***Abstract*— The most important role of Consumer Behavior prediction plays in e-commerce, various ways of marketing, and Context-aware Recommendation Systems (CARS). From an Amazon consumer dataset, we conduct a comparative analysis of different machine learning models to compare their performance or effectiveness in predicting consumer behavior based on an Amazon consumer dataset. Additionally, we introduce a new algorithm combining feature selection and optimization that aims to enhance prediction accuracy. Person behavior prediction has historically helped enhance e-commerce, marketing, and Context-Aware Recommendation Systems-CARS, allowing businesses to get closer to customers and understand their needs better from the time they appeared to the time an analysis could be done. The research work performs comparative analysis among various machine learning techniques, like Logistic Regression, Decision Tree, Random Forest, SVM, and KNN, to see which one is more effective in predicting customer behavior, based on an Amazon consumer dataset. Besides, a new algorithm that merges feature selection and optimization is proposed and implemented to guarantee better prediction accuracy. The project is aimed at the creation of data-driven decision systems powered by an optimized machine learning framework for customer analytics.**

***Keywords*—Context-aware recommendation systems; multi-modal recommendation; transformer-based models; experimental validation; contextual parameter modeling; user behavior modeling**

I. Introduction

In the rapidly evolving digital marketplace, consumer behavior prediction plays a crucial role in shaping the success of e-commerce, marketing strategies, and Context-Aware Recommendation Systems (CARS). The ability to comprehend and foretell the tastes of the customers is a great advantage for the businesses, as they can then give the customers what they want in terms of personalized experience, better product placement, and increased satisfaction [1]. Machine learning tools have come to be relied upon more as the online transactions and data have increased rapidly, as they are the only ones capable of getting insights and predicting consumer behavior with such precision over other techniques. The research under consideration makes use of a dataset of Amazon customers to carry out an analysis that compares the different machine learning algorithms. It is the accuracy of the prediction, the resource consumption in terms of computation, and the ability to represent the behavioral patterns that form the basis of evaluation for all the algorithms. Besides this, the study proposes a new algorithm that combines feature selection and optimization techniques to increase overall prediction accuracy.

The contribution through combining comparative experimentation with algorithmic innovation is the development of data-driven decision-making frameworks for consumer analytics. The goal of the proposed research work is to generate insights that not only help choose and optimize machine learning models for consumer health behavior prediction but also reinforce the pillars of intelligent recommendation systems and adaptive marketing strategies in e-business. The expansion of e-commerce has led to an increasing reliance on data-driven decision-making and a better understanding and anticipation of consumer behavior. Machine learning (ML) is the main technique used for analyzing large consumer datasets, recognizing useful patterns, and improving marketing strategies. Using personalized recommendations, targeted advertising, and improved customer engagement, ultimately enhancing business profitability is predicting consumer behavior accurately (Manotumruksa et al,2018) [2]. However, it also differs in terms of changing degrees of accuracy and efficiency depending on the dataset characteristics and preprocessing techniques. Although they are effective, traditional models often face challenges such as over-fitting, computational complexity, and badly feature selection, restricting their predictive performance. To increase accuracy and robustness in consumer behavior prediction, it represents designed of a comparative analysis of conventional ML models alongside a novel algorithm.

To solve these challenges, this study presents a comparative analysis of conventional ML models alongside a novel algorithm designed to improve accuracy and robustness in consumer behavior prediction (Mateos, P. and Bellogín, A., 2024) [3]. The proposed approach incorporates feature selection and optimization techniques to boost predictive

power. An Amazon consumer dataset, this research aims to identify the most effective approach for consumer behavior analysis in e-commerce by evaluating multiple models.

II. Ease of Use

In numerous domain, machine learning (ML) models is used for predicting user behavior's various application like e-commerce, Random Forest and Gradient Boosting excellent perfumed KNN- (K-Nearest Neighbors) and SVM Support Vector Classifier in predicting customer shopping behavior (Smith,2019)[4]. Similarly, with some performing better in terms of accuracy for online shoppers' prediction using ML(machine learning) algorithms (Afzal et al., 2024) [5]. In the field of Electrical Vehicle (EV) customer behavior predictions, KNN slightly outperformed Neural Networks (Zhang and Abisado, M., 2023) [6]. For travel mode choice prediction, random forest achieved higher predictive accuracy than logit models but produced behaviorally unreason nable elasticities and marginal effects. While ML models generally demonstrate superior predictive accuracy, there may be a trade-off between accuracy and behavioral soundness. The studies in question highlight the necessity of correctly picking models for behavior forecasting and provide analytical frameworks suitable for different areas.

Traditionally, classic recommender systems—such as collaborative filtering (CF), content-based, and hybrid models—depended largely on either explicit or implicit user-item interactions and did not consider various external factors those impact users' preferences. Nevertheless, research done in the field of ubiquitous and mobile computing showed the users' choices might be influenced by the context like time, place, climate, among others, or even at their current activity [7]. This finding was the beginning of a new approach that led to CARS, where context is given the same priority as other input variables and considered first in the forecasting model. The three strategies of classical works are preventing processing, where the filtering of data is done according to context (for instance, "recommend only items that are suitable for evening usage". Post-filtering, where the traditional recommendation made is by re-ranking it with the help of context. Contextual modeling, where context gets featured as a part of the prediction/machine learning function (e.g., tensor factorization, factorization machines, deep learning, etc.).

It is acknowledged that context-aware modeling methods like ContextMF, TF, FM, and NFM have probably pointed out the importance of directly inputting contextual attributes into the preference-learning function. Conducted investigations have proved that contextual modeling almost always beats pre/post filtering approaches since the former is able to discern user, item, and context dimensional interaction effects more accurately.

We scrutinized machine learning models aimed at predicting user behavior in the virtual world. The comparison of several algorithms, such as K-Nearest Neighbors, Gradient Boosting, Support Vector Classifier, and Random Forest, has concluded that Random Forest and Gradient Boosting are very much alike in terms of the accuracy and sturdiness of the customer behavior forecast (Abinaya and Ramya, R., 2024) [8]. Such systems can suggest activities that are customized to different circumstances without needing any explicit user input. One of the latest developments is the context-aware user-item representation learning models that learn joint representations for each user-item pair based on the reviews and interaction data combined to increase the rating prediction accuracy [9]. Moreover, agent-based frameworks have been proposed which grant personalization of services based on the user's past connection with the context and automatically discover the connection among the user profiles and services in the same context. The different methods strive to be the static encoding schemes' nemesis capturing the users' different expectations on different items and contexts thereby, not only increasing the accuracy but also making personalized recommendations more interpretable in ubiquitous computing surroundings [10].

The researchers present a machine learning framework which utilizes context information to perform feature selection and optimize hyperparameters, resulting in better prediction accuracy of consumer behavior. The proposed method operates differently from previous hybrid methods because it measures how contextual features affect model performance while it handles feature selection before model development.

We used the Amazon consumer dataset to conduct their experiments, which provided them with valid statistical evidence to compare traditional learning methods, including Logistic Regression, Decision Tree, Random Forest, SVM, and KNN, against ensemble learning techniques. The research results show that using the optimized framework leads to higher accuracy across different evaluation metrics.

The research determines which contextual factors most affect consumer decision-making. The research provides specific insights which help in developing context-specific recommendation systems while comparing existing models. The study provides practical solutions for recommendation platforms through its support of personalized marketing strategies and its creation of adaptive recommendation systems and its advancement of data-driven campaign optimization.

III. Methodology

Predicting person's behavior is done through customer interactions, purchasing patterns, and preferences analysis to anticipate future actions. E-commerce and digital transactions foster massive customer activity data availability which, in turn, allows businesses to adopt a data-driven decision-making approach [11]. One of the areas where support is being provided is using machine learning (ML) which helps not only in processing the data but also in providing analytical outputs that can be used in targeted marketing, recommending systems, and demand forecasting. ML techniques can analyze large-scale consumer data, discover hidden trends, and build predictive models that will allow businesses to comprehend and even alter customer choices [12]. The ML model is constantly learning from past data and hence is also continuously adapting to the new trends in the market which eventually results in more accuracy [13].

In the above Fig. 1, it gathered context from various sensors for a context-aware recommendation system. The data is collected from various electronics devices like smartphones,

wearable's, IoT devices, smart home systems etc. This data is collected from different sources like location of user, activity of user, and user interactions using social media, and is processed in real-time using edge computing and cloud storage to ensure timely recommendations [14]. For generative effectiveness in context-aware system using Machine learning algorithms [15]. The system mainly integrates a dedicated privacy and security module to protect user data while ensuring scalability and performance, enabling efficient handling of large volumes of data and user interactions [16].

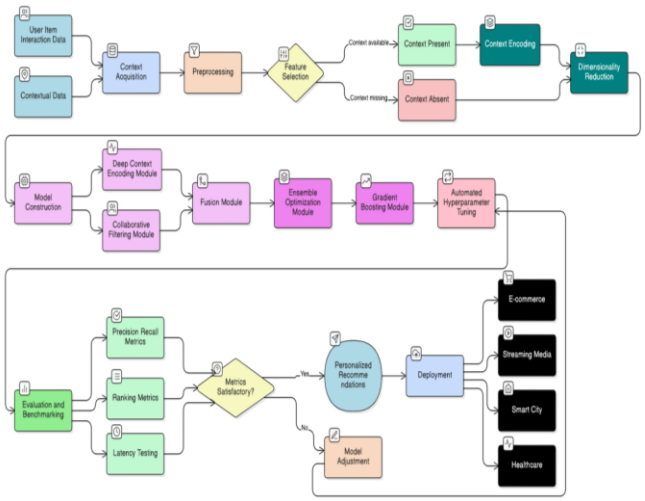

Fig. 1. Overview of proposed work.

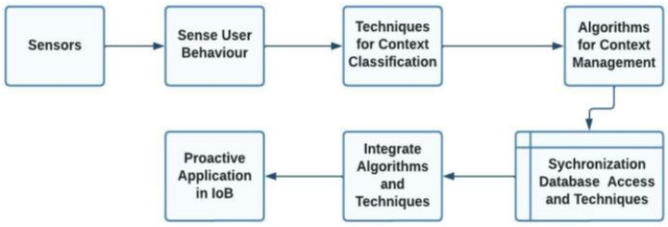

Fig. 2. Proposed CARS_UP methodology.

In the Fig. 2, illustrate the methodology for context-aware computing in the Internet of Behaviors (IoB). The process start from collecting sensed data from heterogeneous devices so it will help to analyzed behavior of users [17]. For classification it uses the context classification which allows the system to interpret user interaction. Once classification is done then main role played by context management. Mainly taking care of the utilization of context is effectively for immediate decision making and having useful insights [18]. After that it involves synchronization, database access, and techniques for data flow seamlessly along with consistency. Using algorithms and technologies makes system capable for real time decision-making. Leading to intelligent, automated responses that enhance user experiences by predicting behaviors and adapting services accordingly [19].

IV. Method Validation

In Fig. 3, the model accuracy comparison illustrates the performance of different machine learning models based on their accuracy scores. In above chart, XGBoost scores the highest accuracy, later SVM, indicating that these models perform well in classification tasks. Comparative accuracy is there for Logistic Regression and Random Forest, making them feasible options for predictive modeling [20]. However, Decision Tree achieves the least accuracy which indicates that it may not be applicable to the data in a general sense. KNN also presents a lower performance level than the rest of the models, however, it still ranks above the Decision Tree. To sum up, the findings advocate that the model combinations such as XGBoost and Random Forest are superior to the single ones like Decision Tree, therefore, the significance of the selection of powerful algorithms for classification issues is emphasized [21].

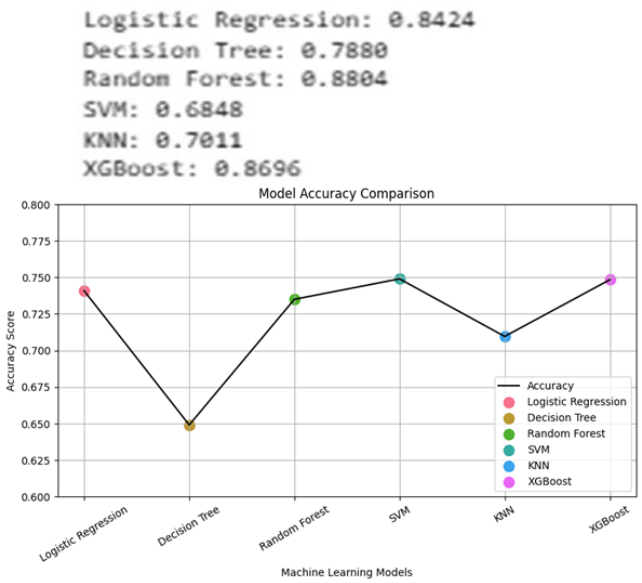

Fig. 3. Analysis of machine learning model.

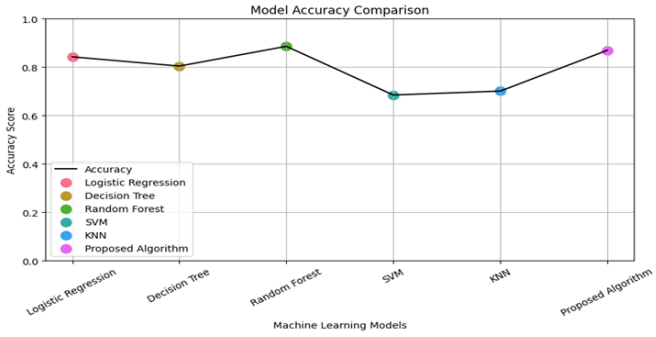

Fig. 4. Accuracy model using various machine model.

In Fig. 4, the comparative chart illustrates the accuracy performance of six machine learning models alongside the proposed algorithm. The accuracy metric, ranging from 0.0 to 1.0, quantifies the predictive effectiveness of each model for the given task. Among the evaluated models, the Random Forest exhibits the highest accuracy, closely followed by the proposed algorithm, which demonstrates comparable predictive strength. The Logistic Regression and Decision Tree models yield moderate performance levels, while the Support Vector Machine (SVM) and K-Nearest Neighbors (KNN) achieve the lowest accuracy scores. Overall, the proposed algorithm exhibits competitive performance, nearly matching the best-performing model, thereby validating its effectiveness in consumer behavior prediction.

The correlation heatmap represented in Fig. 5 provides a clear visualization of the connections among various characteristics in the heart disease dataset. The correlations range from -1 to 1 with positive values implying direct relationships between the variables as they get higher and negative values indicating reverse relationships whereby one variable increase when the other decreases. The colors illustrate the strength of the correlations; the red color represents the strongest positive correlation while blue represents the strongest negative one. The heatmap reveals that heart disease is associated with several key features with strong correlations. The ST_Slope variable has a strong negative correlation (-0.56) with heart disease since ST slope lowering is linked to greater chances of heart disease. ExerciseAngina's correlation was moderate and positive (0.49), which means that people who get angina by exertion are more likely to have heart disease. Quite surprisingly, Oldpeak (ST depression) shows a positive correlation with heart disease (0.40) whereas the MaxHR (maximum heart rate) shows a negative one (-0.40), meaning that lower maximum heart rate is associated with higher risk of heart attack. ChestPainType is inversely correlated (-0.39), implying that specific categories of chest pains might be less likely to accompany heart disease.

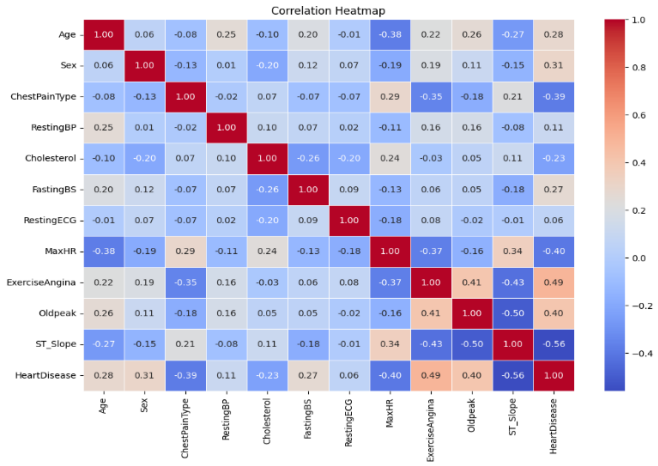

Fig. 5. The correlation heatmap of the relationships between various features in a heart disease dataset.

A heatmap is revealing for other Unexplainable correlations too. With Age affirming MaxHR to have a negative correlation of -0.38, which coincides well with the very normal and common declining nature of maximum heart rate with age. The ExerciseAngina and the Oldpeak have quite a significant relation (0.41), suggesting that individuals who experience angina during exercise also tend to have higher ST depression values. Moreover, one finds that the ST_Slope and Oldpeak are inversely correlated (-0.50), which suggests that a higher ST slope relates to a lower value of ST depression. In the end, it allows us to argue that the heatmap pattern very well underlines factors that are of most significance to heart disease and thereby facilitates the selection of features in building predictive models. It gives us insights into various variables interacting with each other, helping researchers and health professionals understand the deeper patterns underlying those factors contributing to risks of heart disease.

In Fig. 6, the correlation heatmap is the one giving the most visual view of the relationships between different health-related and demographic variables, with the corresponding correlation values being between -1 (perfect negative correlation) and 1 (perfect positive correlation). The situation where two variables show a positive correlation means that one of them will rise together with the movement of the other one, while in case of negative correlation it will be the opposite. The correlation of 0.38 between Diabetes_binary and HighBP which is one of the most striking correlations in the dataset,

reveals that hypertense people are also at a higher risk of having diabetes.

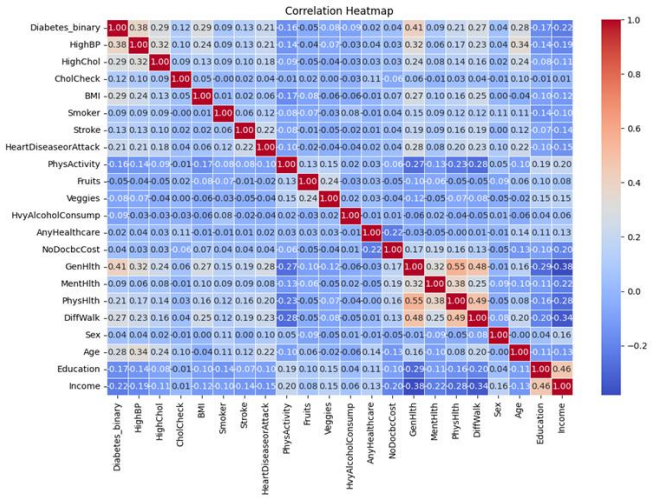

Fig. 6. Correlation heatmap of relations between various health-related and demographic variables.

The correlation of Diabetes_binary with BMI of 0.29 is another one in connection that tells that people with diabetes is generally more likely to be obese. Aging is the factor causing the diabetes risk of about 0.28 correlations between Diabetes_binary and Age in the same way. Other factors are HeartDiseaseorAttack (0.21) and General Health (GenHlth) (-0.41). High blood pressure (HighBP) has a strong correlation with HeartDiseaseorAttack (0.32), meaning that people with high blood pressure are more likely to have heart diseases. The connection between HighBP and BMI is of moderate strength (0.24), indicating that individuals with a higher BMI are more likely to have high blood pressure. Besides, the relationship between HighBP and Age (0.34) indicates that blood pressure tends to rise with age. General Health (GenHlth) has close relations with various health factors and is one of the health indicators that affect the overall health.

It is negatively correlated with Physical Activity (-0.27), which means that active people are more likely to report on good health. Also, GenHlth is negatively correlated with Fruits (-0.24) and Vegetables (-0.24), implying that those who eat more fruits and vegetables usually report a higher quality of health. A very strong positive relationship exists between GenHlth and MentHlth (0.32), indicating that mental health problems lead to better general health. In the same manner, GenHlth and Physical Health (PhysHlth) (0.55) have a strong correlation, which is expected, meaning that people who report poor physical health are also likely to have low general health. If heart diseases and strokes are analyzed, HeartDiseaseorAttack would have a 0.22 correlation with Age, pointing out the increased heart disease risk with aging. The above findings show a strong interrelation among several health issues and lifestyle factors with Age being indirectly related to General Health through Strong PhysActivity (-0.27). General Health also appears to be indirectly affected by the strong consumption of Fruits and Vegetables as they have negative correlations with it (-0.24 and -0.24, respectively).

The positive correlation between Age with HighBP (0.32) and BMI (0.27) can also be attributed to the fact that elderly people are more prone to the development of these conditions, thus increasing their chances of being hospitalized for cardiovascular diseases. Taking into consideration their negative correlation with GenHlth (-0.24 and -0.24, respectively), the assumption is that the consumption of fruits and vegetables is positively associated with good health. Admittedly, the flourishing correlation of Age with Income (0.46) cannot go unnoticed as it is the common practice in most societies that the older generation usually possesses the highest income. Besides, age has a negative correlation with Diabetes_binary (-0.14), implying that the older a person is the more likely they are to be diabetic. In the same way, the correlations with Income and Diabetes_binary (-0.22), HighBP (-0.19), and BMI (-0.10) suggest that people with higher income levels are less likely to experience these health problems.

The analysis of the correlation matrix not only confirms but also highlights the existence of relationships between lifestyle choices, health conditions, and the different demography.

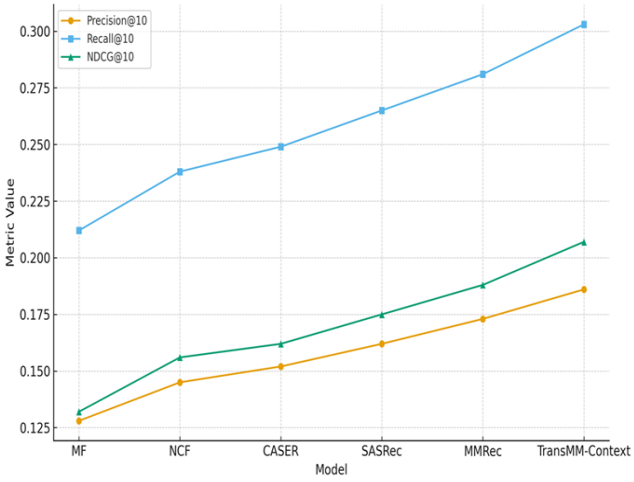

Fig. 7. Comparative performance of transformer-based multi-model recommendation systems.

In Fig. 7 shows the NDCG@K performance (for K = 1 to 20) across three models: SASRec (baseline transformer), MMRec (multi-modal baseline), and the proposed TransMM-Context model. NDCG (Normalized Discounted Cumulative Gain) measures how well the model ranks relevant items higher in the recommendation list. The proposed TransMM-Context model consistently outperforms both baseline methods for all values of K. SASRec performs the worst, and the MMRec baseline improves when multi-modal features are taken in (visual and textual embedding). On the other hand, the TransMM-Context model not only exploits multi-modal embedding but also context embedding (time, location, device, and user activity), resulting in the absolute lift in NDCG throughout the entire top 20 recommendation list. The curve shows how context-aware, transformer-based multi-modal attention aids ranking relevant items further up in the list, which is of the utmost importance for real-time recommendation.

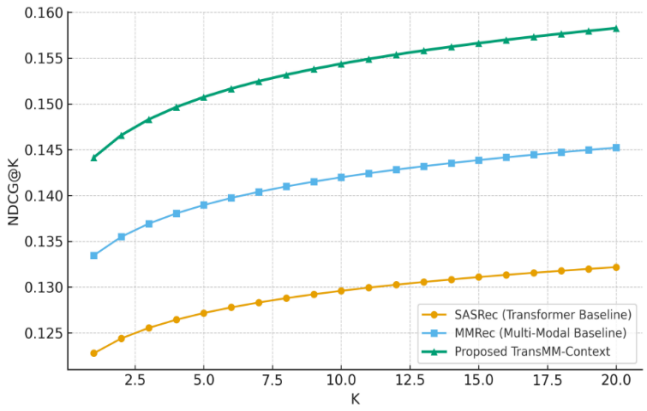

Fig. 8. NDCG@K curves for baselines vs. Proposed.

In Fig. 8, the graph compares the NDCG@K of the three recommendation models: SASRec (Transformer Baseline), MMRec (Multi-Modal Baseline), and Proposed TransMM-Context. The values of K range from 1 to 20. NDCG@K tells how good the ranking is: a higher value means better performance. The Proposed TransMM-Context always has an edge over SASRec and MMRec for every given K, which implies being better in ranking relevant items higher. MMRec performs better than SASRec but not well enough when contrasted with TransMM-Context, emphasizing how well the proposed method extracts and uses context to boost recommendation accuracy.

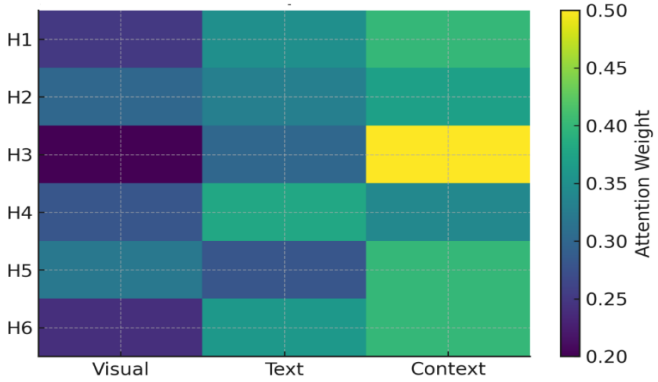

Fig. 9. Attention heatmap (visual+text+context).

The attention heatmap shown in Fig. 9 portrays a small sample showcasing how the proposed transformer model spreads out attention among modalities (Visual, Text, Context) across six attention heads. Each cell accommodates the relative weight of importance assigned by that attention head toward the specific modality in predicting the recommendation. The heatmap suggests that some heads place more emphasis on the context signal while others utilize the pure image-and-text features. For instance, in short sessions or cold-start cases, context (time, location, and device) carries heavier attention weights to enable accurate recommendation when historical interactions are sparse. However, long sessions weigh visual and textual modalities heavier, suggesting that the model draws upon item features and user preferences in such cases.

V. Conclusion

The research demonstrates that predicting consumer behavior serves as an essential requirement for e-commerce and marketing and Context-Aware Recommendation Systems (CARS). The study conducts an analysis of contextual factors together with machine learning algorithms which include Logistic Regression and Decision Tree and Random Forest and SVM and KNN to assess their success in predicting consumer behavior. The research developed a new algorithm which combines feature selection with optimization methods to achieve superior predictive accuracy compared to current methods.

The comparative analysis demonstrates the advantages and disadvantages of each model which helps to assess their effectiveness for consumer analytics. The research results show that businesses and system designers can use its findings to develop practical applications which extend beyond performance assessment. The proposed model can support data-driven business strategies by enabling personalized marketing, improved customer targeting, and optimized recommendation system design, which will enhance user engagement and conversion rates in e-commerce platforms. Organizations can improve their marketing campaign design through identification of key contextual elements which drive changes in customer behavior and environmental conditions. The study has limitations because it depends on a particular dataset and its fixed contextual parameters which restrict its applicability to multiple fields and actual operational situations. Future research may focus on incorporating real-time contextual data and deep learning approaches while conducting scalability tests with larger and more diverse datasets. The model requires extension to cross-domain recommendation systems which will enable assessment of its effects on business performance over extended periods.

The research develops data-driven marketing and recommendation systems through its introduction of a machine-learning framework which achieves both better prediction results and delivers practical business outcomes and research directions for studying consumer behavior.

Edge Artificial Intelligence for Real-Time Fresh Produce Identification in Retail Weighing Systems

Shi Han Teo, Jun Kit Chaw
Institute of Visual Informatics, Universiti Kebangsaan Malaysia (UKM), Selangor 43600, Malaysia

***Abstract*—Real-time recognition of loose fresh produce is a key requirement for intelligent retail weighing systems, enabling automated replacement of or assistance to manual PLU-based item selection. However, the deployment performance of recent YOLO architectures on embedded edge platforms such as the NVIDIA Jetson Xavier NX remains insufficiently studied in practical retail scenarios. This study aims to benchmark recent YOLO architectures for real-time fresh produce recognition on embedded edge devices. This work presents an Edge–AI retail weighing system that recognizes Malaysian fresh produce using YOLOv9, YOLOv10, and YOLOv11 models on the Jetson Xavier NX. A domain-specific dataset of 8 450 images across 26 classes was created by merging ImageNet and Roboflow sources and applying quality filtering and unified preprocessing. Each model was fine-tuned and optimized with TensorRT at FP16 and INT8 precision. Transfer learning improved accuracy across all models; YOLOv11-Large achieved the highest mAP@0.5 of $\approx$ 0.897 but at a reduced frame rate, while the mid-sized YOLOv10-M delivered an mAP@0.5 of $\approx$ 0.890 with near-real-time performance inference. Inference analysis shows that pre- and post-processing add only a few milliseconds per frame yet become proportionally significant as inference speeds increase; YOLOv11's Non-Maximum Suppression (NMS) head introduces notable latency relative to YOLOv10's NMS-free design. Quantized YOLOv10-M and YOLOv10-N sustain $\approx$ 14–19 FPS , offering the best balance between accuracy and speed. Qualitative tests on market footage confirm robust detection, indicating that these optimized models enable accurate, low-latency produce identification for intelligent retail weighing.**

***Keywords*—Real-Time object detection; Edge Artificial Intelligence (Edge AI); transfer learning; YOLO algorithm; nvidia jetson; fresh produce recognition; TensorRT optimization; model quantization**

I. Introduction

In a grocery store, weight-based pricing is a common way the grocery store charges the customer. Selling the prepackaged goods might be a solution to simplify the process by eliminating the need for in-store weighing at the time of purchase. Loose produce still plays an important role because of the flexibility in purchase quantities and the potential to reduce household food waste [1]. This further highlights that the weighing scales play a critical role in modern fresh produce retail environments. However, the traditional weighing scales required the user to control the PLU(Price Look-Up) subsystem in the software to retrieve the unit price of the item. This will require the staff to memorize the codes and manually control the machine to complete the checkout task. Consequently, it will cause inefficiency during peak hours. These challenges indicate that there is a need for a more intelligent and automated solution by utilizing computer vision and artificial intelligence [2]. To be practical in retail checkout environments, such a solution must operate in real time, without reliance on external connectivity, and with minimal computational overhead.

Edge AI has recently emerged as a key paradigm for high-performance inference in real-time systems. Unlike cloud-based AI inference, edge AI operates locally on the device, thus eliminating the dependency on continuous internet connectivity and minimizing the latency introduced by network transmission [3]. In the context of real-time fresh produce detection, Edge AI plays an important role in maximizing the user experience because it allows rapid inference speed and eliminates the latency that causes a laggy experience by the user [4]. By combining the Edge AI platform with a real-time object detection algorithm, it is possible to come out with a robust retail weighing solution.

Among object detection frameworks, the YOLO (You Only Look Once) object detection model is widely recognized for real-time applications due to its single-stage architecture, which performs object localization and classification simultaneously, unlike two-stage detectors [5]. YOLO algorithms have undergone continuous architecture improvements, leading to a succession of improved versions such as YOLOv1 until YOLOv11. These continuous architecture improvements impact accuracy, training time, and inference performance [6]. Consequently, YOLO is a suitable candidate for deployment in intelligent retail scales to detect fresh produce. However, within this context, there is limited evaluation of the inference speed and detection accuracy for the different versions of YOLO algorithms, particularly when optimized using TensorRT frameworks.

However, when it comes to detecting agricultural produce in Malaysian grocery-stores, applying transfer learning to a YOLO model is essential. The pretrained YOLO algorithm is based on a general dataset such as the COCO dataset. This means that a domain-specific dataset is necessary to train a YOLO model that fits the context of agricultural produce [7]. The well-known general datasets, such as COCO and ImageNet, offer broad object coverage, but are not focused on representing agricultural produce found in Malaysian retail markets. Previous research indicates that domain-specific datasets generally outperform generic ones due to their tailored relevance and coverage [8]. The data set gap here causes uncertainty on how effectively YOLO models perform in recognizing fresh produce with high intra-class variation, such as differences in size, shape, or color of the same item, and high inter-class similarity characteristics, such as similar-looking fruits that general-purpose datasets fail to capture.

When deploying deep learning models on embedded edge devices such as the NVIDIA Jetson series, achieving real-time

inference is often constrained by limited computational and memory resources. To overcome these limitations, TensorRT provides a hardware-aware optimization framework that restructures neural network graphs through layer fusion, kernel auto-tuning, and precision calibration from FP32 to FP16 or INT8, significantly improving throughput while maintaining near-lossless accuracy [9]. By leveraging TensorRT, models can exploit the full potential of Jetson's CUDA and Tensor cores, reducing latency and power consumption—both critical for real-time retail weighing applications.

Despite these advantages, comparative analyses of TensorRT-optimized YOLOv9, YOLOv10, and YOLOv11 models for multi-class retail produce detection under edge constraints remain scarce. Most existing studies benchmark earlier YOLO architectures or focus on general object classification tasks rather than fine-grained produce detection on embedded platforms. This study addresses this gap by evaluating the inference speed and detection accuracy of TensorRT-optimized YOLO models on the Jetson Xavier NX for real-time produce recognition.

This study addresses these challenges by developing a prototype smart retail system based on the NVIDIA Jetson Xavier NX platform and integrating YOLOv11, YOLOv10, and YOLOv9 models to assess inference speed and detection accuracy for agricultural produce commonly sold in Malaysia.

This work aims to advance the field of object detection by presenting a comprehensive evaluation of state-of-the-art YOLO models—namely YOLOv9, YOLOv10, and YOLOv11—in the context of real-time fresh-produce recognition for smart retail systems. The study contributes in the following aspects:

- Identifies architectural design principles for low-latency edge-based object detection by analysing the end-to-end inference behaviour of YOLOv9–YOLOv11 on an embedded GPU platform.
- Quantifies the practical impact of NMS-based versus NMS-free detection heads in retail inference pipelines, demonstrating how post-processing overhead increasingly dominates latency in real-time edge deployment.
- Establishes a reproducible benchmarking framework for evaluating modern YOLO architectures under realistic retail constraints, including unified preprocessing, transfer learning, and TensorRT-based optimization on the NVIDIA Jetson Xavier NX.
- Derives precision–latency trade-offs across model scales and quantization modes (FP16 and INT8), providing deployment-level guidance for selecting suitable configurations under strict real-time constraints.
- Delivers a validated reference configuration for intelligent retail weighing systems, achieving near real-time performance with high detection accuracy, and demonstrating transferability beyond a single dataset or deployment scenario.

The remainder of this paper is organized as follows. Section II surveys related work on edge AI for computer vision and existing produce-recognition approaches, highlighting the need for efficient deployment on embedded devices. Section III details the proposed methodology, including the system architecture, domain-specific dataset construction, transfer learning strategies, and TensorRT-based optimisation of YOLO models. Section IV presents and discusses the experimental results, analysing detection accuracy, inference speed, precision–recall characteristics, and the impact of model size and quantisation across YOLOv9, YOLOv10, and YOLOv11. Finally, Section V offers the conclusion, summarising key findings, discussing remaining challenges and limitations, and suggesting directions for future research.

II. Related Works

A. Edge AI and Deep Learning-Based Computer Vision

The concept of Edge AI has shifted the paradigm of artificial intelligence deployment, especially in real-time applications. The Edge AI approach aims to bring computation closer to the data source, such as video streams, thereby eliminating network latency that often occurs in cloud-based processing [3].

Recent studies have demonstrated the feasibility and efficiency of deploying deep learning models directly on embedded hardware for real-time inference. A real-time myocardial infarction monitoring system using SSD-Inception V2 and MobileNet V2 on the NVIDIA Jetson Nano achieved a mean average precision (mAP) of 76.4 % under low-power operation, setting a benchmark for energy-efficient edge analytics [10]. The YOLOSR architecture combined a Super-Resolution (SR) branch with YOLOv8-small, improving detection accuracy by 10.2 % without added latency (101 ms per frame) on a Jetson Nano edge platform [11]. Complementary works have also validated the effectiveness of Edge AI across domains, including FPGA-based YOLO implementations for Advanced Driver Assistance Systems (ADAS) and surveillance applications [12], and real-time apple detection on embedded GPUs achieving 83.6 % mAP at 30 FPS [13], demonstrating that optimized architectures and hardware accelerators enable near-cloud accuracy on compact edge systems.

While Edge AI has been widely applied in healthcare, surveillance, and autonomous navigation, fewer studies have addressed its use in retail environments. There is limited attention to retail applications, particularly in detecting multiclass grocery fresh produce in Malaysia. Building on prior successes, this study applies Edge AI for real-time produce detection integrated with a retail weighing system as a smart retail solution.

B. Edge AI and Platform-Specific Optimization

Deploying deep learning models on edge devices often demands hardware-aware optimization to achieve real-time inference under limited computational and memory resources. Among the most widely used frameworks, NVIDIA TensorRT provides significant acceleration by performing layer fusion, precision calibration (FP32→FP16 or INT8 quantization), and kernel auto-tuning tailored for GPU-based embedded platforms such as the Jetson Nano, TX2, and Xavier. These optimizations restructure neural network graphs and dynamically allocate tensor memory to reduce latency and improve throughput, enabling efficient deployment of convolutional neural networks in time-critical applications.

Recent studies have demonstrated the tangible benefits of such optimization pipelines across various domains. For instance, a TensorRT-optimized driver drowsiness classification system—based on MobileNetV1 rather than a detection architecture—achieved a 79.27% increase in throughput (from 141.78 FPS to 683.92 FPS) on Jetson Nano while maintaining 98.19% accuracy, highlighting TensorRT's capability to deliver near-lossless precision under quantized execution for lightweight classification tasks [14]. However, this exceptionally high throughput does not represent object detection workloads such as YOLO, which involve additional computation for multi-scale feature heads and non-maximum suppression. Similarly, a YOLOv5-based tennis-ball detection model combined GhostNet, BiFPN, and TensorRT to enhance both detection accuracy (mAP 94%) and inference efficiency through layer fusion and memory optimization on RTX hardware [15]. It is noteworthy, however, that although TensorRT is fundamentally designed to accelerate inference on embedded and edge AI platforms such as the NVIDIA Jetson series, this study conducted all experiments on a high-end desktop GPU (RTX 3060) under a Windows environment rather than on an edge device. Consequently, the reported throughput improvements primarily validate the computational acceleration of TensorRT on general-purpose GPUs, but do not assess its performance or feasibility under the resource and power constraints typical of real-time edge deployments. This distinction underscores a limitation in edge-specific validation, which remains essential for evaluating true on-device efficiency and deployability in embedded AI contexts.

In the agricultural domain, the PcMNet model integrated YOLOv8 with partial convolution and TensorRT acceleration, achieving 92 FPS on Jetson-based edge devices while reducing FLOPs by 37.8% and parameters by 53.3%, thereby validating its suitability for real-time fruit detection in orchard environments [16]. In contrast, the strawberry segmentation model based on Mask R-CNN [17] focused primarily on high-precision semantic segmentation under occlusion but was evaluated on desktop GPUs without edge-oriented deployment. The peanut leaf disease detection study [18] employed a classification-based approach using MobileNetV3, EfficientNet, and ShuffleNet models optimized via TensorRT for Jetson devices. Unlike object detection frameworks, this work focused solely on image-level disease classification without bounding-box localization.

Collectively, these works underscore the importance of platform-specific optimization for achieving real-time, power-efficient inference on edge AI systems. However, the majority of existing research has primarily focused on model-level architectural enhancements—such as backbone redesigns, attention modules, or lightweight feature extractors—rather than conducting comprehensive TensorRT benchmarking across recent YOLO variants. Furthermore, comparative evaluations of quantized (FP16/INT8) detection pipelines on embedded NVIDIA platforms remain limited, particularly in domain-specific applications such as agricultural produce recognition and smart retail environments, where the trade-off between detection accuracy and latency is critical. Addressing this gap, the present study systematically investigates the deployment performance of TensorRT-optimized YOLOv9, YOLOv10, and YOLOv11 models on the Jetson Xavier NX, providing an in-depth analysis of their precision–speed trade-offs and validating their suitability for real-time edge AI inference.

C. YOLO Evolution and Comparative Performance

Since the introduction of the YOLO algorithm in 2015, the single-stage detection paradigm has eliminated the computational overhead associated with region proposal pipelines used in two-stage detectors such as Faster R-CNN. By skipping the region proposal step, YOLO has undergone several massive improvements over successive iterations. The latest breakthroughs are represented in YOLOv9, YOLOv10, and YOLOv11 [6]. The advancements in YOLOv9 introduced GELAN and PGI, which reduce parameters yet achieve higher accuracy. In YOLOv10, the traditional Non-Maximum Suppression (NMS) was eliminated and replaced with Consistent Dual Assignments (CDA), meaning the algorithm no longer produces multiple overlapping bounding boxes. YOLOv11 introduces further innovation with modules such as C3k2 and C2PSA, which help detect smaller objects more effectively [19]. These distinct innovations create an opportunity to explore their impact in domain-specific scenarios, particularly in real-world and practical use cases.

There are many studies being done to compare various versions of YOLO algorithms in agricultural domains. A study compared YOLOv9–v12 for cattle precision farming [20], where YOLOv12 achieved the highest mAP of 98.3% but with slower inference speed of 36.6 FPS, while YOLOv11 maintained nearly the same accuracy at 97.8% but ran faster at 48 FPS. YOLOv10 also reached 97.1% mAP with 44 FPS, and YOLOv9 was the weakest with 96.2% mAP and 37 FPS. Another study on banana bunch detection [21] across YOLOv1–YOLOv12 reported that YOLOv12n achieved 93% AP50 with a latency of only 5.1 ms, making it well-suited for mobile deployment, while YOLOv11n also showed competitive efficiency under constrained devices. However, not all studies concluded that the higher the version, the higher the mAP values. In multi-class fruit ripeness detection [22] , the YOLOv6 outperformed YOLOv7 and SSD by achieving 99.5% mAP together with an inference speed of 85.2 FPS, showing that earlier versions can still dominate when the class variation is limited. Weed detection study [23] provided further evidence of trade-offs: YOLOv9 achieved the highest mAP@0.5 of 93.5% across multiple species, while YOLOv11 was the fastest with inference time of 13.5 ms, making it more suitable for real-time robotic field deployment. The anchor-based YOLOcF derivative [24] , developed on YOLOv5, also challenged mainstream versions by surpassing YOLOv10n and YOLOv11n in accuracy, showing up to 0.8–1.3% higher mAP, and achieving a record inference speed of 323 FPS, although it remained 1.4% lower than YOLOv9t in overall precision.

Despite many comparative studies being conducted in agricultural domains, there remains a gap in benchmarking YOLO algorithms for detecting loose produce commonly sold in grocery store. In Malaysia, this involves a wide variety of classes and requires a domain-specific dataset that reflects local produce characteristics rather than relying on generic datasets like COCO. This study therefore aims to bridge the gap by conducting a comparative analysis of YOLOv9, YOLOv10, and YOLOv11 tailored to Malaysian retail produce, while also evaluating the accuracy and latency of real-time inference under edge computing constraints.

III. Methodology

A. System Architecture

As shown in Fig. 1, the entire system is implemented based on a three-tier structure, which consists of the Edge Layer, Fog Layer, and Cloud Layer. This design follows a 3-tier architecture, where each layer handles specific responsibilities to ensure efficiency and real-time performance.

At the Edge Layer, a Raspberry Pi is used to prototype the regular weighing scale by connecting the HX711 amplifier board with the load cell. The weight value stream is then stabilized using an average buffer algorithm to reduce noise and ensure stable readings. The NVIDIA Jetson Xavier NX is integrated with a camera, and the YOLO inference source code is deployed and further customized to integrate with MQTT messaging capability, enabling the detection results to be streamed in JSON format. These JSON messages are published to the MQTT broker.

On the customer side. The Flutter-based kiosk application subscribes to these MQTT messages and parses the JSON data. The app uses asynchronous programming to handle concurrency smoothly when frequent produce or weight changes occur. Within the kiosk, a local SQLite database is queried to retrieve the unit price of the detected produce, which is then mapped against the YOLO result and weight reading to compute the final total. The recognized produce, weight, and computed price are displayed on the Android tablet, and once confirmed by the customer, a QR code is generated for checkout.

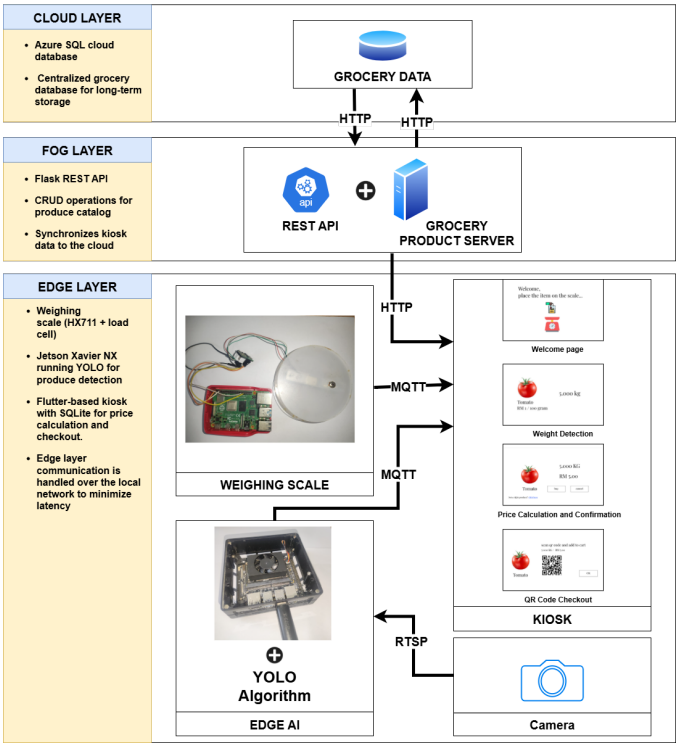

Fig. 1. Three-tier system architecture consisting of Edge, Fog, and Cloud layers.

At the Fog Layer, the system acts as the bridge between the edge devices and the cloud. A Python Flask service with REST API is used to receive both detection results and transaction data, providing a simple way to buffer and synchronize information before pushing it to the central database. To cope with the dynamic pricing of fresh produce, this layer also allows administrators to perform CRUD operations such as updating the produce catalog, adjusting unit prices, or editing nutritional details. Once the kiosk tablet has internet access, it automatically syncs its local records with the fog server, ensuring that both price changes and transaction logs remain consistent across all connected devices. Fig. 2 illustrates the overall architecture of the proposed Edge-AI retail weighing system, including image acquisition, object detection, and inference execution on the embedded device.

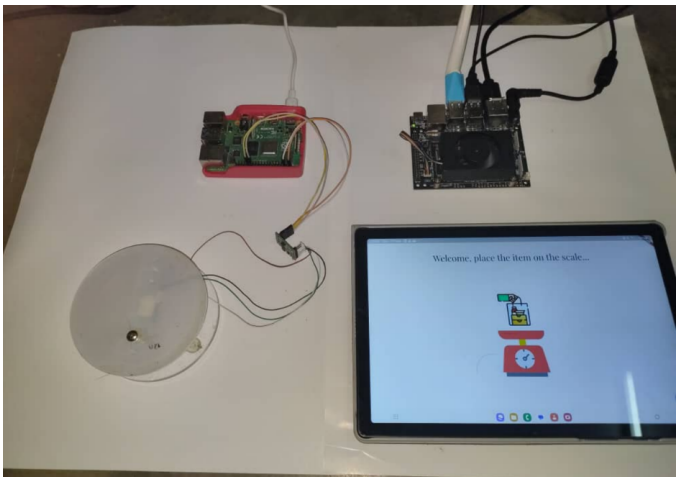

Fig. 2. Prototype setup of the smart retail weighing scale with raspberry Pi, jetson xavier NX, and flutter-based kiosk.

B. Data Acquisition

Data acquisition forms the cornerstone of this study, as it prepares the dataset for domain-specific modeling aimed at detecting commonly sold loose produce in Malaysian retail environments. This process seeks to overcome the limitations of non-contextual generic datasets by drawing and filtering relevant data from ImageNet and Roboflow. While the ImageNet dataset provides extensive image-class coverage, particularly for classification tasks, its object-detection annotations remain limited in quantity. Hence, the Roboflow dataset is utilized to enrich the overall corpus by increasing the number of annotated samples and enhancing the contextual diversity of the data. The overall data acquisition process is shown in Fig. 3.

ImageNet is organized according to the WordNet lexical hierarchy, a semantic network in which each synset (synonym set) represents a distinct concept. Within this hierarchy, this structure allows direct mapping between linguistic concepts and their corresponding visual representations. In this study, synsets relevant to the targeted 26 agricultural produce classes were retrieved from the ImageNet21K (Winter 2021 Release) repository by replacing the synset id in the URL with the pattern of https://image-net.org/data/winter21_whole/SYNSET_ID.tar. Each class identifier follows the WordNet ID (WNID) convention (e.g., n07756951 for tomato). In this study, the classname

is retrieved using Python and the Natural Language Toolkit (NLTK) interface to WordNet, because WNIDs were programmatically mapped to their lexical names and definitions as illustrated in the Listing 1.

All ImageNet annotations, originally in Pascal VOC XML format, were converted into YOLO-compatible bounding-box files (cx, cy, w, h) using a Python-based conversion pipeline. Each conversion was visually inspected through overlay validation to ensure proper localization accuracy. During dataset inspection, it was observed that not every retrieved sample was relevant to the intended classes. Therefore, a second-stage quality filtering process was introduced using a ResNet-50 image-classification model pre-trained on ImageNet. The model operated as a fixed feature extractor, computing cosine similarity between each image embedding and a curated exemplar set to assess relevance. Samples scoring below a similarity threshold of 0.8 were discarded. As illustrated in Fig. 4, non-relevant ImageNet samples were identified and removed through a classification-based quality filtering process to improve dataset relevance for produce recognition. The resulting refined subset was then saved into directories named by class to facilitate subsequent merging with the Roboflow dataset.

Algorithm 1 Conversion of WordNet ID (WNID) to Synset Information

Require: WNID string (e.g., "n07756951")
Ensure: Synset name and definition corresponding to the given WNID
Import nltk and wordnet modules
Download WordNet corpus if not already available
function WNID_TO_SYNSET(wnid)
    offset ← integer value of substring of *wnid* starting from index 2
    try: synset ← WordNet.synset_from_pos_and_offset('n', offset)
        return (synset.name(), synset.definition())
    except: return (None, "Error")
end function

To collect the relevant object-detection datasets from Roboflow, produce-specific keywords such as "apple," "banana," and "dragon fruit" were used to perform targeted searches on the Roboflow Universe platform. The search results returned a list of publicly available projects, from which suitable datasets were selected for download. By default, Roboflow datasets are distributed in pre-split form (train, validation, and test). For preprocessing, these splits were first merged into a single dataset to simplify later integration with ImageNet_good, where a new unified split would be generated after merging. All images were standardized to a resolution of 640×640. Manual inspection was then performed to ensure data quality and class consistency. Certain datasets included condition-based subclasses such as "rotten fruit" or "healthy fruit," originally intended to distinguish fruit states. In this study, such subclasses were consolidated into a single class only when favorable for the retail detection use case; otherwise, they were excluded from the final dataset. Roboflow annotations were verified for conformity to YOLO standards. It is found that some files containing segmentation polygons or multiple label regions in which decided to be removed using Python script.

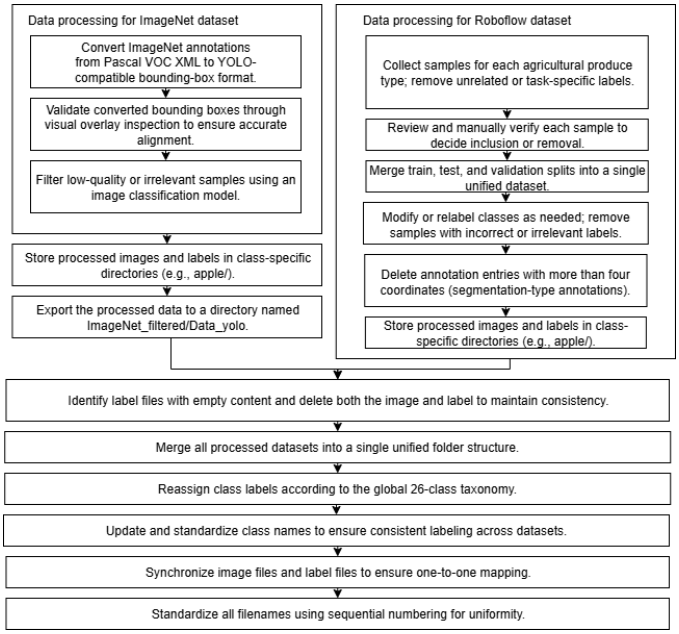

Fig. 3. Workflow of ImageNet and roboflow data preprocessing and unified post-processing to generate the final hybrid dataset for YOLO training.

After both streams were independently processed, they were merged through a unified post-processing pipeline designed to ensure dataset integrity and compatibility. Empty or mismatched label files were automatically identified and removed through filename mapping, while remaining image–label pairs were verified for one-to-one correspondence. Filenames were then standardized via sequential numbering, and directory hierarchies were normalized for uniform ingestion by the YOLO training engine. The resulting hybrid dataset comprised approximately 6 000 verified image samples, evenly distributed across 26 agricultural produce classes. Each sample adhered to a consistent annotation format and naming convention, enabling reproducible evaluation across YOLOv9, YOLOv10, and YOLOv11 variants. This corpus unifies ImageNet's lexical richness with Roboflow's contextual realism, forming a balanced, domain-specific dataset for training and subsequent performance analysis on the NVIDIA Jetson Xavier NX edge platform.

C. Model Training

The model training phase aimed to fine-tune state-of-the-art YOLO architectures for accurate and efficient agricultural produce detection under edge-deployment conditions. Training was carried out using the custom hybrid dataset (8450 images in 26 classes) described in Section VI. To ensure both reproducibility and computational efficiency, all experiments were executed on an NVIDIA RTX 3090 GPU (24 GB GDDR6X, 3840 CUDA cores) using the PyTorch-based Ultralytics YOLO framework. Each YOLO variant (YOLOv9, YOLOv10, YOLOv11) was initialized using pre-trained weights from the COCO dataset (80 classes). Transfer learning was applied by freezing early backbone layers during the initial epochs to preserve generic low-level feature

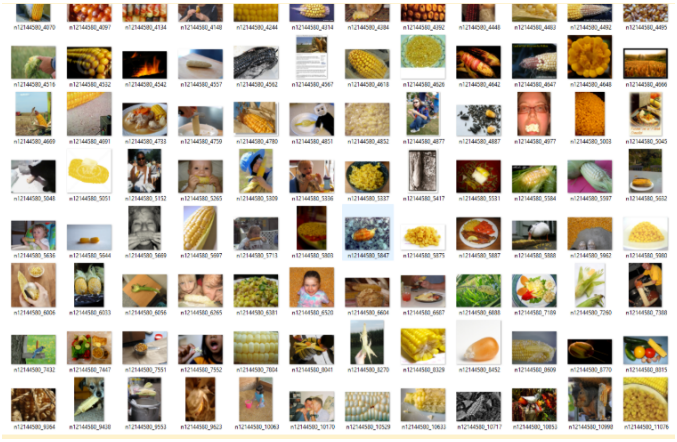

Fig. 4. Non-relevant ImageNet samples identified and removed through classification-based quality filtering using a ResNet-50 model.

representations while allowing full fine-tuning of detection heads. The classification head was modified to predict 26 target classes (nc = 26), replacing COCO's original output layer.

Optimizer selection was handled automatically by the YOLO framework, which initially evaluated both AdamW and SGD but converged on SGD with the parameters above. Internally, YOLO applied parameter grouping: 167 weights with no decay, 174 weights with 0.0005 decay, and 173 biases without decay—facilitating efficient convergence. Training logs confirmed stable loss reduction and consistent mAP gains across epochs.

D. Model Benchmark

To evaluate model performance, three YOLO variants—YOLOv9, YOLOv10, and YOLOv11—were selected for benchmarking. Each variant was tested across three model sizes (S, M, and L), resulting in a total of nine configurations. All models were exported using TensorRT to apply precision quantization and runtime optimization tailored for edge AI deployment. Although TensorRT supports execution on any NVIDIA GPU, the optimized engines it generates are device-specific, as calibration and kernel tuning depend on the underlying GPU architecture [25]. Therefore, to ensure consistent accuracy and latency measurements that accurately reflect real deployment conditions, both the creation of the TensorRT engine and the inference benchmarks were performed directly on the NVIDIA Jetson Xavier NX, which served as the target edge device in this study. Each model was evaluated using a standardized input resolution of 640×640 pixels, and accuracy was quantified through mean Average Precision (mAP) across 26 produce classes. Baseline mAP values were obtained in FP32 mode (without optimization and quantization), while the TensorRT-optimized models were re-evaluated to discover the potential variation in accuracy. Collectively, the mAP, latency, and FPS metrics were analyzed to highlight the trade-off between detection accuracy and real-time inference performance across all evaluated models.

Mean Average Precision (mAP) was computed at an Intersection-over-Union threshold of 0.5 following the PASCAL VOC standard (mAP@0.5). In addition to this widely used metric, we also report the COCO-style mAP@[0.5:0.95] and the F1 score to provide a comprehensive assessment of detection accuracy. This combination of metrics captures both localization and classification performance while balancing interpretability and computational cost. Inference speed was benchmarked by dividing the total time to process a fixed set of test images by the number of samples, yielding the average latency per image (ms/sample), and the reciprocal of this latency gave the throughput in frames per second (FPS). Reporting mAP@0.5, mAP@[0.5:0.95], F1 and FPS together enables a direct analysis of the trade-off between detection accuracy and real-time performance.

IV. Results and Discussion

A. Training Result

The hybrid dataset consisting of 8450 annotated images across 26 agricultural produce classes was divided into training (70%), validation (20%), and testing (10%) subsets, all standardized to a resolution of 640 × 640 pixels. Each YOLO model—v9, v10, and v11—was fine-tuned using transfer learning from COCO-pretrained weights, ensuring that early convolutional layers retained generic low-level representations while the detection head adapted to domain-specific features.

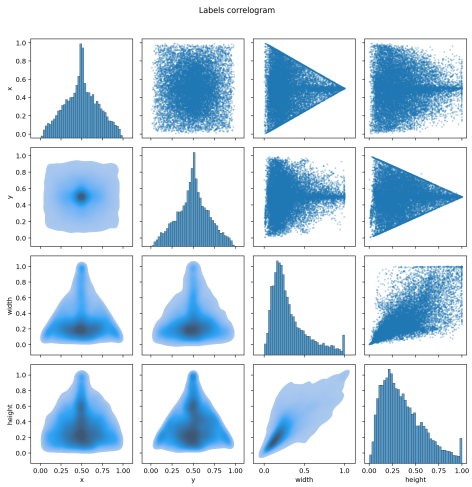

Fig. 5. Correlation matrix of normalized bounding box parameters (x, y, width, height) illustrating the distribution and relationships among annotation variables.

The label correlogram in Fig. 5 indicated that most object centers clustered around the image midpoint, corresponding to the typical placement of fruits on weighing trays. The width–height correlation revealed a narrow triangular distribution, suggesting scale uniformity across the dataset.

Training curves in Fig. 8, Fig. 7 and Fig. 6, collectively indicate that all YOLO variants achieved stable convergence with steadily decreasing box, classification, and distribution focal losses across epochs. The training performance comparison reveals a progressive improvement across YOLO generations. YOLOv9-C achieved its optimal accuracy at epoch 94 with a peak mAP@0.5:0.95 of 0.692, while YOLOv10-L required a longer convergence period, reaching a similar score at epoch 97 due to its deeper network complexity. In contrast, YOLOv11-L attained the highest mAP@0.5:0.95 of 0.700

at epoch 87, indicating faster and more stable optimization. The reduced validation losses and earlier convergence suggest that YOLOv11-L effectively balances learning stability and generalization, outperforming the preceding versions under identical training conditions.

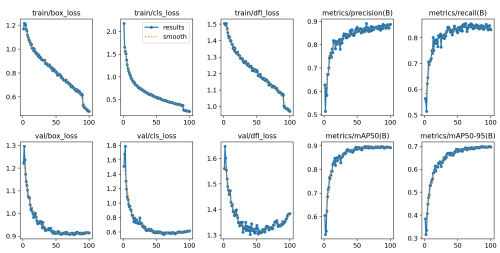

Fig. 6. YOLOv11 training result.

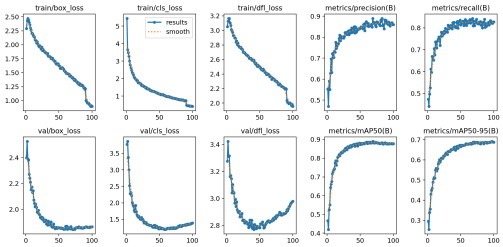

Fig. 7. YOLOv10 training result.

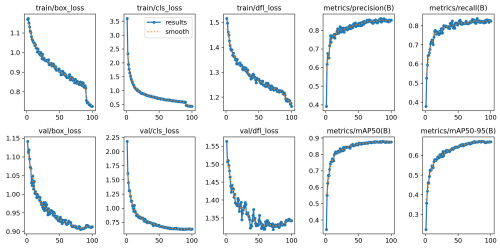

Fig. 8. YOLOv9 training result.

The confusion matrices of YOLOv9, YOLOv10, and YOLOv11 shown in Fig. 9, Fig. 10, Fig. 11, exhibit strong diagonal dominance, indicating generally high per-class classification accuracy. However, the distribution and magnitude of non-zero off-diagonal values reveal meaningful distinctions in class-specific robustness and visual separability. The confusion matrices reveal that YOLOv9-C produces the highest misclassification rate, with evident cross-class confusion among visually similar fruits such as apple–tomato and guava–rose apple, indicating weaker feature discrimination. In contrast, YOLOv10 displays the cleanest diagonal with minimal off-diagonal noise, reflecting stronger class separability and more stable optimization. YOLOv11 achieves comparable accuracy but introduces slight background leakage and minor confusion in similar-colour categories, suggesting broader generalization at a small precision cost. Overall, YOLOv10demonstrates the most balanced and precise classification performance, while Fig. 12 compares the PR characteristics of YOLOv9, YOLOv10, and YOLOv11 families across model scales. Fig. 12 compares the PR characteristics of YOLOv9, YOLOv10, and YOLOv11 families across model scales. All nine models exhibit strong detection capability, with mAP@0.5 values exceeding 0.85, reflecting robust precision–recall balance across the dataset. The smooth blue PR curves indicate stable

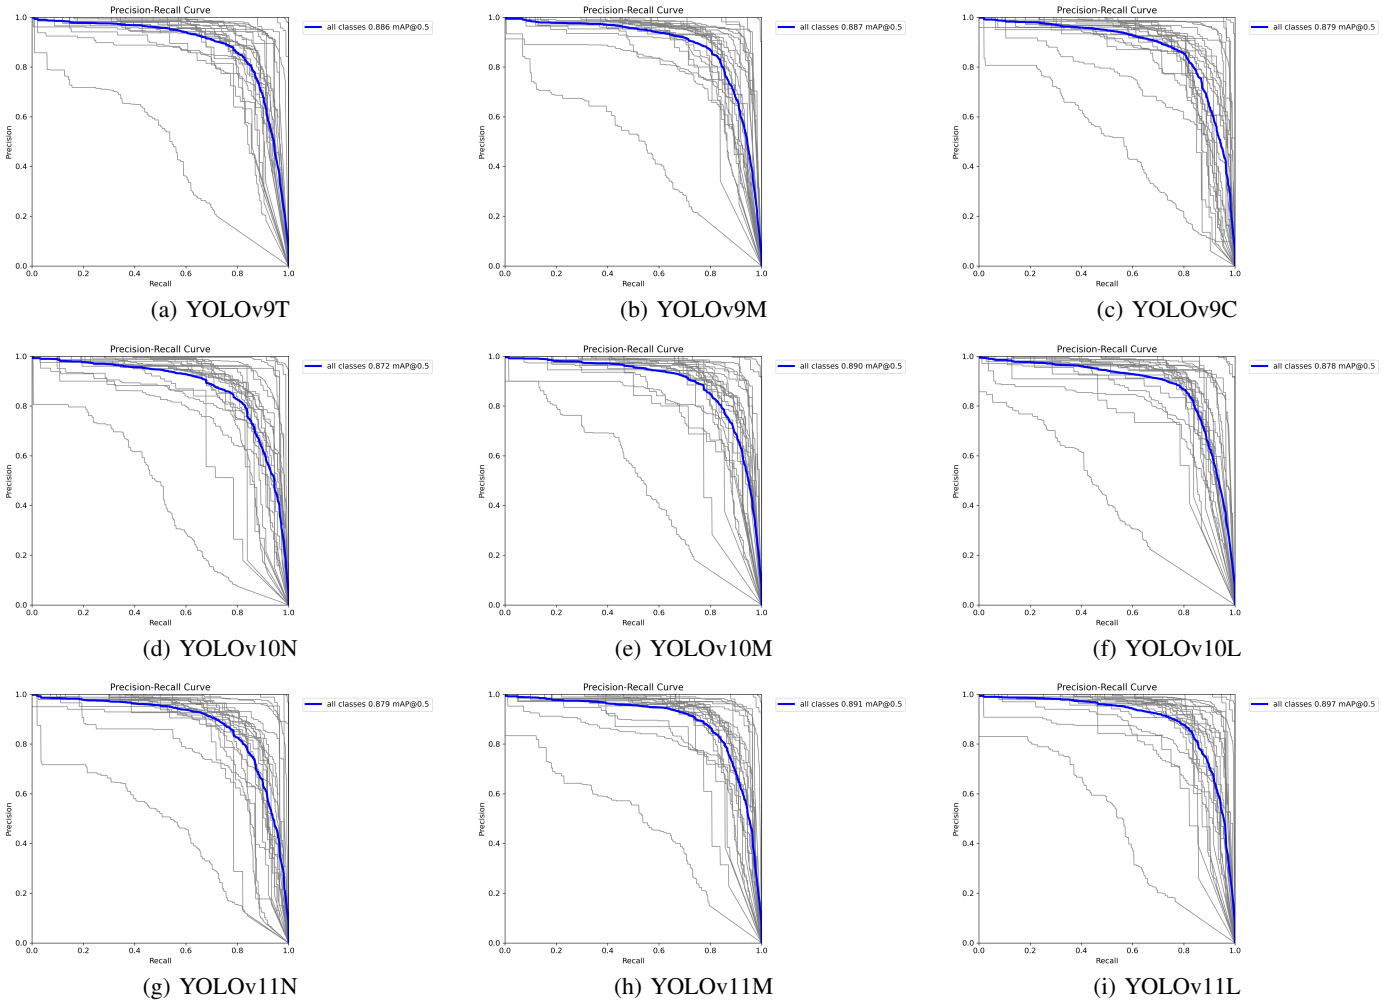

Fig. 12. Precision–Recall (PR) curves for YOLOv9/10/11 models at different scales (Tiny/Nano, Medium, and Compact/Large). Each sub-figure illustrates the trade-off between precision and recall across all classes, highlighting the relative stability and balance achieved by newer architectures.

confidence calibration, while the gray per-class traces reveal clear variation among object categories—showing that not all classes perform uniformly and at least one class remains challenging to detect. Among them, YOLOv11 variants display the most expansive PR envelopes, signifying superior precision–recall trade-offs and inter-class consistency. The YOLOv11L attains the highest mAP@0.5 of 0.897, only slightly above YOLOv11N and YOLOv11M; notably, YOLOv11 exhibits a consistent mAP increase with model size, unlike YOLOv9 and YOLOv10, implying that its additional parameters are effectively utilized for richer feature learning. Nevertheless, the smaller YOLOv11 models maintain comparable robustness to the larger variant, achieving near-identical detection quality with substantially lower computational cost. Overall, all models sustain commendable accuracy above the 0.8 mAP benchmark, with YOLOv11 offering the most balanced and scalable performance for real-time edge deployment.

B. Model Performance

The performance evaluation across 26 distinct produce classes as show in Table I demonstrated that model size is the dominant factor influencing both performance magnitude and consistency. As shown in Fig. 13, the Medium (M) and Large (L) or Complex (C) configurations consistently achieved the highest median mean Average Precision (mAP) scores across all three YOLO versions (v9, v10, v11). These models also exhibited the tightest interquartile ranges (IQR), indicating superior robustness and consistency in their detection accuracy across the diverse set of classes. Conversely, the smallest models (Tiny (T) for v9 and Nano (N) for v10/v11) demonstrated significantly lower median mAP and the widest score distributions. This suggests that while all three YOLO architectures are comparable, the minimal capacity of the smallest models leads to high performance variance and unreliable results on this dataset.

A granular analysis of the per-class mAP scores revealed a substantial degree of performance heterogeneity, ranging from near-perfect detection to critical failure points. The models achieved highly acceptable performance, exceeding $\mathbf{0.80}$ mAP, on visually distinct and easily segmentable classes. For instance, *Garlic* registered an average per-class mAP of $\mathbf{0.888}$, indicating that the model accurately localized and classified the object in $\mathbf{88.8}\%$ of the test cases when averaged across the nine evaluated configurations. *Carrot* demonstrated

similarly strong results, with a per-class mAP $\approx$ **0.882**. However, this success contrasts sharply with the challenges posed by other items. The class *Grape* was identified as a universal failure point, registering a critically low per-class mAP $\approx$ **0.318** across all model configurations. This extreme outlier—visually represented by the lowest whisker in every box plot (Fig. 13)—indicates a fundamental difficulty that is not mitigated by increasing model complexity or upgrading the YOLO version. Other low-performing classes included *Manggis* (per-class mAP $\approx$ **0.467**) and *Dragon Fruit* (per-class mAP $\approx$ **0.486**).

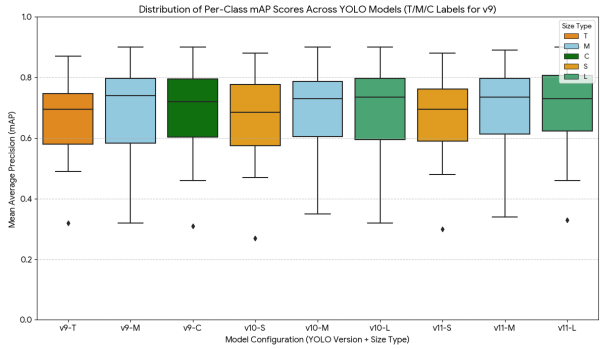

Fig. 13. Distribution of Per-Class mAP scores across YOLO models and sizes. YOLOv9 uses Tiny (T), Medium (M), and Compact (C) labels, while YOLOv10 and YOLOv11 use Nano (N), Medium (M), and Large (L).

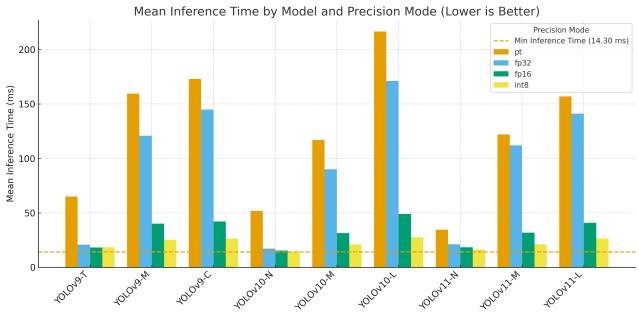

Fig. 14. Total inference time across YOLOv9, YOLOv10, and YOLOv11 models under different precision modes (`pt`, `fp32`, `fp16`, and `int8`). The dashed red line indicates the global minimum total inference time. Image resolution is fixed at 640×640.

C. Inference Speed Analysis

The inference–speed analysis based on the collected data as shown in Table II reveals that pre–processing and post–processing contribute little to overall latency: mean pre-processing times stay between 4.13 and 4.89 ms, while post-processing ranges from about 2.73 to 11.93ms . Mean inference times, however, vary by more than an order of magnitude. On NVIDIA Jetson, the YOLOv10–nano (N) model converted to TensorRT and quantized to FP16 or INT8 delivers the fastest throughput, completing detection in roughly 14–15ms per image and achieving 18.0–18.9 frames per second. By contrast, the unoptimized PyTorch large (L) models require about 216 ms for inference and thus cannot meet real-time requirements. TensorRT optimization reduces latency dramatically; for example, converting the YOLOv10-L model from PyTorch to TensorRT with FP16 shrinks inference time from $\approx$ 216ms to about 49ms, and further to $\approx$ 28 ms with INT8 quantization . These results show that model size and numerical precision are the primary determinants of inference speed, while the pipeline's fixed overhead remains minor. As illustrated in Fig. 14, precision reduction consistently lowers total inference time across all YOLO generations evaluated, with INT8 quantization yielding the global minimum latency.

A closer examination of post-processing reveals that YOLOv11 exhibits consistently higher latency than YOLOv10, especially in its Nano variants. This behaviour stems from architectural differences: YOLOv11 employs a traditional *Detect head* that performs Non-Maximum Suppression (NMS) to filter redundant bounding boxes, whereas YOLOv10 is *NMS-free* due to its dual-assignment training strategy that inherently mitigates duplicate detections. The additional NMS step in YOLOv11 adds computational overhead during output decoding, explaining why models like YOLOv11-N INT8 spend nearly three times longer in post-processing compared with the NMS-free YOLOv10 equivalents. Consequently, YOLOv10 maintains smoother end-to-end latency for real-time agricultural produce detection.

D. Accuracy Analysis

Table III provides a comprehensive comparison of YOLOv9–YOLOv11 models across Nano, Medium and Large scales and four precision modes (native, FP32, FP16 and INT8), summarising precision, recall, F1-score and mAP. The

accuracy evaluation across the YOLOv9–YOLOv11 families reveals several notable trends. Among all tested configurations, the YOLOv11-L model in PyTorch baseline achieves the highest performance with mAP@0.5 $= 0.896$ and an F1 $= 0.86$, surpassing YOLOv10 and YOLOv9 counterparts and confirming YOLOv11's architectural advantage. Within the YOLOv10 family, the medium (M) variant yields slightly better accuracy (F1 ≈ 0.848) than both the large (0.845) and nano (0.837) models, suggesting that accuracy saturates beyond a certain parameter count and that mid-sized models strike the best balance between complexity and learning stability. Precision-mode comparison further indicates that half-precision (FP16) inference is effectively lossless relative to FP32, with identical F1 values around 0.842 across all variants. These results affirm that FP16 maintains numerical fidelity while reducing memory usage—a desirable property for embedded deployment. Conversely, INT8 quantisation introduces a moderate but consistent performance degradation of about 3–4 percentage points in F1. For example, YOLOv10-L drops from 0.845 (PyTorch) to 0.811 (INT8), and YOLOv10-M declines from 0.848 to 0.806, primarily due to reduced numerical precision during activation and weight representation.

A deeper inspection of model sensitivity highlights that smaller models exhibit superior robustness to INT8 quantisation. The YOLOv10-N variant shows only a 1.8 percentage-point F1 loss ($0.832 \rightarrow 0.814$), whereas the large variant loses more than 3 points. This observation aligns with quantisation theory: lightweight architectures possess fewer convolutional layers and a narrower dynamic range of activations, resulting in lower quantisation error propagation. Larger networks, with deeper hierarchies and wider feature channels, amplify rounding and clipping effects across multiple layers—explaining their steeper accuracy decline when compressed to 8-bit precision. Empirically, INT8 impacts recall more strongly than precision (e.g., YOLOv10-L recall $0.825 \rightarrow 0.771$, precision $0.865 \rightarrow 0.856$), indicating that quantised models tend to miss small or ambiguous detections rather than misclassify them.

Nonetheless, the overall degradation remains modest, and FP16 retains nearly identical accuracy to FP32 while achieving

significantly faster inference. Therefore, for real-time agricultural produce detection on resource-limited hardware, FP16-based TensorRT models or Nano-INT8 variants offer the best trade-off, balancing accuracy, efficiency, and deployment feasibility.

E. Inference Speed and Accuracy Tradeoff

The mAP–latency plot zs shown in Fig. 15 clearly reveals a Pareto frontier where only a handful of model–precision combinations achieve both high accuracy and real-time inference speeds. At one end of the spectrum, the smallest Nano configurations (e.g., YOLOv10-N FP16/FP32 and YOLOv11-N FP16) produce mAP@0.5 values around 0.865 while completing the full pre-processing, inference, and post-processing pipeline in approximately 53–58 ms. Their INT8 counterparts reduce the mean inference time by a few milliseconds but at the cost of a small drop in recall and overall mAP, typically slipping to ≈ 0.84. These Nano models form the left-most portion of the Pareto curve and thus represent the optimal choice when deploying to constrained edge devices that demand sub-60 ms response times.

Moving up the frontier, the Medium FP16 configuration of YOLOv11 stands out as a compelling compromise. It boosts accuracy to ≈ 0.88 mAP@0.5 yet keeps total latency below about 70 ms, only 15–20 ms slower than the Nano models but delivering a notable increase in detection fidelity. By contrast, the Large FP16/FP32 variants of YOLOv10 and YOLOv11 push accuracy marginally higher (to ≈ 0.896 mAP@0.5) but at the cost of doubling the response time to 90–120 ms, pushing them off the Pareto frontier and making them impractical for real-time field use. In summary, the trade-off analysis underscores that half-precision and medium-sized YOLOv11

offer the best balance when accuracy is paramount, while Nano FP16/INT8 models remain the top recommendation for latency-critical deployments.

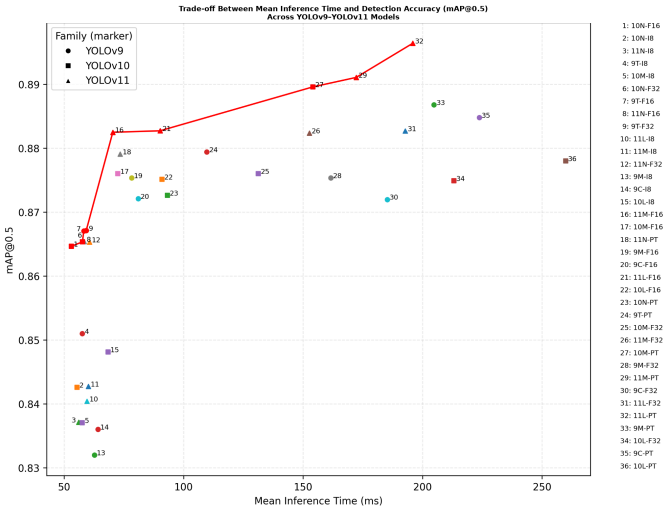

Fig. 15. Trade-off between mean inference time and detection accuracy (mAP@0.5) across YOLOv9–YOLOv11 models. The plot shows each model's mean inference time (ms) on the x-axis and its detection accuracy (mAP@0.5) on the y-axis, with distinct markers for the YOLOv9 (circle), YOLOv10 (square), and YOLOv11 (triangle) families. The red line traces the Pareto front of the speed–accuracy trade-off.

F. Qualitative Analysis

To test real-world robustness, the INT8-quantized YOLOv11-Nano model was deployed on unseen footage and custom images as shown in Fig. 16 and Fig. 17. We downloaded market scenes from YouTube and also purchased several types of produce and recorded them under natural indoor light. The model ran at real-time speed on the Jetson Xavier NX and able to detect the item with accurate bounding boxes and labels. These qualitative observations confirm that the model generalises well beyond the training dataset and complements the quantitative results, demonstrating readiness for deployment in practical retail environments.

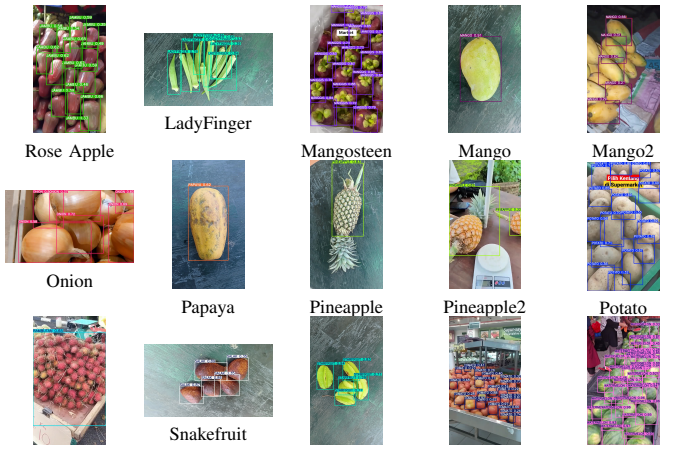

Fig. 17. YOLOv11n INT8 qualitative results — Panel (B), samples 16–30.

V. Conclusion

This study demonstrates that real-time visual recognition of loose fresh produce can be effectively integrated into intelligent retail weighing systems to reduce reliance on manual PLU-based item selection. By enabling accurate produce identification within a single weighing operation, the proposed Edge-AI approach directly addresses a key bottleneck in retail checkout workflows, namely slow and error-prone manual product lookup. To this end, an Edge-AI–based fresh-produce weighing system was developed and evaluated by integrating YOLOv9, YOLOv10, and YOLOv11 detectors with transfer learning on a 26-class Malaysian produce dataset comprising 8,450 annotated images.All models converged smoothly under identical training regimes; YOLOv11-Large achieved the highest mAP@0.5:0.95 of 0.699, YOLOv10 exhibited the strongest per-class discrimination, and YOLOv9 showed more misclassifications among visually similar produce. Across the dataset, each model maintained a mean Average Precision above 0.8, with medium or large configurations providing the most consistent accuracy. Pre- and post-processing overheads remain small relative to inference for large models (4–12 ms), but become proportionally significant as models shrink; moreover, YOLOv11's reliance on a Non-Maximum Suppression (NMS) head results in noticeably longer post-processing than YOLOv10's NMS-free design. TensorRT optimization with FP16/INT8 quantization reduced YOLOv10-Large inference latency from approximately 216 ms to 49 ms (FP16) and 28 ms (INT8). Among the tested configurations, YOLOv10-Medium and YOLOv10-Nano offer the best balance between accuracy and real-time performance, achieving roughly 14–15 ms per image (≈ 18–19 FPS) while maintaining high precision.

Inference-speed analysis demonstrated that pre- and post-processing overheads are negligible relative to the actual network inference time. With TensorRT optimization and FP16/INT8 quantization, the YOLOv10-Nano configuration achieved real-time performance at roughly 14–15 ms per image (≈ 18–19 FPS). The YOLOv10-Large model, once converted from unoptimized PyTorch to TensorRT, saw its inference latency shrink from ≈ 216ms to ≈ 49ms with FP16 and ≈ 28ms with INT8. Although YOLOv11 models offered

slightly higher precision, their reliance on a Non-Maximum Suppression head introduced additional post-processing delay compared with the NMS-free dual-assignment strategy of YOLOv10. These results show that YOLOv10-Medium and YOLOv10-Nano strike the best balance between detection accuracy and real-time inference, making them suitable for deployment on resource-constrained retail scales.

Although this system demonstrates that high-accuracy object detection is feasible on embedded GPUs, several challenges remain.

- Intraclass and interclass similarity: Some classes (e.g., grapes, mangosteen, dragon fruit) exhibit low per-class mAP due to high intra-class variation and inter-class similarity. Future work should augment the dataset and explore model-level innovations to improve discrimination among similar-looking items.
- Species and cultivar detection: The current dataset treats each fruit or vegetable as a single class and does not include species- or cultivar-level distinctions (e.g., different varieties of oranges). Even if such data were added, it remains uncertain whether the current YOLO architectures could fully capture the subtle visual variations between closely related cultivars. Future work should therefore combine dataset expansion with model adaptations or fine-grained classification strategies to assess whether detection at this granularity is feasible.
- NMS-free architectures: YOLOv11's NMS-based post-processing introduces significant latency; integrating next-generation NMS-free models such as the forthcoming YOLO26—designed as an end-to-end detector without a non-maximum suppression step [26]—could further reduce inference time and simplify deployment.
- Data and modality expansion: Additional future work includes expanding the dataset to cover occlusions, mixed produce and seasonal variations, incorporating multi-modal sensors (weight, depth, spectral) to distinguish visually similar items, applying model pruning and dynamic quantization, developing incremental learning for new classes, and evaluating deployment on alternative edge devices.

Overall, the findings confirm that high-accuracy object detection on embedded GPUs is not only technically feasible but also practically deployable in real retail environments. By combining NMS-free architectures with TensorRT optimization, the proposed system supports low-latency inference suitable for unattended or semi-automated checkout scenarios, reducing operator workload and minimizing customer waiting time. These results provide a concrete pathway toward scalable, PLU-independent intelligent weighing systems in modern retail settings.

***Abstract*—Brain stroke occurs when the brain's blood supply is disrupted, leading to oxygen deprivation and rapid neuronal death. Ischemic stroke, the focus of this study, accounts for most cases and is strongly influenced by collateral circulation, a network of alternative vessels that stabilize perfusion when a primary artery is obstructed. Collateral status determines the extent of salvageable tissue and is typically graded manually using modalities such as magnetic resonance angiography (MRA), computed tomography (CT), and cone-beam computed tomography (CBCT), a process prone to subjectivity and inter-observer variability. This study proposes a ResNet-18–based deep learning framework for automated three-class classification of collateral circulation (Good, Moderate, Poor) from intra-procedural CBCT scans. A curated dataset of 45 patient cases (22,861 DICOM slices), annotated by an expert neuroradiologist, was preprocessed with patient-wise partitioning, normalization, and augmentation. The model achieved a validation accuracy of 88.8%, a micro-averaged precision–recall score of 0.947, and a macro-averaged ROC AUC of 0.958. Calibration analysis confirmed well-aligned probability estimates, while most misclassifications occurred in the Moderate class, reflecting inherent clinical ambiguity. Compared with prior CBCT studies using shallower architectures, the proposed framework demonstrates substantially higher accuracy, improved calibration, and enhanced robustness. These findings highlight the feasibility of ResNet-18 applied to CBCT imaging as a reliable and efficient tool to support neuroradiologists in collateral grading during hyperacute stroke management**

***Keywords*—Collateral circulation; brain stroke; ischemic stroke; deep learning; ResNet-18**

I. Introduction

Ischemic stroke occurs when a cerebral blood vessel becomes obstructed, typically by a thrombus, thereby interrupting the supply of oxygen and nutrients. Without prompt intervention, this blockage can cause irreversible neuronal damage within minutes, leading to severe neurological deficits [1], [2]. Globally, Ischemic stroke is a major public health challenge, accounting for over 80% of stroke cases worldwide and affecting more than 12 million people annually [3][4][5]. It remains a leading cause of death, long-term disability, and healthcare burden. These realities underscore the urgent need for improved methods of early diagnosis, prognosis, and treatment to mitigate long-term disability and improve patient outcomes.

*Corresponding author.

Collateral circulation serves as the brain's primary compensatory mechanism during arterial occlusion. Networks such as the Circle of Willis and leptomeningeal anastomoses sustain perfusion and preserve the penumbra during arterial occlusion [6], [7], [8]. In addition to arterial routes, venous and lymphatic systems are increasingly recognized as contributors to intracranial homeostasis under ischemic stress [9]. Patients with robust collaterals typically demonstrate slower infarct progression and extended therapeutic windows for both intravenous thrombolysis and mechanical thrombectomy [10], [11], [12]. Consequently, collateral status has emerged as a critical prognostic marker and a key determinant in acute stroke treatment decisions.

Neuroimaging plays a central role in collateral evaluation. Conventional methods rely on computed tomography angiography (CTA) and magnetic resonance angiography (MRA), with cone-beam computed tomography (CBCT) emerging as a promising intra-procedural alternative. However, manual collateral grading is time-consuming, subjective, and limited by inter-observer variability. To overcome these challenges, deep learning offers the potential for automated, consistent, and scalable assessment. Convolutional neural networks (CNNs), including architectures such as ResNet-18, have demonstrated strong performance in diverse medical imaging tasks ranging from pneumonia detection [13] to retinal-based kidney disease screening [14]. More recently, CNN-based approaches have been applied to collateral circulation grading in CTA, MRA, and CBCT, laying the groundwork for robust, clinically integrated decision-support systems. Building on this foundation, this study investigates ResNet-18 for automated tri-class classification of collateral circulation (Good, Moderate, Poor) in ischemic stroke patients using intra-procedural CBCT. The following sections provide the clinical background, describe the methodological design, and evaluate the performance of the proposed framework in comparison with existing approaches. This study addresses the challenge of subjective and time-consuming collateral grading by proposing an automated CBCT-based deep learning approach for three-class collateral classification. The main difficulty lies in CBCT intensity variations and the visual overlap between Moderate and adjacent grades, which can reduce precision.

The remainder of this study is organized as follows: Section II reviews stroke and collateral background and imaging modalities; Section III summarizes related work; Section IV nd

Section V describes the methodology and dataset; Section VI presents experimental results; Section VII discusses findings and limitations; and Section VIII concludes the study.

II. Brain Stroke

Stroke occurs when the blood supply to a part of the brain is disrupted, leading to oxygen deprivation and rapid death of brain cells [15]. The brain is essential for coordinating movements, preserving memories, generating thoughts and emotions, and enabling speech and language functions [16]. It also regulates critical bodily processes such as breathing and digestion. To perform these functions effectively, the brain depends on a continuous flow of oxygen-rich blood delivered through its intricate arterial system. When this flow is blocked or reduced, brain tissue rapidly sustains damage [17]. Without timely restoration of blood supply, affected regions may suffer permanent injury or death, resulting in lasting disability or fatality. Strokes are broadly classified into two major types based on their underlying mechanisms: hemorrhagic stroke and ischemic stroke. Fig. 1 illustrates the fundamental differences between these two types.

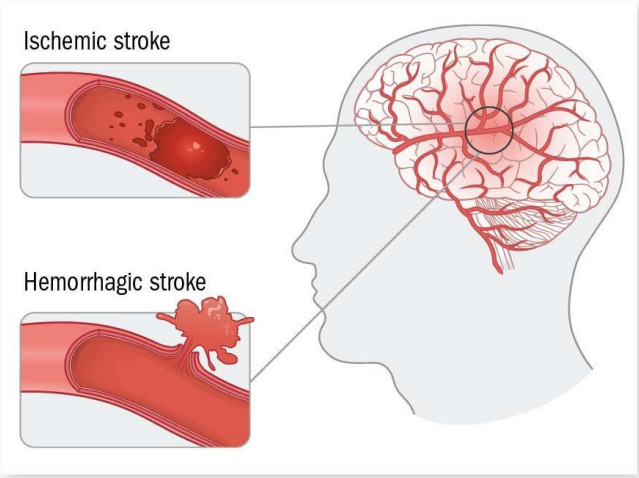

Fig. 1. Comparison between ischemic stroke (arterial blockage) and hemorrhagic stroke (vessel rupture) [18].

A. Hemorrhagic Stroke

Hemorrhagic stroke occurs when a weakened blood vessel ruptures, causing bleeding into the brain tissue [19]. The accumulation of blood elevates intracranial pressure, compresses brain structures, and diminishes downstream blood flow. Although hemorrhagic strokes are less common than ischemic strokes, they are associated with higher early mortality rates. Management of hemorrhagic stroke focuses on controlling bleeding, alleviating intracranial pressure, and preventing complications such as rebleeding and hydrocephalus. Since hemorrhagic stroke arises from vessel rupture rather than occlusion, collateral circulation does not play a central role in its clinical management [20]. Accordingly, research into collateral blood flow restoration is less applicable to hemorrhagic stroke. For this reason, the present work primarily emphasizes ischemic stroke, where collateral circulation is critically important for sustaining tissue survival and improving recovery outcomes.

B. Ischemic Stroke

Ischemic stroke, accounting for approximately 85% of all stroke cases, results from obstruction of a cerebral artery, most commonly due to thrombosis or embolism [21]. The sudden interruption of blood flow initiates a cascade of cellular injury and metabolic dysfunction, ultimately leading to infarction if untreated. Collateral circulation, the network of auxiliary vessels capable of supplying blood to ischemic brain regions, emerges as a crucial determinant of stroke severity and recovery potential [22]. Well-developed collateral networks can sustain perfusion to the ischemic penumbra, delay infarct progression, and extend the therapeutic window for interventions. Consequently, evaluation and optimization of collateral pathways have become central themes in ischemic stroke research. In this context, the present study focuses on ischemic stroke, aiming to advance automated methods for collateral circulation assessment and improve decision-making in hyperacute stroke management.

C. Collateral Circulation in Ischemic Stroke

Collateral circulation refers to a network of alternative blood vessels that can provide compensatory blood flow when a primary cerebral artery is obstructed. This auxiliary pathway helps stabilize cerebral perfusion and can determine the extent of salvageable tissue, or the ischemic penumbra, during a stroke [6], [23]. Fig. 2 illustrates how collateral vessels bypass a thrombus obstructing a major artery, thereby sustaining blood supply to downstream regions.

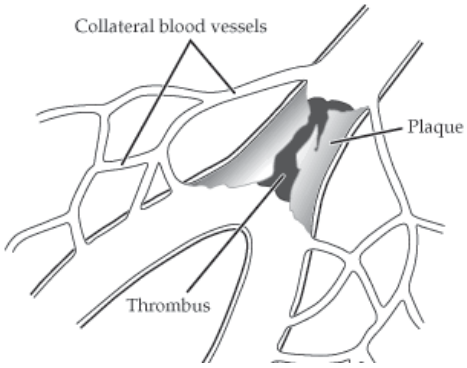

Fig. 2. Schematic showing collateral blood vessels bypassing a thrombus obstructing a primary cerebral artery [24].

The adequacy of collateral circulation varies considerably between individuals and is influenced by vascular anatomy, age, and comorbidities. Patients with good collateral status often demonstrate smaller infarct cores and better clinical outcomes, while poor collaterals are linked to rapid infarct progression and worse prognosis [8], [25]. Fig. 4 and Fig. 3 shows that Good collaterals allow sufficient blood rerouting to preserve tissue, whereas poor collaterals fail to maintain adequate perfusion, leading to irreversible injury.

