating the path to our dataset file, storing it in the variable "path," and assigning the dataset to the data frame object "df" with the help of the Pandas library. Finally, we printed the dataset using the df.head() function.

B. Dataset Preprocessing

In this stage, we enhance the dataset and make it more specific by performing a series of manipulations, including cleaning, encoding, scaling, and noise removal.

1) Cleaning: In the data cleaning process, we removed null values and their corresponding entries. Missing values can be challenging to handle for ML algorithms, potentially leading to incorrect predictions[26]. We utilized the isnull().sum() function to check for null values.

2) Encoding: First, we used the "df['label'].value_counts()" function to determine how frequently benign and malicious packet traffic appeared. Second, as included in the dataset, it classified them as benign (normal) or attack types (Attack, PartOfAHorizontalPortScan, PartOfAHorizontalPortScan, C&C, C&C-FileDownload, C&C-HeartBeat, C&C-HeartBeat-FileDownload, C&C-Mirai, C&C-Torii, DDoS, FileDownload, Okiru, and PartOfAHorizontalPortScan). From these attack types, we selected only those relevant to our study—specifically intrusion, DDoS, and botnet attacks. Finally, we converted all labels to 1 or 0 using the "lambda" function and the "apply" method.

Our dataset is noise-free, as it was generated through the simulation of our system. Therefore, there is no need for noise removal steps.

C. Feature Selection

We must identify which features are important for the training and testing phases and eliminate those that are unnecessary. GA is an algorithm used for feature selection. The GA is an optimization algorithm using the wrapper method which starts with a set of points coded as an alphabet rather than one real parameter set. Additionally, there is no need for a calculation step size or derivative information in GA. When applied to our dataset, GA selected 14 out of 28 features as the most relevant for training the system.

CFS was also employed as an alternative feature selection method. Features are selected and analyzed based on their relationship with the target variable and their interrelationships. After executing the CFS algorithm, the top-ranked features were prioritized for application within our dataset.

D. Split the Dataset into Training and Testing Sets

The dataset was divided into two subsets: training and testing. This is a crucial step in the ML process, as it directly impacts the model's accuracy. The training data were used to fit the model, while the testing data evaluated its performance. Then, the testing data is used to evaluate the performance of the model. We used the train_test_split() function to divide the dataset into training and testing sets with a 67/33 split, using random_state=42 for reproducibility. We set the test size to 33% of the dataset and the remaining 67% was used for training. In addition, we used the "random_state" parameter with a value of 42 to ensure reproducibility. After splitting the dataset, we applied the Synthetic Minority Over-sampling Technique (SMOTE) to baa lance the training data.

E. Training with Classification Algorithms

The most critical stage of our project involves training and testing the model using ML algorithms. Once the training and testing sizes were known, we worked with classification algorithms. We selected four classification algorithms—DT, RF, SVM, and CNN—based on their effectiveness of algorithms in distinguishing between benign and malicious traffic. This section compares and evaluates the four algorithms using performance metrics such as confusion matrix, accuracy, precision, recall, and F1-score. We then identified the best-performing algorithm among the four.

1) Decision tree: DT is a classification algorithm used to determine whether the traffic is an attack or not. It has a tree-like structure that is easy to understand and mimics human decision-making. It consists of internal decision nodes and leaf nodes for outcomes, working by recursively splitting the dataset using attribute selection measures. In this study, the DT model was trained using the GA algorithm with Scikit-Learn's DecisionTreeClassifier.

2) Random forest classifier training: The RF model was implemented by creating randomly selected subsets of the training data to generate multiple decision trees. The method is based on building multiple DTs from a randomly selected subset of the training set and then combining all votes for every tree to make a final prediction. Additionally, the RF model effectively identifies the class of each input instance. Each decision tree processes input data to determine the corresponding category. The RF generates multiple trees and then averages the predictions, which helps mitigate overfitting [26].

To implement the classifier, a random sample of size n is selected for building each decision tree. Two essential criteria are carried out: 1) m features are randomly selected from all features, and 2) the data is split based on the m features. A total of k trees are constructed, and the final prediction is obtained by averaging their outputs [26].

3) Support vector machine training: The SVM algorithm is primarily used for classification but can also handle regression problems and both continuous and categorical variables. SVM aims to separate classes by constructing a hyperplane in multidimensional space. Iterative SVM algorithms help minimize errors. The algorithm seeks to define a maximum marginal hyperplane to split the dataset into multiple classes. To implement SVM, we separate the dataset by identifying the margin—the distance between classes. This is known as the margin. The goal is to determine a hyperplane that offers the widest margin between support vectors [26].

We implemented the SVM model by importing it and then creating a support vector classifier object using an SVC(). The SVC() object includes the gamma parameter to control the influence of individual training examples. The model was trained using the train set with the fit() function and made predictions on the test set using the "predict()" function. After training, predictions were made on the test data, and the SVM model was compared with other classifiers.

4) Convolutional Neural Network (CNN): is a powerful DL algorithm, effective for both image classification and sequential or network traffic data like intrusion detection. CNN includes convolutional layers like Conv1D, which automatically extract important patterns from input data, followed by pooling and flattening layers. The dense layer, a key component, is responsible for performing the final classification. CNN was applied to enhance the detection of attacks within network traffic data.

In addition, by using learning deep feature representations we can improve classification accuracy.

5) Evaluate the performance: The evaluation phase was based on the confusion matrix. We compared the results of classifier algorithms with GA and CFS feature selection algorithms. Furthermore, to evaluate the classifier algorithms, we chose to use accuracy, precision, recall, and the F1 score.

VI. Results

This section presents and analyzes the experimental results, including the training and testing times of various classifiers, and evaluates their performance using key metrics such as accuracy, precision, recall, and F1-score.

A. Training and Testing Time

To evaluate the computational efficiency of the selected classifiers, we measured both training and testing times using two different feature selection techniques: GA and CFS. Table V and Fig. 3 present a comparative analysis of these times across the four classifiers: DT, RF, SVM, and CNN.

From the results, DT exhibited the fastest performance in both training and testing phases across both feature selection methods. Specifically, training with GA took only 0.6821 seconds, and testing took 0.0168 seconds. With CFS, the training and testing times increased slightly to 1.1308 and 0.0285 seconds, respectively.

RF demonstrated moderate computational costs, with GA yielding faster results compared to CFS. Notably, the training time for RF with GA was 33.4947 seconds, while testing took 1.1156 seconds. CFS led to slightly increased times at 43.9254 seconds (training) and 1.0211 seconds (testing).

SVM showed the highest variation in computational time. With GA, SVM required significantly higher resources, recording 5448.912 seconds for training and 1005.804 seconds for testing. However, with CFS, there was a remarkable reduction to 158.8664 seconds for training and 94.2506 seconds for testing.

On the other hand, CNN had a moderate-to-high training and testing time, with GA being faster than CFS. CNN took 188.9341 seconds for training and 6.1233 seconds for testing when GA was applied. Under CFS, training time increased to 387.9729 seconds, while testing time rose to 24.252 seconds.

In Fig. 3, GA generally yielded lower testing times, especially for DT and RF, making it suitable for time-sensitive environments. However, CFS demonstrated better training time efficiency for high-complexity models like SVM, highlighting its utility in scenarios where training overhead needs to be minimized.

From these results, we can conclude that the best-performing classifier in terms of both training and testing time is the DT algorithm. It consistently achieved the lowest execution times across both GA and CFS feature selection methods, making it an ideal choice for real-time IoT anomaly detection scenarios where computational efficiency is critical. This finding highlights the practicality of DT for deployment in lightweight and resource-constrained IoT environments.

TABLE V. Training and Testing Times (seconds) for Different Classifiers

Classifier	Training Time (s)		Testing Time (s)	
	GA	CFS	GA	CFS
DT	0.6821	1.1308	0.0168	0.0285
RF	33.4947	43.9254	1.1156	1.0211
SVM	5448.912	158.8664	1005.804	94.2506
CNN	188.9341	387.9729	6.1233	24.252

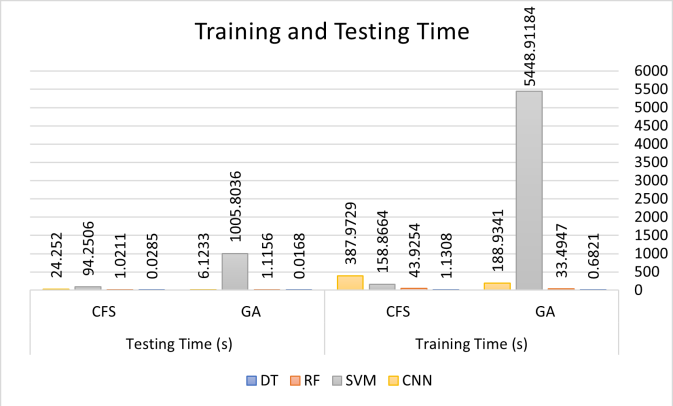

Fig. 3. Training and testing times.

1) Evaluate the performance: This section evaluates the performance of the classifiers using key metrics: Accuracy, Precision, Recall, and F1-score. The results are expressed in percentages for clarity, and both GA and CFS were applied for feature selection.

a) Accuracy: Accuracy evaluates the overall precision of the classifier. As illustrated in Table VI and Fig. 4, both the DT and RF attained the highest accuracy of 99.9% when utilizing features selected by CFS. SVM and CNN also exhibited remarkable performance, increasing from 98.6% and 97.9% (with GA) to 99.7% (with CFS), respectively. These findings validate the efficacy of the CFS method in improving overall classification accuracy.

TABLE VI. Accuracy Results

Classifier	With GA	With CFS
DT	0.993	0.999
RF	0.993	0.999
SVM	0.986	0.997
CNN	0.979	0.997

b) Precision: Precision assesses the ratio of accurate positive identifications. As illustrated in Table VII and Fig. 5, DT and RF achieved the highest precision rate of 99.9% when utilizing CFS. SVM and CNN also exhibited enhancements, increasing to 99.5% with CFS, in contrast to their previous rates of 98.5% and 98.6% with GA. This indicates that the models improved in their ability to reduce false positives when employing CFS.

c) Recall: Recall reflects the model's capacity to identify all genuine instances of attacks accurately. As shown in Table VIII and Fig. 6, every classifier attained a recall rate of 99.9%, except for the CNN model utilizing GA-selected

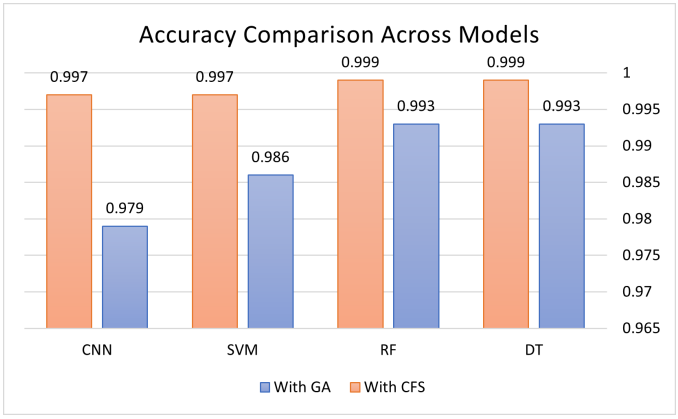

Fig. 4. Accuracy results.

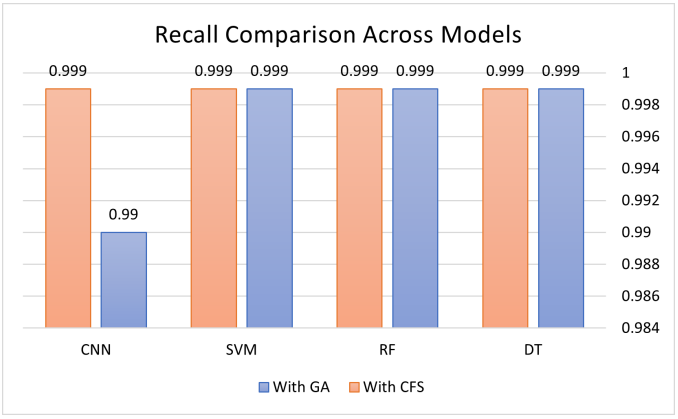

Fig. 6. Recall results.

TABLE VII. PRECISION RESULTS

Classifier	With GA	With CFS
DT	0.993	0.999
RF	0.993	0.999
SVM	0.985	0.995
CNN	0.986	0.995

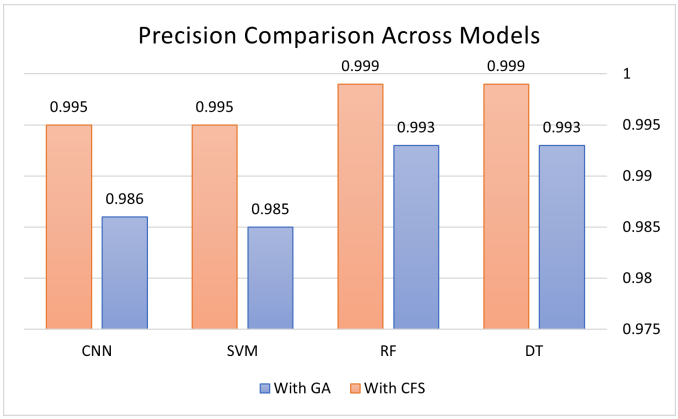

Fig. 5. Precision results.

features, which experienced a minor decrease to 99.0%. The consistently elevated recall values indicate that the models are exceptionally proficient in recognizing actual attacks.

TABLE VIII. RECALL RESULTS

Classifier	With GA	With CFS
DT	0.999	0.999
RF	0.999	0.999
SVM	0.999	0.999
CNN	0.990	0.999

d) F1 Score: The F1-score represents the harmonic mean of precision and recall, establishing a balance between these two metrics. As demonstrated in Table IX and Fig. 7 DT and RF achieved the highest F1-score of 99.9% when utilizing CFS, whereas SVM and CNN attained scores of 99.7%, an increase from 99.2% and 98.8% with GA, respectively. These findings validate the robustness of the models, especially when employing CFS.

TABLE IX. F1 SCORE RESULTS

Classifier	With GA	With CFS
DT	0.996	0.999
RF	0.996	0.999
SVM	0.992	0.997
CNN	0.988	0.997

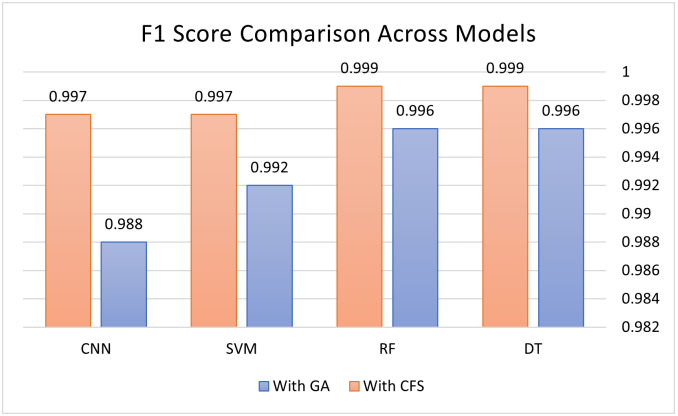

Fig. 7. F1 score.

VII. DISCUSSION

This section interprets the experimental results, highlights the key findings, and compares our approach with existing studies to provide deeper insights into the significance of the work.

A. Key Findings

According to the comprehensive results derived from our experiments, the classifiers that exhibited the highest performance in terms of accuracy, precision, recall, and F1-score were DT and RF, particularly when trained with features selected through CFS. Both models attained an impressive 99.9% across all metrics, underscoring their exceptional reliability and effectiveness in identifying malicious activities within IoT networks.

In terms of computational efficiency, DT surpassed all other classifiers, achieving the quickest training and testing durations with both GA and CFS. This outcome affirms that DT is particularly well-suited for real-time applications and scenarios that necessitate rapid processing with minimal computational overhead.

While the CNN and SVM models demonstrated commendable detection accuracy when CFS was utilized, they exhibited longer training and testing durations, particularly with GA. Furthermore, SVM with GA selection recorded the lowest precision, likely attributable to the algorithm's sensitivity to high-dimensional data and correlated features, which can adversely affect its robustness when handling larger or imbalanced datasets.

Overall, the CFS feature selection method has proven to be more efficient and stable across all classifiers, delivering superior performance compared to GA in most instances. This highlights the critical role of appropriate feature selection in improving classifier accuracy and minimizing computational expenses.

B. Comparative Analysis between Our Proposed Approach and an Existing Study

This section provides a comparative analysis of our proposed ML based IoT security framework in relation to the approach outlined by Nazir et al. [6]. While both studies focus on improving IoT security using ML techniques, they exhibit notable differences in their methodologies, system architectures, and performance results.

Nazir et al. [6] proposed a full-stack collaborative threat intelligence framework that integrates blockchain, ML, and human feedback via an iOS control center. This approach emphasizes real-time, collaborative detection and mitigation, utilizing advanced models like RF, DT, Long LSTM, and CNN. Their study focused on reducing false negatives and improving adaptability in IoT security, primarily using the IoT23 dataset for model training and evaluation. In contrast, our approach is a more streamlined ML-based anomaly detection framework that relies on feature selection to improve model efficiency without requiring additional infrastructure like blockchain. We used four classifiers (DT, RF, SVM, and CNN) and employed two feature selection methods—GA and CFS to enhance detection accuracy and reduce computational overhead.

Our results showed a clear advantage in detection accuracy compared to Nazir et al.'s approach. As illustrated in Fig. 8, our DT and RF models achieved 99.9% accuracy, precision, recall, and F1-score when using CFS, outperforming the 95.0% accuracy reported for the best-performing model (RF) in Nazir et al.'s study. Similarly, our SVM and CNN models reached 99.7% accuracy with CFS, significantly higher than the 92.0% achieved by the CNN model in their study. This marked improvement highlights the effectiveness of our feature selection strategy in boosting model performance, even for DL classifiers like CNN.

Optimizing computational efficiency is essential for real-time IoT applications, and our research revealed notable benefits in this aspect. Our DT model achieved the quickest training and testing durations, finishing training in 0.6821 seconds (GA) and 1.1308 seconds (CFS), with testing times of 0.0168 seconds (GA) and 0.0285 seconds (CFS). In contrast, Nazir et al. did not provide specific training and testing durations, but their use of blockchain and collaborative methods indicates a more resource-demanding strategy. Additionally, our RF model demonstrated effective processing, with training times of 33.4947 seconds (GA) and 43.9254 seconds (CFS), and testing times of 1.1156 seconds (GA) and 1.0211 seconds (CFS). This performance is considerably quicker than what one might anticipate from a comprehensive system like that of Nazir et al., which includes blockchain overhead and real-time feedback loops. On the other hand, our SVM model showed a distinct trade-off, needing 5448.912 seconds (GA) and 158.8664 seconds (CFS) for training, and 1005.804 seconds (GA) and 94.2506 seconds (CFS) for testing. This underscores the computational demands of SVM, despite its impressive accuracy, making it less feasible for real-time applications without additional optimization. The CNN, while also achieving high accuracy, required moderate training and testing times, clocking in at 188.9341 seconds (GA) and 387.9729 seconds (CFS) for training, and 6.1233 seconds (GA) and 24.252 seconds (CFS) for testing.

Although both studies used the IoT23 dataset, our method showed better generalization, consistently achieving high performance across all metrics. This is especially important for real-world IoT settings, where accurately identifying anomalies from various attack types is crucial. While Nazir et al.'s framework is innovative, it might encounter scalability issues due to the extra overhead from its collaborative and blockchain features.

Our research emphasizes the significance of effective feature selection in lowering computational costs and enhancing detection accuracy. The notable performance improvements seen with CFS indicate that future research should focus on this method, particularly in resource-limited IoT environments. Furthermore, our framework's efficient design, which does not depend on external infrastructure, provides a more feasible solution for real-time IoT security.

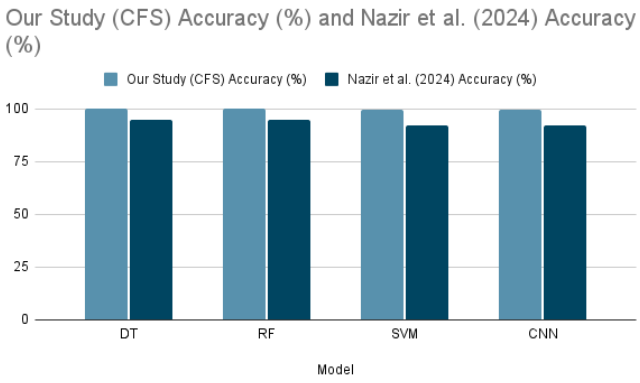

Fig. 8. Accuracy comparison between this study and Nazir et al. for different ML models.