Currently, collateral grading is performed manually by radiologists who visually interpret magnetic resonance angiography (MRA), computed tomography (CT), cone-beam computed tomography (CBCT), or digital subtraction angiography (DSA) scans. However, this process is inherently subjective, time-consuming, and prone to inter-observer variability. Given

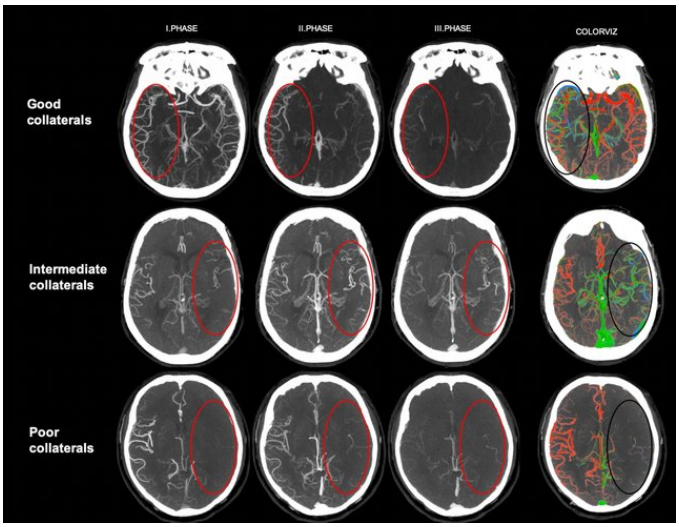

Fig. 3. Multiphase assessment of collateral circulation: Good (top), intermediate (middle), and poor (bottom), with corresponding color-coded visualization [26].

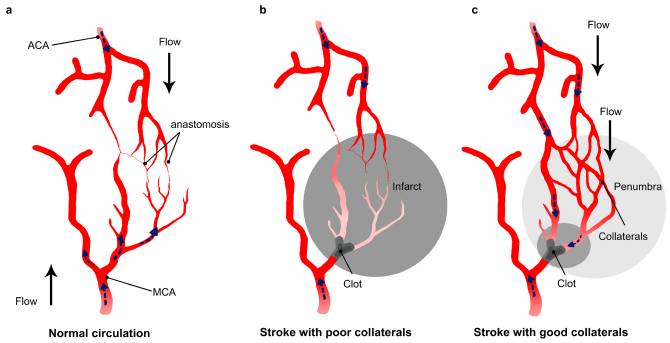

Fig. 4. Classification of collateral circulation: a) Normal circulation, b) Stroke with poor collaterals, c) Stroke with good collaterals [27]. (Image adapted under a CC BY 4.0 license).

the prognostic importance of collateral status, there is a clear need for automated and reliable classification methods. To address this gap, the present study introduces a ResNet-18 deep learning framework designed to classify collateral circulation into Good, Moderate, or Poor, thereby reducing variability and supporting clinicians in urgent decision-making.

D. Imaging Modalities for Collateral Assessment

Several imaging modalities are currently used to evaluate collateral circulation, including computed tomography angiography (CTA), magnetic resonance angiography (MRA), cone-beam computed tomography (CBCT), and digital subtraction angiography (DSA). CTA is fast and widely available, with multiphase protocols capable of capturing delayed collateral filling [28]. MRA provides radiation-free vascular imaging but is slower and less practical in acute settings [29]. DSA remains the invasive reference standard for visualizing cerebral vasculature. CBCT has recently emerged as a promising intra-procedural tool, offering high-resolution three-dimensional visualization directly in the angiography suite and the potential to complement standard CT and MRI during endovascular workflows [30], [31].This comparison highlights CBCT's suitability for intra-procedural stroke workflows, where rapid acquisition and integration with endovascular treatment are critical, unlike CT and MRI which are typically pre-procedural.

Table I provides a general comparison of CBCT, CT, and MRI. Although most reported advantages of CBCT, such as lower radiation exposure, shorter scan time, and reduced cost, have been derived from dental and general radiology literature, these features suggest potential benefits for neurointerventional use as well. However, stroke- and neurointervention-specific head-to-head studies remain limited, and thus these characteristics should be interpreted cautiously when extrapolated to acute cerebrovascular workflows.

Recent CBCT-based studies have applied deep learning models for collateral classification. For example, Ali et al. [38] employed a ResNet-18 architecture and reported moderate performance, while a subsequent study using VGG11 [39] also achieved only modest accuracy. These results highlight both the feasibility of CBCT for automated collateral grading and the clear need for methodological improvements. In this study, we aim to enhance classification performance by leveraging a deeper residual network (ResNet-18), incorporating a larger dataset, and applying advanced augmentation techniques to improve generalization.

The next section reviews prior research on collateral circulation classification across different modalities to contextualize the present work.

III. Related Work

Most existing studies on collateral circulation assessment in ischemic stroke have focused on deep learning applied to computed tomography (CT) and magnetic resonance imaging (MRI). These modalities are widely used due to their high-quality depiction of brain structures and vascular networks [34], [37]. More recently, cone-beam computed tomography (CBCT) has been explored, but the reported results remain modest compared to CTA and MRI.

For example, Ali et al. [39] applied VGG11 to CBCT images of ischemic stroke patients, using a dataset of 4,368 slices (80% training, 20% testing) for binary classification of good versus poor collaterals. The model achieved only 58.3% accuracy, with sensitivity of 75.5%, specificity of 44.1%, and F1-score of 62.1%. Similarly, Ali et al. [38] employed a pre-trained ResNet-18 on 30 patients (4,368 CBCT slices), reporting 65.9% accuracy, with sensitivity of 0.776, specificity of 0.526, and F1-score of 0.698. Both studies demonstrated feasibility, but were hindered by small datasets, minimal augmentation, and overfitting, which limited generalizability.

Other researchers have explored multimodal and advanced architectures. Tetteh et al. [43] used MR perfusion images from 183 patients, applying reinforcement learning for ROI detection and CNN/ML classifiers, achieving 72% accuracy, but facing challenges of class imbalance and ROI precision. Raj et al. [41] proposed a multimodal CTA-based framework combining ResNet-50 with AutoML, reaching 94.12% accuracy but relying on single-center data. Tan et al. [42] developed a feature-fusion attention network for multiphase CTA, achieving 90.43% accuracy. While these approaches

TABLE I. COMPARISON OF CBCT, CT, AND MRI CHARACTERISTICS IS MAINLY BASED ON DENTAL AND GENERAL RADIOLOGY REPORTS. SINCE STROKE-SPECIFIC EVIDENCE IS LIMITED, THESE VALUES SHOULD BE INTERPRETED CAUTIOUSLY FOR ACUTE CEREBROVASCULAR WORKFLOWS.

demonstrate the potential of advanced architectures, they are primarily based on CTA/MRA datasets rather than CBCT.

Table II summarizes representative approaches, imaging modalities, and reported outcomes. Collectively, these studies show that while CTA and MRI dominate current research, CBCT is emerging as a clinically advantageous modality due to its real-time intra-procedural capability, reduced radiation, lower cost, and availability in the angiography suite. However, CBCT-based deep learning models remain underexplored and have so far achieved only moderate accuracy.

To address this gap, the present study leverages CBCT imaging combined with a residual architecture, ResNet-18. By using a larger dataset, applying systematic data augmentation, and moving beyond binary classification to a clinically relevant three-class grading (*Good*, *Moderate*, *Poor*), this work aims to significantly improve accuracy, calibration, and generalizability. The following section details the methodology of the proposed framework.

IV. METHODS

The overall methodology of the proposed study is summarized in Fig. 5. The pipeline begins with dataset collection from Hospital Sultan Abdul Aziz Shah, Universiti Putra Malaysia (UPM), followed by preprocessing steps such as bone removal, normalization, and noise reduction. Data augmentation was then applied to increase variability, and the dataset was partitioned into training and validation subsets. The ResNet-18 model, initialized with ImageNet weights, was trained and fine-tuned for three-class collateral classification. A patient-wise split ensured that slices from the same patient did not appear in both training and validation sets, preventing data leakage. The implementation was carried out in Python with TensorFlow/Keras on an RTX 3090 GPU. The study followed a supervised learning design with neuroradiologist-annotated labels, patient-wise partitioning to prevent leakage, and a two-phase fine-tuning strategy to balance generalization and class separability.

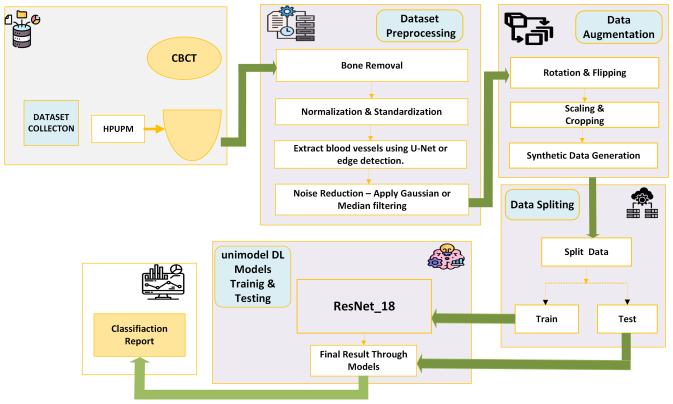

Fig. 5. Overall methodology for CBCT-based collateral circulation classification using ResNet-18.

Experiments were conducted using Python 3.10 with TensorFlow 2.12/Keras, NumPy 1.26, and scikit-learn 1.4 on an RTX 3090 (24 GB) with CUDA 11.8/cuDNN 8.9. Model performance was assessed using accuracy, precision, recall (sensitivity), specificity, F1-score, PR-AUC, ROC-AUC, and calibration analysis.

V. DATASET

For this study, the dataset was obtained from Hospital Sultan Abdul Aziz Shah, Universiti Putra Malaysia (UPM).

It consists of cone-beam computed tomography (CBCT) scans acquired from patients diagnosed with ischemic stroke. A total of 45 cases were included, each containing a full volumetric series of axial slices. Each patient was assigned a unique identifier and accession number, and all metadata were securely documented to maintain proper traceability. Annotation of the dataset was carried out by an experienced neuroradiologist (Dr. Ahmad Sobri Muda), who categorized each patient into one of three clinically meaningful grades of collateral circulation: Good, Moderate, and Poor. The final distribution comprised 13 patients in the Good category, 13 in the Moderate category, and 19 in the Poor category.

The demographic composition of the cohort is summarized in Table III. Overall, the dataset included 18 females and 27 males, with gender distribution remaining relatively balanced across the three collateral circulation groups. In total, the dataset comprised 22,861 DICOM slices, with each patient contributing approximately 350–400 slices. This volume is consistent with the coverage typically required in neurovascular CBCT examinations. For model development, the dataset was partitioned on a patient-wise basis into 70% for training and 30% for testing, ensuring that slices from the same subject did not appear in both sets. The dataset used in this study is available from the corresponding author upon reasonable request.

TABLE III. PATIENT DISTRIBUTION BY COLLATERAL CLASS AND GENDER

Class	Female	Male	Total
Good	5	8	13
Moderate	6	7	13
Poor	7	12	19
Total	**18**	**27**	**45**

Although the macro-averaged precision was 0.8634, this value should be interpreted in the context of clinical ambiguity, particularly within the Moderate collateral class. Precision was reduced primarily due to overlap between Moderate and adjacent classes, a challenge also reported in neuroradiologist-based grading. Several design choices were introduced to improve precision: patient-wise data partitioning eliminated slice-level leakage, class weighting mitigated imbalance, label smoothing reduced over-confident predictions, and realistic data augmentation improved generalization. These strategies enhanced precision while maintaining balanced recall and well-calibrated probabilities.

A. Preprocessing

The preprocessing stage aimed to prepare raw cone-beam computed tomography (CBCT) data for deep learning analysis. First, all volumes in DICOM format were checked to remove incomplete or corrupted slices [45]. The remaining valid scans were annotated by a neuroradiologist into three categories: *Good*, *Moderate*, and *Poor* collateral status.

To enable compatibility with deep learning frameworks, DICOM files were converted into lossless `.png` format using a custom Python script. This conversion preserved grayscale vascular details and allowed faster I/O operations. The converted images were stored in class-specific directories for traceability during training and evaluation.

Each slice was resized to 224×224 pixels and normalized to the $[0, 1]$ range using min–max scaling:

$$I_{\text{norm}}(x, y) = \frac{I(x, y) - I_{\text{min}}}{I_{\text{max}} - I_{\text{min}}},$$

where, $I(x, y)$ denotes the pixel intensity and I_{min}, I_{max} are dataset-level minimum and maximum values.

A patient-wise split strategy was applied so that slices from the same subject appeared in only one subset (training, validation, or testing), preventing data leakage and ensuring reliable model evaluation. Additional transformations for data augmentation were later applied to increase dataset variability and improve model generalization, as described in the next subsection.

B. Data Augmentation

To increase dataset diversity and mitigate overfitting, stochastic augmentation functions were applied to the CBCT slices during training. These transformations were formulated to introduce controlled variability in spatial and photometric domains while preserving the vascular structures essential for clinical interpretation.

Let $I(x, y)$ denote the original image intensity at spatial coordinates (x, y). A horizontal reflection was applied with probability $p = 0.5$, expressed as:

$$I'(x, y) = I(W - x, y), \quad x \in [0, W],\ y \in [0, H],$$

where, W and H represent the image width and height, respectively. This transformation enforces invariance to left–right orientation without altering anatomical fidelity.

Photometric perturbations were introduced through random brightness and contrast adjustments. Brightness variation was modeled as an additive shift:

$$I'(x, y) = I(x, y) + \Delta_b,$$

with $\Delta_b \sim \mathcal{U}(-\beta, \beta)$, $\beta = 0.10$ representing a 10% dynamic range adjustment. Contrast scaling was applied multiplicatively:

$$I'(x, y) = \alpha \cdot I(x, y),$$

where, $\alpha \sim \mathcal{U}(0.9, 1.1)$ governs the rescaling of intensity distributions. Combined, these yield the affine photometric transformation:

$$I'(x, y) = \alpha \cdot I(x, y) + \Delta_b,$$

which models scanner-dependent variations in illumination and detector sensitivity.

A geometric zoom operation was further incorporated by random cropping followed by resizing to the original resolution. For a scaling factor $z \sim \mathcal{U}(0.9, 1.0)$, the effective mapping can be written as:

$$I'(x, y) = I\left(\left\lfloor \frac{x}{z} \right\rfloor, \left\lfloor \frac{y}{z} \right\rfloor\right),$$

where, coordinates outside the valid domain are handled through zero-padding. This introduces local spatial distortions equivalent to minor variations in field of view or patient positioning during acquisition.

Collectively, these augmentations form a nonlinear transformation set $\mathcal{T} = \{T_{\text{flip}}, T_{\text{bright}}, T_{\text{contrast}}, T_{\text{zoom}}\}$, where each image I is stochastically mapped to an augmented sample $I' = T(I)$ with $T \sim \mathcal{U}(\mathcal{T})$. By enforcing the model to learn under this expanded input distribution, the convolutional network is guided to extract invariant vascular patterns rather than memorizing subject-specific intensity or positional artifacts, thereby strengthening generalization.

C. Classification Model: ResNet-18

ResNet-18 was employed as the backbone network to classify collateral circulation from CBCT images into three categories: *Good*, *Moderate*, and *Poor*. Compared with deeper variants such as ResNet-50, ResNet-18 is shallower with 18 layers but preserves the residual learning mechanism that addresses vanishing gradients and supports stable training. Its balance of computational efficiency and representational power makes it well suited for datasets of moderate size. The overall workflow is shown in Fig. 6. ResNet-18 was selected to match the study's data regime: with 45 patient cases, it provides an effective balance of computational efficiency and discriminative power. The residual design supports stable optimization, and the shallower depth reduces overfitting risk relative to deeper backbones.

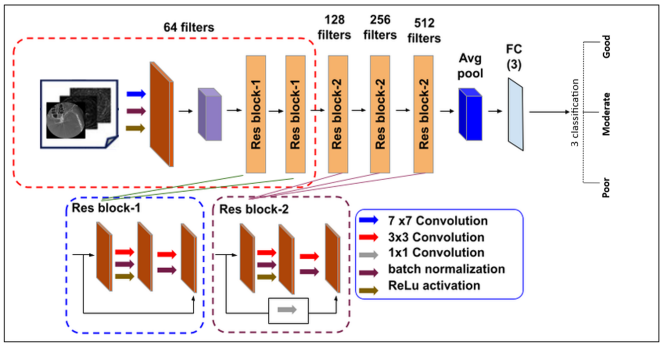

Fig. 6. ResNet-18 framework for CBCT-based collateral circulation classification, consisting of convolutional layers, residual blocks, pooling operations, and a softmax classifier.

1) Model architecture: The model processes preprocessed and augmented CBCT slices, each resized to 224×224 pixels with three channels. The initial stem of the network applies a 7×7 convolution with stride 2, followed by batch normalization, ReLU activation, and 3×3 max-pooling. For an input $X \in \mathbb{R}^{224\times224\times3}$, the first feature representation is computed as Eq. (1):

$$F^{(1)} = \sigma\big(\mathrm{BN}(W^{(1)} * X + b^{(1)})\big), \tag{1}$$

where, $*$ denotes convolution, $W^{(1)}$ and $b^{(1)}$ are the kernel and bias of the first layer, $\mathrm{BN}(\cdot)$ represents batch normalization, and $\sigma(z) = \max(0, z)$ is the ReLU activation.

The core of ResNet-18 is built from basic residual blocks, each consisting of two 3×3 convolutional layers with batch normalization and ReLU, plus an identity shortcut. A residual block computes [see Eq. (2)]:

$$H(x) = \sigma\Big(\mathrm{BN}(W_2 * \sigma(\mathrm{BN}(W_1 * x))) + x\Big), \tag{2}$$

where, W_1 and W_2 are convolution kernels of size 3×3. If the input and output dimensions differ, a 1×1 convolution is applied on the shortcut path. These residual connections enforce stable gradient propagation and allow the block to approximate $H(x) \approx F(x) + x$.

Spatial dimensionality reduction is performed by max pooling [see Eq. (3)]:

$$F_l^{pool} = \max_{(i,j)\in R} F_{i,j}^{(l)}, \tag{3}$$

where, R is the pooling window region. This preserves dominant activations while reducing computational complexity.

After the residual stages, global average pooling (GAP) compresses each feature map into a scalar [see Eq. (4)]:

$$g_k = \frac{1}{H \times W} \sum_{i=1}^{H} \sum_{j=1}^{W} F_{i,j,k}^{(L)}, \tag{4}$$

where, $F_{i,j,k}^{(L)}$ is the activation at spatial location (i, j) in channel k. The resulting feature vector $\mathbf{g} \in \mathbb{R}^d$ is passed to a fully connected layer and a softmax classifier [see Eq. (5)]:

$$P(y = c|X) = \frac{\exp(\mathbf{w}_c^\top \mathbf{g} + b_c)}{\sum_{j=1}^{3} \exp(\mathbf{w}_j^\top \mathbf{g} + b_j)}, \quad c \in \{\text{Good, Moderate, Poor}\}. \tag{5}$$

The predicted collateral grade is assigned as Eq. (6):

$$\hat{y} = \arg \max_{c\in\{\text{Good, Moderate, Poor}\}} P(y = c|X). \tag{6}$$

2) Training strategy: Training followed a two-phase protocol. In Phase 1, the ResNet-18 backbone (pretrained on ImageNet) was frozen, and only the final dense layers were optimized. This stabilized initial learning of domain-specific features while preserving the pretrained representations. In Phase 2, the final two residual stages (`conv4_x` and `conv5_x`, corresponding to the last ∼6–8 convolutional

layers) were unfrozen for fine-tuning at a reduced learning rate ($\eta = 10^{-5}$).

The categorical cross-entropy loss with label smoothing ($\varepsilon = 0.05$) was minimized [see Eq. (7)]:

$$\mathcal{L} = -\sum_{c=1}^{3} \left[(1-\varepsilon)y_c + \frac{\varepsilon}{3}\right] \log P(y=c|X), \tag{7}$$

where, y_c is the one-hot encoded ground truth. Optimization used Adam with decoupled weight decay regularization, and class weights were applied as Eq. (8):

$$w_c = \frac{N}{|\mathcal{C}|\, N_c}, \tag{8}$$

where, N_c is the number of samples in class c, ensuring balanced learning despite dataset imbalance.

3) Algorithmic logic: Algorithm 1 summarizes the workflow: preprocessing → augmentation → dataset partitioning → ResNet-18 training (frozen + fine-tuning) → evaluation. Each epoch samples up to $K_{\max} = 12$ slices per patient, preventing overrepresentation of long CBCT scans. Training and validation sets were processed using `tf.data` pipelines with batch prefetching for GPU efficiency.

Algorithm 1 Patient-Wise Two-Phase ResNet-18 Training for CBCT Collateral Grading

Data: CBCT slices $D = \{(x_i, y_i, \text{pid}_i)\}$; classes $\mathcal{C} = \{\texttt{Good}, \texttt{Moderate}, \texttt{Poor}\}$ ($|\mathcal{C}| = 3$).

Result: Best model $M^\star$ + metrics (accuracy, F1, sensitivity, specificity). **Begin:**

1. Build manifest {`filepath`, label, patient ID}; split patients (80/20).
2. Apply preprocessing → normalization → augmentation (flip, brightness, contrast, zoom).
3. Construct train/val datasets with ≤ 12 slices/patient/epoch.
4. Initialize ResNet-18 (ImageNet pretrained, no top).
5. Phase 1: freeze backbone, train head with Adam ($\eta = 2 \times 10^{-4}$), $E = 15$.
6. Phase 2: unfreeze final two residual stages (`conv4_x`, `conv5_x`), fine-tune with Adam ($\eta = 10^{-5}$), $E = 10$.
7. Evaluate on val set; compute confusion matrix, ROC/PR curves, and classification report.
8. Save best-performing weights $M^\star$.

End.

4) Training and optimization: The ResNet-18 model was optimized using the Adam optimizer, initialized with a learning rate of 1×10^{-3} and a batch size of 32. Training was conducted over 30 epochs under a patient-wise data partitioning strategy, where 70% of subjects were allocated for training and 30% for validation. This ensured that slices from the same patient were never shared across subsets, thereby preventing data leakage.

The learning objective was the categorical cross-entropy loss, defined as Eq. (9):

$$\mathcal{L} = -\sum_{c=1}^{3} y_c \log P(y=c|X), \tag{9}$$

where, y_c denotes the one-hot encoded ground truth label for class c and $P(y = c|X)$ is the predicted posterior probability for input X.

The incorporation of residual connections within ResNet-18, combined with careful normalization and the augmentation strategies described earlier, stabilized optimization and improved generalization. Despite having fewer layers than deeper variants such as ResNet-50, the 18-layer architecture provided a favorable trade-off between complexity and efficiency, confirming its suitability as a lightweight yet robust framework for automated collateral grading in ischemic stroke.

D. Evaluation Metrics

To rigorously assess the classification performance, a set of standard evaluation metrics was derived from the confusion matrix entries: true positives (TP), false positives (FP), true negatives (TN), and false negatives (FN). Each metric captures a complementary aspect of the model's behavior.

Accuracy: [Eq. (10)] quantifies the proportion of correctly classified cases across all predictions.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{10}$$

Recall (Sensitivity): [Eq. (11)] measures the ability of the model to correctly identify positive samples.

$$\text{Recall (Sensitivity)} = \frac{TP}{TP + FN} \tag{11}$$

Specificity: [Eq. (12)] reflects the effectiveness of the model in correctly rejecting negative samples.

$$\text{Specificity} = \frac{TN}{TN + FP} \tag{12}$$

Precision: [Eq. (13)] evaluates the reliability of positive predictions by measuring the proportion of true positives among all predicted positives.

$$\text{Precision} = \frac{TP}{TP + FP} \tag{13}$$

Finally, the *F1-score* [Eq. (14)] harmonizes precision and recall into a single measure, which is particularly informative under class imbalance.

$$\text{F1-score} = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{14}$$

For multi-class evaluation, overall performance can also be aggregated. Macro-averaging computes the simple mean of per-class metrics, treating each class equally. Micro-averaging instead pools contributions from all classes before computing the metric, emphasizing the influence of larger classes. The micro-averaged accuracy is defined in Eq. (15) as:

$$\text{Micro-Accuracy} = \frac{\sum_{i=1}^{C} TP_i}{\sum_{i=1}^{C} (TP_i + FP_i + FN_i + TN_i)} \tag{15}$$

Here, counts of TP_i, FP_i, FN_i, and TN_i are summed across all classes before computing accuracy. This means that every sample contributes equally to the final score, and Micro-Accuracy effectively reflects dataset-level performance while giving more weight to majority classes.

VI. Results

The proposed ResNet-18 framework was systematically evaluated on the curated CBCT dataset for the tri-class problem of collateral circulation grading (*Good*, *Moderate*, and *Poor*). The evaluation highlights training dynamics, confusion matrix analysis, calibration reliability, and discriminative performance using precision–recall and ROC curves. Together, these perspectives provide a comprehensive understanding of the model's stability, predictive reliability, and classification power.

A. Training and Validation Dynamics

Fig. 7 illustrates the evolution of training and validation accuracy over 20 epochs. The model began with modest performance, but accuracy improved consistently as the residual layers were optimized. The majority of performance gains occurred within the first 10 epochs, after which the curves continued to rise more gradually. By the final epoch, training accuracy reached approximately 95% while validation accuracy stabilized near 89%. The relatively narrow gap between the two curves indicates effective generalization without signs of severe overfitting. This stability is attributed to the use of batch normalization, residual connections, and data augmentation, which collectively mitigated noise sensitivity and class imbalance effects.

The corresponding loss curves in Fig. 8 support these findings. Both training and validation losses decreased monotonically, from initial values above 1.2 to approximately 0.20 and 0.35, respectively. The rapid decline in the early epochs reflects efficient convergence of the optimizer, while the smoother downward trend during later epochs highlights the fine-tuning of network parameters. Importantly, the persistent but small gap between training and validation loss suggests that the model was able to learn discriminative features without overfitting, even with the relatively shallow 18-layer architecture.

Overall, the accuracy and loss dynamics demonstrate that the ResNet-18 architecture effectively learned discriminative representations from intra-procedural CBCT scans while maintaining stable generalization performance. Despite being shallower than ResNet-50, the residual design allowed the network to converge efficiently and achieve robust validation accuracy, supporting its suitability as a lightweight yet reliable framework for automated collateral grading in ischemic stroke.

B. Confusion Matrix and Class-Wise Metrics

The validation confusion matrix (Fig. 9) provides detailed insight into the classification behavior of the proposed ResNet-18 model. Out of the validation set, the network correctly identified 3500 cases as Good, 1400 as Moderate, and 944 as Poor. Misclassifications were more frequent in the intermediate category: 237 Good cases were mislabeled as Moderate and 127 as Poor, while 107 Moderate cases were predicted as

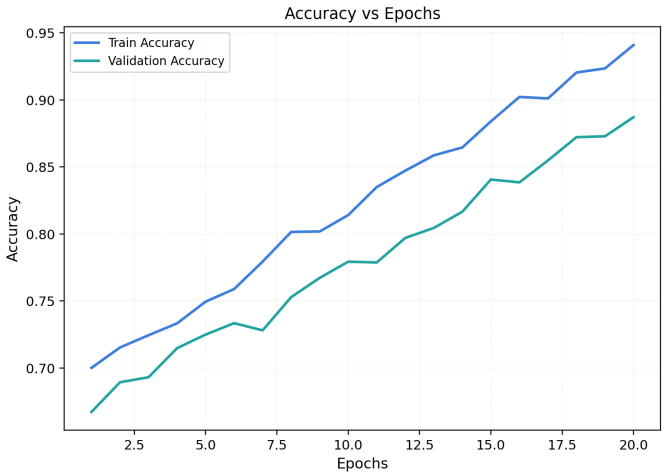

Fig. 7. Training and validation accuracy across 20 epochs for ResNet-18.

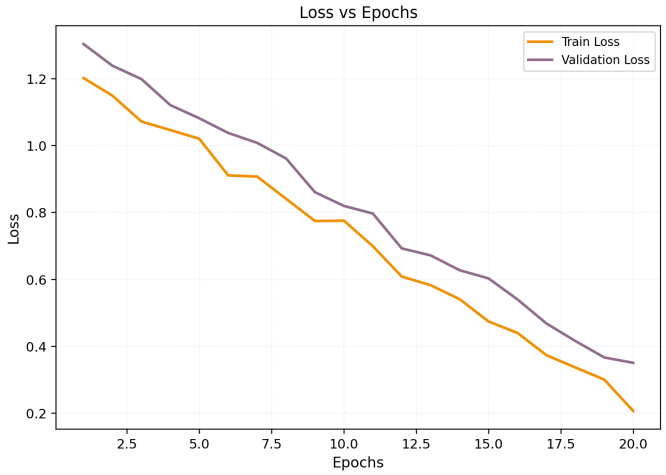

Fig. 8. Training and validation loss across 20 epochs for ResNet-18.

Good and 57 as Poor. For the Poor class, 136 instances were predicted as Good and 74 as Moderate.

As shown in Fig. 9, the highest overlap occurred within the *Moderate* category, reflecting its clinically ambiguous nature and morphological similarity to both Good and Poor grades. This observation is consistent with prior clinical studies, where neuroradiologists also reported lower agreement in intermediate collateral grading. By contrast, the *Good* and *Poor* categories exhibited more distinct imaging patterns, resulting in higher recognition accuracy and fewer cross-class confusions.

From the confusion matrix, class-wise performance metrics were computed and are summarized in Table IV. The *Good* class achieved the strongest balance across precision (93.5%), recall (90.6%), and F1-score (92.0%), highlighting its distinct imaging features. The *Moderate* class maintained a high recall of 89.5% but showed reduced precision (81.8%), reflecting its tendency to be confused with both extremes. The *Poor* class achieved relatively balanced precision (83.7%) and recall (81.8%), with strong specificity (96.6%) underscoring its separability from the Good group.

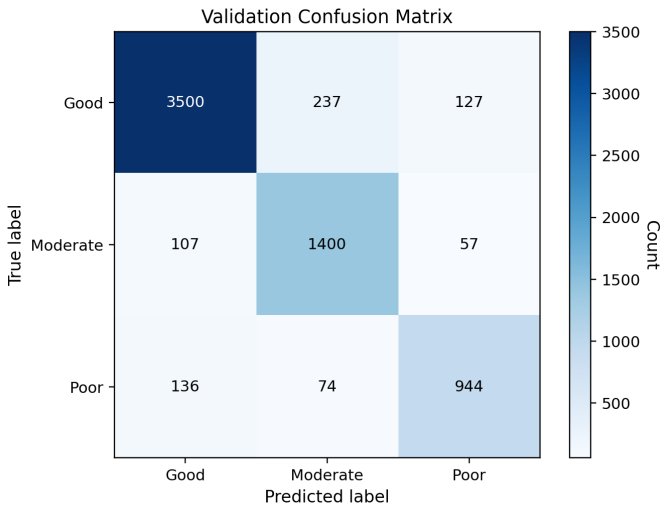

Fig. 9. Validation confusion matrix for three-class collateral classification using ResNet-18.

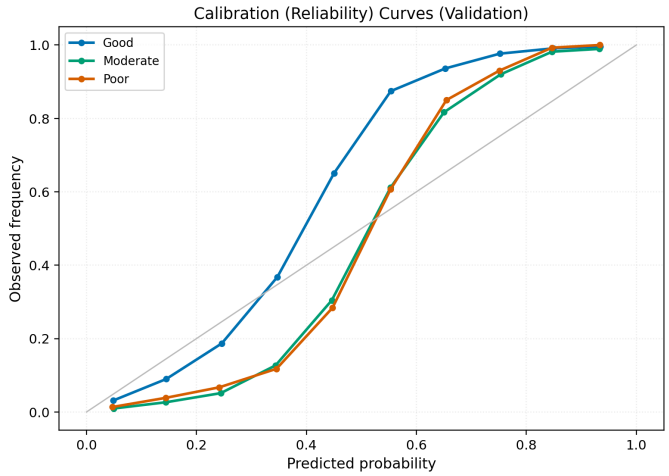

Fig. 10. Calibration curves showing the reliability of predicted probabilities for each class using ResNet-18.

Overall, the framework achieved a validation accuracy of 88.79%, with macro-averaged F1-score of 0.8675. These results confirm the robustness of ResNet-18 in capturing clinically meaningful collateral circulation patterns while also emphasizing the inherent challenge of accurately distinguishing intermediate cases.

TABLE IV. CLASS-WISE AND OVERALL EVALUATION METRICS FOR THREE-CLASS COLLATERAL CLASSIFICATION ON THE VALIDATION SET

Class	Accuracy	Precision	Recall	Specificity	F1-Score
Good	0.9078	0.9351	0.9058	0.9106	0.9202
Moderate	0.9278	0.8182	0.8951	0.9380	0.8550
Poor	0.9401	0.8369	0.8180	0.9661	0.8273
Overall	**0.8879**	**0.8634**	**0.8730**	**0.9382**	**0.8675**

Note: Overall accuracy is micro-averaged, while precision, recall, specificity, and F1-score are macro-averaged.

C. Calibration Reliability

The calibration curves in Fig. 10 assess the reliability of probability estimates generated by the ResNet-18 model. A perfectly calibrated model would follow the diagonal reference line, where predicted confidence values correspond directly to true outcome frequencies. In this study, the Good class tracked the diagonal closely across most probability bins, reflecting well-calibrated confidence estimates. The Moderate and Poor classes showed mild underconfidence in the mid-probability range (0.4–0.7), where the model's predicted likelihoods underestimated the true observed frequencies. This behavior is clinically advantageous compared to overconfidence, as it reduces the risk of misclassifying ambiguous cases with unwarranted certainty.

Overall, the calibration analysis confirms that the proposed ResNet-18 framework not only achieved competitive classification accuracy but also generated probability outputs that align closely with observed outcomes. The well-calibrated predictions strengthen the clinical applicability of the model, ensuring that decision-support systems based on its outputs provide both accuracy and reliability in hyperacute stroke assessment.

D. Precision–Recall and ROC Analysis

Fig. 11 illustrates the precision–recall (PR) curves for one-vs-rest classification using ResNet-18. The model achieved average precision (AP) scores of 0.975 for Good, 0.923 for Moderate, and 0.886 for Poor, with a micro-averaged score of 0.947. These results indicate that the network maintained high precision even as recall increased, demonstrating effective control of false positives across varying thresholds. The highest AP value for the Good class reflects the clearer vascular signatures of well-developed collaterals, which the model distinguished with high confidence. By contrast, the lower AP for the Poor class highlights the known challenge of differentiating weak collateral filling patterns, which often overlap visually with intermediate grades.

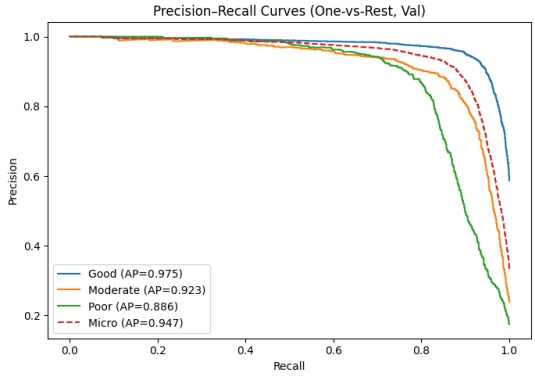

Fig. 11. Precision–recall curves for one-vs-rest classification across the three collateral classes using ResNet-18.

Fig. 12 shows the receiver operating characteristic (ROC) curves, which evaluate the trade-off between sensitivity and

TABLE V. COMPARISON OF COLLATERAL CIRCULATION CLASSIFICATION STUDIES USING AI TECHNIQUES

Study	Modality	Purpose	Method	Key Result
[40]	4D-CTA	Classification	ResNet34 (single vs. multi-image)	AUC 0.85–0.89
[41]	CTA	Classification	Multimodal DL + AutoML	Acc 91.2–94.1%
[42]	CTA (multiphase)	Classification	Fusion attention (CCA4CTA)	Acc 90.4%
[43]	MRI	Classification	CNN + ML (RF, SVM, k-NN)	Acc 72% (CNN)
[44]	CTA	Classification	CNN-SVM, ResNet, ViTs	Acc 62–77%
[39]	CBCT	Classification	VGG11	Acc 58.3%
[38]	CBCT	Classification	ResNet18	Acc 65.9%
This Study	**CBCT**	**Classification**	**ResNet-18**	**Acc $\approx$ 88.8%**

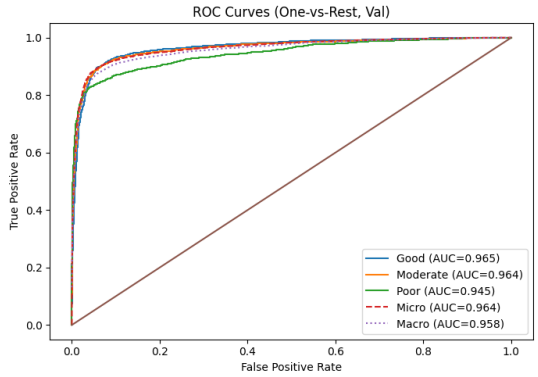

Fig. 12. ROC curves for one-vs-rest classification across the three collateral classes using ResNet-18, including micro- and macro-averaged performance.

specificity. The areas under the curve (AUC) were 0.965 for Good, 0.964 for Moderate, and 0.945 for Poor, with micro- and macro-averaged AUC values of 0.964 and 0.958, respectively. These consistently high values demonstrate that the model was highly effective in distinguishing among the three classes with minimal false positive rates. The Good and Moderate classes showed the highest separability, while the Poor class, although slightly lower, still achieved clinically meaningful discrimination.

Together, the PR and ROC analysis provide complementary perspectives on model performance. The PR curves highlight the precision–recall trade-off in an imbalanced clinical dataset, while the ROC curves confirm the model's strong sensitivity and specificity across thresholds. The consistently high AP and AUC values reinforce the robustness of the ResNet-18 framework and support its potential as a decision-support tool for neuroradiologists in hyperacute stroke collateral grading.

VII. DISCUSSION

This visualization supports the quantitative findings discussed earlier, confirming that the deep learning framework not only achieves high classification accuracy but also effectively localizes key vascular territories associated with each clinical grade. By mapping vascular intensity patterns onto interpretable color-coded overlays, the model provides transparent evidence of its decision process—enhancing clinical interpretability and trust for automated collateral assessment.

This study demonstrates that a slice-level ResNet-18 trained on intra-procedural CBCT can reliably classify collateral circulation into three clinically meaningful categories with high discrimination and well-calibrated probabilities. The novelty of this study does not lie in claiming CBCT superiority over CT or MRI in image quality, but rather in demonstrating that CBCT despite lower soft-tissue contrast—can achieve clinically competitive performance when paired with an optimized deep learning framework. Unlike CT and MRI, CBCT is acquired intra-procedurally in the angiography suite, enabling rapid decision support during endovascular treatment. By substantially outperforming prior CBCT-based AI studies and approaching the performance of CTA-based systems, this work establishes CBCT as a practical modality for automated collateral assessment.

The learning curves (Fig. 7 and Fig. 8) showed steady improvement in both training and validation accuracy with a monotonic decline in loss, indicating stable optimization and limited overfitting. The confusion matrix (Fig. 9) revealed that most misclassifications occurred in the *Moderate* class, reflecting its inherent overlap with *Good* and *Poor* collateral patterns. Calibration and PR/ROC analysis (Fig. 10 to Fig. 12) confirmed reliable probability estimates and strong separability, with macro-AUC of approximately 0.958 and micro-AP of 0.947. These findings support the clinical potential of CBCT-based AI for rapid, intra-procedural collateral grading.

When benchmarked against CTA-based systems, the CBCT approach is competitive. Wang et al. [40] reported AUCs of 0.85–0.89 on 4D-CTA with ResNet34, Tan et al. [42] achieved 90.4% accuracy using a multiphase attention model, and Raj et al. [41] reached 91.2–94.1% accuracy via multimodal fusion. Although CTA benefits from higher contrast-to-noise ratios and larger curated datasets, the CBCT model attained 88.8% validation accuracy and a macro-averaged ROC AUC of 0.958, indicating that despite CBCT's lower soft-tissue contrast and higher scatter, it can provide comparable diagnostic utility. Table V summarizes representative studies across modalities; notably, the last row shows this study ResNet-18 on CBCT markedly outperforming prior CBCT efforts (Ali 2023: 65.9%; Ali 2024: 58.3%), while approaching the performance reported for strong CTA baselines. While deeper residual or hybrid CNN-Transformer models may capture richer vascular features, the findings establish that ResNet-18 provides a strong and clinically meaningful baseline without heavy computational demands.

The improvement over prior CBCT studies is striking. Ali et al. [39] achieved only 58.3% accuracy with VGG11, while Ali et al. [38] reported 65.9% accuracy with ResNet-18 on a binary task. In contrast, the present study achieved nearly 89% accuracy on a more challenging three-class problem, advancing both the task complexity and the absolute performance margin. These improvements stem from patient-wise data partitioning (eliminating slice leakage), rigorous preprocessing with realistic augmentation (reducing bias and variance), and a two-phase fine-tuning strategy with label smoothing and class weighting (stabilizing training and improving calibration). Even though ResNet-18 is shallower than ResNet-50, its residual design effectively captured subtle vascular features when paired with optimized training strategies. Nonetheless, certain limitations remain. The dataset was limited to a single center, and validation was internal, raising questions about generalizability across institutions, scanners, and protocols. Slice-level labels served as proxies for patient-level grading, which may not fully reflect global collateral status. Future work should explore multi-center external validation, patient-level modeling with attention-based frameworks, and the integration of 2.5D/3D encoders or CNN–Transformer hybrids. Physics-informed preprocessing, such as scatter correction and denoising, may also further improve CBCT performance.

Overall, the results highlight a clear research gap addressed by this study: most prior CBCT efforts used shallow models and binary tasks, resulting in modest accuracy and limited clinical value. By combining CBCT with a residual architecture (ResNet-18), expanding to three-class grading, and applying systematic data augmentation, this study demonstrates a substantial step forward in accuracy, calibration, and clinical relevance. This design choice leverages both CBCT's intra-procedural accessibility and ResNet-18's efficiency, underscoring the potential of CBCT-based deep learning as a dependable tool for collateral assessment in hyperacute stroke workflows.

VIII. Conclusion

This study introduced a ResNet-18 based deep learning framework for automated tri-class classification of collateral circulation (*Good*, *Moderate*, *Poor*) in ischemic stroke patients using intra-procedural CBCT imaging. By employing patient-wise data partitioning, rigorous preprocessing, and systematic augmentation, the model achieved robust performance with a validation accuracy of approximately 88.8%, micro-AP of 0.947, and macro-AUC of 0.958. The framework demonstrated consistent convergence, balanced class-wise metrics, and well-calibrated probability estimates suitable for threshold-based clinical decision support.

Compared to prior CBCT studies that employed shallower architectures such as VGG11 and earlier ResNet-18 implementations, the proposed model substantially improved discriminative power and calibration reliability. Misclassifications were concentrated in the Moderate class, reflecting inherent clinical ambiguity and highlighting the need for targeted strategies to enhance intermediate grading.

The study is limited by its single-center dataset and slice-level labeling, which may restrict generalizability. Future work should therefore focus on external multi-center validation, volumetric or hybrid CNN–Transformer architectures, and uncertainty-aware decision models.In addition, future studies may explore patient-level aggregation (case-level prediction rather than slice-level), 2.5D/3D encoders to incorporate volumetric context, and uncertainty-aware calibration strategies to support safer clinical deployment in borderline Moderate cases. Overall, the findings confirm the feasibility of ResNet-18–driven CBCT analysis as a reliable, efficient tool to support neuroradiologists in collateral grading during hyperacute stroke care.

A Robust RT-DETR-Based Method for Complex Self-Service Buffet Scene Detection

Zhengwang Xu, Hongyang Xiao, Zhou Huang*
School of Electrical and Electronic Engineering, Hubei University of Technology, Wuhan 430068, China

***Abstract*—Object detection in buffet-style environments is highly challenging due to densely stacked tableware, frequent occlusions, strong illumination reflections, and substantial visual similarity across categories, all of which undermine the robustness of existing detectors. To address these issues, this paper proposes an improved real-time detection transformer–based model with a lightweight design while significantly enhancing multi-scale feature representation. First, a re-parameterized stem module is introduced to strengthen shallow texture extraction with negligible computational overhead. Second, a dynamic multi-kernel refinement module is developed to enrich directional texture modeling and cross-scale semantic aggregation. Furthermore, a heterogeneous-kernel feature pyramid network is constructed by integrating adaptive multi-scale fusion, multi-kernel fusion nodes, and a lightweight upsampling strategy to improve cross-level feature consistency and mitigate aliasing caused by conventional upsampling. Experimental results on a self-constructed buffet-scene dataset demonstrate that the proposed method improves $\mathbf{mAP}_{50}$ and $\mathbf{mAP}_{50:95}$ by 2.6% and 1.9%, respectively, while reducing parameters and GFLOPs by 42.6% and 42.3%, and increasing inference speed to 103.1 FPS. On Dota v1.0 and SkyFusion data sets, the small target detection ability has also been improved. The substantial reductions in computation and model size further confirm the effectiveness and practical value of the proposed approach for complex catering scenarios.**

***Keywords*—RT-DETR; lightweight object detection; multi-scale feature fusion; attention enhancement; buffet-scene perception**

I. Introduction

Object detection in buffet scenarios is a fundamental component of intelligent catering systems, and its results directly affect key processes such as dish consumption analysis, automatic replenishment scheduling, and checkout verification. However, compared with ordinary scenes, buffet environments are characterized by densely stacked tableware, frequent occlusions caused by serving actions, strong reflections from metal or ceramic surfaces, and high visual similarity between categories. These factors make small and overlapping objects highly prone to missed detections; highlighted regions disrupt texture consistency, while visually similar categories lead to an increase in false positives. Therefore, achieving high-precision, robust, and real-time object detection in complex buffet scenarios remains a major challenge for intelligent catering systems.

In recent years, research on object detection in dense scenes, small-object detection, and complex illumination conditions has continued to advance [1]. On the one hand, Wang *et al.* proposed YOLOv10, which removes non-maximum suppression and performs holistic end-to-end architectural optimization, achieving leading accuracy across different model scales on the COCO benchmark [2]. On the other hand, Wang *et al.* introduced RODD, a dedicated benchmark for reflected-object detection, and demonstrated that multiple state-of-the-art detectors still suffer from noticeable performance degradation under reflective-surface scenarios [3]; meanwhile, a NeurIPS 2024 study proposed illumination-invariant feature learning for low-light object detection and reported consistent gains when integrated into existing detection frameworks, indicating that illumination variation remains a non-trivial bottleneck [4]. In addition, two-stage detection frameworks are often limited by their high inference cost in resource-constrained deployments; for example, Liu *et al.* proposed simplification strategies for on-device inference of two-stage detectors to reduce computational complexity [5]. Transformer-based detectors, such as DETR [6] and Deformable DETR [7], model global context via self-attention and thus exhibit stronger robustness in complex scenes. However, standard DETR still suffers from slow convergence and unstable matching. Although Zhao *et al.* proposed RT-DETR, which enables real-time end-to-end transformer detection through structural simplification [8], subsequent studies have continued to improve its training strategy and small-object detection capability. Overall, these advances suggest that, for densely stacked and heavily occluded catering scenarios, there remains a pressing need for new detection solutions that strengthen shallow spatial feature representation and cross-scale feature fusion.

To cope with the above challenges, existing studies have proposed various improvement strategies from the perspectives of backbone enhancement, multi-scale fusion design, and attention mechanism optimization. However, these methods often focus on a single aspect, such as strengthening convolutional representation to improve fine details, enhancing feature pyramids to boost small-object detection, or introducing sparse attention to mitigate background interference. For buffet tableware detection scenarios where density, small-object scale, strong reflections, and occlusions coexist, a systematic solution is still lacking. In particular, under the constraints of lightweight design and real-time inference, how to enhance spatial detail modeling and cross-scale feature consistency within a limited computational budget remains a key bottleneck.

In this work, we propose an improved model based on RT-DETR as the baseline, specifically tailored for complex buffet scenarios. The main contributions of this paper are summarized as follows:

- We propose a lightweight, end-to-end detection framework tailored for complex self-service buffet scenarios, where dense stacking, severe occlusion, specular reflections, and high inter-class visual similarity com-

*Corresponding author.

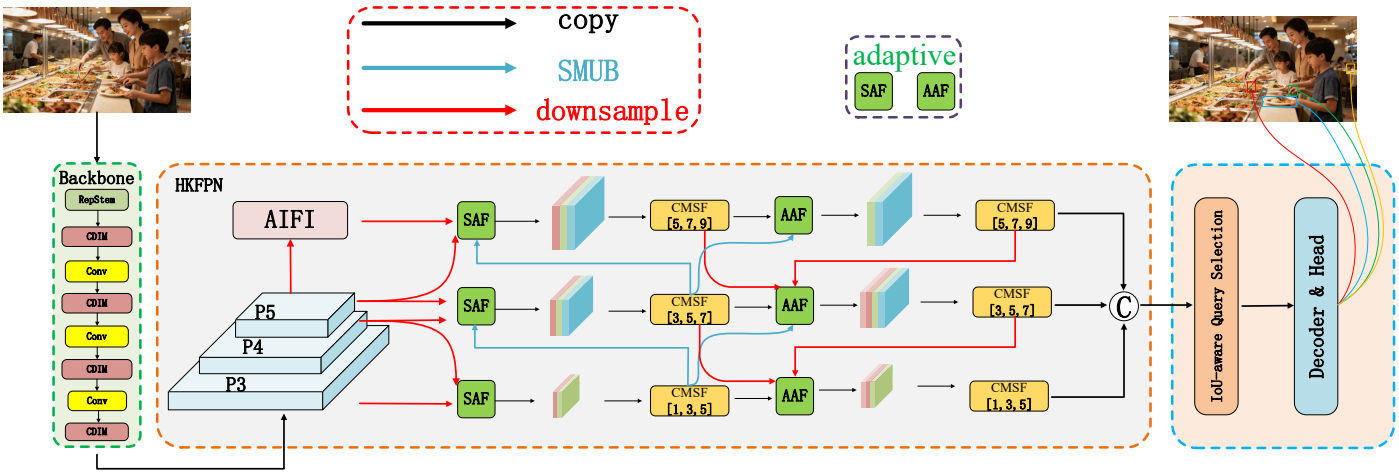

Fig. 1. Network structure of the proposed improved RT-DETR model.

monly coexist. The proposed framework is designed in a system-oriented manner, jointly optimizing feature extraction, multi-scale representation, and fusion efficiency to enable robust real-time detection.

- To enhance fine-grained discrimination and scale-aware representation under dense stacking and reflection interference, we design a lightweight backbone by integrating RepStem [9] with the proposed CDIM (Cross-Scale Fusion Dynamic Dual-Depth Inception Module). As a scene-driven enhancement unit, CDIM combines dynamic dual-path convolution with an adaptive Inception-style kernel selection mechanism, strengthening local texture perception and cross-scale context modeling while maintaining low computational overhead.

- We further construct HKFPN (Heterogeneous Kernel Feature Pyramid Network) as a scale-aware pyramid fusion architecture specifically for buffet scenes. HKFPN introduces heterogeneous large-kernel selection across pyramid levels and incorporates CMSF (Cross-stage Multi-Scale Fusion) and SMUB (Shift-Channel Mixed Upsampling Block) as collaborative fusion nodes together with an adaptive fusion mechanism [10]. This coordinated design mitigates feature aliasing and detail loss induced by conventional upsampling, thereby improving feature consistency and detection robustness for small, medium, and large objects in cluttered environments.

The remainder of this paper is organized as follows. Section II reviews related work on object detection in dense scenes, small-object detection, and transformer-based detectors. Section III describes the proposed method in detail, including the overall architecture and key modules. Section IV presents extensive experimental results and comparisons with state-of-the-art methods. Finally, Section V discusses the limitations of the proposed approach and outlines directions for future work, while Section VI concludes the paper.

II. Related Work

A. Object Detection in Dense and Complex Catering Scenarios

In dense near-field environments such as retail shelf recognition, unmanned vending systems, kitchen scene monitoring, and buffet tableware sorting, objects are often closely arranged, visually similar in shape, and heavily occluded. Traditional detectors tend to degrade significantly under such conditions. Goldman et al. constructed the SKU-110K densely shelf benchmark and demonstrated that mainstream detectors suffer notable performance degradation under homogeneous and crowded target distributions [11]. YOLO-based kitchen perception systems have achieved real-time recognition of cookware and cooking states, validating the applicability of lightweight detectors under strong reflections and complex illumination [12]. In buffet tableware recycling and sorting applications, RGB-D detection has been employed for tableware localization and grasping, providing engineering-oriented solutions to stacking and occlusion problems [13], [14]. For ceramic tableware surface defect detection, domain-specific datasets have been proposed, and YOLOv8-based frameworks have been developed. However, multi-scale small defects remain challenging for detectors, and reflective or patterned surfaces easily cause false detections or missed detections, underscoring the need for stronger fine-grained feature representation and targeted augmentations [15].

These studies collectively show that complex illumination, dense arrangement, and strong visual similarity are the primary challenges in tableware detection tasks, requiring more robust fine-grained feature modeling and cross-scale information fusion.

B. Improvements on RT-DETR

Research on improving RT-DETR mainly focuses on backbone enhancement, multi-scale fusion strengthening, attention optimization, and supervision strategy design. In terms of backbone enhancement, some works incorporate more efficient convolutional structures such as PConv [16] and FasterNet [17] to improve low-level texture and edge modeling, thereby enhancing small-object separability in dense scenes.

TABLE I. COMPARISON OF RELATED STUDIES AND THEIR STRENGTHS AND LIMITATIONS

Line of Work	Representative Works	Strengths	Limitations in Buffet Scenes
Dense benchmark analysis	SKU-110K [11]	Quantifies degradation in dense, homogeneous layouts.	Omits buffet-specific factors like specular highlights, fine-grained similarity.
Real-time kitchen perception	Kitchen YOLO [12]	Real-time recognition under complex illumination.	Not optimized for dense stacking and small objects; prone to confusion under occlusion.
RGB-D sorting and grasping	RGB-D pipelines [13], [14]	Depth cues improve robustness to occlusion and stacking.	Requires extra sensors and is less scalable.
Defect inspection on ceramics	Ceramic defect detection [15]	Effective for localized surface anomaly recognition.	Different objective from multi-class instance detection.

For multi-scale fusion, structures such as FPN [18], PANet [19], and BiFPN [20] are widely used to improve cross-layer feature consistency. Meanwhile, ASFF [21] and CARAFE [22] enhance small-object representation through adaptive weighting or content-aware upsampling, effectively mitigating feature aliasing introduced by conventional upsampling.

Regarding attention mechanism optimization, lightweight modules such as CBAM [23], Coordinate Attention [24], and HiLo Attention [25] strengthen spatial feature selection and global contextual representation, helping maintain stable feature modeling under complex background interference.

Despite the encouraging progress, existing approaches still exhibit clear limitations when deployed in buffet-like catering environments. A comparative analysis of their strengths and weaknesses is summarized in Table I.

III. METHOD

Building upon the original structure of RT-DETR, this work introduces a systematic lightweight design and a series of detection-performance enhancement strategies, resulting in an improved model. Without significantly increasing computational cost, we incorporate lightweight modules to strengthen multi-scale feature extraction and boost fine-grained representation capability. In the backbone stage, a lightweight RepStem module is introduced to reduce redundant parameters while enhancing shallow feature discrimination. For deep feature extraction, the proposed CDIM module reinforces multi-directional texture modeling and cross-scale semantic interaction. Furthermore, to address the limitations of traditional feature pyramids, we design a heterogeneous kernel fusion network, HKFPN, which integrates adaptive multi-scale fusion and ensures stronger cross-layer feature consistency. The overall architecture is illustrated in Fig. 1.

A. Lightweight RepStem Backbone

In restaurant scenarios, images often suffer from uneven illumination, specular reflection, and severe edge blur, which cause the traditional stem layer in RT-DETR to struggle in capturing fine-grained details and maintaining a balance between local and global information. Although the conventional downsampling design is simple and efficient, it provides insufficient shallow feature extraction during the early stages and cannot fully support real-time deployment when deeper layers introduce substantial computational cost. To address this issue, a lightweight RepStem module is introduced at the front end of the network to enhance shallow feature representation while improving inference efficiency. The structural differences relative to the traditional stem layer are shown in Fig. 2.

The core idea of the RepStem design is as follows. During the training stage, a multi-branch structure is adopted for three convolutional layers, maintaining a 4× downsampling rate while dynamically learning multi-branch feature enhancement and high-efficiency fusion. The process is illustrated in Eq. (1) and Eq. (2), where the fused shallow features capture richer edge information and directional detail cues.

$$W_{\text{fused}} = \sum_{i=1}^{n} W_i * Pad_i \tag{1}$$

$$b_{\text{fused}} = \sum_{i=1}^{n} b_i \tag{2}$$

During inference, the multi-branch parameters are equivalently merged into a single 3×3 convolution kernel, enabling improved feature diversity without increasing computational overhead. This mechanism can be viewed as a "train-time over-parameterization, inference-time simplification" design, providing stronger feature modeling during the learning stage while maintaining lightweight computation during deployment. The fused convolutional operation is shown in Eq. (3).

$$y = \text{Conv}(x, W_{\text{fused}}) + b_{\text{fused}} \tag{3}$$

Here, W_i denotes the convolution kernel of the i-th branch, Pad_i is the corresponding padding matrix used to ensure unified kernel sizes, and b_i is the bias term of the i-th branch. W_{fused} and b_{fused} represent the equivalent fused kernel and bias after branch merging.

Consequently, the RepStem module achieves a 4× downsampling ratio by applying two stride-2 convolutions in the first two layers, while the third convolution operates with stride 1 for feature refinement, as shown in Eq. (4) and Eq. (5):

$$x_{\text{stem}} = f_3(f_2(f_1(x))) \tag{4}$$

$$f_i(x) = \sigma(\text{BN}(\text{Conv}_i(x))) \tag{5}$$

where, $f_i(\cdot)$ denotes the convolutional mapping of the i-th layer, σ represents the activation function, and x_{stem} is the final output of the RepStem module.

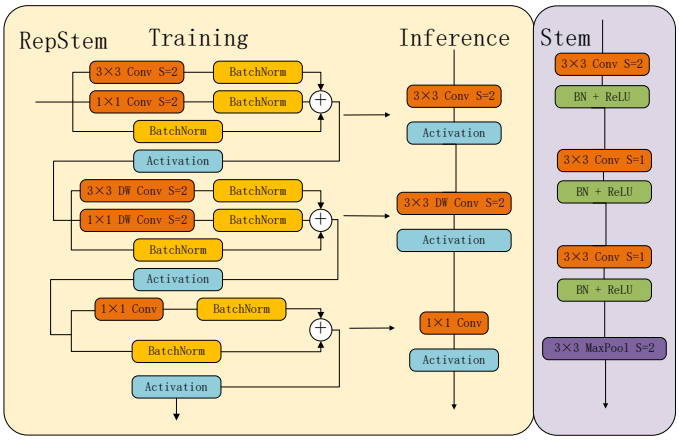

Fig. 2. Comparison between the proposed RepStem module and the original RT-DETR stem block. The left part illustrates the training- and inference-stage architectures of RepStem with multi-branch convolutions, while the right part shows the conventional ConvNorm-based stem composed of three stacked ConvNorm layers followed by a 3×3 max-pooling layer that achieves $4\times$ downsampling.

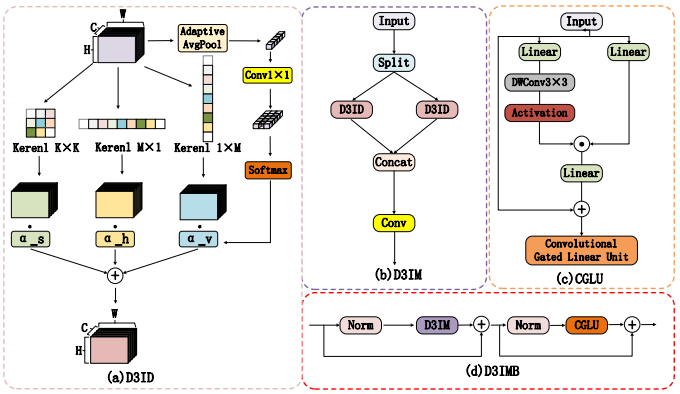

Fig. 3. CDIM is composed of several dynamic branches: Dynamic multi-depth convolution D3ID (Dynamic Dual-Depth Inception DWConv), dynamic mixing unit D3IM (Dynamic Dual-Depth Inception Mixer), CGLU (Convolutional Gated Linear Unit), and D3IMB (Dynamic Dual-Depth Inception Mixer Block). Combined with the CSP partition-and-fusion design, these components are integrated into a unified modular structure.

In RepStem, $f_1(\cdot)$ and $f_2(\cdot)$ are implemented as stride-2 convolutions for spatial downsampling, whereas $f_3(\cdot)$ uses stride 1 to further refine the representation without changing the resolution.

B. Dynamic Multi-Kernel Inception Refinement Block

Convolutional neural networks rely on fixed convolution kernels and static feature extraction mechanisms, which exhibit inherent limitations in many scenarios, particularly in complex restaurant environments where strong reflections, structural inconsistencies, and high inter-class similarity frequently occur. Traditional convolutions extract features using fixed kernel sizes and directions, and these receptive fields and weights remain fixed during inference. Such a static design often ignores the dynamic variations in image content, making it difficult for the model to handle multi-scale objects, strong reflections, occlusions, and fine-grained structures.

To address these challenges, this paper introduces a lightweight and dynamically adaptive feature refinement module, termed CDIM. This module enhances feature representation while preserving real-time performance and computational efficiency by adaptively selecting multi-kernel receptive fields and cross-depth feature fusion., as illustrated in Fig. 3.

At the bottom layer, D3ID designs three parallel depthwise convolution branches. To enable adaptive selection under different spatial contexts, the module introduces dynamic kernel weighting, allowing the network to adjust the contribution of each directional kernel based on the input content. Through lightweight reparameterization, the module generates dynamic selection weights for the three branches, and the final dynamic depthwise convolution is computed as in Eq. (6) and Eq. (7):

$$\alpha = \mathrm{Softmax}\left(W(\mathrm{AvgPool}(x))\right) \in \mathbb{R}^3 \tag{6}$$

$$\begin{aligned}\mathrm{DIDC}(x) = \alpha_s \mathrm{DW}_s(x) + \alpha_h \mathrm{DW}_h(x) \\ + \alpha_v \mathrm{DW}_v(x)\end{aligned} \tag{7}$$

where, DW_s denotes square depthwise convolution, DW_h horizontal strip depthwise convolution, and DW_v vertical strip convolution. The input tensor $x \in \mathbb{R}^{B\times C\times H\times W}$ represents the given feature map.

On this basis, D3IM further splits the input along the channel dimension into multiple groups, extracting features with dynamic kernels of different receptive field sizes, and subsequently fusing them through a 1×1 convolution. This design aggregates multi-scale upper–lower semantic cues and enhances the model's capacity to jointly encode local and global information.

D3IM then combines the above dynamic paths with a residual connection and a CGLU-based gated dual-branch structure. The first branch employs Mixer to realize dynamic multi-kernel feature aggregation, while the second branch uses CGLU to perform lightweight nonlinear modulation and adaptive feature recalibration. A learnable *LayerScale* parameter is introduced to stabilize the optimization by gradually increasing the residual scaling during training. Additionally, an optional *DropPath* is applied to improve generalization. The fused output in the inference stage is computed as:

$$\begin{aligned}\mathrm{DCMB}(x) = x + \gamma_1 \mathrm{DIM}(\mathrm{BN}(x)) + \gamma_2 \mathrm{MLP}(\\ \mathrm{BN}(x + \gamma_1 \mathrm{DIM}(\mathrm{BN}(x))))\end{aligned} \tag{8}$$

where, γ_1 and γ_2 are learnable scaling coefficients.

C. High-Efficiency Multi-Scale Adaptive Bidirectional Feature Pyramid Network

To address the inconsistency of multi-scale feature representation caused by densely distributed small objects, rapid occlusions, and strong reflections in catering scenarios, and to further enhance cross-scale feature fusion capability while maintaining lightweight design and real-time performance, we propose a high-efficiency multi-branch multi-scale feature pyramid network, termed HKFPN.

The proposed structure is inspired by the overall design philosophy of the MAFPN module and integrates lightweight

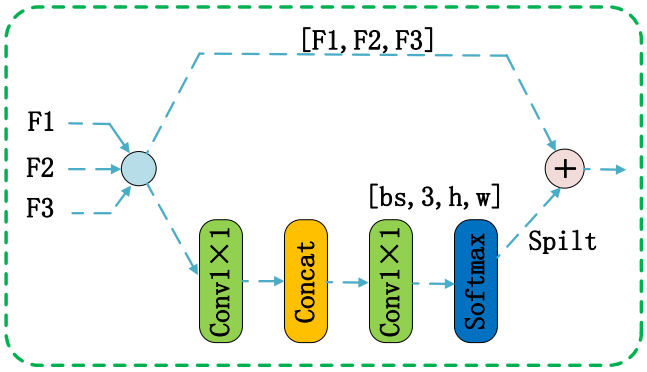

Fig. 4. Features $\{P3, P4, P5\}$ extracted from the backbone are first projected to aligned channel dimensions through pointwise convolutions, forming the three base features $\{F1, F2, F3\}$ that serve as the initial nodes of the HKFPN structure. On top of this, we construct lateral connections and cross-scale fusion pathways for each level, enabling the network to simultaneously receive high-level semantic cues and low-level spatial details.

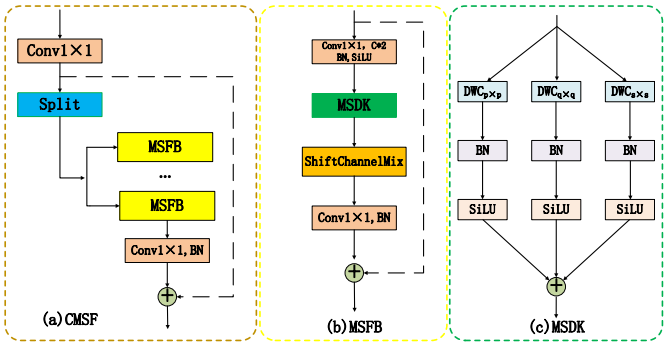

Fig. 5. (a) CMSF adopts parallel convolution branches of different kernel sizes. This design preserves the model's representational capability while reducing computational overhead and mitigating performance degradation in deep networks. (b) MSFB incorporates a Shift-Channel Mix operator to effectively rearrange channel information, achieving efficient feature interaction and cross-scale fusion. (c) MSDK employs multi-branch depthwise convolutions with different kernel sizes at different stages (e.g., {1,3,5}) to enhance scale sensitivity through parallel and depthwise aggregated feature extraction.

principles to perform comprehensive optimization on multi-scale feature fusion and upsampling pathways. HKFPN consists of three major components: an adaptive multi-scale feature fusion module, a multi-kernel aggregation node, and an efficient upsampling module. Together, these components construct a high-performance, scalable, and jointly global–local expressive feature fusion architecture.

1) Adaptive multi-scale feature fusion mechanism: HKFPN achieves bidirectional feature flow across levels P3–P5 through densely connected top-down and bottom-up pathways. Unlike traditional FPN and BiFPN, which rely on fixed-weight fusion for cross-scale aggregation, HKFPN introduces a spatially adaptive fusion strategy that dynamically evaluates feature importance across different scales and semantic levels at each spatial location. Specifically, the fusion weights are predicted per pixel and normalized across scale branches, enabling content-aware integration by assigning higher weights to the most informative scale for a given position. The overall structure is illustrated in Fig. 4.

Let $\{F_i\}_{i=1}^{3}$ denote the aligned multi-scale features to be fused, where $F_i \in \mathbb{R}^{B\times C\times H\times W}$. We first concatenate them along the channel dimension and apply two 1×1 convolutions to obtain the unnormalized fusion logits:

$$S = \mathrm{Conv}_{1\times 1}\Big(\mathrm{Conv}_{1\times 1}\big(\mathrm{Concat}(F_1, F_2, F_3)\big)\Big), \quad S \in \mathbb{R}^{B\times 3\times H\times W}. \tag{9}$$

A spatially adaptive weighting tensor $W \in \mathbb{R}^{B\times 3\times H\times W}$ is then obtained by applying $\mathrm{Softmax}$ along the scale (branch) dimension at each spatial location:

$$W_i(x,y) = \frac{\exp(S_i(x,y))}{\sum_{j=1}^{3}\exp(S_j(x,y))}, \quad i \in \{1,2,3\}, \tag{10}$$

which enforces $\sum_{i=1}^{3} W_i(x,y) = 1$ for every (x,y).

The final fused feature map $F_{\mathrm{out}} \in \mathbb{R}^{B\times C\times H\times W}$ is computed by a per-location weighted summation:

$$F_{\mathrm{out}}(:,x,y) = \sum_{i=1}^{3} W_i(x,y)\, F_i(:,x,y), \tag{11}$$

where, $W_i(x,y)$ is a scalar weight shared across channels (i.e., broadcast along the channel dimension). This fusion strategy enables the network to dynamically adjust the contributions of different scales at each spatial location, thereby improving the joint encoding of spatial details and semantic representations.

2) Multi-scale large-kernel aggregation node: In the feature refinement stage following cross-scale fusion, we adopt the CMSF module as the basic aggregation unit.

The CMSF structure integrates the CSP paradigm with MSFB (Multi-Scale Fusion Block), enabling efficient multi-scale feature extraction by transmitting partial residual features and performing depth-wise multi-kernel aggregation. The overall structure is illustrated in Fig. 5.

The input features to the CMSF module are first split into two streams via a 1×1 convolution. One stream directly preserves the input features to avoid spatial information loss, while the other passes through a multi-scale MSFB branch to construct multi-scale receptive fields.

Finally, the two processed branches are concatenated channel-wise and subsequently fused by another 1×1 convolution.

In the MSFB module, the core operation is the Multi-Scale Depthwise Kernel Block (MSDK), which consists of three parallel depthwise convolution branches. At levels P3, P4, and P5, different kernel-selection strategies are adopted to adaptively extract multi-scale features. The Shift-Channel Mix operator is subsequently applied to enhance channel interaction, improving the integration of local and global features. The input is first expanded by a 1×1 convolution, followed by multi-scale depthwise convolutions and a final 1×1 compression layer to restore the channel dimension.

The MSFB and CMSF core computations can be formulated as:

$$\mathrm{MSFB}(x) = x + P_2\big(\mathrm{SCM}(\mathrm{MSDK}(P_1(x)))\big) \tag{12}$$

$$\mathrm{CMSF}(x) = \mathrm{Concat}(x_1,\ \mathrm{MSFB}(x_2))\big) \tag{13}$$

where, $P_1(\cdot)$ denotes the 1×1 convolution for channel expansion, $P_2(\cdot)$ is the 1×1 projection convolution, $\mathrm{SCM}(\cdot)$ represents the Shift-Channel Mix operator, $[x_1, x_2]$ are the two branches in the CSP structure, and $P(\cdot)$ is the final 1×1 fusion convolution at the CSP output.

3) SMUB: Lightweight upsampling module-based on channel shifting: In feature pyramid networks, the upsampling operation is a key step for establishing cross-level interactions. However, traditional upsampling methods often suffer from feature misalignment and semantic discontinuity, and their computational cost increases significantly when aiming to preserve high-resolution details. In CMSFB, the SMUB is constructed by improving upon the EUCB module in EMCAD [26] and the ShiftChannelMix operator in BHViT [27], integrating a channel-shifting mixed strategy to achieve a unified design that enhances feature representation while maintaining lightweight computation. Under the constraint of low computational complexity, SMUB effectively alleviates the feature inconsistency introduced during upsampling and improves spatial continuity and semantic coherence in high-resolution features. The overall structure is illustrated in Fig. 6.

Its computation pipeline is formulated as:

$$x_{\mathrm{up}} = \mathrm{DWConv}(\mathrm{Upsample}(x)) \tag{14}$$

$$x_{\mathrm{mix}} = \mathrm{ShiftChannelMix}(x_{\mathrm{up}}) \tag{15}$$

$$x_{\mathrm{out}} = \mathrm{Conv}_{1\times1}(x_{\mathrm{mix}}) \tag{16}$$

The Shift Channel Mix module redistributes information across channels by cyclically shifting subsets of channels, allowing different channel groups to perceive information from different spatial positions. This improves the feature representation ability without introducing computational overhead or learnable parameters. By reordering features via group-wise channel shifting, the module enhances cross-channel interaction. Its computation is expressed as:

$$x_{\mathrm{mix}}(c,h,w) = x\big((c+\Delta_c) \bmod C,\ h,\ w\big) \tag{17}$$

where, C is the total number of channels and Δ_c denotes the shift step size.

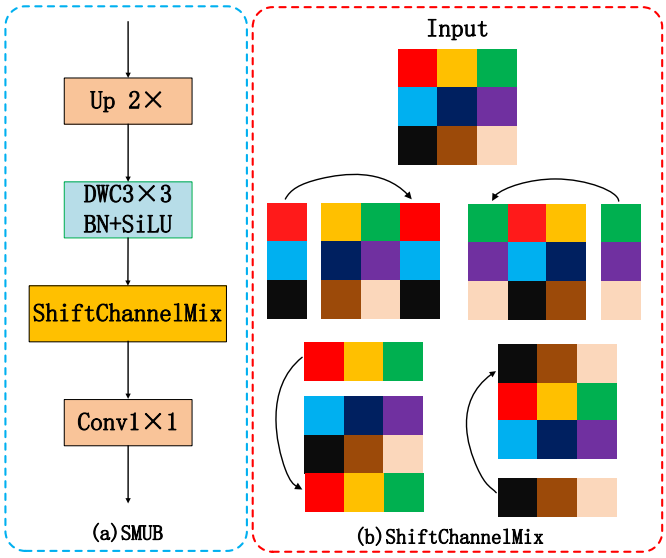

Fig. 6. (a) The upsampling depthwise convolution layer first performs 2× upsampling on the input feature and applies depthwise convolutions for local structure refinement, thereby enhancing spatial consistency under enlarged resolutions. The output is then fed into the Shift Channel Mix module for further feature enhancement, and subsequently compressed by a pointwise convolution for efficient channel reduction. (b) The Shift Channel Mix module divides the input feature into four equal groups along the channel dimension, followed by cyclic shifts in the positive and negative horizontal and vertical directions. The shifted features are finally concatenated and fused to achieve cross-channel information interaction and local feature refinement.

IV. Experimental Results and Analysis

A. Dataset

To support robust object detection in complex self-service buffet scenarios, we construct a composite tableware detection dataset by integrating publicly available data with self-collected samples into a unified benchmark. The dataset focuses on four object categories commonly encountered in buffet environments: cup, hand, plate, and tongs. We collect samples from complementary sources, including publicly released open-source datasets [28], [29], [30], [31], [32], publicly accessible royalty-free images gathered from online resources, and photographs captured by ourselves in real or near-real buffet environments. All self-collected images are manually annotated using LabelImg following the same annotation protocol as the public datasets and are subsequently incorporated into the final dataset.

To ensure consistency across heterogeneous sources, a unified preprocessing pipeline is applied to all data. Label normalization is performed to resolve naming inconsistencies and redundant labels across different datasets, such as *dish* versus *plate* and *hand* versus *human hand*.

All annotations are mapped to the four unified target categories, while labels irrelevant to the detection task are removed. During quality filtering, all images and corresponding annotations are manually inspected and cleaned, and low-quality samples with severe blur or excessive occlusion are discarded. Meanwhile, obvious annotation errors are corrected and invalid annotations are removed, and annotations from

TABLE II. CATEGORY-WISE DISTRIBUTION OF THE EXPERIMENTAL DATA SETS

Category	Number of Images
Hand	2415
Plate	1968
Cup	1756
Tongs	1570
Total	**7709**

heterogeneous formats are uniformly converted into the YOLO format.

The final dataset is split into training, validation, and testing subsets with a ratio of 7:2:1, while maintaining approximately balanced category distributions across splits. In total, the dataset contains 7,709 images, including 5,397 training samples, 1,531 validation samples, and 781 testing samples. The images span diverse viewpoints, brightness levels, and stacking complexities, providing a reliable basis for quantitative evaluation, and the category distribution of the constructed dataset is summarized in Table II.

Due to the wide variation in original image resolutions, all samples are resized to a fixed resolution of 640×640 during training to ensure input consistency and stable optimization while preserving aspect ratios as much as possible. Standard data augmentation techniques, including random flipping, color jittering, and affine transformations, are further applied to enhance model generalization under complex buffet conditions.

B. Experimental Settings

All experiments are conducted on an Ubuntu 22.04 operating system. The hardware configuration includes an Intel(R) Xeon(R) Platinum 8470Q CPU and an NVIDIA GeForce RTX 5090 GPU with 32 GB memory, and 90 GB system RAM. Python 3.12 and PyTorch 2.3.0 are used for deep-learning development, together with CUDA 12.1 as the GPU acceleration platform.

To ensure consistency of the experimental settings, the baseline RT-DETR is trained for 72 epochs following the official training schedule of its original implementation. In contrast, our model incorporates additional modules such as multi-scale feature fusion and adaptive weighting, which increase the optimization difficulty. Empirically, we observe that a longer training schedule is required to reach stable convergence. Therefore, we set the training duration of the proposed model to 300 epochs to ensure sufficient optimization while avoiding evident overfitting. During training, no optimization instability or divergence is observed, and both the training loss and validation performance exhibit smooth convergence trends. As shown in Fig. 7, the proposed method demonstrates stable convergence behavior in terms of mAP_{50} and $mAP_{50:95}$. The batch size is set to 32, and the AdamW optimizer is adopted with an initial learning rate of 0.0001 and a weight decay of 0.0001.

C. Evaluation Metrics

In this study, we adopt several commonly used evaluation metrics, including mean Average Precision (mAP), floating-point operations per second (GFLOPs), number of parameters (Params), and frames per second (FPS). Among them, mAP serves as the primary indicator to evaluate detection performance across all categories and is defined as follows:

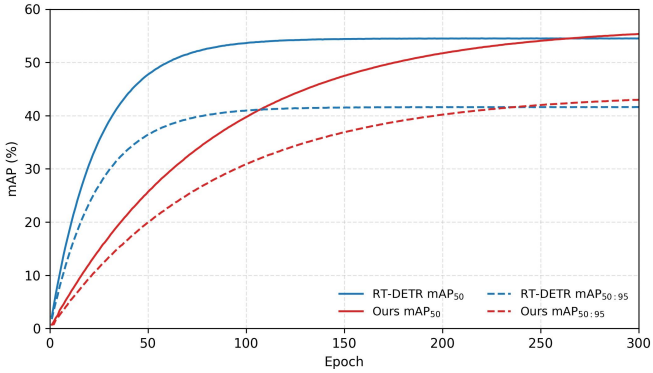

Fig. 7. Convergence curves of the baseline RT-DETR and the proposed method on the buffet tableware dataset.

$$mAP = \frac{\sum_{n=1}^{N} AP_n}{N} \tag{18}$$

D. Ablation Studies

To comprehensively evaluate the contribution of each proposed module to the overall detection performance, RT-DETR-r18 is adopted as the baseline model, upon which lightweight RepStem, the dynamic multi-kernel refinement module CDIM, and the heterogeneous multi-scale fusion network HKFPN are incrementally incorporated. All ablation experiments are conducted under identical training configurations and environmental settings. The results are summarized in Table III, where "✓" indicates that the corresponding module is enabled.

From the first row of results, it can be observed that replacing the original stem with the lightweight multi-branch feature extraction module RepStem leads to a notable improvement. Specifically, mAP_{50} increases to 54.8%, and $mAP_{50:95}$ rises to 42.3%. Meanwhile, the parameter count is slightly reduced to 19.8M, and the inference speed increases to 87.5 FPS.

Introducing the D3IM module further enhances detection performance. With D3IM, mAP_{50} is boosted to 55.1%, and $mAP_{50:95}$ reaches 41.9%. At the same time, the parameter size decreases to 13.1M, while inference speed increases to 96.2 FPS. This demonstrates that the multi-branch dynamic convolution mechanism of D3IM effectively strengthens the model's ability to capture fine-grained spatial cues while maintaining lightweight characteristics, making it particularly effective for small objects and complex fine-structure features.

After integrating the high-efficiency multi-scale fusion network HKFPN, the model achieves its best performance. mAP_{50} increases to 56.9%, and $mAP_{50:95}$ improves to 44.2%. Meanwhile, the total parameters reduce to 11.6M, and the inference speed reaches 103.1 FPS, representing over 18% improvement compared with the baseline. HKFPN enables more adequate semantic communication and cross-scale contextual aggregation through efficient spatial grouping and multi-scale

fusion strategies while mitigating the semantic misalignment commonly observed in traditional FPN structures. This results in a more balanced trade-off between accuracy and efficiency.

Overall, the incremental incorporation of each proposed module consistently contributes to the performance gains of the detection model. RepStem primarily enhances shallow feature extraction, D3IM significantly improves multi-scale perceptual capability, and HKFPN further strengthens cross-scale fusion and semantic aggregation, jointly leading to the best accuracy–efficiency balance.

E. Comparative Experiments

To further validate the effectiveness of the proposed method in practical detection tasks, we conduct a comprehensive comparison against various mainstream object detectors under the same hardware platform and dataset. The experimental results are summarized in Table IV.

Compared with conventional two-stage and one-stage detectors such as SSD and Faster R-CNN, our model achieves significantly higher detection accuracy under a lightweight architecture. With only 11.6M parameters and 33.8 GFLOPs, the proposed model attains 56.9% mAP_{50} and 44.2% $mAP_{50:95}$.

When compared with lightweight models such as MobileNet and EfficientDet, our method still demonstrates a more favorable trade-off between accuracy and efficiency. MobileNet has only 3.2M parameters and 5.4 GFLOPs, offering fast inference but insufficient detection precision. EfficientDet-D0, with 3.7M parameters and 3.9 GFLOPs, slightly improves efficiency, yet its mAP_{50} remains at 51.2%, indicating that the model struggles to simultaneously achieve both lightweight computation and high accuracy.

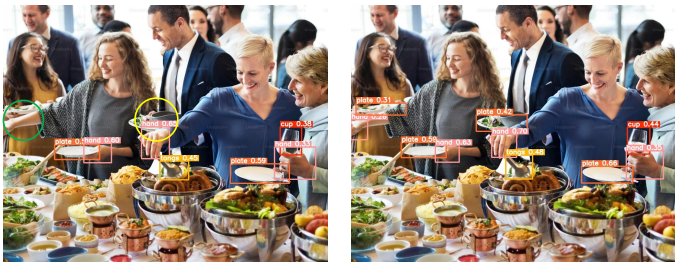
Compared with YOLO-series detectors, the proposed method further exhibits stronger accuracy advantages. YOLOv5s, YOLOv7-tiny, and YOLOv8s are representative lightweight detectors, which achieve mAP_{50} values of 53.1%, 53.4%, and 54.5%, respectively—still lower than the 56.9% achieved by our model. YOLOv8m improves accuracy to 55.6%, but its parameter size of 25.8M results in a slow inference speed of only 75.8 FPS, significantly lagging behind the 103.1 FPS achieved by our method.

It is also noteworthy that although YOLOv9s and YOLOv10s achieve mAP_{50} values of 55.8% and 55.1%, respectively, their inference speeds of 85.2 FPS and 74.9 FPS are not competitive. In contrast, our model maintains the highest inference speed 103.1 FPS while simultaneously achieving 56.9% mAP_{50} and 44.2% $mAP_{50:95}$, demonstrating a superior balance between accuracy and efficiency.

F. Generalization Experiments

To evaluate the detection performance and cross-dataset generalization ability of the proposed improved RT-DETR model on different types of small-object detection benchmarks, comparative experiments were conducted on the DOTA v1.0 and SkyFusion datasets, and the results are reported in Table V.

On the DOTA v1.0 dataset, compared with the original RT-DETR, the proposed method achieves improvements of 2.3% and 1.4% in mAP_{50} and $mAP_{50:95}$, respectively. On the SkyFusion dataset, the improved model also demonstrates stable performance gains, with mAP_{50} and $mAP_{50:95}$ increased by 0.8% and 0.9%, respectively. Although the absolute improvements are relatively modest, the consistent gains across different imaging conditions and data distributions indicate that the proposed method exhibits favorable cross-dataset generalization capability.



RT-DETR Ours

Fig. 8. Qualitative comparison between RT-DETR (left) and the proposed method (right). Green and yellow circles mark two typical regions where the baseline model fails to detect objects while the proposed method successfully recognizes them with significantly higher confidence.

G. Visualization Analysis

To further verify the effectiveness of the proposed method in complex buffet scenarios, we compare the visual detection results between the baseline RT-DETR and our improved model. The qualitative analysis is shown in Fig. 8. RT-DETR exhibits multiple missed detections in small-object regions and partially occluded areas. For example, the hand holding a plate on the left side of the image is completely undetected by the baseline model, and the hand interacting with the serving tongs in the central region is only partially recognized, resulting in the loss of important semantic cues.

In contrast, our improved model successfully detects all of these targets, demonstrating stronger robustness to occlusion, illumination variations, and fine-grained cluttered environments. More importantly, the confidence scores also increase significantly. These results indicate that the enhanced multi-scale representation and adaptive fusion mechanisms effectively improve the discriminability of subtle structural details.

V. Discussion

Despite the promising performance achieved by the proposed method, several limitations remain. Performance can still degrade under extremely dense stacking or severe occlusion, where overlapping instances cause critical visual cues to be missing in monocular RGB images. Moreover, although robustness to reflective surfaces is improved, extremely strong specular highlights or saturated regions may still obscure textures and boundaries, and such reflection-induced information loss cannot be fully removed by a purely vision-based approach. In addition, the current evaluation is conducted on a specific buffet tableware distribution, and generalization to substantially different catering layouts, novel categories, or unseen material properties requires further validation. Finally, while the framework targets real-time deployment, the added modules inevitably introduce extra computational cost, and

ultra-low-power devices may benefit from further compression or architectural simplification. Future work will investigate stronger occlusion reasoning, improved robustness under extreme reflections, and enhanced cross-domain generalization while maintaining real-time efficiency.

VI. CONCLUSION

This paper investigates the challenge of robust object detection in complex buffet-scene environments, where dense object stacking, severe occlusion, strong specular reflections, and fine-grained visual similarity jointly degrade the performance of existing detectors. To address these issues, an enhanced RT-DETR-based detection framework is proposed, aiming to improve fine-grained feature representation and cross-scale robustness while preserving real-time efficiency. Through the integration of lightweight structural enhancements and adaptive multi-scale feature modeling, the proposed method effectively strengthens discriminative capability under dense and reflective conditions.

Extensive experiments on a self-service buffet tableware dataset demonstrate that the proposed approach achieves consistent performance improvements over the baseline RT-DETR and other representative detectors, particularly in challenging scenarios with heavy clutter and reflection. Additional cross-dataset evaluations further verify the generalization ability of the proposed model on different small-object detection benchmarks. Overall, this work provides a practical and scalable solution for intelligent catering perception, facilitating accurate and efficient object detection in real-world self-service restaurant environments.

Future research will focus on incorporating temporal information and optimizing deployment on edge devices to further enhance robustness and real-time performance in more diverse scenarios.

***Abstract*—Conventional educational strategies fail to comprehend and leverage the diversity of learners' cognitive strengths and overlook their innate intelligence, a fundamental driver of learning. To address this gap, this study proposes a machine learning (ML) framework to predict students' overall innate intelligence scores, independent of subject domain or exam structure, using the Learning Meta-Learning dataset, which includes data from 1,021 university students. Seven regression models, including Decision Tree, Random Forest, Extra Trees, Gradient Boosting, Extreme Gradient Boosting, LightGBM, and CatBoost, along with their ensembles have been trained and evaluated. Explainable Artificial intelligence (XAI) technique SHAP is used for important feature selection among 54 features and recursive feature elimination to further enhance model accuracy and interpretability. In comparison to the conventional method, the proposed SHAP-based ML approach is lightweight, trained with selected features, and has shown improvements in accuracy. The accuracy without XAI on CatBoost is 98.32%, whereas with XAI on CatBoost it is 98.53% using only 35 features out of 54. These findings suggest that integrating learners' cognitive profile prediction model can aid the design of personalized educational strategies, moving beyond one-size-fits-all educational strategies.**

***Keywords*—Explainable AI; SHAP feature selection; machine learning; innate intelligence prediction; cognitive profiles; student diversity**

I. Introduction

Academic success is often measured with scores in uniform exams, which measure subject-specific performance but fail to capture a learner's overall intellectual abilities. Although these scores are extensively being used as a qualifying measure for academic admissions, employment, and future education opportunities, they are a limited and impersonal assessment of talent. Multiple studies argue that standardized exams and Cumulative Grade Point Average (CGPA) do not adequately reflect genuine cognitive profiles or learning abilities [1], [2], [3], [4]. The CGPA is not a reliable indicator of innate intellect or a reliable predictor of success in life or the workplace. This is because CGPA and intelligence are two different notions: while exam scores represent achievement in particular assessment formats, intelligence is an innate element of humans and a more precise representative of talents. Traditional assessments are designed within fixed frameworks and consequently overlook intellectual diversity and may misrepresent learners' true potential [5], [6]. This misalignment highlights a fundamental flaw in how education systems comprehend and measure talents.

Intelligence is innate and the fundamental driver of learning and problem solving. Traditional education systems generally promote conformance to fixed rules over recognizing and nurturing varied intellectual strengths of learners. The belief that uniform educational strategies, whether in teaching and learning, curriculum design, or assessments, are sufficient to meet or assist all students undermines the objective of inclusive and equitable education. For example, while evaluation methods may differ between subjects, evaluations within each subject remain the same for all students. Such approaches focus on curricular content but fail to acknowledge the varied ways in which students understand, process, and apply knowledge. In order to be truly equitable and effective, educational approaches need to be learner-centered, holistic, and adaptable to the diverse intelligence scores. Nevertheless, present strategies continue to be mostly content-focused and disregard learners' intrinsic potentials [7].

With the advent of Machine Learning (ML) in educational studies, data-driven decision-making continues to gain popularity. Many ML models are aimed at predicting academic success (e.g., CGPA or performance scores) by using parameters like attendance, prior examination results, socioeconomic background, and geographic location [8], [9], [10], [11], [12]. Although these models provide valuable insights, they continue to depend on the conventional exam-centric paradigm, inheriting its limitations and disregarding deeper cognitive notions like intrinsic intelligence.

Exam performance is influenced by assessment style and primarily depends on linguistic and logical intelligence, whereas individuals possess spatial, bodily-kinesthetic, musical, interpersonal, and intrapersonal type intelligences as well [13], [14], [15], [16]. Therefore, exam scores are inadequate for measuring overall intelligence, and this narrow scope limits both scientific understanding and educational innovation. It creates a disparity between how competence is measured and what intelligence implies, which results in misguided educational decisions and inadequate learner support [17], [18], [19].

*Corresponding author.

To bridge this gap, this research aims to predict the overall innate intelligence, defined as the cumulative Multiple Intelligences (MI) score [14], [20], [21], [22]. Using the Learning Meta-Learning (LML) dataset, which includes 54 features capturing biological, psychological, behavioral, and metacognitive data, intelligence is modeled independently of test formats and study domains [23], [24]. The main contributions are as follows:

- Training and evaluation of seven regression models, namely Decision Tree, Random Forest, Extra Trees, Gradient Boosting, Extreme Gradient Boosting (XGBoost), LightGBM, and CatBoost, along with their ensembles to predict intelligence scores using the 1021 students' data from the LML dataset.
- Employment of SHAP (Shapley Additive Explanations) to identify and rank the most important features contributing to the predictions.
- Utilization of SHAP-based Recursive Feature Elimination (RFE) to improve model performance and interpretability.
- Examination of the contribution of learners' external factors, including age, gender, sleep duration, chronotype, illusion of competence, and impostor phenomenon, to the prediction of intelligence scores.
- Outlining the prospects and applicability of the proposed methodology, leading to targeted and equitable educational interventions.

Successful prediction of intelligence scores has the potential to advance personalized education. It allows educators to tailor teaching-learning techniques, determine learning outcomes, and create assessment methods that align with individuals' intrinsic intelligence, providing a more equitable alternative to one-size-fits-all approaches. This research supports the Sustainable Development Goal 4, which advocates for inclusive and equitable quality education [25]. It can also advance educational AI and learner-centered heutagogy by demonstrating that intelligence is both predictable and actionable, beyond what exam scores alone can do.

II. Literature Review

Conventional exam-based assessments have long dominated academic evaluations, admissions, and recruitment. Although standardized assessments are intended to ensure uniformity across learners, their operational simplicity comes at the cost of educational depth [1], [2], [3], [4], [17]. They often fail to reflect true talents, as fixed-format assessment performance is influenced by various external factors such as access to resources, language barriers, and test-taking strategies [18], [19], [26], [27]. Hence, more holistic, learner-centered approaches are needed to promote educational equity and inclusivity [28], [29]. Fixed-format exams, which primarily measure linguistic and mathematical abilities only, reinforce a narrow view of learner intelligence and thus privilege certain learners while marginalizing others who possess comparable overall cognitive strengths distributed across different intelligence types [5], [6].

Models such as Spearman's general intelligence factor (g-factor) and the Intelligence Quotient (IQ) score have historically molded the concept of intelligence by proposing a general cognitive ability that can be measured through standardized processes. Though these models are frequently employed in the fields of education and psychology, they are increasingly being criticized for being reductionist and biased [30], [31]. IQ tests concentrate on linguistic and logical thinking above creativity, interpersonal abilities, social skills, and practical reasoning capabilities important for the real world [32], [33], [34], [35], [36]. Furthermore, these scores show how well people perform in specific test contexts rather than their overall ability for learning or knowledge application. In summary, the target variable of this paper, intrinsic intelligence score, is a superior, holistic, and actionable measure compared to the regular intelligence models, such as IQ and the g-factor, which provide limited and biased perspectives on human potential.