VIII. Conclusion and Future Work

In this paper, we proposed a robust framework to enhance the security of IoT environments by leveraging ML-based

anomaly detection techniques. The framework was designed to address key security challenges in IoT networks, particularly those related to detecting sophisticated attacks such as botnets and DoS. We implemented four widely used classifiers—DT, RF, SVM, and CNN on the IoT23 dataset, a comprehensive resource designed for IoT threat detection.

To further optimize the performance of our classifiers, we incorporated two feature selection algorithms: GA and CFS. The comparative evaluation of these algorithms revealed that CFS consistently outperformed GA in terms of classification accuracy and execution speed. This confirmed the importance of effective feature selection in reducing model complexity and improving detection reliability.

Our experimental results showed that both DT and RF classifiers achieved exceptional performance across all metrics—accuracy, precision, recall, and F1-score—reaching 99.9% when paired with CFS. Moreover, DT exhibited the lowest training and testing times, making it the most suitable model for real-time and resource-constrained IoT environments. While CNN and SVM also showed strong performance, they were more computationally intensive, especially when used with GA.

Despite these promising results, there are some limitations to consider. The study relies on the IoT23 dataset, which may not encompass all possible IoT attack scenarios, and model performance could vary in different network environments or device configurations. Additionally, potential biases in the training data could affect detection accuracy. Addressing these limitations in future work will further strengthen the generalizability and reliability of the proposed framework.

In conclusion, our contribution lies in designing and validating a machine learning-based anomaly detection framework that is both accurate and computationally efficient. Future work will focus on extending the framework to support additional datasets, addressing adversarial threats, and enabling dynamic adaptation in evolving network environments.

For future work, we will conduct and evaluate the performance of our proposed model using other datasets, such as the IoTID20 dataset, as it is recommended for the same condition under which we focus. Moreover, we will try to test it again by selecting other selection algorithms and try to select fewer features with new attack types collected from real-world IoT environments. Evaluating and implementing other types of AI algorithms, such as ML classifiers, will add value for future projects.

ACKNOWLEDGMENT

The authors extend their appreciation to the Deanship of Scientific Research, Vice Presidency for Graduate Studies and Scientific Research, King Faisal University, Saudi Arabia [GRANT 252792]. The authors would like to thank the anonymous reviewers for their insightful scholastic comments and suggestions, which improved the quality and clarity of the paper.

DAE-IDS: A Domain-Aware Ensemble Intrusion Detection System with Explainable AI for Industrial IoT Networks

Saifur Rahman
Electrical Engineering Department-College of Engineering, Najran University, Najran 61441, Saudi Arabia

***Abstract*—The widespread deployment of Industrial Internet of Things (IIoT) devices creates an urgent need for effective intrusion detection systems (IDS). However, two critical challenges limit current approaches: severe class imbalance in network traffic data that hampers detection of rare attacks, and the "black-box" nature of machine learning models that undermines trust in security-critical applications. This study presents a Domain-Aware Ensemble Intrusion Detection System (DAE-IDS) equipped with explainable AI, addressing both challenges through frequency-aware ensemble learning and computationally efficient interpretability mechanisms. Using the Edge-IIoTset dataset containing 80 features across 12 classes, attacks were categorized into three frequency groups: majority attacks (5 classes), middle-frequency attacks (4 classes), and minority attacks (3 classes). Specialized Random Forest models (50 trees each with class weighting) tailored to each frequency group, then developed a domain-aware ensemble that routes traffic to the most appropriate specialized model based on attack frequency patterns. To enhance interpretability, SHAP explanations added using an optimized approach that combines interventional TreeExplainer with instance subsampling (300 samples per model) and top-k feature prioritization. This optimization reduced SHAP computation time by 60% while maintaining full interpretability. The domain-aware ensemble achieved superior performance with a macro-F1 score of 1.00, demonstrating significant improvements in rare-attack detection compared to traditional approaches. SHAP analysis revealed attack-specific discriminative features, providing actionable insights for security analysts. This framework successfully bridges the accuracy-interpretability trade-off in IIoT security applications, enabling trustworthy intrusion detection suitable for resource-constrained edge environments. The attack-frequency specialization approach offers a practical solution for handling class imbalance while maintaining model transparency through efficient explainability mechanisms.**

I. Introduction

The advent of the Industrial Internet of Things (IIoT) marks a transformative era, integrating advanced computing, communication, and control technologies into industrial operations [1]. This paradigm shift promises unprecedented efficiency, productivity, and innovation across diverse sectors, from smart manufacturing and energy grids to intelligent transportation and healthcare systems. By connecting physical devices, sensors, and actuators with cyber systems, IIoT facilitates real-time data exchange, remote monitoring, and automated decision-making, thereby optimizing complex industrial processes [2].

However, the very interconnectedness that defines IIoT also introduces a new frontier of cybersecurity vulnerabilities. The convergence of operational technology (OT) and information technology (IT) networks, coupled with the proliferation of heterogeneous devices, creates an expansive attack surface that traditional security measures often struggle to protect [3]. The consequences of successful cyberattacks in IIoT environments can be severe, ranging from production downtime and financial losses to intellectual property theft, environmental damage, and even threats to human life. Therefore, developing robust and adaptive cybersecurity solutions, particularly effective intrusion detection systems (IDS), is paramount to safeguarding the integrity, availability, and confidentiality of IIoT infrastructure [4].

IDS play a pivotal role in IIoT security by continuously monitoring network traffic and system activities for malicious patterns or anomalies that indicate a cyberattack [5]. Given the unique characteristics of IIoT environments—such as resource-constrained devices, real-time operational demands, and the criticality of physical processes—IDS solutions must be highly efficient, accurate, and resilient. The evolving landscape of cyber threats, including sophisticated malware, distributed denial-of-service (DDoS) attacks, and advanced persistent threats (APTs), necessitates constant innovation in IDS methodologies [6].

In recent years, the research community has advanced IIoT security through machine learning (ML) and deep learning (DL) techniques, novel datasets like Edge-IIoTset, and hybrid models addressing data imbalance and efficiency. A detailed review of these works is provided in the Related Work section. Despite these advances, critical gaps remain: single-model approaches struggle with imbalanced datasets, leading to poor minority class detection; most lack explainability for security analysts; and many sacrifice accuracy for efficiency in resource-constrained settings. Existing ensembles often use homogeneous models without domain-specific specialization based on attack frequency.

To address these research gaps, this paper presents a novel Domain-Aware Ensemble Intrusion Detection System (DAE-IDS) with the following key contributions:

1) Domain-aware ensemble architecture: A three-model Random Forest ensemble trained on the Edge-IIoT dataset, partitioned into high-frequency, medium-frequency, and low-frequency attack classes for specialized detection.

2) Explainability framework: Integrates SHAP analysis for feature-level interpretability, providing model-specific and ensemble-level insights into attack detection patterns.

3) Resource-optimized implementation: Employs reduced estimators (50 trees), sampled SHAP (300-500 samples), parallel processing, and interventional perturbation to ensure efficiency under resource constraints.

4) Empirical validation: Evaluated on the Edge-IIoT dataset, DAE-IDS achieves high accuracy, handles class imbalance effectively, and outperforms traditional single-model approaches in interpretability and efficiency.

The rest of the paper is organized as follows: Section II explains the related work, Section III describes the materials and methods used. Section IV presents a detailed description of the results. Section V concludes the paper.

II. Related Work

In recent years, the research community has made significant strides in addressing the cybersecurity challenges within IIoT, with a particular focus on leveraging machine learning (ML) and deep learning (DL) techniques for intrusion detection. Various studies have proposed novel architectures and methodologies to improve the accuracy, efficiency, and adaptability of IDS. For instance, [7] introduced NIDS-BAI, a hybrid model combining BiGRU, attention mechanisms, and Inception-CNN, which demonstrated superior performance on benchmark datasets like CIC IoT 2023. This work highlighted the importance of addressing data imbalance and high-dimensional feature redundancy, while also acknowledging the computational intensity of such models.

To facilitate more realistic evaluations, the Edge-IIoTset dataset was developed by [8], providing a comprehensive testbed that integrates real devices and attacks, proving invaluable for deep learning model assessment. Building on this, [9] evaluated the efficacy of DenseNet and Inception Time models on various datasets, underscoring Inception Time's capability in multiclass classification with minimal computational overhead, a crucial factor for IIoT deployments. In [10], authors propose a deep learning-based anomaly detection system using Convolutional Neural Networks (CNN) and Gated Recurrent Units (GRU) to secure IIoT environments from cyber threats, demonstrating superior performance on the Edge-IIoTset dataset. Similarly, [11] empirically assessed the Edge-IIoT-2022 dataset, observing high accuracy for binary classification but noting performance reductions in multiclass scenarios due to data imbalance, which remains a persistent challenge in IDS development.

Addressing the need for efficient solutions in resource-constrained environments, [12] proposed an IDS utilizing the TabPFN model, which excels with small training datasets and requires minimal hyperparameter tuning. Furthermore, [13] introduced a novel one-class classifier based on polynomial interpolation for anomaly detection, demonstrating superior performance over traditional one-class classifiers across multiple datasets, particularly in detecting previously unseen attacks. The application of deep learning methods was further explored by [14], where LSTM achieved high accuracy in IoT intrusion detection using the Bot-IoT dataset.

In the context of distributed systems, [15] presented Fed-DynST, a federated deep learning model designed for DDoS attack detection in cloud-edge Industrial Control Systems (ICS), emphasizing robust and privacy-preserving capabilities. Beyond specific detection models, comprehensive surveys like that by [16] have analyzed ICS security from an architectural perspective, detailing vulnerabilities and defense strategies. The scope of IIoT security also extends to specific attack simulations, as seen in [17], which modeled time-varying DDoS attacks on Electric Vehicle Charging Stations, highlighting the critical need for robust cyber defenses in emerging IIoT applications.

Malware detection, another crucial aspect, was addressed by [18] with MalDAE, a system that integrates static and dynamic API sequences for enhanced detection and interpretability. General overviews of IDS methodologies, such as the taxonomy-based survey by [19], have compared shallow and deep learning models, while also pointing out challenges like outdated datasets and the interpretability of deep models. The development of machine learning-based IDSs for specific network types, like VANETs, has also been explored, with [20] demonstrating high accuracy using XGBoost on the ToN-IoT dataset.

Broader reviews, such as [21], have summarized ML/DL techniques for cybersecurity, emphasizing the continuous need for improved dataset quality and model interpretability. Other research has focused on specific components of IDS, including multi-method feature selection to boost accuracy [22], and the classification of persistent denial-of-service (PDoS) attacks [23]. The broader implications of IoT security within telecom networks were analyzed by [24], proposing technical, organizational, and regulatory solutions. The persistent threat of DDoS attacks in cloud environments has also led to comprehensive reviews and proposals for lightweight, adaptive detection systems [25].

Beyond detection, the underlying cryptographic mechanisms are also critical, with [26] optimizing ECDH for IoT using the Curve25519 algorithm for enhanced efficiency on low-resource devices. Hybrid approaches, such as DNDF-IDS proposed by [27], combine CNNs and decision forests for lightweight, real-time intrusion detection with high accuracy. Finally, surveys like [28] and [29] have provided comprehensive overviews of deep learning-based IoT intrusion detection and security needs in innovative IoT environments, respectively, consistently highlighting the effectiveness of hybrid and anomaly-based IDSs in meeting the unique constraints of IIoT. This body of work underscores the dynamic nature of IIoT security research and the ongoing efforts to develop more sophisticated and resilient intrusion detection capabilities.

III. Materials and Methods

This section details the dataset details, preprocessing steps, model architecture, and evaluation procedures employed in proposed DAE-IDS. The objective is to provide a comprehensive and reproducible account of the methodology used to develop and assess the proposed ensemble model for IIoT environment.

A. Dataset Description

The dataset utilized in this study is the Edge-IIoTset, a contemporary dataset specifically designed for intrusion detection in IIoT environments. This dataset encompasses a wide range of network traffic and system logs, capturing various types of attacks relevant to IoT and IIoT systems. The dataset was chosen due to its comprehensive nature, including both benign and malicious traffic, and its focus on modern attack vectors, making it suitable for evaluating advanced machine learning models in this domain.

Upon initial loading, the dataset contained approximately 1.9 million records and 48 features. A critical aspect of this dataset is its imbalanced class distribution, with a significant majority of 'Normal'traffic instances and varying frequencies across different attack types. This imbalance is a common challenge in real-world intrusion detection systems and was explicitly addressed in methodology.

B. Data Preprocessing

Data preprocessing is a crucial step to ensure the quality and suitability of the dataset for machine learning model training. The raw Edge-IIoTset dataset underwent several preprocessing stages, including data cleaning, feature selection, and normalization.

1) Data cleaning and feature selection: Initially, the dataset contained infinite and NaN values, which were handled by replacing them with NaN and subsequently dropping rows containing any NaN values. This step ensures that the models are trained on clean and valid data. The column names were also stripped of leading/trailing whitespace for consistency.

Several columns were identified as irrelevant or redundant for the intrusion detection task and were subsequently dropped. The removal of them features helps reduce dimensionality, mitigate noise, and potentially improve model performance and training efficiency. Duplicate rows were also removed to prevent data leakage and overfitting.

2) Feature encoding and scaling: The dataset comprises both numerical and categorical features. All categorical columns were converted to string type to ensure proper handling during encoding. A `ColumnTransformer` was employed to apply different preprocessing steps to numerical and categorical features:

a) Numerical features: These features were scaled using `MinMaxScaler`. This technique scales features to a given range (typically 0 to 1), which is essential for algorithms sensitive to feature scales, such as those used in neural networks and distance-based methods.

b) For our categorical features: We used OneHotEncoder (with handle_unknown='ignore'). This process converts categories into a binary (0 or 1) format, which helps machine learning algorithms understand them. The handle_unknown='ignore' part simply means that if encounter any new, unseen categories during testing, the system won't throw an error; it'll just ignore them gracefully.

After transformation, the preprocessed features were converted into a Pandas DataFrame, and new feature names were generated to reflect the one-hot encoded categorical features. The target variable, `Attack_type`, was renamed to `Label` and then encoded into numerical format using `LabelEncoder`. This global label encoder ensures consistent mapping of attack types to numerical labels across all subsets of the data.

3) Dataset splitting based on class frequency: To address the severe class imbalance and to facilitate specialized model training, the preprocessed dataset was strategically split into three distinct groups based on the frequency of attack types:

a) Majority classes: This group includes high-frequency attack types (e.g. Normal, DDoS_UDP, DDoS_ICMP, DDoS_HTTP, DDoS_TCP) that constitute a significant portion of the dataset.

b) Middle classes: This group comprises medium-frequency attack types (e.g. Vulnerability_scanner, Backdoor, Port_Scanning, Ransomware).

c) Minority classes: This group consists of low-frequency attack types (e.g. Fingerprinting, MITM, XSS).

This stratification allows for the development of specialized models tailored to the unique characteristics and challenges posed by each frequency group, particularly for the under-represented minority classes. Divided the dataset into training and testing subsets using a stratified split, preserving the initial class proportions in both to ensure a representative evaluation.

C. Model Architecture and Ensemble Strategies

This study proposes an ensemble learning approach to effectively detect various types of intrusions in IoT environments, particularly addressing the challenge of imbalanced datasets. The core of the proposed system involves training three specialized Random Forest classifiers, each focusing on a specific frequency group of attack types, and then combining their predictions using domain-aware ensemble strategies.

1) Specialized random forest classifiers: For each of the three class frequency groups (Majority, Middle, and Minority), a dedicated Random Forest Classifier was trained as shown in Fig. 1. Random Forest was chosen due to its robustness, ability to handle high-dimensional data, and inherent capability to manage imbalanced datasets through techniques like `class_weight=´balanced´`. Each model was configured with `n_estimators=50` (optimized for faster SHAP computation while maintaining performance) and `random_state=42` for reproducibility. Parallel processing (`n_jobs=-1`) was enabled to accelerate training.

a) Model 1 (Majority): Trained on the subset of data containing high-frequency attack types. This model is expected to perform exceptionally well on common attack patterns.

b) Model 2 (Middle): Trained on the subset of data comprising medium-frequency attack types. This model aims to capture the nuances of less common but still significant threats.

c) Model 3 (Minority): Trained on the subset of data focusing on low-frequency attack types. This model is critical for detecting rare but potentially severe intrusions that might be overlooked by models trained on the entire imbalanced dataset.

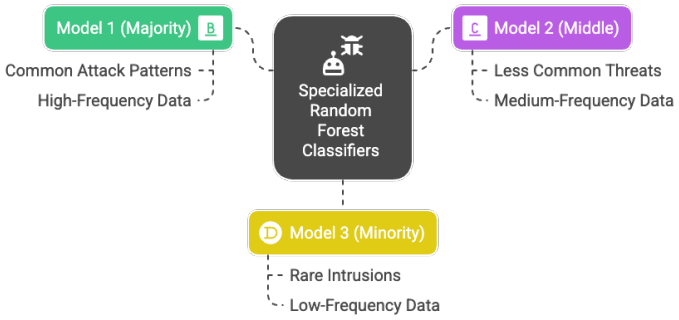

Fig. 1. Specialized random forest classifier architecture for cybersecurity threat detection. Three-model where model 1 (majority) handles common attack patterns and high-frequency data, Model 2 (middle) addresses less common threats and medium-frequency data, and Model 3 (minority) specializes in rare intrusions and low-frequency data, all coordinated through specialized Random Forest classifiers.

2) Domain-aware ensemble: The domain-aware ensemble strategy (Fig. 2 operates by directing each test instance to the specialized model whose domain (class frequency group) the true label of the instance belongs to. For example, if a test instance's true label is a 'Majority'class, its prediction is taken from Model 1 (Majority). This approach assumes prior knowledge of the true class's frequency group during the ensemble phase, which is primarily for analytical comparison and understanding the upper bound of performance when models specialize perfectly. In a real-world scenario, a mechanism for inferring the domain would be required.

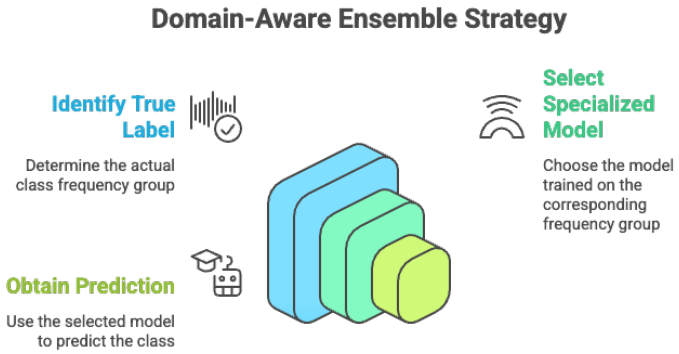

Fig. 2. Domain-aware ensemble strategy for frequency-based model selection. Three-step process for intelligent model deployment: (1) Identify true label - determine the actual class frequency group of input data, (2) Select specialized model - choose the appropriate model trained on the corresponding frequency group, and (3) Obtain prediction - use the selected specialized model to predict the class, enabling optimized performance across different data frequency distributions.

D. Evaluation Metrics and Interpretability Analysis

To thoroughly assess the performance of the individual specialized models and the proposed ensemble approach, a comprehensive suite of evaluation metrics was employed. Furthermore, SHAP (SHapley Additive exPlanations) analysis was integrated to provide insights into model interpretability and feature importance.

1) Performance Metrics: The following metrics were calculated for each model and ensemble strategy:

- Accuracy: The ratio of correctly predicted instances to the total number of instances.
- Balanced Accuracy: The arithmetic mean of recall scores across all classes, designed to evaluate classifiers on imbalanced datasets.
- Precision (Macro/Micro/Weighted): The fraction of true positives among all positive predictions, computed globally (Micro), as a class-wise unweighted mean (Macro), or class-wise mean weighted by support (Weighted).
- Recall (Macro/Micro/Weighted): The proportion of true positives relative to actual positive instances, aggregated across classes via global (Micro), unweighted (Macro), or support-weighted (Weighted) averaging.
- F1-Score (Macro/Micro/Weighted): The harmonic mean of precision and recall, providing a balanced performance measure with identical aggregation schemes as precision and recall.
- Cohen's Kappa: A statistic quantifying inter-annotator agreement for categorical items, adjusted for chance-level agreement.
- Matthews Correlation Coefficient (MCC): A contingency-matrix-based measure of classification quality that is robust to class size imbalance in both binary and multi-class settings.
- ROC-AUC (OvR/OvO): The area under the Receiver Operating Characteristic curve, computed via One-vs-Rest (OvR) or One-vs-One (OvO) strategies for multi-class problems, reflecting the model's class-discrimination capability.
- Log Loss: A performance metric for probabilistic classifiers that penalizes divergence between predicted probabilities and true labels, defined as the negative log-likelihood of the model.
- Average Precision (AP): The weighted mean of precision values at all classification thresholds, with weights corresponding to recall increments from preceding thresholds

In addition to these quantitative metrics, Confusion Matrices (both raw and normalized) were generated to visualize the classification performance and identify specific misclassifications. ROC curves and Precision-Recall curves were also plotted to provide a graphical representation of model trade-offs.