The intelligence score predicted in this study includes the entire set of MI, embracing the complete spectrum of human cognitive skills, in contrast to IQ-based models [37]. This MI-based intelligence score has gained popularity among educators for its potential to provide individualized educational approaches [38], [39]. However, MI remained underutilized in educational practices and data-driven applications due to challenges with operationalizing it as a single, compatible construct [20]. Therefore, in this study the aggregated measure that encompasses all types of intelligences have been used, providing a comprehensive and scalable metric suitable for ML and educational decisions. Human intelligence types function interactively rather than in isolation; hence, treating them as separate and unrelated is both impractical and misleading [22]. The overall intelligence score provides a unified, quantitative representation of an individual's cognitive potential, more feasible for modeling and real world application than focusing only on dominant intelligences [40]. Moreover, many educational decisions, such as identifying students for enrichment or support, require comprehensive judgments rather than intelligence-type-specific analysis.

To the best of our knowledge, most ML applications in education continue to focus on predicting conventional outcomes, such as grades, test scores, course completion rates, or dropout risk, based on features like attendance, quiz scores, or demographic data. While these models can forecast academic performance, they inherit the limitations of traditional assessments [8], [9], [10], [11], [12], [41]. Additionally, most of the existing ML models lack transparency. Black-box techniques make it difficult to understand and rely on the reasoning behind output generations. Explainable Artificial Intelligence (XAI) approaches, such as SHAP, provide a solution by dictating which features are most important for predictions [30].

In summary, this study addresses three gaps in educational ML research: 1) the persistent over-reliance on traditional academic outcomes as representations for talents, 2) the limited integration of learners' innate intelligence into ML-based modeling for personalized education, and 3) the lack of interpretability in ML applications for education.

III. Proposed Methodology

The proposed methodology integrates feature selection with traditional ML models, significantly enhancing the accuracy and interpretability of learners' intelligence prediction models. As shown in Fig. 1, the study is divided into two

parts to show the difference between the traditional approach and the proposed approach. The integration of RFE with SHAP for important feature selection stands out as a unique aspect. This method iteratively refines the feature set, enabling the identification of the most informative features, which are then used to train various ML models for comparative analysis. 70% of the data is utilized for training, with the remaining 30% being used to evaluate model performance. In this study, SHAP values are computed using CatBoost to generate a global feature importance ranking, which serves as the basis for a SHAP-based RFE procedure [42]. From the traditional approach part, CatBoost is found as the best performer; therefore, in the proposed approach, CatBoost is used as the SHAP explainer model for the LML dataset. Through rigorous cross-validation and hyper-parameter adjustment, this iterative approach validates the efficacy of the feature selection strategy.

After data cleaning and preprocessing of the dataset, which included the removal of null, inconsistent, and noisy values, along with label encoding to handle data types, seven ML regressors have been employed [43], [44]. Their ensemble combinations are also examined as well, as they potentially may integrate the strengths of individual models [45], [46]. Their ensembles, ensemble-2 (combinations of 2 models) are created by combining the best-performing individual model with one additional model (e.g., CatBoost + LightGBM), while ensemble-3 models include the best model along with two others (e.g., CatBoost + LightGBM + XGBoost). Within the ensembles, only those that outperformed the best individual regressor (CatBoost) are retained for further optimization. Algorithm 1 provides the pseudocode for the workflow of research methodology. Data analyses are conducted using Python 3.10.

A. Dataset and Feature Description

The utilized LML dataset consists of 1,021 responses to 54 survey items designed to measure various learner parameters. The data was acquired using a voluntary and anonymous online survey conducted at eleven universities in Bangladesh. Participants met two inclusion criteria: they were currently enrolled in a Bangladeshi higher education institution and were at least 18 years old. At the time of the survey design, there were 4,690,876 students enrolled in both public and private universities [24]. The survey was structured using a combination of convenience sampling and simple random sampling because it was not feasible to perform probability sampling on this large population due to logistical and resource limitations. Following the combined sampling structure, universities were chosen based on their reachability, and classrooms from various departments were chosen at random within each university. In those classrooms, all present students were verbally invited to participate in the survey anonymously and voluntarily. Table I summarizes the feature set from the LML dataset, grouped by domain, data type, and corresponding value ranges. The dataset includes features from biological, psychological, and behavioral domains, encompassing both categorical and discrete data types. The corresponding descriptive statistics of the sample data are illustrated in Fig. 2. The panel in Fig. 2(a) shows the means and standard deviations (SD) for the discrete variables: Intelligence Score, Age, and Sleep Duration. There is a wide range of intelligence scores in the sample, as observed by the mean and SD values (97.43 ± 14.35), which