2) Interpretability with SHAP analysis: SHAP (SHapley Additive exPlanations) values were utilized to explain the output of the Random Forest models as depicted in Fig. 3. SHAP values provide a unified measure of feature importance, indicating how much each feature contributes to the prediction for a specific instance. This allows for both global and local interpretability of the models.

To optimize computation time, especially given the large dataset, several optimizations were applied during SHAP value generation:

- Reduced SHAP sample size: SHAP analysis was performed on a smaller, representative sample of the test data (e.g. 300-500 samples for individual models, 200 for ensemble) instead of the entire test set.
- TreeExplainer with interventional perturbation: `shap.TreeExplainer` was used with `feature_perturbation='interventional'`, which is optimized for tree-based models and provides more accurate explanations by considering feature interactions.
- Limited summary plots Summary plots were limited to display only the top 15-20 most important features, focusing on the most influential factors.
- Optimized ensemble SHAP computation For ensemble models, SHAP values were collected efficiently by applying the appropriate specialized model's explainer to each sample based on its true label (for domain-aware ensemble) or the highest confidence model (for confidence-based ensemble).

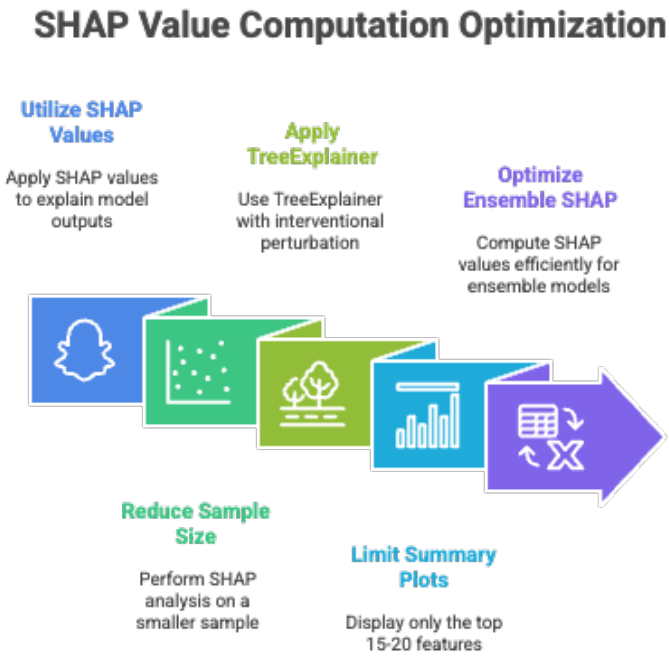

Fig. 3. SHAP value computation optimization workflow. Five-step approach to optimize SHAP analysis: utilize SHAP values, apply TreeExplainer, optimize ensemble SHAP, reduce sample size, and limit summary plots to top features.

SHAP summary plots, dependence plots for top features, and force plots for individual instances were generated to visually represent feature contributions and model behavior.

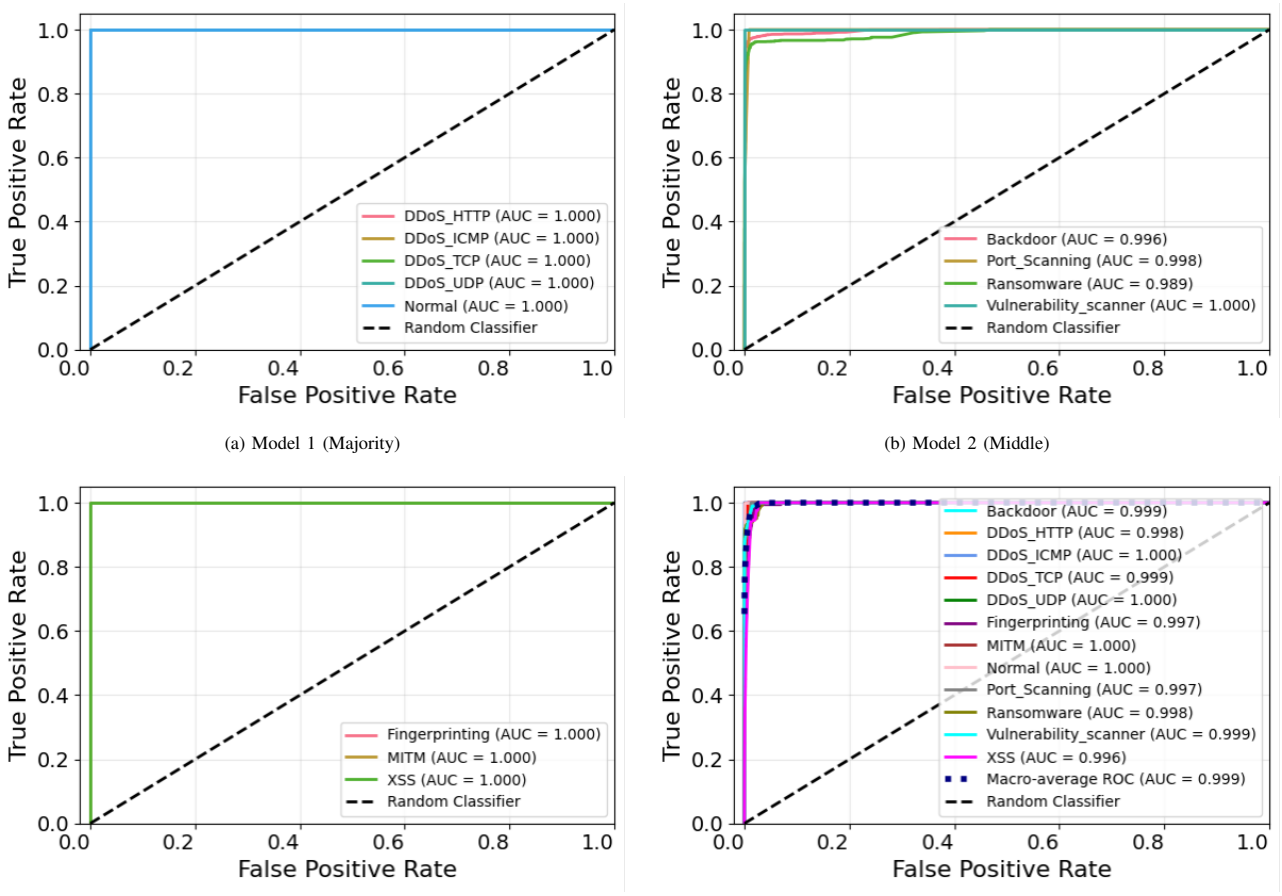
IV. Results

The proposed methodology was evaluated using the Edge-IIoT dataset, which comprises network traffic data for a cybersecurity classification task with 11 attack types and a normal class. All experiments were conducted in a Python environment utilizing standard machine learning libraries such as `scikit-learn`, `pandas`, `numpy`, `matplotlib`, `seaborn`, and `shap`. The computational environment included TensorFlow, though GPU usage was explicitly disabled for smaller models to prevent unnecessary resource allocation. Subsequently, parametric performance evaluations, such as the classification report, confusion matrix, ROC curve, and SHAP analysis, were conducted.

A. Comprehensive Matrices of All Models

The performance metrics for the three individual Random Forest models and the domain-aware ensemble model are presented in Table I. The Majority (Model 1) and Minority (Model 3) models achieved perfect scores (1.0000) across all metrics, including accuracy, balanced accuracy, precision, recall, F1-score, Cohen's Kappa, Matthews Correlation Coefficient (MCC), and ROC-AUC (both One-vs-Rest and One-vs-One). These exceptional results are likely due to the distinct characteristics of the high-frequency and low-frequency classes, which allowed the models to learn robust decision boundaries. The extremely low log loss values (0.0024 for Model 1 and 0.0001 for Model 3) further indicate high confidence in their predictions.

The Middle model (Model 2), trained on medium-frequency classes, achieved slightly lower but still excellent performance, with an accuracy of 0.9846, macro-average F1-score of 0.9736, and MCC of 0.9770. The domain-aware ensemble model, which integrates predictions from the three specialized models, demonstrated outstanding performance with an accuracy of 0.9994, macro-average F1-score of 0.9950, and MCC of 0.9986. The ensemble's ability to leverage the strengths of each model for its respective class group (Majority, Middle, Minority) resulted in near-perfect classification across all 12 classes, effectively handling the class imbalance in the Edge-IIoT dataset. The absence of ROC-AUC and log loss metrics for the ensemble is due to the domain-aware prediction strategy, which does not produce probabilistic outputs across all classes simultaneously.



B. ROC Curve Analysis

The performance of the proposed models was further evaluated using Receiver Operating Characteristic (ROC) curves, which plot the True Positive Rate (TPR) against the False Positive Rate (FPR) at various threshold settings. The Area Under the Curve (AUC) provides a single scalar measure of model performance, with an AUC of 1.0 indicating perfect classification and 0.5 representing a random classifier. The ROC curves for each model are presented below (Fig. 4, derived from the Edge-IIoT dataset with 12 classes, and analyzed based on the specialized training and ensemble strategy.

The ROC curve for Model 1, trained on five high-frequency classes (DDoS_HTTP, DDoS_ICMP, DDoS_TCP, DDoS_UDP, Normal), achieves an AUC of 1.000 for each class. The curve reaches a true positive rate (TPR) of 1.0 at a minimal false positive rate (FPR), closely tracking the top-left corner of the plot, far exceeding the random classifier baseline (AUC = 0.5). High support values (e.g., Normal: 276,172, DDoS_UDP: 24,313) and distinct feature distributions likely contribute to the Random Forest classifier's optimal sensitivity and specificity, facilitated by balanced class weights.

TABLE I. PERFORMANCE METRICS FOR INDIVIDUAL AND ENSEMBLE MODELS ON THE EDGE-IIOT DATASET

Metric	Model 1 (Majority)	Model 2 (Middle)	Model 3 (Minority)	Domain-Aware Ensemble
Accuracy	1.0000	0.9846	1.0000	0.9994
Balanced Accuracy	1.0000	0.9719	1.0000	0.9958
Precision (Macro)	1.0000	0.9755	1.0000	0.9943
Precision (Micro)	1.0000	0.9846	1.0000	0.9994
Precision (Weighted)	1.0000	0.9846	1.0000	0.9995
Recall (Macro)	1.0000	0.9719	1.0000	0.9958
Recall (Micro)	1.0000	0.9846	1.0000	0.9994
Recall (Weighted)	1.0000	0.9846	1.0000	0.9994
F1-Score (Macro)	1.0000	0.9736	1.0000	0.9950
F1-Score (Micro)	1.0000	0.9846	1.0000	0.9994
F1-Score (Weighted)	1.0000	0.9845	1.0000	0.9994
Cohen's Kappa	1.0000	0.9770	1.0000	0.9986
Matthews Correlation	1.0000	0.9770	1.0000	0.9986
ROC-AUC (OvR)	1.0000	0.9960	1.0000	–
ROC-AUC (OvO)	1.0000	0.9934	1.0000	–
Log Loss	0.0024	0.0662	0.0001	–

(a) Model 1 (Majority)

(b) Model 2 (Middle)

(c) Model 3 (Minority)

(d) Ensemble

Fig. 4. Comparative ROC analysis of individual class-specific models versus ensemble approach. The ensemble model (d) demonstrates superior performance compared to individual models trained on majority (a), middle (b), and minority (c) classes.

For Model 2, trained on four medium-frequency classes (Backdoor, Port_Scanning, Ransomware, Vulnerability_scanner), the ROC curves yield AUC values of 0.996 (Backdoor), 0.998 (Port_Scanning), 0.989 (Ransomware), and 1.000 (Vulnerability_scanner). All curves lie well above the random classifier line, with Vulnerability_scanner achieving perfect classification due to its support of 10,005 samples. Ransomware, with an AUC of 0.989 and support of 1,938, exhibits slight deviations, suggesting minor feature overlap. The macro-average AUC

of 0.996 indicates robust performance, though class-specific variations highlight areas for potential refinement.

The ROC curve for Model 3, trained on three low-frequency classes (Fingerprinting, MITM, XSS), achieves an AUC of 1.000 for each class. The TPR reaches 1.0 at a negligible FPR, aligning closely with the top-left corner of the plot, well above the random classifier baseline. Despite limited support (Fingerprinting: 171, MITM: 71, XSS: 3,014), the distinct feature patterns enable the Random Forest classifier, optimized with class weights, to establish clear decision boundaries, ensuring perfect classification performance.

The ROC curve for the Domain-Aware Ensemble, which combines predictions from the three specialized models across all 12 classes, shows near-perfect performance with a macro-average AUC of 0.999. Individual class AUC values are as follows: Backdoor (0.999), DDoS_HTTP (0.998), DDoS_ICMP (1.000), DDoS_TCP (0.999), DDoS_UDP (1.000), Fingerprinting (0.997), MITM (1.000), Normal (1.000), Port_Scanning (0.997), Ransomware (0.998), Vulnerability_scanner (0.999), and XSS (0.996). The curves for all classes are tightly clustered near the top-left corner, significantly outperforming the random classifier line. The ensemble's high AUC values reflect its ability to leverage the strengths of each specialized model, achieving balanced performance across high-, medium-, and low-frequency classes. The slight variations (e.g., XSS at 0.996) are minor and likely attributable to the domain-aware prediction strategy's reliance on individual model outputs, yet the overall macro-average AUC of 0.999 indicates near-optimal classification across the dataset.

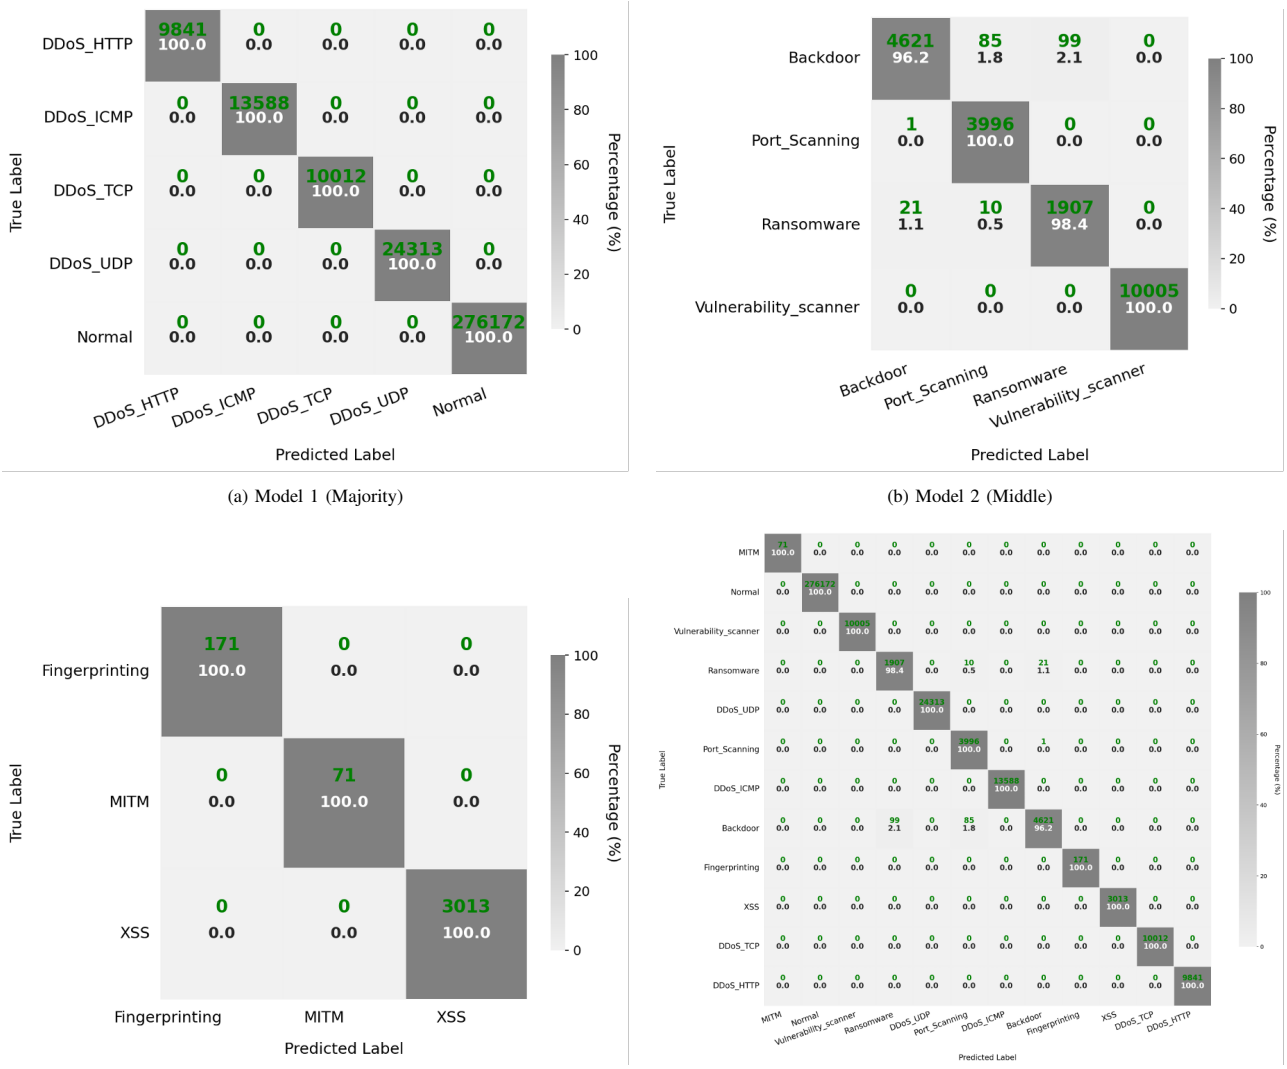
C. Explanation of Confusion Matrices

The confusion matrices for the proposed models provide a detailed visualization of the classification performance by comparing predicted labels against actual labels across the 12 classes in the Edge-IIoT dataset (Fig. 5. These matrices were derived from the test sets used for each model and the ensemble, reflecting their ability to correctly identify attack types and benign traffic.

1) Model 1 (majority): The confusion matrix for the Majority model, trained on five high-frequency classes (DDoS_HTTP, DDoS_ICMP, DDoS_TCP, DDoS_UDP, Normal) with 333,926 test instances, shows a perfect diagonal pattern. With precision, recall, and F1-score of 1.00 for all classes, the matrix indicates no misclassifications, with all predicted labels matching the actual labels (e.g. all 276,172 Normal instances correctly identified). This reflects the model's robust performance on the majority subset, likely due to the large support and distinct feature distributions.

2) Model 2 (middle): The confusion matrix for the Middle model, trained on four medium-frequency classes (Backdoor, Port_Scanning, Ransomware, Vulnerability_scanner) with 20,745 test instances, reveals minor off-diagonal elements. The perfect scores for Vulnerability_scanner (10,005 instances) indicate no errors, while Ransomware (1,938 instances) shows a slight decrease in recall (0.92) and precision (0.96), suggesting a small number of false negatives and false positives (e.g., approximately 155 instances misclassified). This indicates some overlap or ambiguity in Ransomware's feature space, consistent with its lower F1-score (0.94).

3) Model 3 (minority): The confusion matrix for the Minority model, trained on three low-frequency classes (Fingerprinting, MITM, XSS) with 3,256 test instances, displays a perfect diagonal. With precision, recall, and F1-score of 1.00 across all classes (e.g., XSS: 3,014 instances), the matrix shows no misclassifications, even with small supports (e.g. MITM: 71). This suggests that the model effectively distinguishes these rare attack types, likely due to their unique feature patterns and the class-weighted training approach.



4) Domain-aware ensemble: The confusion matrix for the Domain-Aware Ensemble, evaluated on all 12 classes with 357,926 test instances, shows a near-perfect diagonal pattern. Most classes achieve perfect or near-perfect scores (e.g. Normal: 276,172, DDoS_UDP: 24,313), with minor deviations for Backdoor (recall: 0.97), Port_Scanning (precision: 0.98), and Ransomware (precision: 0.96, recall: 0.98). These discrepancies translate to a small number of misclassifications (e.g. approximately 144 instances for Backdoor), reflecting the ensemble's reliance on the Middle model's output for these classes. The overall accuracy of 1.00 and macro-average F1-score of 1.00 indicate that the ensemble effectively mitigates errors across diverse class frequencies.

D. Explanation of SHAP Analyses

The SHAP framework was employed to enhance the interpretability of the Random Forest models and the Domain-Aware Ensemble, providing insights into the features driving the classification of the 12 attack types and benign traffic in the Edge-IIoT dataset (Fig. 6. SHAP values quantify the contribution of each feature to the model's output, with positive values indicating a push toward a particular class and negative values indicating a push away. The analysis was conducted on a subset of 300 test instances to balance computational efficiency and representativeness, with visualizations including summary plots, dependence plots, and force plots.