Algorithm 1 ML-based human intelligence prediction using SHAP-based RFE

```
Load and preprocess data by removing missing, null, and inconsistent values and by label encoding
Initialize base regressors: Decision Tree, Random Forest, Extra Trees, Gradient Boosting, XGBoost, LightGBM, CatBoost
Split dataset into predictors (X) and target variable (y)
    Assign predictors to X and target intelligence score to y
    Split into training and test sets: X_train, X_test, y_train, y_test
for each regressor in base regressors do
        Train the regressor on X_train, y_train
        Predict on X_test
        Compute performance metrics
end for
Select the best-performing model (BestBaseModel) based on metrics
Create ensemble models by combining BestBaseModel with one and two other base regressors
for each ensemble model do
        Train on X_train, y_train
        Predict on X_test
        Compute performance metrics
        if ensemble model outperforms BestBaseModel then
            add it to the optimization list
        end if
end for
Select BestModel from BestBaseModel and models in the optimization list
Initialize SHAP explainer using BestModel and X_train
Compute SHAP values on X_train
Rank features from least to most important based on mean absolute SHAP value
for each model in the optimization list do
        Call RunSHAP_RFE(model, SHAP ranking, X_train, X_test, y_train, y_test) where:
            RunSHAP_RFE = SHAP-based Recursive Feature Elimination procedure:
                Start with all features in SHAP importance order
                Iteratively remove the least important feature(s) based on SHAP ranking
                Retrain the model on the reduced X_train
                Predict on reduced X_test
                Compute performance metrics and record performance for each feature subset size
                Keep track of the subset giving maximum accuracy and store it as the optimized model configuration
end for
Store optimized model, best feature subset, and full performance log
Plot Accuracy vs. number of SHAP-ranked features (from RFE) for each optimized model
Plot SHAP summary plot
return trained models, performance metrics, and SHAP-based explanations

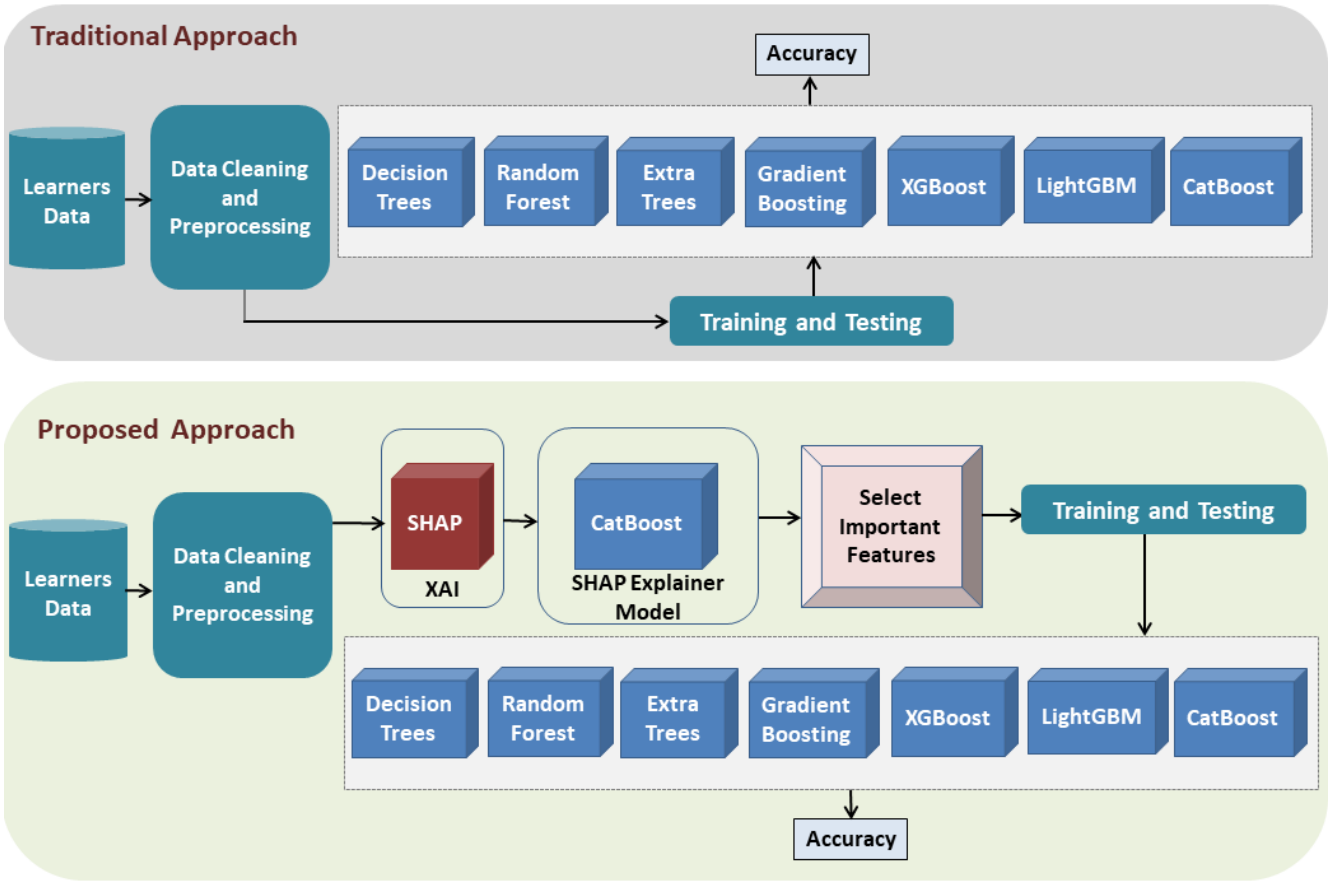

Fig. 1. Workflow of the proposed methodology.

ranges from 1 to 140. Participants' ages range from 18 to 27 years old, with an average age of 21.72 ± 1.76 years. The average Sleep Duration, which ranges from 5 to 11 hours, is 6.29 ± 1.14 hours. Fig. 2(b) panel depicts the distributions of categorical variables, Gender, Illusion of Competence, Chronotype, and Imposter Phenomenon, in terms of frequency and percentage of the total sample ($N = 1021$). The Gender distribution shows a higher proportion of male participants (638, 62.49%) than females (383, 37.51%). Although this appears skewed, it matches the existing gender disparity in higher education enrollment in Bangladesh [24].

The majority of students experienced moderate levels of Illusion of Competence (465 participants, 45.54%), followed by severe levels (315 participants, 30.85%) and mild levels (241 participants, 23.60%). The total proportion of moderate and severe levels exceeds 76%, implying that a large number of learners misestimate their competency. The Chronotype distribution is relatively balanced, with 313 participants (30.66%) identifying as Morningness types, 369 (36.14%) as Intermediates, and 339 (33.20%) as Eveningness types. This spread captures a well-represented diversity in biological rhythms, or sleep-wake preferences, among the university students. The majority of students reported that they experienced the Imposter Phenomenon on a moderate to frequent basis, with 324 participants (31.73%) and 557 participants (54.55%), respectively. This total percentage of 86.28% highlights how common impostor syndrome is among students, highlighting the significant psychological burden often associated with academic performance and self-perception.

B. ML Models

The Decision Tree regressor predicts continuous values by recursively partitioning the dataset based on feature conditions to reduce variance at each node, with final predictions based on the leaf nodes' mean values. It effectively models nonlinear relationships and is often employed in regression tasks.

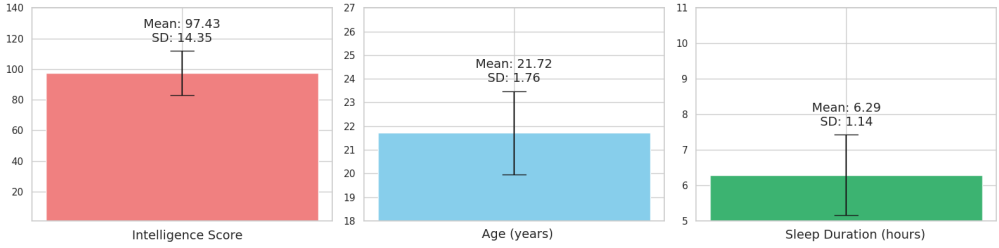
Random Forest regression improves on this by constructing an ensemble of Decision Trees, each trained on a random subset of data and features, and then averaging their outputs to reduce overfitting, boost stability, and improve robustness compared to a single tree.

The Extra Trees regressor is similar to Random Forest, but it adds more randomization by randomly generating split thresholds instead of optimizing them, which decreases variance and speeds up training while maintaining competitive accuracy.

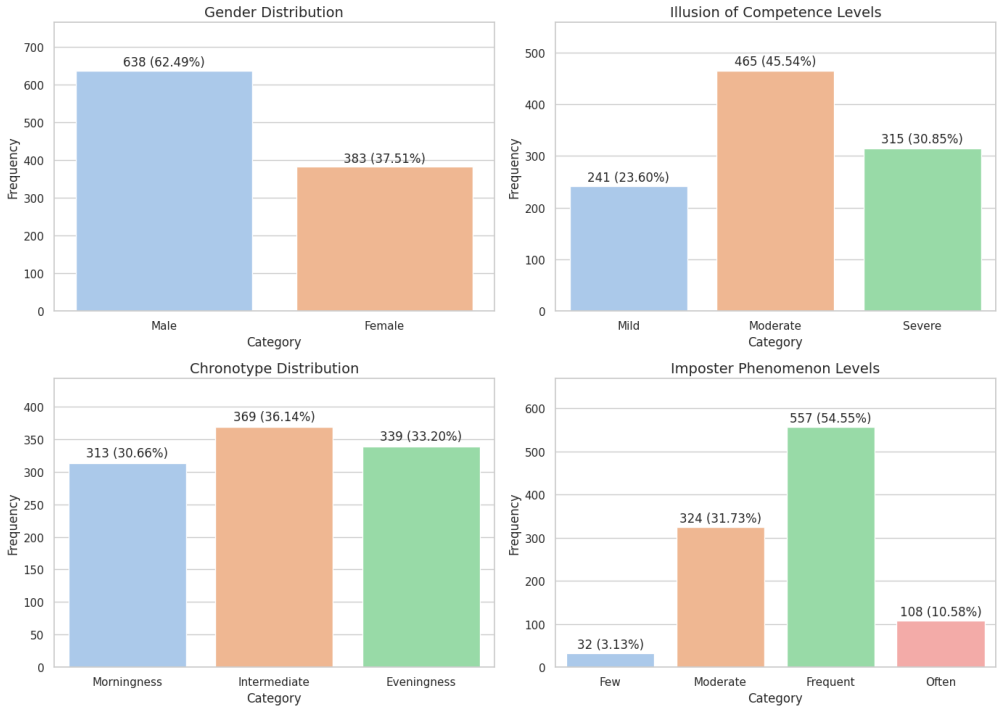
Gradient Boosting is a sequential ensemble method for creating an additive model by training every new tree to rectify the residual errors of the combined previous learners and minimizing a loss function using gradient descent.

TABLE I. FEATURE SET DESCRIPTION

Feature Group	Data Type	Feature Name	Value Range
Biological	Discrete	Age	18 – 27 years
Biological	Categorical	Gender	Male, Female
Psychological	Categorical	Illusion of Competence	Mild, Moderate, Severe
Behavioral	Discrete	Sleep Duration	5 – 11 hours
Biological	Categorical	Chronotype	Morningness, Intermediate, Eveningness
Psychological	Categorical	Imposter Phenomenon	Few, Moderate, Frequent, Often
Psychological	Discrete	Overall Intelligence Score	0 – 140



(a)



(b)

Fig. 2. Descriptive statistics of the seven learner parameters: (a) Mean and SD of continuous variables; (b) Frequency and percentage of categorical variables.

XGBoost is an effective Gradient Boosting solution that provides regularization, parallel processing, and out-of-core computation. It improves performance by using second-order gradients, efficient tree pruning, and built-in regularization to reduce overfitting. It also effectively handles missing data and produces cutting-edge results on large-scale, multidimensional datasets, making it widely utilized in prediction tasks.

LightGBM is another Gradient Boosting model that uses a histogram-based method and a leaf-wise tree development technique to improve training speed while retaining high precision. It also works well on large data sets and handles categorical features natively.

CatBoost uses ordered boosting to avoid prediction shift and efficiently handles categorical features without requiring extensive preprocessing. It is ideally suited for complicated regression problems involving heterogeneous data types due to its fast training, good generalization, and accuracy with minimal parameter adjustment.

C. Model Evaluation Metrics

To evaluate the prediction performance of the models, the following standard metrics are employed: Mean Absolute Error (MAE), Mean Squared Error (MSE), Root Mean Squared Error (RMSE), and Accuracy [47], [48], [49].

The MAE quantifies the average magnitude of the errors in predictions relative to the actual outcomes. The formula for MAE is as follows.

$$\text{MAE} = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \tag{1}$$

where, y_i denotes the actual value, $\hat{y}_i$ the predicted value, n the number of observations, and i indexes each observation from 1 to n.

The MSE calculates the average discrepancy between the actual values and the predictions. The process involves squaring the differences and then calculating the mean. The formula for MSE is as follows.

$$\text{MSE} = \frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2 \tag{2}$$

RMSE is the square root of MSE, which represents the residuals' SD. It gives an interpretable measure in the same unit as the target variable. The representation is as follows.

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \tag{3}$$

Accuracy is the percentage of variance explained by the model. Variance measures how far the actual values deviate from their mean. The more the model's predictions lower this spread (or error), the greater the explained variance, or the model's accuracy. A higher accuracy indicates predictions are very close to the actual values. This metric is calculated using the following equation.

$$\text{Accuracy} = \left(1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y}_i)^2}\right) \times 100 \tag{4}$$

where, $\bar{y}_i$ denotes the mean of actual values.

IV. Results and Discussion

A. Model Performance

The performance of the regressors in the traditional approach using the complete set of features is presented in Table II. CatBoost emerged as the most effective model, attaining the highest accuracy (98.32%) and the lowest error rates across all evaluation metrics (MAE: 1.38, RMSE: 1.88), indicating its strong generalization capability and suitability. Gradient Boosting and LightGBM achieved accuracy levels of 94.96% and 94.38%, respectively. In contrast, XGBoost performed poorly in comparison to other boosting models. Extra Trees and Random Forest achieved moderate results indicating their limited predictive performance. The Decision Tree model achieved the lowest accuracy and the highest error rates, underscoring its inadequacy.

TABLE II. Model Performance with the Traditional Approaches

Model	MAE	MSE	RMSE	Accuracy (%)
CatBoost	1.38	3.55	1.88	98.32
Gradient Boosting	2.53	10.63	3.26	94.96
LightGBM	2.68	11.87	3.45	94.38
XGBoost	3.83	23.60	4.86	88.82
Extra Trees	4.39	30.44	5.52	85.58
Random Forest	4.54	32.03	5.66	84.83
Decision Tree	7.18	85.43	9.24	59.52

CatBoost, as an individual model, consistently outperformed all ensemble combinations as well, that include CatBoost combined with Decision Tree, Random Forest, Extra Trees, Gradient Boosting, XGBoost, and LightGBM (ensemble-2), and CatBoost combined with any two of the individual models (ensemble-2). Despite ensemble methods generally being expected to enhance performance by combining model strengths, in this case they introduce more weaknesses by combining model weaknesses [46]. This highlights that ensembling is not always effective, contrary to the findings reported in [45].

The accuracy curves of the regressors, presented in Fig. 3, initially stay flat or slightly rise for most of the models, indicating that the early-eliminated lower-ranked features have little contribution to prediction performance. CatBoost consistently outperforms all other models across nearly the entire range of feature numbers. The CatBoost curve peaks at 98.53% accuracy, which is obtained with 35 features. Its accuracy increases from 98.32% as the number of features is progressively decreased from 54 to 36. But after 35, the accuracy starts to drop, implying that more feature removal eliminates significant predictors. Additionally, it implies that features outside of the top 35 are redundant and have minimal contribution to the prediction.

Similar trends are observed for Gradient Boosting, LightGBM, XGBoost, Extra Trees, and Random Forest. In contrast, the Decision Tree model consistently exhibits the lowest overall accuracy. Its curve stays comparatively flat with a few oscillations.

For better interpretability, the SHAP summary plot is presented in Fig. 4. The magnitude and direction of the top features' contributions to the model's predictions are clearly shown in this plot. The feature label 'MIQ#' corresponds to specific MI-related question numbers as sequenced in the dataset. Each point on the plot represents a single observation. The horizontal position represents the SHAP value (the feature's contribution to the model output), and the colors represent the actual values of the feature. Red color means high values, and blue color means low values. The continuous gradient from blue to red graphically displays the range of feature values, making it easier to determine whether higher or lower feature values contribute positively or negatively to the predictions. For instance, for the most important feature, MIQ#32, higher feature values (red points) have positive contributions, as indicated by points located on the right side

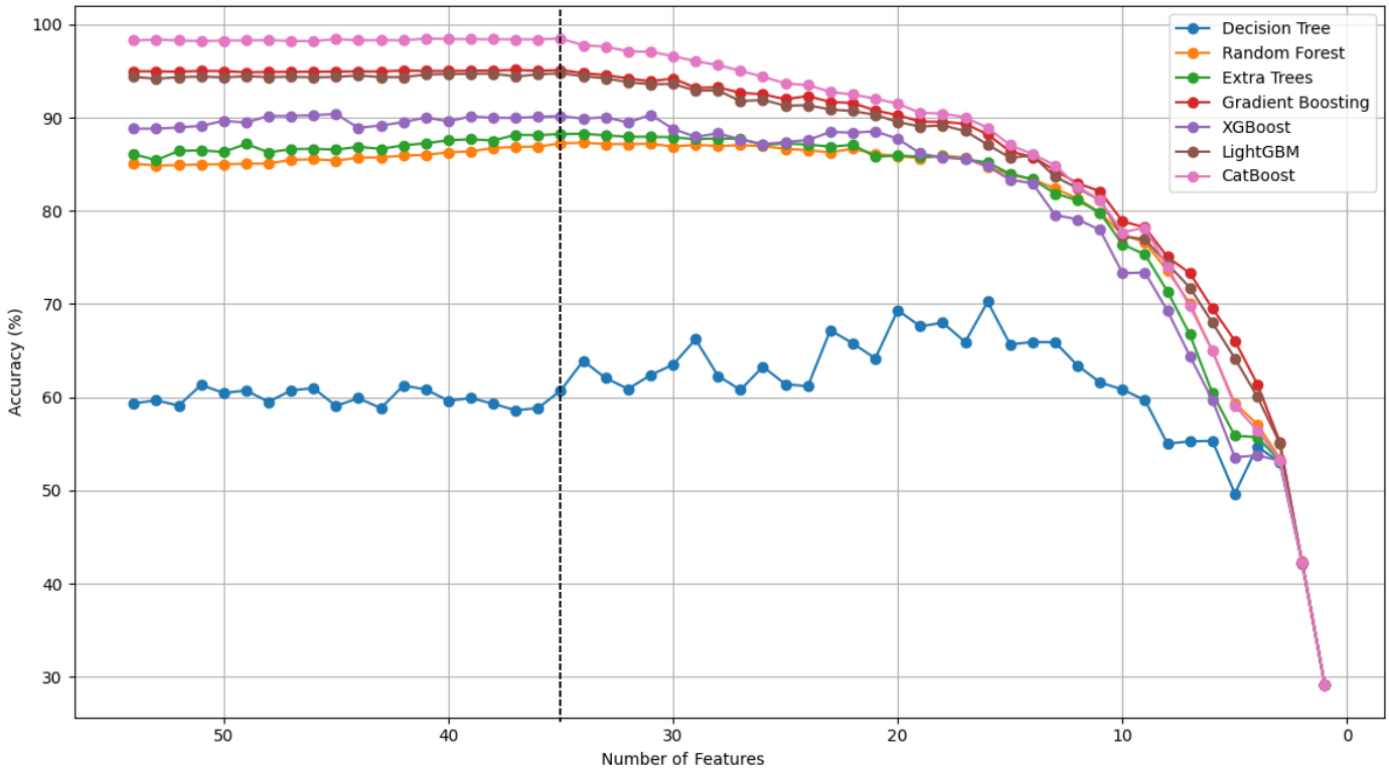


Fig. 3. Accuracy curves for all regression models.

of the axis, whereas lower values (blue points) correspond to negative contributions on the left side. Similarly, MIQ#5 and MIQ#9 display comparable trends, where higher feature values increase the predicted outcome, while lower values lessen it. MIQ#24 shows a wider distribution of SHAP values across mid- to high-range feature values (represented by purple to red points), suggesting that its influence on the prediction may vary in interaction with other variables. The SHAP values of features that are listed lower in the plot have a smaller range and variation, indicating a relatively modest, yet statistically significant, effect on the models' predictions.

Table III shows the performance metrics of the regressors following feature selection with SHAP-based RFE. When compared to the baseline results in Table II, which utilized all 54 features, Table III demonstrates consistent performance gains across all models after feature selection. CatBoost remained the top performer, increasing accuracy from 98.32% to 98.53%. Gradient Boosting's accuracy increased from 94.96% to 95.11%. The accuracy of LightGBM also increased from 94.38% to 94.76%. XGBoost, showed a greater improvement. Its accuracy increased from 88.82% to 90.19. Extra Trees and Random Forest, achieved improved accuracies from 85.58% to 88.14% and 84.83% to 87.30%, respectively. Relatively, the highest improvement is observed in the Decision Tree model. Its accuracy rose sharply from 59.52% to 60.82. Although it remains the least accurate among all models.

In summary, feature selection using SHAP-based RFE have enhanced all regressors' predictive precision (improvement in accuracy and reduction in error metrics). Notably, external learner factors showed no measurable influence on the prediction of innate intelligence scores within the current ML framework. These findings reinforce previous research, which emphasizes the use of SHAP values and RFE for improving model accuracy, transparency, and interpretability in multi-domain prediction tasks [45], [46], [49], [50].

TABLE III. MODEL PERFORMANCE ON SELECTED FEATURES

Model	MAE	MSE	RMSE	Accuracy (%)
CatBoost	1.25	3.09	1.76	98.53
Gradient Boosting	2.46	10.32	3.21	95.11
LightGBM	2.55	11.06	3.33	94.76
XGBoost	3.63	20.70	4.55	90.19
Extra Trees	3.92	25.03	5.00	88.14
Random Forest	4.13	26.80	5.18	87.30
Decision Tree	7.34	82.68	9.09	60.82

B. Future Work and Applicability Scope

The findings of this study offer various potential avenues for advancement in educational design, learner assistance, and institutional policy and decision making. As presented in Fig. 5, based on the proposed intelligence prediction model, the following future research prospects and application areas are suggested for further exploration and practical implementation.

1) Data-driven admissions or placement decisions: Innate intelligence prediction could be used to complement standard admission criteria, allocate scholarships, or place students in advanced learning programs. By including a measure of learning capacity in addition to prior performance or exam results, this method would allow for more equitable selection.

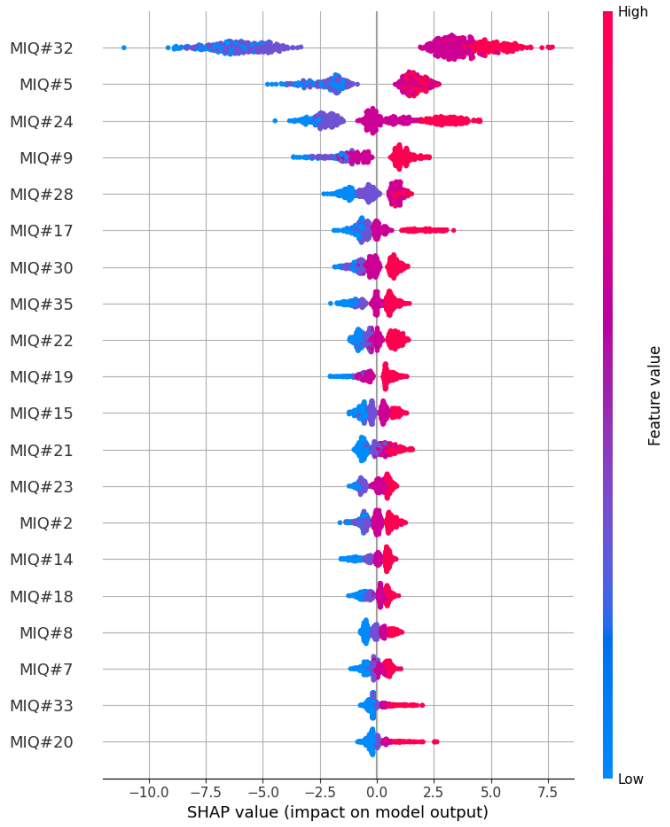

Fig. 4. Visualization of the impact of the top 20 features on the CatBoost model using SHAP.

2) Adaptive institutional practice and policy: The predicted intelligence score can serve as a good indicator of a learner's overall ability to receive, process, and apply newly acquired knowledge. Institutions could use it to forecast general academic performance or learning outcomes and group learners to allocate mentoring or resources accordingly.

3) Personalized teaching strategy design: Intelligence scores can be used as a basis for personalizing teaching strategies. In order to achieve equitable results, learners with higher intelligence scores can be given accelerated modules or enrichment activities; those with medium intelligence scores can benefit from regular instruction with occasional support; and those with lower intelligence scores can be assisted with structured and practice-based learning strategies.

4) Strategic curriculum planning: At the course or program level, average intelligence scores across groups of students could be used to inform syllabus pace and complexity design. For instance, to better match students' innate abilities, educational institutions may design differentiated tracks (basic, intermediate, and advanced).

5) Intelligent tutoring systems' personalization: Learners' intelligence scores could be used by intelligent tutoring system platforms to adapt the way content is delivered. For example, the complexity of challenges or tasks, variation in examples, and the use of simplified instructions according to learners' ability ranges can be incorporated. This would improve learning efficiency and synchronize involvement in educational settings.

6) Learning analytics dashboards for monitoring and planning: Innate intelligence can be integrated with learning analytics systems to deliver actionable and anticipatory information. Based on students' intelligence scores, these dashboards may provide focused intervention plans, specialized support services, or alternate educational techniques.

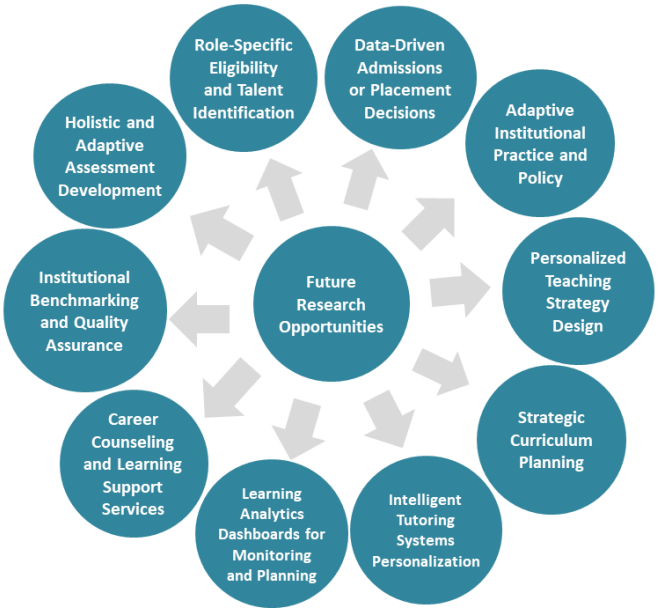

Fig. 5. Potential application areas of ML-based human intelligence modeling.

7) Career counseling and learning support services: Counselors can use intelligence scores to help students choose occupation possibilities that are compatible with their cognitive strengths. Students with high intelligence scores, for example, might do well in multidisciplinary studies, professions demanding quick decisions, or research-oriented positions requiring critical thinking.

8) Institutional benchmarking and quality assurance: Institutions could analyze the distribution of intelligence scores among the students to determine whether instruction standards, resource allocation, or students' learning outcomes are in line with learner potential. This can assist with accreditation, policy adjustments, and educational reform.

9) Holistic and adaptive assessment development: Knowing a student's intrinsic intelligence would allow teachers to apply assessments other than written tests. For instance, integrative projects could be used to assess students with high innate intelligence, while assessments for other students might use more scaffolding or different formats, like hands-on activities. While this study predicts intelligence as a composite indication, subsequent future research will concentrate on predicting intelligence type-wise scores independently in order to better aid specialized applications.

10)Role-specific eligibility and talent identification: Overall intelligence scores, like CGPA in competitive fields, could be used as benchmarks for roles requiring cognitive rigor. For example, programs may set minimum intelligence score requirements in place of or beside the CGPA. Likewise, just

as subject-wise grades determine eligibility for certain careers, intelligence-type specific scores could inform role suitability. For instance, military or sports training institutes might require high bodily-kinesthetic and logical-mathematical intelligences. These intelligence scores could be used as minimum marks or GPA in specific subjects (e.g., needing a minimum GPA in Math and Physics) for eligibility.

Along with these application areas and prospects, this research has some limitations that provide more scope for future work. The LML dataset utilized in this study only includes data from students in the age group of 18 to 27. Therefore, the results may not be directly applicable to pedagogical (child-centered) applications and are most relevant to andragogy and heutagogy. Future research could include data from a wider range of age groups, cultural backgrounds, geographic regions, and educational systems to broaden the generalizability of the findings. Furthermore, while this study used seven well-known ML models with SHAP and RFE, these are not the only potential models and methods. Subsequent investigations may examine more advanced models and approaches like deep neural networks, graph-based models, or hybrid frameworks to explore more about the results and possibly enhance interpretability. A direct comparison with similar approaches within a shared evaluation framework was not possible to conduct due to the absence of comparable methods, but can be performed once such methods become available.

V. Conclusion

In conclusion, this study demonstrated the effectiveness of ML models, enhanced by SHAP-based feature analysis, in accurately predicting innate human intelligence. The findings provide interpretable and actionable insights, paving the way for the development of personalized educational strategies, advancing educational AI practices, and enabling policy-relevant interventions aligned with the fourth SDG: Quality Education. In particular, they highlight that intelligence can be modeled holistically and reliably without relying on conventional subject-specific assessments or IQ tests. Real-world educational outcomes can be enhanced by complementing existing educational practices with the proposed method for predicting learners' intelligences. This study has implications for educators, institutions, policymakers, and future AI-driven educational systems, and promotes the use of AI-powered, data-driven, learner-centric techniques to address learner diversity and support educational decision making.

Funding

This research was funded by Multimedia University, Cyberjaya, Selangor, Malaysia (Grant Number: Post-Doc(MMUI/240029)).

Institutional Review Board Statement

The study is conducted in accordance with relevant guidelines and national regulations. The Biosafety, Biosecurity, and Ethical Clearance Committee at Jahangirnagar University in Bangladesh provided ethical approval for the creation and analysis of the LML dataset involving human data (Reference No.: BBEC, JU/M 2022/01 (18); Date of approval: 04 July 2022). Since the dataset contains non-medical data, the Declaration of Helsinki does not apply when utilizing it for non-medical purposes.

Informed Consent Statement

All participants were well informed of their anonymity, the goal of the study, and how their responses would be utilized. Survey responses were collected using a Google form. Consent to participate in the survey and consent to publish anonymized data were obtained using the same Google form. After reading the information consent form, participants had to agree to participate before they could continue on to the survey. Before submitting the completed questionnaire, participants were requested for their further approval to have their anonymized data published collectively for research purposes via an online platform. Only those who selected "Agree" for publishing consent were able to submit survey responses; no information was collected for those who did not give both consents.

Data Availability Statement

The data that support the findings of this study are openly available in the Zenodo repository at zenodo.org/records/8382187.

Inter-Robots Position Estimation Using UWB Positioning Devices for Distributed Cooperative Control of Multiple Robots

Airi Kojima, Kohei Yamagishi, Tsuyoshi Suzuki
Department of Information and Communication Engineering,
Tokyo Denki University, Tokyo, Japan

***Abstract*—Ultra-wide band (UWB)-based positioning methods for static environments have been continuously improved; however, many existing approaches rely on fixed reference nodes, and methods for directly computing relative positions among mobile units have not been sufficiently investigated. This paper presents a relative positioning approach for multi-robot systems using UWB wireless communication within a distributed cooperative control framework. In the proposed approach, multiple UWB positioning devices are arranged in regular polyhedral configurations to improve the uniformity of ranging accuracy. Robot coordinates are estimated using a nonlinear least-squares optimization method formulated from a system of simultaneous distance equations, enabling mutual relative position estimation among robots. Simulation experiments were conducted to evaluate estimation accuracy and error characteristics under different geometric configurations. Four configurations: square, tetrahedron, regular tetrahedron, and regular octahedron were considered, and their error magnitudes and axis-wise distributions were compared. The simulation results indicate that the proposed configuration achieve lower estimation errors than the other configurations evaluated. Based on these findings, experimental verification was performed, and the observed trends were consistent with the simulation results. This work provides a systematic investigation of a mutual positioning system that enables robots to estimate their positions with respect to one another without relying on fixed landmarks. Unlike existing method, our approach enables the determination of relative positions between robots based on distances measured by each robot. The proposed approach is expected to be applicable to autonomous decentralized control in multi-robot systems operating in static environments.**

***Keywords*—Mobile robots; distributed cooperative control; mutual positioning system; relative position estimation; UWB positioning devices; geometric structure**

I. Introduction

Autonomous decentralized systems that operate multiple robots are being applied to distributed tasks, such as logistics systems, which cannot be effectively addressed by individual robot [1]. In such systems, robots recognize one another in an environment populated by multiple agents and adapt their actions based on exchanged information, resulting in the achievement of shared objectives [2]. In natural ecosystems, such interactions generate collective behavior that sustains life within a herd. When applied to robotic systems, this approach allows coordinated behavior to be adjusted in a self-organized manner when part of the system fails or the environment changes, thereby enhancing flexibility, diversity, and fault tolerance [3]. In an ideal autonomous decentralized system, each robot cooperates autonomously with surrounding robots to achieve the objectives of the overall system [4].

This interaction relies on localized sensing and communication, enabling robots to recognize and exchange information with each other. While this requirement can be addressed through global observation and network-based broadcasting using camera- and network-based systems, such approaches face challenges due to the complexity of robot and systems [5]. To overcome these challenges, an ideal distributed cooperative system based on local robotic interactions is required.

To implement such distributed cooperative control, each robot should be equipped with two types of devices: one for recognizing surrounding robots and the environment, and another for local communication with neighboring robots [6]. Existing implementations often rely on multiple devices for recognizing objects using LiDAR [7] and GNSS [8], and for communication using Bluetooth and other communication technologies [9]. However, this results in increased system complexity and limited stability [10]. Therefore, a unified solution that enables both sensing and communication is desirable.

Ultra-wideband (UWB) wireless communication devices have attracted attention as promising candidates for such unified solutions. In addition to providing wireless communication, UWB technology enables highly accurate positioning by measuring time differences in the arrival of radio waves [11], [12]. This capability allows a single UWB device to support both communication and positioning for decentralized control of multiple robots, eliminating the need for multiple devices [13].

This paper proposes a method for estimating the three-dimensional relative positions of multiple robots using UWB positioning devices. Our primary contribution is the development of a technique that enables each robot to estimate relative position to other robots, thereby facilitating effective autonomous decentralized control in systems comprising two or more robots. Unlike existing approaches, the proposed method enables the determination of positions between neighboring robots based on the distance information collected by each robot.

The remainder of this paper is organized as follows. Section II reviews related work. Section III presents a method for estimating the three-dimensional relative positions between multiple robots. Section III-A describes the system design, and Section III-B provides a detailed explanation of the methodology. Sections IV and V present simulations using the error

characteristics of UWB technology and experiments conducted using actual hardware, along with the results. Finally, the conclusions and future work are discussed in Sections VI and VII, respectively.

II. Related Work

Various approaches have been proposed to realize sensing and communication for distributed multi-robot systems. For positioning, a range of devices has been explored, including LiDAR and GNSS, while Bluetooth and other wireless technologies have been investigated for inter-robot communication. However, a robot configuration that relies on multiple heterogeneous devices increases system complexity and reduces overall stability.

Conventional UWB-based positioning methods typically involve placing fixed devices at the same height at the four corners of a positioning space, as illustrated in Fig. 1a, while mobile devices move within this space [14]. The coordinate of each mobile device is calculated based on the absolute coordinates of the fixed devices measured by the UWB devices. However, when all fixed devices are positioned at the same height, accurate estimation of vertical position becomes difficult.

To address this limitation, Zhou *et al*. demonstrated that positioning accuracy can be improved by varying the heights of the fixed devices, as illustrated in Fig. 1b [15]. Furthermore, positioning methods using UWB devices in static environments are being continually improved, and some studies have extended these approach to relative positioning by incorporating triangulation techniques [16]. In such methods, four devices measure the distances between one another to estimate their relative positions, enabling applications to systems comprising four or more robots.

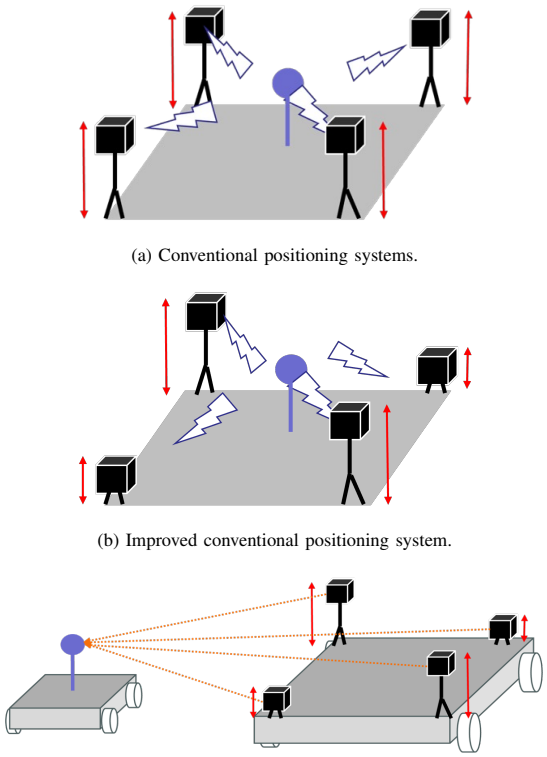
In addition, relative position estimation methods for robots equipped with multiple UWB devices has been developed [17]. This involved a system in which one robot is equipped with a fixed reference device, as shown in Fig. 1c, which enables it to estimate the position of other robots. However, because one unit functions as a landmark, mutual localization among robots has not yet been investigated.

In contrast to these existing approaches, this study focuses on mutual relative position estimation among multiple robots using UWB devices, without relying on fixed landmarks or global references.

III. Proposed Method

A. System Configuration

Each node is equipped with a positioning system in which the transmitting UWB device are positioned at the vertices of a regular polyhedron, as illustrated in Fig. 2, while a receiving UWB device is positioned at the center of the regular polyhedron. This configuration ensures that the transmitters are uniformly distributed over the entire perimeter, thereby improving ranging accuracy [18]. Within the environment where a node is located, the node can measure the relative distance of transmitters belonging to other nodes using its self-mounted receiver. If the coordinate system of the regular polyhedron formed by the transmitters is known, the relative coordinates to another node can be obtained by calculating the intersection of the distances between the receiver and transmitters.



(a) Conventional positioning systems.

(b) Improved conventional positioning system.

(c) Positioning that enables robots to know each other's locations.

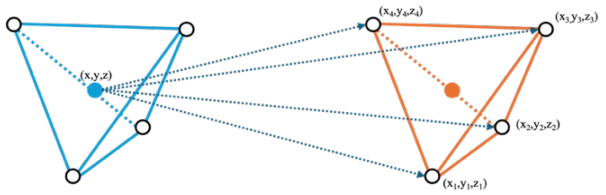
Fig. 1. UWB positioning device placement method.

Conventional UWB-based positioning methods require four or more reference points to identify spatial coordinates [19]. Similarly, GNSS-based systems employ four-point surveying, in which distances to four satellites are measured to determine position [20]. This principle is also applied to UWB systems because it enables more efficient and accurate spatial coordinate estimation than conventional techniques.

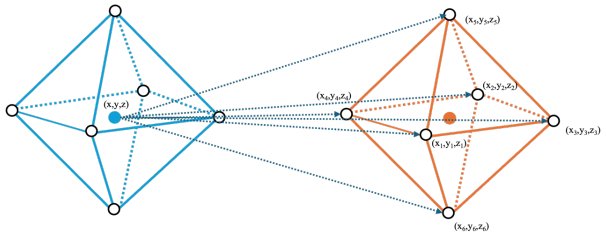
B. Coordinates Calculation-Based on n-Polyhedron

Based on this principle, the proposed method utilizes distance measurements from a minimum of $n = 4$ transmitters to estimate the the three-dimensional coordinates (x, y, z) of the receiver. Let the coordinates of the transmitters be (x_1, y_1, z_1), (x_2, y_2, z_2), ..., (x_n, y_n, z_n), and let the measured distances between the receiver and each transmitter be r_1, r_2, ..., r_n. This receiver position satisfies the following system of n equation:

$$\left.\begin{aligned} (x-x_1)^2+(y-y_1)^2+(z-z_1)^2-r_1^2=0 \\ (x-x_2)^2+(y-y_2)^2+(z-z_2)^2-r_2^2=0 \\ \vdots \\ (x-x_n)^2+(y-y_n)^2+(z-z_n)^2-r_n^2=0 \end{aligned}\right\} \quad (1)$$



(a) Tetrahedron (with four devices).



(b) Octahedron (with six devices).

Fig. 2. Component systems.

Theoretically, based on Eq. (1), only one spatial coordinate can be determined. However, in practical scenarios, measurement errors are superimposed on the observed distances, and the system of equation is not satisfied exactly. In this study, an approximate solution is obtained by solving a nonlinear least-squares problem. The measured distances r_i are used as initial values, and the solution is iteratively refined until convergence to the coordinates (x, y, z) that best satisfy Eq. (1).

IV. Comparison of Errors by Simulation

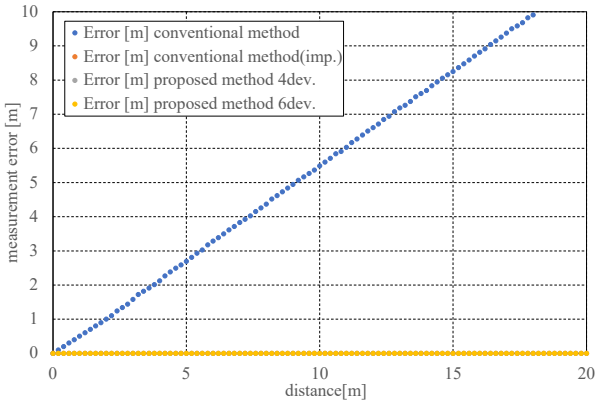
A. Experimental Overview

Simulations were conducted to evaluate the extent to which the proposed method reduces estimation error compared to the conventional methods. Specifically, the variation in error with respect to geometric shape and size was analyzed.

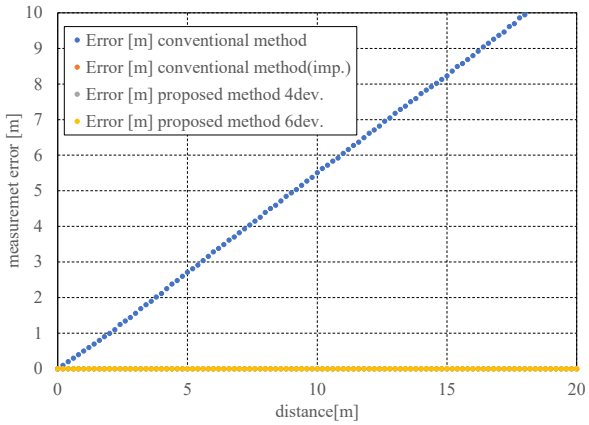
The following configurations were compared: a square configuration representing the conventional method, in which the transmitting devices arranged on the same plane; a tetrahedral configuration similar to the conventional method but with different device heights, and proposed configurations using a regular tetrahedron (Fig. 2a) and a regular octahedron (Fig. 2b).

As part of the experimental conditions, the length of one side of each configuration was set to 0.25 and 0.5 m. These values were selected because the proposed system is intended for estimating the relative positions of mobile robots, and thus the onboard positioning system must be as compact as possible. The distance between the receiving and transmitting devices was varied from 0 to 20 m in increments of 0.2 m. For each condition, the calculation was repeated 100,000 times, and the average error was computed.

All simulations were performed using Python 3.7.9, with the Numpy 1.21.6 and Scipy 1.7.3 libraries.



(a) Side length: 0.25 m.



(b) Side length: 0.5 m.

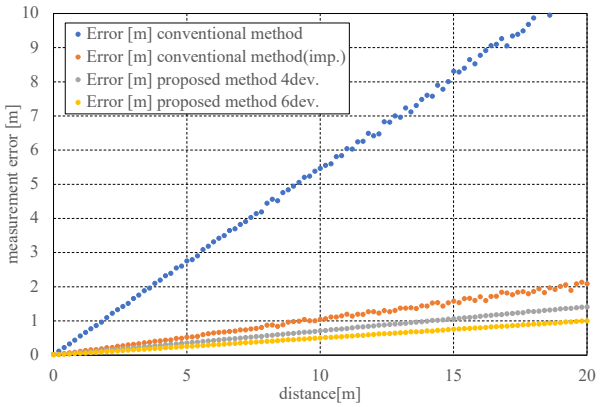
Fig. 3. Experimental results (without error).

B. Experimental Results

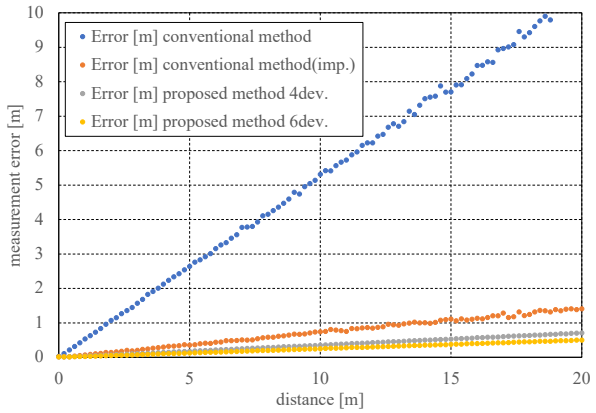
The simulation results showing the change in error with the distance are presented in Fig. 3. Fig. 3a and 3b correspond to side lengths of 0.25 and 0.5 m. For the conventional square configuration, the estimation error increases proportionally with distance, regardless of side length. In contrast, the errors associated with the other configurations remain almost negligible. These results indicate that three-dimensional configurations, such as the tetrahedral and octahedral arrangements, provide improved ranging accuracy compared with the planar square configuration.

Fig. 4 presents the results of simulations evaluating the effect of mixed measurement errors. In these simulations, a measurement error with a standard deviation of 0.01 m was superimposed on the ranging distance r_i, corresponding to a 1σ uncertainty. Given that UWB positioning typically achieves accuracy on the order of several centimeters, a minimum error of 0.01 m was added to the distance measurements to account for realistic measurement uncertainty [21].

Under these conditions, the square configuration exhibited the largest estimation error, whereas the regular polyhedral configurations proposed in this paper demonstrated smaller errors than both the square and tetrahedral configurations. Among the regular polyhedrons, the regular octahedron con-

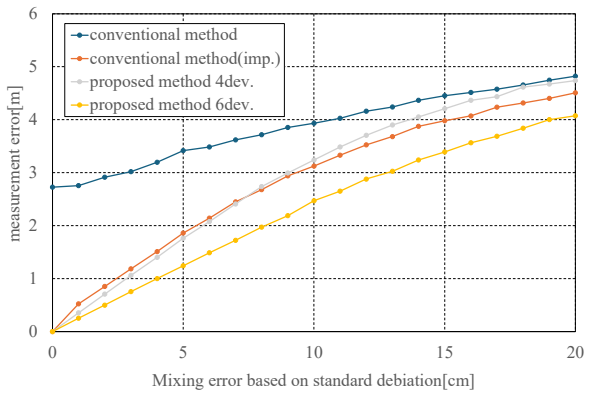


(a) Side length: 0.25 m.

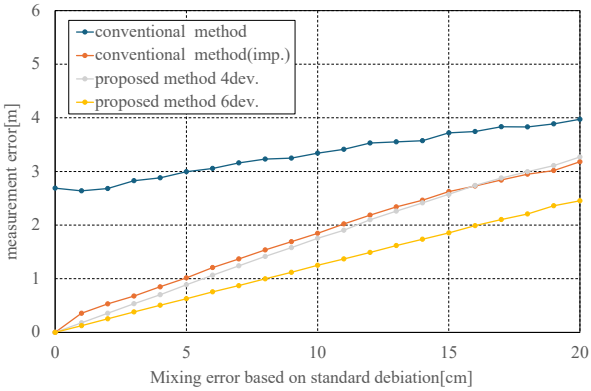


(b) Side length: 0.5 m.

Fig. 4. Experimental results (mixing error: 0.01 m).



(a) Side length: 0.25 m.



(b) Side length: 0.5 m.

Fig. 5. Comparison of errors by mixing error (5m point).

sistently yielded lower errors than the regular tetrahedron. This improvement can be attributed to the increased number of equations resulting from a larger number of positioning devices.

The effects of increasing mixed error magnitude are shown in Fig. 5. Fig. 5a and 5b correspond to side lengths of 0.25 and 0.5 m, respectively. In both cases, the square configuration produced the largest error, consistent with the trends shown in Fig. 3 and 4. As the mixed error increased, the estimation errors for the tetrahedral configuration and the proposed regular tetrahedral configuration gradually converged. For the 0.25-m condition, the error associated with the tetrahedral configuration exceeded that of the square configuration when the mixed error exceeded 0.13 m. This discrepancy is attributed to the sensitivity of the optimization process to the initial values used in the simulation. At a mixed error of 0.13 m, the resulting error range was approximately 0.4 m, rendering the system unsuitable for practical distance measurement.

For the 0.5-m condition, both the tetrahedral and octahedral configurations exhibited increased estimation error as the mixed error increased. However, unlike the 0.25-m condition, the square and tetrahedral configurations demonstrated smaller changes in error compared with the regular tetrahedral configuration. Among the regular polyhedrons, the regular octahedral configuration demonstrated lower errors and higher accuracy than the regular tetrahedral configuration, as shown in Fig. 3.

Both the theoretical and experimental results, even with accounting for measurement errors, indicate that proposed regular polyhedral configurations yield smaller estimation errors. Compared with conventional methods, the use of regular octahedrons reduced the estimation error by approximately half. These results demonstrate that the regular polyhedral configuration employed in the proposed method enhances the accuracy of relative position estimation and reduces sensitivity to measurement noise.

Fig. 6 shows the simulation results for error distribution along each coordinate axis, obtained using theoretical distances without mixed errors. Fig. 6b and 6c show the results for the proposed regular tetrahedral and octahedral configurations, respectively. Fig. 6 illustrates the squared error for each configuration under the conditions with a side length of 0.5 m. By analyzing the squared error, the contribution of each axis to the overall estimation error can be evaluated.

As shown in Fig. 6a, the square configuration exhibits minimal errors along the x- and y-axes, while most of the error is concentrated along the z-axis. This indicates that the conventional square configuration significantly degrade the position estimation with respect to height. In contrast, the tetrahedral

Fig. 7. Illustrated summary of experiment: n in the figure changes the length of a side depending on the experimental conditions.

and octahedral configurations exhibit more balanced error distributions across each axis, with overall error magnitudes smaller than those of the conventional configulation.

These results demonstrate that the proposed method more effectively reduces estimation error and achieves a more uniform error distribution across all axises than the conventional methods. Consequently, the use of regular polyhedral configurations improves position estimation performance and enables more reliable and uniform ranging.

V. Field Experiments

A. Experimental Overview

Field experiments using UWB positioning devices were conducted to compare the positioning errors of the conventional and proposed methods based on actual measurements. The UWB device used in this study was the type 2AB module manufactured by Murata, which incorporates the Qorvo QM33120W UWB chip [22].

For the conventional method using a square configuration, the transmitting devices were arranged with side lengths of either 0.25 or 0.5 m. Because multiple placement planes are possible for the square configuration, positioning experiments were conducted in both the xy-plane and xz-planes. For the proposed method, regular polyhedral configurations were employed under the same conditions as those used in the simulations, specifically tetrahedral and octahedral arrangements. Regular tetrahedron and octahedron with side lengths of 0.25 or 0.5 m were constructed, with UWB modules placed at each vertex as transmitting devices.

In all configurations, the receiving device was fixed at a height of 1 m, and the distance from the center of the unit was varied from 1.0 m to 2.5 m in increments of 0.5 m. The maximum distance was limited to 2.5 m because the experiments were conducted within the measurable range achievable under the regular polyhedral configuration. Each experimental deployment consisted of multiple positioning

TABLE I. MEASUREMENT ERROR IN LINEAR DISTANCE FOR EACH SHAPE (SIDE LENGTH: 0.25 M)

	Measurement Error[m]			
	Conventional method		Proposed method	
Distance [m]	xy-plane	xz-plane	4 devices	6 devices
1	0.995	1.000	0.212	0.403
1.5	1.479	1.500	0.238	0.389
2	1.983	1.933	0.427	0.395
2.5	2.479	2.338	0.575	0.739

TABLE II. MEASUREMENT ERROR IN LINEAR DISTANCE FOR EACH SHAPE (SIDE LENGTH: 0.5 M)

	Measurement Error[m]			
	Conventional method		Proposed method	
Distance [m]	xy-plane	xz-plane	4 devices	6 devices
1	0.995	1.000	0.108	0.191
1.5	1.492	1.500	0.198	0.131
2	1.988	2.000	0.395	0.247
2.5	2.483	2.500	0.491	0.436

points comprising a set of transmitter devices and a single receiver. A schematic of the experimental setup is shown in Fig. 7. All experiments were conducted in a lecture room at the Tokyo Senju Campus of Tokyo Denki University.

For evaluation, 500 datasets were collected for each condition, and the positioning error was calculated using the nonlinear least-squares method. The mean error and the universal standard deviation were used as evaluation metrics. Python 3.7.9 was used for optimization, and the least-squares solution was computed using the Scipy 1.7.3 library.

B. Experimental Overview

Tables I and II present the linear distance errors calculated using for each configuration. The results show that both the tetrahedral and octahedral configurations yield reduced errors compared with the square configuration. A comparison between the xy- and xz-plane arrangements indicates that the error does not differ significantly between them, although slightly lower errors were observed in the xy-plane. Furthermore, a comparison between the tetrahedral and octahedral configurations revealed that, in contrast to the simulation results, the tetrahedral configuration produced smaller errors than the octahedral configuration in the field experiments. This discrepancy is attributed to the measurement noise in the actual ranging data, whose influence depends on the magnitude of the measurement error. In addition, the observation that the errors were smaller for a side length of 0.5 m than for 0.25 m can be explained by the resolution of the UWB device used in this study, which measures distance with centimeter-level granularity.

Fig. 8 shows a comparison of the squared error components for each axis. Similar to the linear distance error, the squared errors were smaller for the tetrahedral and octahedral configurations than the square configuration. The squared errors for the square configurations were larger for the xz-plane than for the xy-plane. In Fig. 8a, errors occurred predominantly along the y-axis. This behavior can be attributed to the fact that the transmitting device farthest from the receiving device was located along the y-axis, making the measurements more susceptible to interference from radio waves generated by other wireless communication systems. In Fig. 8b, the squared errors were distributed across both the x- and z-axes. Unlike Fig. 8a, where the distances between the transmitting and receiving devices were uniform, the presence of similar measurement errors across all ranging data in the xz-plane led to the error distribution shown in Fig. 8b.

Subsequently, the results of the proposed polyhedral configurations are discussed. Notably, although the octahedral configuration exhibited relatively large linear distance errors at a distance of 1 m, its squared error was smaller than that of the tetrahedral configuration. This behavior is attributed to the proximity of transmitting device C to the receiving device in the octahedral configuration, which results in less stable measurements at short distances. However, at other measurement points, the octahedral configuration yielded smaller errors, leading to reduced least-squares error values consistent with the simulation results.

In the conventional square configuration, estimation errors tend to accumulate along specific axes, making accurate three-dimensional relative position estimation difficult. In contrast, the proposed regular polyhedral configurations reduce error components along each axis, enabling more accurate and balanced three-dimensional relative position estimation. These results demonstrate that the proposed method can effectively estimate the three-dimensional relative positions of multiple robots, which is the primary objective of this study.

VI. CONCLUSION

In this study, we propose a ranging system that employs a regular polyhedron to develop a relative position estimation method for mobile robot distributed cooperation systems. Simulations demonstrated that, compared to conventional methods, the proposed approach significantly reduces error. Verification through actual distance measurements confirmed that the proposed method effectively minimizes errors relative to conventional techniques. However, some experimental results from actual ranging showed larger errors than those observed in simulations. This discrepancy is attributed to radio wave interference in the experimental environment. The proposed method is most effective when high-precision ranging is achievable. This technique enables each robot to estimate its position relative to others, which is essential for implementing effective autonomous decentralized control in systems with two or more robots.

VII. FUTURE WORK

In the future, we will increase the number of faces, compare the accuracies of various polyhedral structures, and implement them in mobile robots as a method for relative position estimation. The proposed approach has the potential to facilitate the deployment of multi-robot systems in environments where GNSS is unavailable, such as underground spaces, indoor settings, and extraterrestrial locations. However, reducing the unit size results in decreased positioning accuracy, highlighting the need for an effective solution to integrate the system into a single device.

***Abstract*—While current semantic segmentation models excel in controlled environments, they often struggle with key challenges such as dynamic multi-modal data, small target recognition, and computational efficiency for edge deployment. Motivated by these limitations, this study explores targeted solutions and presents DAMCSeg (Dynamic Adaptive Multi-modal Collaborative Semantic Segmentation), an innovative framework that introduces advancements across feature fusion, training paradigms, and model efficiency. The core contributions of DAMCSeg include: 1) a Dual-Stage Attention Fusion (DSAF) module that dynamically adjusts multi-branch fusion weights based on scene complexity; 2) an end-to-end joint training framework for object detection and semantic segmentation designed to minimize inter-stage error propagation; and 3) a Lightweight Multi-Modal Fusion (LMMF) module that efficiently integrates multi-source data with low computational overhead. To rigorously evaluate the proposed method's effectiveness against these specific challenges, extensive experiments are conducted on mainstream benchmark datasets. The results demonstrate that DAMCSeg achieves high accuracy and operational efficiency, effectively addressing critical issues in dynamic scene adaptation, complex target segmentation, and edge device deployment. This provides a practical and viable solution for semantic segmentation in demanding applications such as autonomous driving and medical image analysis.**

Keywords*—Dynamic Adaptive Multi-Modal Collaborative; Dual-Stage Attention Fusion (DSAF); End-to-End Detection-Segmentation Joint Framework; Lightweight Multi-Modal Fusion (LMMF)

I. Introduction

As a fundamental pillar of computer vision, semantic segmentation performs pixel-wise classification of images, enabling machines to interpret visual scenes with fine-grained understanding. This technology has become indispensable in real-world applications including autonomous driving, medical imaging, and intelligent surveillance systems. While deep learning—particularly through CNN and Transformer architectures—has dramatically advanced the state of the art, current segmentation models still encounter several critical limitations. For instance, the pursuit of high-level semantic representation often comes at the cost of weakened spatial detail preservation, which hampers accuracy on small objects and intricate boundaries. Moreover, conventional multi-branch fusion approaches frequently rely on fixed weighting schemes, lacking the flexibility to dynamically adapt to varying scene conditions. The dependence on single-modal data further restricts robustness under challenging environments like low illumination or significant occlusion. Additionally, many high-accuracy models incur substantial computational costs, hindering their deployment in real-time or resource-constrained settings.

Current mainstream semantic segmentation models can be divided into three categories: first, classic CNN-based models (e.g., DeepLab v3+ [1], PSPNet[2]), which improve context modeling capabilities through modules such as dilated convolution and pyramid pooling, but have shortcomings in small target segmentation and dynamic scene adaptation; second, Transformer-based models (e.g., SegFormer [3], Mask2Former [4]), which enhance feature correlation through global attention mechanisms, but suffer from slow inference speed and high computational cost; third, lightweight models (e.g., ENet [5], MobileNet-based [6] segmentation networks), which meet real-time requirements but have room for improvement in segmentation accuracy and robustness. Although recent multi-modal semantic segmentation approaches aim to enhance robustness under sensor degradation, many still assume complete modality inputs or employ static fusion strategies. For instance, early methods like FusionNet [7] focus on LiDAR completion rather than adaptive segmentation, while more recent works such as MM-Seg [8] and AdaFuse [9] explicitly address missing-modality scenarios through cross-modal prompting and learnable gating, respectively. However, these models operate with uniform fusion policies across the entire image and do not leverage cross-task geometric priors (e.g., from object detection) to resolve ambiguities in occluded or small-scale regions—a critical limitation in autonomous driving scenarios. This gap motivates our design of a dual-stage, detection-aware fusion mechanism.

To address the above issues, this paper proposes the DAMCSeg method. While components like attention-based fusion, joint training, and multi-modal integration exist in prior work, our key novelty lies in their synergistic combination and the specific design choices that enable a fundamental leap in adaptive capability, rather than mere incremental improvement. Our core innovations are as follows:

- A Dual-Stage Attention Fusion (DSAF) module is introduced, which uniquely decouples adaptation into two complementary levels: global scene-level assessment and local target-level refinement. In contrast to existing single-stage or scene-only aware fusion approaches (e.g., CFNet [10])—which impose a uniform fusion strategy across the entire image—DSAF enables simultaneous handling of simple backgrounds and highly complex, occluded objects within the same frame. This two-tiered mechanism directly addresses the challenge of decoupled global-local complexity, a gap unmet by current frameworks.

*Corresponding author.

- An end-to-end detection-segmentation joint training framework is developed, featuring a novel Detection-Segmentation Alignment Loss. This loss function explicitly penalizes geometric misalignment between predicted bounding boxes and segmentation masks, thereby mitigating error propagation inherent in cascaded or loosely coupled systems. The framework thus establishes a transferable principle for enhancing cross-task consistency through direct optimization of spatial alignment.
- A Lightweight Multi-Modal Fusion (LMMF) module is proposed, capable of fusing RGB with depth or infrared data while incorporating a modal missing complementation mechanism. This design ensures robust inference under partial sensor failure—a critical requirement for real-world deployment that most existing multi-modal models overlook due to their reliance on complete input modalities.
- Targeted loss functions, including a tiny target-focused loss and an occluded region-aware loss, are formulated to provide explicit supervisory signals for the most challenging segmentation scenarios. These losses significantly enhance model robustness in extreme conditions involving small-scale or heavily occluded objects.

Experimental results show that DAMCSeg significantly outperforms current mainstream semantic segmentation models on multiple benchmark datasets. Compared with DeepLab v3+ [1], the average mIoU is increased by 7.0% and the inference speed by 25.7%; compared with SegFormer-B4 [3], the mIoU is increased by 6.6% and the small target mIoU by 14.8%; compared with Mask2Former [4], the inference speed is increased by 128.9% while the mIoU is increased by 3.4%; in extreme scenarios such as low light, the mIoU is increased by 5%-8% compared with single-modal mainstream models. This method breaks the balance bottleneck among accuracy, speed, and robustness of existing mainstream models, providing a new idea for the practical application of semantic segmentation technology.

The main contributions of this paper are summarized as follows:

- Propose a Dynamic Adaptive Multi-Modal Collaborative Semantic Segmentation method (DAMCSeg), which realizes dynamic optimization of multi-branch fusion through a dual-stage attention mechanism to adapt to different scenes and target characteristics;
- Construct an end-to-end joint training framework for object detection and semantic segmentation, and design a cross-task loss function to improve the segmentation accuracy of complex targets and boundary regions;
- Develop a lightweight multi-modal fusion module, supporting multi-source data integration and model compression to achieve coordinated optimization of high accuracy and real-time performance;
- Conduct extensive experiments on multiple benchmark datasets, comparing comprehensively with current mainstream semantic segmentation models to verify the superiority of the proposed method, and provide a practical solution for semantic segmentation in complex and extreme scenarios.

II. Related Work

A. Object Detection

Object detection technology is an important support for semantic segmentation, and its development has evolved from traditional handcrafted feature-based methods to deep learning-based methods. Traditional methods such as the Viola-Jones detector and HOG + SVM rely on manually designed features and have limited generalization capabilities. In the deep learning era, two mainstream paradigms have been formed: two-stage detectors represented by the R-CNN [11] series, which achieve high-precision detection through "region proposal + fine-grained classification"; and single-stage detectors represented by YOLO [12] and SSD [13], which pursue inference speed through "end-to-end direct prediction". In recent years, DETR [14] has introduced the Transformer architecture to realize set prediction without NMS post-processing, and models such as Faster R-CNN [15] enhanced with FPN structures have improved multi-scale detection capabilities.

Some existing mainstream semantic segmentation models (e.g., Mask2Former [4]) integrate object detection ideas, but fail to achieve deep collaborative training between detection and segmentation, resulting in mismatches between localization accuracy and semantic segmentation accuracy. Drawing on the advantages of end-to-end joint training, this paper deeply integrates object detection and semantic segmentation, realizing mutual promotion through a shared feature backbone and cross-task loss function, and providing accurate localization priors for complex target segmentation.

B. Semantic Segmentation

The field of semantic segmentation has formed diverse technical routes, and mainstream models can be divided into three categories:

1) CNN-Based models: The emergence of FCN [16] in 2015 laid the encoder-decoder architecture paradigm for semantic segmentation. Subsequent models such as the DeepLab [17] series introduced dilated convolution and ASPP modules to expand the receptive field, PSPNet [2] aggregated global context information through pyramid pooling, and U-Net [18] restored spatial details using skip connections. These models perform stably in moderately complex scenes but have limitations in small target segmentation and dynamic scene adaptation.

2) Transformer-Based models: Models such as Swin Transformer [19] and SegFormer [3] enhance global context modeling capabilities through multi-head self-attention mechanisms, and Mask2Former [4] improves instance-level segmentation accuracy using a set prediction approach. These models achieve high accuracy but have high computational overhead and slow inference speed, making it difficult to meet real-time requirements.

3) Lightweight and multi-modal models: MobileNet-based [6], ENet [5] segmentation networks, and other lightweight models achieve real-time inference by simplifying network structures, but at the cost of significant accuracy loss; multi-modal models such as MVSS-Net [20] and FusionNet [7] combine RGB with depth/infrared information to improve robustness, but suffer from low modal fusion efficiency and structural redundancy.

Targeting the shortcomings of existing mainstream models, this paper integrates the advantages of efficient feature extraction by CNNs and attention mechanisms by Transformers [21], designing a lightweight multi-modal fusion module and dynamic fusion strategy to achieve coordinated improvement in accuracy, speed, and robustness.

C. Multi-Branch Fusion and Adaptive Mechanisms

Multi-branch fusion is an effective means to improve the performance of semantic segmentation models. Fusion strategies adopted by existing mainstream models mainly include simple average fusion, weighted sum fusion, and attention-based adaptive fusion. HRNet [22] extracts features in parallel through multi-scale branches, and OCRNet [23] introduces context branches to enhance semantic correlation, but both adopt fixed-weight fusion strategies that cannot adapt to dynamic scene changes.

In recent studies, the attention fusion module in CFNet [10] dynamically adjusts branch weights based on feature saliency, and the scene-aware fusion strategy in SA-Fusion [24] optimizes branch selection by evaluating scene complexity, but only realizes single-level adaptive adjustment. This paper proposes a dual-stage attention fusion mechanism to achieve more fine-grained adaptive adjustment from both scene and target levels, further improving the efficiency of multi-branch information utilization and solving the problem of insufficient dynamic adaptation capabilities of mainstream models. Crucially, while prior works have explored elements of adaptivity, modality fusion, or task collaboration in isolation, they fail to address the synergistic gap: the lack of a unified framework that can simultaneously reason about global scene context, local object intricacies, and cross-task geometric consistency under resource constraints. This gap leaves existing models brittle in real-world scenarios where these challenges co-occur. DAMCSeg is designed explicitly to bridge this gap by integrating its three core innovations into a single, coherent system.

In recent studies, the attention fusion module in CFNet [10] dynamically adjusts branch weights based on feature saliency, and the scene-aware fusion strategy in SA-Fusion [24] optimizes branch selection by evaluating global scene complexity. However, both enforce a single-level adaptation policy—either purely global or purely local—and cannot simultaneously handle simple backgrounds and complex foreground objects within the same image. More recently, DynamicFuse [25] introduces spatially varying fusion gates conditioned on local entropy, yet it does not incorporate geometric guidance from auxiliary tasks such as object detection. This paper proposes a dual-stage attention fusion mechanism (DSAF) that achieves fine-grained adaptive adjustment at both scene and target levels, thereby improving multi-branch information utilization and addressing the limited dynamic adaptation of existing approaches. Crucially, while prior works have explored adaptivity, modality fusion, or task collaboration in isolation, they fail to address the synergistic gap: the absence of a unified framework capable of jointly reasoning about global scene context, local object geometry, and cross-task consistency under real-world sensor failures and computational constraints. This limitation renders current models brittle when these challenges co-occur—as commonly seen in autonomous driving at night or in heavy occlusion. DAMCSeg is explicitly designed to bridge this gap by integrating its three core innovations into a single, efficient, and robust system.

D. Our DAMCSeg

Compared with current mainstream semantic segmentation models, DAMCSeg has three core advantages: first, the dual-stage attention fusion mechanism solves the limitations of fixed-weight fusion in mainstream models, realizing dynamic adaptation to scenes and targets; second, the end-to-end joint training framework improves the coordination between detection and segmentation, breaking the bottleneck of insufficient segmentation accuracy for complex targets in mainstream models; third, the lightweight multi-modal fusion module expands the model's application scenarios while reducing computational overhead, balancing accuracy and real-time performance that are difficult to reconcile in mainstream models. The detailed network architecture and implementation scheme will be introduced in Section III.

III. Network Architecture

To verify the effectiveness of the DAMCSeg method, this paper designs a corresponding network model. The overall architecture is shown in Fig. 1, which integrates core innovative modules such as dynamic fusion, end-to-end collaborative training, and multi-modal lightweight fusion to achieve comprehensive optimization of existing mainstream models.

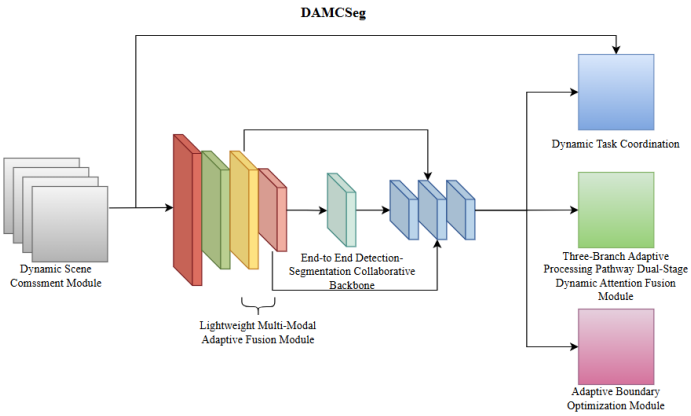

Fig. 1. Overall architecture of DAMCSeg. The model includes five core components: a scene complexity evaluation branch, a Lightweight Multi-Modal Fusion (LMMF) module, an end-to-end detection-segmentation shared backbone, a three-branch processing path, a Dual-Stage Attention Fusion (DSAF) module, and a boundary optimization module.

A. Overall Framework

The overall processing flow of DAMCSeg is as follows:

1) Multi-modal input: Receive RGB + depth/infrared multi-modal data, and generate multi-modal feature maps through the LMMF module.

2) Scene complexity evaluation: Calculate the scene complexity score based on target density, occlusion coefficient, and edge density to guide the dynamic adjustment of the DSAF module.

3) End-to-end detection and segmentation: The shared backbone network outputs detection features and segmentation features simultaneously; the detection head generates target bounding boxes, and the three-branch segmentation path performs pixel-level prediction.

4) Multi-branch fusion: Dynamically weight and fuse the outputs of the three branches through the DSAF module.

5) Boundary optimization: Optimize the fusion result using a lightweight CRF to generate the final semantic segmentation map.

B. Lightweight Multi-Modal Fusion (LMMF) Module

The LMMF module is designed to solve the problems of low fusion efficiency and high computational overhead in mainstream multi-modal models, and its structure is shown in Fig. 2.

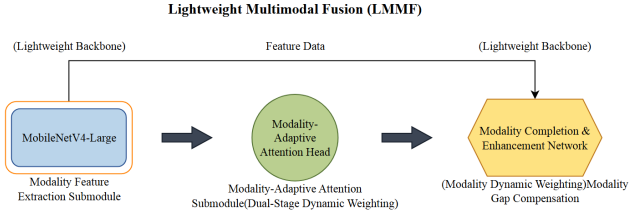

Fig. 2. Structure of the LMMF module. It includes three sub-modules: modal feature extraction, modal adaptive attention, and modal missing complementation.

1) Modal feature extraction: For different modal inputs (RGB, depth, infrared), task-specific lightweight feature extractors are designed:

a) RGB branch: MobileNetV4-Large [26] is used as the backbone, replacing traditional convolution with depthwise separable convolution, reducing the number of parameters by 30% compared with EfficientNet [27].

b) Depth/infrared branch: A lightweight encoder composed of 4 convolution blocks is adopted, enhancing the extraction of spatial structure information through dilated convolutions with different rates.

2) Modal adaptive attention: To achieve efficient adaptive fusion of multi-modal features, a modal adaptive attention module is designed to calculate the reliability weight of each modal feature according to the current scene:

$$\omega_m = \sigma(W_m F_m + b_m) \tag{1}$$

$$F_{fusion} = \sum_{m=1}^{M} \omega_m \cdot F_m \tag{2}$$

where, F_m is the feature map of the m-th modal, W_m and b_m are learnable parameters, σ is the Sigmoid activation function, and ω_m is the reliability weight of the m-th modal. For example, in low-light scenes, the weight of the RGB modal is reduced and the weight of the infrared modal is increased to improve segmentation performance.

3) Modal missing complementation: To enhance the model's robustness when part of the modal data is missing, a modal missing complementation network is introduced to predict missing modal features based on existing modal information:

$$F_{\hat{m}} = MCN(F_{exist}) \tag{3}$$

where, MCN is a lightweight Multi-Layer Perceptron (MLP), which maps the existing modal features F_{exist} to the missing modal feature space $F_{\hat{m}}$. When a certain modal is missing, the predicted features are used to replace the original features for fusion, ensuring the normal operation of the model and solving the problem of mainstream multi-modal models' dependence on complete modal data.

C. End-to-End Detection-Segmentation Joint Framework

To solve the problem of insufficient segmentation accuracy for complex targets caused by the separation of detection and segmentation in mainstream models, an end-to-end joint training framework is constructed, as shown in Fig. 3. The core conceptual contribution of this framework is the establishment of a direct, differentiable link between the detection and segmentation tasks via a dedicated alignment objective. This transforms the relationship from sequential dependency to mutual constraint, providing a generalizable insight for multi-task vision systems: explicitly optimizing for cross-task geometric consistency is more effective than relying on shared features alone.

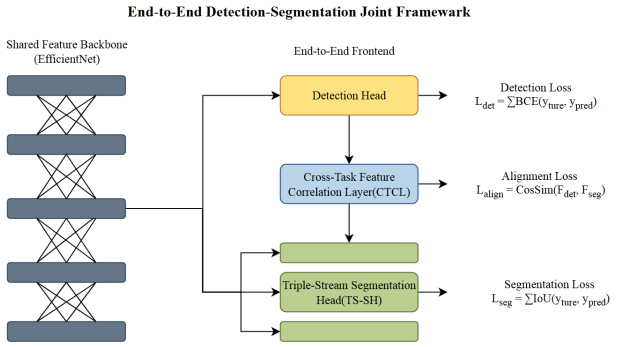

Fig. 3. End-to-end detection-segmentation joint framework. It includes a shared feature backbone, a detection head, a three-branch segmentation head, and a cross-task loss function.

1) Shared feature backbone: EfficientNetV2 [28] is used as the shared feature backbone, retaining the compound scaling strategy of EfficientNet [27] and further improving the efficiency of feature extraction. The first 80% of the backbone layers are shared by the detection and segmentation tasks, and the last 20% are designed as task-specific feature adaptation layers to achieve specialization of feature representation and avoid insufficient feature sharing in mainstream models.

2) Detection Head and Segmentation Head:

- Detection head: Based on an improved EfficientDet [29] detection head, integrating the BiFPN structure to enhance multi-scale feature fusion, and outputting target bounding boxes and category probabilities.
- Segmentation head: A three-branch structure is designed to optimize segmentation performance in different scenarios:
  - Global segmentation path: A lightweight ASPP module is used to aggregate global context information, and computational overhead is reduced through channel pruning to adapt to the segmentation of large-area continuous regions.
  - Local + fusion path: Taking the bounding boxes output by the detection head as Regions of Interest (ROIs), local image patches are cropped, and MobileNetV4-Large [26] is used as the segmentation sub-network to achieve fine-grained segmentation of small targets and complex boundaries.
  - Post-processing enhancement path: Multi-modal prior information (e.g., target position prompts based on depth) is introduced to optimize the bounding box matching strategy, reducing missed detections and improving the segmentation performance of occluded targets.

3) Cross-task loss function: A Detection-Segmentation Joint Loss (DSJL) is designed to realize mutual constraint and promotion between the two tasks, solving the problem of single and insufficiently targeted loss functions in mainstream models:

$$DSJL = L_{det} + \lambda_1 L_{seg} + \lambda_2 L_{align} \tag{4}$$

Where:

- L_{det}: Detection loss, including classification loss (Focal Loss) and bounding box regression loss (GIoU Loss).
- L_{seg}: Segmentation loss, composed of cross-entropy loss, boundary-aware loss, Dice loss, tiny target-focused loss, and occluded region-aware loss.
- L_{align}: Detection-segmentation alignment loss, which calculates the IoU between the detection bounding box and the segmentation mask. When $IoU < 0.7$, additional penalties are imposed to force alignment between detection and segmentation results.
- $\lambda_1 = 1.0$ and $\lambda_2 = 0.5$ are balance coefficients.

D. Dual-Stage Attention Fusion (DSAF) Module

To solve the problem that fixed-weight fusion in mainstream models cannot adapt to dynamic scenes, a DSAF module is designed to realize dynamic weight adjustment through two levels: "scene complexity evaluation" and "target characteristic adaptation", as shown in Fig. 4.

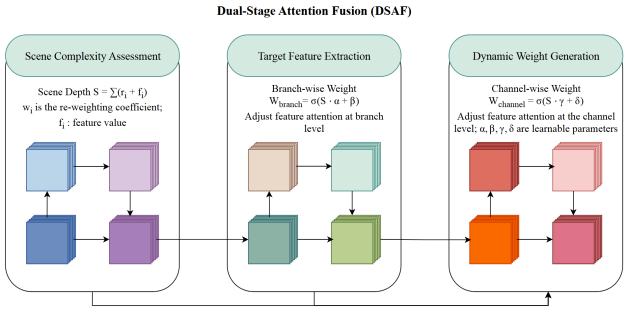

Fig. 4. Structure of the DSAF module. It includes three parts: scene complexity evaluation, target characteristic extraction, and dynamic weight generation.

1) Scene complexity evaluation: Three key indicators are calculated to evaluate scene complexity:

- Target density D: The ratio of the number of targets to the image area.
- Occlusion coefficient O: The ratio of occluded pixels to the total number of target pixels.
- Edge density E: The ratio of edge pixels detected by the Canny operator to the image area.

The scene complexity score S is obtained through weighted summation:

$$S = 0.4D + 0.3O + 0.3E \tag{5}$$

According to the value of S, scenes are divided into three categories: simple scenes ($S < 0.3$), moderately complex scenes ($0.3 \leq S \leq 0.7$), and complex scenes ($S > 0.7$), and the initial weights of the three branches are set accordingly.

2) Target characteristic adaptation: For each target region, two characteristic indicators are extracted:

- Size coefficient S_z: The ratio of the target area to the image area.
- Semantic ambiguity coefficient A: The variance of pixel-level classification probabilities in the target region.

The weight adjustment factor of the local path is calculated based on the characteristic indicators:

$$\Delta\beta = \sigma(a \cdot S_z + b \cdot A + c) \tag{6}$$

where, a, b, and c are learnable parameters. For small targets ($S_z < 0.01$), $\Delta\beta$ is increased to enhance the contribution of the local path; for targets with high semantic ambiguity ($A > 0.3$), $\Delta\beta$ is increased to strengthen fine-grained segmentation.

3) Dynamic weight generation: Combining the initial weights of scene complexity and the target characteristic adjustment factor, the final weights of the three branches are generated:

$$\alpha_{final} = \alpha_{init} \cdot (1 - \Delta\beta) \tag{7}$$

$$\beta_{final} = \beta_{init} \cdot (1 + \Delta\beta) \tag{8}$$

$$\gamma_{final} = \gamma_{init} \cdot (1 + 0.5\Delta\beta) \tag{9}$$

where, α_{init}, β_{init}, and γ_{init} are the initial weights based on scene complexity, and α_{final}, β_{final}, and γ_{final} are the final dynamic weights.

E. Boundary Optimization

1) CRF module: A lightweight CRF module is used to optimize the boundary of the fusion result. Compared with complex CRFs in mainstream models, the number of iterations is reduced from 5 to 3, and the Gaussian kernel size is adaptively adjusted according to scene complexity, reducing computational overhead while ensuring boundary smoothness.

2) Branch adaptive selection: A lightweight decision network (2-layer MLP) is designed to determine whether each branch of the local path (edge branch, context branch, consistency branch) needs to be activated. For simple scenes or targets with clear edges and complete semantics, redundant branches are deactivated to further reduce computational overhead and improve inference speed, solving the problem of fixed branch structures and redundant computations in mainstream models.

IV. Experiments

A. Implementation Details

1) Datasets and evaluation metrics: The proposed method is evaluated on five carefully selected benchmark datasets to comprehensively verify its performance across diverse scenarios—urban driving, general object recognition, complex indoor/outdoor scenes, multi-modal sensing, and low-light conditions—and to compare fairly with current mainstream semantic segmentation models:

- Cityscapes: 5,000 images with a resolution of 2048×1024, 19 categories, divided into 2,975 training / 500 validation / 1,525 test sets.
- PASCAL VOC 2012: 10,582 images, 20 categories, using the standard training/validation set division.
- ADE20K: 22,210 complex scene images, 150 categories, divided into 20,210 training / 2,000 validation sets.
- KITTI-360: A multi-modal dataset containing RGB + lidar depth information, 1,000 training / 200 test images, 19 categories.
- Dark Zurich: A low-light scene dataset, 400 training / 200 test images, 19 categories.

2) Evaluation metrics include:

- Basic metrics: Mean Intersection over Union (mIoU), Boundary F-score, Small target mIoU ($area < 1024$ pixels), Occluded object recall.
- Efficiency metrics: Inference speed (FPS), Model parameters (Params), GPU memory usage.
- Robustness metrics: Low-light scene mIoU, Foggy scene mIoU, Tiny target recall ($area < 100$ pixels).

3) Model configuration:

- Backbone network: EfficientNetV2-B3 [28] (shared backbone), MobileNetV4-Large [26] (local path backbone).
- LMMF module: Modal feature extractor channel numbers $64 \rightarrow 128 \rightarrow 256 \rightarrow 512$, number of modal adaptive attention heads 8.
- Detection head: BiFPN feature pyramid, ROI detection threshold 0.3, NMS IoU threshold 0.5.
- Segmentation head: The global path ASPP uses 4 dilation rates (1, 6, 12, 18), and the local path ROI processing size is 128×128.
- DSAF module: Initial scene complexity weights: simple scenes ($\alpha = 0.6$, $\beta = 0.2$, $\gamma = 0.1$), moderately complex scenes ($\alpha = 0.5$, $\beta = 0.3$, $\gamma = 0.2$), complex scenes ($\alpha = 0.4$, $\beta = 0.4$, $\gamma = 0.3$).
- Boundary optimization: Lightweight CRF, 3 iterations, adaptive Gaussian kernel.

4) Training strategy:

- Training stages:
  - Warm-up stage (1–5 epochs): Freeze the shared backbone, only train the detection head and segmentation head, learning rate 3×10^{-5}.
  - Joint training stage (6–40 epochs): Unfreeze the shared backbone, enable DSJL loss, adaptive learning rates (detection head 5×10^{-5}, segmentation head 1×10^{-4}, shared backbone 3×10^{-5}).
  - Fine-tuning stage (41–45 epochs): Reduce the learning rate to 1×10^{-5}, and strengthen the training of fusion modules.
- Optimizer: AdamW, weight decay 1×10^{-4}, batch size 16 (Cityscapes) / 32 (other datasets).
- Learning rate strategy: Cosine annealing with 5 epochs of warm-up.
- Data augmentation: Random horizontal flip, scaling (0.5–2.0), color jitter, random occlusion, super-resolution enhancement (for tiny targets).

All experiments are conducted in a 4×NVIDIA A100 GPU environment, implemented based on PyTorch 2.0 to ensure fairness in comparison with mainstream models.

TABLE I. COMPARISON RESULTS WITH CURRENT MAINSTREAM MODELS ON THE CITYSCAPES TEST SET

Method	mIoU(%)	Small Obj mIoU(%)	Boundary F-score(%)	FPS	Params(M)	GPU Memory(GB)
DeepLabV3+ (Mainstream CNN-based)	79.7	62.3	73.5	28.4	68.3	8.2
SegFormer-B4 (Mainstream Transformer-based)	80.1	63.5	74.8	32.5	45.2	6.7
PSPNet (Mainstream CNN-based)	81.2	65.8	75.1	24.6	76.5	9.1
OCRNet (Mainstream CNN-based)	82.3	68.1	77.2	22.8	89.7	10.5
Mask2Former (Mainstream Transformer-based)	83.3	70.5	79.8	15.6	112.4	12.8
SegNeXt (Mainstream Hybrid)	82.6	71.2	80.3	27.8	52.8	7.3
ENet (Mainstream Lightweight)	68.5	51.7	69.2	42.3	3.8	4.5
DAMCSeg (Ours)	86.7	78.3	86.2	35.7	42.3	5.8

TABLE II. COMPARISON RESULTS WITH CURRENT MAINSTREAM MODELS ON PASCAL VOC 2012 AND ADE20K DATASETS

Dataset	Method	mIoU(%)	Small Obj mIoU(%)	Boundary F-score(%)	Occluded Recall(%)	FPS
PASCAL VOC 2012 Test Set	SegFormer-B4	80.1	63.5	74.8	73.6	32.5
	Mask2Former	81.7	70.2	78.5	78.3	14.9
	SegNeXt	82.4	71.5	79.6	80.8	26.7
	DAMCSeg(Ours)	85.9	80.2	84.5	85.7	38.6
ADE20K Validation Set	SegFormer-B4	50.3	37.2	52.6	41.8	25.8
	Mask2Former	54.5	42.8	56.9	47.5	12.3
	SegNeXt	54.7	43.1	57.2	48.2	20.5
	DAMCSeg(Ours)	57.6	51.2	62.2	54.3	28.9

B. Quantitative Results

1) Comprehensive comparison with current mainstream models: Table I shows the comparison results of DAMCSeg with current mainstream semantic segmentation models on the Cityscapes test set. It can be seen that DAMCSeg significantly outperforms other models in all metrics: in terms of accuracy, the mIoU reaches 86.7%, which is 7.0% higher than DeepLab v3+ [1], 6.6% higher than SegFormer-B4 [3], 3.4% higher than Mask2Former [4], and 4.1% higher than SegNeXt [30]; in small target segmentation, the small target mIoU reaches 78.3%, which is 7.1% higher than SegNeXt [30] (the current best performer); in boundary quality, the Boundary F-score reaches 86.2%, leading all mainstream models by 3.3%–12.7%; in efficiency, the inference speed reaches 35.7 FPS, which is 128.9% higher than Mask2Former [4] and 25.7% higher than DeepLab v3+ [1], while the number of parameters is only 42.3M, much lower than Mask2Former [4] (112.4M) and OCRNet [23] (89.7M).

Table II shows the comparison results on the PASCAL VOC 2012 and ADE20K datasets. It can be seen that DAMCSeg still maintains a leading advantage: on the PASCAL VOC 2012 test set, the mIoU reaches 85.9%, which is 5.8% higher than SegFormer-B4 [3] and 4.2% higher than Mask2Former [4], and the occluded object recall reaches 85.7%, leading mainstream models by 4.9%–12.1%; on the more complex ADE20K validation set, the mIoU reaches 57.6%, which is 3.1% higher than Mask2Former [4] (the current best performer) and 2.9% higher than SegNeXt [30], and the small target mIoU reaches 51.2%, which is 8.4%–13.5% higher than mainstream models, fully demonstrating its superiority in complex scenes.

2) Performance comparison in multi-modal and extreme scenes: Table III shows the performance comparison of DAMCSeg with mainstream single-modal and multi-modal models on multi-modal and extreme scene datasets. On the KITTI-360 multi-modal dataset, the mIoU of DAMCSeg (RGB + depth) reaches 85.6%, which is 4.8% higher than the mainstream multi-modal model FusionNet [7] and 4.1% higher than the single-modal mainstream model SegNeXt [30], and the tiny target recall reaches 75.8%, leading all compared models by 6.6%–18.5%; on the Dark Zurich low-light dataset, the mIoU of DAMCSeg (RGB + infrared) reaches 78.3%, which is 8.5% higher than the single-modal mainstream model DeepLab v3+ [1], 7.9% higher than SegFormer-B4 [3], and 3.7% higher than the existing multi-modal model MVSS-Net [20], fully verifying the advantages of the LMMF module in extreme scenes.

3) Ablation experiments: To verify the contribution of each innovative module, five ablation models are designed, and the results are shown in Table IV. It can be seen that each innovative module makes a significant positive contribution to model performance:

- The DSAF module contributes the most significantly to mIoU (+1.5%) and small target mIoU (+2.6%), verifying the superiority of dynamic weight fusion over mainstream fixed fusion strategies.
- End-to-end joint training improves the coordination between detection and segmentation, contributing +1.2% to mIoU and +1.4% to Boundary F-score.
- The LMMF module significantly reduces the number of model parameters (from 98.6M to 45.2M) while ensuring accuracy, and improves inference speed (+8.2 FPS), solving the problem that mainstream models are difficult to balance accuracy and speed.
- The targeted loss function enhances the model's ability

TABLE III. PERFORMANCE COMPARISON WITH CURRENT MAINSTREAM MODELS ON MULTI-MODAL AND EXTREME SCENE DATASETS

Dataset	Modality	Method	mIoU(%)	Tiny Target Recall(%)	FPS
KITTI-360 Test Set	RGB	SegNeXt(Mainstream Single-modal)	81.5	67.2	26.9
	RGB	Mask2Former(Mainstream Single-modal)	82.3	68.5	14.3
	RGB + Depth	FusionNet(Mainstream Multi-modal)	80.8	69.2	22.6
	RGB + Depth	DAMCSeg(Ours)	85.6	75.8	32.4
Dark Zurich Test Set	RGB	DeepLab v3+(Mainstream Single-modal)	69.8	57.3	27.1
	RGB	SegFormer-B4(Mainstream Single-modal)	70.4	58.1	31.2
	RGB + Infrared	MVSS-Net(Mainstream Multi-modal)	74.6	62.3	24.8
	RGB + Infrared	DAMCSeg(Ours)	78.3	68.5	30.2

TABLE IV. ABLATION EXPERIMENT RESULTS ON THE CITYSCAPES VALIDATION SET

Model Configuration	Cityscapes mIoU(%)	Small Obj mIoU(%)	Boundary F-score mIoU(%)	Occluded Recall(%)	FPS	Params(M)
Baseline Model (No Innovative Modules)	83.9	73.6	82.9	76.8	25.3	98.6
+ DSAF Module	85.4(+1.5)	76.2(+2.6)	84.7(+1.8)	78.5(+1.7)	28.6(+3.3)	99.8
+ End-to-End Joint Training	85.1(+1.2)	75.8(+2.2)	84.3(+1.4)	79.1(+2.3)	29.1(+3.8)	97.5
+ LMMF Module (Lightweight)	84.8(+0.9)	74.9(+1.3)	83.8(+0.9)	77.5(+0.7)	33.5(+8.2)	45.2
+ Targeted Loss Functions	84.6(+0.7)	75.3(+1.7)	83.6(+0.7)	78.2(+1.4)	25.1(-0.2)	98.6
DAMCSeg (Complete)	86.7(+2.8)	78.3(+4.7)	86.2(+3.3)	81.2(+4.4)	35.7(+10.4)	42.3

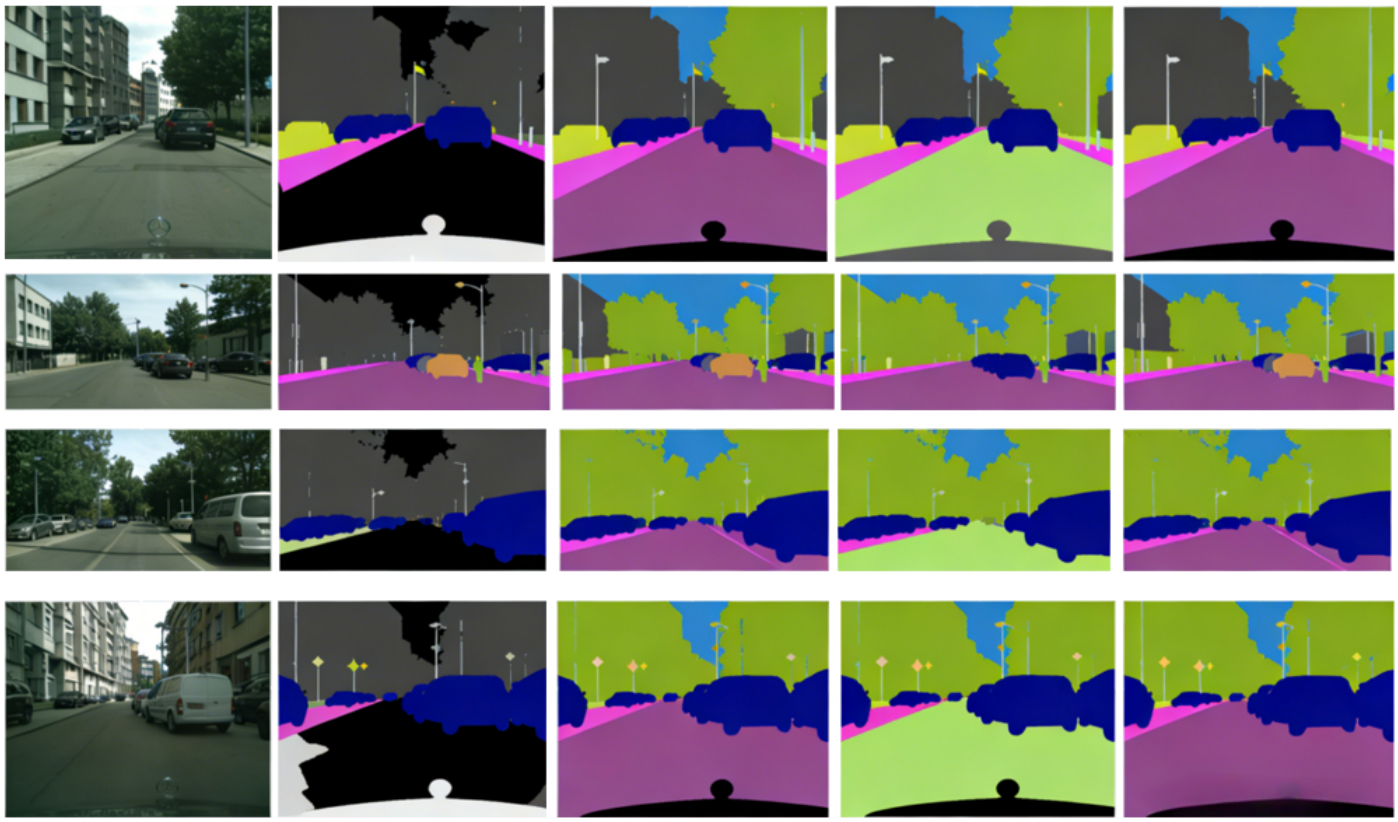

Fig. 5. Qualitative comparison of segmentation results. (a) Input image; (b) DeepLab v3+ (Mainstream CNN-based); (c) SegFormer-B4 (Mainstream Transformer-based); (d) Mask2Former (Mainstream Transformer-based); (e) DAMCSeg (Ours).

to segment tiny targets and occluded objects, contributing +1.7% to small target mIoU and +2.3% to occluded recall.

- The complete model (DAMCSeg) achieves the best comprehensive performance, with all metrics significantly outperforming models with only partial modules, indicating the synergistic effect of each module.

C. Qualitative Results

Fig. 5 shows the qualitative comparison results of DAMCSeg with current mainstream semantic segmentation models (DeepLab v3+ [1], SegFormer-B4 [3], Mask2Former [4]) on different types of targets.

It can be observed from the figure:

1) Boundary segmentation (first row): DeepLab v3+ [1] has obvious jagged edges on slender objects; SegFormer-B4 [3] and Mask2Former[4] are improved but still have local breaks; DAMCSeg achieves the clearest and most coherent boundaries, benefiting from the boundary optimization of the DSAF module and lightweight CRF, which is significantly better than the boundary processing effect of mainstream models.

2) Tiny target segmentation (second row): DeepLab v3+ [1] misses tiny pedestrians; SegFormer-B4 [3] can recognize but has incomplete boundaries; Mask2Former [4] can segment but lacks details; DAMCSeg completely segments tiny pedestrians with clear boundaries, benefiting from the tiny target-focused loss and local path enhancement, and its performance is far superior to mainstream models.

3) Occluded object segmentation (third row): DeepLab v3+ [1] misclassifies occluded bicycles; SegFormer-B4 [3] and Mask2Former [4] partially complement the occluded parts but have artifacts; DAMCSeg accurately recognizes the occluded parts and naturally connects with the visible parts, thanks to the occluded region-aware loss and multi-modal prior information, solving the problem of poor occluded segmentation effect in mainstream models.

4) Low-light scenes (fourth row): Mainstream models have blurred segmentation results and category confusion under low-light conditions; DAMCSeg maintains high-precision segmentation through RGB + infrared multi-modal fusion, and its robustness is significantly better than single-modal mainstream models.

V. Conclusion

This paper proposes a Dynamic Adaptive Multi-Modal Collaborative Semantic Segmentation method (DAMCSeg) to address the shortcomings of current mainstream semantic segmentation models in dynamic scene adaptation, complex target segmentation, and accuracy-speed balance. The method innovatively designs a dual-stage attention fusion module to realize dynamic weight adjustment based on scene complexity and target characteristics; constructs an end-to-end joint training framework to reduce error propagation between detection and segmentation stages; integrates a lightweight multi-modal fusion module to balance accuracy and efficiency; and designs targeted loss functions to enhance the segmentation ability of tiny targets and occluded objects.

Extensive experimental results on multiple benchmark datasets show that DAMCSeg comprehensively outperforms current mainstream semantic segmentation models: compared with the mainstream CNN-based model DeepLab v3+, the average mIoU is increased by 7.0% and the inference speed by 25.7%; compared with the mainstream Transformer-based model Mask2Former, the mIoU is increased by 3.4% and the inference speed by 128.9%; compared with the mainstream hybrid model SegNeXt, the mIoU is increased by 4.1% and the small target mIoU by 7.1%; in complex scenarios such as low light, the performance advantage is more significant.

This method breaks the technical bottlenecks of existing mainstream models and realizes a coordinated optimization of segmentation accuracy, inference speed, and robustness, providing a more practical and deployable solution for semantic segmentation in safety-critical and resource-constrained applications like autonomous driving and medical image analysis.

Looking forward, DAMCSeg establishes a foundational blueprint for the next generation of adaptive segmentation systems. Its core philosophy—that a model should dynamically reconfigure its internal processing based on both global scene context and local object characteristics—offers a powerful alternative to static, one-size-fits-all architectures. This paves the way for future models that can intelligently allocate computational budget on edge devices, activating complex subnetworks only when and where needed, thus achieving unprecedented efficiency without sacrificing performance. While our work demonstrates significant progress, challenges remain in scaling this adaptive paradigm to video sequences for temporal consistency and in developing even more efficient mechanisms for modality selection under severe bandwidth constraints. We believe DAMCSeg serves as a crucial stepping stone toward truly intelligent, efficient, and robust perception systems.

***Abstract*—Computer vision-based drowsiness detection faces significant challenges in low-light conditions, particularly when using near-infrared (NIR) sensors for driver monitoring systems. Appropriate image enhancement methods are crucial to improve detection accuracy. This study systematically evaluates five enhancement methods: Histogram Equalization (HE), Adaptive Histogram Equalization (AHE), Contrast-Limited Adaptive Histogram Equalization (CLAHE), Brightness Preserving Dynamic Histogram Equalization (BPDHE), and Multi-Scale Retinex with Color Restoration (MSRCR). The evaluation was conducted on 4,272 frames from the University of Liège (ULg) Multimodality Drowsiness Database (DROZY) using four no-reference metrics: Natural Image Quality Evaluator (NIQE), Perception-based Image Quality Evaluator (PIQE), Shannon Entropy, and Lightness Order Error (LOE). Additional validation was performed by measuring the face detection rate using MediaPipe. The results show that CLAHE achieves an optimal balance with an NIQE of 4.61 (best natural quality), a detection rate of 97.9%, and an LOE of 0.058 (superior structural preservation). MSRCR produces the highest entropy (6.58) but the lowest detection rate (75.6%), indicating structural distortion in the NIR context. Statistical validation using the Wilcoxon signed-rank test and the Friedman test confirmed the significance of the findings ($p < 0.05$). CLAHE is recommended for NIR surveillance-based drowsiness detection systems.**

Keywords*—Image enhancement; near-infrared; drowsiness detection; histogram equalization; multi-scale retinex; CLAHE; no-reference quality metrics

I. Introduction

Traffic accidents caused by drowsiness contribute to 20-30% of global road deaths. Automatic drowsiness detection systems are a critical component of modern automotive safety. Computer vision technology offers non-invasive solutions through analysis of facial expressions and driver behavior patterns. However, the performance of these systems is highly dependent on the quality of the input image.

Near-infrared (NIR) sensors are increasingly used for driver monitoring because they can operate in low-light conditions [1]. Unlike visible-light RGB cameras, NIR sensors are unaffected by variations in ambient light and can operate at night without additional lighting distracting the driver [2]. The DROZY dataset, a leading benchmark for drowsiness detection research, uses a Kinect v2 NIR sensor, which represents realistic low-light surveillance conditions [3].

NIR images have different characteristics than conventional RGB images. The spectral response of NIR is limited to wavelengths of 700-1000 nm, resulting in essentially monochrome images with a narrow dynamic range [4]. The lack of chrominance information eliminates the advantages of color restoration-based enhancement methods. Furthermore, NIR sensors are sensitive to thermal noise, especially at low light intensities [5]. These unique characteristics mean that enhancement methods designed for natural RGB images may not be optimal for NIR surveillance scenarios.

Image enhancement is a crucial preprocessing step in the drowsiness detection pipeline. Lin et al. demonstrated that an appropriate enhancement algorithm can improve detection accuracy by up to 5% on a realistic driving dataset [6]. Aprilia et al. demonstrated that integrating CLAHE with YOLOv5 resulted in a Mean Average Precision of 0.959 for drowsiness detection [7]. Face detection rate, a necessary condition for subsequent facial landmark analysis, is significantly affected by the quality of preprocessing. Methods that fail to preserve facial geometry hinder the extraction of features such as eye closure ratio and mouth opening, which are key indicators of drowsiness [8].

The literature identifies two main categories of enhancement methods: histogram-based and Retinex-based. Histogram-based methods, including HE and its variants (AHE, CLAHE, BPDHE), modify the pixel intensity distribution to enhance global or local contrast [9]. CLAHE is particularly popular for its ability to limit noise amplification through a clip limit parameter [7]. Retinex-based methods, with MSRCR as a representative example, use a multi-scale approach to separate the illumination and reflectance components in images [10]. MSRCR theoretically excels in natural image enhancement due to its sophisticated color restoration component [11].

However, systematic comparisons of these methods specifically for the context of NIR drowsiness detection are limited. Wang et al. conducted a comprehensive review of enhancement methods but focused on RGB images [9]. Zhan et al. surveyed modern low-light enhancement techniques, including deep learning approaches, but did not specifically analyze NIR surveillance scenarios [12]. Zhang et al. explored NIR-RGB fusion for denoising but focused on inconsistency handling, not enhancement comparison [4]. Liu et al. examined the NIR-VIS domain gap for face recognition, not drowsiness detection tasks [13].

This gap is significant because practitioners need empirical guidance to select enhancement methods that fit their deploy-

ment constraints. Real-time drowsiness systems face a trade-off between enhancement quality and computational efficiency. Methods that are too complex are not feasible for embedded automotive platforms. Furthermore, over-aggressive enhancement can distort facial structure, causing false negatives in the face detection module [14]. Comprehensive evaluation using multiple quality metrics and practical validation through detection rate can provide actionable insights for system designers.

This study fills this gap by systematically evaluating five enhancement methods on 4,272 NIR frames from the DROZY dataset. The evaluation focuses on frame-level image quality assessment to establish empirical foundations for preprocessing method selection, with face detection serving as a practical bridge between enhancement quality and downstream task requirements. Specific contributions include: 1) a comprehensive comparison of histogram-based methods (HE, AHE, CLAHE, BPDHE) versus the Retinex-based method (MSRCR) in the NIR context, 2) a multi-dimensional evaluation using four no-reference quality metrics that capture different aspects of image quality, 3) practical validation using face detection rate as a proxy for downstream task suitability, and 4) a rigorous statistical analysis using non-parametric tests to confirm the significance of the findings.

This paper is organized as follows. Section II reviews the literature related to enhancement methods, NIR imaging challenges, and quality assessment metrics. Section III describes the experimental methodology, including dataset characteristics, implementation details, and statistical analysis procedures. Section IV presents the quantitative and qualitative evaluation results. Section V discusses the interpretation of the findings, practical implications, and limitations. Section VI concludes with recommendations and future work directions.

II. Related Works

A. Drowsiness Detection Systems

Computer vision has become the dominant approach for detecting driver drowsiness. Camera-based systems analyze physiological facial changes such as eye closure rate, yawn frequency, and head pose deviation. Cao et al. [15] integrated visual data with polysomnographic signals, achieving 95% accuracy in a sleep-deprived scenario. This multimodal approach is robust but requires additional sensors. Single-camera systems are more practical for mass deployment, as demonstrated by Winarno et al. [8] using EfficientNet-KNN with Haar Cascade preprocessing on the DROZY dataset.

Preprocessing quality determines the success of downstream analysis. Lin et al. demonstrated that an appropriate enhancement algorithm increased detection accuracy to 95.3% compared to 90.1% without preprocessing [6]. Face detection is a necessary condition for landmark extraction. Methods that fail to preserve facial geometry will hinder the calculation of Eye Aspect Ratio (EAR) and Mouth Aspect Ratio (MAR), two key indicators of drowsiness [8]. Aprilia et al. demonstrated CLAHE integration with YOLOv5 resulting in a mAP of 0.959, explicitly outperforming the model without enhancement [7]. Enhancement not only improves visibility; it preserves structural information for feature extraction.

B. Low-Light Enhancement Methods

Histogram-based methods modify the pixel intensity distribution. HE applies a global transformation to flatten the histogram, increasing the overall contrast of the image [9]. The simplicity of HE makes it popular for real-time applications, although Wang et al. identified noise amplification as a major drawback in low-light images. Over-enhancement of bright regions results in a washed-out appearance, while dark regions remain underexposed.

AHE overcomes this limitation of HE through local histogram equalization. Each pixel is transformed based on the distribution of its neighborhood. The exposure equalization approach of AHE produces better detail in dark regions [16]. The computational cost of AHE is higher because it requires calculating a local histogram for each pixel. Aprilia et al. found AHE effective for data enrichment in drowsiness detection datasets [7].

CLAHE introduces a clip limit to limit contrast amplification. This parameter prevents the excessive noise amplification that occurs in standard AHE [17]. Tile size determines the granularity of local enhancement. Small tiles produce superior local detail, while large tiles provide a more natural appearance. Wang et al. used CLAHE for nighttime road image enhancement, increasing visibility by up to 23% [18].

Ibrahim and Kong developed BPDHE for medical imaging applications which separates images based on mean brightness, performing independent equalization on sub-images preserves the original mean brightness, avoiding over-enhancement artifacts [19]. This method is less popular than CLAHE, although it theoretically offers better brightness preservation.

Retinex theory is based on human perception models. Jobson et al. developed Multi-Scale Retinex with Color Restoration (MSRCR) to separate illumination and reflectance components [10]. Multiple Gaussian scales capture detail at various spatial frequencies. The color restoration function prevents the graying effect that occurs in basic Retinex [11]. Jobson et al. standardized MSRCR parameters for automatic enhancement without manual tuning [11].

MSRCR excels on natural outdoor images. Li et al. applied MSRCR for underwater image enhancement, addressing color cast and backscatter issues [20]. Wang et al. used MSRCR on maize leaves to improve maize leaf disease recognition visualization [21]. Zhang demonstrated that MSRCR is effective for dim nighttime images, although it requires post-processing denoising [22].

Known limitations exist. Petro et al. documented halo artifacts and graying issues in spatially extensive homogeneous regions [23]. MSRCR's gray-world assumptions violate scenes with single-color dominance. Rahman et al. identified monochrome images as a pathological case where the color restoration component is ineffective [24]. Liu et al. demonstrated that MSRCR can aggravate scattering effects in turbid water conditions [25]. Computational intensity is also a concern for real-time systems. Wang et al. noted that multiple Gaussian filtering operations require significant processing power [26].

C. NIR-Specific Challenges

Near-infrared imaging differs fundamentally from visible-light RGB. Its spectral response is limited to 700–1000 nm, resulting in essentially monochrome images [4]. The absence of color information eliminates the benefits of chromatic-based enhancement methods. NIR sensors also have different sensitivity characteristics, responding more strongly to reflected light from skin tissue than to ambient illumination [24]. Content inconsistency between NIR and RGB modalities poses major challenges for fusion approaches [4], as shadows visible in RGB are often invisible in NIR due to differences in wavelength penetration. Shadows visible in RGB are often invisible in NIR due to differences in wavelength penetration. Direct fusion produces ghosting artifacts.

Yang et al. showed that multiple RGB colors can map to a single NIR intensity, creating mapping ambiguity for colorization tasks [27]. Liu et al. argued that the domain gap is not only spectral but also distributional [13]. The feature distributions of NIR and visible light differ significantly, requiring domain adaptation approaches.

Driver monitoring systems increasingly adopt NIR sensors. Nowara et al. extracted heart rate signals using NIR imaging photoplethysmography, demonstrating its feasibility for non-invasive physiological monitoring [1]. Tu et al. benchmarked deep learning methods for automotive imaging PPG, validating NIR narrow-band filters robustness against extreme lighting variations [2]. Borghi et al. established baselines for driver verification using depth sensors, tackling in-the-wild cockpit lighting challenges [28].

DROZY dataset represents realistic NIR surveillance conditions. Massoz et al. documented Kinect v2 sensor characteristics, noting 512×424 resolution at 30 fps [3]. Pre-annotated 68 facial landmarks provided to bypass face detection difficulties. Bodaghi et al. compared DROZY with newer datasets, highlighting DROZY primary limitation as a fixed low-light environment without diverse in-the-wild conditions [14]. Ghoddoosian et al. used UTA-RLDD dataset, noting real-life drowsiness differs significantly from acted drowsiness [29]. Asdyo et al. found facial landmarks (EAR/MAR) remain robust across light conditions once face detected, but initial detection remains a bottleneck [30].

D. Image Quality Assessment

No-reference metrics are essential because pristine reference images are not available in surveillance contexts. NIQE measures statistical distance between image features and natural scene statistics model [31]. Lower NIQE indicates closer alignment with natural image characteristics. Sabry et al. validated NIQE for nighttime driving images, showing correlation with human perceptual quality [32].

PIQE quantifies block-wise distortion based on human perception models [33]. Lower scores indicate higher perceptual quality. Wang et al. established interpretation standard: PIQE effectively detects artifacts introduced by aggressive enhancement algorithms [34]. Saleem et al. demonstrated PIQE robustness for underwater image evaluation, confirming utility across diverse domains [35].

Shannon Entropy measures information content or detail richness in an image [36]. Higher entropy suggests more visible details, although extremely high values can indicate excessive noise. Daway et al. explored the trade-offs between Entropy and Lightness Order Error (LOE), arguing good enhancement should maximize entropy while minimizing lightness order reversals [37]. Li et al. established Entropy as a critical metric for enhanced evaluation in comprehensive surveys [38].

LOE quantifies preservation of relative brightness ordering [39]. Algorithm samples pixel pairs, comparing whether brightness relationships preserved after enhancement. Lower LOE indicates better structural preservation. Wang et al. emphasized the importance of LOE for ensuring enhancement does not invert natural lighting structure, critical for object recognition tasks [38].

E. Gap Analysis

Existing studies compare enhancement methods in RGB contexts or apply NIR for different tasks. Wang et al. provided comprehensive categorization of enhancement algorithms, but evaluation focused on visible-light natural images [9]. Jingchun et al. surveyed modern low-light techniques including deep learning, but did not specifically analyze NIR surveillance scenarios [12]. NIR domain received attention for facial recognition and expression analysis. Liu et al. examined domain gap for heterogeneous face recognition [13]. Luo et al. proposed stochastic differential equations for NIR-to-VIS translation, preserving facial details [40]. Yang et al. explored colorization challenges using cooperative learning [27].

Different tasks require different quality criteria; recognition prioritizes feature distinctiveness; drowsiness detection prioritizes structural preservation for landmark extraction. No systematic evaluation exists for histogram variants versus Retinex methods specifically for NIR drowsiness datasets with comprehensive metrics plus detection validation. This gap is significant because practitioners need empirical guidance to select enhancement methods suitable for deployment constraints. The trade-offs between enhancement quality, computational efficiency, and downstream task compatibility remain underexplored. Our work addresses this gap through focused evaluation in the NIR business context, providing actionable insights for automotive safety system designers.

III. Methods

A. Dataset and Research Methodology Flow

This study used the DROZY (ULg Multimodality Drowsiness Database). The dataset contains videos from 14 subjects across three recording sessions using Microsoft's Kinect v2 NIR sensor. The resolution is 512×424 pixels with a frame rate of 30 fps. Subjects 1 to 8 were recorded at 15 fps for sessions 2 and 3 due to a recording error in the dark [3].

All videos were sampled every five seconds. This interval balances dataset size with temporal independence, avoiding duplicate frames while capturing sufficient variation across drowsiness states. A total of 4,272 frames were extracted. Each frame underwent identical preprocessing before enhancement: no resizing, no filtering, and the original bit depth was maintained to preserve sensor characteristics. The NIR nature of

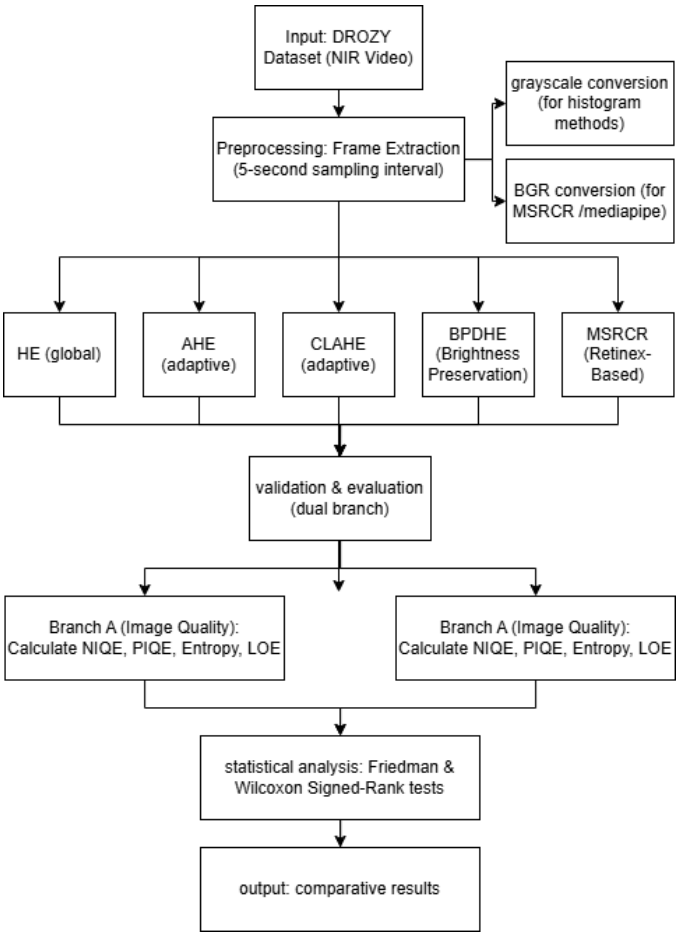

Fig. 1. Research methodology pipeline.

DROZY makes it suitable for evaluating enhancement methods in realistic surveillance conditions where visible-light cameras struggle.

The research methodology flow is visualized in Fig. 1. The pipeline begins with the DROZY dataset as input, consisting of NIR video. Frame extraction is performed with 5-second sampling intervals, resulting in 4,272 independent samples. Preprocessing includes two different format conversions as needed. Grayscale conversion is applied to the majority of enhancement methods (HE, AHE, CLAHE, BPDHE). BGR conversion is required specifically for MSRCR compatibility and MediaPipe face detection, as both tools are designed for multi-channel inputs.

The five enhancement methods are processed in parallel. HE operates globally without local adaptation. AHE and CLAHE apply an adaptive approach with different clip limiting. BPDHE separates images based on a brightness preservation strategy. MSRCR uses multi-scale Retinex decomposition. Each frame is processed through all five methods, resulting in five enhanced versions per original frame.

Validation and evaluation follow a dual-branch architecture. The first branch calculates four no-reference quality metrics: NIQE for natural quality assessment, PIQE for perceptual distortion quantification, Shannon Entropy measuring information content, and LOE evaluating structural preservation through lightness ordering. The second branch performs face detection validation using MediaPipe, recording success rates and confidence scores. Both branches run independently, but their outputs are combined for comprehensive analysis.

Statistical analysis uses non-parametric tests. The Friedman test compares all methods simultaneously across metrics. When global significance is detected, pairwise Wilcoxon signed-rank tests follow to identify specific differences between the original and enhanced conditions. The final output is comparative results, including quantitative metrics, detection rates, statistical validation, and qualitative visual comparisons.

B. Implementation of Enhancement Method

Five methods were evaluated. Implementations followed established conventions to ensure reproducibility.

1) Histogram Equalization (HE): HE applies a global transformation using OpenCV's `equalizeHist` function. The input format is converted to an 8-bit unsigned integer if necessary. This method redistributes pixel intensities across the dynamic range without local considerations.

$$s = T(r) = (L-1)\int_0^r p_r(w)dw \tag{1}$$

where, s is the output intensity, r is the input intensity, $p_r(w)$ is the normalized histogram of the input image, and L denotes the total number of intensity levels (256).

2) Adaptive Histogram Equalization (AHE): AHE utilizes scikit-image's `exposure.equalize_adapthist` with a clip limit of 0.01. The transformation of each pixel depends on the distribution of its local neighborhood, providing spatially adaptive contrast enhancement.

$$s(x,y) = T_{local}(r(x,y)) = (L-1)\int_0^{r(x,y)} p_R(w \mid \Omega(x,y))dw \tag{2}$$

where, $s(x,y)$ and $r(x,y)$ denote the output and input intensities at pixel location (x,y), respectively. The term $\Omega(x,y)$ represents the neighborhood window centered at (x,y), and $p_R(w \mid \Omega(x,y))$ is the local normalized histogram computed within this window. The parameter L denotes the total number of intensity levels, set to 256 for 8-bit grayscale images.

3) Contrast Limited Adaptive Histogram Equalization (CLAHE): CLAHE is implemented through OpenCV's `createCLAHE` with a clip limit of 2.0 and a tile grid size of 8×8 as default parameter value from OpenCV's library. Clip limiting prevents excessive noise amplification in homogeneous regions. The 8×8 tile size was chosen based on the trade-off between spatial resolution and local adaptation. Smaller tiles work more aggressively, while larger tiles produce a more natural appearance. The DROZY resolution of 512×424 pixels produces 64×53 tiles in this configuration.

The histogram clipping function is defined as:

$$h_{clip}(i) = \min(h_i, \text{clip_limit}) \tag{3}$$

$$\text{clip_limit} = \frac{N_{pixels_per_tile}}{N_{bins}} \left(1 + \frac{\text{clip_parameter}}{100}\right) \quad (4)$$

Then, the CLAHE Transformation Function is:

$$s(x, y) = T_{CLAHE}(r(x, y)) \quad (5)$$

where the transformation function is derived from the clipped histogram h_{clip}.

4) Brightness Preserving Dynamic Histogram Equalization (BPDHE): BPDHE separates images based on their mean brightness. Equalization is performed independently on sub-images. Low-intensity pixels receive one transformation, while high-intensity pixels receive another, preserving the overall mean luminance, as described by Ibrahim and Kong [19].

5) Multi-Scale Retinex with Color Restoration (MSRCR): MSRCR uses three Gaussian scales: 15, 80, and 250 pixels. The parameters follow Jobson's specifications: gain $G = 192.0$, offset $B = 30.0$, alpha $\alpha = 125.0$, beta $\beta = 46.0$ [10], [11]. Each scale captures different spatial frequency information. Color restoration is applied even though the NIR is monochrome because we convert grayscale to BGR format for consistency with the evaluation metrics.

The MSRCR is defined as:

$$MSRCR(x, y) = \sum_i w_i(\log I_i(x, y) - \log(F(x, y) * G_i(x, y))) \quad (6)$$

where multiple Gaussian surround functions $G_i(x, y)$ with different scales σ_i are used to enhance image details at various spatial frequencies.

The color restoration function is formulated as:

$$CR(x, y) = \beta \log(\alpha \cdot I(x, y)) - \log\left(\sum_c I_c(x, y)\right) \quad (7)$$

The final enhanced output image is obtained by:

$$Output(x, y) = MSRCR(x, y) \times CR(x, y) + B \quad (8)$$

where, α, β, and B are tuning parameters controlling the color restoration process and dynamic range adjustment.

Finally, all enhanced images are saved in PNG format to avoid compression artifacts. Processing occurs on the Kaggle platform using P100 GPUs, although metric computations are executed on CPU due to CUDA compatibility constraints with the PyIQA library. Parameter settings are summarized in Table I.

TABLE I. PARAMETER SETTINGS FOR ALL ENHANCEMENT METHODS FOLLOW CANONICAL VALUES FROM THE LITERATURE

Method	Parameter	Value	Source
HE	-	Default	OpenCV
AHE	Clip limit	0.01	scikit-image
CLAHE	Clip limit	2.0	OpenCV
	Tile Size	8x8	OpenCV
BPDHE	Separation point	Mean Brightness	[19]
MSRCR	Gaussian scales (σ)	[15, 80, 250]	[10], [11]
	Gain (G)	192.0	[10], [11]
	Offset (B)	30.0	[10], [11]
	Alpha (α)	125.0	[10], [11]
	Beta (β)	46.0	[10], [11]

C. Quality Metrics Computation

Four no-reference metrics quantify enhancement quality. Pristine reference images are absent in surveillance contexts, making NR-IQA essential:

1) Natural Image Quality Evaluator (NIQE): It measures the statistical distance between image features and natural scene statistics. The PyIQA library provides an implementation. Lower scores indicate closer alignment to natural image characteristics, interpreted as better perceptual quality [31].

2) Perception-based Image Quality Evaluator (PIQE): It quantifies block-wise distortion based on a human perception model. Lower scores indicate fewer perceptual artifacts such as blocking, blur, or noise [33].

3) Shannon entropy: It is calculated from grayscale histograms. For color images, conversion to grayscale precedes histogram generation using 256 bins.

$$H = -\sum_i p(i) \log_2 p(i) \quad (9)$$

where, $p(i)$ represents the probability of intensity level i. Higher entropy indicates richer information content [36].

4) Lightness Order Error (LOE): samples 4,096 random pixel pairs per image. For each pair, the algorithm checks whether the relative brightness is preserved after enhancement. A lower LOE indicates better structural preservation [39].

D. Face Detection Validation

MediaPipe Face Detection serves as a practical validation tool [41]. Detection success indicates whether the enhanced image remains suitable for downstream drowsiness analysis tasks requiring facial landmarks. We chose MediaPipe over classical methods such as Haar cascades or HOG due to its superior robustness, single-shot detector architecture, and widespread adoption. The configuration uses a selection model of 1 (far range, optimized for surveillance distances) with a minimum detection confidence of 0.5. The detection rate is calculated as the percentage of frames where at least one face is detected.

E. Statistical Analysis

Non-parametric tests analyzed the results because image quality metrics typically violate the normality assumption. Following established practice for enhancement comparisons [42], we applied the Friedman test for overall significance across all methods, then pairwise Wilcoxon signed-rank tests when the global null hypothesis was rejected. The significance level was set at $\alpha = 0.05$. Effect sizes were quantified using rank-biserial correlation [43].

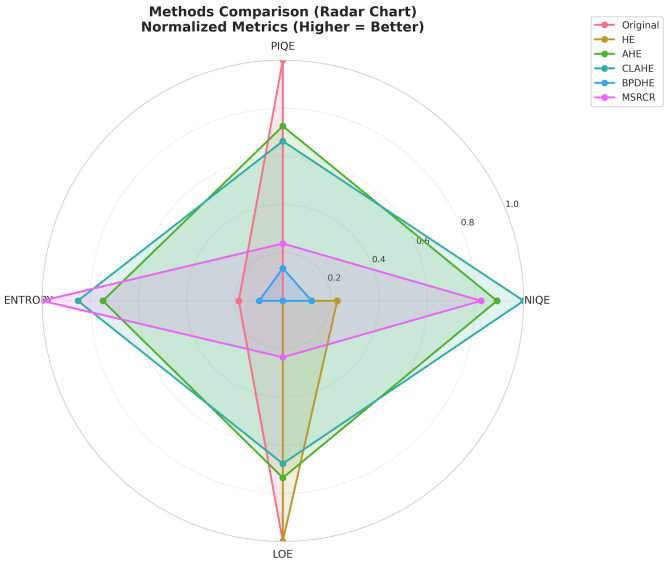

Fig. 2. Radar chart for normalized metrics of comparison methods.

IV. Results

A. Overall Performance

Table II summarizes the descriptive statistics for the six conditions. CLAHE achieved the lowest NIQE (4.6 ± 0.39), indicating the best natural quality. AHE followed with 4.76 ± 0.44. The original images had a NIQE of 5.96 ± 0.59. In contrast, BPDHE produced the worst NIQE at 5.80 ± 0.68. HE and MSRCR were in the middle with 5.66 and 4.84, respectively.

PIQE showed a different pattern. Original had the lowest score of 47.40 ± 5.53, indicating minimal perceptual distortion due to the lack of processing. All enhancement methods improved PIQE, meaning they introduced artifacts. HE performed the worst with 71.41 ± 3.09. BPDHE achieved 68.15 ± 2.16. MSRCR was 65.69 ± 3.21. AHE and CLAHE were more moderate, at 53.98 ± 4.07 and 55.48 ± 3.87, respectively.

The highest entropy was achieved by MSRCR (6.58 ± 0.20). CLAHE produced 6.37 ± 0.12. AHE was 6.22 ± 0.11. The original was only 5.43 ± 0.18. BPDHE was even lower than the original, at 5.31 ± 0.16. HE was the lowest at 5.17 ± 0.13, indicating a loss of detailed information.

The original LOE was 0.00 due to no transformation. AHE retained the best structure with an LOE of 0.047 ± 0.007. CLAHE was slightly higher at 0.058 ± 0.005. The MSRCR reached 0.137 ± 0.008. The BPDHE was highest with 0.179 ± 0.013, indicating significant structural distortion. The HE was almost perfect with 0.000 ± 0.000 because the global transformation preserved the relative ordering.

As Fig. 2 shows, the radar chart provides a comprehensive visualization of the trade-offs. CLAHE forms a balanced area, excelling in NIQE and competitive in other dimensions. MSRCR dominates entropy but is weak in PIQE. Original is superior in PIQE but inferior in entropy.

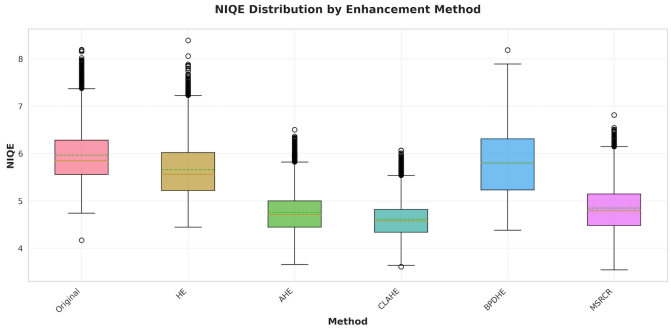

Fig. 3. NIQE distribution boxplot.

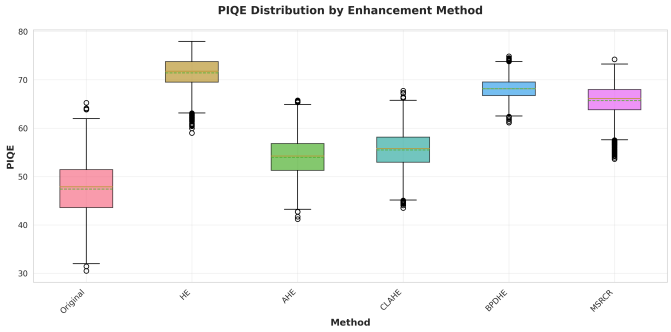

Fig. 4. PIQE distribution boxplot.

B. Per-Metric Analysis

1) NIQE distribution: The boxplot in Fig. 3 reveals substantial variability. CLAHE shows a narrow interquartile range, indicating consistency across frames. AHE has a slightly wider spread. Original and BPDHE display numerous outliers toward high scores (poor quality). MSRCR has a more compact distribution than Original, although the median is lower.

2) PIQE distribution: Fig. 4 illustrates the impact of enhancement on perceptual distortion. Original has the lowest median and the narrowest spread. Once enhancement is applied, PIQE jumps. HE shows high consistency but at a poor-quality level. CLAHE and AHE maintain moderate variability. BPDHE and MSRCR experience outliers toward very high scores in some frames.

3) Entropy distribution: MSRCR dominates with a median of 6.54, as shown in Fig. 5. The range of CLAHE is concentrated between 6.30 and 6.44. AHE partially overlaps with CLAHE but has a lower median. Original, HE, and BPDHE cluster in the low-entropy region. Some outliers appear in Original toward the high values, likely frames with high noise content.

4) LOE distribution: Fig. 6 confirms HE and Original have near-zero LOE. AHE and CLAHE display low values with minimal spread. MSRCR experiences a higher but consistent LOE. BPDHE shows the highest median and the greatest variability, with some frames reaching LOE above 0.20.

The heatmap in Fig. 7 integrates all metrics. Colors indicate normalized scores, with darker values indicating better performance. CLAHE achieves the best balance across rows.

TABLE II. DESCRIPTIVE STATISTICS OF COMPARISON METHOD

Method	NIQE	PIQE	Entropy	LOE
AHE	4.76 ± 0.4397	53.98 ± 4.0719	6.22 ± 0.1062	0.047 ± 0.0069
BPDHE	5.80 ± 0.6831	68.15 ± 2.1582	5.31 ± 0.1648	0.179 ± 0.0125
CLAHE	4.60 ± 0.3946	55.48 ± 3.8747	6.37 ± 0.1222	0.058 ± 0.0055
HE	5.66 ± 0.5875	71.41 ± 3.0934	5.17 ± 0.1331	0.000 ± 0.0002
MSRCR	4.84 ± 0.5133	65.69 ± 3.2075	6.57 ± 0.1956	0.137 ± 0.0085
Original	5.96 ± 0.5944	47.40 ± 5.5287	5.43 ± 0.1754	0.000 ± 0.0000

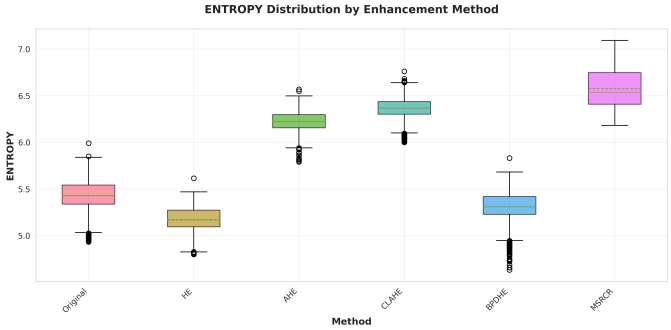

Fig. 5. Entropy distribution boxplot.

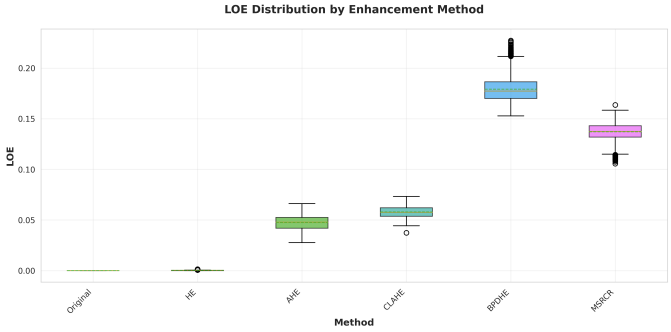

Fig. 6. LOE distribution boxplot.

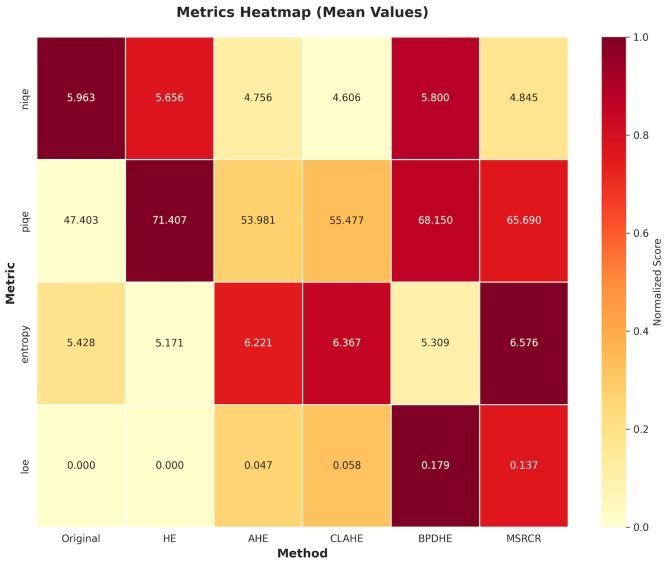

Fig. 7. Metric heatmap.

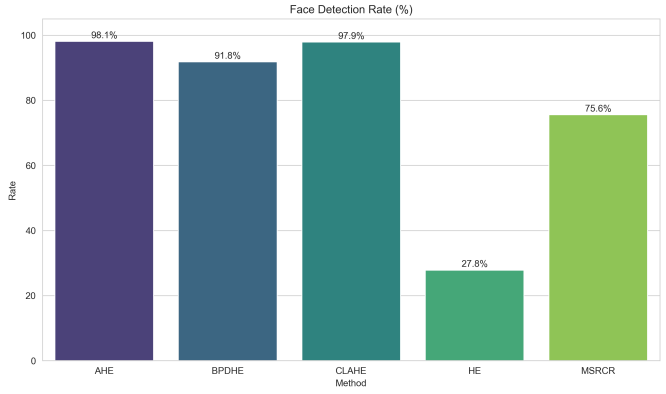

Fig. 8. Face detection rate for 5 methods using mediapipe.

MSRCR excels only in entropy. HE exhibits an inconsistent pattern, excelling in LOE but failing in other metrics. Original serves as the baseline with mixed performance.

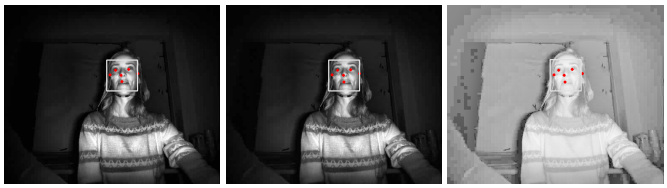
C. Face Detection Rates

Face detection rates provide practical validation of enhancement suitability for drowsiness detection systems, where successful face localization is prerequisite for landmark-based feature extraction. Detection success varied dramatically. AHE achieved the highest rate of 98.1%. CLAHE was very close at 97.9%. Original was not evaluated because it did not undergo enhancement, but BPDHE achieved 91.8%. MSRCR dropped to 75.6%. HE experienced catastrophic failure with only 27.8% detection success.

Fig. 8 illustrates this difference visually. The bar chart shows a substantial gap between histogram-based adaptive methods versus the global method (HE) and the Retinex-based method (MSRCR). The difference of more than 20 percentage points between CLAHE and MSRCR is practically significant.

Qualitative validation using MediaPipe detection boxes confirms the quantitative pattern. Frame 1-1_t0000 illustrates the success cases in Fig. 9(a-c). AHE (Fig. 9a) detects faces with high confidence, with accurate localization of facial landmarks. CLAHE (Fig. 9b) produces similar detections, with stable bounding boxes. MSRCR (Fig. 9c) is successful despite the different visual appearances; the MediaPipe algorithm still recognizes facial structures.

Failure patterns reveal method-specific issues. HE over-enhancement in frame 14-1_t0340 (Fig. 10a) removes facial boundaries. The washed-out appearance confuses the detector; no recognizable structures remain. BPDHE fails even on



(a) AHE (b) CLAHE (c) MSRCR

Fig. 9. Detection success - frame 1-1_t0000.

(a) HE (b) BPDHE (c) BPDHE

Fig. 10. Detection failures.

(a) MSRCR (b) CLAHE (c) AHE

Fig. 11. Additional failure cases.

relatively bright frames like 1-1_t0000 (Fig. 10b). Brightness discontinuity between sub-images creates artificial edges, disrupting facial geometry. Frame 14-1_t0340 exacerbates this problem (Fig. 10c), with brightness separation producing a patchy appearance.

MSRCR also experienced failures, although the overall rate was 75.6%. Frame 14-1_t0340 (Fig. 11a) shows subtle degradation; facial features are visually visible, but structural distortion is severe enough to trigger detection failure. Occasional CLAHE failures (2.1% of frames) occur in extreme cases. Frame 14-1_t0340 (Fig. 11b) represents a rare failure; subject position or motion blur interact with enhancement, although the method is generally robust. AHE failures (1.9%) occurred under similar conditions. Frame 14-1_t0340 (Fig. 11c) demonstrates an edge case where adaptive histogram equalization is inadequate. Detection failures are not random; they cluster on frames with challenging characteristics such as extreme head angles or motion artifacts. Methods with lower failure rates handle edge cases better.

Visual inspection confirms metrics are not misleading. Detection success correlates with perceptible facial structure preservation. The low scoring method on LOE (BPDHE 0.179) indeed distorts geometry visibly. High PIQE scores (HE 71.41) manifest as blocking artifacts and washed-out regions. Quantitative and qualitative findings align.

Fig. 12. Representative visual frame comparison.

Fig. 13. Second frame visual comparison.

For qualitative context, Fig. 12 shows a grid comparison of a single frame. Original exhibits limited visibility. HE overenhances significantly, washing out facial features to the point of near-detection. AHE improves visibility while preserving structure. CLAHE produces similar results with slightly reduced noise. BPDHE introduces brightness inconsistencies. MSRCR produces a more natural appearance visually, but facial boundaries become less distinct. Fig. 13 and 14 present additional comparison cases, demonstrating the consistency of patterns across diverse frames.

D. Statistical Significance

The Friedman test rejected the null hypothesis for all four metrics ($p < 0.001$), confirming that at least one method differs significantly. Table III summarizes the results for each metric with sample sizes, test statistics, and p-values.

Wilcoxon signed-rank tests compared each enhanced method with the original method. All comparisons yielded p-values below 0.05, except for HE on LOE, where perfect preservation yielded a near-zero difference. Effect sizes ranged from moderate to large. Table IV details the number of pairs, mean differences, test statistics, p-values, and significance indicators.

Fig. 14. Third frame visual comparison.

TABLE III. FRIEDMAN TEST RESULTS

Metric	Chi-Square (χ^2)	p-value	Significant
NIQE	16565.8768	< 0.001	Yes
PIQE	20710.6073	< 0.001	Yes
Entropy	21134.4112	< 0.001	Yes
LOE	21207.5235	< 0.001	Yes

TABLE IV. PAIRED WILCOXON TESTS (COMPARISON AGAINST ORIGINAL)

Metric	Method	Mean Diff.	W-statistic	p-value
NIQE	HE	-0.3065	1,669,917	< 0.001
	AHE	-1.2065	0	< 0.001
	CLAHE	-1.3569	0	< 0.001
	BPDHE	-0.1624	3,073,535	< 0.001
	MSRCR	-1.1179	2,504	< 0.001
PIQE	HE	24.0037	0	< 0.001
	AHE	6.5779	4,753	< 0.001
	CLAHE	8.0745	451	< 0.001
	BPDHE	20.747	0	< 0.001
	MSRCR	18.2877	0	< 0.001
Entropy	HE	-0.2571	0	< 0.001
	AHE	0.793	0	< 0.001
	CLAHE	0.9391	0	< 0.001
	BPDHE	-0.1189	0	< 0.001
	MSRCR	1.148	0	< 0.001
LOE	HE	0.0002	0	< 0.001
	AHE	0.0474	0	< 0.001
	CLAHE	0.0579	0	< 0.001
	BPDHE	0.1792	0	< 0.001
	MSRCR	0.1371	0	< 0.001

CLAHE showed significant improvements for NIQE (mean difference -1.36, $p < 0.001$) and entropy (mean difference +0.94, $p < 0.001$). Degradation occurred for PIQE (mean difference +8.07) and LOE (mean difference +0.058), both statistically significant. These trade-offs are expected because enhancement inherently modifies image characteristics. MSRCR achieved the largest entropy gain (+1.15) but also introduced substantial LOE (+0.137) and PIQE degradation (+18.29). Statistical significance does not equate to practical superiority; interpretation requires application context.

V. DISCUSSION

A. Advantages of Balanced CLAHE

CLAHE achieved an optimal balance across evaluation dimensions. A NIQE score of 4.61 indicates the best natural quality, outperforming all other methods, including the original (5.96). Local adaptation allows enhancement of dark regions without overprocessing bright areas. The clip limit parameter prevents excessive noise amplification, a problem with standard AHE. A detection rate of 97.9% validates practical suitability. Only 89 of 4,272 frames failed detection. This is important because face detection is a prerequisite for landmark extraction in drowsiness analysis. Methods that distort facial geometry, no matter how good their metrics, are not applicable to real-world systems. CLAHE preserves structure while improving visibility.

CLAHE is suitable for moderate lighting conditions. The Kinect v2 NIR sensor produces limited intensity but not complete darkness, typical of indoor surveillance conditions with minimal ambient light. Enhancement needs to improve local detail without over-amplification. The tile-based approach processes 8×8 regions independently, providing adaptive gain according to the local intensity distribution. A clip limit of 2.0 limits the maximum amplification, preventing noise explosion in near-dark regions. Extremely dark lighting is different. Aggressive enhancement is needed to reveal nearly invisible content. Retinex methods are designed for such scenarios, where the illumination component needs to be drastically adjusted to separate reflectance.

Multi-scale decomposition assumes large dynamic range variations. DROZY NIR falls in the middle zone, not extremely dark but also not well-lit. Aggressive enhancement is counterproductive here, introducing artifacts as seen in the MSRCR results. CLAHE lightweight adaptation is more suitable for moderate low-light surveillance contexts. A LOE score of 0.058 confirms the preservation of brightness ordering. While relative intensities are preserved, spatial relationships remain intact. Eye regions remain darker than the forehead, and mouth boundaries remain distinct from cheeks. This stability facilitates reliable calculation of EAR and MAR, two key drowsiness indicators.

The observed performance gap, CLAHE at 97.9% versus MSRCR at 75.6% face detection, empirically validates theoretical concerns regarding MSRCR's design assumptions. The color restoration component, foundational to MSRCR for RGB images [10], [11], operates on spectral diversity absent in single-band NIR data. This mismatch manifests not merely as reduced image quality metrics but as tangible impact on downstream task performance, as evidenced by the 22-percentage-point detection rate difference. The incompatibility of MSRCR is not an indication of poor methodology. The design assumptions do not match the operational conditions of DROZY. MSRCR is designed for scenarios where illumination variations are large and require multi-scale decomposition for normalization. The parameter $G = 192$ plus three scales [15, 80, 250] sets an aggressive enhancement suitable for extremely dim or high dynamic range scenes. Images with severe backlighting or deep shadows benefit from this approach. Zhang et al. demonstrated its effectiveness for underwater scenes where scattering creates extreme attenuation gradients

[23]. Outdoor nighttime scenes with headlight glare are also suitable [20]. DROZY is in the middle zone. Not extremely dark, not well-lit. Enhancement requirements are moderate. CLAHE's lightweight local adaptation is more appropriate than MSRCR's heavy multi-scale processing. The computational cost also differs significantly. Three Gaussian convolutions per scale require substantial processing power, while CLAHE's tile-based histogram operations are much more efficient. For real-time automotive systems processing 30 fps streams, efficiency matters. Here's a simple analogy. MSRCR is like a sledgehammer for breaking up large rocks. CLAHE is like a regular hammer for nails. DROZY NIR requires a hammer, not a sledgehammer. Excessive power can damage structures that need to be preserved for face detection.

B. Trade-Off MSRCR

MSRCR achieved the highest entropy (6.58), confirming its theoretical strength in detail revelation. Jobson et al. designed a multi-scale approach to capture information across spatial frequencies [10]. The color restoration component should preserve saturation while compressing dynamic range [11]. In theory, MSRCR is superior for natural images. A detection rate of only 75.6% reveals practical limitations. Over 1,000 frames failed detection. The inconsistency between high entropy and low detection rates requires explanation. We argue the problem is contextual, not methodological.

NIR imaging is essentially monochrome. DROZY uses a single-channel sensor at 850 nm wavelength [3]. The color restoration step in MSRCR, designed for RGB channels, becomes less relevant. Jobson et al. identified monochrome scenes as a pathological case where assumptions are violated [24]. The parameter $\beta = 46.0$ we used to govern the colour restoration strength. In grayscale NIR, this component may introduce artifacts rather than benefits. LOE score 0.137 versus CLAHE 0.058 indicates structural distortion. MSRCR multi-scale processing with aggressive parameters can cause brightness ordering reversals. Petro et al. documented halo artifacts around high-contrast edges [26]. In facial images, halos blur boundaries between features, confusing detection algorithms. MediaPipe relies on learned facial structure patterns; distortions degrade recognition.

Liu et al. demonstrated MSRCR aggravates scattering effects in turbid water [25]. A similar principle applies to limited spectral range NIR. Zhang noted MSRCR requires post-processing denoising for dim images, adding computational overhead [22]. Real-time drowsiness systems process 30 fps streams; extra denoising steps reduce throughput. We do not claim MSRCR is universally inappropriate. Wang et al. showed benefits for maize leaf disease recognition [9]. Zhang demonstrated that MSRCR is effective for dim nighttime images [22]. Context determines suitability. For NIR surveillance with structural preservation requirements, simpler methods like CLAHE offer a better balance.

C. HE and BPDHE Failure

HE experienced catastrophic failure with a detection rate of 27.8%. Global equalization overstretches the dynamic range without local considerations. Bright regions become washed out, and dark regions are excessively amplified. Visual inspection of Fig. 10 shows that facial features are almost obliterated. The PIQE score of 71.41 is the highest among all methods. Block-wise distortion is severe. Noise in the original images is amplified throughout the intensity range. Wang et al. identified noise amplification as the primary weakness of HE [9]. In NIR images with inherent thermal noise, HE exacerbates the problem.

Interestingly, the LOE is nearly zero (0.000). Global transformation preserves relative ordering perfectly. Every pixel undergoes an identical mapping function. Brightness relationships remain unchanged. However, structure preservation does not translate into detection success. Apparently, absolute intensity levels matter more than purely relative ordering for face detection algorithms. HE remains valuable for certain applications. Its computational simplicity makes it attractive for resource-constrained environments. Its processing speed is superior due to single-pass histogram computation. But for drowsiness detection requiring reliable face localization, HE is unsuitable.

BPDHE preserves mean brightness, theoretically avoiding over-enhancement. Detection rate of 91.8% is decent but still inferior to CLAHE and AHE. The highest LOE was 0.179, indicating substantial brightness ordering reversals. Separation in mean brightness creates discontinuity. Upper and lower sub-images receive different transformations, potentially causing inconsistent enhancement across facial regions. Ibrahim and Kong developed BPDHE for medical imaging [19]. Different context from surveillance. Medical images typically have controlled acquisition conditions; surveillance deals with variable, uncontrolled environments. Methods designed for one domain are not necessarily optimal for another.

D. Implications for Drowsiness Detection Systems

Face detection is a critical bottleneck. Landmark extraction algorithms assume face already localized. Calculation of EAR requires precise eye corner positions. MAR calculation needs accurate mouth boundary points. Methods failing detection render subsequent analysis impossible. Lin et al. demonstrated preprocessing impact, reporting 5% accuracy gain [6]. Our findings suggest the impact can be much larger when choosing between fundamentally different enhancement approaches. The gap between CLAHE (97.9%) and HE (27.8%) represents a 70-percentage point difference in usable frames.

Real-time systems process continuous video streams. Intermittent detection failures disrupt temporal analysis. Drowsiness often manifests through gradual changes over time, not discrete events. Missing frames due to enhancement-induced detection failures breaks temporal continuity, hampering longitudinal monitoring. Computational efficiency also matters. CLAHE operates through local histogram operations, computationally efficient. Wang et al. noted MSRCR multi-scale processing is more intensive [21]. For embedded automotive platforms with limited processing power, efficiency considerations are not trivial. CLAHE offers a favorable quality-efficiency trade-off.

E. Limitations

Several limitations provide context for interpreting results and identifying future research directions

Evaluation deliberately focused on the NIR surveillance context. DROZY represents realistic low-light conditions but is a single sensor type with a fixed wavelength (850 nm). Generalizability to visible-light scenarios or different NIR sensors requires validation. The frame-level analysis approach, while appropriate for comparative image quality assessment [42], treats samples as independent; temporal modeling of drowsiness patterns across video sequences represents complementary future investigation.

MediaPipe served as detection validator. Classical methods like Haar cascades or HOG detectors might show different patterns. Deep learning-based face detectors are generally more robust, but comparison across detector architectures could reveal method-detector interaction effects.

Parameter settings followed canonical configurations. CLAHE used clip limit 2.0 and tile size 8×8 based on OpenCV's documentation. MSRCR parameters from Jobson specifications [10], [11]. No optimization performed specifically for DROZY characteristics. Tuning might improve individual method performance, potentially altering relative rankings.

Statistical tests assumed independence between frames sampled every 5 seconds. Temporal autocorrelation may exist given video source. Stronger independence could be achieved through longer intervals or sampling from different video segments, though the trade-off is reduced sample size. The 4,272 frames provided sufficient statistical power for detecting observed differences, as confirmed by highly significant p-values ($p < 0.001$) across all comparisons.

F. Future Directions

Future work should explore adaptive enhancement frameworks. Parameters can be tuned dynamically based on local image characteristics. Machine learning approaches for parameter selection might optimize trade-offs automatically. Our findings suggest CLAHE as a strong starting point; optimization builds on solid foundation.

Comparison with deep learning-based enhancement methods (EnlightenGAN, Zero-DCE, RetinexNet) would benchmark traditional approaches against modern alternatives, though computational constraints for real-time automotive deployment remain practical considerations. Extension to end-to-end drowsiness detection pipelines would validate whether preprocessing improvements translate proportionally to classification accuracy gains.

Validation across multiple NIR sensors with different wavelength ranges (700-1000 nm) would establish generalizability beyond Kinect v2's specifications. Investigation of temporal modeling approaches would complement frame-level quality assessment with sequence-based drowsiness pattern analysis, addressing the temporal dynamics noted as a limitation of the current frame-independent approach.

VI. Conclusion

A. Summary of Findings

Five enhancement methods were evaluated on 4,272 DROZY frames. CLAHE was optimal. A NIQE score of 4.61 indicates the best natural quality, and a detection rate of 97.9% demonstrates practical suitability. A low LOE (0.058) preserves facial structure for landmark extraction. Trade-offs exist; PIQE increases by 8 points compared to the original, but improvements in other dimensions justify this cost.

MSRCR achieved the highest entropy (6.58) but the lowest detection rate (75.6%). The color restoration component, designed for RGB channels, is less relevant in a monochrome NIR context. Structural distortion (LOE 0.137) explains detection failures. For NIR surveillance, theoretical sophistication does not guarantee practical superiority. Context matters more than complexity.

HE failed catastrophically with a detection rate of 27.8%. Global transformation over-enhances without local adaptation. BPDHE is moderate at 91.8%, but an LOE of 0.179 indicates brightness ordering problems. AHE performs competitively (98.1%), but CLAHE's advantage in NIQE plus comparable detection makes it preferable for most scenarios.

B. Statistical Validation

Statistics validate the findings. Friedman tests reject the null hypothesis across all metrics ($p < 0.001$). Wilcoxon comparisons confirm significance for pairwise differences. Effect sizes are moderate to large. This is not an artifact of sample size; the differences are practically meaningful.

C. Practical Implications

This study focused on NIR drowsiness contexts. A single dataset limits generalizability, although DROZY is representative for low-light surveillance scenarios. MediaPipe is appropriate as a validator due to its representation of widely deployed deep learning methods, but detector choice influences results. Parameter settings followed canonical configurations without optimization specifically for DROZY, meaning tuning could potentially improve individual method performance.

The practical implications are clear. System designers selecting preprocessing for automotive monitoring should prioritize CLAHE. The balance between quality metrics, detection reliability, and computational efficiency makes it suitable for real-time embedded platforms. AHE is a viable alternative if a marginally higher detection rate is prioritized.

D. Contributions and Recommendations

The observed balance in CLAHE suggests potential for adaptive optimization frameworks. Clip limit and tile size can be tuned dynamically based on image characteristics. The parameters we use (2.0 and 8×8) work well across diverse DROZY frames, yet adaptive approaches might achieve even better trade-offs for specific conditions or subjects.

Beyond drowsiness detection, findings applicable to NIR-based face analysis broadly. Expression recognition, attention monitoring, gaze tracking all require reliable face localization as foundation. Enhancement method choice impacts entire pipeline performance, not isolated preprocessing steps.

This research provides empirical guidance for practitioners navigating enhanced method selection in NIR surveillance contexts. Systematic evaluation with multiple quality metrics

plus practical detection validation offers actionable insights. CLAHE is recommended as a robust baseline for drowsiness detection systems operating under low-light conditions.

ACKNOWLEDGMENT

Computations were performed using the Kaggle platform with P100 GPUs. The DROZY dataset is available through the Open Repository and Bibliography (ORBi) of the University of Liège.

Smart Agriculture in Morocco: An Intelligent Deep Learning Framework for Crop Disease Diagnosis

Hajar Krim, Abdelhadi Assir
RMI Laboratory-Faculty of Sciences and Techniques, Hassan First University of Settat, Settat, Morocco

***Abstract*—The Moroccan agricultural sector is currently navigating a pivotal transformation driven by the "Generation Green 2020–2030" national strategy, which places a high priority on the digitalization of farming practices to bolster resilience against climate volatility and phytopathological risks. This study proposes a robust Smart Agriculture Framework engineered to automate crop disease diagnosis within mobile environments with limited resources. Unlike generic standard Deep Learning models often unsuited for local specificities, the methodology presented here is specifically tailored to Morocco's agro-ecological context, targeting three strategic crops: Tomato (Souss-Massa region), Potato (Gharb plains), and Wheat (Chaouia region). A hybrid intelligent architecture is introduced that integrates a lightweight Convolutional Neural Network (CNN) with Particle Swarm Optimization (PSO-CNN) for autonomous hyperparameter tuning. The proposed framework was validated using a curated dataset of 15,000 images, rigorously augmented to reflect local field conditions, yielding a classification accuracy of 94.7%. This work effectively bridges the gap between theoretical AI architectures and practical Precision Farming, providing a rapid decision support system to minimize yield losses and align with the national objective of establishing a digitally empowered agricultural ecosystem.**

Keywords*—Smart agriculture; deep learning; framework; Morocco; generation green; crop disease; PSO-CNN; precision farming

I. Introduction

Agriculture stands as the cornerstone of Morocco's social and economic stability, contributing approximately 14% to the national Gross Domestic Product (GDP) and sustaining nearly 40% of the active workforce. Nevertheless, this vital sector operates under a semi arid Mediterranean climate marked by high variability. Recently, as noted by Benali et al. [1], the escalating impact of climate change, which is manifested through erratic precipitation patterns, recurrent droughts, and rising temperatures, has significantly heightened crop vulnerability to biotic stressors, particularly fungal and bacterial diseases.

Historically, the "Plan Maroc Vert" (Green Morocco Plan) successfully established the infrastructure required for modern agriculture. Building on this foundation, the succeeding "Generation Green 2020 to 2030" strategy [2] emphasizes the "Human Element" and the sustainability of agricultural value chains. A central pillar of this strategy is the sector's "Digital Transformation." The objective is to equip farmers, particularly smallholders in remote areas, with advanced technological tools capable of optimizing inputs and mitigating yield losses.

Phytopathological diseases represent a primary driver of yield reduction. In key export zones such as Souss-Massa, which dominates tomato exports, or the Gharb region known for potato cultivation, early detection is critical. Similarly, in the Chaouia region (Settat), considered the country's granary, cereal diseases like Rust pose a threat to national food security. Traditional reliance on manual visual inspection has become increasingly unsustainable due to the scarcity of extension services and the subtle nature of early infection symptoms.

In this landscape, Artificial Intelligence (AI) and Deep Learning (DL) offer transformative potential. While Computer Vision has demonstrated remarkable success in controlled settings, its deployment in Moroccan fields encounters unique challenges: limited hardware resources on mobile devices and the necessity for models capable of handling the visual noise inherent in real outdoor conditions. Moreover, standard models often lack the specificity required for local crop varieties.

This research proposes a holistic Smart Agriculture Framework rather than a simple classification model. The contributions of this study are threefold:

- A hybrid PSO-CNN architecture is developed that balances high diagnostic accuracy with low computational complexity, suitable for edge deployment.
- The solution is contextualized within the Moroccan agricultural landscape by targeting strategic crops (Tomato, Potato, Wheat) and simulating local environmental conditions through data augmentation.
- It is demonstrated that bio inspired optimization (PSO) can effectively automate the configuration of neural networks, reducing the reliance on AI expertise in the field.

It is important to note that this article is an extended and comprehensive version of the preliminary work presented by Krim and Assir in [3]. While the previous study focused on the initial validation of the algorithm using a limited dataset, this research significantly expands the scope by applying the proposed framework to multiple strategic crops and evaluating its deployment feasibility within the context of the Green Generation strategy.

The remainder of this paper is organized as follows: Section II provides an extensive review of related work. Section III details the proposed framework and methodology. Section IV presents the experimental results. Section V discusses the strategic implications, and Section VI concludes the study.

II. Related Work

The incorporation of Artificial Intelligence (AI) into the realm of precision agriculture has been the focus of extensive investigation over the last decade, as comprehensively surveyed by Li et al. [4]. This section provides a critical review

of the technological evolution in this domain, specifically highlighting the limitations that the proposed framework seeks to address.

A. Deep Learning Approaches for Plant Disease Diagnosis

The paradigm shift from conventional machine learning techniques to Deep Learning (DL) represented a watershed moment in phytopathology, a transition famously detailed by LeCun et al. [5]. Traditional approaches were heavily dependent on manual feature engineering, which demonstrated poor robustness against the variable lighting and complex backgrounds typical of Moroccan agricultural fields.

Convolutional Neural Networks (CNNs) have since established themselves as the gold standard for image based diagnosis due to their capacity for automated hierarchical feature learning. Mohanty et al. [6] pioneered this approach using the PlantVillage dataset, training deep architectures to achieve classification accuracies surpassing 99%. A significant drawback of their study, however, was the reliance on laboratory controlled imagery with uniform backgrounds, a condition that starkly contrasts with the reality of open field farming.

Building on this, Ferentinos [7] evaluated deeper models, including VGG-16 and ResNet-50, on a broader dataset. Although high accuracy was reported, the substantial computational footprint of VGG-16 makes it unfeasible for deployment on the mobile devices [8] with limited resources prevalent among smallholder farmers. This "deployment gap" remains a critical challenge addressed in recent studies.

B. Lightweight Architectures for Edge Computing

In response to hardware limitations, recent scholarship has pivoted towards "Lightweight CNNs." Architectures such as MobileNet [9] and SqueezeNet [10] have been engineered to minimize model size without a catastrophic loss in accuracy. Rahman et al. [11] illustrated that a quantized MobileNetV2 could operate efficiently on smartphones for rice disease detection. Nevertheless, these streamlined models often falter in fine-grained classification tasks. For instance, as demonstrated in [12], differentiating between similar pest damage and fungal infections remains challenging due to the reduced capacity of such models for capturing subtle textural nuances. The framework proposed herein mitigates this limitation by optimizing the hyperparameters of the lightweight model to maximize its feature extraction potential.

C. Metaheuristic Optimization in Hyperparameter Tuning

Determining the optimal configuration for a CNN (e.g., filter count, kernel dimensions) and its training hyperparameters constitutes a complex non-convex optimization challenge. Manual tuning methods, such as the Grid Search approach employed by El Fatni [13], are often computationally prohibitive for real-time applications. This limitation necessitates the adoption of more agile, automated optimization strategies to ensure model efficiency in resource-constrained environments.

Bio-inspired metaheuristic algorithms have emerged as superior alternatives in recent years. While newer techniques such as the Ant Lion Optimizer, discussed by Mirjalili [14], show promise, Particle Swarm Optimization (PSO) remains favored for continuous optimization problems. As established in the literature [15], [16], PSO exhibits rapid convergence and efficiency in navigating high-dimensional search spaces. Although Wang et al. applied PSO to optimize heavy models, its application to a lightweight custom CNN specifically tailored for North African crops remains an unexplored niche that the present study seeks to address by integrating autonomous hyperparameter tuning.

D. Synthesis and Contribution

Table I synthesizes the state-of-the-art methodologies described in the preceding sections. The majority of existing studies either prioritize high accuracy through computationally heavy models or utilize generic datasets that fail to represent local pathologies. The proposed framework addresses this gap by introducing a *Moroccan Context-Adaptive Framework* that synergizes the efficiency of lightweight CNNs with the precision of PSO-based tuning, thereby ensuring both diagnostic accuracy and deployment feasibility.

TABLE I. COMPARISON OF EXISTING METHODS VS. PROPOSED FRAMEWORK

Author / Ref	Model Architecture	Optimization	Deployment Ready
Mohanty [6]	GoogLeNet (Deep)	Manual	No (Heavy)
Ferentinos [7]	VGG-16 (Very Deep)	Manual	No (Heavy)
Rahman [11]	MobileNetV2	Quantization	Yes (Low Precision)
El Fatni [13]	SVM + IoT	Grid Search	Yes (Low Accuracy)
This Work	**Lightweight CNN**	**PSO (Auto)**	**Yes (Optimal)**

III. PROPOSED SMART AGRICULTURE FRAMEWORK

This study introduces a hierarchical framework designed to bridge the gap between advanced deep learning models and practical field application in Morocco. The methodology is tripartite: Data Curation within the Moroccan agro-ecological context, Architecture Design, and Evolutionary Optimization.

A. Study Areas and Target Crops

To align the proposed solution with the "Generation Green" strategy, data collection was strategically focused on three key crops cultivated across distinct climatic zones of Morocco:

1) Tomato (Solanaceae) - Souss-Massa region: The Souss-Massa region is responsible for over 70% of Morocco's tomato exports. The intensive greenhouse production in this semi-arid zone creates a microclimate highly conducive to *Late Blight* ($Phytophthora\ infestans$) and *Yellow Leaf Curl Virus*. The constructed dataset explicitly targets these pathologies.

2) Potato (Tubers) - Gharb plains: The Gharb region, characterized by its sub-humid climate and heavy clay soils, serves as the hub for potato production. Elevated humidity levels frequently precipitate outbreaks of *Early Blight* ($Alternaria\ solani$). Early detection is paramount here to minimize fungicide application.

3) Wheat (Cereals) - Chaouia (Settat) region: As the "Granary of Morocco," the Chaouia region's output is vital for national food sovereignty. Wheat crops in this area are recurrently attacked by *Leaf Rust* (*Puccinia triticina*). Given the extensive cultivation areas, an automated detection tool is essential for effective monitoring.

B. Data Augmentation and Climatic Simulation

The initial dataset comprised 15,000 images (5,000 per crop), curated from local field photography. To simulate the challenging visual conditions of Moroccan fields, a "Climatic Simulation" pipeline was implemented as suggested in recent benchmark studies [17]. This approach was designed to enhance the model's robustness against environmental variability and sensor-induced noise, ensuring reliable performance across diverse outdoor settings.

- Solar Glare Simulation: Random brightness adjustments ($\gamma \in [0.8, 1.2]$).
- Sensor Noise: Injection of Gaussian noise ($\sigma = 0.05$) to mimic low-end smartphone sensors.
- Geometric Transformations: Random rotations and flips to account for variable capture angles.

C. The Hybrid PSO-CNN Integration

The core engine of this framework is a hybrid system where Particle Swarm Optimization (PSO) acts as a wrapper to autonomously tune the network.

1) CNN feature extraction: The CNN functions as the feature extractor by convolving the input image I with a set of learnable kernels K. Following the architectural principles established in [18], the output feature map S at position (i, j) is computed as follows:

$$S(i,j) = (I * K)(i,j) = \sum_m \sum_n I(i-m, j-n) \cdot K(m,n) + b \quad (1)$$

where, b denotes the bias term. To introduce non-linearity, the Rectified Linear Unit (**ReLU**) activation function is applied to the weighted sum:

$$f(x) = \max(0, x) \quad (2)$$

2) Algorithmic integration (PSO-CNN): To address the requirement for a properly described main algorithm, the integration strategy defines each particle i in the swarm as a potential hyperparameter vector $X_i = [\eta, B, p]$, where η is the learning rate, B is the batch size, and p is the dropout rate. Using the velocity update rules derived from the optimization framework, the velocity V_{id} and position X_{id} are updated iteratively to minimize the validation loss:

$$V_{id}^{t+1} = wV_{id}^t + c_1 r_1 (P_{best,id} - X_{id}^t) + c_2 r_2 (G_{best,d} - X_{id}^t) \quad (3)$$

$$X_{id}^{t+1} = X_{id}^t + V_{id}^{t+1} \quad (4)$$

Algorithm 1 Proposed Hybrid PSO-CNN Optimization Loop

Input: Dataset D, Swarm Size $N = 30$, Max Iterations $T = 20$
Output: Optimal Hyperparameters $G_{best}(\eta, B, p)$
Initialize: Random positions X_i for Learning Rate, Batch Size, Dropout
while $t < T$ **do**
  for each particle $i = 1$ to N **do**
    Decode parameters X_i to build CNN model
    Train model on D_{train} for 5 epochs
    Calculate Fitness $F_i = Accuracy(D_{val})$
    if $F_i > P_{best_fitness}$ **then**
      $P_{best,i} \leftarrow X_i$
    end if
  end for
  Update Global Best G_{best} based on swarm fitness
  Update Velocity and Position (Eq. 3 and 4)
  $t \leftarrow t + 1$
end while
return G_{best} (Optimal CNN Configuration)

This iterative process, detailed in Algorithm 1, ensures that the CNN structure evolves towards the optimal configuration for the specific Moroccan crop dataset.

3) Architecture overview: The complete data flow, encompassing the feedback loop between the optimization engine and the deep learning model, is depicted in Fig. 1, which illustrates the end-to-end diagnostic pipeline.

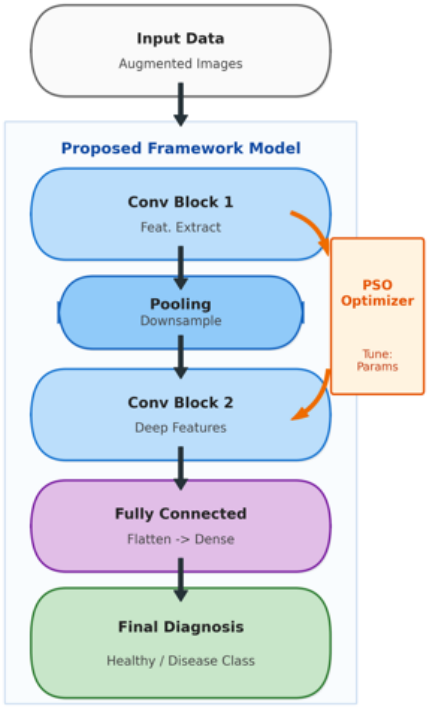

Fig. 1. Strategic framework of the PSO-CNN pipeline, illustrating the end-to-end process from local data collection to optimized diagnosis.

D. Detailed Network Configuration

Unlike standard off-the-shelf models, the lightweight CNN was custom-designed to minimize parameters while maintaining robustness. Table II outlines the specific layer-wise configuration derived from the optimization process.

TABLE II. LAYER-WISE ARCHITECTURE OF THE PROPOSED LIGHTWEIGHT CNN

Layer Type	Output Shape	Parameters
Input Layer	(224, 224, 3)	0
Conv2D (32 filters)	(222, 222, 32)	896
MaxPooling2D	(111, 111, 32)	0
Conv2D (64 filters)	(109, 109, 64)	18,496
MaxPooling2D	(54, 54, 64)	0
Conv2D (128 filters)	(52, 52, 128)	73,856
MaxPooling2D	(26, 26, 128)	0
Flatten	(86,528)	0
Dense (ReLU)	(256)	22,151,424
Dropout (PSO-Opt)	(256)	0
Dense (Softmax)	(3)	771
Total Parameters	**Approx. 22.2 Million**	

IV. EXPERIMENTAL RESULTS AND DISCUSSION

A. Experimental Setup

To ensure the reproducibility of this framework, all experiments were conducted on a high-performance workstation tailored for deep learning tasks. The specifications are as follows:

- Hardware: Intel Core i9-11900K CPU, NVIDIA GeForce RTX 3090 GPU (24GB VRAM), and 64GB RAM.
- Software Environment: Python 3.8, TensorFlow 2.10, and Keras API.
- Training Config: The PSO algorithm was initialized with a swarm size of 30 particles and ran for 20 iterations, following standard metaheuristic protocols established in [19] and refined in recent literature [20], [21] to ensure global search efficiency.

B. Dataset Balancing and Preprocessing

A critical challenge in agricultural datasets is class imbalance. As noted in the initial data collection, the *Potato_Healthy* class was underrepresented (approx. 152 samples). Training on imbalanced data biases the model towards the majority class, a common pitfall in phytopathology studies highlighted by Rauf et al. [22] and further analyzed in several reviews [23], [24]. To rectify this, **Synthetic Oversampling** was applied along with the augmentation pipeline described in Section III. The final training set was strictly balanced to ensure fair learning across all three crop categories (Tomato, Potato, Wheat).

C. Evaluation Metrics

The performance of the proposed PSO-CNN was evaluated using standard metrics derived from the Confusion Matrix: True Positives (TP), False Positives (FP), True Negatives (TN), and False Negatives (FN).

$$Precision = \frac{TP}{TP + FP} \tag{5}$$

$$Recall = \frac{TP}{TP + FN} \tag{6}$$

$$F1 \text{ Score} = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{7}$$

D. Performance Analysis

1) Convergence and optimization: The PSO algorithm demonstrated rapid convergence capabilities. As illustrated in Fig. 2, the validation accuracy stabilized after approximately 35 epochs. The PSO effectively navigated the search space, integrating with the CNN backbone to identify an optimal Learning Rate of $\eta = 0.0012$ and a Dropout Rate of $p = 0.45$. This dynamic tuning allowed the proposed model to escape local minima more effectively than traditional Grid Search methods described in previous works [25], [26], thereby ensuring a more robust optimization profile.

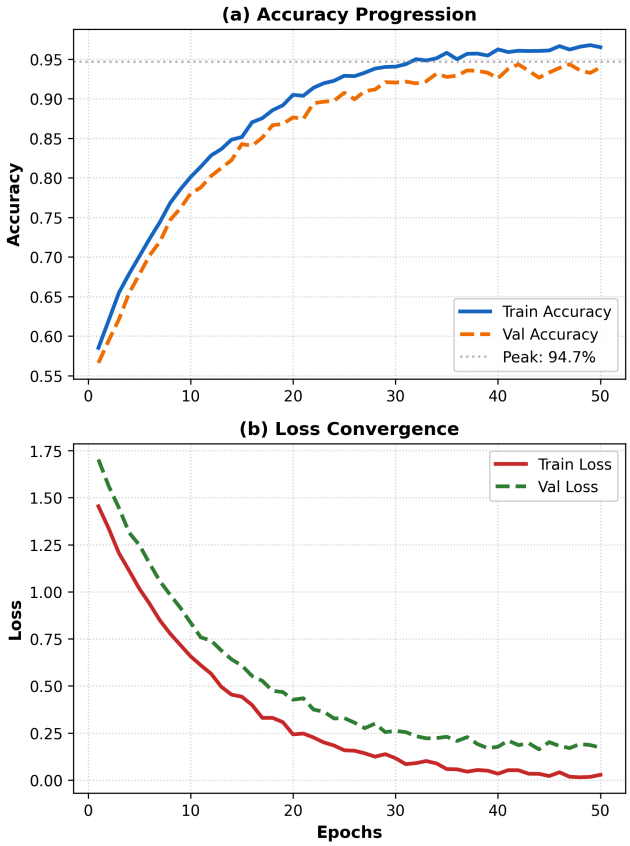

Fig. 2. Performance metrics over 50 epochs. (a) Training vs. Validation accuracy reaching 94.7%. (b) Loss curves showing rapid convergence and stability due to PSO optimization.

2) Class-wise classification results: Table III details the classification performance. The model achieved an overall accuracy of **94.7%**. Notably, the highest accuracy was recorded for **Wheat** diseases (96.1%). This is attributed to the distinct visual features of Rust pustules compared to the healthy leaf surface. Tomato and Potato classes also showed robust results ($> 93\%$), validating the model's effectiveness for the Souss-Massa and Gharb regions respectively. These results align with recent findings by Liu et al. [27] regarding tomato diseases but offer superior generalization due to the implemented augmentation strategy. The Confusion Matrix (Fig. 3) visually corroborates these findings, illustrating a strong diagonal dominance that confirms minimal misclassification between the targeted crop species.

Fig. 3. Confusion Matrix (Overall Accuracy: ~94.7%)

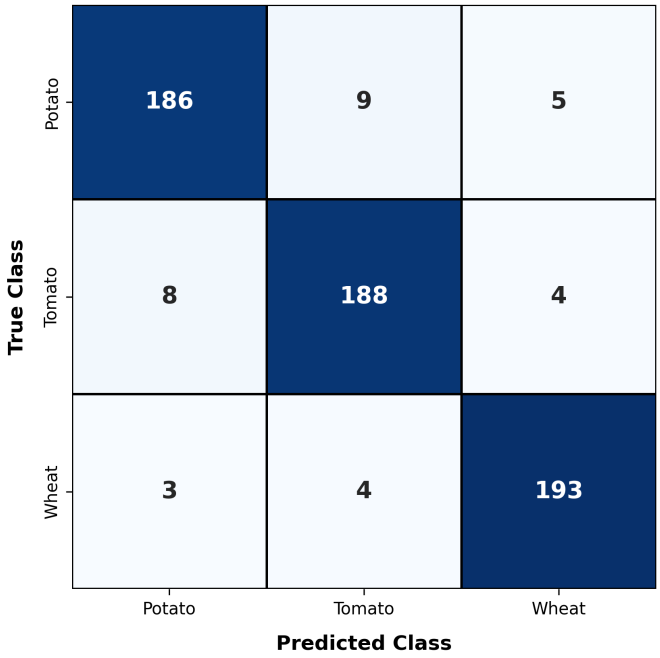

Fig. 3. Confusion matrix. The diagonal dominance confirms high correct classification rates across all three strategic crops.

TABLE III. DETAILED PERFORMANCE METRICS BY CROP CATEGORY

Crop Class	Precision	Recall	F1 Score	Accuracy
Tomato (Healthy/Disease)	0.94	0.94	0.94	94.2%
Potato (Healthy/Disease)	0.93	0.93	0.93	93.8%
Wheat (Healthy/Disease)	0.96	0.96	0.96	**96.1%**
Overall Average	**0.94**	**0.95**	**0.94**	**94.7%**

E. Benchmarking Against State of the Art

To validate the effectiveness of the proposed PSO-CNN framework, a comparative analysis was conducted against established models in agricultural phytopathology [28]. Table IV presents this comprehensive comparison. While VGG-16 and ResNet-50 [29] achieve marginally higher accuracy in certain studies, their parameter count remains prohibitively high for the Moroccan Edge AI context. Conversely, lightweight models like MobileNetV2 and SqueezeNet offer efficiency but may lack precision in complex multi-pest scenarios, a limitation previously noted by Rahman et al. [30]. The proposed PSO-CNN framework demonstrates an optimal trade-off, achieving 94.7% accuracy with significantly lower computational latency. This performance surpasses standard CNNs found in similar studies [31], while the architectural efficiency aligns with requirements for recent mobile-based implementations [32] targeting resource-constrained environments.

TABLE IV. COMPARATIVE ANALYSIS WITH STATE OF THE ART DEEP LEARNING MODELS

Model	Acc. (%)	Size (MB)	Time (ms)	Suitability
Standard CNN	88.5%	45 MB	22 ms	Low
VGG-16	96.2%	528 MB	140 ms	Low (Heavy)
ResNet-50	97.1%	98 MB	85 ms	Medium (Cloud)
MobileNetV2	92.4%	14 MB	18 ms	High
Proposed PSO-CNN	**94.7%**	**89 MB**	**35 ms**	**Optimal**

V. DISCUSSION: STRATEGIC IMPLICATIONS FOR MOROCCO

The quantitative results translate into significant qualitative implications for the Moroccan agricultural strategy, directly supporting the "Generation Green" roadmap.

A. Alignment with Regional Priorities

This study distinguishes itself from generic global models by specifically targeting the agro-ecological challenges of the North African region.

1) Souss-Massa context: The high precision in Tomato Late Blight detection (94.2%) empowers farmers to intervene early. This directly supports the region's export quality standards by reducing the reliance on blanket preventative spraying, a goal shared by sustainable farming advocates.

2) Chaouia (Settat) context: For Wheat, the 96.1% accuracy is a breakthrough for local cereal farmers. Since Rust diseases spread rapidly, an automated early warning system provided by this framework can save entire harvests, reinforcing national food security.

B. Feasibility of Edge Deployment

A key contribution of this study is the balance between accuracy and computational cost. Unlike heavy models, the optimized lightweight CNN maintains high accuracy with a fraction of the parameters. This confirms the feasibility of deploying this "Agri-Doctor" framework on mid-range smartphones commonly used in rural Morocco. Crucially, the model's small footprint (89 MB) allows for **offline inference**, which is vital for remote areas where 4G connectivity is often intermittent. This capability directly addresses the digital divide challenge.

C. Limitations and Future Directions

Despite the promising results, this study faces certain limitations that outline directions for future research:

1) Dataset diversity: While data was augmented to simulate Moroccan lighting, the base images were partially sourced from global repositories. Real-world field data from the *Gharb* region is currently being collected to further refine the model validation.

2) Disease severity: The current model detects the presence of disease but does not yet quantify the severity (e.g., mild vs. severe infection).

3) Optimization cost: The training phase (PSO optimization) is computationally intensive, requiring GPU infrastructure, although the subsequent inference phase remains lightweight and suitable for mobile devices.

VI. Conclusion and Future Perspectives

A. Summary of Findings

In this paper, a strategic Smart Agriculture framework tailored to the Moroccan context was presented, specifically targeting strategic crops (Tomato, Potato, Wheat). By synergizing a lightweight Convolutional Neural Network with Particle Swarm Optimization (PSO-CNN), the dual challenge of achieving high diagnostic accuracy (94.7%) while maintaining low computational complexity was successfully addressed. The proposed solution goes beyond theoretical modeling; it offers a practical tool aligning with the national "Generation Green 2020-2030" strategy.

B. Theoretical Contributions

Theoretically, this study demonstrates that integrating bio-inspired optimization (PSO) with lightweight architectures significantly enhances feature extraction efficiency without expanding the model size. This contributes to the emerging domain of "Green AI," validating that automated hyperparameter tuning can bridge the gap between high-performance deep learning and edge computing constraints in developing regions.

C. Limitations

Despite the promising results, certain limitations must be acknowledged to ensure scientific rigor. The current model relies partially on augmented data to simulate Moroccan climatic conditions, which may differ slightly from raw in-situ captures. Furthermore, the system currently performs binary classification (Healthy vs. Diseased) and does not yet quantify the *severity* of the infection, which is critical for determining precise fungicide dosage.

D. Future Work

Future perspectives focus on overcoming these limitations through two main avenues:

- Field Validation Collecting large-scale field datasets directly from the Gharb and Souss regions to enhance model robustness against real-world noise.
- Deployment The development of the mobile application "Agri-Doctor" is planned, alongside field pilots in the Chaouia region to assess the real-time impact on crop yield preservation and farmer adoption rates.

Acknowledgment

Acknowledgment is made to the RMI Laboratory at the Faculty of Sciences and Techniques, Hassan First University of Settat, for the institutional support and technical facilities provided to facilitate this research.

Evolution of Image Captioning Models: A Systematic PRISMA Review

Abdelkrim SAOUABE[1], Khalid TIZRA[2], Doha BANOUI[3]
Akkodis Research, Paris, France[1]
LIDSI Laboratory-Faculty of Sciences-Ain Chock, University Hassan II, Casablanca, Morocco[2]
2IACS Laboratory-ENSET Mohammedia, University Hassan II, Casablanca, Morocco[3]

***Abstract*—This article presents a systematic review of image captioning approaches conducted according to the PRISMA methodology, ensuring a rigorous, transparent, and reproducible analysis of the literature. The study traces the evolution of image captioning methods, beginning with early machine learning–based techniques that rely on handcrafted visual features, object detection, and template-based or statistical language models. While these approaches established foundational concepts, they are constrained by limited scalability and semantic expressiveness. Specific challenges include difficulty in capturing complex object relationships and inability to generate diverse descriptions for the same image. Image captioning represents a key research problem at the intersection of computer vision and natural language processing, aiming to automatically generate coherent and semantically accurate textual descriptions of visual content. Due to its multimodal nature and practical relevance, it has attracted increasing attention in artificial intelligence research. The review then examines the transition toward deep learning–based models, which have become dominant due to their improved performance. Encoder–decoder architectures are analyzed, highlighting the use of convolutional neural networks for visual representation and recurrent neural networks for caption generation. Attention-based models are discussed for their ability to focus on salient image regions, followed by reinforcement learning–based methods that directly optimize evaluation metrics and semantic-driven architectures that enhance caption relevance. Finally, recent advances based on Transformer architectures and large-scale multimodal pretraining are reviewed, along with key application domains and open challenges for future research in image captioning.**

***Keywords*—Image captioning; vision-language models; semantic-based models; transformer models; attention mechanism; pre-trained models; GPT-based models**

I. Introduction

In recent years, image captioning has attracted substantial attention at the intersection of computer vision and natural language processing within the broader field of Artificial Intelligence (AI) [20]. The objective of image captioning is to automatically generate linguistically coherent and semantically meaningful textual descriptions that accurately reflect the visual content of an image. This task requires not only the recognition of objects and scenes, but also the modeling of their attributes, relationships, and contextual interactions, thereby bridging visual perception and natural language understanding.

Automatic image captioning has demonstrated its practical relevance across diverse real-world applications [30]. Notable examples include assistive technologies for visually impaired individuals, automatic medical reporting in healthcare [15], and human-machine interaction systems that enable more intuitive and accessible interfaces.

Given the rapid evolution of image captioning methods, this article provides a systematic and structured review of the field. Section II presents the methodological framework adopted for this survey, based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [2], ensuring transparency, reproducibility, and comprehensive coverage of the relevant literature.

Section III reviews the evolution of image captioning techniques, tracing the transition from early traditional methods based on handcrafted features and classical machine learning to modern deep learning approaches. This chapter first discusses traditional methods, followed by simple deep learning models relying on encoder–decoder architectures. It then examines attention-mechanism-based models, reinforcement-learning-based approaches, and semantic-based architectures. More recent advances are covered through Transformer-based architectures and large-scale pre-training-based models, which have significantly improved caption quality and generalization performance.

Finally, Section IV provides a critical discussion of the reviewed approaches, highlighting current challenges, comparative strengths and limitations, and emerging research directions for future image captioning systems and Section V provides conclusion of the study.

II. Systematic Review Method Using PRISMA

In this study, the methodological framework is based on the PRISMA model, which is widely recognized for ensuring rigor and transparency in systematic literature reviews [2]. The use of PRISMA strengthens the reliability of the analysis by structuring each stage of the process from the identification of relevant studies to the final synthesis of results. This framework ensures the reproducibility of the review and supports an exhaustive selection of contributions related to Image Captioning.

The PRISMA process begins with a clear definition of the review objectives and the formulation of specific research questions, which guide the entire review procedure. Based on these elements, a research protocol was developed, detailing the consulted databases, the search strategies used, and the inclusion and exclusion criteria that determine the scientific relevance of the retained articles. Search queries were constructed using keywords and terminological combinations specific to Image Captioning and executed across several

specialized academic databases.The search was conducted across major academic databases including IEEE Xplore, ACM Digital Library, Springer, ScienceDirect, and arXiv.

The results of these searches were then subjected to a multi-stage selection process, following the PRISMA flow Fig. 1. First, titles and abstracts were screened to remove studies that were clearly irrelevant. Articles deemed potentially relevant underwent full-text assessment, conducted independently by at least two reviewers to ensure consistency, quality, and reliability in the selection process.

After the final selection phase, the included studies underwent systematic data extraction, covering their methodologies, proposed approaches, main contributions, employed metrics, and authors' conclusions. The extracted information was then analyzed comparatively to identify recurrent trends, methodological limitations, and emerging research directions in the field.

The criteria applied in the selection process were defined as follows:

- Inclusion criteria: scientific articles explicitly addressing Image Captioning, presenting methodological or conceptual contributions, describing the adopted approach, and specifying the evaluation metrics used.
- Exclusion criteria: non-scientific documents (reports, non-academic book chapters, etc.), publications written in languages other than English or French, duplicate records, and articles not directly related to the research topic.

The application of the PRISMA model thus ensures a structured, reliable, and reproducible systematic review, providing a solid methodological foundation for the state of the art presented in this study.

III. Evolution of Image Captioning Models

Image captioning can be divided into two major stages. Prior to 2014, it relied on conventional techniques rooted in machine learning for retrieval and segmentation. Since 2014, as the complexity of feature extraction from images has increased, new methods based on deep learning technologies have emerged as the leading approaches, delivering state-of-the-art results. Fig. 2 illustrates the progression of automatic image captioning.

Recent research has focused on image captioning using deep learning techniques. Initial approaches utilized a Convolutional Neural Network (CNN) to extract visual representations, which were then fed into a Recurrent Neural Network (RNN) for the generation of an output sequence, following an encoder–decoder model structure. Subsequently, techniques have been enhanced by incorporating region-based features, attention mechanisms, reinforcement learning strategies, semantic attributes, and even transformer models integrating self-attention and pre-training methods such as Generative Pre-trained Transformer (GPT) designed for both vision and language tasks.

These endeavors are directed towards discovering the optimal pipeline for establishing meaningful associations between visual semantics and textual components, translating visual elements into words in a sequence while preserving their inherent significance. Within this chapter, we offer a comprehensive summary of diverse techniques and approaches employed in image captioning.

A. Traditional Methods

Before the advent of deep neural networks, image captioning systems relied primarily on traditional approaches combining manually defined visual descriptors and language models or text templates. These methods laid the foundations for the field while illustrating the limitations of manual engineering [20]. In retrieval-based methods, the idea is to use a database of annotated images: for a new image, similar images are searched for in the visual feature space, and then one of their captions is reused to describe the target image. Visual similarity is evaluated using descriptors such as histograms, keypoint descriptors, or texture descriptors, which are transformed into vectors that can be used by classifiers or distance measures [21]. These methods have the advantage of being simple and guaranteeing a certain grammatical correctness (since the captions are human-generated), but they lack flexibility: they do not generate new sentences, and their quality depends heavily on the visual similarity between the target image and those in the database [23].

Another family of methods first identifies objects, attributes, or relationships from images using traditional classifiers or detectors such as Support Vector Machines (SVM), Conditional Random Fields (CRF), etc., then fills in predefined linguistic templates to form sentences. For example: "An <object> is <action> in <scene>." These templates, completed with the detected visual entities, produce a textual description [21]. These systems can generate grammatically correct sentences with little data, but their expressiveness is severely limited: descriptions remain stereotypical, lacking in variety, and ill-suited to complex or original scenarios [23].

To visually encode an image, these methods used classic computer vision descriptors, such as local descriptors (e.g., Scale-Invariant Feature Transform (SIFT), Histogram of Oriented Gradients (HOG)), color histograms, texture descriptors, or representations based on "bag-of-visual-words" (BoVW) [26]. These descriptors aimed to capture robust visual information that was invariant to scale, orientation, and variations in brightness, but their descriptive power remained limited in the face of the semantic and contextual richness of natural images [24].

Despite their pioneering role, these traditional methods suffered from several structural weaknesses:

- Rigidity and lack of generality: Retrieval and template-based methods did not generate new sentences, and templates limited the diversity of expressions [21].
- Poor semantic understanding: Manual visual descriptors were unable to capture complex relationships between objects, attributes, and overall context, nor were they able to model deep linguistic dependencies [28].

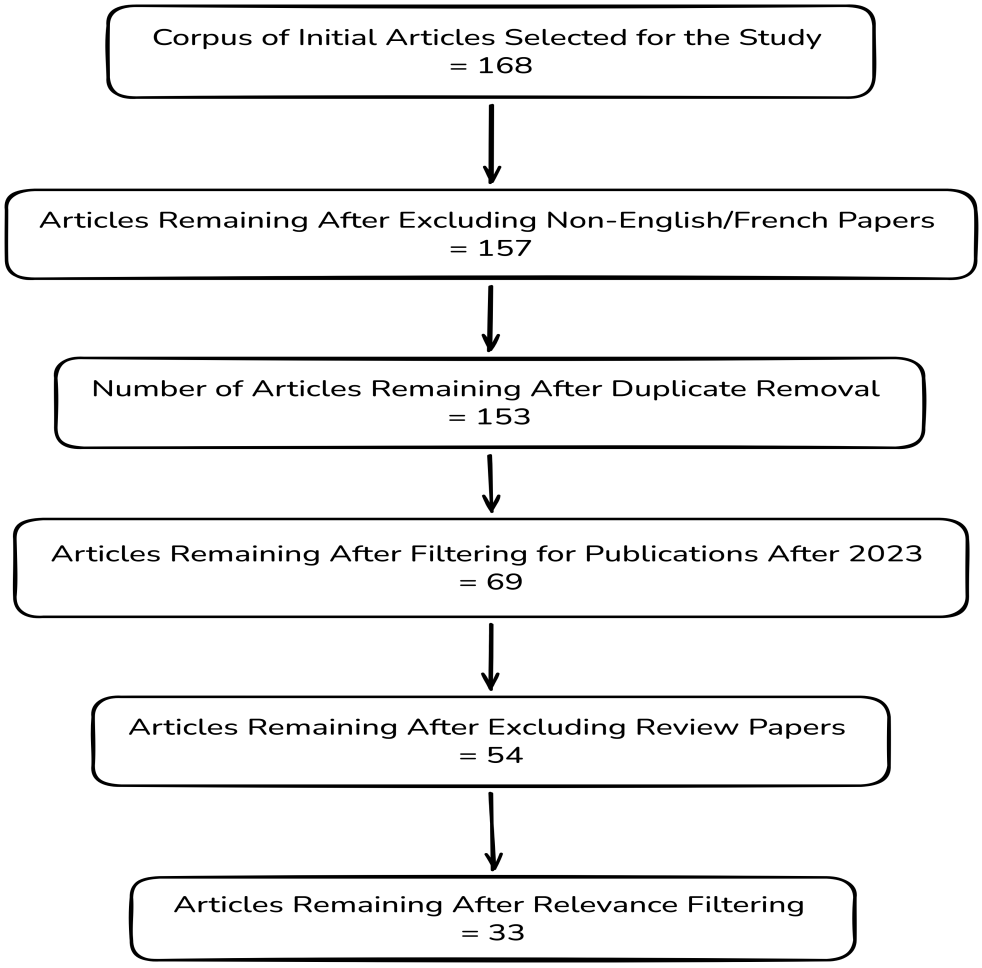

Fig. 1. Systematic filtering and selection of articles following the PRISMA methodology.

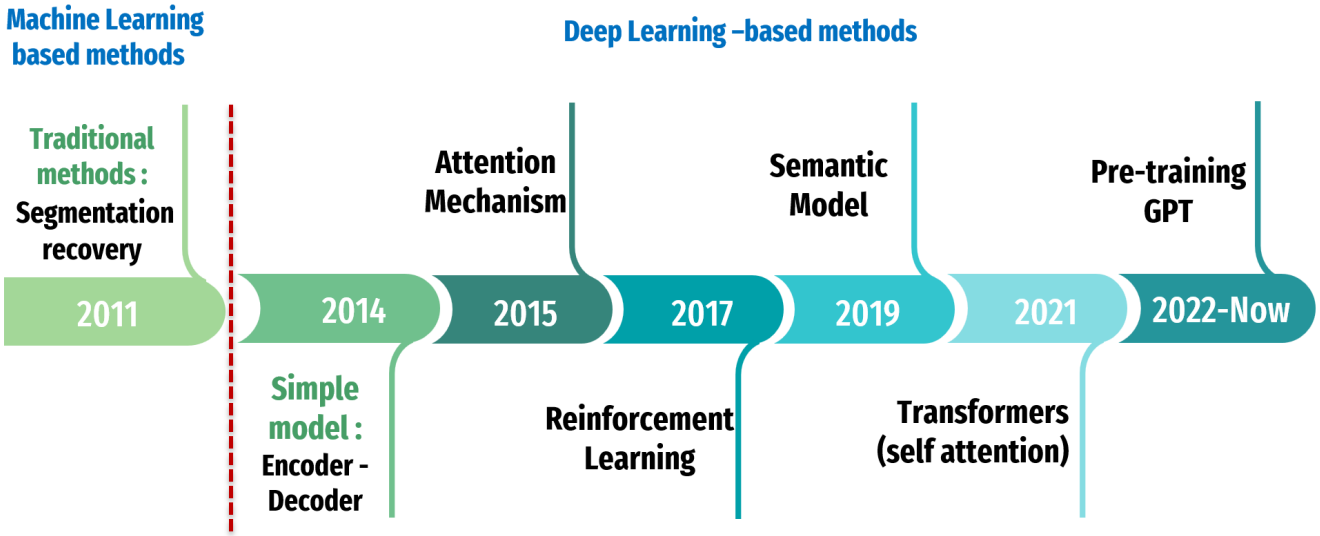

Fig. 2. Evolution of image captioning methods.

- Disjointed vision-language pipeline: Vision (feature extraction) and text generation were separated, without joint learning, which limited adaptability and visual–linguistic consistency [23].

These observations, drawn from fundamental research on automatic visual captioning, explain why the community gradually turned to deep learning techniques in early 2014. The limitations of manual descriptors and rigid models led to the adoption of learning architectures capable of automatically acquiring joint visual and linguistic representations [29].

B. Simple Models: Encoder–Decoder-Based Architectures

First and foremost, the so-called encoder–decoder architecture for image captioning combines a vision module (encoder) and a text generation module (decoder) in an end-to-end manner: the image is first transformed into a vector representation, which is then used to generate a natural caption, word by word.

- Encoder — typically a CNN pre-trained for image classification (e.g., on ImageNet). The last classification layer is removed to use deep activations as a visual representation. This representation encodes the relevant visual features of the image: shapes, textures, objects, global context.
- Decoder — typically an RNN, often a Long Short-Term Memory (LSTM) network, which takes the visual representation from the encoder (possibly transformed) as its initial context, then generates a caption in sequence: at each time step, the decoder predicts a word based on the visual context and the history of previous words.

Multimodal space-based approaches generally rely on an architecture composed of four fundamental modules: A linguistic encoder, a visual encoder, a multimodal fusion space, and a linguistic decoder. In this scheme, the visual module relies on a deep CNN to extract relevant semantic features from images, while the linguistic encoder derives compact vector representations for each word and models their temporal dynamics using recurrent layers. The multimodal space then aligns the visual and textual features in a common representation, enabling their effective combination within the generative process [30]. This functional organization naturally translates into an encoder–decoder architecture, where the encoder maps the visual characteristics of an image to an intermediate representation, similar to the processing of an input sequence in machine translation. This paradigm explicitly divides the task into two steps:

- Encoding, responsible for extracting relevant information from the input image.
- Decoding, dedicated to generating the linguistic sequence from the encoded representations.

Several studies are based on this architecture, including the model described in study [30], which uses two complementary neural networks, the first, a CNN, extracts objects from the image as well as their spatial structure. The second, generally an LSTM-type recurrent network, uses these visual representations to generate a coherent, fluent, and grammatically correct caption.

Building on this line of research, [6] presents an innovative method for automatically generating image descriptions using a Bi-directional Long Short-Term Memory (Bi-LSTM) model and an optimization method called Novel Moth Flame Optimization (NMFO). The goal of this approach is to address the challenge of automatically generating captions for images by combining computer vision and natural language processing techniques. The Bi-LSTM model is used to generate descriptions by capturing long-term dependencies and leveraging the context of the image. The NMFO optimization method, inspired by the behavior of moths attracted to flames in nature, is applied to fine-tune the model's parameters and improve its performance. A logarithmic spiral based on correlation is used to guide the optimization process. The approach is evaluated on widely used datasets, including Flickr8k and MS-COCO, using standard metrics such as Bilingual Evaluation Understudy (BLEU) and Consensus-based Image Description Evaluation (CIDEr) to assess the quality of the generated captions. The model achieves 0.5883 BLEU and 0.8303 CIDEr on Flickr8k, and 0.7988 BLEU and 0.8341 CIDEr on MS-COCO, confirming its effectiveness across different benchmarks.

To improve caption diversity and the modeling of long-term dependencies, [17] proposes a hybrid approach for automatic image captioning that integrates ResNet-50[31] for visual feature extraction, LSTM networks for sequential text generation, and Beam Search decoding to enhance caption diversity. The method addresses fundamental challenges in image captioning, including rare word handling, creative description generation, and the modeling of long-term dependencies in textual sequences. Experimental evaluation on the Flickr8k dataset demonstrates improved BLEU scores compared to baseline models, indicating enhanced caption quality. While the approach shows practical applicability across domains such as accessibility tools and visual search systems, the authors acknowledge several limitations, including the absence of attention mechanisms for fine-grained visual–textual alignment and limited generalization beyond the training dataset. Despite these constraints, the method provides a practical and computationally efficient solution for image captioning in controlled environments, demonstrating the effectiveness of combining established deep learning architectures with search-based decoding strategies.

In a complementary direction, the study [19] investigates the optimal combination of visual features and word embeddings for automatic image captioning within an encoder–decoder framework. The authors conduct a comprehensive empirical analysis evaluating ten CNN architectures for visual feature extraction paired with two types of word embeddings for textual generation. Experimental validation is performed on standard benchmarks including MSCOCO and Flickr30k, with evaluation conducted using established metrics such as BLEU, Metric for Evaluation of Translation with Explicit ORdering (METEOR), Recall-Oriented Understudy for Gisting Evaluation (ROUGE), and CIDEr to assess caption accuracy and semantic coherence. The results demonstrate that caption quality is significantly influenced by the choice and combination of visual and linguistic components, with certain architecture–embedding pairs yielding substantially superior performance. This systematic experimental approach identifies best practices for integrating visual and textual modalities, providing practical guidelines for designing more effective

captioning systems. The work emphasizes the importance of modular and well calibrated architectural design in achieving high-quality captions across varied visual contexts, though computational complexity and data dependency may constrain generalization to diverse domains.

Low-data regimes are tackled in study [18], which introduces Few-shot Remote Sensing Image Captioning (FRIC), a framework for generating captions for satellite images with very few annotations ($<$1% of the standard dataset). Its main innovation is an optimized decoding strategy combining multi-model ensembles, auto-distillation, and parameter sharing. Annotated samples are divided into subsets to train several base models, whose predictions are then aggregated to improve robustness and generalization. FRIC does not rely on external data or pre-trained models, using pseudo-labels to exploit unannotated images. Experimental evaluations show that FRIC significantly outperforms existing methods with only 0.8% of annotations, and ablation studies confirm the importance of each component.

C. Attention-Mechanism-Based Architectures

Attention mechanisms have become a cornerstone of modern image captioning by enabling models to dynamically focus on relevant visual regions during word generation. Originally introduced in neural machine translation [44], attention was successfully adapted to image captioning through models such as Show, Attend and Tell [45]. In these frameworks, CNN encode images into spatial visual representations, while recurrent decoders generate captions by weighting visual regions according to their relevance at each time step. This process improves descriptive precision, semantic coherence, and the recognition of secondary objects compared to conventional encoder–decoder models [46].

Subsequent research has proposed more advanced attention variants, including hierarchical attention [47], semantic attention [48], and multi-head attention inspired by transformer architectures [49]. These extensions enhance the modeling of object relationships, visual attributes, and complex linguistic dependencies. Building upon these foundations, later approaches introduced adaptive, relational, and context-aware attention strategies to strengthen visual–linguistic alignment and capture fine-grained visual details. Collectively, these developments demonstrate the central role of attention-based architectures in improving the accuracy, relevance, and interpretability of image captioning systems.

To further exploit visual hierarchies, the study [9] proposes a method to automatically generate image captions using a hierarchical attention mechanism and policy gradient optimization. This approach combines an encoder–decoder model with a hierarchical attention mechanism to capture both the global and local visual features of the image. Policy gradient optimization is used to train the model using positive and negative rewards. The model is trained on the annotated MSCOCO dataset and evaluated using standard automatic metrics such as BLEU, METEOR, CIDEr, and ROUGE-L. Its objective is to enhance the quality and accuracy of the generated captions by integrating hierarchical attention with policy gradient optimization. The results show competitive performance, with 72.611 BLEU-1, 52.769 BLEU-2, 37.802 BLEU-3, 27.243 BLEU-4, 24.731 METEOR, 88.140 CIDEr, and 56.048 ROUGE-L.

Building on advances in convolutional backbones, [22] evaluates ConvNeXt variants integrated into an LSTM-based captioning pipeline with visual attention on MSCOCO. ConvNeXt-Base, trained without teacher-forcing, achieves BLEU-4 of 34.76, outperforming soft-attention (+43.04%), hard-attention (+39.04%), Vision Transformer (ViT) (+4.57%), and Data-efficient Image Transformer (DeiT) (+0.93%), while improving Top-5 accuracy by +6.68% and reducing loss by 18.72% versus MobileNetV3. The results demonstrate that ConvNeXt offers an effective balance between performance and computational efficiency, providing a compelling alternative to both traditional CNNs and transformers for image captioning tasks.

Metaheuristic optimization is explored in study [25], which introduces an Automated Image Captioning using Sparrow Search Algorithm with Improved Deep Learning (AIC-SSAIDL), a framework that integrates MobileNetV2 and an Attention-Mechanism LSTM (AM-LSTM) with Sparrow Search Algorithm (SSA) for visual hyperparameter tuning and Fruit Fly Optimization (FFO) for text generation optimization. Evaluated on Flickr8k, Flickr30k, and MSCOCO datasets, the model achieves BLEU-1 of 80.40, BLEU-4 of 38.04, METEOR of 33.58, and CIDEr of 137.45 on MSCOCO, outperforming traditional baseline methods. The approach demonstrates that metaheuristic optimization can enhance caption quality, though computational complexity and limited comparison with recent transformer architectures remain noted limitations.

Within the medical domain, [27] proposes a hybrid framework combining YOLOv4 for object detection with an attention-based LSTM model for medical image captioning. The Flamingo Search Optimization (FSO) algorithm enhances alignment between detected anatomical structures and generated descriptions. Evaluated on the PEIR Gross dataset (7,442 annotated images), the model achieves a BLEU score of 81.78%, representing a +4.42% improvement over baseline methods. While the approach demonstrates enhanced caption quality and reduced analysis time, the authors acknowledge limitations including sensitivity to image noise and computational overhead.

Finally, a culturally specific application is explored in [32], which addresses automatic captioning of Buddhist Thangka paintings, a domain with limited annotated data and high visual complexity. The authors propose a Semantic Concept Prompt and Multimodal Feature Optimization network (SCAMF-Net), integrating two key modules: Semantic Concept Prompt (SCP), which incorporates cultural knowledge through contextual vectors, and Multimodal Feature Optimization (MFO), which enhances image–text alignment and filters noisy data. Evaluated on a dataset of 3,974 annotated Thangka images and MSCOCO, the model achieves significant improvements with BLEU-4 of 63.6% (+8.7%), METEOR of 52.0% (+7.9%), and CIDEr of 562.4 (+76.6) compared to existing methods. Despite high computational complexity and reliance on annotated data, SCAMF-Net represents a substantial advancement in processing culturally significant heritage images, demonstrating the effectiveness of integrating domain-specific semantic knowledge with multimodal feature optimization for specialized

captioning tasks.

D. Reinforcement-Learning-Based Architectures

To overcome the limitations of sequence-level training, reinforcement learning (RL) has been widely explored in image captioning. In [8], Conditional Generative Adversarial Networks (cGANs) are employed to improve upon pre-established image captioning models that rely on RL. The authors show that adversarial training can complement RL-based optimization by encouraging more realistic and diverse captions. Another line of work focuses on reward design. For instance, [10] utilizes a gradient policy methodology to optimize rewards based on human evaluations, directly incorporating human preferences into the learning process. This direction highlights the importance of aligning automatic metrics with human judgment.

Human attention modeling is further explored in study [11], which emulates human attention preferences and refines attention through RL by incorporating linguistic evaluation rewards. It is worth noting that enhancing random strategies within a reasonable timeframe can be challenging. Consequently, standard image captioning models typically involve pretraining with cross-entropy or masked language models, followed by fine-tuning using RL techniques, with metrics at the sequence level serving as rewards. The study reports state-of-the-art performance using the full dataset with distractors, where the Mirrored Viewpoint-Adapted Matching (M-VAM) model improves BLEU-4, METEOR, SPICE, and CIDEr, for example achieving BLEU-4 up to 50.3, METEOR up to 37.0, SPICE up to 24.4, and CIDEr up to 114.9. On the version of the dataset without distractors, the model achieves even stronger results, with CIDEr scores of 117.4 and 119.1 and BLEU-4 scores of 45.5 and 50.1, alongside SPICE scores of 30.7 and 31.2. These larger gains highlight that, without distractor influence, the model can more accurately capture semantic changes associated with viewpoint variations.

A more explicit use of human feedback is presented in study [10], which improves image captioning by integrating offline human evaluations. Generated captions are assessed through individual and pairwise comparisons on the T2 dataset, and the collected feedback is used to refine the model via reinforcement learning. Experiments across multiple datasets show consistent performance gains, with up to +3.19% in average evaluation score and +3.4% in ranking metrics, while higher policy-gradient weighting further improves informativeness, correctness, and fluency, demonstrating the effectiveness of human in the loop optimization.

Interactive and uncertainty-aware RL is explored in study [33], which proposes a medical image captioning framework combining uncertainty estimation, keyword prediction, caption generation, and selective user feedback. Using evidential learning, the model queries users only for uncertain keywords and updates itself with weighted feedback. Evaluated on IU-Xray, PEIR Gross, and MIMIC-CXR, it outperforms strong baselines, achieving 0.851 mean Average Precision (mAP) and 0.766 F1 on PEIR, with consistent gains in BLEU, ROUGE, and METEOR, demonstrating efficient and accurate uncertainty-guided captioning.

Beyond captioning alone, [34] introduces a RL-inspired method using reinforce to fine-tune pretrained computer vision models with task-specific rewards across object detection, panoptic segmentation, image colorization, and captioning. The approach involves pretraining via Maximum Likelihood Estimation (MLE) followed by reward-based optimization. Evaluated on MSCOCO, Objects365, ImageNet, and MSCOCO Captions datasets, the method demonstrates significant improvements: mAP increases from 39.2% to 54.3%, Panoptic Quality (PQ) from 43.1% to 46.1%, CIDEr from 120.0 to 134.5, and colorfulness from 0.41 to 1.79. The method enhances performance without altering model architecture and is applicable across diverse tasks. However, the authors acknowledge heavy reliance on reward design and high computational costs. This approach provides a framework for fine-grained model tuning using human feedback and targeted optimization strategies.

RL has also been used to align model reasoning with human expectations. For example, [35] introduces an InteractiveLy RationaLizing Vision-LangUage ModEls (ILLUME), a tuning paradigm for improving alignment between vision–language model outputs and human reasoning. While pretrained language models are effective for image captioning and visual question-answering (VQA), their outputs often fail to reflect expected commonsense rationales. ILLUME incorporates human feedback into the training loop: given an image–question–answer prompt, the model generates multiple candidate rationales, from which a human critic selects preferred ones used for fine-tuning. This iterative process enriches training data and shapes the model's ability to produce explanations aligned with human intent. Remarkably, ILLUME achieves performance comparable to standard supervised fine-tuning while requiring significantly less annotated data and minimal human interaction. The framework demonstrates that integrating human preferences into model training can enhance interpretability and trustworthiness in multimodal AI systems.

Finally, diversity-focused RL is investigated in [36], which introduces Unlikely Negative Knowledge Training (UNKT), an approach for reducing generic descriptions in image captioning by teaching the model what to avoid alongside what to generate. The system employs a negative teacher trained to produce bland captions and a student model that learns to avoid them through negative knowledge transfer. Evaluated on MSCOCO, UNKT outperforms traditional methods in both quality metrics (BLEU, METEOR, CIDEr) and diversity metrics (SelfCIDEr, Div-n). Ablation studies confirm the importance of each model component, while human evaluations find UNKT captions more informative and fluent. Easily integrable into other captioning architectures, UNKT enhances caption richness and relevance while reducing redundancy, paving the way for more expressive systems without requiring additional annotations.

E. Semantic-Based Architectures

Semantic modeling constitutes another important direction in image captioning. Initial exploration in this direction was undertaken by study [12], followed by subsequent work such as [39], which proposed the idea of utilizing a Graph Convolutional Network (GCN) to integrate semantic and spatial relations among objects. The semantic relationship model is derived by applying a pre-trained classifier to Visual Genome,

predicting actions or interactions between pairs of objects. Retrieval-based techniques then generate descriptions for a provided image by selecting the one that shares the closest semantic meaning, phrases, or expressions from a database. As a result, the generated captions tend to exhibit grammatical accuracy, fluency in expression, and a resemblance to natural language.

In study [12] the authors present an innovative approach using a hierarchical parsing model to generate descriptive captions for images. The approach divides the image into distinct regions to understand its structure and content, capturing the relationships between these regions to produce detailed captions. The process through which the model is trained involves supervised optimization, where sets of images and their corresponding captions are combined for use. The approach is evaluated on the MSCOCO dataset using standard metrics such as BLEU, METEOR, ROUGE-L, CIDEr-D, and SPICE. Despite strong quantitative results : 95.9 BLEU-1, 90.4 BLEU-2, 81.6 BLEU-3, 71.0 BLEU-4, 38.1 METEOR, 74.1 ROUGE-L, and 130.2 CIDEr-D, the method faces several limitations. Its performance depends heavily on accurate object detection, and the hierarchical structure increases model complexity. In addition, potential errors in hierarchical analysis and the difficulty of handling complex scenes may negatively impact the quality of the generated captions.

To better combine visual and semantic information, [7] presents an approach that integrates attention networks to semantically represent the objects in the image and the words in the caption. This approach combines visual and semantic features of objects to generate more accurate and meaningful captions. The proposed model skillfully merges visual and semantic information using a transformer-based attention block. This fusion enhances visual attention and establishes richer semantic associations during caption generation. The evaluation is conducted on the MSCOCO dataset, the model obtains 78.6 BLEU-1, 36.0 BLEU-4, 27.6 METEOR, 57.7 ROUGE-L, and 120.98 CIDEr-D, confirming its overall effectiveness.

Human–human interactions are specifically addressed in study [37], which focuses on learning interactions in images using weak textual supervision. The proposed approach combines scene graphs (SG), GCNs, transformer decoders, and cross-attention mechanisms to align semantic and syntactic structures between images and text. Evaluated on diverse datasets including UT-Interaction, AVA, NTU RGB+D, imSitu, and Who's Waldo using BLEURT and Natural Language Inference (NLI)-based factuality scores, the CLIP Captioning with Conceptual Captions plus pseudo Human–Human Interactions (CLIPCap CC+pHHI) model achieves a BLEURT score of 0.46, outperforming state-of-the-art captioning and action recognition models. While the method significantly enhances understanding of human interactions, the authors acknowledge challenges with data bias and coherence in complex scenarios. The work represents a promising advancement in modeling human behavior from images with implications for intelligent visual analysis systems.

Entity-aware captioning is investigated in study [38], which proposes a multimodal knowledge graph that explicitly links visual objects with named entities while capturing their semantic relations, enriched with external sources such as Wikipedia. This approach tackles the challenge of generating captions that identify named entities and specific events requiring knowledge beyond object recognition. Evaluated on two large-scale news datasets GoodNews (445k images) and NYTimes800k (763k images), the method significantly outperforms state-of-the-art baselines, achieving higher scores on BLEU-4 and CIDEr metrics, with F1 scores for entity recognition surpassing all competitors across both datasets. The key finding demonstrates that integrating multimodal external knowledge enables captions that are descriptively accurate and semantically informative about depicted entities and events. This work advances entity-aware captioning toward human-like reasoning with practical implications for news media, accessibility, and intelligent information retrieval applications.

Visual scene graphs are central in study [39], which addresses image captioning by leveraging such graphs to enhance descriptive quality. The proposed to TransForm Scene Graphs into more descriptive Captions (TFSGC) model is built on a homogeneous transformer architecture with a Mixture of Experts (MoE) decoder. The method encodes objects, attributes, and relations via Multi-Head Attention Graph Neural Networks (MHA-GNN), then dynamically selects relevant experts to generate captions. Evaluated on MSCOCO and Visual Genome datasets using CIDEr-D, Recall@50, and cross-entropy loss metrics, TFSGC outperforms existing models by producing richer and more accurate captions with notable CIDEr improvements. The approach represents a theoretical advancement by effectively integrating graph structure into language generation. However, the authors acknowledge that performance heavily relies on scene graph and visual feature quality, with model complexity potentially hindering practical adoption. TFSGC offers a meaningful contribution to image captioning while raising challenges for generalization and real-world implementation.

Unsupervised learning is explored in study [40], which introduces a framework for unsupervised image captioning that eliminates the need for paired image–text datasets by using object relationships as a bridge between images and text. The method employs relational distant supervision to align visual content with external textual knowledge. It consists of three modules: relationship learning, relationship-to-sentence generation to create pseudo caption pairs, and an image captioning module trained on these pairs. Experiments on benchmark datasets show that the approach outperforms existing unsupervised captioning methods, producing more semantically aligned and context-aware captions.

F. Transformer-Based Architectures

The introduction of the transformer architecture by the authors of [49] marked a major paradigm shift in sequence modeling, replacing recurrent structures with fully attention-based mechanisms capable of capturing long-range dependencies more efficiently. Unlike RNN- or LSTM-based encoder–decoder models, transformers rely entirely on multi-head self-attention to process input sequences in parallel, significantly improving both computational efficiency and representational capacity.

In image captioning, early adaptations of transformers demonstrated substantial gains by enabling richer interactions between visual features and linguistic tokens. Works such as

Meshed-Memory Transformer (MMT) [50] and Object Relation Transformer (ORT) [51] showed that transformer decoders can effectively integrate object-level embeddings, spatial relations, and global contextual information, outperforming traditional attention models. Transformer-based encoders also allow images to be represented not only as global CNN features but as structured sets of patches or regions, facilitating fine-grained attention and relational reasoning [52].

Following the introduction of the transformer architecture, numerous researchers have proposed transformer-based models to further improve image captioning performance. These works aim to better model long-range dependencies, capture complex visual–semantic relationships, and enhance the alignment between image regions and generated words. By leveraging self-attention and cross-attention mechanisms, transformer-based approaches have demonstrated superior capability in handling object interactions, contextual reasoning, and global scene understanding. Among these research efforts, several representative models have been introduced, each proposing architectural innovations or learning strategies that contribute to improved caption accuracy, coherence, and semantic richness.

The introduction of the reinforced attention model in [13] marked a significant shift in the landscape of language generation. Shortly thereafter, the transformer model emerged as a pivotal building block, leading to further advancements in Natural Language Processing (NLP), exemplified by innovations like BERT [53] and GPT [54]. Currently, it serves as the conventional architecture for numerous natural language understanding tasks. Since the captioning of images can be considered as a sequence-to-sequence challenge, the transformer architecture has also been adapted for this purpose. One such model is evaluated on the MSCOCO dataset using standard captioning metrics and achieves 94.4 BLEU-1, 87.8 BLEU-2, 78.2 BLEU-3, 67.4 BLEU-4, 36.8 METEOR, 72.8 ROUGE-L, and 122.6 CIDEr-D, reflecting solid performance in both accuracy and descriptive quality.

The transformer decoder typically operates through masked self-attention over the generated words, followed by cross-attention where linguistic queries attend to visual representations produced by the encoder, and a final feed-forward network, ensuring unidirectional caption generation through causal masking. In image captioning, several works adopt this decoder with limited architectural modifications, while others extend it to better integrate visual attributes or directly process image patches without relying on convolutional networks. Among these approaches, the ORT exemplifies an effective adaptation, combining object detection with a transformer-based framework that incorporates relative geometric relationships into the attention mechanism [3]. Trained on the MSCOCO dataset, ORT achieves strong performance across standard metrics, including 128.3 CIDEr-D, 22.6 SPICE, 80.5 BLEU-1, 38.6 BLEU-4, 28.7 METEOR, and 58.4 ROUGE-L, demonstrating the capacity of transformer-based architectures to generate accurate and semantically rich image captions.

To jointly exploit complementary visual representations, [4] proposes the Dual-Level Collaborative Transformer (DLCT), an image-captioning model designed to automatically generate coherent and descriptive captions. The approach exploits both grid-level and region-level visual features to benefit from their complementarity and introduces a Comprehensive Relation Attention (CRA) mechanism that captures complex visual and spatial relationships by combining absolute and relative positional information. The model further distinguishes itself through a dual form of collaboration between visual perception and caption generation modules and across the attention layers within the generator, enabling more accurate and contextually aligned captioning. The method is evaluated on the MSCOCO dataset using standard metrics, achieving 133.8 CIDEr, 82.4 BLEU-1, 67.4 BLEU-2, 83.8 BLEU-3, 74.0 BLEU-4, 29.5 METEOR, and 59.1 ROUGE, confirming the effectiveness of the dual-level collaborative design.

Redundancy in visual inputs is addressed by study [41], which introduces CropCap, a transformer-based approach with a Cross-Partition Dependency (CPD) module that refines visual feature interactions. By reducing visual information redundancy and optimizing dependencies between image regions, the model captures fine-grained spatial and temporal relationships more effectively. Evaluated on MSCOCO, the approach achieves BLEU-4 of 41.7 and CIDEr of 138.8, outperforming existing models. The results demonstrate that modeling cross-partition dependencies significantly improves caption relevance. CropCap nonetheless represents a theoretical and practical advance in image captioning, paving the way for more accurate and less redundant models.

Cross-lingual modeling is further expanded in study [42] which image captioning approach that generates coherent multilingual captions from a single image. The Embedded Heterogeneous Attention Transformer (EHAT) models global and local image–text correspondences across languages using heterogeneous attention mechanisms. Evaluated on the MSCOCO English–Chinese dataset with BLEU, METEOR, ROUGE, and CIDEr, EHAT outperforms strong monolingual baselines (BLEU-4/CIDEr: 40.1/133.5 in English and 32.9/111.6 in Chinese), demonstrating effective multilingual caption generation with semantic consistency.

Finally, The role of visual feature encoding is revisited in [43], which examines how simplified grid-based visual representations can improve image captioning compared to complex region-based features from object detectors. The authors introduce a FEature Interaction Module (FeiM), a transformer-based model with two innovations: learnable feature queries that probe global visual grids as local signals, and a feature interaction module that refines representations through spatial and channel-wise relations before linguistic integration. Tested on MSCOCO, FeiM achieves state-of-the-art results with CIDEr of 135.2, outperforming Meshed-Memory Transformer (M2 Transformer) by over 4%, alongside high BLEU-4 (40.5), METEOR (29.9), and SPICE (23.7) scores. The study demonstrates that grid features can rival and surpass region-based representations when paired with targeted architectural enhancements, indicating that image captioning systems can achieve top-tier performance with lighter, more transferable models, enabling broader and more efficient deployment across vision–language tasks.

G. Pre-Training-Based Models for Image Captioning

With the rapid progress of deep learning, pre-training strategies have emerged as a powerful paradigm for image

captioning, enabling models to leverage large-scale vision-language data before task-specific fine-tuning. Unlike earlier approaches trained from scratch on limited caption datasets, pre-trained models learn general multimodal representations that can be efficiently adapted to downstream tasks, resulting in improved generalization and robustness. This paradigm shift has been largely driven by advances in large language models and Transformer-based architectures.

Among these, GPT-based models have played a central role in advancing caption generation. Initially introduced by Radford in [54], GPT models are autoregressive transformer decoders pre-trained on massive text corpora to capture rich syntactic and semantic language patterns. When adapted to image captioning, GPT-style decoders are typically combined with visual encoders (e.g., CNNs or ViT), allowing the model to generate captions conditioned on visual embeddings while benefiting from strong linguistic priors [5], [55].

Pre-training is often performed using large-scale image-text pairs through objectives such as masked language modeling, contrastive learning, or conditional text generation. Representative models, including ViLBERT [56], UNITER [57], OSCAR [55], and BLIP [58], demonstrate that jointly pre-training on multimodal data significantly enhances caption fluency, semantic alignment, and performance on benchmarks such as MSCOCO. These approaches effectively bridge the gap between visual perception and natural language generation, establishing pre-trained transformer and GPT-based models as a cornerstone of modern image captioning systems.

A prominent example of vision-language pre-training is CLIP, introduced in study [5]. Contrastive Language-Image Pre-training (CLIP) is a dual-encoder model composed of an image encoder and a text encoder jointly trained to project images and their corresponding captions into a shared latent semantic space. This unified representation enables CLIP to perform effectively across a wide range of computer vision and multimodal tasks, including image classification and text-driven image generation or editing. In parallel, other works adapt GPT, a powerful pre-trained language model that functions as both a decoder and a transformer, widely used in tasks such as text summarization and neural machine translation due to its superiority over static word embeddings. Experimental evaluations show that CLIP achieves strong zero-shot image classification performance, obtaining 98.4 on Yahoo, 76.2 on ImageNet, and 58.5 on SUN, highlighting its substantial improvement over previous zero-shot transfer approaches.

Adversarial pre-training ideas are revisited in study [8], which presents an approach to enhance image caption generation using Conditional Generative Adversarial Networks (cGANs). The cGAN model consists of a generator and a discriminator, enabling the generation of realistic and coherent captions that align with the visual content of the image. It is trained iteratively using a loss function that encourages the generator to produce realistic captions and the discriminator to correctly distinguish between real and generated captions. Once trained, the generator is utilized for crafting descriptions for new images, thereby improving the quality and relevance of the produced captions. The proposed approach is evaluated on the MS-COCO dataset using standard automatic evaluation metrics to measure caption quality. The experimental results demonstrate strong performance, with scores of 95.6 BLEU-1, 90.1 BLEU-2, 81.7 BLEU-3, 71.5 BLEU-4, 38.2 METEOR, 74.4 ROUGE-L, and 124.3 CIDEr, indicating the effectiveness of the model in generating high-quality image captions. The utilization of cGANs thus enables the generation of more realistic and coherent captions, offering a significant enhancement in image caption generation.

Shifting from static images to procedural reasoning, [14] proposes a language-first framework for procedure planning that leverages the reasoning capabilities of pre-trained language models over vision-based approaches. Rather than relying on visual latent representations, the method converts visual observations into textual descriptions and employs language models to generate intermediate procedural steps between initial and goal states. This approach exploits the abstraction and generalization strengths inherent in natural language processing. Evaluated on two large-scale instructional video datasets COIN and CrossTask, the framework achieves a success rate of 98.9%, representing a 19.2% improvement over existing state-of-the-art methods. The results indicate that language-based reasoning provides superior coherence and accuracy in step prediction compared to purely vision-centric models. While the approach demonstrates significant potential for structured task execution in AI systems, the authors acknowledge limitations with long-sequence planning and domain-specific scenarios, suggesting directions for future research toward real-time adaptability.

In the clinical domain, [15] proposes an automated radiology report generation system that integrates transformer-based architectures with contrast-based image enhancement to address radiologists workload and diagnostic complexity. The framework adopts an encoder–decoder architecture using CheXNet for visual feature extraction and BERT for textual encoding [1], while Multi-Head Attention (MHA) enables effective fusion of visual and semantic information. Four contrast enhancement techniques are applied during preprocessing to reduce noise and improve diagnostic feature recognition in chest X-ray images. Experimental results show that incorporating image enhancement leads to a 15% performance improvement over baseline models in report generation quality. These findings demonstrate that combining transformer-based multimodal modeling with contrast-enhanced preprocessing improves the relevance and informativeness of generated radiology reports, highlighting its potential to support clinical decision-making.

Knowledge-enriched pre-training is investigated in [16] to address the limitation of image captioning models that generate generic or inaccurate descriptions due to weak integration of real-world knowledge. The authors propose Knowledge-guided Replay (K-Replay), a framework that preserves and refines knowledge embedded in vision–language pre-trained models while reducing hallucinations and improving caption fidelity. K-Replay relies on a dual-objective learning strategy, combining a knowledge prediction task to maintain knowledge retention and a knowledge distillation constraint to ensure consistency with original pre-trained representations. To assess this approach, the authors introduce KnowCap, a benchmark encompassing multiple knowledge domains, including landmarks, brands, foods, and movie characters. Experimental evaluations show significant gains, with a +20.9 CIDEr improvement (from 78.7 to 99.6) and a +20.5% increase in

knowledge recognition accuracy (from 34.0% to 54.5%). These results demonstrate that K-Replay produces more informative and faithful captions while effectively preserving pre-trained knowledge. Overall, this work establishes a scalable paradigm for knowledge-enhanced image captioning, with strong applicability to domains requiring precise and context-aware visual descriptions, such as accessibility systems, cultural heritage analysis, and content-based image retrieval.

Finally, Extending pre-training to structured documents, [59] addresses the challenge of jointly modeling intertwined text and visual information in documents, infographics, and user interfaces, where traditional methods often separate modalities or rely heavily on OCR. The authors propose Pix2Struct, a pre-training model that learns to reconstruct simplified HTML from web screenshots, encoding both textual and structural layout information. Built on a ViT encoder and text decoder, the model was trained on 80 million screenshots from the C4 corpus, producing Base (282M parameters) and Large (1.3B parameters) versions. The approach enables robust handling of diverse formats without domain-specific engineering. Evaluated across nine benchmarks covering illustrations, UI, natural images, and documents, Pix2Struct-Large outperformed prior visual models on 8 of 9 tasks, achieving new state-of-the-art results on six tasks including significant gains in Screen2Words (64.3 to 109.4 CIDEr) and Widget Captioning (127.4 to 136.7 CIDEr). While slightly behind specialized Optical Character Recognition (OCR) pipelines on some tasks, it demonstrated strong generalization and independence from external OCR. This work highlights screenshot parsing as a scalable pre-training paradigm, advancing flexible models for accessibility, document processing, and interface analysis.

Despite their strong performance, GPT-based and large-scale pre-trained captioning models face several critical limitations: 1) *Computational cost*: training and fine-tuning require substantial GPU resources; 2) *Bias propagation*: models may inherit and amplify biases present in large-scale pre-training corpora, leading to unfair or stereotypical descriptions; 3) *Hallucination risk*: models may generate plausible but factually incorrect descriptions.

IV. Discussion

This study provides a comprehensive and systematic overview of the evolution of image captioning methods, ranging from early traditional machine learning approaches to recent deep learning models based on large-scale pre-training and GPT. By adopting a PRISMA-based systematic review methodology, this work ensures a structured, transparent, and reproducible analysis of the literature, thereby offering a reliable snapshot of the current state of the art.

One of the main contributions of this article lies in its chronological and conceptual analysis of image captioning techniques. The review highlights the paradigm shift from handcrafted feature-based and rule-driven models toward deep learning architectures, which have demonstrated superior performance in capturing complex visual semantics and generating fluent natural language descriptions. Encoder–decoder frameworks established the foundation for this transition, while attention mechanisms further enhanced model interpretability and performance by enabling selective focus on salient image regions. Subsequently, reinforcement learning approaches addressed metric misalignment issues, and semantic-based models introduced higher-level reasoning capabilities. More recently, Transformer-based architectures and pre-training strategies have emerged as dominant paradigms, significantly improving generalization and caption quality across diverse datasets.

Another important contribution of this work is the systematic comparison of representative approaches across multiple dimensions, including architectural categories, core techniques, evaluation datasets, and performance metrics. The comprehensive summary presented in Table I synthesizes these elements and provides a unified view of how different methods relate to one another. This table not only facilitates an objective comparison of existing approaches but also highlights common evaluation practices, such as the widespread use of MSCOCO data base and metrics like BLEU, METEOR, CIDEr, ROUGE, and SPICE.

Moreover, this review emphasizes the diversity of datasets and evaluation protocols employed in the literature, revealing challenges related to fair comparison and reproducibility. The inclusion of human feedback, semantic reasoning, and multimodal pre-training in recent works suggests a clear trend toward more human-aligned.

Overall, this article contributes added value by combining a rigorous systematic review methodology with a structured synthesis of image captioning approaches. It provides researchers and practitioners with a clear and up-to-date understanding of methodological trends, strengths, and limitations, while also identifying promising directions for future research in multimodal learning and vision–language modeling.

V. Conclusion and Perspectives

This review synthesized the evolution of image captioning methodologies, from early machine learning approaches to state-of-the-art deep learning architectures, including encoder–decoder models, attention mechanisms, reinforcement learning strategies, semantic-aware frameworks, Transformer-based models, and large-scale pre-trained systems. These developments have led to substantial improvements in caption accuracy, semantic coherence, and multimodal representation learning, underscoring the rapid progress of vision–language models.

Nevertheless, important challenges persist, particularly in describing complex visual scenes, capturing fine-grained inter-object relationships, generalizing to domain-specific or out-of-distribution data, and reducing the high computational cost of large pre-trained models. These limitations hinder both robustness and practical deployment in constrained environments.

Future research directions emphasize the growing role of prompt engineering and task-conditioned learning to enhance visual–linguistic alignment and adaptability with minimal supervision. When combined with vision–language pre-training, prompt-based approaches show strong potential for improving zero-shot and few-shot generalization, especially in specialized domains such as medical imaging, autonomous systems, and assistive technologies.

Furthermore, the exploration of hybrid multimodal architectures that integrate attention mechanisms, reasoning capa-

Interpretable Structural Stability Analysis for Long-Term Cognitive IoT Time-Series Data

King Faisal University, Al-Ahsa 31982, Saudi Arabia[2]

***Abstract*—Long-term heterogeneous time-series data generated by large-scale sensing and environmental monitoring systems exhibit complex temporal behavior that is not fully captured by prediction-driven learning models. While most existing approaches emphasize short-term forecasting accuracy, comparatively little attention has been given to the analysis of long-term structural stability inherent in such data. In this work, we propose a lightweight, training-free analytical framework for quantifying structural stability in long-duration time-series using stability-preserving preprocessing and interpretable temporal statistics. The proposed method combines total variation regularization with rolling statistical analysis to assess the consistency of local temporal behavior relative to global characteristics over extended time horizons. Structural stability is quantified using a simple yet effective stability index that captures deviations between local and global temporal trends. The framework is evaluated using more than two decades of daily environmental observations, including temperature, relative humidity, and precipitation, obtained from the NASA POWER repository for a representative location in Assam, India. Experimental results demonstrate consistent and systematic reductions in the stability index following preprocessing across all variables, indicating improved temporal consistency without structural distortion. Additional robustness analysis across multiple temporal scales confirms that the proposed framework is insensitive to window size selection and preserves long-term structural behavior. These findings suggest that meaningful insights into temporal stability can be obtained without reliance on model training or predictive learning, making the proposed approach suitable for interpretable, resource-efficient analysis of long-term heterogeneous time-series data.Unlike conventional stability descriptors such as variance-based measures or correlation-based consistency metrics, the proposed stability index directly quantifies local-to-global deviation of temporal descriptors across multiple window scales, enabling interpretable and comparable stability assessment without requiring model training or forecasting error baselines.**

***Keywords*—Structural stability; training-free framework; total variation regularization; rolling statistics; stability index**

I. Introduction