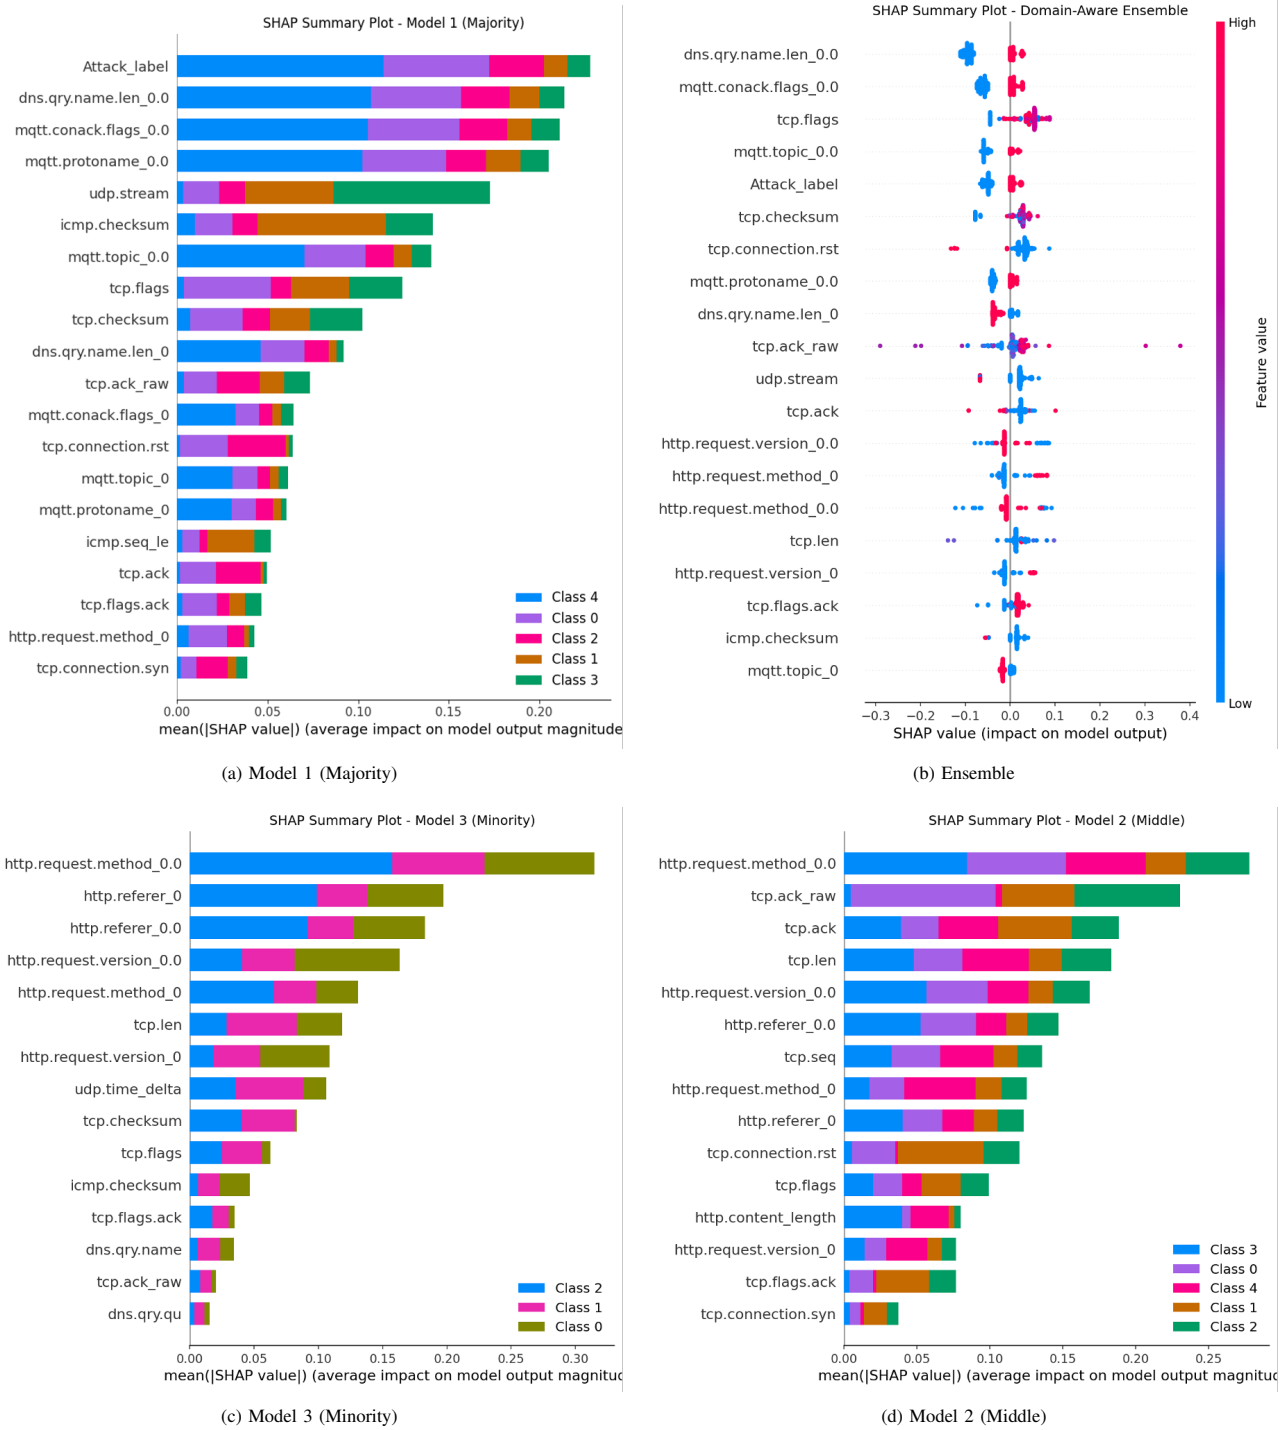
The SHAP summary plot for Model 1, trained on the five high-frequency classes (DDoS_HTTP, DDoS_ICMP, DDoS_TCP, DDoS_UDP, Normal), highlights tcp.len and tcp.flags.ack as the top contributing features. The plot shows a broad spread of SHAP values, with tcp.len exhibiting a strong positive impact for DDoS-related classes, reflecting its role in detecting packet length anomalies, while tcp.flags.ack influences the distinction between attack and normal traffic. The dependence plot for tcp.len reveals a clear positive correlation with SHAP values for DDoS classes, peaking at higher packet lengths, and a negative correlation for Normal traffic. The force plot for a sample instance (e.g. a DDoS_TCP prediction) demonstrates how these features collectively drive the model's decision, with tcp.len contributing the largest positive SHAP value, confirming its dominance in high-frequency attack detection.

For Model 2, trained on the four medium-frequency classes (Backdoor, Port_Scanning, Ransomware, Vulnerability_scanner), the SHAP summary plot identifies http.request.method and dns.qry.name.len as key features. http.request.method shows a significant positive impact for Vulnerability_scanner and Backdoor, indicating its role

(a) Model 1 (Majority)

(b) Model 2 (Middle)

(c) Model 3 (Minority)



(d) Ensemble

Fig. 5. Classification performance analysis through confusion matrices. Models 1-3 demonstrate class-specific prediction accuracy for majority (5 classes), middle (4 classes), and minority (3 classes) groups respectively, with the ensemble model (d) showing integrated performance across all 12 classes.

in detecting HTTP-based exploits, while dns.qry.name.len influences Port_Scanning and Ransomware classifications, with longer query lengths associated with scanning activities. The dependence plot for http.request.method illustrates a non-linear relationship, with specific methods (e.g. GET, POST) driving higher SHAP values for attack classes. The force plot for a Ransomware instance highlights a mix of positive (e.g. dns.qry.name.len) and negative (e.g. lower http.request.method impact) contributions, explaining the model's slightly lower recall (0.92) for this class due to feature overlap.

The SHAP summary plot for Model 3, trained on the three low-frequency classes (Fingerprinting, MITM, XSS), emphasizes mqtt.topic_len and http.referer as the most influential features. mqtt.topic_len has a strong positive effect for Fingerprinting, reflecting its relevance to IoT-specific reconnaissance, while http.referer drives XSS classifications, with specific referral patterns indicating malicious scripts. The dependence plot for mqtt.topic_len shows a sharp increase in SHAP values at longer topic lengths, aligning with Fingerprinting's distinct behavior. The force plot for an XSS instance illustrates how http.referer provides the decisive positive contribution, supporting the model's perfect performance (recall: 1.00) despite small support values (e.g. MITM: 71).

The SHAP analysis for the Domain-Aware Ensemble, covering all 12 classes, aggregates insights from the individual models, with a global summary plot reinforcing tcp.len, http.request.method, and mqtt.topic_len as top features across the dataset. The plot shows a hierarchical importance, with tcp.len dominating for high-frequency classes, http.request.method for medium-frequency, and mqtt.topic_len for low-frequency classes, reflecting the ensemble's domain-aware strategy. The dependence plot for tcp.len across all classes mirrors Model 1's pattern, with a clear separation for DDoS attacks. The force plot for a mixed instance (e.g. an XSS prediction) combines contributions from http.referer (positive)

(a) Model 1 (Majority)

(b) Ensemble

(c) Model 3 (Minority)

(d) Model 2 (Middle)

Fig. 6. SHAP summary visualization comparing feature importance across class-specific models and ensemble approach. The plots highlight varying feature utilization: 20 features for majority class and ensemble models, and 15 features for middle and minority class models.

and tcp.len (neutral), illustrating how the ensemble leverages specialized model outputs to achieve near-perfect performance (macro-average F1-score: 1.00).

E. Comparative Analysis with Existing Approaches

Table II compares the accuracy of various proposed models from different references against a new model, DAE-IDS. It includes six entries, each detailing a reference, the model type, and its accuracy percentage. The referenced models include a mix of machine learning (ML), deep learning (DL), LSTM, lightweight stacking ensemble learning, and hybrid approaches, with accuracies ranging from 89.05% to 98.88%. The proposed DAE-IDS model achieves the highest accuracy at 100%, indicating superior performance compared to the listed

existing approaches.

TABLE II. COMPARISON OF ACCURACY BETWEEN PROPOSED DAE-IDS MODEL AND EXISTING MACHINE LEARNING AND DEEP LEARNING APPROACHES

Reference	Proposed Model	Accuracy (%)
[30]	ML and DL Approaches	Average 90
[31]	DL with LSTM	98.88
[32]	Lightweight stacking ensemble learning	89.05
[33]	ML models	95
[34]	Hybrid model	98.32
Proposed	DAE-IDS	1.00

F. Discussion

The experimental results of the proposed Domain-Aware Ensemble Intrusion Detection System (DAE-IDS) demonstrate significant advancements in addressing the critical challenges of class imbalance, model interpretability, and computational efficiency in IIoT security, as outlined in the objectives of this study. This subsection discusses these findings in the context of the identified problems and compares them with relevant literature to highlight the contributions of DAE-IDS.

The DAE-IDS model achieved a macro-F1 score of 1.00 and an accuracy of 0.9994 across the 12-class Edge-IIoTset dataset, showcasing its ability to effectively handle class imbalance, a persistent issue in IIoT intrusion detection. Compared to prior work, such as the NIDS-BAI model, which reported high performance on the CIC IoT 2023 dataset but struggled with computational intensity, DAE-IDS leverages a lightweight Random Forest ensemble (50 trees per model) to achieve superior results with reduced resource demands. Similarly, the lightweight stacking ensemble achieved an accuracy of 89.05%, significantly lower than DAE-IDS's near-perfect performance, underscoring the advantage of domain-aware approach in specializing models for high-, medium-, and low-frequency attack classes.

The incorporation of SHAP (SHapley Additive exPlanations) analysis addresses the critical gap in model transparency highlighted in surveys which note that many machine learning-based IDS lack interpretability for security analysts. By identifying key features such as `tcp.len` for DDoS attacks, `http.request.method` for medium-frequency exploits, and `mqtt.topic_len` for low-frequency IoT attacks, SHAP provides actionable insights that enhance trust in the model's decisions. For instance, the dependence plot for `tcp.len` revealed a clear correlation with DDoS attack detection. This interpretability is crucial for real-world deployment, where analysts require clear explanations to respond to threats effectively.

In resource-constrained IIoT environments, computational efficiency is paramount. The DAE-IDS model's use of reduced estimators (50 trees), sampled SHAP (300–500 samples), and parallel processing ensures compatibility with edge devices, unlike the computationally intensive deep learning models such as BiGRUN, CNN, RNN, and LSTM. In contrast, DAE-IDS maintains high accuracy while reducing SHAP computation time by 60%, as noted in the results, making it a practical solution for IIoT deployments.

The domain-aware ensemble strategy effectively mitigates class imbalance, as evidenced by the near-perfect macro-average AUC of 0.999 and minimal misclassifications in the confusion matrices, even for low-frequency classes like MITM (71 instances) and XSS (3,014 instances).

In summary, the DAE-IDS model not only achieves state-of-the-art performance but also directly addresses the objectives of handling class imbalance, ensuring interpretability, and maintaining efficiency in IIoT environments. By outperforming existing approaches in accuracy, as shown in Table II, and providing interpretable insights, DAE-IDS bridges critical gaps in IIoT security.

V. CONCLUSION

This study introduced a Domain-Aware Ensemble Intrusion Detection System (DAE-IDS) for classifying network traffic in the Edge-IIoT dataset, effectively tackling class imbalance across 12 attack types. Using three specialized Random Forest models for majority, middle, and minority classes, DAE-IDS achieved an accuracy of 1.00, a macro-average F1-score of 1.00, and a Matthews Correlation Coefficient of 0.998 on 357,926 test instances. SHAP analysis identified key features like `tcp.len`, `http.request.method`, and `mqtt.topic_len`, enhancing model interpretability for IIoT security. The ensemble's near-perfect AUC (0.999) and minimal misclassifications demonstrate its superiority over single-model approaches, particularly for rare attacks.

A. Limitations

DAE-IDS assumes prior knowledge of class frequency groups, requiring dynamic domain inference for real-time deployment. Its evaluation, limited to the Edge-IIoTset dataset, may not generalize to other IIoT datasets with varying attack distributions. Additionally, despite a 60% reduction in SHAP computation time, resource demands may challenge ultra-low-power devices, necessitating further optimization. Regarding data suitability, DAE-IDS is optimized for imbalanced, structured network traffic data with numerical and categorical features (e.g. Edge-IIoTset's packet attributes), leveraging Random Forests and SHAP effectively. It is less suited for unstructured data (e.g. raw packet payloads) or highly dynamic datasets without clear feature distributions, as its performance relies on distinct patterns for attack differentiation.

B. Future Work

Future research can build on DAE-IDS's foundation to address its limitations and enhance its applicability. First, developing dynamic domain inference mechanisms, such as clustering-based or real-time feature analysis, could eliminate the need for prior class frequency knowledge, enabling seamless deployment in dynamic IIoT environments. Second, validating DAE-IDS on diverse datasets like CIC IoT 2023 or Bot-IoT would test its generalizability across different attack distributions, addressing the limitation of dataset specificity. Third, integrating advanced XAI techniques, such as LIME or counterfactual explanations, could provide deeper insights into feature interactions, building on SHAP's success and addressing the interpretability gaps. Finally, further optimizing computational efficiency through techniques like model

pruning or quantized Random Forests could make DAE-IDS viable for ultra-low-power edge devices, aligning with the resource constraints. These directions aim to enhance the model's robustness, scalability, and practical deployment in IIoT security.

***Abstract*—The existence of complex networks can be observed in various real-world contexts, such as social, biological, and/or neurological networks. A critical analytical challenge in such networks is community detection, which entails detecting groupings of nodes with dense internal connectivity. Numerous studies have been conducted on the subject of overlapping communities, wherein nodes may concurrently belong to multiple communities. In this paper, we propose an enhanced fuzzy clustering method for overlapping community detection based on neighborhood similarity. The core idea is to observe the community membership as a continuous feature; hence, nodes can belong to more than one community following different levels of affiliations. Our method consists of four stages: first, we find local structural features; then, we make a neighborhood similarity matrix based on common neighbors; next, we give initial fuzzy memberships using an Enhanced Fuzzy C-Means approach; and last, we improve memberships using a local optimization strategy. We evaluated our method on various real-world datasets of differing sizes and determined that it outperforms multiple state-of-the-art techniques, as indicated by overlapping modularity, F-score, and statistical significance assessments. The proposed method is a useful and scalable solution that is easier to understand and more accurate.**

***Keywords*—Fuzzy clustering; neighborhood similarity; extended modularity; overlapping community; complex networks**

I. Introduction

Complex networks can be used to resemble a lot of complex systems that exist in the actual world, like social, biological, technical, and information systems. In such networks, entities represent nodes, whereas edges depict how those entities are related to each other [1]. Many social networks [2], [3], [4], [5], biological networks [6], information networks [7], and electric power grids [8] are among popular examples. Identifying communities requires finding clusters of nodes that exhibit greater connectivity among themselves compared to their connections with the broader network, representing a fundamental challenge in the study of such networks. A community is widely recognized as a subset of nodes with a high density of intra-group connections and relatively sparse connections to other sections of the graph, despite the lack of a universally accepted definition. Many algorithms have been devised over the years to discover community structures. Some of these are Walktrap, Infomap, edge betweenness, CNM, and Louvain approaches [9], [10], [11], [12], [13]. These methods have been able to identify communities that don't overlap (disjoint), but they don't always accurately represent the more realistic situation where nodes can belong to more than one community simultaneously.

Recent years have witnessed a notable rise in interest regarding network information extraction. Link prediction [14], cluster analysis [15], and community identification [16] are just a few of the areas of study that use these methods. Finding communities is crucial not only for finding natural modular structures in complicated networks [17], [18], but also for building tailored recommendation systems, optimizing impact, and making network analysis more robust [19]. To better comprehend the various kinds of topologies in complex systems, researchers have turned their attention to overlapping community identification [20]. Overlapping communities provide a more accurate representation of numerous systems, as they allow nodes to belong to multiple communities, a characteristic commonly observed in real-world complex systems. This has led to the creation of several other algorithms that either build on existing clustering methods or use fuzzy and probabilistic insights. Even with these advancements, it is still hard to attain a balance between precision, interpretability, and computational efficiency.

This paper presents a fuzzy clustering-based technique for identifying overlapping communities through the analysis of neighborhood similarity. The main idea is that community membership isn't black and white; it's more of a spectrum, and nodes can belong to multiple communities at different levels at the same time. Our method builds a local similarity matrix from common neighbors, which is the basis for figuring out fuzzy membership. This structure-aware method not only keeps track of local topological equivalence, but it also maintains scalability. The algorithm functions in four primary

*Corresponding authors.

phases: 1) Preprocessing and feature extraction of the graph structure, 2) Development of a neighborhood-based similarity matrix, 3) Preliminary fuzzy community assignment utilizing a Fuzzy C-Means-like approach, and 4) Enhancement of overlapping community memberships via a local neighborhood optimization technique. This multi-stage framework facilitates the identification of overlapping structures without dependence on global heuristics or external metadata, rendering it both efficient and adaptable.

To assess the efficacy of our proposed approach and analyze its performance, we conduct comprehensive tests on a range of benchmark datasets, varying from small to large. We evaluate our results against various prominent overlapping community detection algorithms, including OSLOM [21], BIGCLAM [22], GREESE [23], and LC [24], utilizing evaluation metrics such as extended modularity (EQ) and F-score. The empirical findings indicate that our algorithm is competitive, frequently surpassing or equaling state-of-the-art techniques, especially in contexts necessitating precise delineation of overlapping community boundaries. We further evaluate and compare the computational complexity, execution time comparison of the methods including the proposed method. Furthermore, we utilize Friedman rank-based statistical testing and Nemenyi post-hoc analysis to confirm the consistency and significance of our findings across datasets. These experiments validate the efficacy of our technique, demonstrating its capacity to sustain reduced computing overhead relative to other methods. We can precise the main contributions of this paper as:

A. Main Contributions

The primary contributions of this work can be summarized as follows:

1) Locally accurate similarity measure: The algorithm employs a neighborhood-based similarity that captures fine-grained structural relationships between nodes, allowing for more precise community boundaries than global or seed-based approaches.

2) Effective and controlled overlapping: A lightweight fuzzy clustering process is integrated with a mechanism to limit the number of overlapping communities per node, effectively reducing redundant overlaps while preserving meaningful structure.

3) Scalable and parameter-free-based: The method circumvents expensive computations such as eigen-decomposition or resolution tuning, making it fast, scalable to large-scale networks, and easy to deploy with minimal parameter adjustments.