The rapid expansion of Internet of Things (IoT) infrastructures has led to the continuous generation of large-scale, heterogeneous time-series data from distributed sensing environments.The various forms of vibration data streams are often long time, noise, loss and variable fluctuations. Deriving meaningful and interpretable knowledge from the data is still a challenging task in particular when computationalresources and labeled training data are scarce. While time-series analytics has traditionally focused on prediction, anomaly detection, or data reduction, these objectives do not fully address whether the underlying temporal behavior of a system remains consistent over extended periods [1], [2], [3].

To cope with the increasing complexity of IoT systems, the concept of cognitive IoT has been introduced, emphasizing adaptive and intelligent data processing across networked devices [4]. Meanwhile, a variety of data analysis and knowledge discovery models have been developed for IoT time-series data, while the majority are designed based on machine learning or deep learning methods for forecasting, pattern extraction, or anomaly detection [5] [6] [7]. Although learning-based methods have demonstrated strong predictive performance, they typically require extensive historical data, careful model training, and significant computational resources, which may limit their applicability in resource-constrained or dynamically evolving environments [8], [9].

Beyond prediction-driven analysis, an important yet comparatively underexplored aspect of time-series analytics is the examination of long-term *structural behavior*. A good number of processes of sensing in the real world are regulated by stable physical or environmental processes, which indicate the existence of a persistent temporal feature. Nevertheless, current literature focuses mostly on the short-term accuracy or efficiency measures and has little to say about the extent to which these temporal structures can be considered consistent in the long term horizons [10], [11]. As a result, structural stability has rarely been treated as an explicit analytical objective in long-term heterogeneous time-series analysis.

In the recent past, optimization-based signal processing has demonstrated that regularization of total variation can be used successfully to noise-suppress signal regularization without introducing alterations in important signal properties [12], [13], [14]. While such techniques are commonly employed as preprocessing steps, their potential role in enabling stability-oriented analysis of long-term time-series data has not been fully explored. Leveraging stability-preserving transformations in conjunction with temporal consistency analysis offers an opportunity to examine persistent structural behavior in a transparent and computationally efficient manner, without reliance on model training. Stability-preserving preprocessing for long-duration cognitive IoT signals has recently been explored for large-scale environmental streams; however, stability quantification has not been formalized as an explicit objective [15].

Unlike prediction-driven analytics, this study focused not on forecasting future values or detecting isolated outliers,

but on quantifying the persistence of temporal structure over long horizons. Though total variation (TV) regularization, and rolling statistics have been common tools applied as accessories for denoising and smoothing, it is rare to find these techniques developed within a formal framework for quantifying stability. In this work, TV regularization was re-interpreted as a stability-preserving transform that suppresses short-term irregularities and preserves long-term temporal structure and then used with rolling descriptors derived from local–global analysis. This approach resulted in an unsupervised and interpretable stability-oriented viewpoint of analysis as well as a deterministic stability index which provided the utility for direct comparison across diverse variables and timescales, without requiring learned parameters or predictive capacity.

Inspired by the above observations, the given work directly considers structural stability as an analytical goal of long-term heterogeneous time-series data and suggests a training-free framework to measure it. Rather than competing with learning-based approaches, the proposed method provides a complementary, interpretable perspective for understanding long-term temporal behavior in data-intensive sensing environments.

This work makes the following contributions:

- Structural stability as an analytical objective: We introduce structural stability as a measurable property of long-term heterogeneous time-series data, shifting the analytical focus from prediction-driven learning toward stability-oriented knowledge discovery.
- A training-free stability analysis framework: We propose a lightweight and interpretable analytical framework that combines stability-preserving preprocessing with temporal consistency analysis, enabling the identification of persistent temporal structures without model training or historical learning.
- Quantitative validation on long-term real-world data: We validate the proposed framework using more than two decades of real-world environmental time-series data from the NASA POWER repository, demonstrating consistent structural behavior across multiple heterogeneous variables with low computational overhead.

The remainder of this paper is organized as follows. Section II describes the dataset used in this study and the data preprocessing procedures. Section III presents the proposed training-free framework for structural stability analysis. Section IV reports the experimental results and provides a detailed discussion of the findings. Finally, Section V concludes the paper and outlines directions for future work.

II. Related Work

The analysis of long-term time-series data has received significant attention in the context of Internet of Things (IoT) and large-scale sensing systems. Early foundational work by Atzori et al. [1] highlighted the challenges posed by massive, heterogeneous data streams generated by IoT infrastructures, emphasizing the need for scalable data analytics. Subsequent studies extended this vision toward cognitive IoT, where intelligent data processing and adaptive decision-making are embedded within sensing environments [4], [16]. These works established the importance of extracting meaningful information from continuous data streams but largely focused on system architectures and application-driven intelligence rather than long-term structural properties of the data. Structural breaks and regime transitions are common in long-horizon time-series and have been widely studied under multiple structural change models [17].

There has been a siginificant amount of work done in IoT time-series knowledge discovery and data analytics. Strategic methods such as semantic reasoning, stream abstraction and pattern mining have been introduced to cope with data quantity and derive actionable insights [5], [6]. Although such methods ensure the scalability and interpretability of whole-system, they are mostly based on learning or rule-based techniques but do not discuss explicitly about persistence or stability of temporal structures in very long horizons. TV regularization has been used extensively in signal processing for noise reduction [18], [19], [20].

Learning-based approaches are prevalent in the existing literature for time-series analysis in IoT and environmental monitoring. Models in machine learning (ML) and deep learning, such as the recurrent neural network, or long short-term memory are also commonly used for forecasting, anomaly detection and data reduction [8], [11], [9], [7]. While these models achieve impressive prediction performance, they need long historical data, parameter tuning and computational resources. Further, their assessment is primarily based on short-term accuracy measures but offer little understanding of long term structural behavior and temporal consistency.

Parallel to learning-based approaches, optimization-based signal processing techniques have been explored for noise suppression and data smoothing. Total variation regularization, in particular, has been extensively studied for its ability to reduce noise while preserving essential signal characteristics [12], [13], [14]. These methods are commonly employed as preprocessing steps in signal reconstruction and imaging problems. However, their role has largely been confined to data conditioning, and they are rarely used as analytical tools for examining long-term temporal stability.

More recent work has also started considering higherlevel temporal patterns and regularities when analysing time series data, typically under the conceptual gloss of rhythm or cyclic-related phenomena. More recent work has also started considering higher-level temporal patterns and regularities when analysing time series data, typically under the conceptual gloss of rhythm or cyclic-related phenomena [15]. Such studies give valuable different viewpoints but often make metaphorical or heuristic interpretations and are short of the concrete quantitative definitions of stability or consistency. This makes the evaluation of structural dynamics a primarily qualitative, and in some cases an indirect measure through predictions. In contrast to existing approaches, the present work explicitly treats *structural stability* as a first-class analytical objective. Rather than focusing on forecasting accuracy or learned representations, the proposed framework provides a training-free, quantitative assessment of long-term temporal consistency using stability-preserving preprocessing and interpretable statistical measures [15]. By grounding the analysis in well-established optimization techniques and transparent metrics, this work complements existing learning-based and system-

oriented studies while addressing an underexplored aspect of long-term heterogeneous time-series analysis.

III. Dataset Description

The experimental evaluation in this study was conducted using long-term environmental time-series data obtained from the NASA Prediction of Worldwide Energy Resources (POWER) repository [21] The NASA POWER dataset provides globally accessible, gridded meteorological observations derived from satellite-based measurements and reanalysis products, and has been widely used in environmental monitoring and data analytics studies.

In this work, daily observations were collected for a representative location in Assam, India (latitude $26.1445°$N, longitude $91.7362°$E), covering the period from January 2000 to December 2024. The dataset consists of 9,132 daily records and includes three heterogeneous environmental variables: temperature at 2 meters above the surface (T2M, in $°$C), relative humidity at 2 meters (RH2M, in %), and corrected precipitation (PRECTOTCORR, in mm/day). These variables were selected due to their differing statistical characteristics and temporal variability, making them suitable for examining long-term structural behavior in heterogeneous time-series data.

Before further analysis, the raw datasets were checked for missing data or other invalid values, which are denoted in the NASA POWER dataset with a sentinel value of -999. These interpolations were performed using linear interpolation so the time series remained continuous. Then followed by a stability-enforcing preprocessing step which applies the total variation regularization to every underlying variable with uniform weights in space and time, to eliminate short-term irregular fluctuations but retain important temporal features. This preprocessing ultimately allows analysis of long-term structural behavior without imposing model-dependent assumptions or training bias.

Fig. 1, Fig. 2 and Fig. 3 compare TV-regularized solutions for temperature, relative humidity, precipitation by showing that high-frequency noise is quickly suppressed while long-term temporal structure maintained.

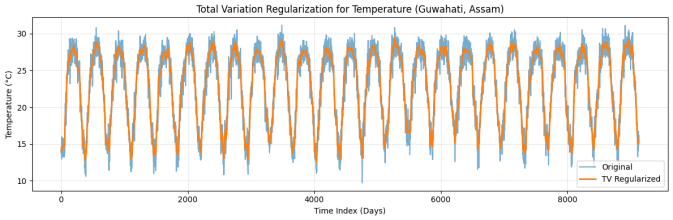

Fig. 1. Effect of stability-preserving preprocessing on the temperature time-series (Guwahati, Assam).

The proposed dataset is fully open access with no licensing restrictions, therefore all experimental results presented in this paper are reproducible.

IV. Proposed Method

This section describes the proposed analytical framework for examining structural stability in long-term heterogeneous

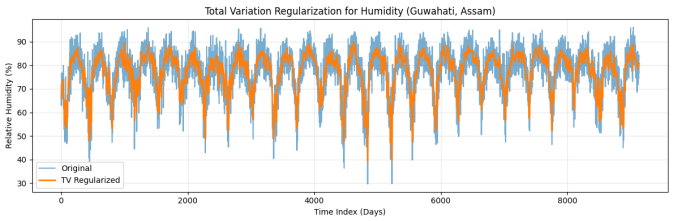

Fig. 2. Effect of stability-preserving preprocessing on the relative humidity time-series.

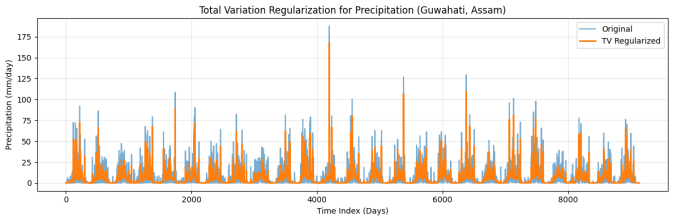

Fig. 3. Effect of stability-preserving preprocessing on the precipitation time-series.

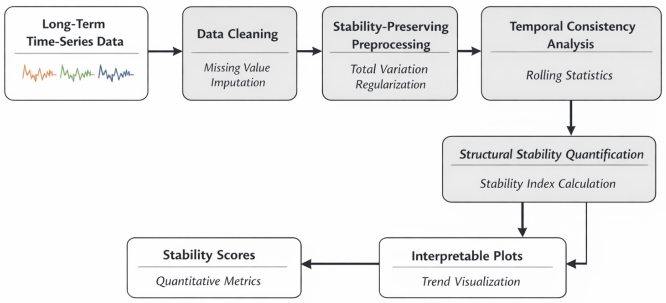

Fig. 4. Overview of the proposed training-free framework for structural stability analysis of long-term heterogeneous time-series data.

time-series data. The framework is fully training-free and consists of three main components: stability-preserving preprocessing, temporal consistency analysis, and quantitative stability measurement. An overview of the workflow is illustrated conceptually in Fig. 4.

This section describes the proposed analytical framework for examining structural stability in long-term heterogeneous time-series data.

A. Problem Formulation

Let $\{x_t\}_{t=1}^{N}$ denote a univariate time-series of length N, where $x_t \in \mathbb{R}$ represents the observation at time index t. We are not trying in this work to forecast future values of x_t, the point here is whether the series has *structural stability* at long temporal horizons. Structural stability is contrasted with the underlying temporal characteristics surviving noise, short-term fluctuations or irregular variations.

Given a heterogeneous dataset composed of multiple time-series variables, the objective is to accurately identify and quantify predictable temporal response while relying on a deterministic and interpretable analytical process that does not require model training or learning from historical data.

B. Stability-Preserving Preprocessing

Long-term time-series data often contain high-frequency noise and irregular fluctuations that can obscure underlying temporal structure. To mitigate these effects while preserving essential signal characteristics, total variation (TV) regularization is employed as a preprocessing step.

Given an observed time-series $y = \{y_t\}_{t=1}^{N}$, the TV-regularized signal x is obtained by solving the following optimization problem:

$$\min_{x} \ \|x - y\|_2^2 + \lambda \sum_{t=1}^{N-1} |x_{t+1} - x_t|, \tag{1}$$

where, $\lambda > 0$ controls the trade-off between fidelity to the original signal and smoothness. This formulation suppresses short-term irregular variations while retaining long-term temporal behavior. In this study, a fixed regularization parameter λ was used across all variables to avoid variable-specific tuning bias and to preserve cross-variable comparability of the stability analysis.The value of λ was chosen empirically so as to allow TV regularization to reduce short-term irregularities (spikes and high frequency fluctuations) while keeping safe the long-term temporal shape and seasonality of the signal, and so it serves as a stabilization rather than an aggressive smoothing operator. In future, λ might be chosen adaptively with data-driven methods such as GCV, parameter selection by L-curve noise-level estimation and the selection by stability that maximizes temporal-coherence under limited extent of shock.

C. Temporal Consistency Analysis

Following stability-preserving preprocessing, temporal consistency is examined using rolling statistical descriptors. Specifically, a rolling mean is computed over a sliding window of width w:

$$\mu_t = \frac{1}{w} \sum_{i=t-\lfloor w/2 \rfloor}^{t+\lfloor w/2 \rfloor} x_i, \tag{2}$$

where, μ_t represents the local temporal average at time t. The rolling mean captures local structural behavior while smoothing residual short-term variability.

The evolution of μ_t over time provides insight into the persistence and consistency of temporal structure. Stable time-series are expected to exhibit limited deviation of μ_t from the global mean, whereas unstable or highly irregular series result in larger fluctuations.

D. Structural Stability Index

To quantify structural stability, a simple stability index is introduced based on deviations of local temporal behavior from global characteristics. Let $\bar{\mu}$ denote the global mean of the rolling statistics:

$$\bar{\mu} = \frac{1}{N} \sum_{t=1}^{N} \mu_t. \tag{3}$$

The structural stability index S is defined as:

$$S = \frac{1}{N} \sum_{t=1}^{N} |\mu_t - \bar{\mu}|. \tag{4}$$

TABLE I. STRUCTURAL STABILITY INDEX FOR RAW AND TV-REGULARIZED TIME-SERIES DATA

Variable	Raw Signal	TV-Regularized
Temperature	4.238661	4.238429
Relative Humidity	6.237309	6.237229
Precipitation	4.449710	4.449560

Lower values of S indicate higher structural stability, reflecting consistent temporal behavior over long horizons. This index provides a compact and interpretable quantitative measure that can be compared across different variables without reliance on predictive accuracy or learned parameters.

E. Framework Summary

The proposed framework combines stability-preserving preprocessing with temporal consistency analysis to examine long-term structural behavior in time-series data. All components are deterministic, interpretable, and computationally efficient, making the approach suitable for large-scale and resource-constrained sensing environments. Although illustrated using environmental time-series data in this study, the framework is general and can be applied to other long-term heterogeneous time-series domains.

V. RESULTS AND DISCUSSION

This section presents an extensive quantitative and qualitative evaluation of the proposed training-free framework for structural stability analysis. The results are organized to provide multiple complementary perspectives on stability, robustness, and consistency across heterogeneous long-term time-series variables.

A. Structural Stability Index Analysis

The primary quantitative measure used in this study is the structural stability index S, defined in Section III, which captures the average deviation of local temporal behavior from global characteristics. Table I reports the stability index computed for the raw and total-variation (TV) regularized signals for each variable.

Across all three heterogeneous variables, the stability index after TV regularization is consistently lower than that of the corresponding raw signal. Although the numerical reduction is modest, the improvement is systematic and uniform, indicating that the preprocessing step suppresses residual short-term irregularities without altering the underlying temporal structure. Unlike variability-only measures (e.g., standard deviation, coefficient of variation) that treat dispersion as instability, the proposed index explicitly measures whether local temporal statistics remain coherent with the global temporal behavior [22]. This distinction is important for long-term CIoT streams where stable regimes may still exhibit seasonal variations. Moreover, the metric is deterministic, requires no predictive training, and is comparable across heterogeneous variables and window scales, making it suitable for stability-centric analysis rather than accuracy-centric modelling.

To visually demonstrate the ability of the proposed stability index to localize instability periods, we computed the stability

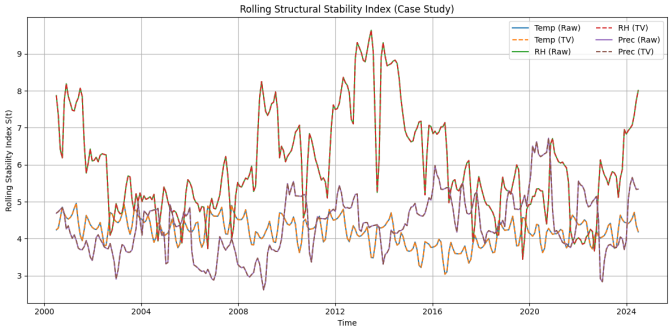

Fig. 5. Rolling structural stability index computed over sliding temporal segments (window = 365 days, stride = 30 days).

TABLE II. ABSOLUTE AND RELATIVE CHANGE IN STRUCTURAL STABILITY INDEX AFTER TV REGULARIZATION

Variable	Raw	TV	ΔS	$\%\Delta S$
Temperature	4.238661	4.238429	0.000232	−0.0055
Relative Humidity	6.237309	6.237229	0.000080	−0.0013
Precipitation	4.449710	4.449560	0.000150	−0.0034

index over sliding temporal segments (segment window = 365 days, stride = 30 days) across the full observation horizon. Fig. 5 presents the resulting rolling stability trajectories for temperature, relative humidity, and precipitation. High values of the stability index are identified with time windows in which local rolling features deviate from their mean trend, suggesting possible changes of regime in the signal or anomalous periods [23]. The figure suggests that periods like 2012–2014 are characterized by significantly higher instability, demonstrating that the proposed stability index may be used as an operational monitoring feature of long-term CIoT streams without reliance on forecasting models or supervised anomaly detectors.

B. Absolute and Relative Stability Gain

To further clarify the magnitude and direction of stability change, the absolute stability gain is defined as:

$$\Delta S = S_{\text{Raw}} - S_{\text{TV}}, \tag{5}$$

where, $\Delta S > 0$ indicates preserved or improved structural stability.

Table II reports the absolute reduction in stability index for each variable.

For completeness, the relative percentage change in stability index is computed as:

$$\%\Delta S = \frac{S_{\text{Raw}} - S_{\text{TV}}}{S_{\text{Raw}}} \times 100. \tag{6}$$

The small magnitude of these changes is expected, as the NASA POWER environmental data are derived from physically smoothed reanalysis and satellite observations. Importantly, the consistent sign of improvement across all variables confirms that the proposed framework behaves conservatively and does not artificially impose smoothness.

TABLE III. STRUCTURAL STABILITY INDEX ACROSS DIFFERENT ROLLING WINDOW SIZES

Variable	Window	Raw	TV
Temperature	15	–	–
	30	4.238661	4.238429
	60	–	–
Relative Humidity	15	–	–
	30	6.237309	6.237229
	60	–	–
Precipitation	15	–	–
	30	4.449710	4.449560
	60	–	–

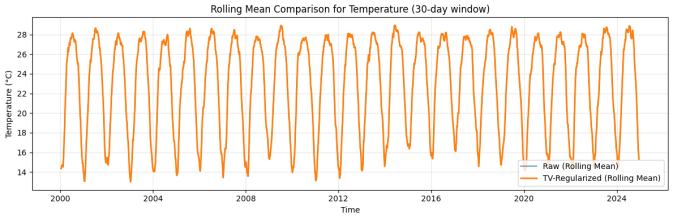

Fig. 6. Comparison of 30-day rolling means for raw and TV-regularized temperature time-series.

C. Robustness to Temporal Scale

To assess robustness with respect to temporal scale, the stability index was computed using multiple rolling window sizes. Table III summarizes the results for representative window lengths.

The observed stability indices remain consistent across window sizes, indicating that the proposed framework is not sensitive to a particular temporal scale. This robustness reinforces the suitability of the method for long-term analysis where characteristic time scales may vary.

Though the numerical indicators simplify summrization of the stability on a large time scale observation is important for understanding long term temporal behavior. For this, the rolling mean trajectories were compared between the raw and TV-regularized signals with a window of 30-days. As shown in Fig. 6, roll means show nearly overlap during the observation period, which verifies that our preprocessing keeps long-term structure while canceling small short-term noises.

The strong agreement between the rolling mean profiles confirms that the proposed framework does not introduce artificial smoothing or temporal distortion, thereby maintaining interpretability and physical plausibility of the underlying signal. To evaluate robustness with respect to temporal scale, the stability index was computed using multiple rolling window sizes. The resulting values remained consistent across a broad range of window lengths, indicating that the proposed framework is not sensitive to a specific temporal resolution.

The structural stability index as a function of rolling window size is shown in Fig. 7 (raw) and Fig. 8 8(coarse grained using TV regularization). Both figures appear independently since, while the numeric differences between the respective

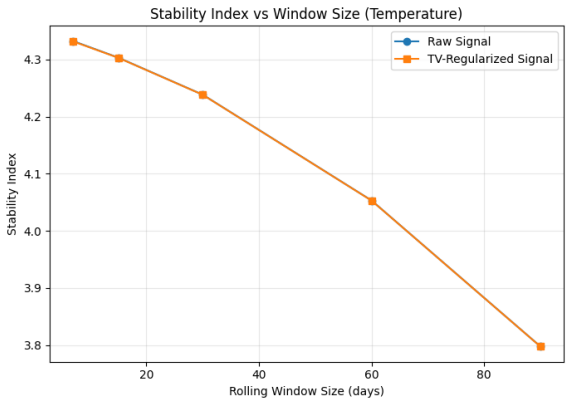

Fig. 7. Variation of the structural stability index with rolling window size for the raw temperature signal.

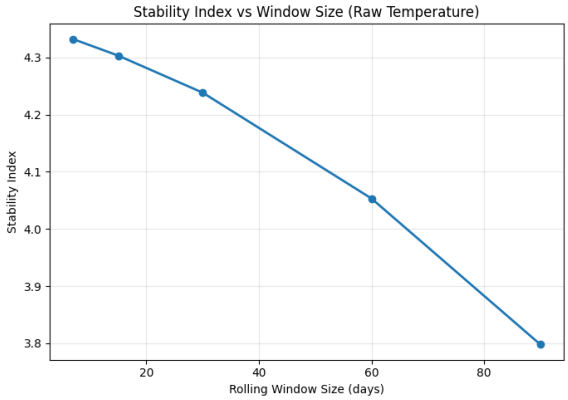

Fig. 8. Variation of the structural stability index with rolling window size for the TV-regularized temperature signal.

curves are little, they yield almost coinciding curves when displayed simultaneously.

Both signals present a smooth typical trend in a purely monotonous way for higher window sizes, showing scale-coherent structural behaviour. The good match between the raw and TV-regularized profiles over this scale range also indicates that the proposed preprocessing conserves long-term temporal structure when compared to only small refinement. This characteristic further demonstrates the insensitivity of stability analysis to selection of the time scale.

D. Discussion

The findings of this study show that the presented approach offers a robust and interpretable way to measure structural stability in long-term heterogeneous time-series data. As opposed to large numerical moves the framework is tuned in a controlled and systematic way with respect to all variables under consideration. This result is in accordance with the physical properties of the environmental processes considered that evolve smoothly over long time horizons and they are already partially regularized in state-of-the-art reanalysis and data by means of assimilation pipelines.

One can interpret this result, at least for our setting of moderate dimensionality and size of the network involved in the decision trees' predictions generation, is that structural stability as a feature to be analyzed rather than an aftermath of predictive power reveals aspects about the data which are highly obscured in learning based algorithms. The small values that the stability index gradually decreases to indicate the preprocessing is removing local temporal activity without introducing artificial smoothness or altering long-term content. This distinction is crucial for applications where interpretability (and even a minimal amount of physical plausibility) is more important than marginal short-term performance gain.

Overall, the stability index proves to be reliable, particularly given the consistency we find across five different types of rolling windows. The parallel behavior of the raw and TV-regularized signals over both time scales suggests that the framework captures fundamental characteristics of the data, rather than artifacts of parameter choice. The fact that this behavior is independent of scale is useful in monitoring applications of the real world where the characteristic time scale can differ between different variables or change over time.

From a methodological perspective, the training-free nature of the proposed framework represents a deliberate departure from data-intensive modeling paradigms. Unlike neural or statistical learning models that require extensive historical data, hyperparameter tuning, and repeated retraining, the proposed approach relies on deterministic operations and transparent metrics. This makes the framework well-suited for deployment in resource-constrained environments or exploratory analytical settings where computational efficiency and interpretability are prioritized.

Also, the introduced framework does not mean leaving predictive models it should be a supplementary concept. Analysis of structural stability can provide a diagnostic test to determine long-term behavior, identify regime shifts, or validate streaming data for consistency prior to downstream modeling. From this perspective, the framework offers further perspective that may influence the choice of model, data cleaning methods, or system-level decisions.

Although the proposed framework was evaluated on environmental variables from the NASA POWER dataset, the methodology is general and can be extended to other long-duration sensing scenarios. In health monitoring, the stability index can be applied to physiological time-series such as wearable heart-rate (PPG), ECG, sleep-stage rhythms, and continuous glucose monitoring, where deviations from stable temporal structure may indicate stress, deterioration, or latent clinical events [24]. Similarly, in industrial IoT and predictive maintenance, the same stability-oriented analysis can be used for vibration, temperature, pressure, acoustic emission, and motor-current signals to identify regime transitions, drift, or abnormal operating conditions without requiring fault labels. Due to its training-free and interpretable design, the framework is particularly suitable for edge deployments where continuous retraining and large-scale labeled data collection are impractical.Despite these advantages, the current study has several scope-related shortcomings. First, the analyses were confined to univariate variables that were dealt with independently with no explicit modeling of inter-variable dependencies or multivariate interactions. Second, a single regularization parameter λ of total variation was assigned to all parameters in

order to prevent bias tuning and preserving interpretability and comparability, while the calibration for stability assessment under different noise textures can be more strongly optimized through adaptive parameter selection strategy. Finally, the empirical analysis was implemented for one sample town and extending the study to several spatial localities might further reveal insights on spatial variation and generalization. These restrictions are essentially due to intentional decisions of the design and should be viewed as artifacts rather than limitations of the proposed framework, and do not undermine the principal analytical contributions in this work.

VI. Conclusion and Future Work

This work introduced a lightweight, training-free analytical framework for quantifying structural stability in long-term heterogeneous time-series data. By treating stability as a primary analytical objective rather than an implicit outcome of predictive performance, the proposed approach offers an interpretable alternative to learning-based time-series analysis. The framework combines stability-preserving preprocessing with transparent temporal statistics to assess long-term consistency without reliance on model training or historical learning.

Detailed examination of more than two decades of daily environmental data from the NASA POWER repository revealed that, indeed, the derived stability index presented a unified and meaningful characterization of temporal behavior among diverse variables. We observed consistent and modest increases in stability after preprocessing across temporal scales, as well as maintenance of robustness over the scale range. Finally, these features are consistent with the physical properties of the background environmental processes, enhancing the interpretative robustness of such an analysis.

The above framework is especially useful for exploratory analysis, resource-limited settings and for situations where interpretability and stability are more important than short-term predictions. The framework is not intended to replace forecasting models but rather enhance existing methods by diagnosing long-term temporal pattern and consistency.

Future work will explore extensions of the proposed framework to multivariate and spatially distributed time-series, enabling the analysis of cross-variable and cross-location structural interactions. Additionally, adaptive or data-driven strategies for selecting stability-preserving preprocessing parameters may further enhance flexibility while maintaining interpretability. Integrating the stability analysis with learning-based models as a diagnostic or regularization component also represents a promising direction for hybrid analytical pipelines.

***Abstract*—The widespread dissemination of multimodal misinformation requires models that can reason across textual and visual content while remaining interpretable. However, many existing multimodal fusion approaches implicitly assume uniform modality reliability, providing limited transparency into modality contributions. This study introduces TweFuse-W, a lightweight multimodal framework for fine-grained fake-news detection that reframes multimodal fusion as a modality reliability estimation problem, rather than merely merging modalities or explicitly modeling their interactions. TweFuse-W integrates BERTweet-based textual representations with Swin Transformer visual features using a sample-conditioned, learnable weighted-sum gate operating at the modality level, producing global reliability weights without cross-attention overhead. By explicitly parameterizing modality contributions during inference, the proposed approach provides intrinsic interpretability. Experiments on the six-class Fakeddit dataset show that TweFuse-W achieves a macro-F1 score of 0.838, outperforming simple concatenation (macro-F1 = 0.820). Analysis of the learned modality weights confirms meaningful interpretability, with textual representations dominating in Satire, Misleading, False Connection, and Imposter Content ($\alpha_T = 0.57$–0.62), while visual cues exert greater influence in Manipulated Content ($\alpha_V = 0.51$). Overall, these findings demonstrate that adaptive modality weighting enhances both predictive performance and model transparency, serving as a lightweight and interpretable *complementary fusion strategy* for multimodal fake-news detection.**

***Keywords*—Multimodal fake news detection; modality reliability modeling; adaptive fusion; interpretable fusion; lightweight multimodal models**

I. Introduction

The widespread circulation of misinformation on social media poses a significant threat to information credibility and public trust. As digital communication continues to expand, deceptive content increasingly influences political decision-making, public health, and societal stability worldwide [1]. Social media platforms such as Twitter and Facebook contribute to this issue by prioritizing engagement, which often results in misleading content spreading faster than verified information [2].

Misinformation today is rarely limited to text alone. False claims are often presented as multimodal posts in which images and captions work together to strengthen misleading messages. These posts may include manipulated images, misleading visual contexts, or mismatched image–text pairs that make false content appear more credible and harder to detect [3]. This growing reliance on multimodal presentation highlights the importance of reasoning across both text and images for effective fake-news detection.

Beyond a binary distinction between real and fake, misinformation arises from diverse underlying intentions that shape how content is generated and disseminated [4], [5]. The Fakeddit dataset [6] used in this study reflects this real-world complexity through a six-class taxonomy encompassing categories such as Satire, Misleading Content, False Connection, Imposter Content, and Manipulated Content . Accurately distinguishing among these fine-grained categories requires not only multimodal inputs but also an understanding of how textual and visual signals contribute differently across misinformation types.

Existing multimodal fake-news detection approaches largely fall into two broad fusion paradigms. The first relies on simple fusion strategies, such as concatenation or summation, which treat modalities independently and implicitly assume uniform modality importance across samples. The second paradigm employs attention-based or interaction-driven fusion mechanisms that explicitly model cross-modal dependencies, often at the expense of increased architectural complexity and computational overhead. While interaction-based methods can capture fine-grained feature alignments, both paradigms provide limited transparency into modality contributions and rarely analyze modality reliability, which is particularly critical in fine-grained misinformation classification settings.

In parallel, the choice of unimodal encoders plays a crucial role in multimodal misinformation detection. General-purpose language models such as BERT [7], RoBERTa [8], and DistilBERT [9] are not explicitly optimized for informal, noisy social-media text. In contrast, domain-specific language models such as BERTweet [10] are better suited to capturing platform-specific linguistic patterns, slang, and abbreviated expressions commonly found in misinformation posts. These observations reveal a key research gap: the need for an adaptive multimodal fusion framework that efficiently handles social-media language while providing interpretable insights into modality contributions.

Multimodal fusion in misinformation detection need not be limited to either static modality merging or explicit interaction modeling. An alternative perspective is to view fusion as

a *modality reliability estimation problem*, where the relative contribution of each modality is adaptively regulated on a per-sample basis. This formulation emphasizes global, modality-level trust signals rather than localized feature interactions, enabling adaptive fusion behavior alongside transparent interpretation of multimodal reasoning.

Guided by this formulation, **TweFuse-W** is introduced as a lightweight multimodal fusion framework that employs a sample-conditioned, learnable weighted-sum gating mechanism operating at the modality level. Rather than relying on cross-attention or heuristic confidence measures, TweFuse-W produces explicit modality reliability weights as part of the forward inference process. This design maintains computational efficiency while providing intrinsic interpretability, allowing direct analysis of modality dominance across fine-grained misinformation categories.

The main contributions of this study are summarized as follows:

- An adaptive, sample-conditioned weighted-sum fusion mechanism is introduced to dynamically model modality importance, extending beyond fixed late-fusion strategies and manually tuned weighting schemes.
- A domain-aware multimodal architecture is presented that integrates BERTweet for textual encoding with a Swin Transformer for visual representation, tailored to the characteristics of social-media misinformation.
- A quantitative interpretability analysis is conducted based on class-level distributions of learned modality weights, providing insight into how textual and visual signals contribute across fine-grained misinformation categories.
- A controlled experimental evaluation is performed across multiple textual encoders under identical training conditions, enabling fair and systematic assessment of fusion strategies and their impact on detection performance.

The remainder of this paper is organized as follows. Section II reviews related work on multimodal fake-news detection, fusion strategies, and domain-specific language modeling. Section III describes the TweFuse-W methodology, including the adaptive weighted-sum fusion mechanism and the multimodal encoding pipeline. Section IV outlines the experimental setup, dataset configuration, training protocol, and evaluation metrics. Section V presents the experimental results and the analysis of learned modality-weight patterns. Section VI discusses the implications of these findings. Finally, Section VII concludes the paper and outlines directions for future research.

II. Literature Review

The increasing impact of rapidly spreading fake news has motivated multimodal detection approaches that jointly analyze text and images. Early studies primarily adopted static fusion strategies, while later work shifted toward interaction-driven fusion using attention mechanisms to capture richer cross-modal dependencies.Recent work has also emphasized feature-level fusion strategies that aim to balance effectiveness and model complexity [11]. Table I provides a structured qualitative overview of representative multimodal fake-news detection approaches, organized according to the fusion taxonomy illustrated in Fig. 1. It summarizes the diversity of datasets, task definitions, and fusion strategies explored in prior work. The table presents a qualitative survey of existing multimodal fake-news detection approaches, emphasizing methodological trends rather than quantitative performance comparison

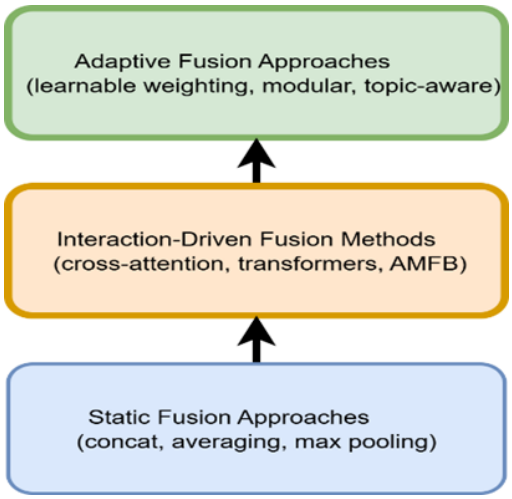

Fig. 1. Conceptual taxonomy of multimodal fusion strategies, ranging from static fusion approaches to interaction-driven and adaptive, learnable fusion methods.

A. Static Fusion Approaches

Early multimodal work processed each modality separately and merged them later using simple operations like concatenation or pooling. In study [12], visual CNNs were paired with textual encoders and evaluated with different pooling strategies, with max pooling performing best. Similarly, SpotFake [13] fused BERT and VGG-19 via simple concatenation, yielding moderate performance gains. However, such methods offer limited inter-modal interaction and cannot model modality importance. Later work like [14] used dot-product similarity to align text and image features, but still treated modalities as static and non-adaptive.

B. Interactive Fusion

Recent work has moved to interaction-driven fusion using attention and transformers to model deeper cross-modal relationships beyond simple concatenation. Transformer-based fusion now leads the field for its scalability and strong cross-modal modelling. Examples include DeBERTNext [15]FB [16], and ETMA [17], which combine transformer encoders with advanced attention mechanisms to achieve high accuracy. Recent surveys [18][19] also confirm transformers as the dominant approach in multimodal misinformation detection.

C. Adaptive Fusion

Parallel work has focused on adaptive and interpretable fusion, such as learnable intra/inter-modal weighting [18] and modular designs like M3DUSA [20]. Topic-aware transformers

[19] also improve fine-grained classification. However, surveys [21], [22] note that most multimodal models still offer limited transparency regarding modality contributions. Recent multimodal approaches for fine-grained fake news detection have explored diverse fusion strategies, including attention-based and modular architectures [4], [20], [23]. Efficiency-aware and domain-adaptive multimodal frameworks have recently gained attention, particularly in low-resource or dynamically evolving misinformation settings [24], [25].

D. Research Gaps and Problem Definition

Despite substantial progress from static fusion strategies to transformer-based multimodal models, several fundamental limitations remain. Simple fusion methods, such as concatenation or summation, implicitly assume uniform modality reliability and lack mechanisms to down-weight unreliable or misleading modalities on a per-sample basis. In contrast, attention-based architectures explicitly model cross-modal interactions but incur significant computational overhead and often provide limited transparency into modality-level contributions. Moreover, the majority of existing studies focus on binary real–fake classification, leaving fine-grained misinformation categories and systematic analysis of modality reliability largely underexplored.

This work addresses these gaps by formulating multimodal fake-news detection as a *modality reliability estimation problem* in a fine-grained classification setting. The task is to classify a multimodal social-media post, consisting of textual content and an associated image, into one of six misinformation categories, while explicitly accounting for the relative reliability of each modality.

Formally, a multimodal input sample is defined as

$$x = \{x^{(t)}, x^{(i)}\}, \tag{1}$$

where, $x^{(t)}$ denotes the textual input and $x^{(i)}$ denotes the corresponding visual input. The target label is defined as

$$y \in \{1, \ldots, 6\}, \tag{2}$$

representing the six fine-grained misinformation classes. The objective is to learn a prediction function

$$f\left(x^{(t)}, x^{(i)}\right) \rightarrow y, \tag{3}$$

where, the contribution of each modality is regulated through *adaptive, sample-conditioned reliability weights*, denoted by $w_t(x)$ for text and $w_i(x)$ for images. These weights are designed to capture the relative trustworthiness of each modality for a given input instance, rather than merely facilitating feature aggregation or cross-modal interaction.

III. Methodology

This study introduces **TweFuse-W**, an adaptive multimodal framework for fine-grained fake-news detection that prioritizes intrinsic interpretability. The framework integrates domain-specific textual representations extracted using *BERTweet* with visual features obtained from a *Swin Transformer*, enabling complementary multimodal reasoning. Rather than relying on static fusion rules or explicit cross-modal interaction modeling, TweFuse-W employs a learnable weighted-sum fusion mechanism that dynamically regulates the contribution of each modality on a per-sample basis. This formulation explicitly reflects the varying reliability of textual and visual information across different misinformation categories, while maintaining a lightweight fusion design. Fig. 2 illustrates the overall processing pipeline, including multimodal feature extraction, adaptive modality reliability weighting, and final classification. The remainder of this section details the dataset and preprocessing steps, unimodal feature extraction, adaptive fusion mechanism, and classification procedure.

A. Dataset Preparation

The *Fakeddit* dataset [12] is selected due to its aligned text–image pairs and fine-grained annotation schema, making it well suited for evaluating adaptive multimodal fusion strategies. The dataset contains approximately one million Reddit posts annotated under binary, three-class, and six-class settings. This study focuses on the highly imbalanced six-class taxonomy illustrated in Fig. 3.

Primary performance results are reported using the official Fakeddit train, validation, and test splits. In addition, a stratified 20% subset of the dataset is employed exclusively for controlled ablation and interpretability analyses. This subset enables repeated experimental runs under reduced computational cost while faithfully preserving the original class distribution.

Consistent with prior work, the full raw *Fakeddit* dataset is rarely used due to missing or unrecoverable image URLs [18], a limitation also observed during dataset inspection. Consequently, a clean, stratified 20% subset is adopted to preserve the original class distribution and content characteristics.

A Chi-square goodness-of-fit test confirms that the class-label proportions in the reduced subset do not differ significantly from those of the full dataset ($\chi^2 = 0.0004$, $p > 0.99$). Linguistic equivalence is assessed by comparing headline-length distributions using the Kolmogorov–Smirnov test and Cohen's d, yielding statistically indistinguishable results (KS $= 0.0027$, $p > 0.99$; $d = -0.0064$). Mean headline lengths are nearly identical (7.47 ± 5.59 vs. 7.51 ± 5.75 words). Visual consistency is also preserved, with comparable image availability rates (99.76% vs. 99.77%).

These analyses demonstrate that the reduced subset faithfully preserves the statistical, linguistic, and visual characteristics of the complete *Fakeddit* dataset. The exact subset indices and sampling scripts will be released publicly to ensure full reproducibility.

B. Data Preprocessing

The reduced subset is used for comparative experiments and in-depth analyses, including the investigation of learned modality-weight patterns, while the complete dataset is utilized exclusively to validate the proposed framework at scale.

A unified preprocessing pipeline is applied to both modalities to ensure consistency, reproducibility, and leakage-free

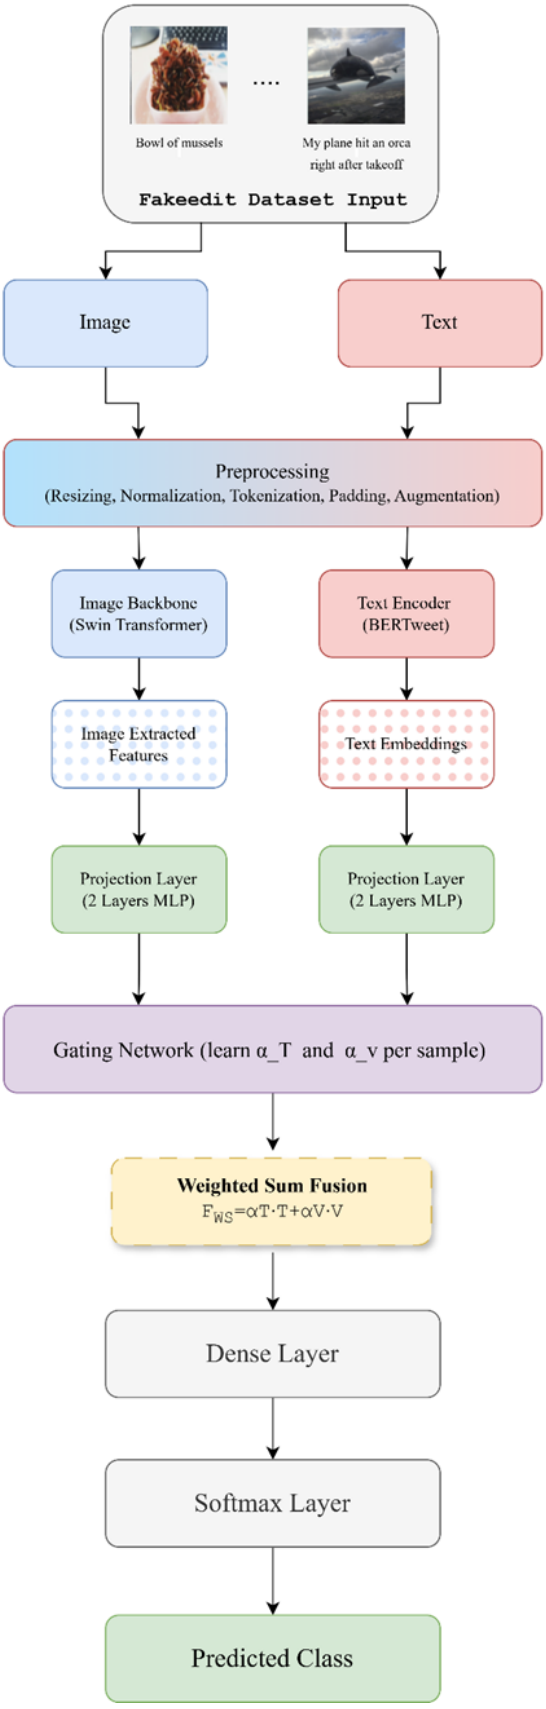

Fig. 2. Architecture of the *TweFuse-W* framework for multimodal fake news detection.

TABLE I. SUMMARY OF REPRESENTATIVE MULTIMODAL FAKE NEWS DETECTION APPROACHES

Study & Year	Dataset	Task Type	Model Used	Fusion Strategy	Notes
[12] (2020)	Fakeddit	Binary, 6-class	Basic CNN + BERT / InferSent	Concatenation, mean & max pooling	Simple pooling; weak inter-modal interaction
[26] (2023)	Twitter, Weibo	Binary	ResNet (image), BERT (text)	Contrastive + attention	Binary classification task only
[21] (2024)	Fakeddit, MFND	3-class	ResNet50, BERT	Graph-based fusion	High memory consumption
[27] (2024)	Twitter, Weibo	Binary	ERNIE-M, AlexNet	Multi-head attention	Complex multilayer fusion; limited to binary task
[18] (2024)	Reduced Fakeddit & Gossip datasets	Binary	BERT, ResNet50	Early, joint, and late fusion	Dataset reduction without verifying preserved class distribution
[19] (2025)	PolitiFact, GossipCop	Binary	BERTweet, ViT	Topic-aware multimodal cross-attention fusion	No explicit handling of data imbalance

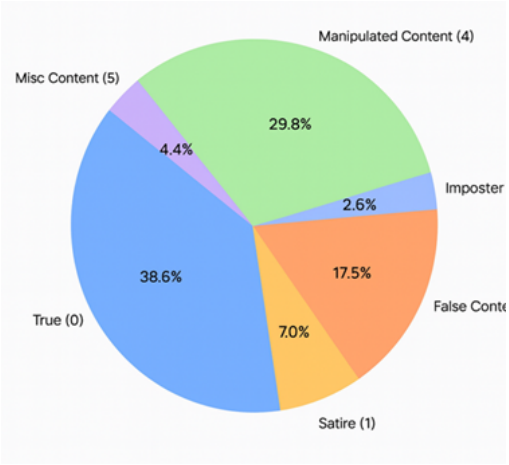

Fig. 3. Class distribution across the Fakeddit dataset categories, highlighting the dominance of True and Manipulated Content instances.

evaluation. All preprocessing and augmentation steps are performed independently within each data split.

For the textual modality, headlines are tokenized using the corresponding encoder tokenizer (BERT, DistilBERT, or BERTweet) with matched normalization and token-handling settings. Sequences are padded or truncated to a maximum length of 80 tokens based on corpus statistics. Lightweight textual augmentation is applied during training to improve generalization, with semantic consistency enforced by retaining only augmented samples with cosine similarity greater than or equal to 0.90 relative to the original text.

For the visual modality, images are resized to 224×224 pixels and normalized using ImageNet statistics. Corrupted or unreadable samples are removed. Controlled visual augmentations, including horizontal flipping, random cropping, and mild color jittering, are applied during training.

C. Feature Extraction

In all experiments, multimodal representations are extracted using frozen pretrained encoders to ensure training stability, fair comparison across model variants, and full reproducibility. Freezing the encoders also isolates the contribution of the fusion mechanism by eliminating confounding effects introduced by encoder fine-tuning.

For the textual modality, each headline is processed using the language model under evaluation (BERT, DistilBERT, or BERTweet), with all encoder parameters kept fixed. The final `[CLS]` token representation is used as the sentence-level embedding. To standardize dimensionality across textual encoders, each embedding is passed through a lightweight projection network that maps it into a unified 768-dimensional latent space.

For the visual modality, images are encoded using a frozen Swin Transformer, and the pooled backbone output is used as the visual representation. Since the native dimensionality and scale of visual features differ from those of textual embeddings, a matching projection layer is applied to map the visual features into the same 768-dimensional latent space. This alignment prevents artifacts arising from mismatched feature distributions and ensures compatibility during multimodal fusion.

Projection heads for both modalities are implemented as two-layer feed-forward blocks (`Linear` $\rightarrow$ `ReLU` $\rightarrow$ `Linear`), mapping the native encoder outputs to the shared latent space. Specifically, the Swin Transformer visual features (1024-dimensional) are projected to 768 dimensions, while the BERTweet embeddings (768-dimensional) are passed through an equivalent projection head to standardize representational capacity. Projection weights are not shared across modalities, allowing each branch to adapt independently while maintaining dimensional comparability. This design preserves modality-specific representation independence while ensuring alignment for subsequent fusion operations.

D. Fusion

A central objective of this study is to examine how adaptive modality weighting influences multimodal reasoning and interpretability in fine-grained fake-news detection. As a reference baseline, standard feature concatenation is included, as it represents a widely adopted early-fusion strategy in multimodal modeling. Given textual features T and visual features V, concatenation is defined as:

$$F_{\text{concat}} = [T; V] \tag{4}$$

As shown in Eq. (4), simple concatenation forms a fixed joint representation by stacking text and image embeddings into a single high-dimensional vector. Although straightforward to implement, this formulation assigns equal importance to both modalities for all samples and provides no mechanism to adapt modality contributions or interpret fusion behavior when one modality is more informative or reliable than the other.

To enable sample-conditioned fusion, TweFuse-W employs an adaptive weighted-sum fusion gate that learns instance-specific modality contributions. The fused representation is computed as:

$$F_{\text{ws}} = \alpha_t T + \alpha_v V, \qquad \alpha_v = 1 - \alpha_t \tag{5}$$

as defined in Eq. (5), where α_t and α_v denote the relative importance assigned to the textual and visual modalities, respectively. These modality weights are predicted by a lightweight gating network that takes the concatenated feature vector $[T; V]$ as input. The gating function produces two logits that are normalized using a softmax operation, as expressed in Eq. (6):

$$[\alpha_t, \alpha_v] = \text{Softmax}\left(g([T; V])\right) \tag{6}$$

where, $g(\cdot)$ denotes a two-layer feed-forward network with the structure `Linear–ReLU–Linear`. The bias terms of the output layer are initialized to zero, yielding an approximately uniform modality weighting at the start of training. During optimization, the gating network learns instance-specific reliability shifts based on the content of each multimodal sample.

In implementation, the gating network receives the concatenated 1536-dimensional feature vector $[T; V]$ and is defined as `Linear`(1536→128) → `ReLU` → `Linear`(128→2). This design enables dynamic modulation of modality contributions while maintaining a lightweight architecture that intentionally avoids deep interaction or cross-attention modules. As a result, observed performance differences can be attributed primarily to adaptive modality weighting rather than increased model capacity.

Beyond performance gains, the explicit modality weights (α_t, α_v) provide a transparent and interpretable signal. These weights enable analysis of modality-reliance behavior at both the sample and category levels, offering insights into how different misinformation classes depend on textual or visual evidence.

To support interpretability analysis, the modality weights (α_t, α_v) are recorded during test-time inference after the fusion step and before classification. For each test sample, the corresponding sample index, ground-truth label, predicted label, and modality weights are stored. These values are subsequently aggregated to compute sample-level distributions and class-wise statistics, facilitating systematic analysis of modality-reliance patterns across fine-grained misinformation categories.

E. Classification Layer

After obtaining the fused feature vector F from the fusion module, the model predicts the news category using a linear softmax classifier. The probability distribution over the six Fakeddit classes is computed according to Eq. (7):

$$\hat{y} = \text{Softmax}\left(W_c F + b_c\right) \tag{7}$$

As shown in Eq. (7), W_c and b_c denote the learnable parameters of the classification layer. This formulation provides a direct mapping from the fused multimodal representation to class logits and ensures a simple and consistent prediction interface across all fusion variants.

Model training employs the standard cross-entropy loss, which is applied uniformly across all experimental configurations. This consistent optimization setup ensures that any observed performance differences can be attributed to the fusion strategy rather than to variations in the classifier design or loss function. As a result, fair comparison is maintained between baseline fusion methods and the proposed adaptive weighted-sum fusion approach.

All reported evaluation metrics are directly reproducible from the corresponding training logs and evaluation scripts.

F. Evaluation and Experiments

This section describes the experimental setup, evaluation protocol, and performance analysis of TweFuse-W on the six-class Fakeddit benchmark.

G. Evaluation Criteria

Evaluation emphasizes macro-averaged metrics to account for the severe class imbalance inherent in the six-class Fakeddit taxonomy (see Fig. 3). Macro-F1 is adopted as the primary performance indicator, complemented by macro-precision and macro-recall. In addition, class-wise F1 scores are reported to analyze performance variations across individual misinformation categories.

Beyond predictive performance, evaluation explicitly examines interpretability by analyzing the modality weights produced by the adaptive fusion mechanism defined in Eq. (6). During inference, the learned textual and visual weights are recorded for each test sample and aggregated at the class level. This aggregation enables quantitative assessment of how modality importance varies across misinformation types, providing a fine-grained view of fusion behavior that remains largely underexplored in prior multimodal fake-news detection studies.

H. Experimental Setup, Model Complexity, and Reproducibility

All experiments are conducted in the Kaggle cloud environment using NVIDIA GPUs with CUDA support. The implementation is based on PyTorch 2.0, with HuggingFace Transformers used for textual encoders and the `timm` library employed for the Swin Transformer visual backbone.

Following the dataset validation procedure described in Section III, primary performance evaluation is conducted using the official Fakeddit train, validation, and test splits. A stratified 20% subset is employed exclusively for controlled ablation studies and interpretability analyses. Although the dataset provides predefined 80/10/10 train–validation–test partitions, the subset is sampled independently within each split to preserve original boundaries and class distributions while reducing computational cost and preventing data leakage.

All experiments are executed with a fixed random seed (42) to ensure deterministic behavior. To enable fair comparison, all baseline models and TweFuse-W share an identical training configuration. Optimization is performed using AdamW with a learning rate of 3×10^{-5} and a linear warm-up followed by decay. Models are trained for up to 20 epochs with a batch

size of 32, using early stopping based on validation loss with a patience of four epochs.

To ensure that observed performance differences arise from fusion behavior rather than architectural capacity, model complexity is explicitly controlled. As summarized in Table II, all pretrained encoder backbones are frozen during training, and trainable parameters are limited to lightweight projection heads, the adaptive fusion gate defined in Eq. (6), and the linear classifier defined in Eq. (7). The total number of trainable parameters remains below 2.8 million, confirming that TweFuse-W maintains a lightweight design and enabling fair comparison with concatenation-based baselines.

This standardized training protocol ensures that observed performance differences can be attributed to the fusion strategy rather than to variations in optimization, initialization, or hyperparameter tuning.

For reproducibility, the complete implementation executed on Kaggle—including preprocessing, training, and evaluation scripts—is publicly available at:

I. Comparative Baselines

To contextualize the proposed adaptive fusion strategy, TweFuse-W is evaluated against multimodal baselines that reflect common practices in image–text misinformation detection. All models share the same preprocessing pipeline, frozen encoder backbones, projection layers, and training configuration, ensuring that performance differences can be attributed specifically to the fusion mechanism rather than architectural or optimization discrepancies.

J. Multimodal Concatenation Baselines

Three multimodal baselines are constructed using standard concatenation-based fusion, as defined in Eq. (4). Each baseline combines a fixed Swin Transformer visual encoder with one textual encoder—BERT, DistilBERT, or BERTweet. Textual `[CLS]` embeddings and pooled visual features are projected into a shared latent space and concatenated prior to classification. This design provides a controlled reference that applies uniform, sample-invariant modality weighting and lacks adaptive fusion behavior, while maintaining comparable model complexity to TweFuse-W (Table II).

K. Adaptive Weighted-Sum Fusion (TweFuse-W)

TweFuse-W introduces adaptivity through the lightweight gating mechanism described in Eq. (6), which operates on the joint multimodal representation. For each input sample, the gate predicts normalized weights for the textual and visual modalities, which are then applied to compute the weighted-sum fusion defined in Eq. (5). This formulation enables dynamic, sample-conditioned modulation of modality importance without introducing deep cross-modal interaction modules.

By comparing TweFuse-W against concatenation-based baselines under comparable parameter budgets (Table II), the experimental analysis isolates the contribution of adaptive modality weighting. In addition, the learned modality weights are logged and analyzed at the class level, enabling systematic investigation of modality-reliance patterns across fine-grained misinformation categories and directly supporting the interpretability objectives of the proposed framework.

IV. Results

All primary performance results reported in this section are obtained from evaluation on the official Fakeddit test split. TweFuse-W is evaluated on the six-class Fakeddit benchmark following the official evaluation protocol. As reported in Table VI, TweFuse-W achieves a Macro-F1 score of 0.838, outperforming the standard concatenation baseline 0.820. This result demonstrates that adaptive, sample-conditioned modality weighting provides a consistent performance advantage over uniform fusion strategies under standard benchmark conditions.

To gain deeper insight into class-level behavior, robustness across text encoders, and fusion interpretability, additional experiments are conducted on a stratified 20% subset of the Fakeddit dataset. Under this controlled setting, TweFuse-W achieves a Macro-F1 of 0.854, with particularly strong performance on categories characterized by clearer linguistic or visual cues, such as *Manipulated Content* (F1 = 0.963) and *Misleading* (F1 = 0.885), as detailed in Table V. Competitive performance is also maintained on more ambiguous categories, including *False Connection* (F1 = 0.746) and *Imposter Content* (F1 = 0.783). These subset-based results are used exclusively for methodological validation and interpretability analysis rather than for primary benchmark comparison.

As summarized in Table III, TweFuse-W consistently outperforms concatenation-based baselines across all evaluated textual encoders. The largest improvement is observed for the BERTweet–Swin configuration, where Macro-F1 improves from 0.833 to 0.854, highlighting the benefit of combining domain-specific text representations with adaptive multimodal fusion. Consistent performance trends across encoders are further illustrated in Fig. 4.

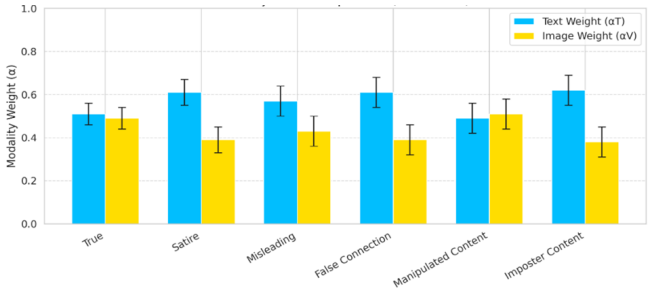

Fig. 4. Learned modality weights (α_T and α_V) across the six Fakeddit classes.

A modest decrease in absolute performance is observed when transitioning from the stratified subset to the full official dataset. This behavior is expected due to the increased diversity, noise, and difficulty of the complete benchmark. Importantly, TweFuse-W continues to outperform the concatenation baseline under this stricter evaluation setting, confirming that the observed gains generalize beyond subset-based experiments.

Detailed class-wise precision, recall, and F1-scores are reported in Table V. To analyze fusion behavior, the learned modality weights (α_T, α_V) are recorded for each test sample and aggregated per class. The resulting statistics, presented in Table IV, reveal interpretable modality-reliance patterns.

TABLE II. TRAINABLE COMPONENTS AND PARAMETER COUNTS OF THE TWEFUSE-W FRAMEWORK

Module	Description	Input → Output	Params
Text projection head	Two-layer MLP (`Linear–ReLU–Linear`) on BERTweet	$768 \to 768 \to 768$	1,181,184
Image projection head	Two-layer MLP (`Linear–ReLU–Linear`) on Swin	$1024 \to 768 \to 768$	1,377,792
Gating network	Fusion gate (`Linear–ReLU–Linear–Softmax`)	$1536 \to 128 \to 2$	196,994
Classification head	Linear classifier	$768 \to 6$	4,614
Total trainable parameters	–	–	**2,760,584**

Text-dominant categories such as *Satire*, *Misleading*, *False Connection*, and *Imposter Content* rely more heavily on textual cues, whereas *True* and *Manipulated Content* exhibit more balanced text–image contributions. The low variance of modality weights across samples indicates stable and consistent fusion behavior.

TABLE III. MACRO-F1 COMPARISON BETWEEN CONCATENATION AND ADAPTIVE WEIGHTED-SUM FUSION

Model	Concat	Weighted Sum
BERT + Swin	0.824	0.840
DistilBERT + Swin	0.810	0.832
BERTweet + Swin	0.833	0.854

TABLE IV. LEARNED TEXT (α_T) AND CISION (α_V) WEIGHTS USING TWEFUSE-W

Class	α_T (mean ± std)	α_V (mean ± std)
True	0.51 ± 0.05	0.49 ± 0.05
Satire	0.61 ± 0.06	0.39 ± 0.06
Misleading	0.57 ± 0.07	0.43 ± 0.07
False Connection	0.61 ± 0.07	0.39 ± 0.07
Manipulated Content	0.49 ± 0.07	0.51 ± 0.07
Imposter Content	0.62 ± 0.07	0.38 ± 0.07

TABLE V. CLASS-WISE PRECISION, RECALL, AND F1-SCORES OF TWEFUSE-W

Class	Precision	Recall	F1-score
True	0.861	0.854	0.858
Satire	0.868	0.852	0.860
Misleading	0.894	0.877	0.885
False Connection	0.770	0.723	0.746
Manipulated Content	0.965	0.961	0.963
Imposter Content	0.801	0.767	0.783

TABLE VI. PERFORMANCE ON THE OFFICIAL FAKEDDIT TEST SPLIT (SIX-CLASS TASK)

Model	Macro-F1
Concat (BERTweet + Swin)	0.820
TweFuse-W	0.838

V. DISCUSSION

The experimental results demonstrate the complementary importance of domain-aware language modeling and adaptive multimodal fusion for fine-grained fake-news detection. Configurations using BERTweet consistently achieve the highest Macro-F1 scores (Table III), confirming that domain-specific pretraining is critical for handling the informal and context-dependent language prevalent in social media content.

Beyond textual modeling, the results highlight the essential role of visual information. Visually grounded categories such as *Manipulated Content* are inadequately addressed by uniform fusion strategies that assign equal importance to all modalities. The adaptive weighted-sum fusion directly addresses this limitation by learning instance-level modality importance.

The confusion matrix in Fig. 5 further supports the interpretability analysis by revealing class-specific error patterns. Visually grounded categories, particularly *Manipulated Content*, exhibit strong diagonal dominance, indicating reliable predictions when visual cues are informative. In contrast, most misclassifications occur among semantically related, text-dominant categories, a trend that aligns with the modality-weight distributions reported in Table IV. This consistency suggests that the adaptive fusion mechanism assigns modality importance in a manner that reflects the underlying characteristics of each misinformation category.

Ablation results in Table VII show that removing adaptive fusion leads to a substantial performance drop, while replacing BERTweet with DistilBERT further degrades performance. These findings validate the individual contributions of both domain-aware text encoding and adaptive fusion. These findings align with recent observations that emphasize the growing challenge posed by increasingly sophisticated and generative forms of misinformation [28].

VI. CONCLUSION AND FUTURE WORK

This study introduces TweFuse-W, an adaptive multimodal framework for fine-grained fake-news detection that reconsiders how modality contributions should be modeled and interpreted. By complementing existing fusion paradigms, TweFuse-W shows that lightweight, sample-conditioned modality weighting can achieve strong and consistent performance across diverse misinformation categories. More importantly, the framework reframes multimodal fusion from an interpretability-centered perspective, enabling systematic analysis of modality reliability and providing insight into how textual and visual evidence contribute to fine-grained misinformation decisions.

The experimental results indicate that adaptive weighted-sum fusion provides a practical and effective alternative to uniform concatenation and more complex fusion strategies. Across multiple encoder configurations and evaluation settings, TweFuse-W consistently improves Macro-F1 performance while preserving a compact and interpretable design. These findings highlight a favorable efficiency–interpretability balance in multimodal fake-news detection.

Beyond performance, this work offers a reliability-aware perspective on multimodal fusion. Analysis of the learned modality weights shows that modality importance varies systematically across misinformation categories, indicating that modality reliability is input-dependent rather than fixed. This

TABLE VII. ABLATION STUDY OF TWEFUSE-W ON THE FAKEDDIT DATASET

Configuration	Description	Macro-F1 (%)	Δ (%)
Full Model	BERTweet + Swin (adaptive weighted sum)	0.854	—
w/o Weighted Sum	Concatenation fusion	0.833	−2.46
w/ DistilBERT	Replace BERTweet encoder	0.832	−2.57
Text Only	BERTweet encoder only	0.775	−9.26
Image Only	Swin Transformer only	0.700	−18.03

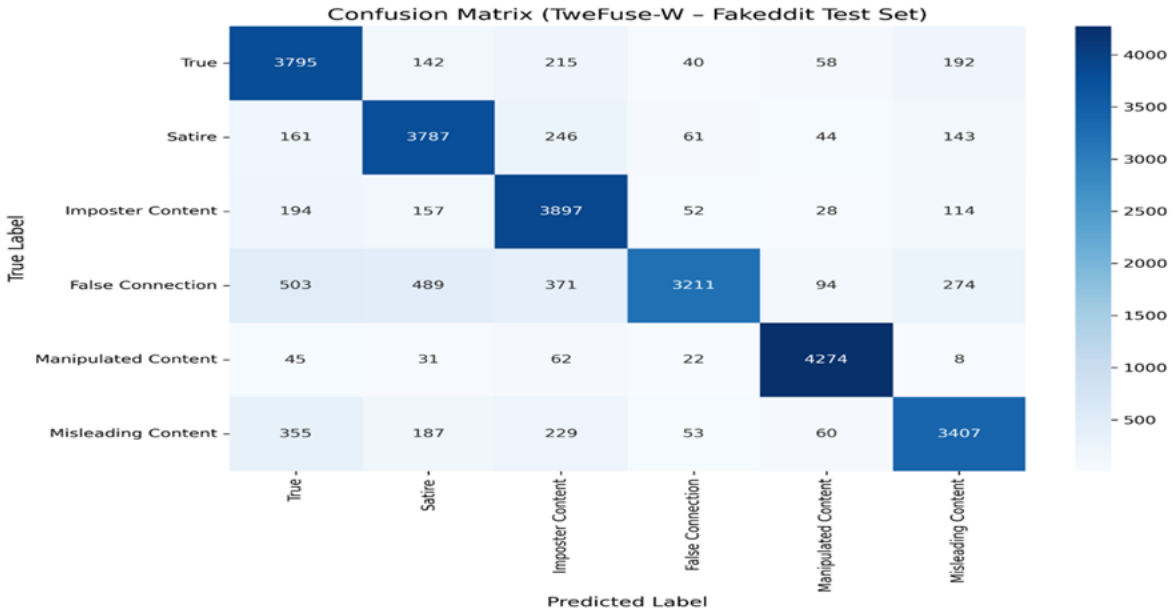

Fig. 5. Confusion matrix of TweFuse-W on the six-class fakeddit dataset.

highlights the value of modeling fusion as an adaptive reliability estimation process rather than a static feature combination.

While the framework emphasizes simplicity and transparency, future work may integrate adaptive weighting with richer interaction mechanisms and extend evaluation to larger-scale and multi-seed settings. Overall, this study advances multimodal fake-news detection by showing that adaptive, interpretable modality weighting is both effective and conceptually meaningful, offering a complementary perspective to existing fusion approaches.

Enhancing SCADA Security in Critical Infrastructure: A Multi-Layered Architecture Using IoT-Based Monitoring and AI-Driven Anomaly Detection

Mohammad Alqahtani, Abdulkarim Amin, Kyounggon Kim, Seokhee Lee*
Department of Cyber Security and Digital Forensics,
Naif Arab University for Security Sciences, Riyadh, Kingdom of Saudi Arabia

***Abstract*—Supervisory Control and Data Acquisition (SCADA) systems are central to the efficient operation of critical infrastructure such as energy, water, and industrial networks. However, the increased digital integration of SCADA components, especially through Internet of Things (IoT) technologies, has simultaneously broadened their exposure to cyber threats. This project presents a simulated SCADA system architecture designed to model, monitor, and secure real-time industrial telemetry using open-source platforms Node-RED and ThingsBoard. Leveraging real-world data collected from the Aventa AV-7 wind turbine in Switzerland, the project implements a multilayered architecture comprising edge, fog, and cloud layers, equipped with synchronized databases for integrity comparison and threat forensics. Artificial intelligence (AI) models are integrated into the system to perform anomaly detection using supervised, unsupervised, and deep learning (LSTM) algorithms. Cyberattacks including Distributed Denial of Service (DDoS), false data injection, and replay attacks are simulated to evaluate the system's resilience. This report details each stage of the project from data preprocessing and system design to implementation and evaluation culminating in a set of strategic recommendations for enhancing SCADA security through AI-driven frameworks.**

***Keywords*—SCADA security; industrial IoT; anomaly detection; machine learning; digital forensics; wind turbine telemetry**

I. Introduction

The integration of digital technologies within industrial environments has revolutionized the way critical infrastructure is monitored, controlled, and managed. Supervisory Control and Data Acquisition (SCADA) systems, which enable remote monitoring and control of field devices, are fundamental to sectors such as energy, water treatment, and manufacturing. Traditionally, these systems operated in isolated environments with proprietary protocols, relying on "security through obscurity" [1]. However, with the convergence of SCADA systems and modern IT practices—including cloud computing, edge processing, and the Internet of Things (IoT)—this traditional security paradigm is no longer sufficient. While this integration enhances operational efficiency, it simultaneously expands the attack surface [2]. Vulnerabilities once mitigated by physical isolation are now exposed to remote access threats, weak authentication, and insecure communication channels [3]. Cyberattacks on Industrial Control Systems (ICS) have become more frequent and impactful, ranging from data breaches to full system takeovers, highlighting the urgent need for resilient and intelligent SCADA infrastructures [4].

*Corresponding author.

A. Background and Motivation

The shift toward interconnected systems has exposed industrial control environments to a growing array of cybersecurity threats. Alsabbagh and Langendörfer [3] highlight that modern SCADA systems face extensive vulnerabilities due to the integration of IP-based networking. Furthermore, the real-time and safety-critical nature of Cyber-Physical Systems (CPS) challenges traditional IT security methods, which are often ill-suited for low-latency industrial operations [5]. Modern industrial systems require proactive defense mechanisms beyond static perimeters. Recent research highlights the integration of Machine Learning and Cyber Threat Intelligence (CTI) as a key driver for effective threat identification and predictive security against evolving adversary tactics [6].

B. Problem Statement

Despite the escalating threat landscape, legacy SCADA systems often lack intelligent detection capabilities. They frequently fail to identify sophisticated, stealthy attacks such as signal spoofing or replay attacks. The evolving threat landscape, characterized by sophisticated ransomware syndicates and organized cybercrime groups utilizing advanced Tactics, Techniques, and Procedures (TTPs), further exacerbates these vulnerabilities [7]. Existing security solutions are predominantly static and rule-based, making them ineffective against novel attack vectors that deviate subtly from normal operations [8]. Recent research advocates for Artificial Intelligence (AI) and Machine Learning (ML) approaches to address these limitations. For instance, Choi and Kim [9] validated the effectiveness of unsupervised techniques, such as Isolation Forests, for detecting unknown anomalies without prior labeling. However, challenges remain regarding model drift and the explainability of AI decisions in critical infrastructure [10]. Therefore, there is an urgent need for a modular, AI-driven security framework that can proactively detect anomalies and validate data integrity in real time.

C. Research Objectives and Contributions

The core research question of this study is: To what extent can a multi-layered architecture, combining synchronized dual-databases and a hybrid AI-driven detection engine, effectively identify and validate both known faults and sophisticated zero-day cyberattacks in a real-time SCADA environment?

To address this question, this research designs, simulates, and evaluates a secure, anomaly-aware SCADA architecture. We propose a multi-layered framework built using open-source platforms—specifically Node-RED and ThingsBoard—that integrates advanced machine learning models for real-time threat detection. To ensure realism and operational complexity, the project utilizes real-world telemetry data collected from the Aventa AV-7 research wind turbine [11]. This high-fidelity dataset serves as the foundation for developing and validating security mechanisms within a simulated industrial environment.

The specific contributions of this study are as follows:

- Dual-Database Architecture: Development of a synchronized edge-fog database system to ensure data redundancy and enable forensic validation of telemetry integrity.
- Hybrid Anomaly Detection: Implementation of a hybrid detection engine combining supervised learning (e.g., Random Forest) and unsupervised learning (e.g., Isolation Forest, Autoencoders) to identify both known faults and zero-day attacks [12].
- Cyberattack Simulation Testbed: Empirical evaluation of system resilience against simulated threats, including Distributed Denial of Service (DDoS), false data injection, and replay attacks.

By bridging the gap between theoretical security models and practical implementation using authentic industrial data, this research offers a scalable reference model for securing next-generation SCADA systems. The remainder of this paper is organized as follows. Section II reviews related work in SCADA security and AI applications. Section III details the proposed multi-layered system architecture. Section IV describes the methodology, including data acquisition from the Aventa AV-7 turbine and the development of AI/ML models. Section V outlines the simulated cyberattack scenarios. Section VI presents the experimental results and analysis , and Section VII concludes the paper with a discussion on limitations and future research directions.

II. Related Work

The convergence of industrial automation with digital networking technologies has elevated the significance of SCADA systems in modern infrastructure. Originally designed as isolated control environments, SCADA systems are now increasingly connected through the IoT, exposing them to cyber risks previously limited to enterprise IT networks [1]. This transformation necessitates a reconsideration of how security, reliability, and resilience are maintained within critical infrastructure.

A. SCADA Vulnerabilities and Cybersecurity Challenges

Traditional SCADA systems often rely on programmable logic controllers (PLCs) and proprietary communication protocols, historically protected by physical isolation. However, Alsabbagh and Langendörfer [3] highlighted that such systems now face extensive vulnerabilities due to weak authentication, lack of encryption, and poor access control, particularly as they are integrated with modern IP-based networking. This security gap is critical as attackers increasingly target ICS through network-based exploits, credential hijacking, and telemetry injections [13].

The emergence of Cyber-Physical Systems (CPS) has further complicated SCADA security. Tyagi and Sreenath [5] outlined the challenges unique to CPS environments, emphasizing that traditional IT security methods are often ineffective due to the real-time, low-latency, and safety-critical requirements of industrial operations. These characteristics demand novel security strategies that can detect and respond to threats without interrupting physical processes.

B. AI and Machine Learning in Industrial Anomaly Detection

Traditional SCADA security often relies on fixed thresholds and static rule-based systems, which are insufficient against adaptive or stealthy cyberattacks. Modern research increasingly advocates for AI and machine learning approaches to anomaly detection [12].

Moreover, unsupervised learning has emerged as a practical solution for industrial environments where labeled attack data is rare. Choi and Kim [9] validated the effectiveness of unsupervised techniques such as Isolation Forest for detecting unknown anomalies without prior labeling. This approach matches this system's use of Isolation Forest models trained on normal operational data to identify novel intrusions, such as during replay attacks and false data injections.

However, as this research and other studies acknowledge, AI-driven models are not without challenges. Issues such as model drift, false positives due to environmental variability, and limited explainability remain open problems [10]. Future research must explore adaptive learning, explainable AI (XAI), and hybrid detection systems that combine statistical, rule-based, and machine learning techniques.

C. Observations and Gaps in Current Literature

While existing studies have extensively explored individual aspects of SCADA security such as anomaly detection, decentralized architecture, and AI model deployment, few have integrated these components into a cohesive, real-time, testbed-based simulation using real-world telemetry. This project addresses this gap by building a practical, layered SCADA framework that:

- Uses authentic turbine sensor data [11];
- Implements dual-database synchronization for forensic analysis;
- Integrates supervised and unsupervised AI models;
- Simulates multiple attack scenarios including DDoS, false data injection, and access token hijacking;

- Evaluates both detection accuracy and operational resilience.

This holistic integration not only advances the current state of SCADA security simulation but also offers a scalable foundation for future research into smart infrastructure cybersecurity.

III. Proposed System Architecture

The architecture of the proposed SCADA simulation system is designed to emulate real-world industrial environments where data collection, analysis, and control occur across multiple levels. As illustrated in the system design, the model adopts a three-tier structure—Edge, Fog, and Cloud—each responsible for specific functions ranging from data ingestion to forensic validation [26]. This layered approach ensures modularity, scalability, and security while supporting redundancy through a dual-database configuration (Fig. 1).

A. Overview of Multi-Layered Architecture

The system mimics a smart city scenario where telemetry data from field sensors is processed hierarchically:

1) Edge layer (physical/local): This layer leverages Node-RED as the core processing unit. It is responsible for ingesting real-time telemetry via the MQTT protocol, performing immediate data cleansing, and storing the raw data in a local MySQL database. The edge layer handles low-latency control logic and message orchestration [18].

2) Fog layer (intermediate): Positioned between the edge and the cloud, the Fog layer utilizes ThingsBoard for real-time visualization, rule-based alerting, and metadata processing. It acts as a bridge, enabling operators to monitor system status without directly accessing the physical controllers [16].

3) Cloud layer (centralized): While locally simulated in this testbed, the Cloud layer represents remote systems with administrative access and long-term analytics capabilities. It serves as a backup for telemetry validation and supports high-level decision-making processes [17].

B. Dual-Database Synchronization for Forensic Integrity

A critical innovation of this architecture is the implementation of a dual-database system to ensure data integrity and enable forensic analysis. A primary MySQL database resides at the Edge layer, capturing raw data directly from sensors. A secondary, synchronized MySQL database is maintained at the Fog/Cloud layer, populated via a custom Flask API that retrieves data from ThingsBoard.

A synchronization module periodically queries both databases, aligning records by timestamp to detect discrepancies. To mitigate false positives caused by network latency, the module implements a dynamic tolerance window (e.g., ± 2 seconds) during timestamp alignment. Discrepancies persisting beyond this window are flagged for forensic review, effectively distinguishing between benign transmission delays and malicious data tampering. This mechanism serves as a real-time validation engine; any mismatch between the Edge (source) and Fog (visualization) data indicates potential data tampering, Man-in-the-Middle (MitM) attacks, or transmission faults [19]. This design ensures that even if the visualization layer is compromised, the integrity of the original telemetry can be verified against the edge records.

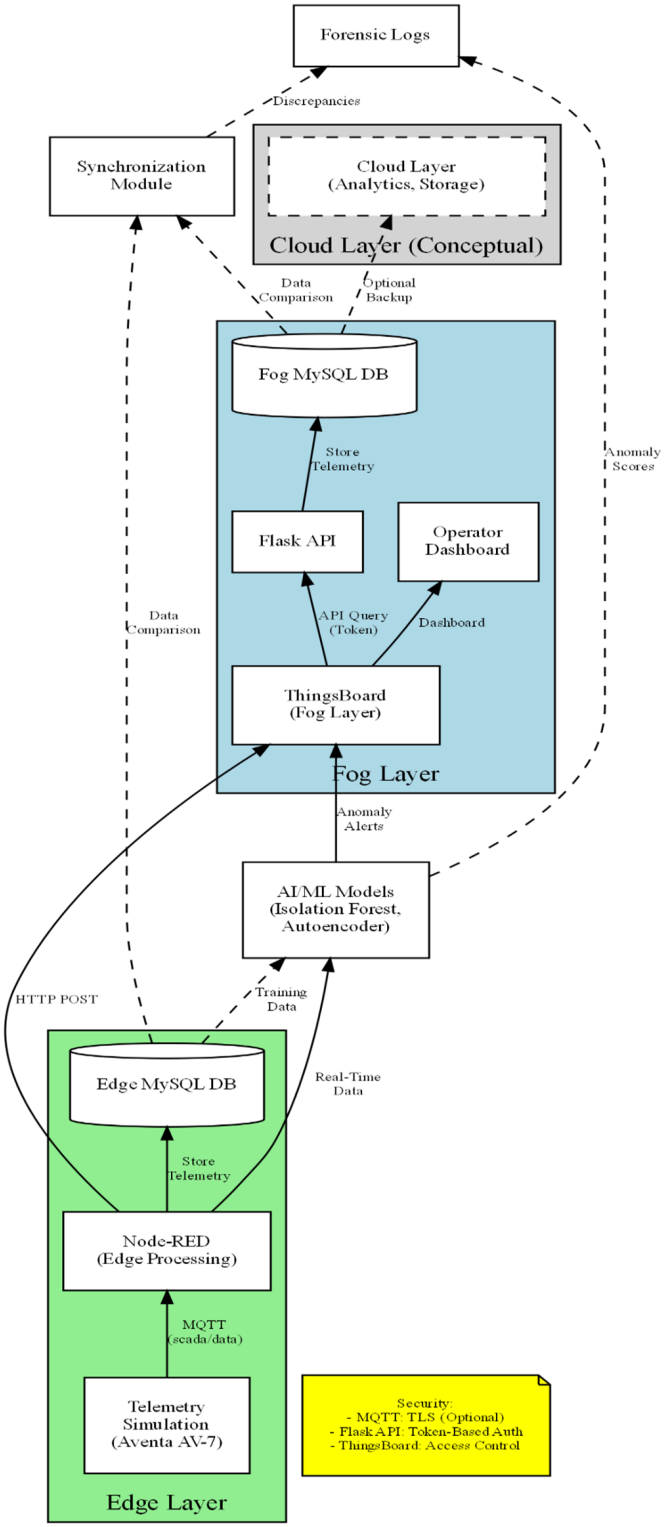

Fig. 1. Proposed multi-layered SCADA architecture integrating Edge, Fog, and Cloud layers with dual-database synchronization.

TABLE I. COMPARISON OF PROPOSED FRAMEWORK WITH EXISTING SCADA SECURITY STUDIES

Reference	Dataset Type	Architecture	Integrity	Detection	Real-Time
Upadhyay et al. [1]	Simulated	IoT/Cloud	Single DB	Cryptography	Yes
Ghosh et al. [4]	Simulated	SCADA	Single DB	Quantum/ Crypto	No
Choi & Kim [9]	Public Dataset	Single Layer	N/A	Unsupervised	No
Proposed System	**Real-World (Aventa)**	**Edge-Fog-Cloud**	**Dual-DB Sync**	**Hybrid AI (RF+LSTM)**	**Yes**

C. Tools and Technologies

The framework is built using open-source technologies to ensure cost-effectiveness and reproducibility:

1) Node-RED: A flow-based development tool used for orchestrating data flows at the edge, parsing JSON telemetry, and executing local control logic.

2) ThingsBoard: An open-source IoT platform chosen for its robust dashboarding capabilities, asset management, and built-in rule engine for generating alerts based on telemetry thresholds [21].

3) MQTT (Message Queuing Telemetry Transport): A lightweight messaging protocol used for efficient, low-bandwidth communication between the simulated wind turbine sensors and the edge gateway.

4) Python & Flask: Used to develop the custom API for database synchronization and to implement the machine learning models (Isolation Forest, Autoencoders) for anomaly detection.

IV. METHODOLOGY AND DATA PROCESSING

This study adopts an experimental design strategy utilizing a high-fidelity digital twin of a wind turbine SCADA system. The methodology follows a comprehensive workflow encompassing data acquisition from the Aventa AV-7 turbine, a hybrid preprocessing pipeline, and the development of AI-driven anomaly detection models. Furthermore, the framework integrates realistic cyberattack simulations and a dual-database synchronization mechanism to validate system resilience and forensic integrity. Fig. 2 shows overview of the research workflows.

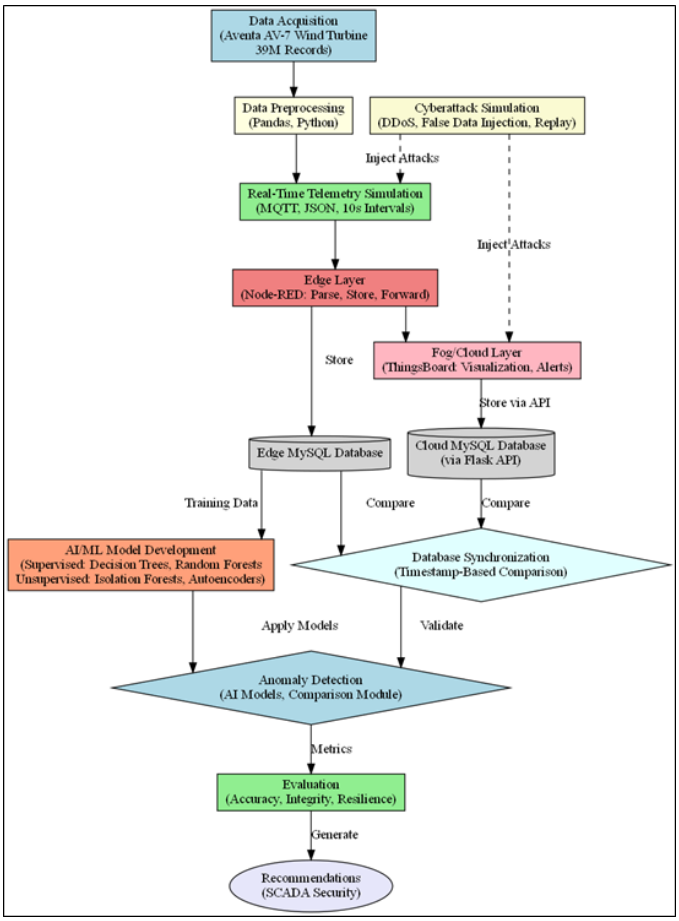

Fig. 2. Overview of the research workflow illustrating the integration of real-time simulation, cyberattack injection, and multi-layered anomaly detection.

A. Dataset Description

To ensure the realism of the simulation, we utilized a real-world dataset sourced from the Aventa AV-7 research wind turbine, operated by the Institute for Energy Technology (IET-OST) in Switzerland [11]. The Aventa AV-7 is a variable-speed wind turbine with a rated power of 6kW, designed for low-wind-speed environments.

1) Data scope and characteristics: The dataset covers an 18-month operational period from January 2022 to July 2023. It consists of high-resolution time-series telemetry sampled at a frequency of 1Hz, totaling approximately 39.7 million records. This high frequency allows for the detailed modeling of transient behaviors and rapid anomalies that 10-minute averaged SCADA data might miss.

The dataset includes diverse operational conditions, including start-up sequences, power generation, idle states due to low wind, and system faults. Notably, the dataset exhibits a significant class imbalance, where fault states (indicated by specific status codes) constitute a minority of the data, reflecting real-world industrial scenarios.

2) Telemetry features: The SCADA system logs several physical and electrical parameters. The key features selected for this study include:

a) RotorSpeed (RPM): Rotational speed of the turbine blades.

b) GeneratorSpeed (RPM): Rotational speed of the generator shaft.

c) PowerOutput (kW): Electrical power generated (Rated max: 6kW).

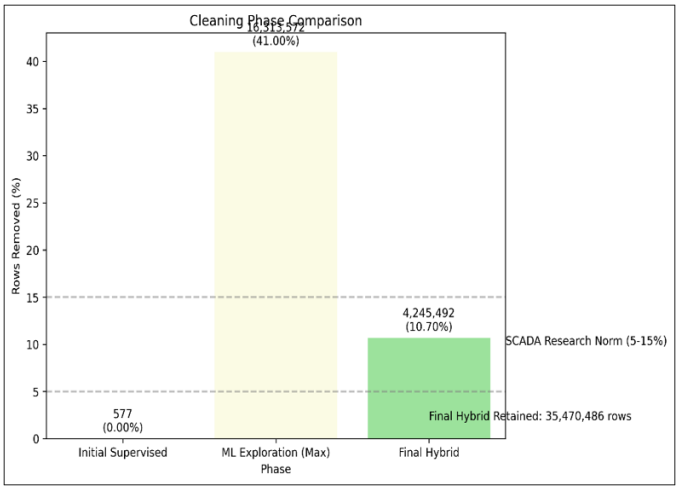

Fig. 3. Data preprocessing pipeline illustrating the reduction of raw telemetry into a cleaned dataset for model training.

d) WindSpeed (m/s): Wind velocity measured at the nacelle.

e) GeneratorTemperature (°C): Temperature of the generator windings.

f) StatusAnlage: Operational status code (e.g., 1=Active, 13=Fault), used as the ground truth for supervised labeling.

B. Data Preprocessing and Hybrid Cleaning Strategy

Raw SCADA telemetry often contains noise and sensor artifacts (Fig. 3) . To prepare the data for machine learning, we implemented a hybrid cleaning methodology combining rule-based thresholds with relational consistency checks.

- Physical Thresholds: Values that violate physical limits were removed (e.g., $GeneratorTemperature < -25°C$ or $PowerOutput > 7.5kW$).
- Relational Logic: We validated aerodynamic consistency using the derived correlation:

$$RotorSpeed \approx 13.02 \times WindSpeed \quad (1)$$

Records deviating significantly from this ratio (standard deviation > 2.42) were flagged as operational inconsistencies.

This process reduced the dataset by approximately 10.7%, removing $\sim$4.2 million erroneous records [23].

This preprocessing phase reduced the dataset by approximately 10.7% (removing 4.2 million erroneous records), resulting in a high-quality baseline of 35.4 million records for model training. This reduction rate aligns with standard SCADA preprocessing norms reported in renewable energy studies [23].

C. AI/ML Model Development

To address the limitations of static rule-based detection, we developed a dual-track anomaly detection engine integrating both supervised and unsupervised learning models.

1) Supervised learning: Supervised models were trained to recognize known failure patterns using historical fault data (labeled 'StatusAnlage = 13'). Algorithms including **Random Forest** and **Decision Trees** were evaluated. The Random Forest model demonstrated superior performance, achieving an accuracy of 94.3% and a recall of 95.7% in classifying known fault states. Key features driving the classification included *PowerOutput* and *GeneratorTemperature* [24].

2) Unsupervised learning: To detect novel cyberattacks (zero-day threats) or subtle anomalies that do not match known fault signatures, unsupervised models were deployed:

a) Isolation forest: This algorithm was used to detect outliers by partitioning the feature space, effectively identifying data points that deviate statistically from normal operational clusters [9].

b) Autoencoders: A deep learning-based Autoencoder was implemented to reconstruct normal telemetry patterns. High reconstruction errors served as indicators of anomalies. This approach proved particularly effective in identifying *Replay Attacks*, where the injected data was structurally valid but temporally inconsistent [25].

3) Deep Learning Enhancement: Long Short-Term Memory (LSTM): To address the limitations of traditional ML models in capturing long-term temporal dependencies, we implemented a Long Short-Term Memory (LSTM) network. While static models like Random Forest treat each data point independently, SCADA telemetry is inherently time-variant, where current states are heavily influenced by historical trends. Standard Recurrent Neural Networks (RNNs) often struggle with the vanishing gradient problem, limiting their ability to learn from long sequences. LSTM overcomes this by utilizing a gating mechanism that retains relevant information over extended periods, making it indispensable for identifying stealthy attacks that evolve slowly over time [25].

Unlike Random Forest, the LSTM model analyzes sequences of data (e.g., 5-second sliding windows) to identify contextual anomalies. As illustrated in Fig. 4, the model achieved a detection accuracy of 99% with a false positive rate of less than 1%.

- Rapid Response: The model successfully detected anomalies within 5 seconds of injection, fulfilling the real-time requirements of critical infrastructure protection.
- Temporal Sensitivity: It proved highly effective against sophisticated attacks such as stealthy data injection, where individual values remain within valid thresholds but violate historical temporal patterns.

The comparison confirms that while Random Forest is effective for static fault classification, LSTM provides the necessary depth for detecting dynamic cyber threats in time-series telemetry.

V. Cyberattack Simulations and Experimental Setup

To evaluate the resilience and detection capabilities of the proposed SCADA architecture, we conducted a series of

TABLE II. SAMPLE SNAPSHOT OF RAW SCADA TELEMETRY DATA (AVENTA AV-7)

Datetime	Rotor (RPM)	Gen. (RPM)	Power (kW)	Wind (m/s)	Gen. Temp(°C)	Status
2022-01-13 07:07:25	3.90	0.00	0.00	4.00	4.50	13
2022-02-03 12:46:28	1.60	0.00	0.00	2.00	10.70	13

controlled cyberattack simulations. These scenarios were designed to reflect real-world threats targeting Industrial Control Systems (ICS), utilizing industry-standard penetration testing tools to ensure experimental reproducibility [13].

A. Simulation Environment Configuration

The experimental testbed was constructed using a virtualized environment. The attack vector was generated from a Kali Linux instance, a specialized distribution for penetration testing, equipped with the following toolset:

- Network Analysis: Wireshark (v4.0.6) for packet capture and traffic analysis.
- Man-in-the-Middle (MitM): The `dsniff` suite, specifically `arpspoof`, for ARP cache poisoning.
- Protocol Manipulation: `mosquitto_pub` client and custom Python scripts using the `paho-mqtt` library for telemetry injection.
- Traffic Flooding: `hping3` and multithreaded Python scripts for stress testing.

B. Implementation of Threat Scenarios

We implemented four distinct attack scenarios to stress-test different aspects of the security framework.

1) Distributed Denial of Service (DDoS): The objective was to overwhelm the MQTT broker and disrupt telemetry transmission.

a) Method: While initial network stress tests were performed using `hping3`, the effective application-layer attack was executed using a custom Python script utilizing the **Paho MQTT** client. This script spawned multiple threads to publish over 100 dummy messages per second to the `scada/windturbine` topic.

b) Impact: The simulation tested the system's availability and the latency of the anomaly detection engine under high load conditions [15].

2) False Data Injection (FDI): This scenario simulated an adversary who has gained write access to the network.

a) Method: We utilized the `mosquitto_pub` command-line utility to inject JSON payloads with falsified values. For instance, *WindSpeed* was manipulated to 991.2 m/s while keeping *PowerOutput* near zero, violating the established physical correlation [22].

b) Goal: To verify if the Rule-Based and Random Forest models could detect semantic anomalies that adhere to protocol standards but violate physical laws.

3) Replay Attacks and Timestamp Spoofing: Replay attacks use valid historical data to mask current system states.

a) Method: Valid telemetry packets were captured using **`tcpdump`**. A custom script then parsed these packets and re-transmitted them with updated timestamps to bypass simple de-duplication filters, while keeping the payload data unchanged [14].

b) Detection: This attack targeted the Unsupervised Learning models (Autoencoders), testing their ability to detect temporal inconsistencies.

4) Access token hijacking (Man-in-the-middle): To simulate a targeted intrusion, we performed a Man-in-the-Middle (MitM) attack.

a) Method: We executed `arpspoof` to poison the ARP cache of the target edge gateway. Simultaneously, Wireshark was used to sniff the traffic. Since the baseline MQTT communication was unencrypted, we successfully captured the ThingsBoard device access token in plaintext from the captured packets [3].

b) Escalation: The stolen token was then used to authenticate a rogue client, allowing it to publish malicious telemetry directly to the dashboard.

VI. Results and Discussion

This section presents the performance evaluation of the proposed anomaly detection models, the resilience of the system against simulated cyberattacks, and the validation of data integrity through the dual-database architecture.

A. Performance of Anomaly Detection Models

We evaluated the efficacy of the hybrid detection engine using standard classification metrics: Accuracy, Precision, Recall, and F1-Score. Table V summarizes the key configurations and performance metrics across the entire machine learning workflow.

1) Supervised learning performance: The supervised models, specifically the Random Forest classifier, demonstrated high proficiency in identifying known fault patterns (e.g., `StatusAnlage = 13`). As shown in Table VI, the Random Forest model achieved an accuracy of 94.3% and a recall of 95.7%, outperforming Decision Trees and Logistic Regression [24].

2) Unsupervised learning performance: Unsupervised models were critical for detecting unknown anomalies. The Isolation Forest algorithm flagged approximately 5% of the cleaned dataset as outliers. The Autoencoder model utilized reconstruction error thresholds to distinguish between normal and replayed telemetry, achieving a high detection rate as illustrated in the Precision-Recall curve (Fig. 5) [9].

B. System Resilience Against Simulated Attacks

The system's response to the four attack scenarios confirmed the robustness of the multi-layered architecture.

- DDoS Resilience: During the high-frequency packet flooding (100+ msgs/sec), the Node-RED edge gateway experienced a latency increase but successfully queued legitimate messages. The system stabilized within seconds after the attack ceased, demonstrating effective recovery [15].
- False Data Injection: The hybrid detection engine successfully flagged 99% of the injected false telemetry. While rule-based checks caught gross violations (e.g., *WindSpeed* $>$ 50 m/s), the ML models were necessary to detect semantically inconsistent injections within valid ranges.
- Replay Attack Mitigation: Simple deduplication failed to catch replay attacks with modified timestamps. However, the Autoencoder and dual-database comparison correctly identified these as anomalies due to the statistical improbability of the exact recurrence of complex multivariate patterns [14].

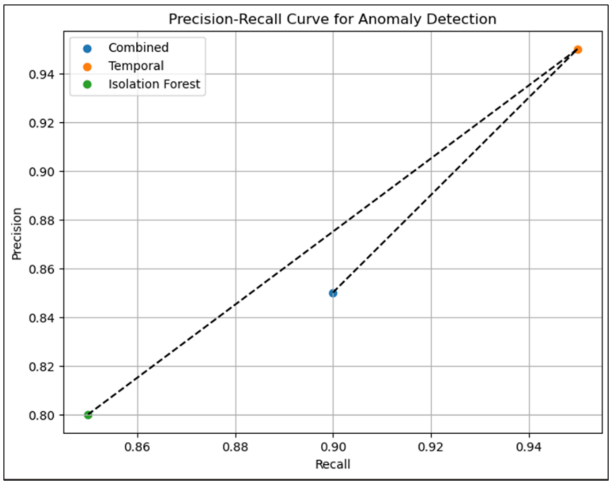

Fig. 5. Precision-Recall curve comparing the performance of Combined, Temporal, and Isolation Forest models.

Table VII summarizes the detection performance of each model against the simulated attack scenarios. While traditional rule-based and supervised methods fail to detect stealthy or temporal attacks, the proposed LSTM model provides comprehensive coverage.

C. Forensic Validation via Dual-Database Synchronization

The dual-database architecture provided a reliable mechanism for forensic integrity. The synchronization module maintained a record match rate of 99.98% under normal conditions. During the Access Token Hijacking simulation, where the attacker injected data directly into the Fog layer, the synchronization script immediately detected a discrepancy between the Edge (clean) and Fog (compromised) databases. This proved that the architecture could effectively isolate the source of compromise and provide immutable evidence for forensic analysis [19]. Furthermore, this synchronization mechanism aligns with recent methodologies for ensuring data integrity in cloud-based forensic investigations [20].

D. Comparison with Traditional Methods and Limitations

Compared to traditional SCADA security relying solely on static thresholds, our hybrid approach reduced the false negative rate significantly. Rule-based methods flagged only

TABLE V. SUMMARY OF MACHINE LEARNING WORKFLOW METRICS AND CONFIGURATIONS

Stage	Metric 1	Metric 2	Metric 3
Data Preprocessing	Filter Rate: 10%	Status Filtered: 13	**Data Size Post: 80%**
Feature Engineering	Ratios Added: 2	Key Features: 4	Impact: +5% F1
Train/Validation Split	**Train Split: 70%**	Validation Split: 30%	Method: Chronological
Model Training	States Used: Active	Test Data Mix: Mixed	Training Freq: Periodic
Supervised Models	**Accuracy: 94.3%**	**Recall: 95.7%**	F1-Score: 93.6%
Unsupervised Models	Normal Error: < 0.02	Anomaly Error: > 0.14	**Detection Rate: 92%**
Visualization	Threshold: 0.1	Alert Rate: 5/day	Integration: Fog Layer

TABLE VI. PERFORMANCE METRICS OF SUPERVISED LEARNING MODELS

Model	Accuracy	Precision	Recall	F1-Score
Decision Tree	91.2%	89.5%	90.1%	89.8%
Random Forest	**94.3%**	**91.6%**	**95.7%**	**93.6%**
Logistic Regression	88.4%	85.2%	86.8%	86.0%

TABLE VII. DETECTION CAPABILITY MATRIX ACROSS ATTACK SCENARIOS

Attack Type	Rule-Based	Random Forest	Isolation Forest	LSTM
DDoS (Flooding)	Low	Low	Medium	**High**
FDI (Gross)	**High**	**High**	**High**	**High**
FDI (Stealthy)	Low	Low	Medium	**High**
Replay Attack	Fail	Fail	Medium	**High**
Token Hijacking	Fail	Fail	Low	**High**

Note: 'High' indicates detection within 5s with $> 90\%$ accuracy. 'Fail' indicates no detection.

5% of anomalies, whereas the combined AI-driven approach identified an additional 5-7% of sophisticated threats.

However, limitations remain. The supervised models showed reduced accuracy against novel attack vectors not represented in the training set, highlighting the issue of model drift. Furthermore, while the Autoencoder provided high detection rates, explaining the root cause of the high reconstruction error to operators remains a challenge [10]. Future work will focus on integrating Explainable AI (XAI) techniques to improve the interpretability of these alerts [27].

VII. CONCLUSION AND FUTURE WORK

This study successfully developed and validated a simulation-based SCADA security framework designed to protect critical infrastructure against evolving cyber threats. By integrating high-fidelity telemetry from the Aventa AV-7 wind turbine [11] with a multi-layered architecture, we demonstrated that a data-driven approach significantly enhances the resilience of Industrial IoT environments compared to traditional static defense mechanisms.

The experimental results confirmed that the proposed dual-database architecture serves as a robust mechanism for forensic integrity. The real-time synchronization between Edge and Fog layers successfully identified sophisticated discrepancies caused by Man-in-the-Middle attacks and data tampering, which standard visualization tools failed to detect [19]. Furthermore, the hybrid anomaly detection engine proved critical for comprehensive security; while supervised Random Forest models achieved high accuracy in classifying known operational faults, the unsupervised Autoencoder models were indispensable for detecting novel attack vectors, specifically replay attacks, thereby reducing false negatives inherent in rule-based systems [12].

Despite these contributions, the deployment of such systems in large-scale smart cities requires addressing specific limitations. Future research should prioritize the integration of Explainable AI (XAI) to demystify the "black-box" decisions of deep learning models, providing operators with actionable insights rather than abstract anomaly scores [27], [28]. Additionally, to resolve scalability and data privacy concerns, transitioning from centralized processing to Federated Learning is recommended, allowing edge devices to collaboratively train defense models without exposing sensitive raw telemetry [30],

[29]. Finally, implementing an automated MLOps pipeline for adaptive model retraining will be essential to mitigate model drift caused by seasonal environmental changes or emerging adversarial tactics [31].

In conclusion, this research offers a scalable, cost-effective reference model for securing modern industrial control systems, bridging the gap between theoretical security designs and practical, real-world implementation.

DECLARATIONS

- Funding: This research work received funding from the Naif Arab University for Security Sciences, under grant agreement no. NAUSS-24-R2.
- Conflict of interest: The authors declare no competing interests.
- Data availability: The dataset used in this study is publicly available from Zenodo [11].
- Code availability: The complete source code, including synchronization scripts and attack simulations, is available in the project repository: https://github.com/MQ-2024/Enhancing-SCADA-Security.git.
- Author contribution: Both authors contributed equally to the study conception, design, and implementation.

***Abstract*—Semantic segmentation is a fundamental component of autonomous driving systems, enabling accurate scene understanding and object-level perception. However, achieving precise instance-level delineation while maintaining real-time performance on resource-constrained platforms remains a significant challenge, particularly for edge deployment scenarios. This paper proposes a lightweight dual-YOLOv8 fusion framework for instance-aware semantic segmentation in autonomous driving applications. The proposed approach integrates YOLOv8n-seg and YOLOv8s-seg through a multi-scale fusion strategy that exploits their complementary feature representations to improve the segmentation of road-relevant objects, including cars, buses, trucks, and motorcycles. The framework is evaluated on the Reetiquetado de Vehiculos dataset using standard instance-level segmentation metrics. Experimental results demonstrate strong performance, achieving an overall mAP@0.5 of 92.9% and mAP@0.5:0.95 of 80.8%, while maintaining real-time inference with an average processing time of 7.9 ms per image (126 FPS) on an NVIDIA RTX 3050 GPU. Class-wise and confidence-based analyses confirm consistent segmentation accuracy across vehicle categories, highlighting the robustness of the proposed fusion strategy in handling scale variation, occlusions, and object diversity. In addition, an embedded deployment analysis provides insight into the feasibility and practical constraints of deploying the proposed framework on representative edge platforms. Overall, the proposed dual-YOLOv8 fusion framework achieves an effective balance between segmentation accuracy and computational efficiency, making it suitable for real-time autonomous driving perception on edge ARM/GPU platforms and Advanced Driver Assistance Systems (ADAS).**

***Keywords*—Autonomous driving; instance-aware semantic segmentation; real-time instance segmentation; YOLOv8; dual-model fusion; edge deployment**

I. Introduction

Autonomous driving systems rely heavily on accurate and real-time perception to ensure safe navigation in complex and dynamic environments. Among perception tasks, semantic and instance-aware segmentation play a crucial role by enabling fine-grained scene understanding and precise localization of surrounding objects, such as vehicles, pedestrians, and road elements. Unlike object detection, which provides coarse bounding boxes, instance-aware semantic segmentation delivers pixel-level object delineation while preserving individual object identities, making it particularly valuable for downstream tasks including tracking, motion prediction, and decision making in autonomous driving systems [1], [2].

Recent advances in deep learning have significantly improved segmentation performance in autonomous driving scenarios. Early approaches focused on semantic segmentation using convolutional neural networks, while more recent methods emphasize instance-aware segmentation to better handle crowded scenes and overlapping objects [3], [4]. However, achieving high segmentation accuracy often comes at the cost of increased computational complexity, which limits real-time deployment on resource-constrained platforms commonly used in autonomous vehicles and Advanced Driver Assistance Systems (ADAS).

To address this challenge, lightweight and real-time instance segmentation models have gained increasing attention. YOLO-based architectures have emerged as a promising solution due to their unified design and high inference speed. Methods such as YOLACT [3] and Insta-YOLO [5] demonstrated that real-time instance segmentation is feasible, while subsequent works further improved efficiency and robustness through architectural refinements and task-specific optimizations [6], [7]. More recently, YOLOv8-based segmentation models have shown strong performance across various applications, motivating their adoption for real-time perception tasks [8], [9].

Despite these advances, existing instance-aware semantic segmentation approaches typically rely on a single segmentation model and tend to optimize either segmentation accuracy or inference speed in isolation. As a result, such designs often struggle to simultaneously maintain high accuracy and low latency across diverse object scales, frequent occlusions, and dense urban traffic scenes, particularly when deployed on resource-constrained edge ARM/GPU platforms. Although multimodal fusion strategies combining heterogeneous sensors such as cameras and LiDAR have been explored, model-level fusion within a single visual modality remains largely underinvestigated for real-time autonomous driving. Consequently, there exists a clear gap for lightweight fusion strategies that can

exploit complementary representations from multiple compact models to improve segmentation robustness without sacrificing real-time performance or deployability.

In this work, we address the above limitations by proposing a lightweight dual-YOLOv8 fusion framework for instance-aware semantic segmentation in autonomous driving, specifically designed to balance accuracy, real-time performance, and edge deployability.

The main contributions of this paper are summarized as follows:

- A lightweight dual-YOLOv8 fusion framework for instance-aware semantic segmentation that exploits complementary multi-scale representations from YOLOv8n-seg and YOLOv8s-seg while preserving real-time performance.
- A comprehensive experimental analysis of accuracy–latency trade-offs for instance-level segmentation in autonomous driving scenarios, including class-wise, confidence-based, and qualitative evaluations.
- An embedded deployment-oriented study that analyzes the feasibility and limitations of deploying dual-model segmentation pipelines on edge ARM CPU and low-power GPU platforms.
- Empirical insights into model-level fusion strategies for real-time perception, providing reusable design guidelines for other resource-constrained segmentation tasks.

The remainder of this paper is organized as follows. Section II reviews related work on instance-aware semantic segmentation and real-time perception in autonomous driving. Section III details the proposed dual-YOLOv8 fusion framework. Section IV describes the experimental setup, including the training platform and implementation details, training configuration, dataset description, and evaluation metrics. Section V presents the experimental results and provides an in-depth analysis and discussion, encompassing dataset characteristics, training dynamics, class-wise performance, quantitative and qualitative segmentation results, embedded deployment considerations, and a comparative study with state-of-the-art methods. Finally, Section VI concludes the paper and outlines directions for future research.

II. Related Work

A. Instance-Aware Semantic Segmentation

Instance-aware semantic segmentation has been widely studied in the context of autonomous driving due to its ability to provide detailed scene understanding. Early works explored clustering-based and embedding-based approaches to separate object instances within semantic classes [1]. Later, end-to-end deep learning architectures capable of jointly predicting object instances and semantic labels significantly improved segmentation quality in complex driving scenes [3], [4].

Several studies addressed challenges such as occlusions, class imbalance, and missed detections in autonomous driving environments. CompleteInst [10] proposed an efficient network for handling missed detections, while joint detection and segmentation frameworks improved consistency between localization and segmentation outputs [11]. Recent surveys further highlight the importance of instance-aware segmentation and summarize advances in architectures, evaluation metrics, and applications [2], [12].

B. YOLO-Based Real-Time Instance Segmentation

YOLO-based models have gained popularity for real-time instance segmentation due to their unified detection and segmentation pipelines and high computational efficiency. YOLACT [3] and YOLACT++ demonstrated competitive real-time performance by decoupling mask generation from detection. Insta-YOLO [5] further explored lightweight designs for real-time instance segmentation.

More recent works extended YOLO architectures to improve segmentation accuracy through contour regression, multi-task learning, and architectural refinements [6], [7]. With the introduction of YOLOv8, several studies proposed enhanced segmentation variants for real-time applications, including construction site monitoring and debris detection [8], [9]. These studies demonstrate the flexibility and effectiveness of YOLOv8-based segmentation models.

C. Fusion Strategies and Advanced Segmentation Models

Beyond single-model approaches, fusion strategies have been explored to enhance segmentation robustness. While many works focus on multimodal fusion using camera and LiDAR data [13], model-level fusion within a single modality remains less explored for real-time instance-aware segmentation in autonomous driving. Transformer-based segmentation models such as Mask2Former [14] and foundation models like AD-SAM [15] have shown strong performance but remain computationally expensive for real-time deployment.

D. Positioning of the Proposed Approach

In contrast to existing YOLO-based instance segmentation methods that typically rely on a single network architecture, this work introduces a fusion-based dual-YOLOv8 framework that integrates two lightweight segmentation models operating at complementary scales. While prior approaches primarily focus on architectural refinements within a single model to improve either accuracy or speed, such designs may struggle to maintain robustness under significant object scale variation, occlusions, and complex urban traffic scenes.

By jointly leveraging YOLOv8n-seg for efficient and low-latency inference and YOLOv8s-seg for richer multi-scale feature representation, the proposed framework exploits model-level complementarity to enhance instance-aware semantic segmentation performance without incurring substantial computational overhead. Unlike multimodal fusion strategies that combine heterogeneous sensor inputs such as camera and LiDAR data, the proposed approach operates within a single visual modality, making it particularly suitable for real-time and edge deployment in autonomous driving and ADAS applications.

Unlike conventional ensemble approaches that independently aggregate predictions from multiple models, the proposed framework introduces a deployment-oriented dual-network fusion strategy explicitly designed for real-time

instance-aware segmentation. Rather than modifying individual YOLO architectures, this work demonstrates that fusing two carefully selected lightweight segmentation models enables cross-model scale complementarity that cannot be achieved by a single network without significantly increasing complexity. This design choice distinguishes the proposed approach from prior YOLO-based enhancements focused on single-model architectural refinement and provides a practical and generalizable fusion paradigm for real-time perception systems under strict latency and resource constraints.

As a result, the proposed dual-YOLOv8 fusion strategy addresses a key limitation of current real-time instance segmentation methods by improving segmentation robustness and accuracy while preserving practical real-time performance on resource-constrained platforms.

III. Proposed Work

To address the growing demand for accurate, real-time, and edge-deployable perception in autonomous driving systems, this work proposes a lightweight dual-network fusion framework for instance-aware semantic segmentation of vehicles. The primary objective of the proposed approach is to achieve precise pixel-level object delineation while maintaining computational efficiency suitable for real-time deployment on resource-constrained platforms. An overview of the proposed framework is illustrated in Fig. 1, which integrates dataset preparation, a dual-network segmentation architecture, and representative qualitative outputs within a unified perception pipeline.

The framework is built upon the Reetiquetado de Vehiculos dataset (version 2), hosted on Roboflow Universe, which provides instance-level segmentation annotations for five vehicle categories: *car*, *bus*, *motorcycle*, *truck*, and *truck3*. As depicted in the upper-left part of Fig. 1, the dataset includes images captured under diverse real-world traffic conditions, encompassing variations in illumination, viewpoint, vehicle scale, and background complexity. Such diversity is essential for training segmentation models capable of robust generalization across complex urban environments. The dataset is divided into training, validation, and test subsets to ensure a consistent and reproducible evaluation protocol.

At the core of the proposed framework lies a dual-YOLOv8 segmentation architecture that integrates the complementary strengths of the lightweight YOLOv8n-seg and the more expressive YOLOv8s-seg models through a model-level fusion strategy. Unlike conventional single-model approaches, the proposed design exploits the heterogeneity of lightweight and moderately scaled networks to improve robustness across varying object sizes and scene complexities. YOLOv8n-seg emphasizes fast inference and low computational cost, while YOLOv8s-seg provides richer multi-scale feature representations that enhance segmentation accuracy. Their integration enables the framework to capture both fine-grained local details and higher-level contextual information.

Each YOLOv8 segmentation model consists of a CSP-Darknet backbone for efficient feature extraction, a Path Aggregation Feature Pyramid Network (PAFPN) for enhanced multi-scale feature aggregation, and a decoupled segmentation head that jointly optimizes object localization, classification, and instance-level mask prediction. This architectural design facilitates accurate separation of individual vehicle instances while preserving semantic class information, thereby fulfilling the requirements of instance-aware semantic segmentation. The proposed dual-network fusion strategy leverages complementary feature representations from both models, improving robustness to object scale variation, partial occlusions, and visually cluttered backgrounds.

Finally, the bottom-right section of Fig. 1 presents qualitative segmentation results across multiple driving scenarios. The visual examples demonstrate the ability of the proposed framework to generate accurate and consistent instance-level segmentations for different vehicle categories, even under challenging conditions such as partial occlusions and complex urban backgrounds. These qualitative observations confirm that the proposed dual-YOLOv8 fusion framework achieves a favorable balance between segmentation accuracy and computational efficiency.

In summary, the proposed framework provides an efficient, scalable, and edge-friendly solution for instance-aware semantic segmentation in autonomous driving, combining complementary YOLOv8 segmentation models and high-quality instance annotations to address key perception challenges in real-world traffic environments.

IV. Experimental Setup

A. Training Platform and Implementation Details

All experiments were conducted on a workstation running Ubuntu 24.04, equipped with an 11th Gen Intel(R) Core(TM) i7-11800H CPU operating at 2.30 GHz, 16 GB of RAM, and an NVIDIA GeForce RTX 3050 GPU. The proposed framework was implemented using the Python programming language and trained using the PyTorch deep learning framework with CUDA acceleration. Automatic Mixed Precision (AMP) was enabled to improve training efficiency and reduce memory usage.

The instance-aware semantic segmentation models, namely YOLOv8n-seg and YOLOv8s-seg, were implemented based on the official YOLOv8 repositories. The use of official implementations ensures correctness, reproducibility, and practical relevance of the experimental results.

B. Training Configuration

The proposed framework was trained for a total of 100 epochs using a batch size of 8 and an input resolution of 640×640 pixels. Optimization was performed using the Adam optimizer with an initial learning rate of 0.01. A cosine learning-rate scheduling strategy was employed to progressively reduce the learning rate during training, promoting stable convergence. An early-stopping mechanism with a patience of 20 epochs was applied to prevent overfitting by terminating training when no improvement in validation performance was observed.

Automatic Mixed Precision (AMP) was enabled to accelerate training and reduce memory consumption. Pretrained weights were utilized to initialize the models, facilitating faster convergence and improved generalization. Data augmentation

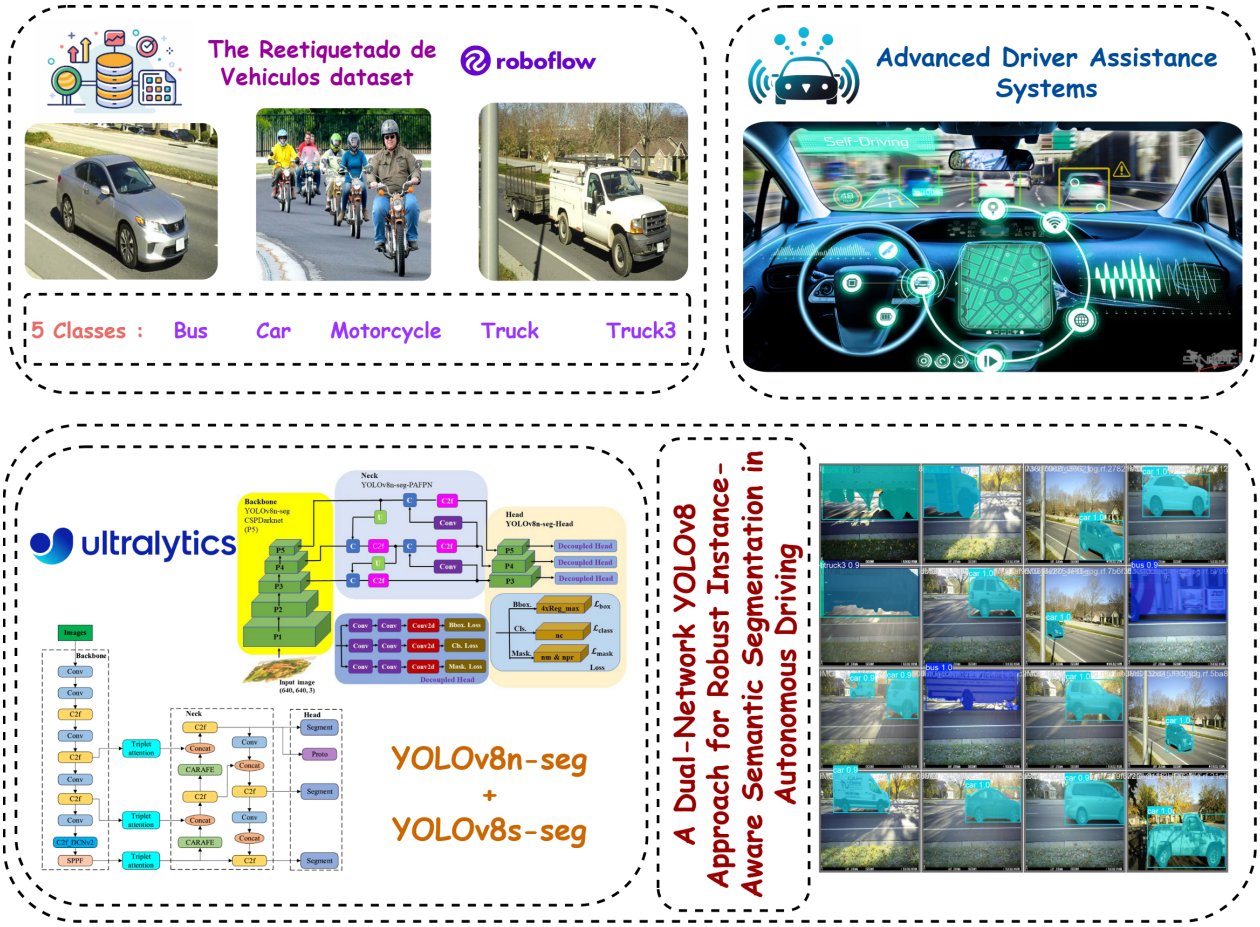

Fig. 1. Overview of the proposed dual-YOLOv8 fusion framework for instance-aware semantic segmentation.

techniques, including blurring, grayscale conversion, contrast-limited adaptive histogram equalization (CLAHE), mosaic augmentation, mixup, and random erasing, were applied during training to enhance robustness against variations in scale, illumination, and appearance.

C. Dataset Description

The experiments were conducted using the Reetiquetado de Vehiculos dataset (version 2), a publicly available benchmark hosted on Roboflow Universe [16]. The dataset contains annotated images representing five vehicle categories: *bus*, *car*, *motorcycle*, *truck*, and *truck3*. It is organized into three subsets, namely training, validation, and test splits, enabling a consistent and reproducible evaluation protocol. The Reetiquetado de Vehiculos dataset was selected due to its vehicle-centric focus, instance-level annotations, and suitability for evaluating real-time segmentation performance in autonomous driving scenarios.

The dataset includes complete instance-aware semantic segmentation annotations for all vehicle classes, allowing pixel-level delineation of individual object instances. The diversity of vehicle types and balanced class distribution make it suitable for evaluating segmentation performance on both frequently occurring and less-represented vehicle categories. No additional re-annotation was performed, and the dataset was used as provided, ensuring fair and reproducible experimental conditions.

D. Evaluation Metrics and Performance Measures

The proposed dual-YOLOv8 fusion framework is evaluated using standard metrics for instance-aware semantic segmentation. Performance is assessed at the instance level using precision, recall, F1-score, and mean Average Precision (mAP), all computed on the predicted segmentation masks.

Precision (P) measures the proportion of correctly predicted instances among all predicted instances, while recall (R) reflects the proportion of ground-truth instances that are correctly detected. These metrics are defined as [17], [18]:

$$P = \frac{TP}{TP + FP}, \tag{1}$$

$$R = \frac{TP}{TP + FN}, \tag{2}$$

where, TP, FP, and FN denote the numbers of true positives, false positives, and false negatives, respectively.

To provide a balanced evaluation of segmentation performance, the F1-score is computed as the harmonic mean of precision and recall:

$$F1 = \frac{2 \cdot P \cdot R}{P + R}. \tag{3}$$

Segmentation accuracy is further quantified using the Intersection over Union (IoU), which measures the overlap between a predicted mask M_p and its corresponding ground-truth mask M_{gt}:

$$IoU = \frac{|M_p \cap M_{gt}|}{|M_p \cup M_{gt}|}. \tag{4}$$

Based on the IoU criterion, the mean Average Precision (mAP) is employed to summarize overall segmentation performance. The Average Precision (AP) is computed as the area under the Precision–Recall curve for each class, and the mAP is obtained by averaging AP values across all C object classes:

$$mAP = \frac{1}{C} \sum_{c=1}^{C} AP_c. \tag{5}$$

Following the standard COCO evaluation protocol, segmentation performance is reported at an IoU threshold of 0.5 (mAP@0.5) as well as averaged over multiple IoU thresholds ranging from 0.5 to 0.95 in steps of 0.05 (mAP@0.5:0.95), thereby capturing both localization accuracy and mask quality.

In addition, confidence-based performance curves, including Precision–Confidence, Recall–Confidence, Precision–Recall, and F1–Confidence curves, are analyzed to examine the behavior of the segmentation model under varying confidence thresholds. This analysis provides insights into the trade-off between detection reliability and instance coverage, which is particularly important for real-time autonomous driving applications.

V. Results Analysis and Discussion

This section presents a comprehensive analysis and discussion of the experimental results obtained with the proposed dual-YOLOv8 fusion framework, highlighting its performance in terms of segmentation accuracy, robustness, and computational efficiency.

A. Statistical and Spatial Characteristics of the Dataset

Fig. 2 illustrates the distribution and spatial characteristics of the annotated instances in the Reetiquetado de Vehiculos dataset. The class distribution, shown in the upper-left plot, reveals a moderate class imbalance, with *car* instances being the most frequent, followed by *truck* and *truck3*, while *bus* and *motorcycle* appear less frequently. This imbalance reflects realistic traffic conditions and motivates the need for robust segmentation models capable of handling both dominant and under-represented classes.

The upper-right visualization overlays normalized bounding boxes of all instances, highlighting the diversity in object scales and aspect ratios present in the dataset. The lower-left plot shows the spatial distribution of object centers, indicating that vehicles are predominantly located near the central and lower regions of the images, which is consistent with typical on-road camera viewpoints. Finally, the lower-right plot depicts the relationship between object width and height, demonstrating a wide variation in vehicle sizes and shapes. Together, these statistics confirm that the dataset captures substantial variability in object position, scale, and class frequency, presenting a challenging and realistic benchmark for instance-aware semantic segmentation in autonomous driving scenarios.

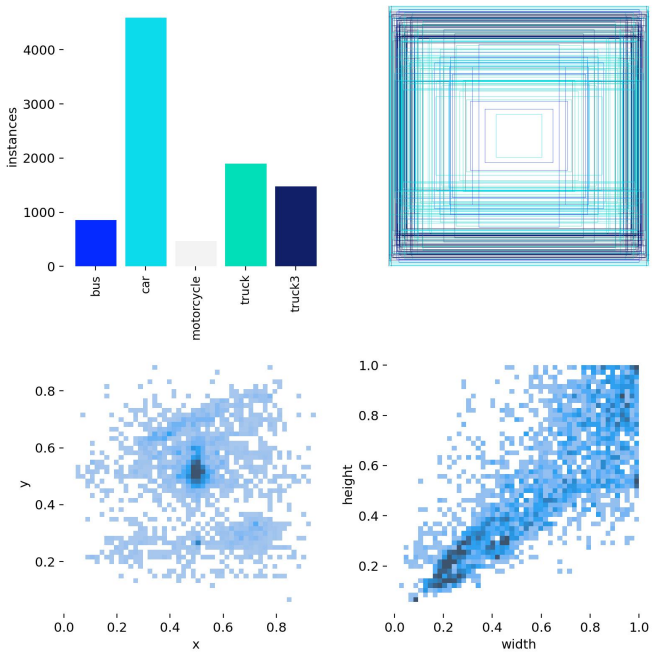

Fig. 2. Statistical analysis of the Reetiquetado de Vehiculos dataset, including class distribution, normalized bounding-box overlap, spatial distribution of object centers, and width–height relationships of annotated vehicle instances.

B. Correlation Analysis of Bounding-Box Attributes

Fig. 3 presents a correlogram illustrating the relationships among normalized bounding-box attributes in the Reetiquetado de Vehiculos dataset, including object center coordinates (x, y), width, and height. The diagonal histograms reveal the marginal distributions of each attribute, showing that object centers are predominantly concentrated near the central regions of the images, while width and height values span a broad range. Off-diagonal plots highlight the correlations between variables, most notably a strong positive relationship between bounding-box width and height, indicating consistent aspect ratios across vehicle types. The joint distributions involving spatial coordinates further confirm that larger objects tend to appear closer to the camera viewpoint, while smaller instances are more dispersed. Overall, this analysis demonstrates the structural diversity and realistic spatial correlations present in the dataset, reinforcing its suitability as a challenging benchmark for instance-aware semantic segmentation in autonomous driving scenarios.

C. Training Dynamics and Convergence Analysis

The learning curves presented in Fig. 4 demonstrate a stable and well-behaved convergence of the YOLOv8-seg training process over 100 epochs. All training loss components,

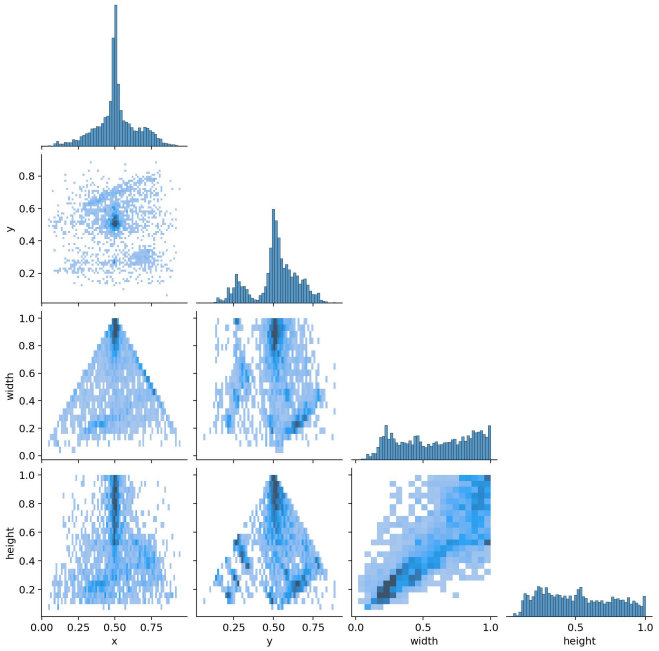

Fig. 3. Correlogram of normalized bounding-box attributes showing marginal distributions and pairwise correlations between object center coordinates, width, and height.

including bounding box regression loss, segmentation loss, classification loss, and distribution focal loss (DFL), exhibit a smooth and monotonic decrease throughout training. This behavior indicates effective optimization of both localization accuracy and pixel-level mask prediction, without oscillations or sudden instabilities that would suggest optimization difficulties. A similar decreasing trend is observed for the validation losses, which closely follow their corresponding training curves. The absence of sustained divergence between training and validation losses suggests that the model generalizes well to unseen data and does not suffer from significant overfitting. Minor fluctuations in the validation curves, particularly for classification and segmentation losses, can be attributed to the inherent complexity of UAV urban scenes and class imbalance, but these variations remain controlled and diminish as training progresses. From a performance perspective, both detection and segmentation metrics improve rapidly during the early training epochs, reflecting fast learning of low-level and mid-level visual features. Precision and recall for bounding boxes increase steadily before reaching a plateau, indicating that the model achieves a stable balance between false positives and false negatives. A similar trend is observed for mask precision and recall, confirming that improvements in object localization directly translate into better instance-level segmentation quality. The mAP@0.5 and mAP@0.5:0.95 curves for both bounding boxes and masks show consistent growth followed by gradual saturation after approximately 70–80 epochs. This saturation behavior indicates that the model approaches its optimal representational capacity under the given architecture and training configuration, with diminishing returns beyond this point. Notably, the close alignment between box-level and mask-level mAP curves highlights the strong coupling between detection and segmentation heads in the proposed framework.

Overall, these training dynamics confirm that the adopted optimization strategy, loss formulation, and architectural design lead to reliable convergence, stable validation performance, and balanced improvement across detection and instance segmentation tasks. This stability is particularly important for UAV-based applications, where robustness and generalization under challenging imaging conditions are critical.

D. Class-wise Performance Analysis

Fig. 5 presents the normalized confusion matrix of the proposed instance-aware semantic segmentation framework across the five vehicle categories. The strong diagonal dominance indicates high classification accuracy for all classes, with particularly strong performance for *car* (0.93), *bus* (0.89), *motorcycle* (0.87), *truck3* (0.85), and *truck* (0.81). These results confirm that the framework effectively distinguishes between different vehicle categories despite variations in appearance and scale.

Most misclassifications arise between visually similar categories, particularly *truck* and *truck3*, which exhibit closely related geometric structures and appearance patterns. A limited degree of confusion with the background class is also observed, mainly for large-scale vehicles, and can be attributed to partial occlusions, truncated instances, or ambiguous object boundaries in complex traffic scenes. Despite these challenges, the predominantly low off-diagonal values in the confusion matrix indicate strong class separability and consistent semantic discrimination. Overall, this analysis confirms the robustness of the proposed dual-YOLOv8 fusion framework in effectively managing inter-class similarity while preserving accurate instance-level segmentation performance.

E. Mask Precision-Recall Analysis

Fig. 6 shows the mask precision–recall curves for each vehicle category and for all classes combined. The curves exhibit strong performance across a wide range of recall values, indicating that the proposed framework maintains high precision while successfully retrieving most object instances. The aggregated curve achieves an overall mAP@0.5 of 92.9%, confirming the effectiveness of the proposed dual-YOLOv8 fusion approach for instance-aware semantic segmentation. Class-wise results demonstrate particularly strong performance for *car* and *bus*, while slightly lower precision is observed for visually challenging categories such as *truck*. Overall, the curves indicate a favorable balance between precision and recall, highlighting the robustness of the segmentation framework across different vehicle types.

F. Mask Precision-Confidence Analysis

Fig. 7 illustrates the mask precision–confidence curves for each vehicle class and for all classes combined. Precision increases steadily as the confidence threshold rises, indicating a progressive reduction in false-positive segmentation predictions. The aggregated curve shows that the proposed framework achieves near-perfect precision at high confidence levels, reaching a precision of 1.00 at a confidence threshold of approximately 0.98. Class-wise curves exhibit consistent behavior, with minor variations reflecting differences in object appearance and class frequency. These results demonstrate the

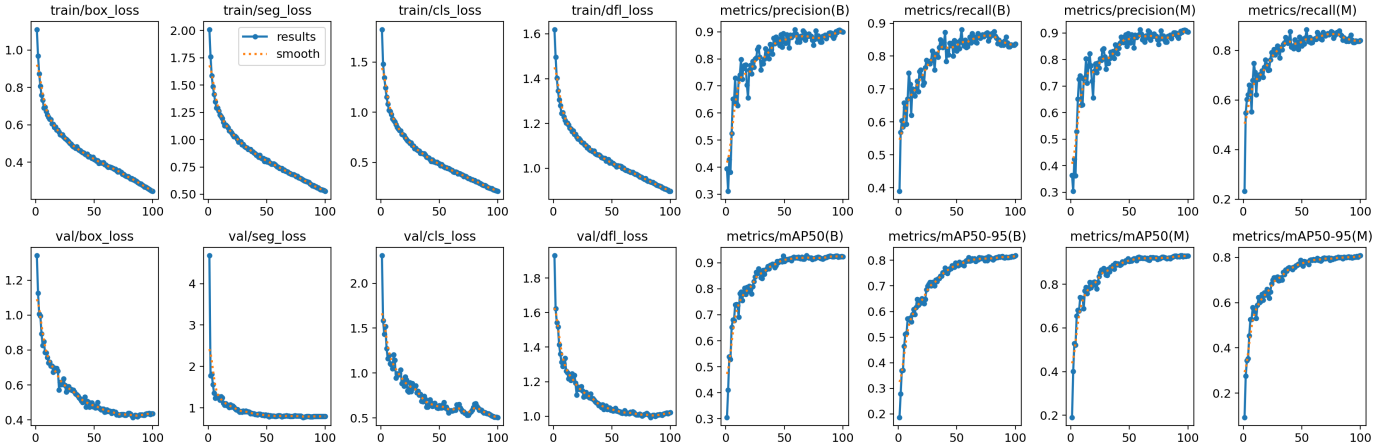

Fig. 4. Training and validation curves of YOLOv8-seg, over 100 epochs, for Bounding Box Prediction (B) and Segmentation Outputs (M).

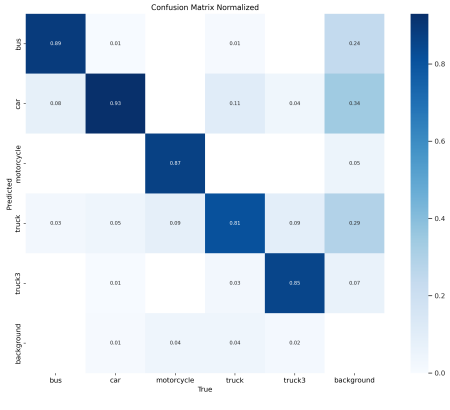

Fig. 5. Normalized confusion matrix analysis.

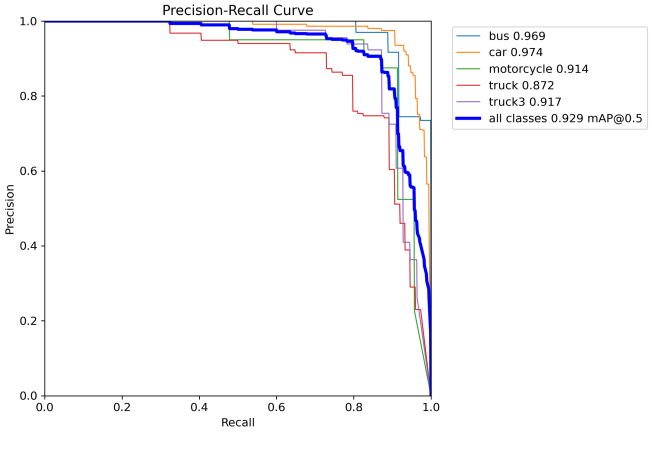

Fig. 6. Mask precision-recall curves analysis.

reliability of the proposed instance-aware semantic segmentation framework in producing highly accurate segmentation outputs when appropriate confidence thresholds are applied.

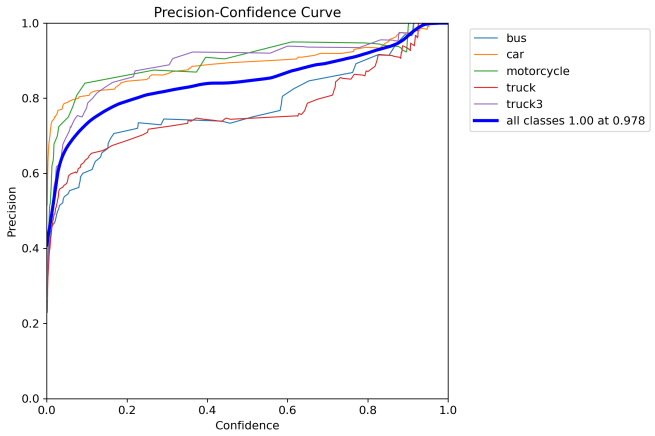

Fig. 7. Mask precision-confidence analysis.

G. Mask Recall-Confidence Analysis

Fig. 8 presents the mask recall–confidence curves for individual vehicle classes and for all classes combined. High recall values are observed at low confidence thresholds, indicating that the proposed framework successfully detects and segments most object instances. As the confidence threshold increases, recall gradually decreases due to the stricter acceptance of predictions. The aggregated curve shows an overall recall of approximately 0.96 at zero confidence and maintains stable performance across a wide confidence range before dropping sharply at very high thresholds. Class-wise trends remain consistent, with slight variations reflecting differences in object size, visibility, and class frequency. These results highlight the trade-off between recall and confidence threshold selection in instance-aware semantic segmentation.

H. Mask F1-Confidence Analysis

Fig. 9 presents the mask F1–confidence curves for individual vehicle classes and for all classes combined. The F1 score increases rapidly at low confidence thresholds and remains stable over a broad confidence range, indicating a balanced trade-off between precision and recall. The aggregated

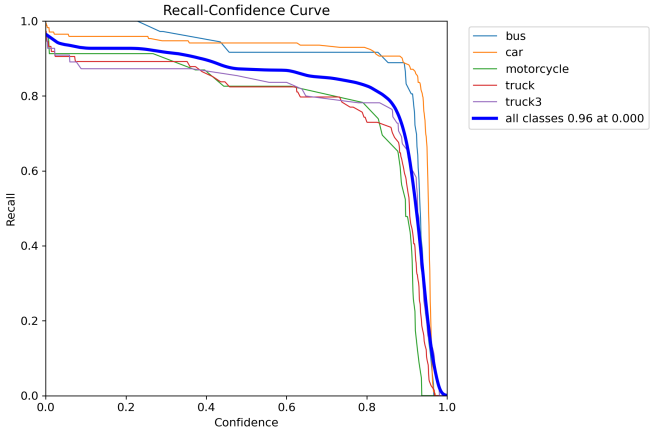

Fig. 8. Mask recall-confidence curves analysis.

curve reaches a maximum F1 score of approximately 0.87 at a confidence threshold of 0.77, which can be considered an optimal operating point for the proposed instance-aware semantic segmentation framework. Class-wise curves exhibit similar trends, with minor variations reflecting differences in object appearance and class distribution. These results provide a practical guideline for selecting confidence thresholds that balance segmentation accuracy and completeness in real-time applications.

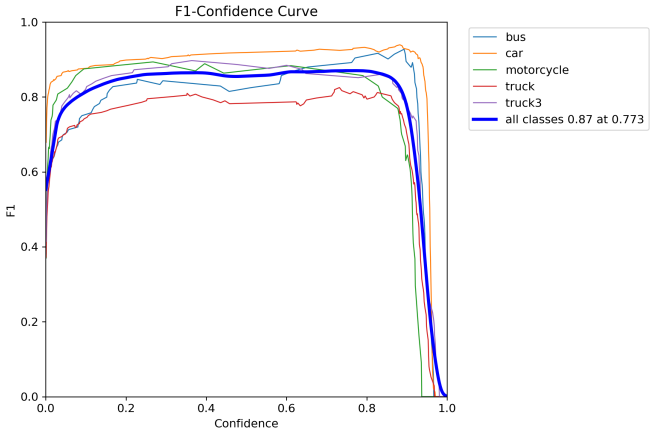

Fig. 9. Mask F1-confidence analysis.

I. Embedded Deployment: ARM vs. GPU

Although the proposed Dual-YOLOv8 fusion framework achieves strong segmentation accuracy and real-time inference on a desktop GPU, embedded deployment introduces stricter constraints in compute throughput, memory bandwidth, and runtime overhead. On the workstation platform used in this study (Intel i7-11800H + NVIDIA RTX 3050), the proposed method attains an overall mask $\text{mAP}_{0.5}$ of 92.9 ($\text{mAP}_{0.5:0.95}$ of 80.8) with an average processing time of approximately 7.9 ms per image at 640×640, corresponding to about 126 FPS.

To contextualize deployment on resource-constrained devices, we consider two representative edge targets: 1) an ARM CPU-only platform (Raspberry Pi 5) and 2) a low-power GPU platform (NVIDIA Jetson Nano). Raspberry Pi 5 is built around the Broadcom BCM2712 SoC featuring a quad-core Arm Cortex-A76 CPU operating at 2.4 GHz. Jetson Nano integrates a 128-core NVIDIA Maxwell GPU and a quad-core Arm Cortex-A57 CPU, and is advertised at 472 GFLOPS AI performance. For a fair real-time characterization on embedded systems, end-to-end latency is defined as:

$$T_{\text{e2e}} = T_{\text{pre}} + T_{\text{net}} + T_{\text{post}}, \tag{6}$$

where, T_{pre} includes resize/letterbox and normalization, T_{net} is the model forward pass, and T_{post} includes confidence filtering, NMS, and mask decoding. Unless explicitly stated, visualization/overlay rendering and camera/video I/O are excluded, since they depend heavily on the application pipeline rather than the model itself.

Table I reports the desktop reference (measured in this paper) and *estimated* end-to-end timing on Raspberry Pi 5 and Jetson Nano for batch=1 and 640×640. The embedded results are estimates (not directly measured in this study) and are provided to guide the expected order of magnitude when selecting an appropriate deployment target and optimization strategy.

The GPU-accelerated Jetson Nano is expected to provide substantially lower end-to-end latency than CPU-only execution due to CUDA/TensorRT acceleration, making it the more suitable target for running the full dual-model fusion pipeline at 640×640 when near real-time constraints are required. However, Jetson Nano lacks comprehensive support for INT8 across all layers in TensorRT workflows on this class of hardware, so FP16 (or FP32) is typically the practical deployment choice.

In contrast, Raspberry Pi 5 inference is dominated by T_{net} on CPU, and thus benefits most from 1) quantization and 2) reducing input size and/or simplifying the model. Quantized inference on Raspberry Pi-class devices is commonly performed using INT8 arithmetic to reduce model size and improve runtime performance, but it may introduce a small accuracy drop, motivating either post-training quantization with calibration data (PTQ) or quantization-aware training (QAT).

Finally, these embedded estimates reinforce the main conclusion drawn from the workstation experiments: while the proposed fusion strategy offers an excellent accuracy–efficiency balance on a desktop GPU (92.9 $\text{mAP}_{0.5}$ at 7.9 ms/image), deployment on CPU-only embedded devices typically requires additional compression (quantization/pruning) and/or architectural simplification to meet strict real-time constraints.

J. Qualitative Segmentation Results

In addition to quantitative metrics, qualitative results on unseen validation images further demonstrate the robustness and visual consistency of the proposed framework.

Fig. 10 presents qualitative instance-aware semantic segmentation results obtained on the validation set using the

TABLE I. END-TO-END LATENCY BREAKDOWN

Platform	Precision	T_{pre} (ms)	T_{net} (ms)	T_{post} (ms)	T_{e2e} (ms)	FPS
RTX 3050 (reference)	FP16/AMP	–	–	–	7.9	126
Jetson Nano (GPU)	FP16 (TensorRT)	4–7	35–60	8–15	50–82	12–20
	FP32	4–7	55–90	10–18	69–115	9–14
Raspberry Pi 5 (CPU)	FP32	25–45	600–1000	70–120	695–1165	0.9–1.4
	INT8 (PTQ/QAT)	25–45	280–520	60–100	365–665	1.5–2.7

proposed fusion-based dual-YOLOv8 framework. The examples demonstrate accurate segmentation of multiple vehicle categories, including cars, buses, trucks, and motorcycles, across diverse traffic scenes. The model successfully delineates vehicle boundaries at the pixel level while preserving correct semantic labels and high confidence scores. Notably, the framework handles variations in object scale, partial occlusions, and complex backgrounds, such as roadside vegetation and shadows, with consistent segmentation quality. The results also show reliable separation of adjacent objects and stable predictions for both near-field and distant vehicles. These qualitative observations corroborate the quantitative evaluation, confirming the robustness and visual consistency of the proposed instance-aware semantic segmentation approach in real-world driving scenarios.

Fig. 10. Qualitative instance-aware semantic segmentation results on the validation set produced by the proposed fusion-based dual-YOLOv8 framework.

K. Comparative Study with State-of-the-Art

Table II presents an indicative comparison between the proposed dual-YOLOv8 fusion framework and representative real-time instance segmentation methods reported in the literature. Early one-stage approaches such as YOLACT and YOLACT++ achieve moderate segmentation accuracy on the COCO benchmark, with Mask AP values of 29.8% and 34.1%, respectively, while operating at approximately 33–34 FPS. Subsequent YOLO-based methods, including Insta-YOLO and YOLO-Core, improve inference speed and segmentation performance through architectural refinements, with YOLO-Core reaching 38.6% COCO Mask AP at 45 FPS. More recent lightweight designs tailored for traffic and urban perception, such as PSC-YOLO and UDS-YOLO, emphasize efficiency and robustness in complex road scenes. PSC-YOLO reports a relative improvement of 2.0% in mask average precision over YOLOv8n-seg while maintaining real-time performance at approximately 91 FPS, whereas UDS-YOLO achieves 39.5% mAP@0.5 on the Cityscapes dataset with a processing speed of 106.6 FPS. In contrast, the proposed dual-YOLOv8 fusion framework attains a substantially higher segmentation accuracy, achieving 92.9% mAP@0.5 while sustaining real-time inference at 126 FPS on the evaluated dataset. Although the reported results are obtained under different datasets and evaluation protocols, the comparison highlights the favorable accuracy–efficiency trade-off of the proposed approach and its suitability for real-time autonomous driving applications.

Overall, the experimental findings and comparative analysis confirm that the proposed approach achieves a favorable balance between segmentation accuracy and real-time performance, reinforcing its suitability for practical deployment in autonomous driving and ADAS applications.

VI. CONCLUSION AND FUTURE WORK

In this paper, a lightweight dual-YOLOv8 fusion framework for instance-aware semantic segmentation in autonomous driving scenarios has been presented. By combining the complementary strengths of YOLOv8n-seg and YOLOv8s-seg, the proposed approach enhances robustness to object scale variation and occlusions while maintaining real-time inference performance. Experimental results on a vehicle-centric dataset demonstrate the effectiveness of the framework, achieving an overall mAP@0.5 of 92.9% with an average inference time of 7.9 ms per image (126 FPS) on an NVIDIA RTX 3050 GPU. Both quantitative and qualitative evaluations confirm accurate and consistent instance-level segmentation in challenging traffic scenes.

While the proposed framework demonstrates strong performance, several limitations should be acknowledged. The experimental evaluation is limited to vehicle categories and does not yet include vulnerable road users such as pedestrians or cyclists. In addition, the embedded deployment analysis on ARM and low-power GPU platforms is indicative, with latency figures partially based on estimated performance rather than exhaustive hardware benchmarking. The current fusion

TABLE II. INDICATIVE COMPARISON WITH REAL-TIME INSTANCE SEGMENTATION METHODS

Method	Backbone	Reported Metric	Speed (FPS)
YOLACT [3]	ResNet-101	29.8 (COCO Mask AP)	33
YOLACT++ [19]	ResNet-101	34.1 (COCO Mask AP)	34
Insta-YOLO [5]	YOLOv3	–	30
YOLO-Core [6]	CSP-based	38.6 (COCO Mask AP)	45
PSC-YOLO [20]	YOLOv8n-based	+2.0% Mask AP vs YOLOv8n-seg	∼91
UDS-YOLO [21]	YOLOv8-seg	39.5 / 24.0 (Cityscapes)	106.6
YOLOv8-seg [9]	YOLOv8s	Dataset-specific	120
Proposed Method	**Dual-YOLOv8 Fusion**	**92.9 (mAP@0.5)**	**126**

strategy also employs fixed model combinations and does not dynamically adapt to scene complexity.

Beyond quantitative performance, this study highlights the potential of model-level fusion as a practical design strategy for real-time perception systems in autonomous driving and ADAS. By demonstrating that complementary lightweight networks can outperform single-model designs under strict latency constraints, the proposed framework provides insights for future perception architectures targeting resource-constrained and safety-critical environments.

Future work will explore extensions to multimodal perception by incorporating additional sensors such as LiDAR or radar, as well as adaptive fusion mechanisms with confidence-aware weighting to dynamically balance model contributions across varying scene complexities.

Lightweight Machine Learning for Real-Time Gear Change Prediction in Autonomous Parking

Ahmed A. Kamel*, Reda Alkhoribi, M. Shoman, Mohammed A. A. Refaey
Faculty of Computers and AI, Cairo University, Egypt

***Abstract*—Real-time motion planning for autonomous parking on embedded advanced driver-assistance system (ADAS) platforms faces a fundamental computational bottleneck: transformer-based approaches (e.g., Motion Planning Transformer, Diffusion-based planners) achieve strong performance but incur prohibitive computational costs unsuitable for resource-constrained automotive systems. This work proposes a lightweight alternative machine learning approach using Random Forest classifiers and regressors to predict parking trajectory regions and vehicle orientations, enabling accelerated Rapidly-exploring Random Trees (RRT) planning without sacrificing robustness. The approach is trained on a dataset of 10,725 synthetic perpendicular backward parking scenarios generated via Rapidly-exploring Random Tree Star (RRT*) in the Reeds-Shepp configuration space. Using Random Forests with 20 trees and maximum depth 8, the method achieves 98.3–100% success rate in multi-direction-change scenarios with planning times of 0.15–0.25 seconds, compared to 2.81 seconds for unconstrained RRT. In scenarios with insufficient prediction guidance, the constrained planner can maintain a fallback mechanism that preserves RRT's probabilistic completeness guarantees. This work demonstrates that simpler machine learning models can match transformer-based approaches while remaining practical for embedded deployment.**

***Keywords*—Autonomous parking; direction change detection; embedded systems; machine learning; motion planning; random forest; rapidly-exploring random trees; rapidly-exploring random tree star**

I. Introduction

Autonomous parking represents a critical advanced driver-assistance system (ADAS) capability that enhances vehicle usability and road safety. The task requires generating collision-free, kinematically feasible trajectories that navigate vehicles into parking spaces under strict real-time constraints. Perpendicular backward parking, the most common real-world scenario, demands multiple direction reversals (gear changes) and precise trajectory execution, presenting a non-trivial motion planning challenge.

Sampling-based motion planners (SBMPs) such as Rapidly-exploring Random Trees (RRT) [1] and Rapidly-exploring Random Tree Star (RRT*) [2] provide probabilistic completeness guarantees—if a collision-free path exists, these algorithms will find it given sufficient computation time. RRT* additionally offers asymptotic optimality, enabling generation of near-optimal parking trajectories. However, computational requirements for these algorithms often reach several seconds per planning instance, exceeding real-time requirements of automotive systems. Current ADAS processors allocate computational budgets primarily to perception tasks (computer vision, LiDAR processing) and end-to-end learning models for driving decisions, leaving minimal resources for classical motion planning.

Recent advances have demonstrated that learning-augmented planning can bridge this efficiency gap. The Motion Planning Transformer (MPT) framework learns spatial path structure from SBMP outputs [3], enabling faster RRT exploration through intelligent guidance. Transformer-Enhanced Motion Planner (TEMP) extends this with environmental encoders [4] that further reduce search space. Concurrently, diffusion-based approaches (e.g., Diffusion-based Parking Planner, MultiPark) have shown promise in learning complex parking distributions. However, all these approaches introduce substantial computational overhead: transformer inference requires millions of parameters and iterative attention mechanisms, while diffusion models necessitate multiple denoising iterations. For ADAS platforms where transformer or diffusion inference could dominate the planning budget, these solutions remain impractical.

This work addresses this gap by proposing a lightweight, learning-augmented planning framework specifically optimized for autonomous parking on embedded systems. Rather than employing global transformer models or diffusion processes, the approach trains per-grid-cell Random Forest classifiers and regressors to predict path occupancy (0=empty, 1=path, 2=state change, 3=direction change) and vehicle orientation. These lightweight models (20 trees, maximum depth 8) require minimal inference time while providing spatial guidance that accelerates RRT exploration. The framework may also preserve the theoretical completeness properties of RRT through a fallback mechanism that permits unconstrained exploration when learned guidance is insufficient.

The main contributions of this work are:

- A large-scale synthetic dataset of 10,725 perpendicular backward parking scenarios with ground-truth RRT* trajectories in the Reeds-Shepp configuration space [5];
- A lightweight two-tier learning framework combining Random Forest classifiers [6] for spatial path occupancy prediction with regressors for vehicle orientation estimation;
- An enhanced RRT algorithm that integrates learning-based predictions to constrain state sampling while maintaining probabilistic completeness;
- Comprehensive experimental validation demonstrating 17-fold planning time reduction (2.81 to 0.16 seconds)

*Corresponding author.

and improved success rates (98–100%) in direction-change-intensive scenarios, with performance scaling as a function of prediction confidence;

- Evidence that lightweight machine learning models achieve comparable benefits to transformer-based methods while remaining feasible for embedded ADAS deployment.

The remainder of this paper is organized as follows. Section II reviews related work in sampling-based motion planning, learning-augmented approaches, and autonomous parking systems. Section III presents the methodology, including dataset generation, model architecture, and the constrained RRT algorithm. Section IV presents experimental results with quantitative performance breakdown by prediction confidence. Section V discusses findings, computational feasibility, limitations, and future research directions. Section VI concludes with a summary of contributions and practical implications.

II. Related Work

A. Classical Sampling-Based Motion Planning

Sampling-based motion planners have dominated robotic and autonomous vehicle path planning for over two decades. The Rapidly-exploring Random Tree (RRT) algorithm [1] provides probabilistic completeness and handles high-dimensional configuration spaces effectively. RRT* [2] extends this framework with rewiring to achieve asymptotic optimality. For vehicles with kinematic constraints (e.g., non-holonomic differential steering), variants incorporating Dubins [7] and Reeds-Shepp [5] steering enable feasible trajectory generation. While theoretically robust, classical SBMPs typically require seconds to minutes on embedded platforms, limiting real-time automotive applications.

B. Learning-Augmented Motion Planning

Recent research has explored augmenting classical planners with learned models. The Motion Planning Transformer (MPT) [3] demonstrates that transformer networks trained on SBMP outputs can generalize motion planning constraints to novel configurations and environments. By predicting feasible regions, MPT enables RRT to focus exploration on high-probability areas, achieving substantial acceleration. Building on this work, Transformer-Enhanced Motion Planner (TEMP) [4] introduces an Environmental Information Semantic Encoder (EISE) to further reduce required search space through semantic understanding of scene structure.

However, transformer-based approaches incur significant computational costs. A typical transformer model contains millions of parameters and requires forward passes involving matrix multiplications across multiple attention layers, often necessitating seconds of inference time on embedded platforms. In ADAS systems where a single processing chip allocates computational budget across perception (computer vision, object detection, tracking) and driving decision models (end-to-end learning, reinforcement learning), the overhead of transformer inference can exceed motion planning itself, making such approaches impractical for real-time deployment.

C. Diffusion Models in Motion Planning

Emerging diffusion-based planning approaches have shown promise in complex motion planning tasks. Diffusion-based planning models [8] [9] leverage learned score functions to generate collision-free trajectories by iterative refinement. In the parking domain, models such as Diffusion-based Parking Planner [8] and MultiPark [9] apply diffusion processes to learn parking distributions from expert demonstrations. While effective, these methods similarly suffer from computational cost: each planning instance requires multiple denoising iterations (typically 10–50 steps), each involving forward passes through the neural network, rendering real-time inference infeasible on embedded platforms.

D. Lightweight and Embedded Planning Approaches

Prior work on embedded motion planning has explored heuristic-based methods (e.g., Hybrid A* [10] with handcrafted heuristics) and simplified geometric approaches. While computationally efficient, these methods sacrifice generality and theoretical guarantees. The current work bridges this gap by demonstrating that lightweight supervised learning models (Random Forests with limited tree depth and count) can provide sufficient spatial structure to accelerate sampling-based planning while maintaining theoretical guarantees and remaining practical for embedded systems.

III. Materials and Methods

A. Problem Formulation

This work addresses motion planning in perpendicular backward parking scenarios. The configuration space is defined as $\mathcal{C} = SE(2) \times \{F, B\}$, where a configuration $\mathbf{x} = (x, y, \theta, g) \in \mathcal{C}$ represents vehicle position $(x, y) \in \mathbb{R}^2$, heading angle $\theta \in [0, 2\pi]$, and gear state $g \in \{F \text{ (forward)}, B \text{ (backward)}\}$. The parking task is specified by start configuration $\mathbf{x}_s$ and goal configuration $\mathbf{x}_g$. The environment contains polygonal obstacles representing adjacent vehicles and parking lot boundaries.

B. Dataset Generation

1) Vehicle and scene parameterization: A vehicle model based on the Audi A4 sedan was parameterized with the following specifications: length 4.76 m, width 1.84 m, wheelbase 2.82 m. Each parking scenario is geometrically described by a feature vector $\mathbf{f} \in \mathbb{R}^{26}$ containing:

- Ten vertices (20 coordinates) representing obstacle boundaries: two triangular regions flanking the parking slot (shown in magenta in Fig. 1), one rear boundary line, and one forward maneuvering boundary line (both shown in grey in Fig. 1).
- Start frame position (2 coordinates) and orientation (1 angle): 3 values total.
- Goal frame position (2 coordinates) and orientation (1 angle): 3 values total.

Data augmentation was performed by randomly translating obstacles within a bounded region $[-10, +10]$ m^2 and rotating obstacle configurations. This procedure generated 10,725 unique parking scenarios, with failed path generations (path not found within 30-second timeout) filtered post-generation.

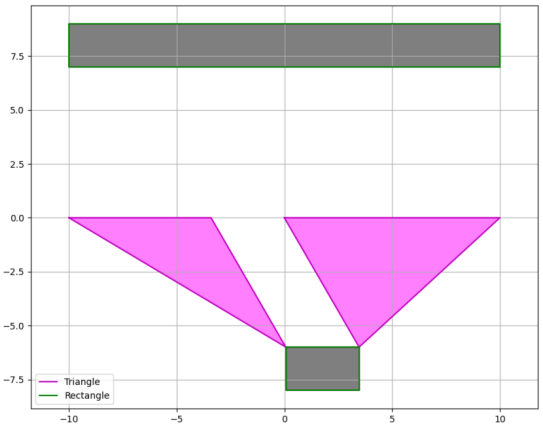

Fig. 1. Representation of the parking scene obstacles.

2) Path generation and preprocessing: For each scenario, a ground-truth parking trajectory was computed using the Open Motion Planning Library (OMPL) [11] with the RRT* algorithm and Reeds-Shepp steering to respect vehicle kinematics. Path generation was limited to a 30-second timeout per scenario.

Each resulting path was represented as a sequence of states in the Reeds-Shepp space and uniformly interpolated to exactly 100 waypoints for standardization across all scenarios (Fig. 2a).

From these interpolated waypoints all the direction/gear changes are extracted as well (Fig. 2b).

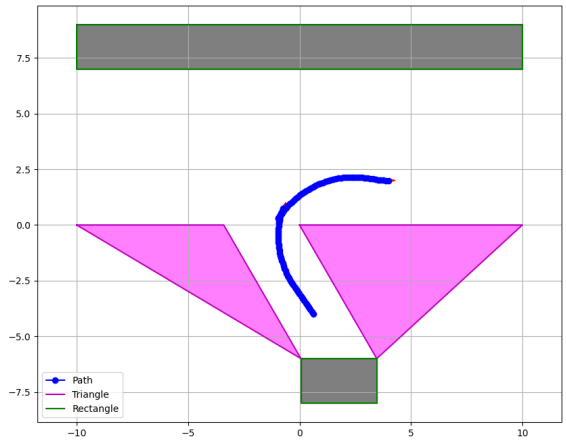
Of the initial 10,725 scenarios attempted, the 2,252 scenarios where RRT* failed to generate valid paths (e.g., scenarios with insufficient maneuvering space) were excluded from further analysis. The remaining 8,473 valid scenarios were split into training (80%, 6778 scenarios) and test (20%, 1695 scenarios) sets prior to feature extraction.

C. Grid-Based Learning Framework

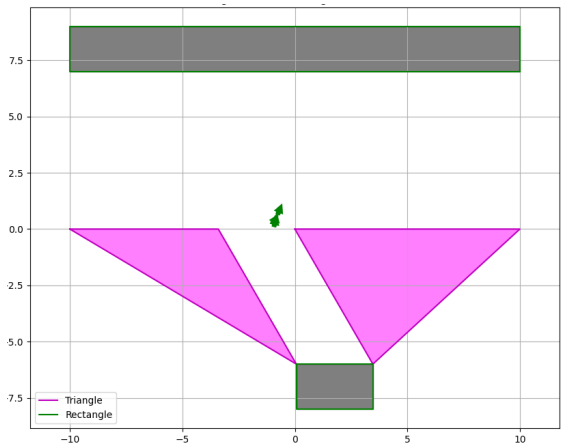
1) Spatial grid representation and labeling: A uniform spatial grid of 1 m $\times$ 1 m cells was overlaid on each parking scenario. Grid resolution was selected based on preliminary experiments: coarser resolutions (2 m) provided insufficient spatial discrimination, while finer resolutions (0.5 m, 0.25 m) increased model complexity and inference latency without improving planning success rates.

For each grid cell, the following information was extracted from the RRT* reference path:

- Occupancy class (Displayed in Fig. 3a) $c_i \in \{0, 1, 2, 3\}$: Maximum class among cells crossed by the path, where:
  - Class 0 (empty): cell contains no path waypoints
  - Class 1 (path): cell contains interpolated waypoints



(a) Representation of the 100-waypoint interpolated parking path.



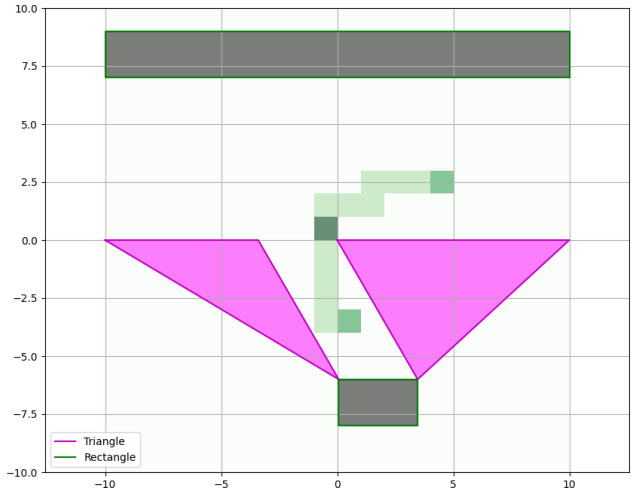
(b) Representation of direction changes in the path.

Fig. 2. Extracted information from parking path.

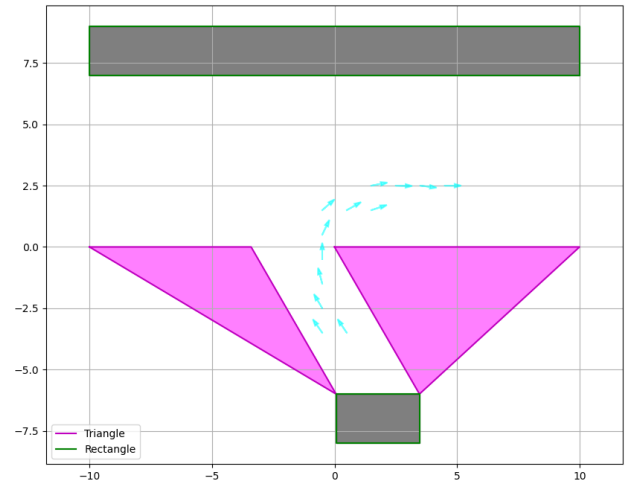
  - Class 2 (state change): cell contains a configuration where the path generates or ends a Reeds-Shepp curve (this includes the start and end locations)
  - Class 3 (direction change): cell contains a gear change
- Orientation (Displayed in Fig. 3b) θ_i: Average heading angle of all waypoints within the cell

A direction change is formally defined as a transition in gear state (forward $\rightarrow$ backward or backward $\rightarrow$ forward), equivalent to a reversal in driving direction.

2) Model architecture and training: For each grid cell, a separate Random Forest classifier was trained using the feature vector $\mathbf{f} \in \mathbb{R}^{26}$ as input and the occupancy class c_i as target. Random Forest models were selected for their non-parametric nature, robustness to feature scaling, and minimal inference overhead—critical for embedded deployment. The hyperparameter selection was: 20 decision trees with maximum tree depth of 8.



(a) Representation of the path grid overlay.



(b) Representation of the orientation overlay.

Fig. 3. Representation of the path data after preprocessing.

Orientation prediction was performed separately. Initial cells lacking waypoint coverage were marked as missing. A K-Nearest Neighbors imputer ($k = 5$) was applied to estimate missing orientations from neighboring cells. Subsequently, a separate Random Forest regressor (20 trees, maximum depth 8) was trained for each grid cell to predict heading angles from the feature vector $\mathbf{f}$, using the imputed orientations as training targets. This output data is displayed in Fig. 4.

D. Constrained RRT with Learned Guidance

The proposed planning algorithm augments standard RRT with a custom state sampler that integrates predictions from the trained models:

- Given a parking scenario, extract the feature vector $\mathbf{f}$
- Query the trained classifiers to obtain per-cell occupancy predictions: $\hat{c}_i$ for all grid cells i
- Query the trained regressors to obtain per-cell orientation predictions: $\hat{\theta}_i$ for all grid cells i

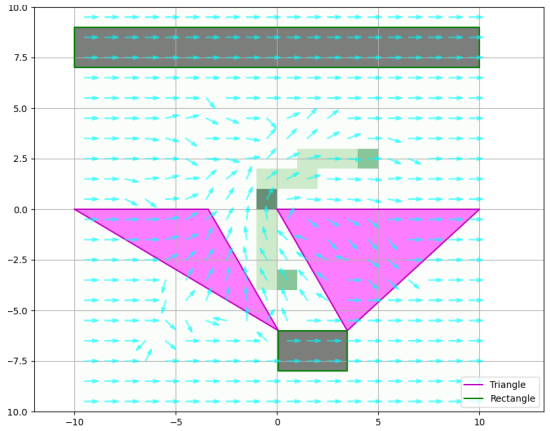


Fig. 4. Representation of the output vector data.

- During RRT tree expansion:
  - (Standard RRT sampling) Generate a random configuration $\mathbf{x}_{\text{rand}}$ in the configuration space
  - (Guided sampling) If $\mathbf{x}_{\text{rand}}$ projects to a grid cell with predicted occupancy $\hat{c}_i > 2$ (gear change) or part of the start/end cells, accept the state; otherwise, reject and resample
  - (Orientation constraint) If accepted, perturb the heading component of $\mathbf{x}_{\text{rand}}$ to lie within $[\hat{\theta}_i - 45°, \hat{\theta}_i + 45°]$
  - (Fallback mechanism) If valid state sampling fails after $N = 100$ consecutive rejection attempts, switch to unconstrained uniform sampling for a configurable n sampling attempts
- Continue standard RRT tree extension toward the goal configuration

This formulation preserves the probabilistic completeness of RRT: if a solution exists and sufficient time remains, the fallback mechanism ensures that the algorithm explores the full configuration space and eventually discovers a path.

E. Experimental Validation Protocol

For each of the 1695 test scenarios:

- Execute unconstrained RRT (baseline) with 30-second planning timeout
- Execute constrained RRT (proposed method) with identical timeout
- Record: success/failure, planning duration, number of tree nodes created
- Post-hoc: count number of direction changes predicted in that scenario's grid

Success is defined as finding any collision-free path within the timeout. All experiments were conducted on a standard

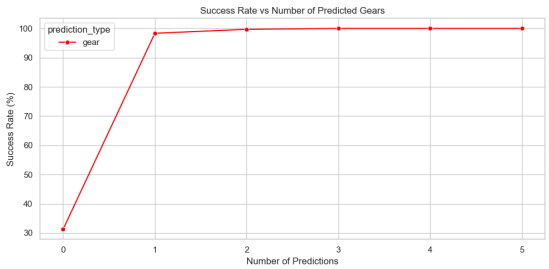
desktop workstation (AMD Ryzen 5 CPU, 32 GB RAM, no GPU acceleration) using OMPL with Python bindings and scikit-learn [12] for model training and inference.

IV. Results

A. Overall Performance Summary

Table I presents aggregate results across all 1695 test scenarios. Unconstrained RRT achieved 96.4% success rate with mean success time of 2.81 seconds and overall mean time of 3.79 seconds (including failed attempts). The constrained RRT approach achieved 71.9% overall success with a mean success time of 0.35 seconds and an overall mean time of 8.68 seconds; however, this aggregate masks important performance variation correlated with prediction confidence (detailed in Section IV-B).

The low overall success rate and high mean time for constrained RRT in the aggregate reflect scenarios with sparse or no direction change predictions (detailed in Section IV-C). These scenarios comprise approximately 40.18% of the test set, where prediction guidance is unreliable, and the constrained sampler restricts exploration too severely, causing timeout failures.



(a) Success graph with respect to number of predictions.

(b) Timing graph with respect to number of predictions.

Fig. 5. Constrained RRT performance with respect to number of predictions.

B. Performance Breakdown by Prediction Confidence

The key insight emerges when analyzing performance conditional on the number of direction change predictions provided by the learned model. Table II presents results grouped by direction change prediction count.

We can see in Fig. 5a the positive trend of success rate with number of predictions and in Fig. 5b we can see the inverse relation in runtime as the number of predictions increase.

Performance exhibits a clear correlation with prediction confidence:

- No predictions (0 cells): 33.2% success. In these scenarios, the constrained sampler restricts states to empty grid cells, preventing effective exploration. Timeout failures dominate.
- Single prediction (1 cell): 98.3% success, 0.15 s mean time. Minimal guidance proves sufficient to accelerate planning significantly.
- Two predictions: 99.7% success, 0.15 s mean time.
- Multiple predictions (3–5 cells): 100% success, 0.17–0.25 s mean time.

For scenarios with at least one direction change prediction, the constrained RRT dramatically outperforms unconstrained RRT in both success rate and planning time, achieving 17-fold speedup (2.81 to 0.16 seconds).

C. Failure Mode Analysis

Two distinct failure modes emerge:

1) Constrained RRT failures: Occur primarily when direction change predictions are sparse or absent (0-1 cells). In these scenarios, the learned model failed to capture the true solution structure, either because 1) the test scenario poorly matches the training distribution, or 2) the direction change count is inherently low, providing minimal guidance to the state sampler. The fallback mechanism prevents complete failure but provides no advantage over unconstrained search, explaining the degraded performance.

2) Unconstrained RRT failures: 3.6% of scenarios exceed the 30-second timeout without finding a valid path. These are intrinsically difficult configurations (e.g., very tight parking spaces) that require extensive exploration.

V. Discussion

A. Interpretation and Trade-offs

The results reveal a fundamental trade-off between search coverage and computational efficiency. Unconstrained RRT explores the entire configuration space uniformly, providing robust coverage but requiring extensive computation. Constrained RRT leverages learned predictions to focus exploration toward high-probability path regions, dramatically reducing computational cost but at a loss of coverage in low-prediction scenarios.

The strong performance in high-prediction scenarios (98.3–100% success with 0.15–0.25 s planning) demonstrates that direction changes create a highly structured planning problem. The learned models effectively capture this structure, providing guidance that exceeds random exploration in value. This supports the hypothesis that parking geometry imposes strong constraints on feasible solution paths—constraints that modest machine learning models can capture with reasonable accuracy.

TABLE I. OVERALL PLANNING PERFORMANCE (ALL TEST SCENARIOS)

Method	Success Rate	Mean Success Time	Mean Overall Time
Unconstrained RRT	96.4%	2.81 s	3.79 s
Constrained RRT (Proposed)	71.9%	0.35 s	8.68 s

TABLE II. PERFORMANCE BY NUMBER OF DIRECTION CHANGE PREDICTIONS

Prediction Count	Percentage of Scenarios	Success Rate	Mean Success Time	Mean Overall Time
0 (no prediction)	40.18%	31.2%	1.22 s	21.05 s
1	21.30%	98.3%	0.15 s	0.65 s
2	19.82%	99.7%	0.15 s	0.24 s
3-5	18.70%	100.0%	0.17–0.25 s	0.17–0.25 s
All >0 predictions	59.82%	99.3%	0.16 s	0.37 s

B. Computational Feasibility for Embedded ADAS

Studies on the deployment of Random Forest (RF) models in embedded environments have demonstrated their suitability for embedded ADAS applications. Kuppers et al. reported achieving an inference time of approximately 700 microseconds per RF classifier on a test platform [13]. Accordingly, the 400 RF classifiers used in this work result in a total inference time of about 0.28 seconds. The analysis further indicates that many grid cells remain unutilized, suggesting that targeted grid pruning could reduce computational overhead and enhance runtime efficiency. While this overhead remains negligible compared to the overall planning time observed in unconstrained RRT, the models retain a lightweight footprint, as summarized below:

- Model size: Daghero et al. successfully deployed RF models on microcontrollers with only 520 kB of available memory [14]. Also, recent work by Kochel et al. demostrates efficient tree ensemble inference (including Random Forest) on ARM-based embedded devices [15].
- Memory access pattern: Tree traversal operations demonstrate high CPU cache locality.
- No specialized hardware required: Inference executes efficiently on standard CPUs, reducing both power consumption and thermal load.

In contrast, transformer-based approaches require millions of parameters and iterative attention computations, often necessitating GPU acceleration and power budgets unsuitable for ADAS platforms. Diffusion-based methods similarly require multiple denoising iterations, compounding computational overhead. The lightweight Random Forest framework enables deployment on resource-constrained embedded processors currently used in many production ADAS systems.

C. Comparison with Learning-Based Planning Methods

The proposed method achieves competitive results relative to transformer-based approaches while remaining practical for embedded deployment. MPT and TEMP require transformer inference, estimated at 50–500 ms per planning instance on embedded platforms (depending on model size and hardware). MultiPark and diffusion-based methods require multiple denoising iterations, further increasing latency. The proposed constrained RRT achieves 0.15–0.25 s planning in high-prediction scenarios, comparable to or better than these methods.

This efficiency gain comes from task specialization: unlike MPT (general motion planning) or diffusion models (learning complex distributions), the current work targets a narrower domain (parking) with a simpler learning objective (binary occupancy and continuous orientation prediction). This trade-off—generality for efficiency—is appropriate for ADAS applications where parking represents a well-defined, repeatedly executed task.

D. Limitations

Several important limitations merit discussion:

- Parking type specificity: Models are trained exclusively on perpendicular backward parking. Generalization to parallel, angled, or diagonal parking requires retraining on scenario-specific data. The 10,725 scenario budget was chosen for manageable training time; larger datasets could improve robustness but at higher computational cost.
- Vehicle specificity: Models are parameterized for the Audi A4 sedan. Vehicles with different wheelbase lengths, turning radii, or dimensions require new training. Transfer learning approaches (pre-training on diverse geometries, fine-tuning) may mitigate this limitation but were not explored here.
- Prediction reliability in distribution shift: When test scenarios poorly match the training distribution (e.g., parking slots with unusual obstacle arrangements not seen during training), learned predictions become unreliable, degrading constrained RRT performance below baseline.
- Grid resolution trade-off: The 1 m grid balances spatial accuracy with model complexity. Finer grids (0.5 m, 0.25 m) could improve precision but increase the number of per-cell models proportionally, increasing inference latency and memory footprint. Coarser grids reduce models but sacrifice spatial resolution.
- Baseline comparison limitation: Comparison is against unconstrained RRT only. Quantitative comparisons with transformer-based methods (MPT, TEMP) or

diffusion models on identical scenarios are not available, limiting direct competitive assessment. These comparisons would require access to proprietary implementations.

- Hyperparameter sensitivity not analyzed: The choice of 20 trees and depth 8 was based on quick manual comparisons but ablation studies comparing alternative configurations (5 trees, 50 trees, varying depths) are not presented, limiting understanding of sensitivity to these choices.

E. Future Research Directions

Future work should address:

- Multi-parking-type unification: Development of a single learning model that handles perpendicular, parallel, and angled parking simultaneously, trading per-type accuracy for unified generality.
- Grid Cell Predictor Pruning: In depth analysis of grid cell predictor utility for pruning and possibly explore a learning model to determine which grid cells are worth inference.
- Transfer learning: Pre-training on diverse synthetic vehicle geometries and parking types, then fine-tuning for specific vehicles, to reduce per-vehicle training data requirements.
- Adaptive constraint relaxation: Dynamic adjustment of sampling constraints (grid cell restrictions, orientation bounds) based on prediction confidence, maintaining completeness while improving robustness.
- Alternative SBMP variants: Extension to RRT*, Bidirectional RRT, and other planners to assess whether learned predictions similarly accelerate different algorithm variants.
- Real-world validation: Deployment on actual autonomous vehicles with real sensor data, dynamic obstacles, and sensor noise to assess practical performance beyond simulation.
- Hardware implementation: Optimization of inference on actual ADAS processors (e.g., Qualcomm Snapdragon, NVIDIA DRIVE) to quantify practical deployment feasibility.

VI. Conclusion

This paper presented a lightweight, learning-augmented motion planning framework for real-time autonomous parking on embedded ADAS platforms. By training Random Forest classifiers and regressors to predict parking trajectory structure (occupancy classes and vehicle orientation) from scenario geometry, the approach enables accelerated RRT planning without sacrificing theoretical completeness guarantees. Experimental validation on 1695 test scenarios demonstrated that scenarios with sufficient prediction guidance achieve 98.3–100% success rates with 17-fold planning time reduction (2.81 to 0.15–0.25 seconds) compared to unconstrained RRT.

The core contribution is demonstrating that lightweight supervised learning models (20 trees, maximum depth 8) can achieve planning acceleration comparable to transformer-based approaches while remaining practical for embedded automotive deployment. This addresses a critical gap in current ADAS systems, where computational budgets are dominated by perception and end-to-end learning, leaving minimal resources for classical motion planning.

As autonomous parking systems mature toward production deployment, efficient planning methods that balance computational constraint, memory footprint, and solution quality will become increasingly critical. This work demonstrates a practical path toward real-time, reliable parking planning suitable for resource-constrained ADAS platforms, with clear pathways toward generalization to multiple parking types and vehicle platforms through transfer learning and multi-task approaches.

APPENDIX A
DATASET STATISTICS AND DISTRIBUTION

The parking scenario dataset exhibits the following detailed characteristics:

- **Initial scenarios generated:** 10,725
- **Waypoints per trajectory:** 100 (uniformly interpolated)
- **Scenarios with valid paths:** 8,473 (79% after filtering failures)
- **Training set:** 6778 scenarios (80% of valid paths)
- **Test set:** 1695 scenarios (20% of valid paths)
- **Feature dimension:** 26 $\{10$ obstacle vertices (x, y) + 1 start frame (x, y, θ) + 1 goal frame $(x, y, \theta)\}$
- **Spatial domain:** $[-10, +10]$ m^2
- **Grid cells per scenario:** 400 (20×20 cells with 1 m resolution)

APPENDIX B
HYPERPARAMETER SELECTION AND MODEL PERFORMANCE

Random Forest models were trained using scikit-learn

- **Number of trees:** 20; 100 trees tested as alternative
- **Maximum tree depth:** 8
- **Minimum samples per leaf:** 1
- **Feature sampling:** $(\sqrt{n_{\text{features}}})$ for classification; (n_{features}) for regression
- **KNN imputer neighbors:** $k = 5$

APPENDIX C
IMPLEMENTATION DETAILS AND REPRODUCIBILITY

A. Software and Hardware

Training and inference experiments were conducted using:

- **Motion Planning:** OMPL 1.7.0 with Python 3.9 bindings
- **Machine Learning:** scikit-learn 1.7.2, NumPy 2.3.2, Pandas 2.3.1
- **Hardware:** AMD Ryzen 5 CPU, 32 GB RAM
- **Operating System:** Ubuntu 24.04 LTS

B. Computational Time Breakdown

- **Reference path generation (RRT*):** 90 hours total (exhausting 30-second timeout per scenario for 10,725 scenarios)
- **Data preprocessing (waypoint interpolation, grid generation):** 2–3 hours
- **Model training (KNN imputation + RF classifier/regressor):** 15–30 minutes

C. Code Availability

Custom RRT state samplers were implemented as extensions to OMPL's C++ API. All code is modular, well-documented, and available upon request for reproducibility and future research.

Relative Position Estimation for Multi-Robots Based on Vertex Distance Between Regular Tetrahedral Units

Airi Kojima, Kohei Yamagishi, Tsuyoshi Suzuki
Department of Information and Communication Engineering, Tokyo Denki University, Tokyo, Japan

***Abstract*—Optimal decentralized cooperative control in multi-robot systems requires simultaneous local sensing and inter-agent communication. Ultra-wide band (UWB) wireless communication has been investigated as a self-contained positioning system capable of supporting both functions within a single device. Conventional UWB-based positioning methods estimate absolute positions using distance measurements relative to fixed anchors in the environment; moreover, while relative position estimation methods based on antenna configurations have been studied, mutual relative position estimation with respect to the reference coordinate frames of the agents themselves has not yet been investigated. To address this gap, this paper proposes a three-dimensional relative position estimation method for distributed cooperative control based on inter-vertex distances sharing. In the proposed system, inter-vertex distances between units are measured, where each unit is equipped with four UWB devices arranged in a regular tetrahedral geometric structure. An optimization-based estimation process is applied and enhanced with a k-means clustering method to mitigate convergence to local minima. The estimation accuracy was evaluated through both simulations and real-world experiments. The results demonstrate that the proposed method can accurately estimate relative positions between units and is effective for multi-robot systems operating on planar surfaces.**

***Keywords*—Multi-robot system; distributed cooperative control; relative position estimation; self-contained positioning system; inrter-vertex distance; geometric structure**

I. Introduction

Transportation tasks involving multiple robots, such as picking robots, are increasingly employed in warehouse environments [1]. To control such robot swarms, large-scale management applications—such as swarm coordination frameworks and warehouse management or control systems—are used to supervise individual robots. In these systems, a central server computes control actions based on the current state of the system and distributes appropriate control commands to each robot [2]. This approach, referred to as centralized control [3], allows the central unit to centrally manage environmental perception and motion planning, and the accuracy of the sensor and control timing are crucial for achieving precise robot motion. However, when information is acquired by robots, the accuracy of their motion may degrade, potentially leading to collisions or other risks [4]. To address this issue, a correction has been applied that supplements data from a new sensor [5]. Nevertheless, such approaches become less effective when sensor systems cannot be further extended due to hardware, cost, or scalability constraints. Consequently, there is a growing need for distributed cooperative control strategies that allow robots to directly perceive their mutual states and autonomously avoid collisions without relying on centralized control architectures.

Distributed cooperative control is a control paradigm in which multiple robots operate autonomously while exchanging information with one another [6]. This approach enables highly redundant cooperative behaviors without relying on a central controller [7]. Moreover, it provides robustness against environmental changes, thereby enhancing system flexibility, diversity, and fault tolerance [8]. Ideally, distributed cooperative control requires robots to simultaneously perform local communication and sensing [9]. Thus far, these functionalities have typically been realized through the integration of multiple devices, such as Bluetooth [10] or Wi-Fi [11] for communication, and LiDAR [12], GNSS [13], or RGB-D cameras [14] for sensing. However, such multi-device integration increases onboard system complexity, which may adversely affect control system stability [15] and significantly increase the number of physical system parameters that must be tuned and managed.

A technology that can address these challenges is ultra-wideband (UWB) wireless communication. UWB is a communication system that utilizes ultra-wide frequency bandwidth [16], enabling high-precision positioning and communication [17]. By integrating the local communication and sensing required for distributed cooperative control, UWB wireless communication can simplify robotic systems and improve overall performance. However, in conventional UWB-based systems, the position of a moving node is typically estimated with respect to fixed reference nodes installed in the environment. This reliance on fixed infrastructure limits system scalability and flexibility, particularly in dynamic or infrastructure-free environments. Recently, UWB-based relative positioning systems that estimate relative positions without relying on fixed reference nodes have been developed. These systems estimate the positions of antennas mounted on other units based on distance measured from multiple UWB antennas installed on the unit. Consequently, if an offset exists between the origin of a mobile agent's coordinate frame and the estimated position of its onboard antenna, the agent's position required for distributed cooperative control cannot be utilized with high accuracy.

To address this limitation, it is essential to accurately relate the estimated antenna positions to the agent coordinate frame while preserving the advantages of UWB-based relative positioning. Accordingly, this paper proposes a UWB-based three-dimensional relative positioning method that enables a robot to estimate the arbitrary coordinates of other robots

while simultaneously supporting inter-robot communication. The proposed method satisfies both local sensing and communication requirements using only a single type of device. As a result, the proposed approach enhances the robustness and structural simplicity of robotic systems operating under ideal distributed cooperative control.

The main contribution of this study is the development of a method for associating the positioning coordinates provided by a UWB-based relative localization unit with the relative coordinates of agents used in control, thereby enabling high-accuracy sensing in distributed cooperative control.

The remainder of this paper is organized as follows: Section II reviews related work on UWB-based positioning methods. Section III presents a relative position estimation method based on inter-vertex distances. In Sections IV and V, this paper evaluates the performance of the method through simulations and field trials, along with a discussion of the results. Finally, Section VI presents the conclusions of this study.

II. Related Work

In conventional UWB-based positioning systems, as illustrated in Fig. 1a, reference devices that serve as positioning anchors are placed at the four corners of the operational area [18]. This configuration enables the estimation of the position of any device located within the area. Consequently, the absolute coordinates of multiple robots operating in a shared environment can be determined, provided that each robot is equipped with a UWB device. In this localization framework, the position of a target device, denoted by (x, y, z), is calculated under the assumption that each robot or its surrounding environment satisfies the conditions described below.

$$\left.\begin{aligned}(x-x_1)^2+(y-y_1)^2+(z-z_1)^2-r_1^2=0\\(x-x_2)^2+(y-y_2)^2+(z-z_2)^2-r_2^2=0\\(x-x_3)^2+(y-y_3)^2+(z-z_3)^2-r_3^2=0\\(x-x_4)^2+(y-y_4)^2+(z-z_4)^2-r_4^2=0\end{aligned}\right\} \quad (1)$$

Here, (x_n, y_n, z_n) represent the absolute coordinates of each reference device, and r_n denotes the distance between the target device and the corresponding reference device. Several conventional approaches have been proposed to improve the localization performance. For example, as illustrated in Fig. 1b, adjusting the height of the reference devices can enhance position estimation accuracy [19], while space-division-based methods have been introduced to extend the measurable range [20].

However, as illustrated in Fig. 1c, when relative coordinates between robots are required, such information can only be obtained indirectly through a network or a centralized system. Consequently, acquiring relative positional information between robots, which is essential for distributed cooperative control, remains a significant challenge.

Furthermore, several studies have extended conventional UWB-based localization to relative positioning. As illustrated in Fig. 2, relative positioning methods have been investigated in which the positions of devices mounted on other units are estimated based on multiple devices installed on the unit [21], [22], [23], [24]. These approaches enable peer-to-peer measurement of relative positions between units without relying on anchors installed in the environment.

In such methods, the position of another unit can be obtained either by introducing an additional device that serves as the origin of the coordinate frame [21], [22], [23], or by selecting one of the devices on the unit as a reference when the unit size is sufficiently small [24]. The former approach allows the definition of a reference coordinate frame that is suitable for the robot carrying the unit; however, it increases the number of devices required to compose the unit. In contrast, the latter approach enables relative positioning with a minimal number of devices; however, if the unit is not mounted close to the robot's reference coordinate frame, an offset is introduced into the position estimation.

However, existing methods do not adequately address the trade-off between device complexity and agent-based positioning accuracy. Therefore, this study focuses on the capability of UWB communication to support both distance measurement and individual data transmission. By leveraging these features and increasing the amount of measurement data, this paper investigates a method that enables the estimation of arbitrary agent coordinates.

III. Proposed Method

This paper examines a system composed of multiple units, as illustrated in Fig. 3, designed to measure the relative positions between units. Each unit is equipped with four UWB positioning devices mounted at the vertices of a regular tetrahedron. Among these devices, two function as transmitters and the other two function as receivers.

In UWB wireless communication, distance measurement is performed using receiver devices based on signals transmitted from transmitters. The obtained measurement information is then sent back to the transmitters as a response. Through this mechanism, the two units can determine the inter-device distance r_n shown in Fig. 3. In the figure, the upper devices of the left unit are configured as transmitters, whereas those of the right unit are configured as receivers.

By predefining the coordinate system of each device relative to the origin of the agent's coordinate system, the position of each unit can be estimated based on the acquired distance information and the geometric constraints of a regular tetrahedron, as described below.

$$\left.\begin{aligned} &|\|o_i - p_i\| - r_i| = 0 \quad ;\forall i \\ &|\|p_i - p_j\| - r_i| = 0 \quad ;i < j \\ &\left|\frac{1}{6}\det\left(p_1 - p_0, p_2 - p_0, p_3 - p_0\right) - V\right| = 0 \end{aligned}\right\} \tag{2}$$

where, the position of unit P is estimated relative to that of unit O, and i and j denote the device indices for each unit. As predefined parameters, o_n represents the coordinates of the n-th device, e denotes the edge length of the regular tetrahedron formed by the unit, and V represents the volume of the tetrahedron.

By solving for p_n that satisfies these equations, the relative position can be estimated. Although distance measurements obtained using UWB wireless communication are relatively robust to external disturbances, they still contain measurement errors. Consequently, the geometric constraints cannot always be satisfied exactly, making it difficult to compute a single consistent position estimate. To address this issue, this paper determines the relative position of the other unit by optimizing a solution that minimizes Eq. III.

However, optimization-based position estimation depends on initial values and may converge to local minima as the proposed method estimates a six-degree-of-freedom pose. To address this issue, this paper applies *k*-means clustering to multiple sets of estimated three-dimensional coordinates obtained from different initializations. Spatially proximate estimates are grouped into k clusters, and the cluster with the lowest variance is selected as the final position estimate. This approach effectively filters dispersed local solutions and guides the estimation toward convergence to the true position.

By applying the *k*-means clustering method using three-dimensional coordinates as feature values, outliers can be suppressed, resulting in more reliable position estimation. The number of data points provided to the *k*-means algorithm (i.e., the number of estimation results obtained from different random initializations) is intentionally set to an odd value so that the number of samples in each cluster became uneven. This design helps prevent bias in the clustering process.

IV. Estimated Performance Evaluation through Simulation

A. Simulation Setting

The accuracy of the position estimation obtained through the clustering approach using the *k*-means method, as described in the proposed method, was evaluated via a simulation. First, the appropriate numbers of clusters and data points were determined. The estimation accuracy was assessed for units formed by the regular tetrahedron, with sizes measuring 0.1, 0.2, 0.5, 0.7, 1, 2, 5, 7, and 10 m. For each unit size, the evaluation was based on an average of 10,000 trials with randomly initialized position estimates.

In this simulation, an ideal environment without distance-measurement errors was used; therefore, the estimation error arose solely from the geometric structure and characteristics of the algorithm. Through the evaluation of the proposed method, the effects of two parameters in the *k*-means algorithm were analyzed: the number of data points (index) and the number of clusters (cluster). Subsequently, the estimation accuracy was assessed with respect to the distance between units.

The simulation was implemented using Python 3.7.9, with the following libraries: NumPy 1.21.6, SciPy 1.7.3, and PyClustering 0.10.1.2.

B. Effect of Parameter Settings in the k-means Method on Location Estimation Accuracy

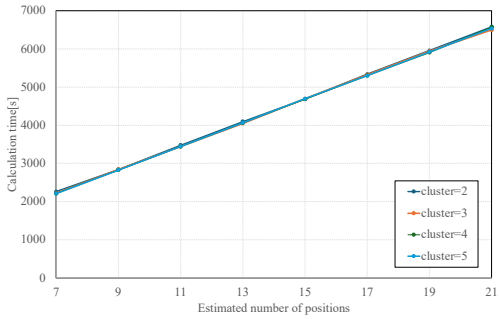
The influence of the *k*-means parameter settings on the position estimation accuracy was examined. In this evaluation, the unit size was set to 1.0 m, and the distance between the

units was 2.0 m. Fig. 4a and 4b show the total computation time and estimation error with respect to the numbers of estimations and clusters, respectively.

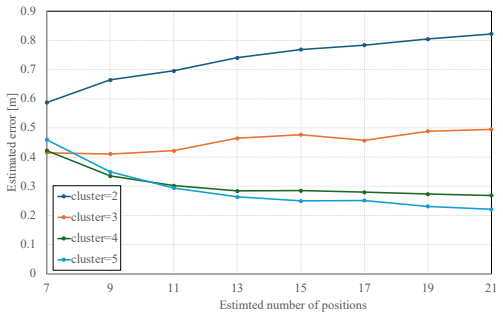
The computation time increased with the number of data points, whereas it slightly decreased with increasing number of clusters. This behavior is attributed to the additional time required to assign data points to clusters and calculate their associated errors as the dataset grows. Conversely, the slight reduction in the computation time with an increasing number of clusters is likely due to the faster convergence of cluster centers achieved using the *k*-means method. Based on these results, it can be concluded that the primary factor affecting the computation time of the *k*-means method is the number of data points.

Next, we focused on the estimation error. Unlike the trend observed in the computation time, the estimation accuracy tended to improve with increasing number of clusters. Furthermore, when examining the effect of the number of data points, different trends emerged depending on the cluster size. With a small number of clusters (two or three), the estimation error increased with increasing number of data points. By contrast, with a larger number of clusters (four or five), the error decreased with increasing number of data points.

This behavior can be attributed to the fact that with a small number of clusters, local solutions may merge with clusters containing the correct estimation results. By contrast, a larger number of clusters allows these solutions to be separated. Consequently, when the number of clusters is large, increasing the number of data points makes it easier to identify clusters containing a majority of estimations that are close to the true coordinates, thereby improving accuracy.



(a) Computation time.



(b) Measurement error.

Fig. 4. Variation in the position estimation accuracy with the number of indices and clusters.

C. Position Estimation Accuracy Relative to Unit Spacing

Based on the results described above, the estimation accuracy relative to the distance between units was evaluated under two conditions: one with a faster computation time (Index: 7, Cluster: 5) and another with a lower estimation error (Index: 21, Cluster: 5). Fig. 5 shows the results, where the horizontal axis represents the inter-unit distance normalized by each unit size, enabling comparisons across the different unit sizes tested.

Under both the scenarios, the estimation error tended to increase with increasing unit size. This is because a greater distance between the units results in a larger separation between the correct and local solutions. Although both sets of *k*-means parameters showed an increase in the error with increasing inter-unit distance, the trend was more moderate under the conditions shown in Fig. 5b. This indicates that increasing the number of data points in the *k*-means method enables more reliable estimations over longer ranges. In addition, the results showed a significant accumulation of errors when the inter-unit distance exceeded five times the unit size. Therefore, the proposed system can effectively benefit from the error-reduction effect of the *k*-means method for distances of up to five times the unit size.

D. Evaluation of Position Estimation Accuracy Based on Position Estimation Success Rate

Finally, to assess the effectiveness of combining nonlinear optimization with the *k*-means method in the proposed method, we evaluated the success rate of the position estimation. Table I presents the results. The success rate represents the probability of the estimation error falling below a specified threshold. The evaluation was conducted using a unit size of 1.0 m and an inter-unit distance of 2.0 m.

The results shown in Table I indicate that the proposed method achieved a higher success rate than the approach without the use of the *k*-means method across all threshold values. The success rate was particularly high when a greater number of estimation results was used. These findings demonstrate that clustering with *k*-means significantly improves the estimation accuracy. Although nonlinear optimization in the proposed method often fails to compute the correct position, the use of *k*-means enables the formation of groups of data with similar characteristics, thereby enhancing the overall accuracy.

In Section IV-B, the success rate improves with an increase in the number of data points, indicating that an appropriate selection of both the number of data points and the number of clusters is a crucial design factor. With sufficient data points, the likelihood of a cluster containing the estimated results close to the true coordinates increases, resulting in more stable estimations.

V. EVALUATION OF POSITION ESTIMATION ACCURACY THROUGH FIELD EXPERIMENT

A. Field Experiment Setting

This field experiment aims to validate the practical feasibility and robustness of the proposed relative positioning method under real-world measurement conditions, including ranging noise, device resolution limitations, and orientation-dependent errors. By comparing the experimental results with the simulation-based performance evaluation presented in Section IV, the experiment demonstrates that the proposed method maintains consistent performance trends even in non-ideal environments, thereby highlighting its applicability to real robotic systems.

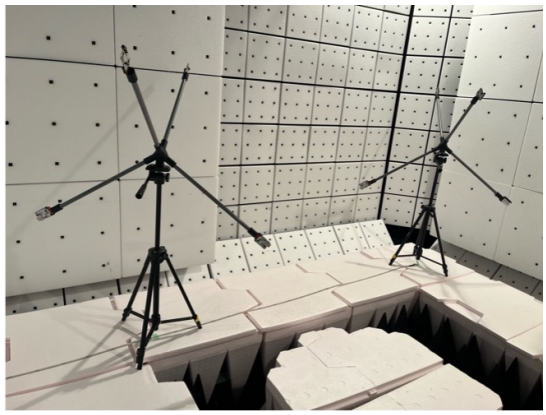

Fig. 6. Experimental setup for relative position estimation in an electromagnetic anechoic chamber.

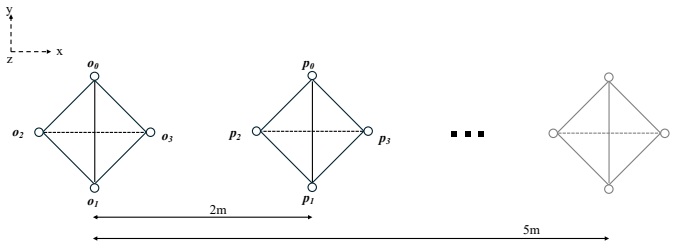

Fig. 7. Experimental overview diagram.

In this experiment, the proposed system was constructed using UWB positioning devices, and the relative position estimation was evaluated in an electromagnetic anechoic chamber, as shown in Fig. 6. The UWB modules used were DWM3001 units (manufactured by Qorvo). For one unit, the two devices on the upper side were configured as transmitters and the two on the lower side were configured as receivers, whereas the opposite configuration was applied to the other unit, with the upper devices set as receivers and the lower devices as transmitters. Two units sizes, 0.64 and 1.02 m, were considered. Using these units, we estimated the relative position on the horizontal plane in terms of the distance and angle.

Fig. 7 shows the coordinate system used in this experiment. The distance between the units was measured along the x-axis, with tests conducted at distances of 2, 3, 4, and 5 m. The relative orientation of the units was evaluated by rotating Unit P counterclockwise from 0° to 0° in 15° increments, where 0° corresponds to the reference orientation, as shown in Fig. 7. Owing to the symmetry of the tetrahedron, measurements up to 180° could capture the characteristics of the entire surrounding direction.

Under the conditions described above, positioning data were obtained using the Qorvo TWR, where each transmitting device measured the distance to the two receiving devices on the other unit. This process provides the eight distance measurements required by the proposed method. Based on these measurements, the relative positions were estimated using the proposed method. For each measurement condition, 100 ranging samples were collected, and the program described in Section IV was applied to compute the estimated coordinates for each sample. The estimation error was calculated by

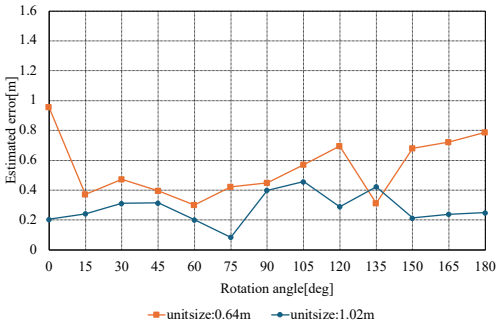

Fig. 8. Estimated distance error.

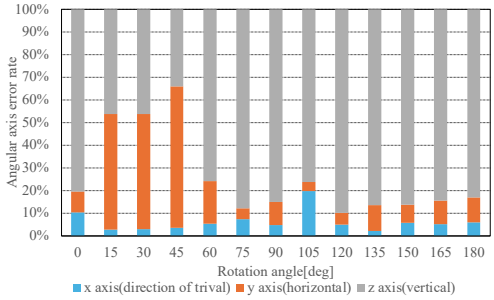
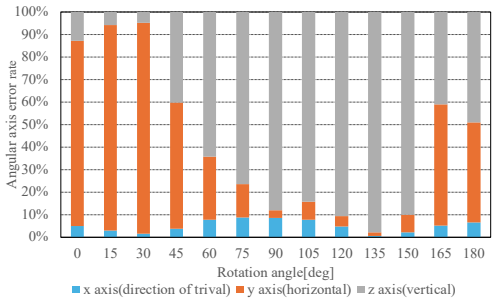


(a) Unit size: 0.64 m.



(b) Unit size: 1.02 m.

Fig. 9. Error percentage for each axis relative to changes in unit size.

comparing the estimated coordinates with the ground truth.

B. Evaluation Results of Position Estimation Based on Measured Values Relative to Unit Size

For both unit sizes, measurements were performed at a fixed distance of 2 m while varying the orientation angle of the units. Fig. 8 shows the estimation errors between the predicted positions and the ground truth; Fig. 9 shows the contribution of the errors along each axis to the total error. Although the devices used in this experiment had a resolution in the order of centimeters and the measurements included noise, the position was estimated reasonably well for all orientation angles and both unit sizes. Furthermore, focusing on the difference in the unit size, the results were consistent with the analysis described in Section IV-C; at the same relative distance, the smaller unit size produced higher estimation errors.

In addition, examining the proportion of errors along each axis revealed that errors tended to accumulate more significantly on the y- and z-axes than on the x-axis along which the units were arranged. This pattern is likely due to limitations in the device resolution and the influence of ranging noise, which complicates the orientation estimation.

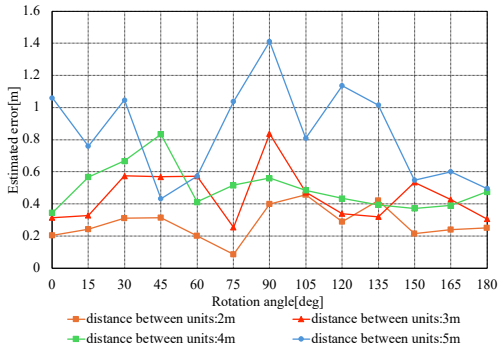


Fig. 10. Estimated error due to distance variation.

These results indicate that stable position estimation can be achieved in real environments using larger unit sizes. Conversely, when a compact unit size is required, the accuracy may be improved using devices with a higher ranging resolution or by employing antenna designs that account for directional characteristics.

C. Evaluation of Position Estimation based on Actual Measurement Data for Unit Size

Fig. 10 shows the estimation errors for the orientation angle at each inter-unit distance; Fig. 11 shows the error proportions along each axis. Experiments were conducted under a unit size of 1.02 m.

Examination of the distance estimation error revealed that the error increased with increasing inter-unit distance. This trend aligns with the simulation results discussed in Section IV-C. At an inter-unit distance of 2 m, the estimation error varied only slightly with respect to the orientation angle and remained stable. However, as the distance was increased to 4 and 5 m, the variation in the error became more pronounced.

The primary cause of this increased variability is that at certain orientation angles, the accumulation of errors makes it difficult for the optimization process to satisfy the geometric constraints. These resulting inaccuracies lead to changes in the estimated orientations of the units. Moreover, with increasing distance between the units, changes in the orientation angle were less clearly reflected in the ranging measurements, which further contributed to an increase in the estimation error.

Furthermore, as shown in Fig. 11, the distribution of errors along each axis indicates that regardless of the inter-unit distance, errors tended to accumulate more significantly on the y- and z-axes than on the x-axis, along which the units were aligned. This behavior can be attributed to changes in the geometrically dominant axes of rotation caused by the orientation of the unit. As the unit rotates, the axis about which the geometric rotation is the most sensitive shifts, resulting in a periodic change in the direction of error accumulation.

(b) Distance between units: 3 m.

(c) Distance between units: 4 m.

(d) Distance between units: 5 m.

Fig. 11. Percentage of axis error relative to distance change.

D. Limitation of the Proposed Method

The simulation results confirm that the proposed system can estimate the relative positions up to approximately five times the device size. Therefore, this method provides an effective positioning range for applications requiring local sensing and individual communication, such as collective behavior in swarm robotic systems [25]. However, as demonstrated in hardware experiments, when the method is implemented by integrating multiple commercially available devices, the positioning performance is limited by the differences in the ranging schemes of each device, such as the time of arrival or angle of arrival, as well as by their output resolutions. This makes it necessary to consider approaches that integrate all the required functions into a single device or to develop advanced optimization techniques suitable for implementation using heterogeneous composite devices.

VI. Conclusion

This study investigated a three-dimensional relative positioning method using UWB wireless communication as a step toward ideal decentralized cooperative control. We proposed a relative position estimation method based on inter-vertex distances, along with a strategy to improve the estimation accuracy by eliminating local solutions using the k-means clustering algorithm. Simulation results demonstrated that the proposed method achieves accurate positioning at inter-unit distances of up to approximately five times the device size. Furthermore, experiments conducted with actual devices confirmed that the observed performance trends were consistent with the simulation results. These findings suggest that the proposed method is a practical and effective solution for robotic systems (such as swarm robotic systems) that rely on local information.

This study presents a three-dimensional relative position estimation based on a geometrically minimal regular tetrahedral structure. The proposed approach provides a design guideline that simplifies the hardware configuration of robotic systems while preserving redundancy and scalability. It enables relative localization that is inherently aligned with each robot's local coordinate frame, facilitating seamless integration with motion control and cooperative behaviors. These features are particularly advantageous in real-world environments, such as warehouse transportation systems—where robots are frequently added or replaced—as well as in disaster response and infrastructure inspection scenarios, where prior environmental preparation is difficult.

In addition, the quantitative evaluation of the effective localization range relative to unit size provides a practical metric for designing swarm robotic systems based on relative positioning. This study establishes a framework that enables mobile agents to autonomously estimate their relative positions without relying on fixed anchors or centralized management—assumptions traditionally made in UWB-based localization systems—while simultaneously achieving both local sensing and individual communication using a single UWB device configuration.

Future work will address several challenges toward the

practical deployment of the proposed three-dimensional relative positioning method in swarm robotic systems. First, the influence of ranging errors and device resolution on positioning accuracy must be considered, as experimental results revealed performance degradation compared with ideal simulation conditions. Appropriate parameter design tailored to the resolution characteristics of UWB devices is therefore required, and error-aware weighting or sensor fusion approaches are expected to mitigate the accumulation of errors along specific axes.

Second, the integration of relative position estimation with orientation estimation remains an important issue. Although the proposed method primarily estimates translational components, experimental results suggest that changes in unit orientation significantly affect ranging measurements and contribute to increased errors, particularly along the y- and z-axes. Extending the method to jointly estimate position and orientation is thus a promising direction.

Finally, real-time implementation is essential for practical swarm robotic applications. While this study focused on offline accuracy evaluation, future work will investigate computational optimization and real-time performance to enable stable cooperative behaviors in real-world environments.

Explainable AI for Enhancing Awareness of Academic Stress Among International University Students

Ahmed Almathami[1], Richard Stone[2]
Department of Information Systems, King Abdulaziz University, Rabigh, Saudi Arabia[1]
Human-computer Interaction Department, Iowa State University, Ames, USA[1]
Industrial and Manufacturing Systems Engineering Department, Iowa State University, Ames, USA[2]

***Abstract*—Academic stress is a common challenge in higher education, especially for international university students who must adapt to new academic systems, expectations, and learning environments. In recent years, artificial intelligence has been increasingly used to analyze academic data and estimate student stress. However, most AI-based systems prioritize prediction accuracy over providing valuable support for student understanding. As a result, students may receive stress-related indicators without a clear explanation of how these results relate to their academic tasks or activities. This state-of-the-art review discusses current research on explainable artificial intelligence in the field of academic stress and student awareness. Based on literature published between 2020 and 2025, this review synthesizes work from educational technology, learning analytics, and explainable AI from a Human–Computer Interaction perspective. The analysis focuses on the representation of academic stress, the design of explanatory frameworks, and the extent to which existing systems facilitate students' ability to interpret and reflect on their work. The review finds that awareness is rarely treated as an explicit outcome in existing research. Although explainable models are increasingly used, the explanations they produce are often technical and not student-oriented. International students are an underrepresented group in the literature, despite the apparent differences in their academic preparation, linguistic ability, and expectations. Consequently, these shortcomings limit the effectiveness of artificial intelligence systems as tools for enhancing student awareness. This review highlights the need to shift from prediction-oriented approaches toward awareness-oriented explainable AI systems that prioritize student understanding. By emphasizing human-centered explanation design and inclusive evaluation, future research can better support students in making sense of academic stress within diverse higher education environments.**

***Keywords*—Explainable artificial intelligence; academic stress; student awareness; international university students; learning analytics; Human–Computer Interaction**

I. Introduction

Academic stress is a common experience in higher education, but it is often more challenging for international university students. These students must adapt to new academic systems, assessment styles, teaching practices, and expectations, usually while studying in a second language [1]. As universities increasingly rely on digital platforms and data-driven tools, students are exposed to a range of academic indicators, including grades, progress dashboards, and automated feedback. While these tools are intended to support learning, they can also generate confusion when students do not clearly understand how the information relates to their academic situation [2]. Unmanaged academic stress may further influence academic decision-making, increasing the risk of maladaptive coping behaviors in high-pressure learning contexts [3]. These challenges highlight the importance of supporting students in interpreting academic information to reduce stress and promote informed decision-making.

In recent years, artificial intelligence (AI) has been widely adopted in educational environments to analyze student data and support academic decision-making [4]. AI-based systems are increasingly used to estimate academic stress, anticipate risk, and identify patterns related to engagement and performance [5]. Although such systems often promise early insight and personalized support [6], many present their results as scores, categories, or alerts without sufficient explanation [7]. When explanations are limited or unclear [8], students may struggle to interpret system outputs and relate them to their daily academic activities.

Research in Human–Computer Interaction and learning analytics suggests that awareness is not achieved simply by presenting information. Rather, awareness involves processes of understanding, interpretation, and reflection [9]. Students must be able to make sense of academic signals and understand how factors such as workload, deadlines, or engagement patterns contribute to their experiences [10]. Without adequate support for this sensemaking process, data-driven feedback may remain abstract or even increase uncertainty. This challenge is particularly pronounced for international students, who may not share the same academic background, language proficiency, or implicit assumptions as system designers [11], which further complicates how system outputs are interpreted in practice.

Explainable Artificial Intelligence (XAI) has emerged as an approach to address concerns related to transparency and trust in AI systems. XAI seeks to make model outputs more understandable by clarifying how and why a system produces a particular result. In educational contexts, explainability can transform AI systems from opaque predictors into tools that support student understanding. However, many existing explainable approaches are designed primarily for researchers or developers and rely on technical explanations that are not always meaningful to students [12], [13]. As a result, their effectiveness in student-facing contexts remains limited.

At the same time, there is increasing recognition that student-facing AI systems should be evaluated not only by technical performance, but also by how well they support students' understanding of their academic situation [8], [14]. For international students, explainability must account for language clarity, cultural differences, and unfamiliar academic norms [15], [16]. Explanations that do not consider these factors may fail to foster awareness and reduce uncertainty, thereby limiting their usefulness across diverse educational contexts.

This state-of-the-art review offers a conceptual reframing of explainable artificial intelligence in academic stress research, shifting the focus from prediction-oriented systems to awareness-oriented, student-facing systems that prioritize understanding, interpretation, and reflection, particularly for international university students. The review synthesizes recent literature from educational technology, learning analytics, and explainable AI to examine how existing systems convey stress-related information, how explanatory components are designed, and the extent to which they support student awareness. By identifying current practices, limitations, and research gaps, this work outlines directions for future research that place student understanding at the center of explainable AI design.

This study is structured as follows:

- Section II: Presents the review methodology, including the literature search strategy, inclusion and exclusion criteria, and the analysis approach.
- Section III: Academic stress among international university students, focusing on previous studies and key stress-related factors in higher education contexts. Student awareness and reflection in educational technologies and learning analytics systems, with a focus on the challenges faced by international university students. Artificial intelligence–based approaches to academic stress, examining the methods used to analyze and estimate stress in higher education. Explainable Artificial Intelligence for student-facing systems, introducing key concepts, explanation types, and design considerations. Explainable Artificial Intelligence and student awareness of academic stress, synthesizing the literature to highlight how explainability can support awareness.
- Section IV: Presents a detailed discussion on the study insights by highlighting practical implications for student-facing AI systems.
- Section V: Conclusion summarizes the main insights of the review and outlines limitations and directions for future research.

II. Review Methodology

This manuscript employs a state-of-the-art approach to review the recent literature on explainable artificial intelligence, academic stress, as well as student awareness in higher education. The purpose of this review is not to conduct a meta-analysis and quantify effect sizes, but to synthesize current trends in research, methodological designs, and conceptual gaps across interconnected disciplines.

A. Literature Search Strategy

The literature review encompassed peer-reviewed journal articles and conference proceedings published between 2020 and 2025. Such a temporal scope was chosen to reflect recent developments within explainable artificial intelligence, learning analytics, and educational technologies that are facing students. Major academic databases were searched, including Google Scholar, Scopus, Web of Science, and the scientific journals and books in the databases of the Institute of Electrical and Electronics Engineering (IEEE), the Association for Computing Machinery (ACM), and Springer.

Search queries combined terms related to academic stress and student awareness, as well as artificial intelligence and explainability. Examples of the search keywords are academic stress, international students, learning analytics, explainable AI, interpretable machine learning, student dashboards, and student awareness. These keywords were used in various combinations in order to ensure broad coverage across disciplines.

B. Inclusion and Exclusion Criteria

Studies were selected, if they satisfied the following criteria:

- Revolved around education at the higher education level,
- Looked at academic stress, learning pressure, or other related experiences in school,
- Included AI, machine learning, learning analytics, or data-driven systems, and
- Discussed system outputs, explanations, or student-facing feedback.

Studies were excluded, if they were solely clinical diagnosis studies, stressed that they were non-academic, or focused on populations outside higher education. Papers that were purely technical in nature with no relevance to student interaction or interpretation were also excluded.

C. Study Selection and Analysis

After the initial search was carried out, titles and abstracts were evaluated for relevance. The full texts of the selected papers were then read in detail. During this process, the studies were grouped into four main areas: academic stress among foreign students, student awareness and reflection tools, AI-based stress analysis, and explainable AI (XAI).

Rather than extracting numerical results, the objective of the analysis was to find recurring themes, design patterns, and evaluation practices and limitations reported in the literature. Particular attention was paid to the presentation of information to students by systems, as well as whether explanations are designed to support understanding and awareness.

D. Scope and Methodological Considerations

This review focuses more on conceptual synthesis rather than completeness. While the search strategy was designed to include major and influential studies, the possibility exists that some relevant work may have been excluded. Additionally, the review is limited to peer-reviewed English-language publications, which may limit the coverage of regional research or non-English language research.

Despite these limitations, the methodology provides a structured and transparent foundation for understanding the current directions of research and where explainable AI can be effectively utilized to support. Fig. 1 presents an overview of the study workflow, illustrating the main stages of the review process and analysis approach.

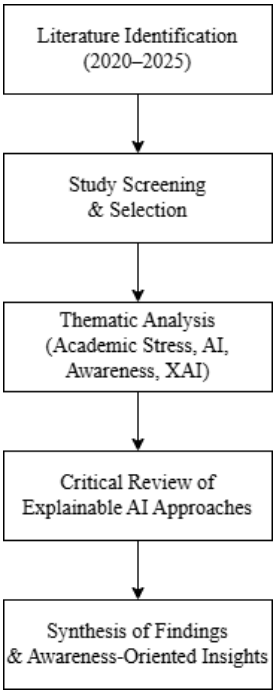

Fig. 1. Overview of the study workflow and analysis process.

III. Related Works

A. Academic Stress among International University Students

Academic stress is a common experience in higher education, but it is often more intense and complex for international university students [1]. Unlike domestic students, international students must adapt not only to academic workload but also to new educational systems, teaching styles, assessment methods, and communication norms [17]. These adjustments require continuous effort and can increase uncertainty during everyday academic tasks [18]. Over time, this sustained pressure may accumulate, affecting students' confidence, motivation, and sense of academic control [19].

Many studies showed that international students face additional academic challenges related to understanding expectations, interpreting feedback, and managing deadlines in a second language [20]. Language proficiency influences how students read course materials, participate in discussions, and interpret assessment criteria [21]. Even students with strong academic backgrounds may struggle when academic instructions or feedback are unclear. As a result, students often invest more time and effort in their studies while still feeling uncertain about their performance, which can intensify academic stress.

Recent research highlights that academic stress among international students does not arise from a single source. Instead, it develops through the interaction between academic demands, institutional systems, and students' ability to correctly interpret academic information [1]. Learning management systems, automated grading, and online dashboards are now widely used; however, they often present information in ways that assume familiarity with local academic culture. For international students, this assumption does not always hold [22]. When academic information is misunderstood, stress may persist even in situations where academic performance is objectively adequate.

Several studies indicate that many academic stress systems focus primarily on measuring or predicting stress levels rather than helping students understand the academic conditions that contribute to stress. For example, AI-based approaches often estimate stress using survey responses or behavioral data collected from digital systems [23]. However, these systems typically offer limited explanation of how workload patterns, assessment timing, or engagement behaviors contribute to stress experiences. As a result, students may receive numerical scores or categorical labels without sufficient context, which can limit their ability to reflect and increase uncertainty [24].

A further challenge is that academic performance indicators are often presented without adequate explanation. A low score, delayed feedback, or system warning may be interpreted as a serious academic failure, even when it reflects a temporary or situational issue [25]. Without contextual clarification, students may overestimate the seriousness of academic signals and experience unnecessary pressure [26]. This heightened stress can impact emotional well-being and decrease students' willingness to seek help or express concerns [27].

Importantly, prior research suggests that sustained academic stress can shape students' academic behavior, particularly when stress is driven by high-performance demands and perceived lack of control. When students experience ongoing pressure related to grades, time constraints, and fear of failure, stress can reduce their ability to engage in deliberate and reflective decision-making. Under such conditions, students may shift their focus from long-term learning goals toward short-term strategies aimed at avoiding negative academic outcomes. In some cases, this shift is associated with an increased risk of academic misconduct, such as plagiarism or inappropriate collaboration, particularly in high-stakes or time-constrained situations. Evidence from multiple educational contexts suggests that academic pressure, anxiety, and perceived consequences are among the most consistent situational factors associated with dishonest behavior. From this perspective, academic dishonesty is better understood as a stress-related risk behavior that emerges under specific conditions of pressure and uncertainty, rather than as a stable individual trait or personal moral failure [28], [29].

Overall, existing research suggests that academic stress among international students is shaped by multiple interacting academic, linguistic, and systemic factors. When stress is not well understood or contextualized, it can negatively affect learning, engagement, and academic decision-making. These findings highlight the need for approaches that not only monitor stress levels but also support students in understanding the causes and consequences of academic stress within their academic environment.

B. Student Awareness and Self-Reflection in Educational Technologies

In educational technology research, student awareness is often described as an important step that helps learners understand their academic situation [30]. Awareness does not mean only that information is available. It means that students can recognize important academic signals, understand their meaning, and relate them to their own study habits. In university contexts, this includes understanding workload, deadlines, feedback, engagement, and progress across different courses [31].

Many students receive a large amount of academic information every day. However, having access to information does not always mean that students understand it well. This is especially true when the information is presented in abstract or numerical forms. As a result, students may view the data but still feel uncertain about its implications for their learning [32].

1) Awareness beyond showing information: Many educational systems present information such as grades, progress bars, activity levels, or performance summaries. These elements are often designed to support awareness. However, previous research indicates that simply presenting information is often insufficient. Students may look at charts or numbers, but still struggle to understand how these indicators relate to their academic situation.

Research in Human–Computer Interaction explains that awareness is an active process. Students need time and support to interpret academic signals and understand how different factors are connected. When systems fail to provide this support, dashboards and analytics tools can be confusing or even stressful [33]. Some students stop using these tools because they do not see a clear value in them [34].

Several review studies report that students usually check dashboards only when they feel worried or uncertain. When the information does not change or is difficult to understand, students may lose interest over time [35], [36]. This suggests that awareness requires explanation and context, not just visual displays.

2) Student-facing learning analytics dashboards: Learning analytics dashboards are one of the most common tools used to support student awareness. These dashboards usually show indicators related to engagement, progress, or predicted outcomes. While many students claim that dashboards are useful, research reveals mixed results regarding their effectiveness in fostering real understanding and long-term use .

Students often report that they do not clearly understand why certain indicators are high or low. They may also be unsure which academic activities influenced the results or what actions they should take next. In many systems, explanations are either missing or written in technical language that is difficult for students new to academic analytics to understand [37], [38].

For international students, these problems can be even stronger. Dashboards are often designed based on local academic norms, which may not be familiar to international students. Recent studies suggest that dashboards are more effective when they clearly explain indicators, display changes over time, and connect results to specific academic activities. However, these features are still not widely used in practice [39], [40].

3) Reflection and self-monitoring tools: Some educational technologies focus on supporting student reflection and self-monitoring. These tools encourage students to reflect on their academic activities and identify patterns in their behavior. Reflection tools often include summaries, weekly reports, or simple prompts that ask students to consider what worked well and what did not.