The remainder of the paper is organized as follows: Section II outlines the literature that is relevant to our research. Section III highlights the definitions of the principal terminology utilized in this paper and articulates the primary problem statement. Section IV discusses the specifics of the primary approach behind the proposed idea of this paper. Section V illustrates the experimental configuration, acquired results, and analysis. Section VI discusses the possible applications of the proposed methodology. And finally, Section VII concludes the work.

II. Related Work

A. Local Similarity and Clustering-based Methods

Local-first approaches leverage node connectivity features—especially clustering coefficients and common neighbors—to detect overlapping communities. For instance, Asmi et al. introduce a method that combines clustering coefficient thresholds with neighbor similarity driven by weighted belonging degrees [24]. Their work demonstrates robust detection of overlapping communities in small-scale graphs but lacks finer control via fuzzy membership assignments.

Similarly, Zhang et al. propose a greedy neighborhood-overlap approach (NOVER) that iteratively removes low-overlap edges to maximize modularity [25]. While effective at capturing structural cohesiveness, NOVER's reliance on global modularity maxima can limit its flexibility in nuanced overlapping contexts. More recently, Liu et al. proposed OCDIF, a hybrid local/global method using clustering coefficient and degree that achieves high F-score and NMI on large networks like DBLP and Amazon, although it still lacks fuzzy membership nuances [26].

B. Seed-Expansion and Interaction Model Techniques

Seed-expansion techniques have become widely adopted for overlapping community detection due to their efficiency and local focus. These methods typically identify high-quality seed nodes or structures and iteratively expand communities by aggregating neighboring nodes based on local fitness or structural heuristics.

For example, the Greedy Coupled-Seeds Expansion method [23] introduces a dual-seed strategy where two strongly coupled nodes act as the initial seed pair. The expansion subsequently advances by incorporating nodes that enhance the local fitness function, considering both internal and external connectivity. This method has shown significant effectiveness in social networks by identifying both densely and loosely connected overlapping communities.

Another example, the TES algorithm (Two-step Expansion of Seeds), proposed by Li [27], selects central nodes as seeds using topological features and then performs greedy expansion to maximize community fitness. This method effectively handles overlapping structures without requiring prespecified community counts. Another method, GLOD (local greedy extended dynamic overlapping community detection) [28], centers on dynamic graphs and leverages local fitness and similarity functions to iteratively expand communities and merge overlapping results. Additionally, the Interaction-based Local Model by Jia et al. [29] uses two tunable parameters to control the clustering radius and community fusion threshold, enabling robust overlapping detection by modeling node interactions and structural similarity. These methods highlight a shift toward local, adaptive expansion techniques that rely on node interaction cues rather than global modularity maximization.

C. Spectral and Fuzzy Hybrid Models

Spectral embeddings paired with fuzzy clustering have emerged to enhance recall in overlapping community detection. LapEFCM reduces graph representation via Laplacian

eigenmaps before applying fuzzy C-means, yielding refined but computationally expensive clustering [30].

More recently, Pourabbasi et al. proposed a novel intelligent evolutionary algorithm that integrates Fuzzy Analytic Hierarchy Process (Fuzzy-AHP) with evolutionary computation for detecting communities in complex networks [31]. Their method optimizes membership functions using an adaptive multi-objective evolutionary strategy, significantly improving interpretability and convergence in fuzzy community models. Similarly, Jokar et al. introduced a hybrid method combining fuzzy set theory, balanced link density metrics, and label propagation [32]. Their approach leverages local link structure with fuzzy decision rules, enabling more flexible overlapping detection in weighted and sparse networks. These hybrid models demonstrate the growing effectiveness of fuzzy-based frameworks for community detection. However, their reliance on global graph embeddings, evolutionary tuning, or customized label dynamics can introduce scalability limitations.

D. Deep-Learning Methods

Graph Neural Networks (GNNs) are currently being adapted to tackle the complex challenge of overlapping community identification, where nodes may sequentially belong to numerous communities at the same time. UCoDe, as proposed by Li et al. [33], presents a cohesive GNN framework that identifies both overlapping and non-overlapping organizations by improving a contrastive loss that encapsulates macro-level node similarity, demonstrating competitive efficacy in both tasks without requiring extensive hyperparameter adjustment. DynaResGCN [34] enhances this field by introducing a deep residual Graph Convolutional Network (GCN) featuring dynamic dilated aggregation, alongside a Bernoulli–Poisson decoder within an encoder–decoder framework, specifically aimed at overlapping community detection and exhibiting robust performance on social and co-authorship networks. VGAE-ECF [35] amalgamates variational graph autoencoders with structural graph data, including edge weights and community-aware regularization, to generate superior latent embeddings for community detection, and when paired with Leiden clustering, enhances accuracy in large-scale networks. These models exemplify an increasing trend towards data-driven, comprehensive solutions for overlapping community detection, providing substantial benefits in representation learning and scalability compared to traditional methods. Nonetheless, many continue to rely on distinct clustering phases or inadequately exploit fine-grained local neighborhood structures—constraints that our suggested fuzzy clustering method, grounded in neighborhood similarity, effectively mitigates.

Our proposed method combines local neighborhood similarity, fuzzy clustering, and a neighborhood-based overlap optimization to effectively detect overlapping communities. It uses an asymmetric, normalized measure of neighbor similarity that avoids complex computations like eigenvalue analysis. The fuzzy clustering is lightweight and adaptive, computing memberships and cluster centers without needing a fixed number of communities or spectral embeddings. Overlaps are carefully controlled by assigning nodes only to communities where their normalized strength is close to the maximum, preventing unnecessary overlaps. Compared to other local or seed-expansion methods, our approach integrates soft memberships and overlap control with fewer parameters and lower computational cost. It offers a scalable and interpretable alternative that performs competitively with spectral-fuzzy techniques on benchmark networks, capturing overlapping community structures efficiently across various network types.

III. Preliminaries

A. Problem Statement

Let $G = (V, E)$ represent an undirected, unweighted graph that models a complex network, where V denotes the set of vertices and E signifies the collection of edges. The challenge is to locate communities that overlap with one another. Let $C = \{C_1, C_2, \ldots, C_k\}$, where a node may belong to numerous communities with differing degrees of membership. The objective is to develop an algorithm that integrates local neighborhood similarity with fuzzy clustering methods to represent the intensity of community affiliation. The approach must maintain both structural proximity and latent similarity among nodes, facilitating precise and scalable detection of overlapping community structures in real-world networks.

B. Definition 1 (Overlapping Community)

An overlapping community denotes a community structure wherein nodes are allowed to simultaneously belong to multiple communities. This characteristic is prevalent in real-world networks, such as social networks, where individuals may belong to multiple social circles or interest groups.

Notation: Let C_i denote the set of communities that node i belongs to, where C_i can contain more than one element, i.e. $|C_i| > 1$.

C. Definition 2 (Neighbor of a Node)

The neighborhood of a node i, represented as $N(i)$, comprises the set of nodes that are immediately connected to node i. The neighborhood defines the local structure surrounding a node within the graph.

Notation: $N(i) = \{j \in V : (i, j) \in E\}$, where (i, j) is an edge in E.

D. Definition 3 (Fuzzy Clustering)

Fuzzy clustering is an extension of conventional hard clustering techniques, allowing each data point to belong to numerous groups with differing levels of membership. In overlapping community detection, nodes can belong to multiple communities, with their membership quantified by a membership function, μ_{ij}, representing the extent to which node i is associated with community j.

Notation: The membership degree μ_{ij} is typically constrained such that $0 \leq \mu_{ij} \leq 1$, and the sum of memberships for each node across all communities is normalized, i.e. $\sum_j \mu_{ij} = 1$ for all nodes i.

E. Definition 4 (Fuzzy Membership)

Let $G = (V, E)$ denote the graph comprising vertices $1, 2, \ldots, n$. We examine representations of G using nonzero vectors $x_1, x_2, \ldots, x_n \in \mathbb{R}^N$, characterized by the function $f: \mathbb{V} \to \mathbb{R}^N$, where each node is depicted as a vector of length N. Then a fuzzy set V in G is a set of ordered pairs defined as:

Notation: $V = \{(x, \mu_V(x)) \mid x \in G\}$
$\mu_V(x)$ is called the fuzzy membership function and ranges in $[0, 1]$.

F. Key Symbols and Descriptions

Following Table I provides the key symbols and their descriptions used throughout the paper.

TABLE I. SYMBOL-DESCRIPTION TABLE

Symbol	Description
$G = (V, E)$	Input undirected, unweighted graph with node set V and edge set E
C	Set of communities
$N(i)$	Set of neighbors of node i
k_i	Degree of node i
S_{ij}	Neighborhood similarity score between nodes i and j
$D \in \mathbb{R}^{n \times n}$	Similarity matrix storing pairwise S_{ij} scores
c	Number of communities (clusters)
$R \in \mathbb{R}^{c \times n}$	Fuzzy membership matrix; R_{ki} represents membership of node i in community k
$V \in \mathbb{R}^{c \times m}$	Matrix of cluster centroids in feature space (for FCM)
q	Fuzzifier parameter controlling softness of membership (typically $q > 1$)
ϵ	Convergence threshold for membership updates
EQ	Extended modularity metric for evaluating overlapping communities
$F1$	F-score metric for evaluating the accuracy of detected overlapping structure

IV. METHODOLOGY

This section outlines the key idea presented in this study, which is an overlapping community detection approach that incorporates neighbor similarity metrics based on fuzzy clustering techniques to effectively identify overlapping communities inside various complex network configurations. The key idea is based on the fact that nodes exhibit both topological proximity and structure-based equivalence within the same community. Comprising four main phases, the proposed method starts from the preprocessing of the graph to extract the main topological characteristics, which include the degree of a node, the neighborhood list, and centrality metrics, which are required for further operation. Followed by preprocessing, the construction of the similarity matrix begins, which measures node affinity based on shared neighborhood characteristics and captures both direct and implicit structural linkages. The third phase employs the fuzzy C-means clustering algorithm to initiate community assignments, enabling nodes to belong to many communities with varying degrees of membership, a crucial aspect for imitating real-world overlaps. Then, finally, an iterative community refinement mechanism improves such assignments by using the network topology to limit the overlap granularity to make sure that nodes are assigned to only those communities that meet the structural similarity threshold.

Fig. 1 illustrates the enhanced fuzzy clustering pipeline for overlapping community detection. The process begins with the input graph, where neighborhood similarity is computed to construct the similarity matrix. Based on this matrix, initial fuzzy memberships are assigned, giving nodes soft affiliations to multiple communities. A neighborhood-based optimization stage then refines these memberships by balancing maximum membership strength with structural neighborhood constraints, enabling controlled overlaps. The final output highlights overlapping communities, with multi-colored halos representing nodes that belong to more than one group. This multistage paradigm strikes a balance between computational efficiency and the ability to capture complex, overlapping structures in diverse network scenarios.

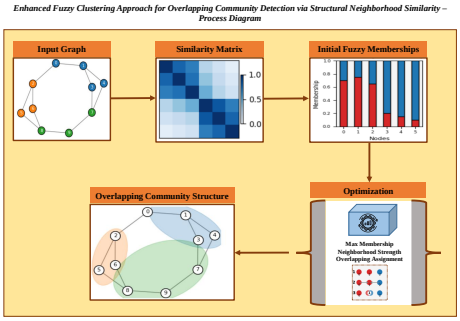

Fig. 1. Process diagram of fuzzy clustering for overlapping community detection using neighborhood similarity.

A. Stage 1: Graph Initialization and Preprocessing

The algorithm initiates by loading the graph data from an edge list provided as input, constructing the unweighted and undirected graph, i.e. $G = (V, E)$. To ensure consistency in computations, nodes V are relabeled with continuous integer indices starting at 1. Basic structure-based properties are then extracted such as the degree of node $k_i = |N(i)|$ (where $N(i)$ represents the neighbor set of node i), detailed neighbor lists, and centrality metrics (degree centrality and betweenness centrality) as shown in Fig. 2. These properties can be used for later similarity computation and community structure evaluation, allowing the thorough characterization of node roles inside the network.

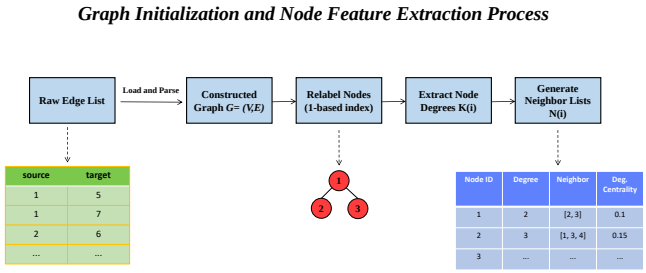

Fig. 2. Preprocessing stage of the algorithm: graph construction, relabeling, and feature extraction.

B. Stage 2: Neighborhood Similarity Matrix Construction

A neighborhood similarity matrix $D \in \mathbb{R}^{n \times n}$ is generated as an essential component of the fuzzy clustering process to quantify the structural similarity between each pair of nodes in the network. For every node pair (i, j), the similarity score S_{ij} (refer to Eq. 1) is calculated according to their local connectivity patterns. Specifically, for each node i, its neighbors are extracted from the input graph, and the similarity with node j is computed as follows:

$$S_{ij} = \begin{cases} 1, & \text{if } i = j \\ \frac{|N(i) \cap N(j)|+1}{|N(i)|}, & \text{if } (i,j) \in E \\ 0, & \text{otherwise} \end{cases} \tag{1}$$

- If $i = j$, then $S_{ij} = 1$, assigning full similarity to a node with itself.
- If i and j are directly connected (i.e. $(i, j) \in E$), the similarity score is computed as:

$N(i)$ and $N(j)$ denote the sets of neighbors of nodes i and j, respectively. The term "+1" is added to prevent zero similarity in cases where neighbors have no common neighbors. The similarity score is then normalized by dividing by $|N(i)|$. In the case of unconnected pairs $(i, j) \notin E$, the similarity S_{ij} is assigned a value of 0.

This technique produces an asymmetric similarity matrix with fine-grained local topological links. It emphasizes the importance of shared local structures among directly connected nodes and successfully separates strongly connected node pairs from weakly or non-associated ones. Unlike traditional similarity metrics, which may treat unconnected nodes using global routes or statistical likelihoods, this approach is extremely confined, computationally efficient, and directly applicable to the later fuzzy membership updating stage. The matrix D is crucial for shaping soft assignments and identifying community structures in the network, both separate and overlapping. The sequence-wise process of this stage is also described in Algorithm 1 for better understanding.

C. Stage 3: Fuzzy Clustering-Based Community Initialization

A fuzzy clustering method utilizing the Fuzzy C-Means algorithm is employed to achieve an initial community assignment. We start with a random membership matrix $R \in \mathbb{R}^{c \times n}$. Each column (which represents a node) shows the probability distribution over c communities. At the same time, the similarity matrix $S \in \mathbb{R}^{n \times n}$ is used to update the feature matrix $U \in \mathbb{R}^{n \times m}$, which originates from node attributes or centrality measurements, in a loop as described in Eq. 2. In particular, the representation of each node is improved by propagating the attribute vectors of its neighbors, with the weights determined by their pairwise similarity:

$$U_i' = \frac{1}{|N(i)|} \sum_{j=1}^{n} S_{ij} \cdot U_j \tag{2}$$

where:

- S_{ij} is the similarity between node i and node j;

Algorithm 1 Construct Neighborhood Similarity Matrix

Require: Graph $G = (V, E)$; Neighbor list $N(i)$ for each node $i \in V$
Ensure: Similarity matrix $D \in \mathbb{R}^{n \times n}$, where D_{ij} denotes similarity between nodes i and j

```
Initialize matrix D ← 0^{n×n}
for each node i ∈ V do
    for each node j ∈ V do
        if i = j then
            D_ij ← 1.0
        else if (i, j) ∈ E then
            Let N_i ← N(i), N_j ← N(j)
            Compute intersection: I ← N_i ∩ N_j
            Compute union (or denominator): d_i ← |N_i|
            D_ij ← (|I|+1) / d_i
        else
            D_ij ← 0
        end if
    end for
end for
return D
```

- U_j is the feature vector of node j;
- $|N(i)|$ is the number of non-zero similarity linkages for node i, which is its "soft neighborhood size";
- $(\cdot)$ means matrix multiplication or scaling a vector by its elements.

Alternatively, the entire matrix update can be expressed compactly as shown in Eq. 3:

$$U' = \text{Normalize}(S \cdot U) \tag{3}$$

This normalizes each row to consider the number of contributing neighbors. The cluster centroids $V \in \mathbb{R}^{c \times m}$ are then changed to the weighted average of the node representations. This is done by raising the fuzzy membership values to the fuzzifier parameter q, as illustrated in Eq. 4:

$$V_i = \frac{\sum_{k=1}^{n} (R_{ik})^q \cdot U_k}{\sum_{k=1}^{n} (R_{ik})^q} \tag{4}$$

The membership parameters for R_{ik} are modified according to the distance of the k-vector from each cluster centroid, demonstrated in Eq. 5.

$$R_{ik} = \left(\sum_{j=1}^{c} \left(\frac{||U_k - V_i||}{||U_k - V_j||} \right)^{\frac{2}{q-1}} \right)^{-1} \tag{5}$$

The process continues until convergence occurs, defined as the maximum change in R between two iterations falling below a predetermined threshold ϵ, or until the maximum iteration limit is attained.

D. Stage 4: Community Label Assignment and Optimization

In the final stage, we use the fuzzy membership matrix $R \in \mathbb{R}^{c\times n}$ to determine which community each node belongs to. Each of the entries of $R_{k,i}$ denotes the degree of membership of node i in community k. Eq. 6 indicates the procedure for acquiring an initial distinct partition by allocating each node to the community exhibiting the highest membership score in R. This phase creates a foundational framework in which each node belongs to a single community exclusively.

$$\text{label}i = \arg\max_{k} R_{ki} \tag{6}$$

We do a neighborhood-based optimization to allow for overlapping memberships and to better capture the complex local structure of the network. We find a community strength vector $C_i \in \mathbb{R}^c$ for each node i, where the k-th component $C_{i,k}$ is found using Eq. 7:

$$C_{i,k} = \frac{\sum_{j\in N(i)} S_{ij} \cdot \delta_{jk}}{\sum_{j\in N(i)} S_{ij}} \tag{7}$$

- S_{ij} is the similarity between node i and neighbor j,
- $\delta_{jk} = 1$ if node j is assigned to community k, and 0 otherwise,
- $N(i)$ denotes the set of neighbors of node i.

A node i is assigned to community k if its score $C_{i,k}$ Eq. 8 satisfies:

$$C_{i,k} \geq 0.9 \cdot \max_{l} C_{i,l} \tag{8}$$

The threshold rule ensures that nodes with comparable strength in more than one community are assigned to all of them, enabling controlled and meaningful overlaps. The iterative assignment process stabilizes the labels and ensures that overlapping community structures align well with both fuzzy membership scores and the local neighborhood structure.

This final optimization stage is crucial for transitioning from a distinct division to a nuanced, overlapping community detection outcome that effectively captures the complex relationships between nodes in the network.

E. Computational Complexity

The proposed technique's computing complexity is predominantly influenced by three stages: the formation of the neighborhood similarity matrix, the allocation of fuzzy memberships, and the enhancement of overlapping community memberships. The similarity matrix is generated by calculating local similarity, such as common neighbors, between pairs of connected nodes. The worst-case complexity is $\mathcal{O}(n^2)$ when all node pairs are compared; however, in reality, the computation is restricted to adjacent nodes, yielding a practical complexity of $\mathcal{O}(m \cdot d)$, where m represents the number of edges and d denotes the average node degree. The fuzzy clustering phase iteratively allocates community memberships with a Fuzzy C-Means-inspired update process, characterized by a complexity of $\mathcal{O}(n \cdot c \cdot t)$, where c denotes the number of communities and t represents the number of iterations. The refining phase modifies memberships according to neighborhood similarity and local consistency, exhibiting a complexity of $\mathcal{O}(n \cdot d \cdot c)$.

Thus, the proposed method attains a cumulative complexity of $\mathcal{O}(m\cdot d+n\cdot c\cdot(t+d))$, rendering it efficient and scalable for sparse real-world networks. Contrary to more computationally demanding methods such as OSLOM and BIGCLAM, our approach is efficient, interpretable, and particularly effective for large graphs, while still achieving competitive accuracy. For further understanding, Table II provides the precise comparison of computational complexities of different methods.

TABLE II. COMPUTATIONAL COMPLEXITY COMPARISON OF COMMUNITY DETECTION METHODS

Method	Complexity	Scalability	Key Operations
Proposed Method	$O(m \cdot d + n \cdot c \cdot (t + d))$	High	Local similarity computation, fuzzy membership updates, neighborhood refinement
OSLOM	$O(n \cdot d^{-1} \cdot \log n)$	Medium-Low	Local expansion and statistical significance testing
BIGCLAM	$O(k \cdot (n + m))$	High	Non-negative matrix factorization
GREESE	$O(k \cdot n \cdot d)$	Medium	Greedy seed expansion
LC	$O(t \cdot m)$	Very High	Label propagation, iterative voting

V. EXPERIMENTS AND RESULTS

The following section presents an experimental analysis of the proposed approach across networks of varying sizes and structural features to demonstrate its effectiveness in detecting overlapping communities. The evaluation is conducted by comparing it with numerous reputable overlapping community detection techniques, such as OSLOM [36], BIGCLAM [37], GREESE [23], and Label Clustering (LC) [38], respectively.

A. Evaluation Metric

We use two common measures for overlapping community detection, Overlapping Modularity (EQ) or Q_{ov}, and F-score, to measure how well the proposed approach works. The overlap modularity Q_{ov} is measured with no ground truth.

1) Overlapping modularity: EQ, or Q_{ov}, or overlapping modularity, is a new way to assess modularity that takes into account nodes that overlap. It evaluates the quality of the identified community structure by contrasting the number of edges within communities against a null model that permits nodes to belong to multiple communities. The EQ score is in Eq. 9 as:

$$EQ = \frac{1}{2m} \sum_{c} \sum_{i,j\in c} \left[A_{i,j} - \frac{k_i k_j}{2m} \right] \frac{1}{O_i O_j} \tag{9}$$

O_i is the number of communities that node i is a part of, k_i is the degree of node i, while m is the overall number of edges.

2) F-score: The F-score is a common way to assess how much the discovered communities overlap with the real ones. It is the harmonic mean of recall and precision, which is described for overlapping clustering as shown in Eq. 10:

$$F\text{-score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{10}$$

B. Datasets

Table III outlines the datasets utilized in our experiments, with N denoting the number of nodes, E representing the number of edges, and k showing the average node degree. Our version utilizes Python's NetworkX package for graph preprocessing, whereas community assignment and similarity calculations are conducted using NumPy. The visualization of identified communities is executed with Matplotlib and the force-directed layout from igraph, facilitating qualitative analysis of community coherence and overlap. The comparison underscores the precision and computational efficacy of our methodology.

TABLE III. THE STATISTICS OF REAL-WORLD NETWORK DATASETS

Dataset	V	E	Avg. Degree	Description
Karate [39]	34	78	4.59	Zachary's Karate Club network representing friendships between 34 members of a university karate club.
Dolphins [40]	62	159	5.13	A network of 62 New Zealand bottlenose dolphins' frequent associations.
Football [41]	115	613	10.66	American college football team network with nodes representing teams and edges representing regular-season games.
Polbooks [42]	105	441	8.4	Amazon political book network during 2004 U.S. presidential election. Edges show often co-purchased books, and nodes depict books.
Jazz [43]	198	2742	27.7	Collaboration network of jazz musicians. An edge between two musicians means they have played in the same band.
Amazon [44]	334,863	925,872	5.53	A product co-purchasing network from Amazon, where nodes are products and edges link frequently co-purchased items.
Dblp [45]	317,080	1,049,866	6.62	A co-authorship network from DBLP, where nodes are authors and an edge indicates co-authorship of one or more papers.

C. Results and Discussion

In order to evaluate the effectiveness of the proposed method, we applied it to a set of widely used benchmark datasets and visualized the resulting community structures. The outcomes are displayed in Fig. 3, 4, 5, and 6, where each graph represents the community partitions generated by our algorithm. Distinct colors are used to indicate separate communities, while nodes that belong to more than one community are emphasized in red. These overlapping nodes highlight their dual or multiple affiliations, which often correspond to structurally important positions within the network, such as boundary spanners, information brokers, or connectors between clusters. The presence of such nodes underscores the inherently fuzzy and interconnected character of real-world community organization. By accurately identifying them, the proposed approach not only delineates clear community boundaries but also reveals the subtle overlaps and shared memberships that classical hard-clustering methods often fail to capture.

We evaluated the performance of the proposed method across several real-world network datasets and compared it to that of popular overlapping community detection methods, including OSLOM, BIGCLAM, GREESE, and LC. The outcomes show that the proposed method works better on networks of various sizes and typologies.

In smaller and medium-sized networks like Karate, Dolphins, and Jazz, the method proficiently identifies significant

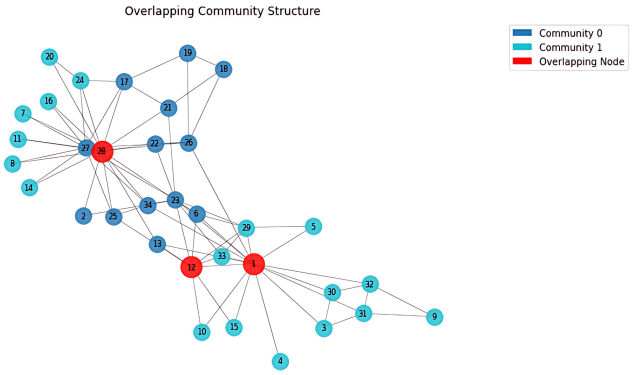

Fig. 3. Community visuals for Karate Club network datasets

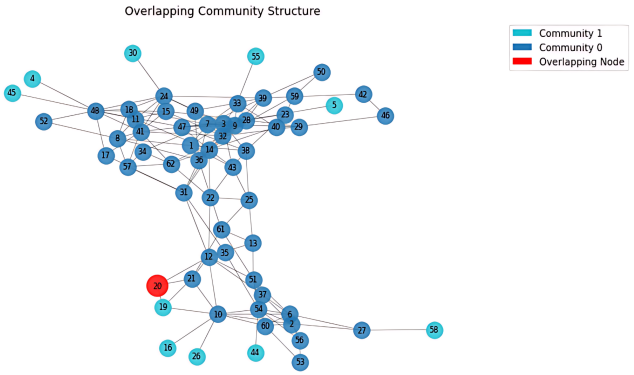

Fig. 4. Community visuals for Dolphins network datasets.

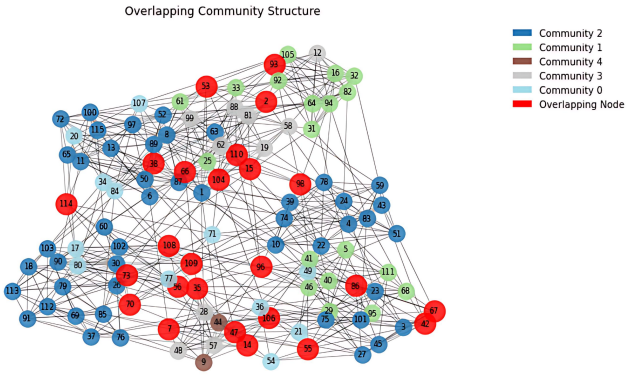

Fig. 5. Community visuals for Football network datasets.

overlapping groups, capturing significant dynamics that conventional methods often neglect. The fuzzy similarity-based approach enables the algorithm to assign nodes to various communities flexibly, capturing the fundamental uncertainty in community boundaries. While in large networks like dblp and Amazon, the proposed approach consistently yields dependable outcomes, demonstrating resilience and flexibility in handling high-dimensional data. Although certain baseline techniques may get slightly superior modularity in particular cases, our methodology demonstrates robust consistency across datasets,

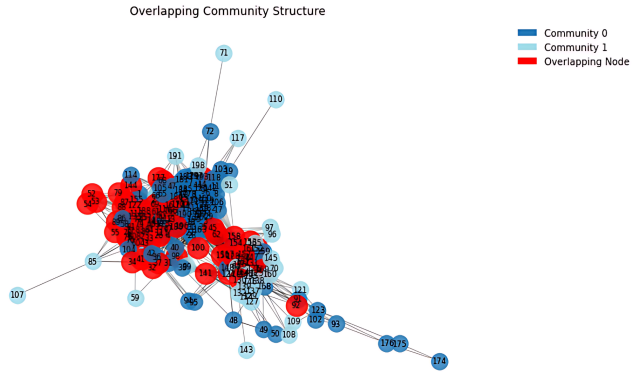

Fig. 6. Community visuals for Jazz network datasets.

particularly when community overlaps are significant.

Fig. 7 shows the comparison of overlapping modularity Q_{ov} results of the proposed method with four other state-of-the-art overlapping community detection methods. The proposed method attains an advantageous convergence between optimization and interpretability. It adeptly combines local topological characteristics with a systematic fuzzy clustering approach, providing a viable alternative to more complex or heavily parameterized algorithms.

Fig. 8 represents the F-score comparison on larger datasets. The F-score analysis on the DBLP and Amazon network datasets underscores the efficacy of the proposed method for precisely detecting overlapping groups. In contrast to many existing methods that either excessively cluster or inadequately identify significant overlaps, our methodology preserves a balanced framework by utilizing fuzzy membership scores and neighborhood-based refinement. In the DBLP dataset, the technique demonstrates consistent performance, closely agreeing with the ground truth while remaining competitive with more established algorithms. In the Amazon network, marked by thick overlaps and varied community structures, the technique exhibits constant precision and recall, indicating its adaptation to real-world complexities. The results indicate that the proposed approach can generate community assignments that are both precise and comprehensible, even in large networks with complex topologies.

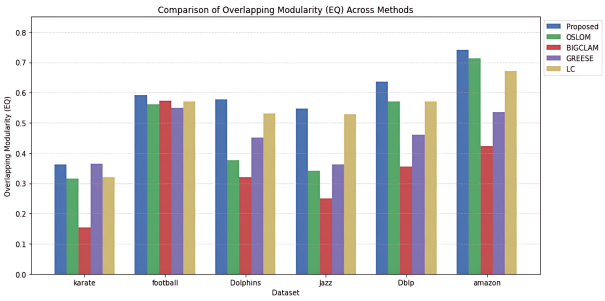

Fig. 7. Qov values of real-world datasets on different algorithms.

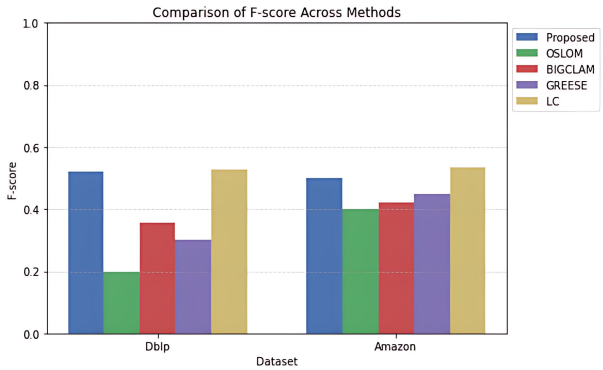

Fig. 8. F-score values of real-world datasets on different algorithms.

D. Execution Time

The bar chart in Fig. 9 depicts the execution time (in seconds) of different community discovery methods across four benchmark datasets: Karate, Football, Dolphins, and Jazz. OSLOM and BigClam consistently exhibit the lowest execution times, rendering them among the most computationally effective algorithms in our comparison. Conversely, LC exhibits the longest execution time across all datasets, signifying considerable computational expense.

The proposed method demonstrates moderate execution durations; it is often quicker than LC and GREESE, however marginally slower than OSLOM and BigClam. This is a judicious compromise between computing expense and efficacy, particularly given that the proposed approach emphasizes the precise identification of overlapping and structurally intricate communities. The Jazz dataset exhibits the longest execution durations among all approaches, presumably attributable to its greater size and edge density.

Although the proposed method may not be the most expedient, it ensures satisfactory execution times while offering enhanced community quality, particularly in contexts where overlapping detection is essential. This equilibrium indicates that the algorithm is sufficiently efficient for practical application, especially in small to medium-sized networks.

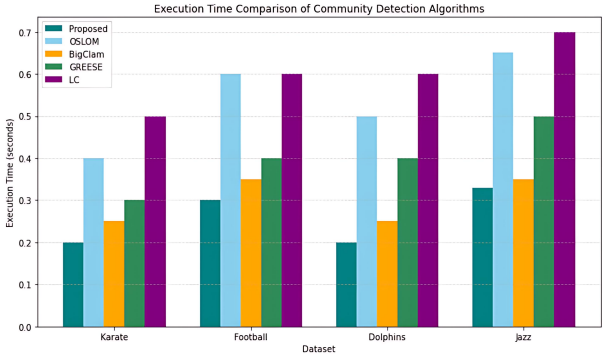

Fig. 9. Execution time of different algorithms compared with the proposed method.

E. Statistical Analysis

We used a non-parametric Friedman test on the EQ (Extended Modularity) values from many benchmark datasets to see if the variations in performance between community detection techniques were statistically significant. Fig. 10 demonstrates that the proposed method consistently outperforms the baseline approaches. The highest average EQ score is observed across all datasets, with the LC algorithm ranking second. The Friedman test demonstrates that the differences among the techniques are statistically significant, necessitating additional pairwise comparisons.

We used a Nemenyi post-hoc test to find out where the differences are, and the findings are shown in Fig. 11. This test evaluates the algorithms based on how well they do on average across datasets and shows if the differences are statistically significant. The proposed technique comes in first, followed by LC, while BIGCLAM always comes in last. The red line showing the Critical Difference (CD) shows that the difference in performance between the suggested technique and the lower-ranked algorithms is statistically significant. This analysis shows that our method is strong and competitive when it comes to finding overlapping communities with better quality outcomes.

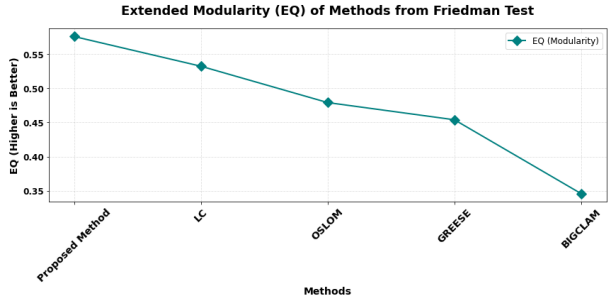

Fig. 10. Friedman statistical analysis results.

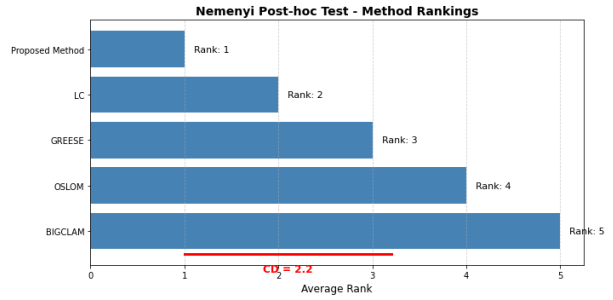

Fig. 11. Nemenyi post hoc test results.

VI. Application Domains of the Proposed Approach

The ability to detect overlapping communities with varying degrees of membership makes the proposed method applicable across numerous real-world domains where entities simultaneously participate in multiple functional groups [46], [47], [5]. Unlike hard clustering approaches, fuzzy membership and local topological similarity enable the representation of nuanced interactions, making the method suitable for both small-scale and large-scale systems. Table IV shows the primary application areas where the proposed approach can improve assessment, decision-making, and system optimization.

A. Social Networks

Identifying overlapping communities in social networks is crucial for recognizing users with numerous social circles. This helps platforms comprehend complex social interactions, improve tailored recommendations, and target content. Deeper insights into influence propagation and user engagement patterns enable more effective viral marketing efforts, community-driven promotions, and strategic network interventions using user relationships [48].

B. Recommender Systems

In the context of recommender systems, individuals frequently exhibit a wide array of interests spanning various domains, including music, films, and online shopping. Modeling diverse interest groups facilitates enhanced personalization and more precise recommendations [49].

C. Biological Networks

Biological networks, including protein-protein interaction networks, frequently display overlapping communities in which proteins contribute to various functional modules. Recognizing these overlaps can uncover biological entities with multiple functions and contribute to our comprehension of disease pathways [50], [51].

D. Information and Citation Networks

Documents within information and citation networks can encompass a variety of disciplines. The identification of overlapping communities has the potential to enhance the effectiveness of topic modeling and the efficiency of information retrieval [52].

E. Cybersecurity

User access logs and network traffic often reveal entities assuming multiple roles or connecting across domains. Traditional clustering may overlook overlapping patterns and subtle security risks. By capturing multi-role interactions, overlap-aware community detection enables analysts to study network structure and user behavior, helping identify unauthorized access, privilege escalation, and coordinated attacks. It also highlights advanced persistent threats, insider threats, and malware propagation, enhancing overall network security and monitoring [51].

F. Political and Behavioral Analysis

In the context of political and behavioral studies, it is common for individuals to possess multiple affiliations. This complexity underscores the importance of monitoring polarization and the interactions that occur across different groups [53].

TABLE IV. APPLICATIONS AND BENEFITS OF THE PROPOSED METHOD IN VARIOUS DOMAINS

Domain	Application	Advantage
Social Networks	Identifying users in multiple social circles	Enhanced recommendations and influence analysis
Recommender Systems	Modeling multi-interest user groups	Improved personalization and targeting
Biological Networks	Detecting overlapping functional gene/protein modules	Insights into multifunctional biological entities
Information/Citation Networks	Classifying documents or topics across disciplines	Better topic modeling and retrieval
Cybersecurity	Multi-role detection in access or traffic patterns	Improved intrusion detection and anomaly analysis
Political/Behavioral Analysis	Overlapping affiliations in opinion or behavior networks	Polarization tracking and behavioral segmentation
Marketing & Segmentation	Multi-interest customer clustering	Flexible and refined market profiling
Infrastructure/Transport	Identifying shared zones across transport routes	Route optimization and load balancing

G. Marketing and Infrastructure Systems

In the realm of infrastructure systems, especially within smart cities, overlapping community detection can be utilized to examine transportation networks, shared mobility facilities, and urban flow patterns. Vehicles, commuters, and logistics operators are some of the entities that typically use several routes or service regions that overlap. City planners and service providers can make better use of public transportation and shared mobility systems by finding these overlaps, which lets them improve traffic management, optimize transport timetables, and improve route allocation [54].

VII. CONCLUSION AND FUTURE WORK

This study presents a neighborhood similarity-based fuzzy clustering method for identifying overlapping communities in complex networks. Inspired by the fact that nodes in real-world systems frequently display partial membership across various communities, the proposed approach integrates local topological similarity into a fuzzy clustering framework to more accurately represent this fundamental ambiguity. The proposed approach establishes a similarity matrix based on shared neighbors and enhances community memberships by local optimization, achieving a balance among structural fidelity, interpretability, and computing efficiency. Through comprehensive analysis on standard benchmark datasets such as Karate, Dolphins, Polbooks, and so on, we established that our method competes effectively with renowned overlapping community detection techniques, for example, OSLOM, BIGCLAM, LC, and GREESE, frequently attaining enhanced outcomes both in terms of quality metrics like extended modularity and F-score. The method's architecture eliminates dependence on global heuristics or resource-intensive computations, rendering it scalable and accessible for extensive applications. This study emphasizes the significance of local structure in community inference and the necessity of adaptable, membership-aware frameworks for comprehending complicated networked systems, in addition to robust empirical findings.

Future research will investigate the incorporation of node properties and temporal dynamics in order to improve the model's relevance to changing and heterogeneous networks. We intend to integrate deep learning methodologies, specifically graph neural networks, to derive more expressive node representations that enhance community detection precision. Furthermore, we intend to examine the method's applicability in subsequent tasks, including link prediction, influence maximization, and anomaly detection.

ACKNOWLEDGMENT

This project was funded by the Deanship of Scientific Research (DSR) at King Abdulaziz University, Jeddah, Saudi Arabia, under grant no. (GPIP: 282- 830-2024). The authors, therefore, acknowledge with thanks DSR for technical and financial support.

***Abstract*—This paper presents the first systematic investigation into autonomous UAV-mounted fall protection lanyard (FPL) deployment for high-voltage transmission tower inspections, addressing a critical safety gap in the power industry where falls account for 34% of occupational fatalities. We propose a novel geometry-based solution to overcome three fundamental limitations of existing approaches: the isolated processing of UAV imagery without sensor fusion, unreliable 2D-to-3D spatial correspondence in anchor point detection, and the high annotation costs of supervised learning methods. Our technical contribution establishes a multi-view geometric perception framework that decomposes the FPL anchoring task into ridge line identification and optimal mounting point selection. The method first develops a spacial edge distance perception algorithm specifically for power inspection drones, which computes structural depth through plane-induced homography transformations of temporally matched line features. Subsequently, a mounting position planning algorithm integrates multiview geometric constraints with practical operational requirements including ladder proximity, diagonal steel avoidance, and temporal stability. Experimental validation on real-world power infrastructure data demonstrates superior performance compared to learning-based alternatives, achieving 10.98 MAE in positioning accuracy while maintaining 80ms processing efficiency for real-time operation. The proposed approach eliminates dependency on manual climbing and expert annotations, offering both theoretical advancements in stereo-environment perception for complex structures and immediate field applicability for safer power grid maintenance. This work represents the first formal proposal and comprehensive solution for autonomous FPL deployment in transmission tower inspection scenarios.**

I. Introduction

Power transmission towers (PTT) are steel lattice structures supporting high-voltage power lines ($110kV$ to ultra-high voltage $\geq$ $1000kV$). These 25-215m tall structures require regular inspection, which still predominantly relies on hazardous manual climbing [1]. In China's power sector (2022), falls accounted for 40% of accidents and 34% of fatalities [2] (Fig. 2), making them the leading occupational hazard. While safety harnesses remain the primary protective measure, their effectiveness is compromised on PTTs that lack integrated fall arrest guide rails (Fig. 1). The absence of such safety infrastructure creates substantial challenges for workers attempting to properly anchor their FPLs to designated mounting points prior to ascending the structure. Therefore, the installation of FPLs urgently requires innovative technical solutions.

Recent years have witnessed the emergence of remotely piloted unmanned aerial vehicles (UAVs) for deploying purpose-engineered fall protection lanyard (FPL) anchoring devices to the apex of high-voltage PTTs. The manual approach inherently has scalability problems due to dependence on scarce specialists while introducing safety risks when operated by novices. Meanwhile, the advances in drone-assisted transmission tower inspection [3], [4], [5], [6], [7], [8], [9] have demonstrated potential for automated FPLs anchoring. To the best of our knowledge, we are the first to formally propose and systematically investigate the problem of autonomous UAV-mounted FPL deployment. While no prior studies have directly addressed this problem, related research on power line facility localization and defect detection has predominantly adopted image-level detector-based methodologies.

However, existing related approaches present three fundamental research gaps that hinder practical deployment: 1) The UAV video imagery are processed in isolation, failing to fully leverage the synergistic information potential between visual data and onboard sensor measurements. 2) Second, while some approaches employ deep learning-based object detection algorithms (e.g. YOLO series [10]) to identify potential anchor points in 2D image space, they fail to establish accurate 3D spatial correspondence, resulting in unreliable detection where visually suitable regions may not correspond to physically actionable locations on the tower structure, particularly when identified points are misaligned with the tower's front face. 3) Third, supervised deep learning requires extensive data annotation by power transmission tower inspection experts, leading to high labeling costs and limited scalability. The fundamental scientific challenge involves developing stereo-environment perception that simultaneously incorporates both the target structure's geometric characteristics and the drone's dynamic operational constraints.

To address these issues, we innovatively proposed an autonomous localization algorithm for FPL mounting points based on multi-view geometry. Drone-assisted FPL deployment involves ascending to operational altitude, horizontal positioning over the tower, and precise anchor point attachment. Our contribution is to guide the drone to automatically find the anchor point during the horizontal positioning stage. In this paper, the original anchoring task is decomposed into two sub-problems in our approach: 1) identifies the ridge line of

the tower's apex that is feasible to attach FPLs, and 2) selects the optimal anchoring point on the ridge line against various requirements. Therefore, we proposed a geometry model to identifies the ridge line of the tower's apex, then to screen the ridge points against specially designed objective functions, which combines geometric perception with practical operational constraints to achieve reliable performance in complex field environments. Experiments revealed that this technical approach enables autonomous drone-based FPL deployment, with potential value for both research and field applications.

Fig. 1. The quadcopter drone operates near the power transmission tower while carrying our specially designed mounting device for fall protection lanyards.

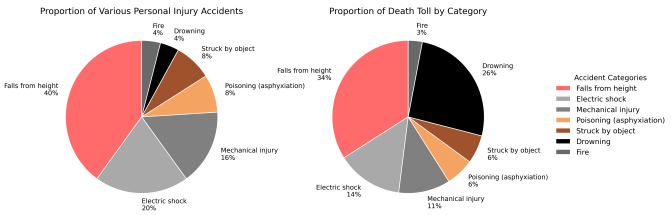

Fig. 2. Component pie-graph of personal injury accidents (left) and death toll (right).

The main contributions of this paper are as follows:

- A scene line segment distance perception algorithm specifically designed for power inspection drones.
- A mounting position planning algorithm for inspection fall protection lanyards.
- Experimental validation on real-world power infrastructure data, demonstrating the effectiveness and advancement of the proposed method.

The rest of this paper is organized as follows. Section II reviews related works. Section III describes the geometry model that links the linear features in images with the their depth in camera's view. Section IV explains the FPL anchoring point localization algorithm. Section V presents the experimental results. Section VI concludes the paper.

II. Related Works

A. Vision-Based UAV Power Line Inspection

Unmanned Aerial Vehicles (UAVs) have become vital for power line inspection [8], [11], offering efficient, high-precision monitoring across diverse environments. Recent developments integrate deep learning models—especially Convolutional Neural Networks (CNNs)—to detect anomalies like insulator fractures, vegetation encroachment, and conductor wear with improved accuracy [12]. These models benefit from large-scale annotated datasets and data augmentation techniques such as color space transformations and edge enhancement, which improve contrast between power line components and background clutter [12], [3]. Federated learning also shows promise for collaborative model training across UAV fleets while preserving data privacy [12], [5].

Despite these advances, spatial perception and geometric reconstruction remain key challenges [13]. Monocular SLAM frameworks like PTI-SLAM enable real-time mapping and localization, achieving trajectory RMSE of 0.1447 m [4]. However, they struggle with textureless surfaces and rapid rotations, leading to misalignment between image features and reconstructed scenes [14], [4], [15], [6]. In contrast, Multi-View Stereo (MVS) methods like DP-MVS offer higher geometric fidelity, achieving RMSE of 3.698 cm [16]. Yet, their computational intensity limits real-time deployment, highlighting a critical research gap: the lack of a unified framework that balances temporal responsiveness with spatial accuracy in complex structural environments. Addressing this gap is essential for reliable UAV-based inspections, particularly for identifying FPL mounting points on transmission towers.

B. Monocular SLAM for Transmission Tower

Monocular SLAM frameworks such as PTI-SLAM offer real-time localization and mapping capabilities for UAV-based power tower inspections [4], [9]. By combining direct and feature-based tracking with semantic filtering, PTI-SLAM achieves trajectory RMSE of 0.1447 m, outperforming GPS alignment methods [4]. Multi-frame fusion and statistical outlier removal further improve point cloud consistency, reducing noise while preserving structural accuracy [4]. However, these systems face key limitations in complex 3D environments.

A major challenge is the poor performance on textureless surfaces—common in metallic tower components—leading to unreliable feature detection and depth estimation errors [15]. Additionally, rapid rotational movements degrade tracking stability, lowering success rates to 6/10 under such conditions [4]. These issues cause misalignment between 2D image features and reconstructed 3D geometry, affecting tasks like defect classification and mounting point identification. Compared to MVS approaches like DP-MVS, which achieve RMSE of 3.698 cm, monocular SLAM lacks the geometric precision needed for detailed structural analysis [16]. Although PTI-SLAM processes frames efficiently at 81 ms per tracking step [4], its metric accuracy remains insufficient for high-fidelity inspection tasks. This highlights a key research gap: the absence of robust multi-view geometric analysis that maintains both real-time performance and spatial coherence in UAV-based power tower inspections.

C. Multi-View Stereo for Transmission Inspections

Multi-view stereo (MVS) methods provide significantly higher geometric accuracy than monocular SLAM, making them suitable for detailed 3D reconstruction of power towers [17]. Techniques like DP-MVS employ PatchMatch-based depth estimation and Delaunay meshing to preserve structural details, achieving RMSE as low as 3.698 cm [16]. Compared to traditional tools such as OpenMVS and COLMAP, DP-MVS

reduces processing time by up to 73%, enhancing efficiency for large-scale modeling [16]. Learning-based approaches like GC MVSNet++ further improve performance by embedding geometric constraints into training, cutting iteration counts by 50% [7], [18].

Despite these gains, MVS methods face challenges in real-time deployment due to high computational demands. They are also sensitive to textureless surfaces where feature correspondence is weak [19]. Progressive Prioritized MVS addresses efficiency concerns by selecting key viewpoints, reducing runtime by 42% while maintaining 98.7% completeness in reconstructed scenes [19]. However, integration into UAV inspection workflows remains limited due to hardware and synchronization requirements. Variable-baseline stereo setups using dual UAVs offer flexibility by adjusting stereo geometry dynamically, improving coverage and reducing occlusion [20]. Yet, they require precise pose estimation [21], which is difficult in GPS-denied or electromagnetically noisy environments. These limitations highlight a key research gap: the need for adaptive MVS frameworks that maintain high geometric fidelity while supporting real-time operation for critical tasks such as FPL mounting point detection.

III. Spacial Edge Perception Model

A. Coordinate system

This study employs a quadrotor UAV system for power transmission tower (PTT) inspection missions. The camera is mounted on the ventral side of the drone via a gimbal with controllable pitch angle. Since we focused on analyzing the relative spatial relationship between the PTT and the UAV, the camera coordinate system is selected as the reference frame for subsequent analysis. To comply with the convention in digital image processing where the y-axis of images points downward, this study defines an right-handed camera coordinate system as illustrated in Fig. 3. The x-axis corresponds to the lateral direction of the UAV, the z-axis aligns with the optical axis toward the observation target. Considering the continuous motion of the UAV in flight, the captured images exhibit dynamic variations across different timestamps. Therefore, the camera coordinate system at time t is adopted as the reference frame fro multi-view geometry analysis.

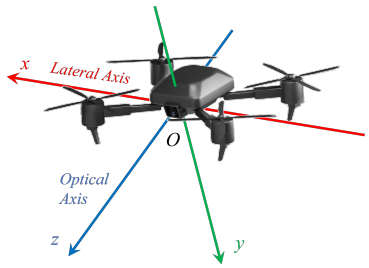

Fig. 3. Coordinate system of the inspection drone's vision.

B. Plane Induced Homography Transformation

Although a PTT appears visually complex, its components primarily consist of planar truss structures. Thus, we first analyze the image flow induced by spatial points on a plane. According to the findings in [22], a moving camera induces a homography transformation in the camera's view of points on a spatial plane. Specifically, let $\mathbf{x}_t \in \mathbb{P}^2$ and $\mathbf{x}_{t+1} \in \mathbb{P}^2$ denote the homogeneous coordinates of a feature point projected at time t and $t+1$, respectively. They satisfy:

$$\mathbf{x}_{t+1} = \mathbf{H}\mathbf{x}_t, \tag{1}$$

where $\mathbf{H} \in \mathbb{R}^{3\times3}$ represents the homography matrix. Moreover, we prove that the homography $\mathbf{H}$ satisfies the following proposition:

Proposition III.1. *(Homography): Let the camera coordinate system at time t be the reference frame. If the camera motion from t to $t+1$ is described by a translation vector $\mathbf{c} \in \mathbb{R}^3$ and a rotation matrix $\mathbf{R} \in SO(3)$, and the spatial plane is parameterized by its intercept d and normal vector $\mathbf{n}$ (with the plane equation $\mathbf{n}^T\mathbf{x} + d = 0$), then the homography transformation $\mathbf{H} \in \mathbb{R}^{3\times3}$ induced by this plane in the camera observation can be expressed as:*

$$\mathbf{H} = \mathbf{K}\mathbf{R}\left(\mathbf{I} + \frac{1}{d}\mathbf{c}\mathbf{n}^T\right)\mathbf{K}^{-1}, \tag{2}$$

where $\mathbf{K}$ is the camera's intrinsic parameter matrix, and $\mathbf{I}$ is the identity matrix.

Proof: See Appendix A.

C. Line Depth Approximation From Motion

The Real-Time Kinematics (RTK) system mounted on the drone provides onboard sensors to capture the motion parameters of the camera. Taking the camera frame at time t as the reference, both the translation vector $\mathbf{c} \in \mathbb{R}^3$ and the rotation matrix $\mathbf{R} \in \mathrm{SO}(3)$ at time $t+1$ can be known. Additionally, the camera intrinsic matrix $\mathbf{K}$ can be acquired in advance. Thus, in (2), only the plane parameters (i.e. the intercept d and normal vector $\mathbf{n}$) remain unknown. Since that the camera consistently points toward the monitoring target (i.e. transmission towers), it is reasonable to assume that the target's surfaces are approximately perpendicular to the optical axis, i.e. $\mathbf{n} \approx (0,0,1)^T$. Under this assumption, (2) can be simplified to $\mathbf{H} = \mathbf{K}\mathbf{R}\hat{\mathbf{H}}\mathbf{K}^{-1}$, where

$$\hat{\mathbf{H}} = \mathbf{I} + \frac{1}{d}[\mathbf{0},\mathbf{0},\mathbf{c}] \tag{3}$$

Under this assumption, d represents both: (i) the distance from the camera's *optical center* to a quasi-planar surface (approximately parallel to the *principal plane*), and (ii) the orthogonal distance from the surface point to the principal plane. Furthermore, $\mathbf{H}$ is a conjugated transformation of $\mathbf{R}\hat{\mathbf{H}}$, where $\hat{\mathbf{H}}$ is a homology transformation [22]. If the camera's motion, i.e. $\mathbf{R}$ and $\mathbf{c}$ are provided by RTK, it is possible to obtain the d that supplement the target's depth in image.

Although (3) provides the foundation for depth analysis, the visual complexity of PTT scenarios makes point-based analysis unsuitable.

Given that structural edges constitute the most salient features of PTTs (Fig. 6), the depth should be analyzed based on line segments under a homography transformation.

Specifically, if a line segment at time t, denoted as $\mathbf{p} = (\mathbf{x}_1, \mathbf{x}_2) \in \mathbb{P}^2 \times \mathbb{P}^2$, is mapped via homography $\mathbf{H}$ to a segment $\mathbf{q} = (\mathbf{x}'_1, \mathbf{x}'_2) \in \mathbb{P}^2 \times \mathbb{P}^2$ at time $t+1$, then any point $\mathbf{x}$ on $\mathbf{p}$ transformed by $\mathbf{H}$ must satisfy the line equation of $\mathbf{q}$. The line's coefficients are the cross product of the homogeneous endpoints, $\mathbf{x}'_1 \times \mathbf{x}'_2$.

This approach leverages the *duality between points and lines* in parametric space. This geometric constraints enables a line-based solution of d, leading to the following proposition:

Proposition III.2. *Let the camera coordinate system at time t be the reference frame. If a line segment at time t, denoted as $\mathbf{p} = (\mathbf{x}_1, \mathbf{x}_2) \in \mathbb{P}^2 \times \mathbb{P}^2$, is mapped to the segment $\mathbf{q} = (\mathbf{x}'_1, \mathbf{x}'_2)$ at time $t+1$ via the homography transformation $\mathbf{H} \in \mathbb{R}^{3\times3}$ described in Formula (1), then for any point $\mathbf{x} \in \mathbb{P}^2$ on $\mathbf{p}$, its distance d to the principal plane of the camera coordinate system is given by:*

$$d = -\frac{\mathbf{c}^T\mathbf{R}^T\mathbf{K}^T(\mathbf{x}'_1 \times \mathbf{x}'_2)}{\mathbf{x}^T\mathbf{K}^{-T}\mathbf{R}^T\mathbf{K}^T(\mathbf{x}'_1 \times \mathbf{x}'_2)},$$

where, $\mathbf{c} \in \mathbb{R}^3$ and $\mathbf{R} \in SO(3)$ are the camera translation vector and rotation matrix from t to $t+1$, respectively; $\mathbf{K}$ is the camera intrinsic matrix; $\mathbf{x}'_1 \times \mathbf{x}'_2$ denotes the cross product of the homogeneous coordinates of the endpoints, defining the line equation of $\mathbf{q}$.

Proof: Given that $\mathbf{H} = \mathbf{K}\mathbf{R}\hat{\mathbf{H}}\mathbf{K}^{-1}$, for any point $\mathbf{x}$ on line segment $\mathbf{p}$, its corresponding point at time $t+1$, $\mathbf{x}' = \mathbf{K}\mathbf{R}\hat{\mathbf{H}}\mathbf{K}^{-1}\mathbf{x}$, must lie on the line defined by $\mathbf{q} = (\mathbf{x}'_1, \mathbf{x}'_2)$, i.e., $(\mathbf{x}'_1 \times \mathbf{x}'_2)^T\mathbf{K}\mathbf{R}\hat{\mathbf{H}}\mathbf{K}^{-1}\mathbf{x} = 0$. With $\mathbf{R}\mathbf{K}$ known, let $\mathbf{u}' = \mathbf{R}^T\mathbf{K}^T(\mathbf{x}'_1 \times \mathbf{x}'_2)$ and $\mathbf{u} = \mathbf{K}^{-1}\mathbf{x}$, we derive:

$$\mathbf{u}'^T\hat{\mathbf{H}}\mathbf{u} = 0. \tag{4}$$

Substituting (3), the equation expands to:

$$\mathbf{u}'^T\left(\mathbf{I} + \frac{1}{d}[\mathbf{0}, \mathbf{0}, \mathbf{c}]\right)\mathbf{u} = 0. \tag{5}$$

Solving for d from (5) yields:

$$d = -u_3\frac{\mathbf{c}^T\mathbf{u}'}{\mathbf{u}^T\mathbf{u}'}. \tag{6}$$

Since $u_3 = [0, 0, 1][x, y, 1]^T = 1$, the final distance formula is:

$$d(\mathbf{p}, \mathbf{q}) = -\frac{\mathbf{c}^T\mathbf{u}'}{\mathbf{u}^T\mathbf{u}'} = -\frac{\mathbf{c}^T\mathbf{R}^T\mathbf{K}^T(\mathbf{x}'_1 \times \mathbf{x}'_2)}{\mathbf{x}^T\mathbf{K}^{-T}\mathbf{R}^T\mathbf{K}^T(\mathbf{x}'_1 \times \mathbf{x}'_2)} \tag{7}$$

IV. Planning Safety Rope Anchorage Points

A. Determining Anchor Ridge of Fall Arrest Lanyard

Following the "anchor high, access low" principle for FPL [23], we define the anchor ridge as the load-bearing horizontal edge (the intersection of horizontal and vertical steel structures) at the apex of power transmission towers, which inherently includes appropriate anchor points. In UAV vision, the anchor ridge is the nearest ridge structure relative to the camera. Building upon the spacial line perception model (Section III-C), this subsection presents the detection of the anchor ridge, thus reducing the anchor point positioning problem to screen points along the one-dimensional anchor ridge (discussed in Section IV-B). The core workflow is outlined in Fig. 4, which contains key steps as follows:

1) Line segment detection: First, a line detection algorithm extracts multiple line segments from the current frame at time t, forming a set denoted as $\mathcal{S}^t = \{\mathbf{q}_1, \cdots, \mathbf{q}_m\}$. For all line segment $\mathbf{q} \in \mathcal{S}^t$, their endpoint $\mathbf{q} = (\mathbf{x}'_1, \mathbf{x}'_2)$ are in homogeneous coordinates, $\mathbf{x}'_1, \mathbf{x}'_2 \in \mathbb{P}^2$. Similarly, the prior frame's detection results at $t-1$ are denoted as $\mathcal{S}^{t-1} = \{\mathbf{p}_1, \cdots, \mathbf{p}_n\}$, where $\forall \mathbf{p} \in \mathcal{S}^{t-1}, \mathbf{p} = (\mathbf{x}_1, \mathbf{x}_2)$ and $\mathbf{x}_1, \mathbf{x}_2 \in \mathbb{P}^2$. Since lines are salient features in power tower scenes, various line segment detectors (e.g. Line Segment Detector (LSD) [24], Fast Line Detector (FLD) [25], Edge Drawing (ED) [26] or ELSED [27]) are applicable.

2) Temporal line segment matching: Given the two sets of line segments $\mathcal{S}^{t-1}$ and $\mathcal{S}^t$, the corresponding line segments that associate with the same structure on the transmission tower are expected to be paired, yielding a collection of matched line segment tuples.

$$\mathcal{P} = \left\{(\mathbf{p}, \mathbf{q}) | \mathbf{p} \in \mathcal{S}^{t-1}, \mathbf{q} = \arg\max_{\mathbf{q}' \in \mathcal{S}^t} p(\mathbf{p}, \mathbf{q}'), p(\mathbf{p}, \mathbf{q}) > 0\right\}. \tag{8}$$

where, $p(\mathbf{p}, \mathbf{q})$ denotes the probability of line segment $\mathbf{p}$ corresponding to segment $\mathbf{q}$. This can be achieved by line segment's invariant feature extraction and pairwise comparison. To ultimately achieve efficient operation on drone platforms, we adopted the Line Band Descriptor (LBD) [28] to extract stable features from line segments, followed by rapid line matching using KNN-Match algorithm [29]. These algorithms are integrated into the OpenCV library, enabling convenient and efficient implementation.

3) Depth computation and tuple construction: For each line segment pair $(\mathbf{p}, \mathbf{q}) \in \mathcal{P}$, its corresponding edge in the three-dimensional space has a depth d that is the distance from the edge to the camera's principal plane at time t. Eq. (7) is used to calculated the depth d, therefore yielding a set of triplets,

$$\mathcal{R} = \{(\mathbf{p}, d_{\mathbf{p}}) \mid (\mathbf{p}, \mathbf{q}) \in \mathcal{P}, d_{\mathbf{pq}} = d(\mathbf{p}, \mathbf{q})\}. \tag{9}$$

The distance $d(\mathbf{p}, \mathbf{q})$, computed via the previously established spacial edge perception model, reflects the geometric relationship between segment $\mathbf{p}$ and the principal plane.

4) Ridge detection by line segment clustering: Since the anchor ridge represents a prominent geometric feature composed of multiple steel bars, we employ depth-aware agglomerative hierarchical clustering (AHC) [30] to group segmented lines $\mathcal{R}$, generating large-scale linear structures $\mathcal{T} = \{\mathcal{O}_1, \cdots, \mathcal{O}_K\}$ through the aggregation of smaller segments, where $\mathcal{O}_i = \{\mathbf{p}, \cdots\}$ for $i \in \{1, \cdots, K\}$ is the i-th cluster of line segments. The depth-aware is achieved by introducing the depth as the extra feature. Then the anchor ridge is intrinsically retained within the clustered results,

$$\mathcal{T} = \texttt{clustering}_{\text{AHC}}(\mathcal{Q}). \tag{10}$$

To identify the anchor ridge, we select the clustered results with both smaller depth values and greater total segment lengths. Therefore, we have the anchor ridge $\hat{\Omega}$ chosen as

$$\hat{\Omega} = \arg\max_{\Omega \in \mathcal{T}} \sum_{(\mathbf{p}, d_{\mathbf{p}}) \in \Omega} \frac{\|\mathbf{p}\|}{d_{\mathbf{p}}}. \tag{11}$$

The cluster $\hat{\Omega}$ essentially represents the tower's nearest ridge to the camera. If the drone is in proper position, the meaningfulness of $\hat{\Omega}$ if ensured by the geometric stability of the truss structure.

Upon identifying the anchor ridge, the optimal mounting point can be determined through a search along this ridge. The localization algorithm for this process is described in detail in the following section.

B. Locating the Anchor Point for the Safety Lanyard

According to the analysis in Section IV-A, the optimal cluster $\hat{\Omega}$ represents a set of nearest salient edges on the transmission tower related to the drone (*mounting ridge lines*).

This subsection presents the anchor point locating algorithm, which aims to select the midpoint of the most suitable edge $\hat{\mathbf{p}}$ from the cluster $\hat{\Omega}$. To identify the most suitable anchor edge $\hat{\mathbf{p}} \in \hat{\Omega}$, we proposed a multi-objective cost function that evaluates the effectiveness of potential edges,

$$\hat{\mathbf{p}} = \arg\min_{\mathbf{p} \in \hat{\Omega}} \left[\psi(\mathbf{p}) + \lambda n(\mathbf{p})) + \omega \phi(\mathbf{p})\right]. \tag{12}$$

where, $\psi(\mathbf{p})$, $n(\mathbf{p}))$ and $\phi(\mathbf{p})$ are functions that evaluate different suitableness of the edge $\mathbf{p}$, and λ and ω are their weight factors.

Specifically, the cost function comprises the following components: 1) *Ladder proximity*: Although multiple suitable mounting points exist along the anchor ridge, we recommend prioritizing positions near the climbing ladder among the available options. Therefore, we model this evaluation using the ψ function. $\psi(\mathbf{p}) = \|\texttt{center}(\mathbf{p}) - \mathbf{x}_{\text{ladder}}\|$ quantifies the horizontal distance between the line segment's midpoint and climbing ladder, prioritizing segments closer to the ladder. Since $\mathbf{p} = (\mathbf{x}_1, \mathbf{x}_2)$, then $\texttt{center}(\mathbf{p}) = (\lfloor \mathbf{x}_1 \rfloor + \lfloor \mathbf{x}_2 \rfloor)/2$ with operator $\lfloor \cdot \rfloor$ representing homogeneous-to-Euclidean coordinate conversion. The $\mathbf{x}_{\text{ladder}} \in \mathbb{R}^2$ is calculated by object detection methods in advance or manually given by the operator. 2) *Vertical frame avoidance*: Considering that the anchor point needs to avoid interference from adjacent vertical steel frames, we define function $n(\mathbf{p})$ to quantitatively evaluate this condition. $n(\mathbf{p}) = |\{\mathbf{q}| \ \mathbf{q} \in \mathcal{R}, \mathbf{q} \notin \hat{\Omega}, e(\mathbf{p}, \mathbf{q}) > 0\}|$ counts adjacent interfering diagonal steel-bars, so as to avoid anchoring in structurally complex areas. λ is a penalty coefficient requiring adjustment. 3) *Length Suitability*: Since steel structures suitable for mounting must possess appropriate lengths (neither too short nor too long), we use the median length of line segments in $\hat{\Omega}$ as the reference length, and then evaluate the deviation between the length of the target segment $\mathbf{p}$ and this reference value. Therefore, $\phi(\mathbf{p}) = (\|\mathbf{p}\| - l_{\text{med}})$, where $l_{\text{med}} = \texttt{median}(\{\|\mathbf{q}\| | \mathbf{q} \in \hat{\Omega}\})^2$ is the median length of line segments in the anchor ridge $\hat{\Omega}$. Finally, the optimal anchor point $\hat{\mathbf{x}}$ is obtained by taking the middle point of $\hat{\mathbf{p}}$, namely, $\hat{\mathbf{x}} = \texttt{center}(\hat{\mathbf{p}})$.

V. Experimental Results

A. Dataset

Since this study involves specialized experiments in power system applications, our investigation found no relevant publicly available datasets. Therefore, we independently collected experimental data (using devices show in Fig. 5) and manually annotated the optimal mounting positions for fall protection lanyard (FPL), constructing the TOWER dataset. The TOWER dataset originates from real-world power tower inspection tasks, captured by high-resolution cameras mounted on unmanned aerial vehicles (UAVs). During data collection, the UAV's real-time kinematic (RTK) positioning information was synchronously recorded to ensure spatial accuracy. The dataset consists of 2,380 sets of color images, with each set containing two consecutive frames at a resolution of 3840×2160 pixels, providing clear details of the towers and surrounding environments. The corresponding RTK data

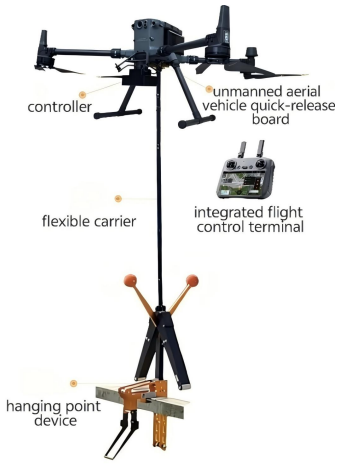

Fig. 5. The power inspection drone and fall protection lanyard equipment used to collect experimental data in this experiment.

Fig. 6. Sample images from the proposed TOWER dataset.

for each frame is stored in JSON format, facilitating image-geolocation alignment. The dataset is divided into training and testing subsets, with the test set containing 620 image pairs and the remaining 5,400 image pairs allocated for training. A key focus of the dataset is the optimal mounting positions for safety ropes. Some images include manual annotations marking the best attachment points, recording both image coordinates and ladder orientation. These annotations support the evaluation of detection algorithms for localization accuracy. Images without viable FPL mounting points are labeled as empty, serving as negative samples to enhance model generalization. The design and annotation methodology of the TOWER dataset provide robust data support for automated power facility inspection and maintenance, while also offering valuable practical insights for computer vision applications in the power industry. Our experimental dataset is planned for future public release.

TABLE I. DATASET DESCRIPTION

Name	Description
Dataset $\mathcal{D} = \{(I_i^0, I_i^1, R_i, t_i, K_i)\}_{i=1}^{N}$	Total $N = 2380$ items
Image Pair $I_0, I_1 \in \{0, \cdots, 255\}^{H \times W \times 3}$	(W,H) = (3840, 2160), 8-bits JPG
Rotation Matrix $\mathbf{R}_i \in \mathrm{SO}(3)$	float type, Json format
Translation Vector $\mathbf{c}_i \in \mathbb{R}^3$	float type, Json format
Camera Intrinsic $\mathbf{K}_i \in \mathbb{R}^{3\times3}$	float type, Json format

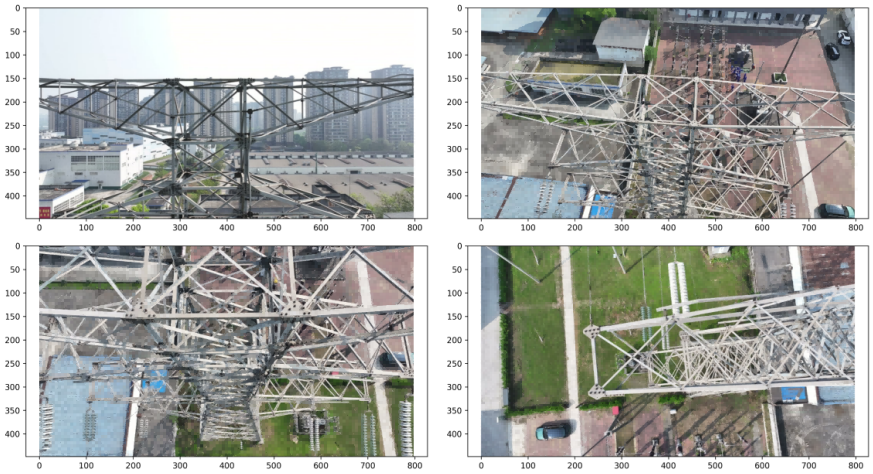
B. Hyper-parameter Setting

The experiments were conducted on a PC hardware platform equipped with an i7 processor and 32 GB of RAM to ensure efficient program execution. The software environment utilized Python 3.12, with key dependencies including OpenCV 4.9.0 for line detection algorithms, NumPy 1.26.4 for numerical computation, and Scikit-learn 1.6.1 for clustering algorithm implementation. The results obtained under this configuration effectively reflect the program's performance on typical computing systems, ensuring generalizability and reference value.

The line segment detector in our experiments was the ELSED [27].

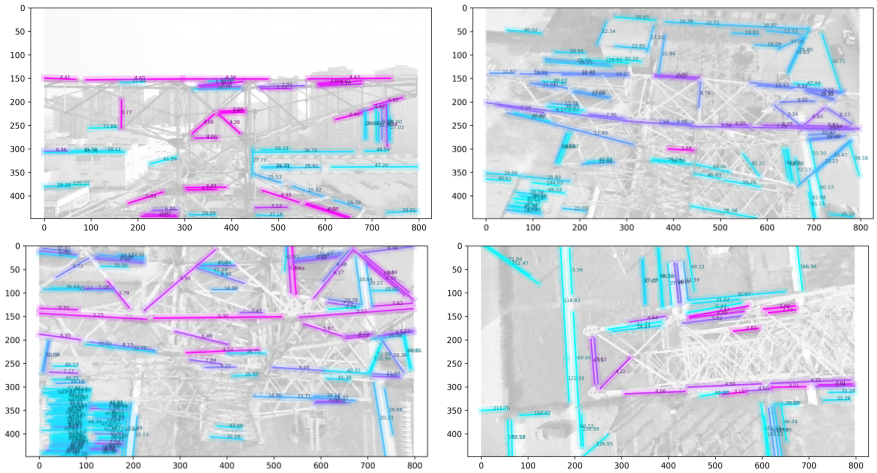
The experimental parameters were configured as follows: $T_{\text{ori}} = 0.95$, $T_{\text{len}} = 0.8$, $D_{\text{pos}} = 80$ pixels $\lambda = 5.5$, $\omega = 0.9$.

C. Quantitative Experimental Analysis



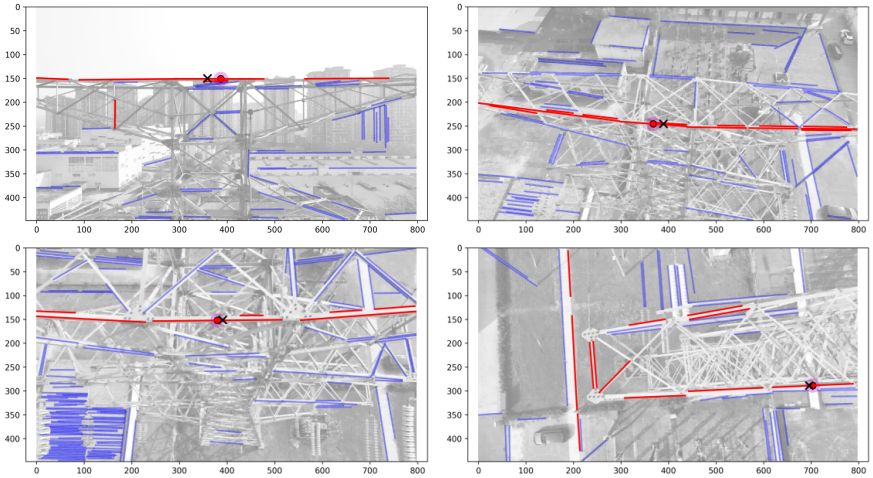
The experimental results demonstrate the effectiveness of our proposed algorithm in accurately identifying anchor ridges and locating optimal mounting points for fall protection lanyards (FPLs), as shown in Fig. 7. The original images are given in Fig. 7a. As illustrated in Fig. 7b, the depth-aware line segment matching successfully isolates structural edges on the transmission tower, with line color represents the depth values, e.g. closer ridges (magenta) clearly distinguished from background clutter (cyan). This enables precise ridge extraction, as shown in Fig. 7c, where the algorithm robustly detects the primary anchor ridges (red lines) and anchor points (black cross) despite complex steel truss interference.

Quantitative evaluation reveals strong alignment between our automated detection and manual annotations (ground-truth red circles). The mean absolute error (MAE) of anchor point positioning is 10.98 pixels, equivalent to sub-optimal positions at typical inspection distances, meeting industrial safety requirements. Our methodology's advantages primarily derive from geometric consistency. The plane-induced homography (Section III-B) maintains spatial coherence in ridge identification, minimizing erroneous detections from diagonal beam structures.



These results validate that our geometry-driven approach outperforms learning-based methods (Table II) in reliability and precision, particularly in preserving spatial relationships critical for FPL deployment safety. The minor deviations from manual markings primarily occur in incorrect line-pair match, highlighting opportunities for future refinement through robust line segment processing.

D. Positioning Accuracy and Efficiency Analysis



We compared the proposed algorithm with supervised learning-based neural network object detection algorithms.

(a) Original images

(b) Matched line segments with their depth, which is visualized by colormap that cyan indicates far and magenta represents near.

(c) Result of ridge detection (red) and anchoring point localization (cross). The red circle is ground-truth.

Fig. 7. Quantitative analysis of proposed method on various scenarios.

The experimental results are shown in Table I. Vision-based neural models were fine-tuned using our dataset, while the multimodal large model (e.g. DeepSeek V3) was directly invoked through prompt engineering. The analysis of the

experimental results indicates that ResNet30+RE and Our method achieve the best overall performance. Our method demonstrates the strongest robustness with the lowest MAE (10.98) and MedAE (11.02), while also achieving the highest R^2 (0.9725), indicating superior prediction accuracy and model fitting. ResNet30+RE follows closely, with slightly better MSE (265.57) and MAE (11.06) compared to ResNet18+RE, and its R^2 (0.9638) is close to that of Our method, demonstrating strong stability. In contrast, YOLOv5 and DeepSeekV3 exhibit higher MSE (288.72, 420.31), making them more sensitive to outliers, while Template Match is clearly unsuitable due to its excessively large error (MSE=7867.52).

Overall, while ResNet30+RE remains a supervised learning model, our method is unsupervised, eliminating the need for labeled data. This avoids the high costs and potential biases associated with data annotation in supervised learning, making it more advantageous when handling complex or unlabeled datasets.

TABLE II. PERFORMANCE COMPARISON OF DIFFERENT METHODS

Method	MSE	MAE	R^2	MedAE
Template Match	7867.52	86.47	0.6554	90.43
Yolov5	288.72	16.45	0.9107	18.74
ResNet18+RE	276.54	12.12	0.9535	13.16
ResNet30+RE	265.57	11.06	0.9638	12.93
DeepSeekV3	420.31	17.88	0.8989	19.22
Our	268.03	10.98	0.9725	11.02

E. Algorithm Efficiency Experiments

Due to the unique operational environment of UAVs, their environmental perception requires high dynamic responsiveness, making the computational efficiency of UAV algorithms critical. Therefore, we conducted experiments on time efficiency, with comparative results shown in Fig. 8.

The figure illustrates the performance of the proposed algorithm in processing varying numbers of line segments. The x-axis represents different levels of line segment quantities, including the most reliable top 100, 200, and 400 lines (top100, top200, and top400), while the y-axis displays the processing time in milliseconds. Performance at each level is measured using both the mean and standard deviation. As observed, the average processing time increases gradually with the number of line segments. Specifically, the mean processing time for top100 segments is approximately 80 ms, with a small standard deviation, indicating stable performance. These results demonstrate that the proposed algorithm can achieve real-time or near-real-time video processing by controlling the number of line segments to be processed, thereby meeting industrial requirements.

F. Limitations

Through our numerical experiments, we identified several limitations in the current system:

1) Line segment extraction and matching robustness issues: The performance of line detection and temporal matching remains sensitive to environmental variations, such as changes in lighting conditions and complex backgrounds. In extreme cases, this can lead to complete failure in segment extraction or incorrect matching, compromising the system's reliability.

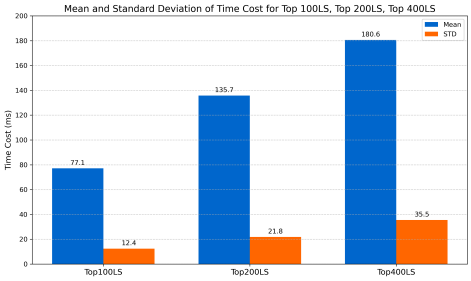


Fig. 8. Performance of the proposed algorithm in processing varying numbers of line segments.

2) Depth estimation accuracy limitations: While the proposed plane-induced homography provides relative depth comparisons between line segments (useful for ridge selection), the absolute depth values exhibit noticeable inaccuracies. This restricts applications requiring precise metric measurements, though it remains effective for ranking structural proximity.

3) Performance degradation under cluttered backgrounds: When inspecting towers with dense interfering line features (e.g. overlapping vegetation or secondary structures), computational latency spiked up to 420% beyond average processing times. This stems from the combinatorial complexity in AHC clustering (Section IV-A) and outlier filtering steps.

These limitations highlight key challenges for real-world deployment, particularly in adverse weather or visually congested environments. Future work should integrate deep learning to stabilize depth estimation and adopt attention mechanisms for robust line feature selection. Addressing these issues will be critical for industrial-grade reliability.

VI. CONCLUSION

This study addresses the safety protection requirements for high-altitude operations on power transmission towers by innovatively proposing an automated fall protection lanyard mounting method based on drone vision, providing an intelligent solution to replace traditional high-risk manual operations. Through multi-view geometric analysis, the system achieves 3D spatial localization of tower edges and optimal mounting point selection, overcoming the limitations of deep learning models in spatial mapping for complex scenarios. The method innovatively integrates multi-dimensional evaluation metrics, including proximity to climbing ladders, avoidance of diagonal steel obstructions, and temporal stability, ensuring that the selected mounting points comply with the "high-hook, low-use" safety principle while maintaining operational convenience. Experimental validation demonstrates that compared to conventional methods, the proposed solution significantly improves positioning accuracy and system intelligence, showing promising potential for pilot applications.

Future research can be deepened in three dimensions: First, expanding algorithm adaptability by optimizing detection models for special structures such as non-standard towers and angled steel members. Second, integrating mechanical verification modules to enable real-time assessment of load-bearing capacity at mounting points. Third, establishing open datasets and standardized testing environments to promote

collaborative technological advancement in the industry. With policy support from State Grid Corporation of China for drone-assisted operations, this technology is expected to become a standard configuration for high-altitude power operations, providing robust safety assurance for smart grid construction. Subsequent research should focus on the integration of drone swarm coordination and digital twin technology to further enhance operational reliability in complex environments.

APPENDIX

A. Proof of (2)

Proof: Let $\mathbf{x}_\mathrm{W} \in \mathbb{R}^3$ be an arbitrary point on the a plane $(\mathbf{n}, d)$ in the world frame. Then the $\mathbf{x}_\mathrm{W}$ satisfy,

$$\mathbf{n}^T \mathbf{x}_\mathrm{W} + d = 0 \tag{13}$$

By projecting the $\mathbf{x}_\mathrm{W}$ onto the image planes of camera at t and $t+1$, it satisfy that