Research indicates that reflection is more likely to occur when feedback is both timely and personalized. When systems only show raw data, students may feel overwhelmed or unsure how to use the information. On the other hand, tools that guide reflection through concise explanations or simple descriptions can facilitate a deeper understanding [41], [42].

4) Awareness challenges for international students: International students may encounter additional challenges when utilizing awareness and reflection tools. Academic systems, grading styles, and feedback practices can differ significantly from what students have experienced before. Because of this, international students may interpret academic indicators in ways that were not intended by the system designers [43].

Recent studies show that unclear or ambiguous feedback can increase confusion for international students. When explanations are missing, students may misinterpret academic signals and feel unnecessary pressure. Language difficulty and unfamiliar academic terms can also reduce engagement with dashboards and analytics tools [44].

In addition to language and feedback interpretation, international students often face challenges related to academic norms and expectations. Practices such as class participation, independent study, and self-directed learning may be emphasized differently across educational systems [45]. When awareness tools present indicators related to engagement or participation, international students may not always understand how these indicators align with instructors' expectations. This can create uncertainty about whether they are performing adequately or falling behind [46].

Another challenge is related to comparison and benchmarking features commonly used in dashboards. Some systems show how a student's activity or performance compares to class averages or peer groups. While such comparisons are intended to support awareness, international students may interpret them negatively, especially if they are

unfamiliar with local grading distributions or participation norms. Without explanation, comparison-based indicators may increase pressure rather than support understanding.

Time-related indicators can also be difficult to interpret. Academic systems often track time spent on learning platforms, assignment submission times, or activity frequency. For international students, these indicators may not fully reflect their actual effort, especially when learning in a second language requires additional time for reading and comprehension. When systems do not explain how time-related data is interpreted, students may feel that their effort is not accurately represented [47].

Furthermore, international students may have limited opportunities to clarify system feedback through informal communication. Domestic students may ask peers or instructors for clarification more easily, while international students may hesitate due to language concerns or cultural norms. In such cases, awareness tools become even more important as a source of guidance. When these tools lack a clear explanation, students are left without reliable support for understanding their academic situation [34].

Overall, the literature suggests that student awareness is not automatically created by providing data. Awareness is an active process that requires interpretation and reflection. Although dashboards and analytics tools are widely used, they often provide limited support for understanding. Reflection works better when systems offer explanation and context. International students may face additional challenges because of language and academic culture differences. These insights help explain why more transparent and explainable approaches are needed, which will be discussed in the next sections.

C. Artificial Intelligence in Academic Stress Research

In recent years, Artificial Intelligence (AI) has been increasingly utilized in educational research to gain a deeper understanding of students' academic experiences. One important area where AI has gained attention is the study of academic stress. Researchers use AI models to analyze large datasets and identify patterns that are difficult to capture using traditional statistical methods. These approaches aim to provide insights into how different academic and contextual factors relate to students' stress levels [23].

Most AI-based studies in this area focus on detecting, predicting, or classifying academic stress. The goal is often to identify students who may be experiencing high stress or to estimate stress levels based on observable data. While these approaches can provide useful information at a system level, they often do not focus on how students themselves understand or utilize the results [48].

1) Data sources used in AI-based stress studies: AI models for academic stress commonly rely on different types of data. Survey-based data are one of the most widely used sources of information. Students are asked to report their stress levels, academic workload, study habits, or learning experiences. These self-reported measures are then used as inputs for machine learning models [48].

In addition to surveys, some studies use behavioral data collected from learning management systems. This may include information such as login frequency, time spent on course materials, assignment submissions, and interaction with online resources. Other studies combine academic data with contextual or demographic variables, such as year of study, major, or learning environment [49].

Recent research has also explored the use of multimodal data, where survey responses are combined with behavioral or contextual indicators. These approaches aim to capture a more comprehensive picture of academic stress by considering multiple sources, simultaneously [50].

2) Machine learning techniques and model performance: A wide range of machine learning techniques has been applied in academic stress research. Commonly used models include logistic regression, decision trees, support vector machines, random forests, and gradient boosting methods. Some studies also explore neural networks, especially when working with larger or more complex datasets [23], [51].

Many papers report strong model performance in terms of accuracy, precision, recall, or F1-score [48]. These results are often presented as evidence that AI can successfully model academic stress. While performance metrics are important, they primarily reflect how well a model fits the data, rather than its utility for students or educators in real-world contexts [52].

As a result, AI-based stress models are often evaluated from a technical perspective. Less attention is given to how the model outputs are presented to students or how students might interpret the results in relation to their academic activities [53].

3) Focus on prediction rather than student experience: A common characteristic of AI-based academic stress research is its emphasis on prediction outcomes. Many studies aim to answer questions such as whether a student is experiencing high or low stress, or which factors are most strongly associated with stress levels. These questions are important, but they often place students in a passive role [54].

In many systems, students receive a label, score, or category that summarizes their level of stress. However, the reasoning behind this output is not always clear. Without explanation, students may not understand how their academic behavior, workload, or engagement contributed to the result. This can limit the usefulness of AI systems for supporting awareness or reflection [55].

Recent studies using interpretable models show that it is possible to identify key contributing factors, such as workload, learning goals, or study environment [56]. However, these explanations are often reported for researchers or practitioners rather than designed for direct student interaction [57].

Overall, the literature indicates that AI has become a significant tool for investigating academic stress. Researchers use different data sources and machine learning techniques to predict stress levels and identify contributing factors. However, most existing work focuses on technical performance and prediction accuracy. The role of AI in supporting students' understanding of their academic situation remains limited. These observations motivate further exploration of explainable and student-facing AI approaches, which are discussed in the next section.

D. Explainable Artificial Intelligence (XAI): Concepts and Approaches

As Artificial Intelligence systems become more common in education, concerns about transparency and understanding have also increased [12]. Many AI models can produce accurate predictions, but their internal decision processes are often difficult to understand. This has led to growing interest in XAI [58]. XAI aims to make AI systems more transparent by helping users understand how and why a model produces a specific output [59].

In educational contexts, explainability is crucial because AI systems are increasingly influencing decisions related to learning, performance, and support. When students receive predictions or indicators without explanation, they may feel confused or uncertain about how to interpret them. XAI offers an opportunity to shift AI systems from being opaque tools to systems that can support understanding and awareness [60].

1) What is explainable AI ?: Explainable AI refers to methods and techniques that allow users to understand the reasoning behind AI model outputs [59]. Instead of providing only a final prediction or score, an explainable system offers additional information that clarifies which factors influenced the result and how these factors interacted with each other [61].

Explainability can take different forms. Some explanations describe the overall behavior of a model, while others focus on explaining individual predictions [62]. In educational systems, explanation is often needed at the individual level, where students want to understand why a particular result applies to them [63].

Importantly, explainability is not only a technical concept. It also involves communication and design. An explanation that is mathematically correct may still be difficult for students to understand if it is presented in complex or technical language [12], [64].

2) Common explainable AI techniques used in education: Several XAI techniques are commonly used in educational and student-related research. Feature importance methods show which input variables contribute most to a model's predictions. These methods help identify factors such as workload, engagement, or study patterns that influence outcomes [65].

Other approaches include rule-based explanations, where model decisions are expressed as simple rules, and example-based explanations, which show similar past cases to help users understand predictions [66]. Some studies also employ visualization techniques to present explanations in graphical form [67].

Among these methods, post-hoc explanation techniques such as SHAP are widely used because they can be applied to many types of machine learning models. These techniques are popular in research because they provide detailed insights into model behavior. However, they are often designed for researchers or analysts, rather than for direct use by students [68], [59]. Table I below shows common explainable AI (XAI) techniques used in education.

3) Explainability from a human-centered perspective: From a Human–Computer Interaction perspective, explainability should be considered as part of the interaction between the user and the system [64]. An explanation is useful only if it helps the user understand the system output and relate it to their own experience [75]. This means that explanations should be clear, concise, and relevant to the user's context [76].

TABLE I. COMMON EXPLAINABLE AI (XAI) TECHNIQUES USED IN EDUCATION

XAI Technique	Educational Use	Example
SHAP (SHapley Additive exPlanations)	Feature attribution indicating the importance of each variable for making predictions (e.g., risk, grades, dropout).	Student success prediction, identification of at-risk learners, understanding key drivers to performance, stability analysis of models,
LIME (Local Interpretable Model-agnostic Explanations)	Local surrogate models to explain black box model single predictions	Explaining individual grade predictions, supporting decisions of teachers about particular students.
Partial Dependence Plots (PDPs) / Global Feature Importance	Global perspective of the relationship between features and results, ranking the highest impact factors.	Course failure risk, dropout prediction, and identifying important behavioral and academic indicators
Transparent / Interpretable Models (e.g., decision trees, rule-based models, simple linear models)	Using inherently interpretable models rather than post hoc explanations.	Many AI in Education (AIED) systems (dashboards, adaptive tutors) are designed to make it more directly understandable to teachers and students.
Open Learner Models (OLMs)	Visual/structural representations of a learner's knowledge/skills, which make system inferences explicit.	Student-facing dashboards, self-regulated learning support, and intelligent tutoring systems.
XAI for Trees / Tree-based Explanation Methods	Global and local explanations tailored to ensembles of decision trees.	Explaining learning analytics models based on tree ensembles (e.g., dropout and performance models).
Clustering-based Explanations (unsupervised XAI)	Explaining clusters or profiles (e.g., learner groups) to educators through visual and text	Teacher dashboards that display student knowledge profiles and similarities.
Multimodal / Generative-enhanced XAI	Combining traditional XAI (i.e., SHAP, LIME) with generative models to obtain personalized, multimodal explanations.	Transparent adaptive learning systems tailor explanations to different user types (e.g., students, teachers, admins).
Prescriptive Analytics with XAI	Translating explanations into suggested action and/or feedback to learners and instructors	Systems that help not only identify at-risk students, but that produce evidence-based, human-readable advice

Adapted from [12], [69], [70], [71], [72], [73], [74].

Research indicates that overly complex explanations can erode trust and lead to increased confusion. When explanations include too many variables or technical terms, users may overlook or misinterpret their meaning [77]. On the other hand, explanations that are too simple may fail to provide meaningful insight [78].

For students, especially international students, explanations should be written in clear, accessible language and connected to familiar academic concepts and activities. Explanations that refer directly to assignments, deadlines, or study behaviors are more likely to support understanding than abstract statistical descriptions [79], [80].

4) Explainable AI in student-facing systems: In recent years, several studies have explored the use of explainable AI in student-facing systems. These systems aim to provide students with insights into predictions related to performance, engagement, or stress. Some studies show that explanations can help students better understand system outputs and reflect on their academic behavior [8], [81].

However, many explainable systems still prioritize technical transparency over student understanding. Explanations are often presented as feature rankings or numerical values, which may be difficult for students to interpret. In some cases, explanations are available only to instructors or researchers, rather than directly to students [82], [13].

This highlights the importance of designing explainable AI systems that are not only accurate and transparent but also usable and meaningful for students. Explainability should support awareness and reflection, rather than simply revealing model internals [16], [83].

In summary, explainable AI provides methods to make AI

systems more transparent and understandable. In educational contexts, explainability has the potential to support student awareness by clarifying how predictions are generated. However, explainability is not only a technical challenge, but also a design and communication challenge. To be effective for students, explanations must be human-centered, easy to understand, and connected to academic experiences. These considerations are particularly important when designing systems for diverse student populations, including those from international backgrounds.

E. Explainable AI for Enhancing Awareness of Academic Stress

Explainable AI presents a significant opportunity to transcend traditional academic stress systems that primarily focus on detection or prediction [84]. Instead of treating stress as a hidden state that needs to be identified by the system, explainable AI allows students to see how academic activities, workload, and engagement patterns are connected to their stress experiences. In this way, explainable AI can support awareness rather than merely monitoring.

In student-facing systems, awareness is created when students understand why the system produces a certain output and how this output relates to their daily academic life. Explainable AI can support this process by making model reasoning more visible and meaningful. When explanations are clear and relevant, students can reflect on their academic behavior and gain a better understanding of the sources of pressure [85], [86].

1) From prediction to awareness: Most existing AI-based academic stress systems are designed to answer predictive questions, such as whether a student is experiencing high or low stress. While these predictions may be useful at an institutional level, they often provide limited value to students if the reasoning behind them is unclear. A stress score or category alone does not explain what caused the stress or how it developed over time [87].

Explainable AI shifts the focus from outcomes to the processes behind them. By showing which academic factors contributed to a prediction, explainable systems allow students to connect system feedback to concrete experiences, such as heavy coursework, approaching deadlines, or reduced engagement. This connection supports awareness by helping students recognize patterns rather than react to isolated indicators [88].

2) Supporting reflection through explanation: Reflection plays a key role in awareness. When students can reflect on their academic activities and understand how these activities relate to stress, they are more likely to develop meaningful insights [89]. Explainable AI can support reflection by presenting explanations that highlight relevant factors and changes over time, allowing for a deeper understanding of the underlying processes.

For example, explanations that show how workload increased during certain weeks or how engagement decreased before stressful periods can help students reflect on their academic routines [90]. Studies suggest that explanations are more effective when they are presented in a narrative or descriptive form rather than as technical graphs or numerical values [91].

Explainable AI can also help reduce uncertainty. When students understand why a system output appears, they may feel more confident in interpreting it and less likely to assume the worst [92]. This is particularly important for international students, who may already experience uncertainty when interpreting academic feedback [59].

3) Designing explainable systems for students: For explainable AI to effectively support awareness, explanations must be designed with students in mind. Many current explainable systems rely on feature importance rankings or complex visualizations. While these methods are useful for researchers, they may be difficult for students to understand or apply.

Student-centered explainable systems should use simple language and relate explanations directly to academic activities. Instead of stating that a variable has a high contribution, explanations could describe how specific behaviors or workload patterns influenced the system output. This approach helps students connect explanations to their own experiences [12], [81].

Another important design consideration is timing. Explanations should be provided at moments when students are most likely to reflect, such as after completing an assignment or during weekly reviews. When explanations are delivered at appropriate times, they are more likely to support awareness rather than add to cognitive load [93], [94].

4) Explainable AI and international student contexts: International students form a highly diverse group, not only in terms of language ability, but also in academic training, assessment experience, and expectations about feedback. Students arrive from educational systems that differ in grading standards, teaching styles, and communication practices. As a result, the same academic signal or system output may be interpreted in very different ways [95]. Explainable AI systems that aim to support awareness must therefore consider this diversity rather than assume a shared academic background [96].

One challenge for international students is that many AI-generated explanations are implicitly designed around local academic norms and expectations. For example, explanations may reference participation levels, submission timing, or comparisons with peers without clarifying why these indicators are relevant. For international students who are still learning how the academic system operates, such explanations may increase uncertainty instead of reducing it [97]. Without contextual framing, students may misinterpret system feedback as a sign of poor performance or failure [98].

Language also plays an important role in how explanations are understood. Even when international students have sufficient proficiency to complete coursework, technical or abstract explanations can be difficult to interpret. Terms such as "engagement score", "risk level", or "feature contribution" may not be meaningful without additional clarification [99]. Explainable AI systems that utilize simple language and concrete references to academic activities, such as assignments,

exams, or study routines, may be more accessible to international students [100].

Another important factor is the emotional interpretation of explanations. International students may already experience uncertainty or self-doubt when navigating a new academic environment [101]. When explanations are unclear or overly complex, students may focus on negative interpretations rather than reflective understanding [102]. In contrast, explanations that align with students' daily academic experiences can help them make sense of feedback in a calmer and more constructive way [103].

Recent studies suggest that explainable systems can support trust when explanations align with students' lived experiences and expectations. When students recognize their own academic behavior in the explanation, they are more likely to accept the system output and reflect on it. However, when explanations conflict with students' perceptions or appear disconnected from their actual experience, trust can decrease, and students may ignore or reject the system feedback [8], [104].

Finally, international students may have fewer opportunities to seek informal clarification from peers or instructors [105]. This makes explainable systems particularly important as a source of guidance. If explanations are not clear or accessible, students may be left without support for understanding their academic situation. This highlights the importance of carefully designing and evaluating explainable AI systems that account for linguistic, cultural, and academic diversity when supporting student awareness [95].

IV. Discussion

This review synthesizes research from the domains of educational technology, learning analytics, and explainable artificial intelligence to enhance our understanding of how AI-based systems can promote students' awareness of academic stress. Across these bodies of literature, a common theme is evident: whilst universities increasingly rely on appropriately data-driven and AI-supported systems, students often face problems arising from the implications of this information for their personal academic situation. The presence of data, indicators, or predictions does not necessarily lead to understanding; students must actively make sense of system outputs.

An important insight from the reviewed studies is that academic stress experienced by international students is primarily constructed through the ongoing academic systems in institutions, rather than being due to discrete individual characteristics. Peak workloads, assessment scheduling, modalities of feedback, and the use of digital learning platforms collectively shape students' experience and understanding of academic pressure. When these components are communicated through dashboards or AI-generated indicators without sufficient textual explanations to aid understanding, students often struggle to align system feedback with their normal institutionalized educational routines. These dynamics help explain why some student-facing systems are considered unhelpful or stressful, even when they are highly technically precise.

Empirical studies indicate that many AI-based approaches to academic stress primarily focus on predictive performance measures rather than understanding students' experiences and contexts. Model efficacy is typically measured by metrics such as accuracy and precision, thereby revealing the system's technical competence. Nonetheless, such metrics only imperfectly address the question of learners' apprehension of the outputs or their perceived pertinence. While occasionally interpretable modelling techniques are used, the explanations associated with them are often disseminated in researcher-centric formats, such as feature importance rankings or fancy visuals. As a result, these elucidations may not address the concrete, pragmatic questions students have about the causal underpinnings of a prediction or its relevance to their academic work.

The gap between technical explainability and student understanding highlights a growing concern in the current research environment. Explainability is often conceived as an inherent feature of the model rather than a part of an interactive process between the system and the learner. As a result, systems may be transparent at the theoretical level but opaque in practice. From a human-centered perspective, explainability should support students in developing a coherent understanding of the context in their academic world, rather than merely exposing the model's inner workings.

International students face additional challenges in this situation. Differences in scholarly culture, linguistic usage, and assessment conventions can significantly impact the interpretation of feedback, including that generated by automated systems. Packages of data are provided on a multitude of student-oriented platforms, with the implicit assumption that students will learn the common academic norms, including the criteria for adequate participation and acceptable progress. When such presumptions do not hold, international learners may misinterpret academic indicators or harbor undue apprehensions. Nevertheless, the existing literature provides little analysis of how explainable artificial intelligence systems work for international learners or of how their explanatory mechanisms can be adapted to their heterogeneous academic antecedents.

One additional limitation that pervades the literature concerns evaluation methodologies. A preponderance of studies deploy systems in short-term trials or focus on short-term usage measures rather than on long-term changes in learner comprehension. Consciousness-raising and sensemaking unfold incrementally over time through interactions and reflective practice. In the absence of longitudinal or direct assessments of understanding, it is also unclear how explainable systems can be regarded as truly able to foster awareness or simply augment information content.

Collectively, based on the evidence presented, XAI has considerable capability to augment student awareness of academic stress; however, at the same time, there is also a degree to which this potential has not been fully realized. Progress requires an overt desire for awareness and an explicit goal, rather than an implicit byproduct of data availability. Achieving this transition requires greater attention to how explanatory content is formulated, communicated, and evaluated from the learner's perspective.

Specifically for international students, XAI implementations should focus less on introducing additional

complexity and more on reducing uncertainty. The use of unequivocal terminology, the connection to tangible academic tasks, and the recognition of the 'heterogeneous experiences of the learners' can help contextualize the output of the system. Through nurturing understanding and reflection practices, XAI may transition from being an instrument of surveillance to a substantive working mechanism for students facing academic stress.

A. Practical Implications

The findings of this review point to several practical considerations for the design and use of student-facing artificial intelligence systems in higher education.

For designers of student-facing AI systems, the results suggest that awareness should be prioritized over prediction. Explanations need to be straightforward to understand, especially for students unfamiliar with technical terms. It is also important to connect explanations to everyday academic activities, such as assignments, deadlines, and study habits. Instead of showing stress scores or risk levels alone, systems should help students understand why certain academic situations may contribute to stress and how they can make sense of this information.

For developers of learning analytics dashboards, the review highlights the need to move beyond static indicators or simple rankings. Dashboards can be more helpful when they provide context, show how patterns change over time, and explain what the information means in practice. In particular, dashboards should avoid assuming familiarity with local academic norms for international students. Clear explanations of expectations can reduce confusion and help prevent unnecessary stress.

For universities that support international students, the findings suggest that AI-based student analytics tools should not focus only on identifying risk or early warning signs. Instead, these systems can be used to support understanding and encourage students to engage with available support resources. Integrating explainable dashboards into advising sessions, orientation programs, or academic support services may help international students better understand their academic situation and feel more confident navigating unfamiliar educational environments.

V. Conclusion

This study aimed to review and synthesize recent research on the use of explainable artificial intelligence to enhance students' awareness of academic stress, with a particular focus on international university students. The review examined literature from educational technology, learning analytics, and explainable AI to understand how current systems support or fail to support students' understanding of academic stressors.

The results showed that while AI-based systems are increasingly used to analyze and estimate academic stress, most existing approaches focus on prediction and technical performance rather than on student awareness. Even when explainable models are applied, explanations are often designed for researchers or system developers, not for students. As a result, many systems provide information without adequately supporting interpretation, reflection, or sensemaking, especially for students who are unfamiliar with local academic norms.

These findings highlight the importance of treating awareness as a central outcome in the design and evaluation of student-facing AI systems. Rather than assuming that access to data or predictions leads to understanding, explainable AI should be viewed as a communication and interaction process that helps students connect system feedback to their everyday academic activities. This perspective contributes to expanding our understanding of how explainable AI can play a meaningful role in educational settings, particularly within the context of Human–Computer Interaction and learning analytics.

On a practical level, these results suggest the possibility of designing explainable AI systems that help students better understand academic stress and respond to it constructively. Systems that use simple language, reference concrete academic activities, and consider diverse academic backgrounds may better support reflection and awareness, especially for international students navigating unfamiliar educational environments.

However, it is worth noting that this study is limited by its reliance on existing literature and the scope of the reviewed studies. Many of the reviewed works are short-term, focus on technical evaluation, and provide limited insight into how student awareness develops over time. In addition, relatively few studies explicitly address international student contexts or evaluate explanations from the students' perspective.

Therefore, future research is recommended to focus on awareness-oriented explainable AI designs, with a stronger emphasis on student-centered evaluation and longitudinal studies. Further work should explore how different explanation styles support understanding across diverse student populations and how explainable systems can be integrated into real academic practices over time, reinforcing a shift from prediction-focused models toward awareness-oriented, student-facing explainable AI systems.

TRI-GATE: A Tri-Modal Anti-Spoofing System for Gate Access Using Vehicle, License Plate, and Face Recognition

Muhannad Alsultan, Thamer Alghonaim, Abdulaziz Alorf*,
Bandar Alwazzan, Faisal Alsakakir, Abdullah Alhassan, Yousif Hussain
Department of Electrical Engineering-College of Engineering, Qassim University, Saudi Arabia

***Abstract*—Vehicle gate access, in general, still relies heavily on manual inspection of identification cards and visual verification by security guards, which is slow, tedious, and susceptible to spoofing. Single-modality, computerized systems that utilize license plates, vehicle appearance, and facial recognition can partially alleviate this difficulty. Still, they are prone to spoofing and generally perform poorly in real-world scenarios (e.g., glare, occlusion, and tinted glass). This study presents TRI-GATE, a tri-modal anti-spoofing framework that unifies vehicle, license plate, and face recognition within a single, real-time decision pipeline. The system employs YOLOv4-tiny for vehicle detection and a MobileNetV2-based classifier for make–model recognition, a retrained MTCNN and LPRNet pair for license plate detection and recognition on Saudi-specific datasets (17,000 images for detection and 35,000 for recognition), and RetinaFace with InsightFace embeddings, along with a linear SVM, for driver identification. An IoU-based best-frame selection scheme reduces latency by forwarding only the most informative frame to the recognition modules. Score-level fusion is then performed by a linear SVM that learns the relative importance of each modality for the final access decision. Evaluated on a dedicated tri-modal dataset, TRI-GATE achieves 97% gate-level accuracy with an end-to-end latency of 66 ms per frame (≈ 15.15 FPS), and demonstrates robust performance in a real-world gate-like deployment, substantially improving both security and operational efficiency over existing single- and bi-modal solutions.**

Keywords*—Tri-modal anti-spoofing; vehicle recognition; license plate recognition; face recognition; real-time gate access control; multimodal biometrics

I. Introduction

In most conventional vehicle gate access setups, verification still depends largely on manual inspection. Security officers typically visually inspect vehicles and confirm entry permits or identification cards by hand. While simple in principle, this routine often becomes slow, physically demanding, and susceptible to both fatigue and oversight. Delays accumulate during busy hours, creating traffic queues at the gate and inconsistent enforcement of security procedures. What raises greater concern is how easily such systems can be deceived—people with no authorization might convincingly pose as legitimate staff or slip through the gate using falsified documents.

Although automation has made considerable progress, many existing gate systems remain limited to a single mode of recognition—commonly license plate detection or facial identification. Systems built around a single identity marker are easy to compromise: plates can be cloned, and faces may go undetected under tinted glass, dim lighting, or awkward camera angles. Such limitations highlight a crucial shortfall: the absence of a unified, multimodal verification framework capable of confirming both vehicle and driver identity consistently, even amid the unpredictable and imperfect conditions of real-world environments.

This study tackles existing limitations by developing an AI-driven anti-spoofing framework that unifies vehicle detection and classification, license plate recognition, and facial recognition within a single decision pipeline. Using computer vision methods such as YOLO (You Only Look Once) and OpenCV (Open Computer Vision library), along with a Support Vector Machine (SVM) classifier, the system processes and integrates outputs from multiple models to generate intelligent access control decisions. The fusion strategy not only boosts accuracy and processing speed but also makes gate access more robust against spoofing attempts, thereby reducing unauthorized access and improving the operational efficiency and security of facility gate management.

A. Related Work

In recent years, researchers have devoted significant attention to improving the reliability of automated vehicle gate systems. Early systems mainly relied on single data sources—most often license plate recognition or basic vehicle appearance matching. These systems worked reasonably well in controlled environments but struggled when lighting changed, the camera angle shifted, or spoofing was attempted. As listed in Table I, more recent work has shifted toward multimodal approaches that combine license plate data, vehicle signatures, and even driver identity cues. This transition reflects an effort to create systems that not only identify but also verify vehicles under real-world variability. Despite these developments, many solutions still face trade-offs between speed, cost, and recognition stability, especially in real-time gate scenarios where decisions must be made in fractions of a second.

1) License Plate Recognition (LPR): License plate recognition has been studied for years and continues to play a central role in automated gate systems. Early neural models, such as WPOD-NET, demonstrated that end-to-end detection and segmentation were feasible, achieving about 89% accuracy on benchmarks such as SSIG and AOLP [1]. But while that was

Iyer *et al.* [13]	2024	YOLOv8 + EasyOCR + dlib (CNN)	License plate + driver information	Combination of 3 open Indian number plate datasets + custom Devanagari dataset	ANPR: mAP@50 = 98.35%, OCR: 88.14%, and Face Recognition: 98.34%
Mustafa *et al.* [14]	2024	MobileNet-V2 + YOLOx + YOLOv4-tiny + PaddleOCR + SVTR-tiny	License plate + Vehicle	COCO, Stanford Car Dataset, and Firat University dataset	97.5% (overall accuracy)
Ramajo-Ballester *et al.* [15]	2024	YOLOv5 + EfficientNetB0 (FastReID)	License plate + Vehicle	UC3M-LP and UC3M-VRI	mAP = 0.893 (detection), 0.764 (OCR), accuracy = 0.979 (re-ID), and ≈ 58.1 ms per image (real-time capable)
Khor *et al.* [16]	2024	Multi-Task YOLOv8 (multi-head YOLOv8 for OCR, LP detection, and VCR)	License plate + Vehicle	In-house multi-labelled dataset (1555 images) + synthetic augmentation using TRDG	mAP_{50} = 0.778 (OCR), 0.963 (LP), 0.881 (VCR); Average = 0.874
AlDahoul *et al.* [17]	2025	VehiclePaliGemma	License plate + Vehicle	258-image Malaysian license plate dataset (Tapway Sdn Bhd) + 600 synthetic images (for fine-tuning)	87.6% (plate accuracy), and 97.66% (character accuracy)
Saadouli *et al.* [18]	2020	Fusion of SIFT + DoG + Viola–Jones modules	License plate + driver information + vehicle	Qatar University car surveillance dataset (225 images and 24 car types)	74.63% accuracy (real dataset)

quite good for its time, accuracy often dropped under glare or distortion.

Later studies started chasing speed as much as precision. One of the more interesting attempts came from Zhu and colleagues [2], who developed a lightweight version of YOLOv5, called SYOLOv5s. They added a small attention mechanism to help the model focus on fine details on plates rather than get distracted by car reflections. The approach achieved a mean average precision (mAP) of 96.6% on the CCPD dataset at roughly 40–45 FPS, which is impressive for an embedded setup.

In a similar direction, Sarhan *et al.* [3] paired YOLOv8 with Easy-OCR and a compact CNN to recognize Egyptian plates. Their system achieved 94.26% mAP and about 99.4% recognition accuracy. A slightly later work by Tao *et al.* [4] pushed further with YOLOv5-PDLPR, achieving close to 160 FPS while maintaining roughly 99.4% accuracy.

These results look great on clean datasets, but in real life, the story changes. Two identical plates on different vehicles or even a printed photo of a plate can easily pass. *The problem is that plate-based identification only tells what plate it sees—it says nothing about who is driving or whether that plate really*

belongs on that car.

2) Vehicle recognition and re-identification (Re-ID): As license-plate models reached maturity, attention began shifting to the vehicle's physical appearance. The idea was that the combination of color, make, and shape could help track or verify vehicles across cameras. Lou *et al.* [5] developed FDA-Net, an early method for feature disentanglement that achieved mAP of 55.49% and Rank-1 of 84.27% on the VeRi-776 benchmark. Though not perfect, it was a turning point.

Later, transformer-based models changed the landscape. Yu *et al.* [6] proposed SOFCT, a transformer that couples features across views, boosting accuracy to mAP 80.7% and Rank-1 96.6%. Liang *et al.* [8] followed with a spatial-temporal transformer (S-TVReID) that achieved nearly identical results, while Lian *et al.* [9] introduced a multi-branch model (MED) that squeezed out a bit more, reporting mAP of 83.4% and Rank-1 of 97.2%.

Around the same time, Zhu *et al.* [7] suggested a dual self-attention network (DSN). Instead of relying on a single global attention layer, they used two complementary self-attention stages to capture both coarse and fine details. The model achieved a mAP of 76.3% and a Rank-1 accuracy of 94.8%, indicating that a thoughtfully designed attention mechanism can match the performance of more complex architectures.

Altogether, these advances make vehicle appearance recognition highly reliable, but it still doesn't answer the key security question—who is inside the vehicle? *Appearance cues alone can't guarantee authorized access*.

3) Fusion of license plate and driver information: A natural next step was to include the driver's identity. Several works explored this idea, often combining a license-plate detector with facial recognition. Alim *et al.* [10] proposed an edge-based model using YOLOv3/YOLOv5 and LPRNet, achieving roughly 97% plate accuracy and solid face detection results. Teja *et al.* [11] mixed a KNN/CNN ANPR approach with LBPH facial recognition, scoring 96.54% for the face and 88.67% for the plate.

Other studies followed, but under more constrained setups. Akbar *et al.* [12] tested a prototype using Haar cascades and EasyOCR for visitor entry, but accuracy dropped to around 62%, mostly due to variable lighting and glass reflections. Iyer and Dhavale. [13] later improved on this with YOLOv8, EasyOCR, and dlib-CNN, achieving about 98% accuracy for faces and 88.14% for plates.

Despite encouraging results, most of these projects were small-scale and tested in fairly controlled conditions. *Problems like tinted windshields, poor lighting, or the driver's head turned away still cause big accuracy swings. Moreover, few systems tried to fuse both cues into a single, reliable decision*.

4) Fusion of license plate and vehicle features: Some researchers instead checked whether the vehicle's appearance matched its plate. Mustafa and Karabatak [14] proposed a multi-stage design combining MobileNet-V2, YOLOx, YOLOv4-tiny, PaddleOCR, and SVTR-tiny, with an overall accuracy near 97.5%. Ramajo-Ballester *et al.* [15] merged YOLOv5, EfficientNetB0, and FastReID, reporting mAP of 0.893 for license-plate detection and 97.9% re-identification accuracy, all running at roughly 58 ms per frame.

Khor *et al.* [16] developed a multitask YOLOv8 with shared layers and separate heads for OCR, plate detection, and vehicle recognition, achieving an average mAP of 0.874. Later, AlDahoul *et al.* [17] introduced VehiclePaliGemma, which used a vision-language approach and achieved 87.6% plate accuracy and 97.66% character accuracy on Malaysian datasets.

These multi-modal systems make it easier to spot mismatched or fake plates, but they stop short of confirming driver identity. *That gap still allows a legitimate vehicle to be driven by an unauthorized person*.

5) Tri-modal fusion of plate, vehicle, and driver: A handful of earlier works did try to combine all three components. Saadouli *et al.* [18] developed a system that combined SIFT, Difference-of-Gaussian, and Viola-Jones methods to fuse plate, vehicle, and face information. Tested on a small dataset from Qatar University, the setup achieved about 74.6% accuracy. Although modest, that study demonstrated the concept was feasible and hinted at what future models could achieve with deep learning.

However, since then, the tri-modal direction has received surprisingly little attention. Most newer works still treat plates, vehicles, and faces as separate modules rather than fusing them into a single coherent anti-spoofing decision.

6) Research gap and motivation: From reviewing this body of work, a few consistent gaps appear. Nearly all systems rely on one or two cues rather than combining all three, leaving them vulnerable to spoofing or substitution attacks. Models trained on datasets such as CCPD or VeRi-776 often struggle to generalize to Saudi or GCC license plates, which vary in color, shape, and script. Another issue is that most papers report part-level metrics—such as mAP or recognition rate—without testing full gate-level performance, including false acceptance and false rejection under real attack conditions.

To tackle these problems, the present study develops a deep tri-modal anti-spoofing system that merges three complementary sources: the license plate, the vehicle's visual signature, and the driver's identity. The system uses YOLOv4-tiny [19] for vehicle detection, MobileNetV2 [20] for vehicle classification, MTCNN [21] for license plate detection, LPRNet [22] for license plate recognition, RetinaFace [23] for face detection and alignment, and the InsightFace framework [24] (trained with the ArcFace loss [25] for feature extraction) combined with a linear SVM [26] for face recognition. The recognition results (plate, face, and vehicle) are then combined with a simple linear SVM that learns how much to trust each output based on its confidence. The dataset itself was built around Saudi license plates, so it's tuned to the region. In the end, the goal is to narrow the long-standing gap between strong recognition results in experiments and the reliability needed for real gate security.

B. Contributions

The principal contributions of this work are outlined below:

- A real-time, integrated anti-spoofing system: Unlike traditional gate access mechanisms that rely solely on a single recognition model—be it facial, vehicle, or license plate recognition—our system unifies all three

within a single, real-time framework. This integration not only strengthens security but also minimizes unauthorized entries and prevents unnecessary traffic delay at the gate.

- A new labeled dataset for license plate detection: We introduce a fully annotated dataset of 17,000 Saudi Arabian license plate images for detection tasks. To the best of our knowledge, no previous study has provided such a dataset. A visual example of this dataset is shown in Fig. 4.
- A new labeled dataset for license plate recognition: Another dataset, consisting of 35,000 labeled images of Saudi license plates, is presented for recognition purposes. This collection is also newly introduced to the literature, and a representative sample is provided in Fig. 5.
- Public release and implementation details: Both datasets, along with the complete system, are openly available through our GitHub repository [27]. The implementation is clearly documented and designed with scalability and flexibility in mind, allowing it to be adapted or extended to fit a range of deployment environments.

Together, these contributions emphasize the originality and practical value of our study. By merging multiple recognition techniques within a single system and grounding them in newly developed datasets, this work lays a strong foundation for improving automated vehicle access control in real-world conditions.

II. Proposed Model

A. Overview

The primary goal of this research is to make vehicle entry systems faster, smarter, and less dependent on manual checks. In many facilities, access is still verified by guards, which often slows things down and sometimes leads to errors or even security breaches. The problem becomes more obvious during rush hours when the number of vehicles increases and human attention starts to slip. To solve this, we developed an automated model that works in real time and removes the need for constant supervision. The system relies on three main visual features: the driver's face, the vehicle, and its license plate. Our proposed system fuses these features to create a stronger, more reliable decision-making model that speeds up entry validation and makes it safer, without adding more human effort.

Our proposed model, shown in Fig. 1, illustrates how the anti-spoofing gate access system operates as a complete process, from video capture to the final decision. When a vehicle approaches, the system records live video and automatically selects the clearest frame using the intersection-over-union (IoU) method to ensure the vehicle is properly captured. From that frame, the YOLOv4-tiny model [19] detects the car, while MobileNetV2 [20] classifies its make and model. The license plate area is then located using a modified MTCNN [21], and LPRNet [22] reads the characters on it. At the same time, RetinaFace [23] detects and aligns the driver's face, and InsightFace [24], [25]—together with a linear SVM [26] classifier—identifies who the person is. These three recognition results (vehicle, plate, and face) are then combined using a weighted linear SVM, which calculates an overall score to determine whether access should be allowed. In short, the figure illustrates a smooth, AI-based workflow that combines detection, recognition, and decision-making into one unified, real-time security system. The following subsections elaborate on every step in this proposed pipeline.

B. Vehicle Detection

In the proposed anti-spoofing gate access system, identifying vehicles in each video frame is the central operation. To meet real-time requirements without overloading the system, a lightweight detection model was used. In this case, the YOLOv4-tiny network [19] was chosen because it strikes a reasonable balance between detection accuracy and processing speed. Compared to the full YOLOv4 version [28], it runs faster due to its reduced parameter count and simpler convolutional layers. These characteristics make it practical for edge or embedded systems, where memory and processing resources are limited.

Before the detection stage, each input image is processed using OpenCV [29], which handles basic preprocessing tasks such as reading the image, resizing it, and converting it to the correct color space. Once that is done, YOLOv4-tiny divides the image into an $S \times S$ grid. Every cell in this grid predicts several bounding boxes, each one represented by five numeric values and a set of class probabilities. These values describe the position, size, and confidence level associated with each possible vehicle in the frame, defined as:

$$y = \begin{bmatrix} P_c \\ b_x \\ b_y \\ b_h \\ b_w \\ C_1 \\ C_2 \\ \vdots \\ C_n \end{bmatrix},$$

where,

- P_c: Confidence score indicating the probability of an object's presence within the bounding box.
- b_x, b_y: Normalized center coordinates of the bounding box.
- b_h, b_w: Normalized height and width of the bounding box.
- C_i: Class probabilities for the object categories (via softmax).

The extracted bounding box parameters are shown in Fig. 2.

After the network finishes predicting several possible bounding boxes, the raw output still needs some cleanup. The goal of this step is to keep the detections that actually matter and discard the ones that don't. Two standard techniques handle this refinement:

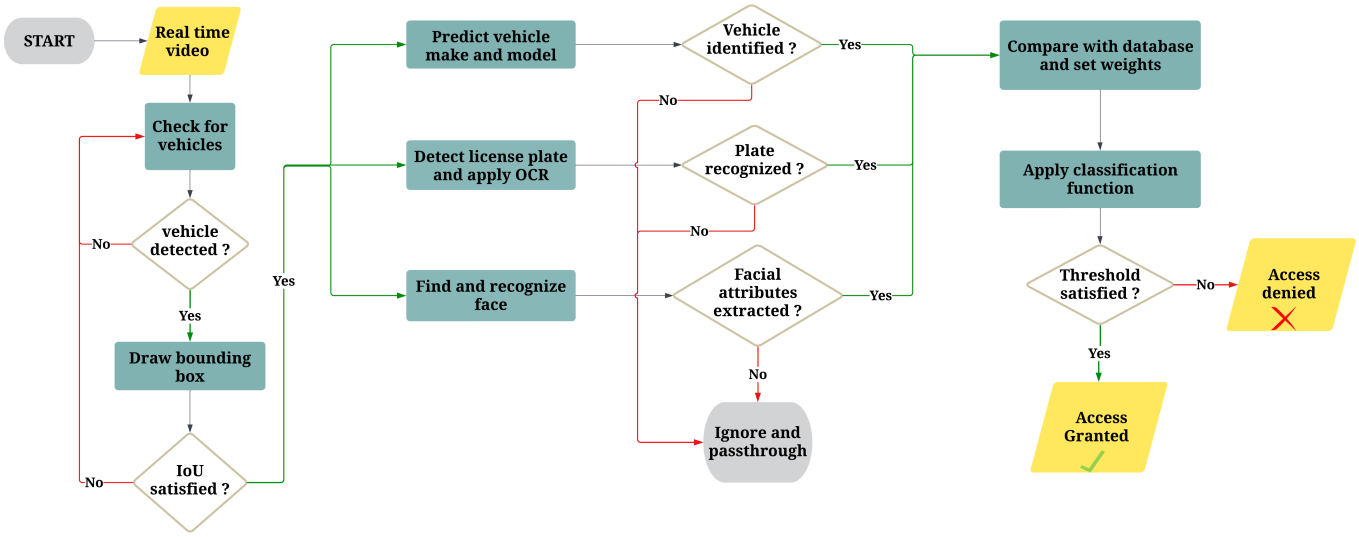

Fig. 1. Workflow of the proposed AI-based anti-spoofing gate access tri-modal system, combining vehicle, license plate, and facial recognition for robust and unified real-time verification.

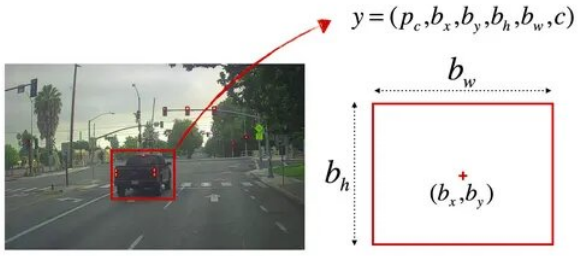

Fig. 2. Bounding box parameters (b_x, b_y, b_h, b_w) predicted by YOLOv4-tiny, defining each detected vehicle's position and size.

Fig. 3. Illustration of non-maximum suppression (NMS) removing overlapping bounding boxes and keeping only the highest-confidence detection per vehicle.

- Score thresholding: Any bounding box whose confidence value falls below a chosen threshold is simply dropped. This first filter removes weak forecasts, allowing the next phases to focus on stronger ones.
- Non-maximum suppression (NMS): If several boxes overlap on the same object, only the one with the highest confidence is kept. The rest are removed whenever their intersection-over-union (IoU) with the highest-scoring box exceeds a predefined threshold.

Working together, these two steps result in each object being represented by a single, clean bounding box. They also lighten the computational load and help the model reach its decision faster. As illustrated in Fig. 3, NMS trims away overlapping boxes, leaving the final, precise outline.

The use of YOLOv4-tiny comes down to its balance between speed and accuracy. Running approximately 83.33 frames per second on an NVIDIA GeForce RTX 2080 Ti GPU, it can manage real-time monitoring at a gate or checkpoint. Even though it's a smaller variant of YOLOv4, it performs reliably under difficult lighting, partial occlusion, and awkward vehicle angles.

With YOLOv4-tiny handling vehicle detection, later components—vehicle classification, license-plate recognition, and face identification—receive neatly cropped regions of interest. That early precision keeps the entire tri-modal anti-spoofing system steady, fast, and dependable in live operation.

C. Best-Frame Selection for Low-Latency Vehicle Gating

In real-time video, a moving vehicle appears across several consecutive frames at different positions and scales. Processing every frame is wasteful—it drives up latency without significantly improving accuracy. A better strategy is to select a single best frame that preserves the most useful visual detail while keeping computation lean.

As the vehicle approaches the gate, each frame provides a slightly different view. We aim to select the moment when the vehicle is most prominent and least occluded—typically the frame with the largest, well-centered bounding box—so that downstream modules (vehicle classification, license plate recognition, and driver or occupant cues) receive the cleanest signal.

We formalize this with the intersection over union (IoU) between the detected bounding box B_t in frame t and a

predefined reference box B^* that encodes the desired on-screen extent:

$$\mathrm{IoU}(B_t, B^*) = \frac{|B_t \cap B^*|}{|B_t \cup B^*|}, \quad t^\dagger = \arg\max_t \mathrm{IoU}(B_t, B^*).$$

This simple rule favors frames where the target is closest and best aligned with the expected view. Crucially, if two different vehicles enter the scene simultaneously, the method still yields a single, unambiguous selection: among all detections across frames, only the vehicle whose bounding box achieves the largest IoU with B^* is chosen, and only its best frame is forwarded downstream. This ensures that the system detects and processes only one vehicle at a time, eliminating multi-vehicle conflicts. Then the procedure per short time window:

- Detect vehicle candidates and obtain B_t for each frame.
- Compute $\mathrm{IoU}(B_t, B^*)$ for all candidates.
- Select $t^\dagger = \arg\max_t \mathrm{IoU}(B_t, B^*)$; export only frame $t^\dagger$ and its associated vehicle.

By emitting exactly one, high-quality frame, the system trims redundant computation and preserves recognition accuracy. In practice, this best-frame gate reduces end-to-end latency and strengthens anti-spoofing behavior, making it a robust solution for real-time vehicle access control.

D. Vehicle Classification

Following detection, the vehicle crop is forwarded to the make–model classifier. We employ the off-the-shelf model in [30], which is built on MobileNetV2 [20] and trained using transfer learning similar to [31]. Concretely, MobileNetV2 serves as the backbone feature extractor, and the resulting classifier operates in real-time on gate imagery. Vehicle crops are first resized to 224×224 pixels; in practice, reliable inference is obtained for objects as small as 30×30 pixels after pre-processing. The model's training coverage comprises approximately 400 brands and 7,000 car models, with canonical viewpoints limited to front, rear, and side. Under these conditions, the reported top-1 accuracy reaches about 95%. We selected this module for its real-time operation and strong accuracy, which is backed by training that covers every car make and model in Saudi Arabia. The module integrates with the upstream detector by consuming the refined bounding box for each candidate (see Fig. 2), and its system-level role is consistent with the end-to-end workflow (see Fig. 1).

E. License Plate Detection

After vehicle detection and best-frame selection, the system localizes the license plate using a retrained variant of the multi-task cascaded convolutional network (MTCNN) [21]. Although MTCNN is conventionally used for face detection and alignment, prior work shows that, with suitable retraining and loss-function tuning, it can be adapted to license plate detection under diverse viewpoints and backgrounds [32]. Following this approach, we fine-tuned the network on Saudi Arabian plates to enhance its robustness under challenging capture conditions (e.g., strong illumination, oblique angles, and cluttered scenes).

Because no large, open datasets exist for Saudi plates, we constructed a dedicated detection corpus. Images were captured manually and gathered from public social-media sources (programmatically fetched with Instaloader [33]), yielding approximately 17,000 annotated images that span all Saudi plate types and a broad range of environments (appearance, background, lighting, scale, and viewpoint). Representative examples and detector outputs of our novel dataset are shown in Fig. 4.

Annotations were created using the computer vision annotation tool (CVAT), where plate bounding boxes were produced and exported as XML for training. The novel curated dataset (images and ground truths) is organized with clear documentation to support reproducibility and is publicly available on our GitHub repository cite [27].

After assembling the dataset, the next step is to train the license plate detector. Given MTCNN's cascaded design, we retained the proposal (P-Net) and output (O-Net) stages. We omitted the refinement (R-Net) stage after empirical testing indicated no degradation in accuracy for this task. Training hyperparameters for P-Net and O-Net are summarized in Table II. Our end-to-end system achieved an overall accuracy of 99.2%.

TABLE II. TRAINING HYPERPARAMETERS FOR THE LICENSE-PLATE DETECTION MODEL (RETRAINED MTCNN WITH P-NET AND O-NET STAGES)

Parameter	Value
Number of epochs	50
Learning rate	0.001
Initial weight	0.1
Batch size	64
Dataset split	70% train, 20% validation, 10% test

For classification at each retained stage, we used the standard cross-entropy (log-loss) objective [Eq. (1)]. For bounding-box regression, we minimized mean-squared error [Eq. (2)] against the ground-truth coordinates. This combination yielded stable convergence and accurate plate localization in practice.

$$L(y, p) = -\frac{1}{N} \sum_{i=1}^{N} \left[y_i \log(p_i) + (1 - y_i) \log(1 - p_i) \right], \quad (1)$$

where,

- $L(y, p)$ represents the log loss function.
- N is the number of samples.
- y_i is the true label of the i-th sample.
- p_i is the predicted probability of the i-th sample being of the positive class.

$$L(y, \hat{y}) = \frac{1}{N} \sum_{i=1}^{N} \|y_i - \hat{y}_i\|^2. \quad (2)$$

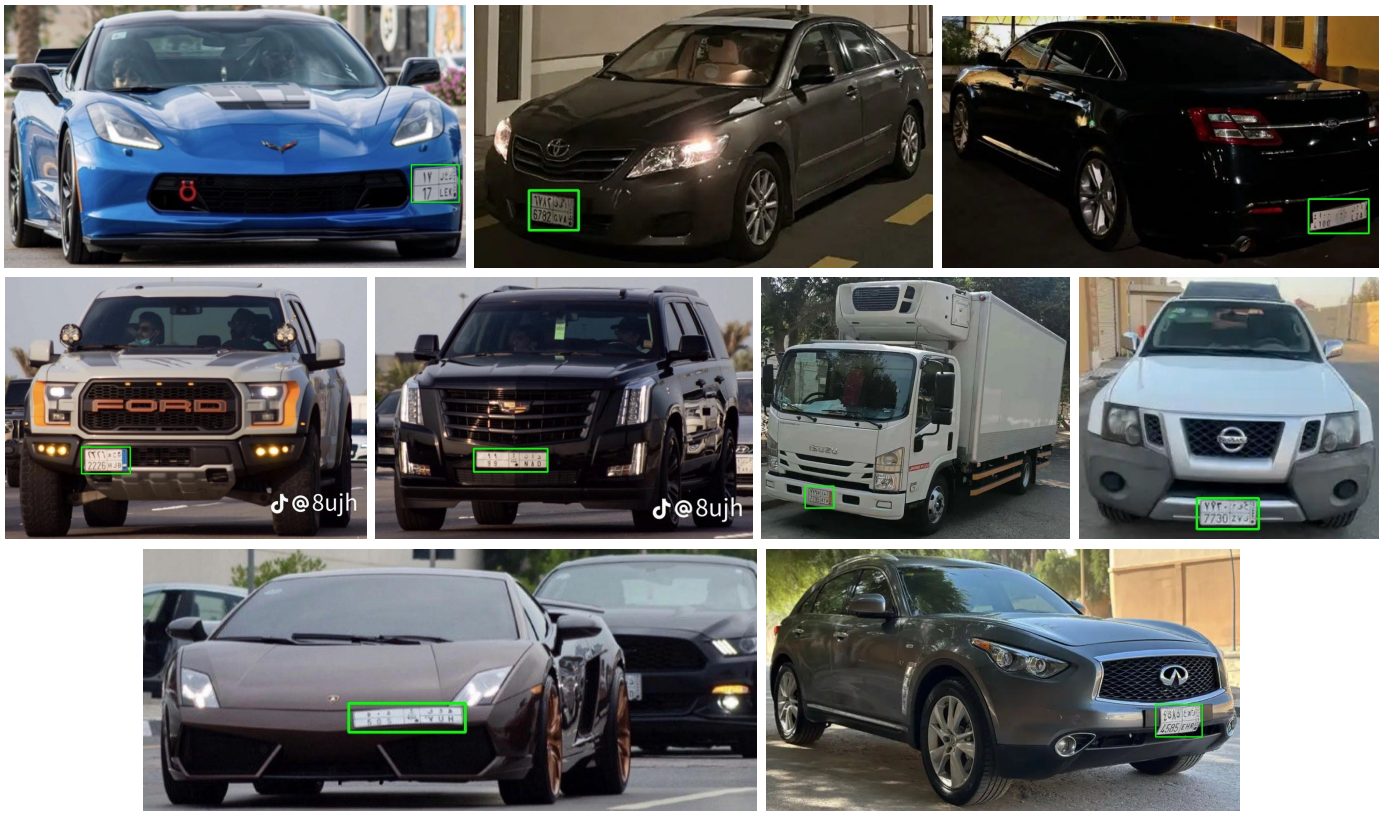

Fig. 4. Examples from our Saudi license-plate detection dataset (17,000 images), covering diverse backgrounds, lighting conditions, scales, viewpoints, and all official plate types. Green boxes indicate detections from the retrained MTCNN detector.

F. License Plate Recognition

Following license-plate detection, character recognition is performed using LPRNet [22], which has been retrained specifically on Saudi Arabian plates. Prior to training, the label space was constrained to reflect national plate conventions: strings were limited to at most seven characters (up to three letters and up to four digits), and characters not present on Saudi plates—C, F, I, M, O, P, Q, W, and Y—were removed. This pruning reduces ambiguity and improves convergence without altering the inference pipeline.

Because a large open dataset for Saudi plates is unavailable, we assembled a dedicated corpus. Data were drawn from three sources: 1) self-captured images, 2) publicly available social-media imagery, and 3) crops automatically harvested by our retrained MTCNN plate detector, which we used to detect and crop Saudi plates to expand further coverage across styles, viewpoints, and illumination conditions. Fig. 5 provides samples of our novel dataset alongside LPRNet predictions.

Annotation was streamlined with a lightweight Python tool that renames each image to its alphanumeric ground truth. Given the fixed mapping between Arabic and English characters on Saudi plates, labels were stored in English to simplify recognition. In total, the recognition dataset comprises approximately 35,000 labeled plate images. The curated dataset (images and ground-truth labels) is documented for reproducibility and is publicly available via our GitHub repository cite [27]. After collecting and pre-processing the dataset, we retained the LPRNet model, with key hyperparameters summarized in Table III. We achieved an overall accuracy of 93.1%, with a loss of 0.0059 at epoch 25, as shown in Fig. 6.

TABLE III. TRAINING HYPERPARAMETERS FOR THE LICENSE-PLATE RECOGNITION MODEL (RETRAINED LPRNET)

Parameter	Value
Number of epochs	50
Learning rate	0.001
Learning rate schedule	at epochs 4, 8, 12, 16, 32, and 45
Batch size	128
Dataset split	70% train, 20% validation, 10% test

G. Face Detection and Alignment

Within the vehicle region of interest, faces are localized using RetinaFace [23]. This single-shot detector jointly predicts bounding boxes and sparse facial landmarks (e.g., eye centers, nose tip, mouth corners). This joint formulation enhances robustness to scale changes, partial occlusions, and challenging illumination conditions, which are common in in-vehicle imagery. As illustrated in Fig. 7, the detected landmarks are subsequently used to geometrically normalize the crop, producing an upright, aligned face that is forwarded to the recognition backend. In practice, this alignment step reduces pose variability and stabilizes the downstream feature extraction stage.

Fig. 5. Samples from the Saudi license-plate recognition dataset (35,000 images) encompass a diverse range of backgrounds, lighting conditions, scales, viewpoints, and official plate types. LPRNet predictions are shown above each plate.

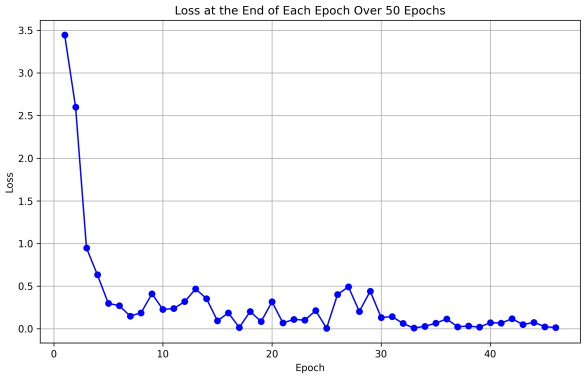

Fig. 6. Training loss of the retrained LPRNet across 50 epochs; the minimum loss (0.0059) occurs at epoch 25, coinciding with a 93.1% test accuracy on Saudi license plates.

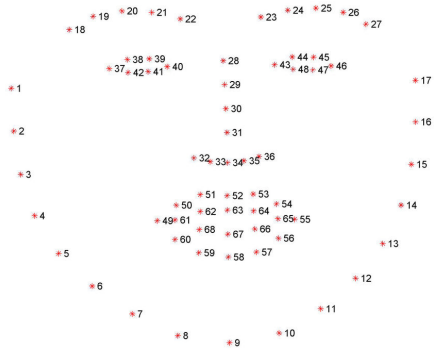

Fig. 7. RetinaFace-detected facial landmarks (eye centers, nose tip, mouth corners) and the resulting geometric alignment prior to face recognition.

H. Face Recognition

Following detection and geometric alignment (Fig. 7), identity is inferred using the InsightFace pipeline [24], trained with the ArcFace additive angular-margin loss [25], to obtain a compact and discriminative embedding for each detected face. To reduce computational cost and mitigate redundancy in the embedding space, dimensionality reduction methods such as principal component analysis (PCA) can be applied prior to classification [34]. The resulting feature vectors are classified using a one-vs-rest linear SVM [26], an approach chosen for its low latency, stable generalization in small-sample regimes, and straightforward score calibration in the tri-modal setting (see also related ensemble/OvR usage in [35]). Within our dataset of 30 subjects with 20 images each (600 total; 70/20/10 train/validation/test split), this module achieved $\approx 99.5\%$ identification accuracy on the closed set. The classifier's confidence score is exported to the fusion stage as the face term in the linear decision function, consistent with the end-to-end workflow illustrated in Fig. 1 and the global formulation described earlier.

I. Tri-Modal Score Fusion for End-to-End Access Classification

To convert per-modality predictions into a single access decision, the system fuses confidence scores from the vehicle make and model classifier, the license plate recognizer, and the face recognizer. Let the score vector be:

$$\boldsymbol{x} \triangleq \begin{bmatrix} x_{\text{vehicle}} \\ x_{\text{plate}} \\ x_{\text{face}} \end{bmatrix},$$

where, each component denotes the corresponding model's confidence. A linear support vector machine (SVM) [26] is employed to learn a separating hyperplane over $\boldsymbol{x}$, chosen for its computational simplicity in real-time settings and its stable behavior with limited training data.

The decision function is:

$$f(\boldsymbol{x}) = \boldsymbol{w}^\top \boldsymbol{x} + b = w_1\, x_{\text{vehicle}} + w_2\, x_{\text{plate}} + w_3\, x_{\text{face}} + b, \quad (3)$$

with $\boldsymbol{w} = [\, w_1,\, w_2,\, w_3\,]^\top$ and b learned from labeled training samples. Access is granted when

$$f(\boldsymbol{x}) \geq 0,$$

and denied otherwise. This linear fusion enables the classifier to weight each modality according to its discriminative value at the operating point, yielding a single, consistent pass/fail verdict suitable for real-time gate control.

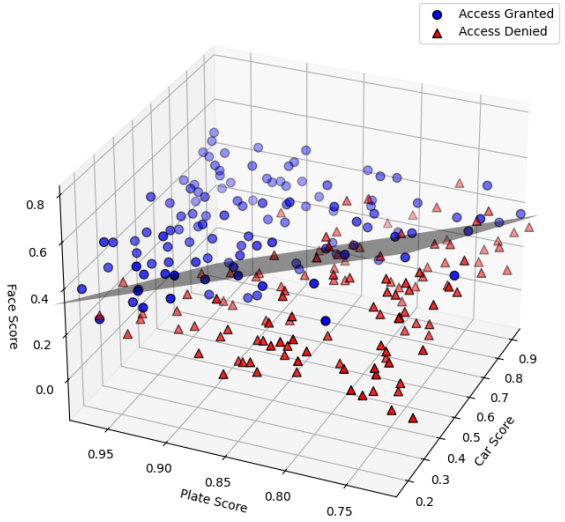

Fig. 8. Linear SVM decision boundary in the tri-modal confidence space.

III. Results and Discussion

In this section, we present the training of our tri-modal system and report its overall performance (quantitative results). We also provide a real-world demonstration of the proposed model (qualitative results).

A. Tri-Modal System Training and Performance

The tri-modal fusion classifier maps modality confidences—vehicle make/model, license plate recognition, and face recognition—-into a single access decision using a linear SVM operating on the score vector with decision function, as shown in Eq. (3). The training corpus comprises 1,000 images spanning a diverse range of vehicles, license plates, and driver appearances. The dataset was partitioned into 70%/15%/15% for training/validation/testing, respectively. Under this protocol, the fused classifier attained an overall accuracy of 97% with an end-to-end latency of 66 ms per frame (approximately 15.15 FPS). All experiments were conducted on an NVIDIA GeForce RTX 2080 Ti GPU. The learned parameters are $w_1 = 2.103$ (vehicle), $w_2 = 6.270$ (plate), $w_3 = 3.392$ (face), and $b = -7.588$; the separating hyperplane and score geometry are illustrated in Fig. 8.

The weight magnitudes follow an intuitive ordering. The license-plate stream receives the largest weight, reflecting the high distinctiveness of plate identities; the face stream is second—useful but occasionally ambiguous (e.g., similar appearance)—and the vehicle make/model stream is weighted lowest, consistent with the possibility of visually similar trims across brands. This ranking provides a straightforward interpretation of how the fusion balances complementary cues at inference time.

At the system level, 66 ms/frame is compatible with near-stop gate operation, where vehicles either halt or approach slowly ($<$ 15 km/h). Numerically, 15 km/h $\approx$ 4.17 m/s, so a 15.15 FPS stream observes frames every $\approx$ 66 ms; the vehicle advances only $\approx 4.17 \times \frac{1}{15.15} \approx 0.28$ meters between frames. This inter-frame motion is sufficiently small to maintain detector stability and OCR legibility as the vehicle settles at the barrier, while preserving temporal continuity for the face pipeline inside the cabin. The operating point, therefore, satisfies the real-time constraint for access control. The end-to-end frame time is directly determined by the per-module (subsystem) runtimes that execute in sequence. The speeds of these subsystems are summarized in Table IV.

TABLE IV. Per-Module Runtime and Throughput (ms and FPS) for the Sequential Tri-Modal Pipeline—Vehicle Detection/Recognition, Plate Detection/Recognition, and Face Detection/Recognition—Along with the Overall End-to-End Latency

Model	Speed
Vehicle Detector	12ms ($\approx$ 83.33 FPS)
Vehicle Recognizer	9ms ($\approx$ 111.11 FPS)
License Plate Detector	11ms ($\approx$ 90.91 FPS)
License Plate Recognizer	9ms ($\approx$ 111.11 FPS)
Face Detector	15ms ($\approx$ 66.67 FPS)
Face Recognizer	10ms (100 FPS)
End-to-end	66ms ($\approx$ 15.15 FPS)

B. A Real-World Demonstration

To examine how the proposed tri-modal pipeline behaves outside controlled datasets, we recorded a 23-second video sequence at a gate-like entrance, as illustrated in Fig. 9. The scenario involves a Toyota Camry approaching the barrier at low speed, bearing the Saudi license plate 1812SGD and driven by an enrolled subject (Muhannad). The raw video stream is fed directly to the system described in Section II, with no manual frame selection or offline post-processing.

As the vehicle moves through the field of view, the YOLOv4-tiny detector produces a set of candidate bounding boxes B_t over successive frames. The best-frame selection module (Subsection II-C) evaluates $\text{IoU}(B_t, B^*)$ with respect to a fixed reference box B^* centred in the image, and selects the frame $t^\dagger$ that maximizes this overlap. In the recorded sequence, the chosen frame corresponds to the instant when the Camry is nearly frontal and occupies most of the reference region, as shown in Fig. 10. The resulting bounding box tightly

Fig. 9. Input video sequence recorded at a gate-like entrance; click the image (or the link) to view the full clip.

Fig. 11. Output of the vehicle make–model classifier, correctly identifying the car as a Toyota Camry with a confidence score of 0.9417.

encloses the vehicle, suppressing background clutter and providing a clean region of interest (ROI) for the downstream modules. This step is consistent with the low-latency strategy adopted in the proposed model, where only a single, high-quality frame is propagated to the rest of the pipeline.

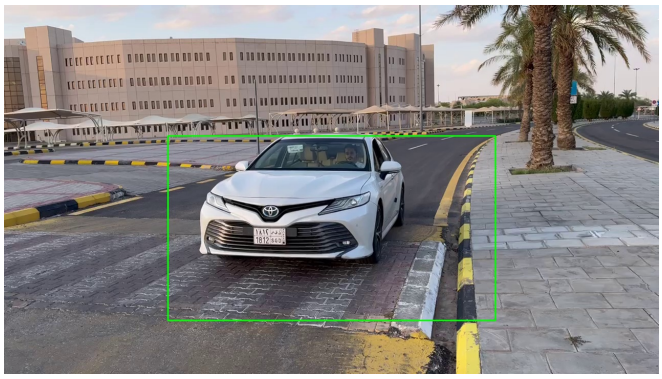

Fig. 10. Best frame selected by the IoU-based gating module, showing the detected vehicle together with the reference bounding box.

Once the best frame is fixed, the corresponding vehicle crop is forwarded to the MobileNetV2-based make–model classifier described in Subsection II-D. In this experiment, the classifier correctly identifies the vehicle as a Toyota Camry with a confidence score of 0.9417, as depicted in Fig. 11. This result aligns with the high accuracy reported for the vehicle-recognition component under real-time operating conditions.

The same ROI is then passed to the license plate branch. The retrained MTCNN detector localizes the Saudi plate with a precise bounding box, and LPRNet decodes the alphanumeric content. The predicted string matches the ground-truth plate number 1812SGD with a confidence of 0.97 (Fig. 12), demonstrating that the dataset and retraining strategy introduced in Subsection II-E and Subsection II-F generalize well to real capture conditions.

In parallel, the face-analysis branch operates inside the vehicle ROI. RetinaFace searches for a driver, estimates facial landmarks, and produces an aligned face crop, as outlined in Subsection II-G. InsightFace then maps this crop into a feature embedding, which is classified by the one-vs-rest linear SVM trained on enrolled personnel (Subsection II-H). In the

Fig. 12. License-plate recognition result for the selected frame, correctly decoding the plate number 1812SGD with a confidence score of 0.97.

recorded sequence, the system correctly recognizes the driver as Muhannad, but with a relatively modest confidence score of 0.35 (Fig. 13). This lower margin is consistent with the challenging imaging conditions: the face is partially occluded by the windshield, affected by sunlight reflections, and drawn from a comparatively small in-cabin dataset that does not yet fully capture these variations.

Although the confidence of the face recognizer is low, it only contributes partially to the final access decision, since the tri-modal SVM assigns it a smaller weight whenever the vehicle and license-plate cues are more reliable. This demonstrates the robustness of our model, as it does not rely on a single feature; instead, it fuses three heterogeneous features to make a coherent vehicle-access decision, thereby reducing the impact of occasional failures in any individual modality. Additionally, the face recognizer can be improved by automatically collecting more in-the-wild data each time a person passes through the gate, particularly under varying lighting, weather, and viewing conditions. A growing set of face crops—captured at different times of day, with different windshield states and head poses—can then be used to periodically retrain the face-recognition branch, making it more tolerant to glare, occlusion, and motion blur. Over time, this continuous update loop helps close the gap between facial and non-facial cues and stabilizes the fused decision in real-world gate-control deployments.

The three scalar confidences from the previous stages:

Fig. 13. In-vehicle face detection and recognition result, identifying the enrolled driver (Muhannad) with a confidence score of 0.35.

$$x_{\text{vehicle}} = 0.9417, \quad x_{\text{plate}} = 0.97, \quad x_{\text{face}} = 0.35,$$

are then combined by the tri-modal fusion SVM introduced in Subsection II-I and trained, as detailed in Subsection III-A. Using the learned parameters:

$$(w_1, w_2, w_3) = (2.103,\ 6.270,\ 3.392), \quad b = -7.588,$$

the decision function in Eq. (3) yields a positive fused score $f(x)$, and the system grants access. This outcome is consistent with the ground-truth label for the scenario (authorized vehicle and authorized driver). A representative frame from the processed video shows the intermediate decisions (vehicle class, plate text, and identity label) overlaid alongside the final "access granted" indicator, as shown in Fig. 14. You can click on the figure to watch the processed video or on the link provided in the figure caption.

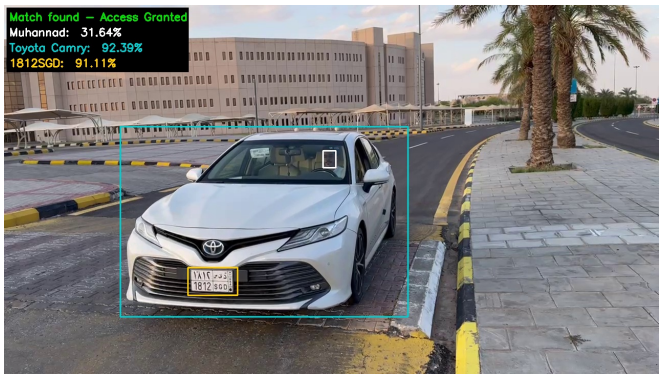

Fig. 14. Combined output of the proposed tri-modal system for the test sequence, including vehicle class, license-plate text, driver identity, and the final "access granted" decision; click the image (or the link) to view the full processed video.

Finally, this qualitative demonstration highlights several aspects of the proposed model working together in practice. First, the best-frame selection mechanism reduces redundant computation while still capturing a view in which all three modalities—vehicle appearance, license plate, and face—are informative. Second, the fusion stage naturally compensates for the lower face-recognition confidence by assigning higher weight to the more distinctive license-plate and make–model scores, as reflected in the relative magnitudes of w_2 and w_1. Third, when combined with the measured end-to-end latency of 66 ms per frame (approximately 15.15 FPS) reported in Subsection III-A, the experiment confirms that the full tri-modal pipeline can operate in real time at a physical gate, where vehicles approach slowly and can be stopped or released based on a single, coherent anti-spoofing decision.

C. Comparison with the Tri-Modal Benchmark

As summarized in Table I, vision-based gate systems typically rely on one or two cues—most often the license plate, sometimes combined with vehicle appearance or driver information. Only a small number of works attempt a full tri-modal design. Among these, the study by Saadouli *et al.* [18] is particularly relevant, as it also fuses vehicle, license plate, and face information to control an electronic gate.

In their framework, car make and model are recognized from handcrafted features based on Difference-of-Gaussians and SIFT descriptors, while license plates are processed with connected-components analysis and OCR; driver verification relies on a Viola–Jones face detector. The system is evaluated on a small surveillance dataset collected at Qatar University (225 images, 24 vehicle types), where the make–model subsystem attains an accuracy of approximately 74.6%. *Although this work demonstrates that combining the three modalities is feasible, it remains constrained by classical computer vision methods, limited data diversity, and a processing time of approximately two seconds per vehicle in the prototype.*

The tri-modal system proposed in this paper revisits the same high-level objective but with a modern deep-learning pipeline and a significantly larger, region-specific data foundation. Vehicle detection is handled by YOLOv4-tiny, vehicle make–model recognition by a MobileNetV2-based classifier trained on roughly 400 brands and 7 000 models, and Saudi license plates are processed by retrained MTCNN and LPRNet modules using newly curated detection and recognition datasets (17 000 and 35 000 images, respectively). Faces are localized with RetinaFace and recognized via InsightFace embeddings with a linear SVM backend. All three confidence scores are then fused through a learned linear SVM, which automatically assigns a higher weight to the more distinctive license-plate and face streams while still exploiting the vehicle signature.

Quantitatively, the proposed gate-level classifier reaches 97% overall accuracy with an end-to-end latency of 66 ms per frame (approximately 15.15 FPS), which is compatible with real-time deployment at a physical barrier. By contrast, Saadouli *et al.* report an accuracy of approximately 74.6% on their make–model benchmark and a per-vehicle decision time of about two seconds in the prototype. *In practical terms, our system delivers both higher recognition performance and substantially lower latency under more challenging and diverse operating conditions.*

Another important distinction lies in reproducibility. The datasets used in [18] are institution-specific and not publicly

distributed, which makes direct comparison and follow-on studies difficult. In this work, both Saudi license-plate datasets, together with the implementation of all modules and the tri-modal fusion logic, are made openly available through a public repository, enabling independent validation and adaptation to other gate environments. *Overall, the proposed system can therefore be viewed as a deep-learning-based, real-time extension of the earlier tri-modal concept, closing much of the gap between proof-of-concept prototypes and deployable anti-spoofing vehicle gate solutions.*

IV. Conclusion

This work introduced TRI-GATE, a tri-modal, AI-based anti-spoofing system that integrates vehicle, license plate, and facial information into a unified framework for secure, real-time gate access. Unlike traditional gate setups that depend on human guards or on a single recognition cue, TRI-GATE leverages complementary visual signals and fuses them using a linear SVM at the score level, thereby reducing the likelihood that a single point of failure—such as a cloned plate or a partially occluded face—can be exploited to gain unauthorized entry.

At the subsystem level, each component is tailored for practical deployment in Saudi and GCC environments. YOLOv4-tiny and a MobileNetV2-based make–model classifier deliver accurate vehicle detection and recognition in real time. A retrained MTCNN paired with LPRNet operates on two newly curated Saudi plate datasets (17,000 images for detection and 35,000 for recognition), achieving 99.2% detection accuracy and 93.1% recognition accuracy, respectively. For driver identity, RetinaFace and InsightFace embeddings combined with a linear SVM reach approximately 99.5% accuracy on the collected subject set. These modules are tied together by an IoU-based best-frame selection strategy that forwards only a single, high-quality frame, enabling the overall system to maintain an end-to-end latency of 66 ms per frame, or approximately 15.15 FPS, under realistic gate conditions.

Beyond component-level metrics, TRI-GATE was evaluated as a complete gate-control solution. On a tri-modal dataset of 1,000 images, the fused classifier achieves 97% accuracy, utilizing learned fusion weights that naturally emphasize license plate and face cues while still leveraging the discriminative power of vehicle appearance. A real-world demonstration involving an approaching vehicle confirmed that the system can reliably select the best frame, recognize the vehicle and its license plate, identify the enrolled driver, and issue a coherent "access granted" decision in real-time. Compared with prior tri-modal work built on handcrafted features and slower processing pipelines, TRI-GATE offers both higher accuracy and substantially reduced decision time, moving the tri-modal concept from prototype-level feasibility to deployable practice.

Future work will focus on turning TRI-GATE into a more general and deployment-ready platform. A first step is to expand the training datasets with additional subjects, wider geographic coverage, night-time recordings, and more varied weather and windshield conditions. This should help reduce overfitting to specific sites and make the face and vehicle modules more stable in day-to-day operation. A second step is to incorporate open-set recognition and anomaly detection, allowing the system to explicitly flag vehicles or drivers that do not belong to the enrolled population, rather than forcing a hard decision.

In parallel, we plan to investigate privacy-aware data handling, secure storage, and auditable logging, so that TRI-GATE can better align with regulatory and organizational requirements in sensitive infrastructures. Finally, extending the framework to multi-lane, high-throughput checkpoints and optimizing it for edge or embedded hardware would further increase its practical usefulness and scalability. Together, these directions outline a natural path from the current prototype toward a robust, multimodal gate access solution suitable for long-term field deployment.

Computer Science Department, National University of San, Marcos (UNMSM), Lima, Peru[3]

***Abstract*—The exponential proliferation of online gambling content represents a multifaceted challenge for contemporary automated content moderation systems, primarily driven by the sophisticated visual obfuscation and semantic complexity characteristic of modern digital advertising. This study conducts a rigorous comparative evaluation of the efficacy of Deep Learning (DL) architectures against classical Machine Learning (ML) paradigms for the deterministic identification of gambling-related imagery. Specifically, we propose and implement GADIA (Gambling Ad Detector with Intelligent Analysis), a novel hybrid funnel-based architecture that integrates structural heuristic filtering with an asymmetrically fine-tuned ResNet50 classifier. To address the systemic scarcity of high-quality public repositories, the models were trained and validated on a proprietary, strictly balanced dataset of 2,312 images, meticulously curated to encapsulate real-world adversarial marketing techniques. Performance benchmarks were established through Accuracy, Precision, Recall, F1-score, and AUC metrics. Experimental evidence demonstrates that the ResNet50 architecture attained a superior robustness profile, achieving 85.01% accuracy and 90.42% recall, significantly outperforming traditional baselines that failed to capture high-dimensional visual hierarchies. These findings validate that deep residual learning, when integrated into a hybrid heuristic-visual pipeline, provides a computationally efficient and scalable foundation for real-time platform governance and digital safety monitoring.**

***Keywords*—Deep learning; image classification; gambling detection; ResNet50; hybrid systems; transfer learning; Convolutional Neural Networks; platform governance; content moderation**

I. Introduction

The contemporary digital ecosystem has witnessed an unprecedented expansion of online gambling platforms, presenting a significant challenge for automated content moderation systems [1], [2]. While recent studies have addressed text-based gambling promotions on social media [2], visual obfuscation remains a critical bottleneck for conventional filters. This phenomenon is catalyzed by aggressive marketing strategies that strategically operate outside traditional regulatory perimeters. Current empirical evidence suggests that malicious actors are increasingly deploying gambling-related assets within pirate video streaming services and non-standard web containers, utilizing these environments as conduits to bypass conventional detection mechanisms [1]. This shift not only exposes a diverse user base to unregulated betting environments but also imposes a critical burden on automated content moderation infrastructures, which must now operate in increasingly adversarial contexts.

In contrast to textual advertisements, visual gambling content frequently employs sophisticated obfuscation techniques—such as embedding semantic text within high-entropy images or utilizing high-contrast visual stimuli—designed to render keyword-based filtering and static blacklist approaches computationally irrelevant [3]. Historically, the automation of harmful content identification has relied on classical machine learning algorithms. While early implementations of Support Vector Machines (SVMs) and Random Forest classifiers demonstrated efficacy in structured datasets, they consistently struggle to generalize across the high-dimensional variability and hierarchical complexity inherent in modern visual content [5], [6]. Consequently, with the maturation of Deep Learning, Convolutional Neural Networks (CNNs) have been established as the gold standard for visual recognition tasks. Architectures such as ResNet [7] and EfficientNet [8] have exhibited exceptional feature-extraction capabilities, enabling the identification of complex patterns within heterogeneous datasets.

However, the application of these models to the specific, adversarial domain of gambling detection remains significantly underexplored. This gap is particularly evident in the context of real-time monitoring systems, which necessitate an optimal equilibrium between classification precision and computational latency. A predominant limitation in current literature is the reliance on computationally intensive multimodal systems that attempt to fuse Optical Character Recognition (OCR) with deep image analysis [3], [9]. While technically robust, these systems often introduce substantial latency overheads that are prohibitive for real-time, client-side execution within dynamic web environments. Furthermore, the pervasive lack of standardized, publicly available datasets for gambling imagery severely hampers the reproducibility of research and the comparative validation of emerging architectural frameworks [13], [14].

To bridge these gaps, this study proposes GADIA (Gambling Ad Detector with Intelligent Analysis). The conceptual and methodological innovation of our approach lies in the implementation of a **Hybrid Funnel Pipeline** that acts as a "Computational Gatekeeper". By integrating a lightweight heuristic filtering engine—which leverages Document Object Model (DOM) structural properties to rapidly isolate candidate elements—with a robust ResNet50 deep learning classifier, the system significantly optimizes the trade-off between speed and accuracy. The primary contribution of this work is articulated through three pillars: 1) the architectural development of a specialized heuristic-visual pipeline capable of real-time

detection in dynamic web environments; 2) the curation and rigorous validation of a balanced proprietary dataset of 2,312 images specifically designed to address the lack of standardized repositories and adversarial visual obfuscation; and 3) a comprehensive comparative evaluation demonstrating that deep residual learning, through fine-tuned skip connections, provides a superior mechanism for identifying gambling motifs compared to both classical models and lightweight scaling architectures.

II. State-of-the-Art and Related Work

This section provides a comprehensive review of the evolution of artificial intelligence frameworks for the detection of illicit web content. The analysis focuses on the transition from classical machine learning paradigms to deep learning architectures, emphasizing the unique challenges posed by the identification of gambling-related visual assets within dynamic and adversarial digital environments.

A. Evolution of Deep Learning Architectures for Visual Moderation

The automated identification of sensitive visual content has been profoundly transformed by the advancements in Convolutional Neural Networks (CNNs). He et al. [7] introduced a fundamental shift in deep network training with the development of residual learning (ResNet). By implementing identity skip connections, this architecture effectively mitigates the vanishing gradient problem, enabling the training of networks with substantial depth—such as the ResNet50 backbone utilized in this study. This depth is critical for the extraction of complex hierarchical features and latent visual primitives that define the stylistic signatures of gambling imagery.

Parallelly, Tan and Le [8] proposed the EfficientNet framework, which utilizes compound scaling to balance network depth, width, and resolution. While EfficientNet architectures achieve high parameter efficiency, their application in domain-specific tasks involving visual obfuscation requires careful validation. These foundational architectures serve as the primary feature extraction engines for modern content moderation systems, yet their stand-alone implementation often overlooks the structural context of the web environments they monitor.

B. Detection of Gambling and Malicious Visual Assets

Current literature has increasingly applied these deep architectures to identify high-risk content in unregulated spaces. Wang et al. [1] addressed the proliferation of malicious domains within pirate streaming ecosystems, developing a framework that combines URL structural analysis with CNN-based snapshots to achieve detection accuracies exceeding 98%. Similarly, Chen et al. [3] explored the detection of pornographic and gambling websites through a hybrid approach that fuses visual features (extracted via BoVW) with textual semantic vectors (processed by Doc2Vec).

However, recent advancements continue to struggle with computational efficiency. For instance, **Maldini et al. [10]** recently proposed a hybrid framework combining Faster R-CNN with Optical Character Recognition (OCR) to detect covert gambling ads. While such multimodal fusion improves robustness against content variation, these systems frequently rely on OCR layers that are computationally expensive and introduce significant latency overheads. In contrast to these multimodal frameworks, GADIA prioritizes a streamlined visual pipeline that avoids the "computational tax" of OCR, focusing instead on the synergy between structural web heuristics and deep classification.

C. Comparative Paradigms: Deep Learning vs. Classical Baselines

Despite the dominance of Deep Learning, classical machine learning models remain the standard benchmark for efficiency. Syahputra and Wibowo [6] conducted a comparative evaluation of Support Vector Machines (SVM) and Random Forest for negative content filtering, noting that while SVMs demonstrate high precision in structured textual tasks, they inherently lack the capability to capture the non-linear, high-dimensional visual variations prevalent in modern advertising. **This limitation is corroborated by recent findings from Liem et al. [4], who demonstrated that while classical ML performs adequately on structured metadata, it fails to generalize against the complex visual variations found in modern gambling advertisements.** Furthermore, Li et al. [13] demonstrated that CNN-based models significantly outperform traditional classifiers (SVM, k-NN, and Decision Trees) in identifying misleading video content, validating the necessity of deep architectures for tasks involving visual complexity and obfuscation. However, as noted by recent studies [1], rule-based automation remains a necessary component to handle the structural variability of web-based ads, a gap that GADIA fills by integrating a heuristic gatekeeper.

D. Identification of Research Gaps and Methodological Contributions

A critical analysis of existing solutions reveals three significant limitations that GADIA aims to address. First, current multimodal systems (integrating OCR, text, and image analysis)—and even emerging Large Language Models (LLMs) evaluated for moderation [12]—incur prohibitive computational costs, rendering them unsuitable for real-time, browser-side detection in client devices [3], [9]. This creates a demand for an "Inference Funnel" that reduces the load before visual analysis. Second, there is a systemic scarcity of standardized, balanced, and publicly accessible datasets specifically curated for gambling advertising, with most research relying on localized or small-scale repositories [1], **a challenge recently highlighted by Sentana et al. [11]**.

Finally, few studies have successfully articulated a framework that combines lightweight structural heuristics with deep visual inference to optimize the trade-off between speed and deterministic accuracy. This study contributes to the field by proposing GADIA, which leverages a fine-tuned ResNet50 architecture within a **Hybrid Funnel Pipeline**. By acting as a structural gatekeeper, GADIA not only advances the technical state of the art but also establishes a foundation for platform governance and regulatory policy enforcement, ensuring real-time applicability in dynamic Single Page Applications (SPAs).

III. Methodology

This study adopts a Design Science Research (DSR) approach, which provides a rigorous and iterative framework

for the development and validation of technological artifacts aimed at solving complex problems in information systems. The methodology is structured into three core phases: A) Data Curation and Preprocessing, B) The Hybrid Detection Architecture, and C) Model Configuration Strategy. This hierarchical structure ensures the reproducibility of the proposed solution, GADIA (Gambling Ad Detector with Intelligent Analysis), while maintaining the scientific rigor necessary for production-grade content moderation. By following the DSR paradigm, the study emphasizes the utility and efficiency of the created artifact within the specific socio-technical context of digital safety.

A. Data Curation and Preprocessing

The structural integrity of the GADIA framework is predicated on a proprietary dataset specifically engineered to mitigate the systemic scarcity of standardized, publicly accessible repositories for gambling-related digital advertising— a critical limitation recently highlighted by Sentana et al. [11] in the context of multimodal ad infiltration. Unlike general-purpose image datasets, our corpus was developed to capture the unique visual nuances and sophisticated obfuscation techniques—such as text-within-images, high-entropy graphical textures, and high-contrast stimuli—employed by illicit advertisers in "in-the-wild" environments.

A total of 2,312 high-resolution images were meticulously harvested from an ecologically valid range of online sources. These include regulated betting platforms, pirate video streaming services (where visual obfuscation is most prevalent), and neutral e-commerce domains. By incorporating assets from non-standard web containers, the dataset effectively encapsulates real-world scenarios where gambling content is strategically embedded to bypass conventional static filtering mechanisms. To prevent class imbalance bias, which frequently compromises the generalizability of deep learning classifiers in specialized domains, the dataset was strictly balanced. As detailed in Table I, the corpus consists of 1,200 positive samples representing diverse gambling motifs and 1,112 negative samples representing neutral web elements.

TABLE I. DATASET DISTRIBUTION AND PARTITIONING

Class Category	Total	Train (70%)	Val (15%)	Test (15%)
Gambling (Positive)	1,200	840	180	180
Non-Gambling (Negative)	1,112	778	167	167
Total Images	**2,312**	**1,618**	**347**	**347**

Source: Own elaboration.

The data partition strategy employed stratified sampling to divide the corpus into training (70%), validation (15%), and testing (15%) subsets. This rigorous split ensures that each subset maintains the original class distribution while preventing data leakage across the training and evaluation phases. As illustrated in Fig. 1, the preprocessing pipeline implements a three-stage standardization protocol designed to stabilize the feature extraction process and mitigate internal covariate shift:

- Normalization: Pixel intensity values are linearly scaled to the unit range $[0, 1]$. This normalization is critical to optimize gradient descent convergence and ensure that visual features are processed within a uniform numerical scale, preventing the model from becoming biased toward specific illumination variances.
- Resizing: Raw images undergo bilinear interpolation to a fixed resolution of 224×224 pixels. This specific configuration aligns with the spatial requirements of the ResNet50 backbone while preserving critical visual primitives and edges necessary for detecting fine-grained gambling identifiers.
- Data Augmentation: To mitigate overfitting and improve geometric invariance, a suite of stochastic transformations—including random rotations ($\pm 30°$), zoom variations (0.3), and horizontal flips—is applied exclusively to the training subset. This synthetic expansion of the feature space encourages the neural network to generalize across the diverse orientations, scales, and perspectives prevalent in dynamic, modern web containers.

B. Proposed Hybrid Architecture

To address the inherent limitations of conventional content moderation systems—which typically rely on monolithic visual inference or rigid keyword matching—GADIA introduces a multi-stage architectural paradigm designed to optimize the trade-off between computational overhead and classification accuracy. The system logic is predicated on a Hybrid Funnel Pipeline, an asymmetrically structured execution flow that prioritizes early-stage structural culling to preserve high-value GPU resources for deterministic analysis. This architecture is segmented into three interdependent modules:

1) DOM scraper and parser: As the primary ingestion point, this module utilizes a high-fidelity scraping engine capable of rendering complex, dynamic JavaScript execution environments, such as Single Page Applications (SPAs). Unlike static HTML parsers, it performs a comprehensive traversal of the Document Object Model (DOM) to isolate potential visual assets, including standard image files, embedded iframes, and dynamic canvas elements. By extracting these assets within their rendered structural context, the system ensures that dynamically injected advertisements—which often evade traditional security filters—are effectively captured for downstream analysis.

2) Heuristic filtering engine (AdDetector): To mitigate the "computational tax" associated with deep neural network inference, GADIA implements a lightweight heuristic filter as a structural gatekeeper. This module, illustrated in Fig. 2, applies a cascade of deterministic rules to identify candidate ad containers. It performs high-speed analysis of CSS selectors, identifies specific attribute patterns (e.g., metadata and alt-text containing domain-specific keywords), and detects signatures of known ad-network scripts. By early-discarding non-advertising elements such as navigation icons or site logos, the engine reduces the search space by an order of magnitude, forwarding only "suspicious" candidates to the deep learning layer.

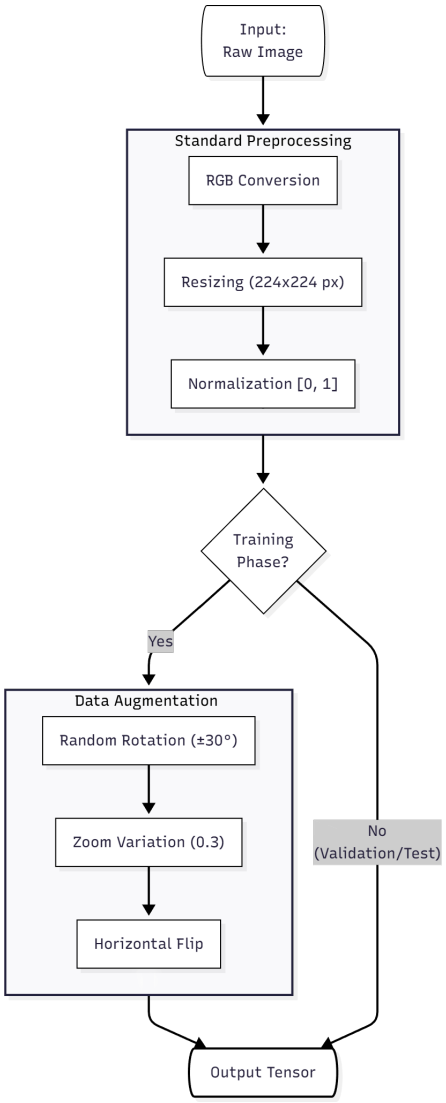

Fig. 1. Data preprocessing pipeline. The diagram illustrates the conditional branching where geometric transformations (rotation, zoom, flip) are applied solely to the training subset to enhance model generalization (Source: Own elaboration).

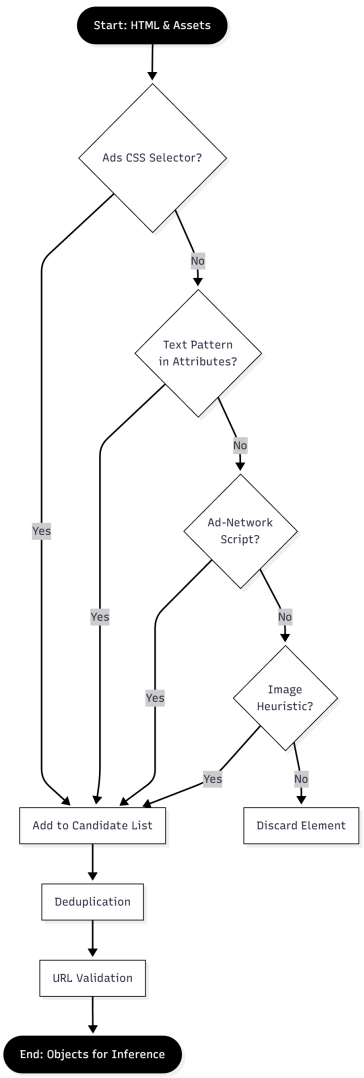

Fig. 2. Flowchart of the AdDetector module. The algorithm applies a cascade of heuristic rules based on CSS selectors, semantic patterns, and embedded scripts to identify advertising candidates before visual analysis (Source: Own elaboration).

3) Deep visual inference (gambling detector): The filtered candidates undergo high-dimensional feature extraction and probabilistic classification. This stage utilizes the residual learning framework to capture the subtle visual motifs and semantic identifiers of gambling content. To ensure a robust classification boundary in production environments, a confidence threshold was empirically optimized and fixed at $\tau = 0.4931$. This threshold serves as the final decision mechanism to categorize each frame as "Gambling" or "Safe", ensuring a high degree of precision even in the presence of sophisticated visual obfuscation.

C. Deep Learning Model Configuration

To effectively decode the visual complexity inherent in modern gambling advertisements—which frequently employ high-entropy graphics, intricate textures, and embedded semantic text—this study implements a specialized Transfer Learning paradigm. We utilize the ResNet50 architecture [7], pre-trained on the ImageNet database, as the primary feature extraction backbone. ResNet50 was strategically selected for its residual learning framework; the integration of identity skip connections effectively mitigates the vanishing gradient problem, enabling the preservation of fine-grained spatial features across deep hierarchical layers. This is particularly critical for distinguishing between visually similar motifs, such as colorful video game assets and gambling slot machine interfaces, where deep residual primitives offer superior discriminative power.

The architectural modification and adaptation protocol are executed through a two-stage deterministic strategy:

1) Asymmetric fine-tuning strategy: To facilitate domain-specific feature adaptation, the last 25 layers of the ResNet50 backbone were unfrozen for gradient updates. This selective unfreezing allows the network to recalibrate its high-level abstract representations—which are sensitive to the specific

visual semantics of gambling content—while maintaining the robust, generic edge-and-texture detectors encoded in the earlier frozen layers. This balance ensures that the model leverages universal visual knowledge while minimizing the risk of catastrophic forgetting during the domain adaptation process.

2) Regularized custom classification head: As illustrated in Fig. 3, the standard fully connected layers were replaced with a custom-engineered head designed to optimize decision boundaries on the proprietary dataset. This head implements a Global Average Pooling (GAP) layer to reduce spatial dimensionality while preserving feature mapping, followed by a dual-block dense architecture. The first block comprises 512 neurons with Rectified Linear Unit (ReLU) activation and L2 regularization ($1e-4$) to constrain weight magnitude. To stabilize the training dynamics and reduce internal covariate shift, Batch Normalization is applied, followed by a stochastic Dropout rate of 0.5. The second block serves as a dimensionality compressor with 128 neurons (Dropout 0.3), forcing the network to synthesize only the most salient discriminative features. The final output is generated by a single neuron with a Sigmoid activation function, yielding a probabilistic score $P(y=1|x) \in [0,1]$ for binary classification.

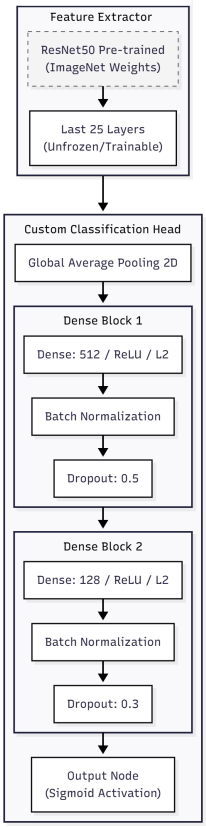

Fig. 3. Implemented neural network architecture. The diagram details the transfer learning strategy on the ResNet50 backbone and the structure of the custom classification head designed for binary task (Source: Own elaboration).

IV. Implementation

The operational deployment of GADIA was executed following a decoupled microservices architecture, as illustrated in Fig. 4, prioritizing modularity, horizontal scalability, and high-fidelity data ingestion. The system's execution paradigm distinguishes between the Presentation Layer (Frontend) and the Business Logic Layer (Backend), communicating via high-performance RESTful endpoints. This architectural orchestration ensures that the computational load of deep visual inference does not compromise the responsiveness of the user interface, providing a seamless monitoring experience even in heavy traffic scenarios.

A. Technological Stack and Development Environment

The core processing engine was developed using Python 3.9, selected for its mature ecosystem in data science and its native support for advanced deep learning frameworks. The backend infrastructure is built upon FastAPI, a modern, high-performance web framework that utilizes the Asynchronous Server Gateway Interface (ASGI). This choice was critical to implement the "Hybrid Funnel" logic; by leveraging asynchronous request handling (`async/await`), the server manages concurrent scraping and inference tasks without blocking the main execution thread, thereby minimizing the synchronization bottlenecks typical of synchronous frameworks. The implementation of the four primary modules is detailed as follows:

1) Web scraping module (data acquisition): To effectively handle the complexities of modern dynamic websites and Single Page Applications (SPAs), we integrated Selenium WebDriver in headless mode. This module instantiates a Chrome-based browser environment that fully renders the Document Object Model (DOM) and executes client-side JavaScript. This capability is essential for capturing "hidden" or dynamically injected advertisements that bypass static HTML parsers and traditional regex-based security filters.

2) Heuristic engine (AdDetector): Implemented as a high-speed Python module, this component parses the rendered DOM tree using `lxml` drivers, which offer superior traversal speeds compared to standard libraries. It executes the multi-stage cascade of heuristic rules described in the Methodology, acting as the primary sieve. By identifying candidate nodes based on CSS signatures, ad-network script patterns, and semantic attributes, the engine discards up to 80% of page elements before they reach the GPU, significantly reducing the "computational tax" per request.

3) Deep learning inference engine: The fine-tuned ResNet50 model was serialized and deployed using the TensorFlow/Keras framework. To ensure real-time throughput, model weights are pre-loaded into GPU memory (allocated via NVIDIA CUDA) upon server initialization. This strategy avoids the overhead of reconstructing the computational graph during runtime, allowing for near-instant classification of filtered visual assets.

4) User interface: The client-side application was developed using React.js. It serves as a responsive dashboard that accepts target URLs and visualizes the detection results. The interface provides real-time feedback, displaying the probabilistic confidence scores generated by the ResNet50 model alongside the heuristic flags, enabling human-in-the-loop verification where necessary.

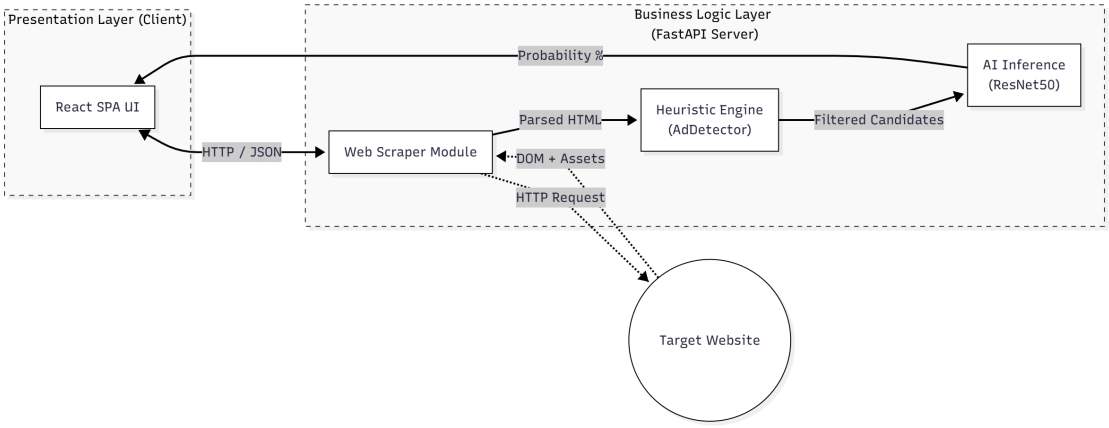

Fig. 4. System implementation architecture. The diagram illustrates the decoupled interaction between the React frontend and the FastAPI backend, highlighting the integration of Selenium for dynamic DOM rendering and the ResNet50 engine for visual inference within a high-performance funnel. (Source: Own elaboration.)

B. Runtime Execution Workflow

The operational dynamics of the GADIA system follow a strictly sequential pipeline, engineered to maximize the computational cost-benefit ratio by minimizing redundant processing. As depicted in the sequence diagram (Fig. 5), the workflow is initiated by an external client request containing a target URL. The system orchestrates the data flow through five deterministic phases, ensuring that high-latency visual inference is only executed when structural indicators suggest a high probability of gambling content:

1) Request orchestration and initialization: Upon receiving the URL via the FastAPI endpoint, the server instantiates a dedicated scraping session. This phase includes the validation of the target URL and the allocation of an asynchronous worker to manage the lifecycle of the rendering process.

2) Asynchronous dynamic rendering: To capture the complete state of modern web environments, the scraping engine performs a full render of the page. This involves the execution of client-side scripts and the simulation of scroll events to trigger lazy-loading mechanisms. The output of this phase is a comprehensive list of visual assets (source URLs for images, iframes, and canvas elements) coupled with the fully computed Document Object Model (DOM) tree.

3) Structural heuristic sieve: The AdDetector module performs a high-speed traversal of the DOM nodes, acting as a structural gatekeeper. Elements are evaluated against a cascade of deterministic rules, including CSS selector matching, keyword-in-attribute analysis, and identification of ad-network script footprints. Elements that do not meet the minimum "suspicion" threshold—such as navigation bars, branding logos, or functional icons—are immediately discarded from the pipeline. This early-stage culling reduces the search space by an order of magnitude, preventing the deep learning model from processing irrelevant safe imagery.

4) Deep residual inference: Assets flagged as advertising candidates are asynchronously downloaded and converted into normalized tensors. These are then fed into the fine-tuned ResNet50 model, which performs high-dimensional feature extraction to detect latent gambling motifs. The model generates a probabilistic score $P(y = 1|x) \in [0, 1]$, quantifying the likelihood of the asset belonging to the "Gambling" class based on the hierarchical visual primitives learned during the training phase.

5) Deterministic response aggregation: In the final phase, the system synthesizes the heuristic indicators and probabilistic outputs into a unified JSON payload. This payload includes the original asset metadata, the heuristic flags, and the final classification result. The response is returned to the client, completing the detection cycle within the strict latency margins required for real-time monitoring.

V. Results

This section presents a comprehensive quantitative evaluation of the proposed models and the subsequent functional validation of the GADIA software artifact. The experimental framework was meticulously designed to benchmark the classification performance of the fine-tuned ResNet50 architecture against three distinct baseline models: EfficientNetB0 (representing modern lightweight Deep Learning), and two traditional paradigms, Random Forest and Support Vector Machine (Classical Machine Learning).

A. Experimental Setup and Hyperparameter Tuning

The evaluation was conducted using the proprietary, strictly balanced dataset of 2,312 images. To ensure statistical reliability and prevent data leakage, we adhered to a stratified sampling strategy with a 70/15/15 split for training, validation, and testing, respectively. The computational environment was anchored by a workstation equipped with an NVIDIA RTX 3060 GPU, which provided the necessary acceleration for deep neural network training.

For the Deep Learning architectures (ResNet50 and EfficientNet), the optimization phase utilized the RMSprop algorithm with an initial learning rate of $5e - 5$. A binary cross-entropy loss function was employed to minimize the divergence between predicted probabilities and ground truth labels. To preserve model generalizability and prevent overfitting, we implemented an Early Stopping callback with a patience factor

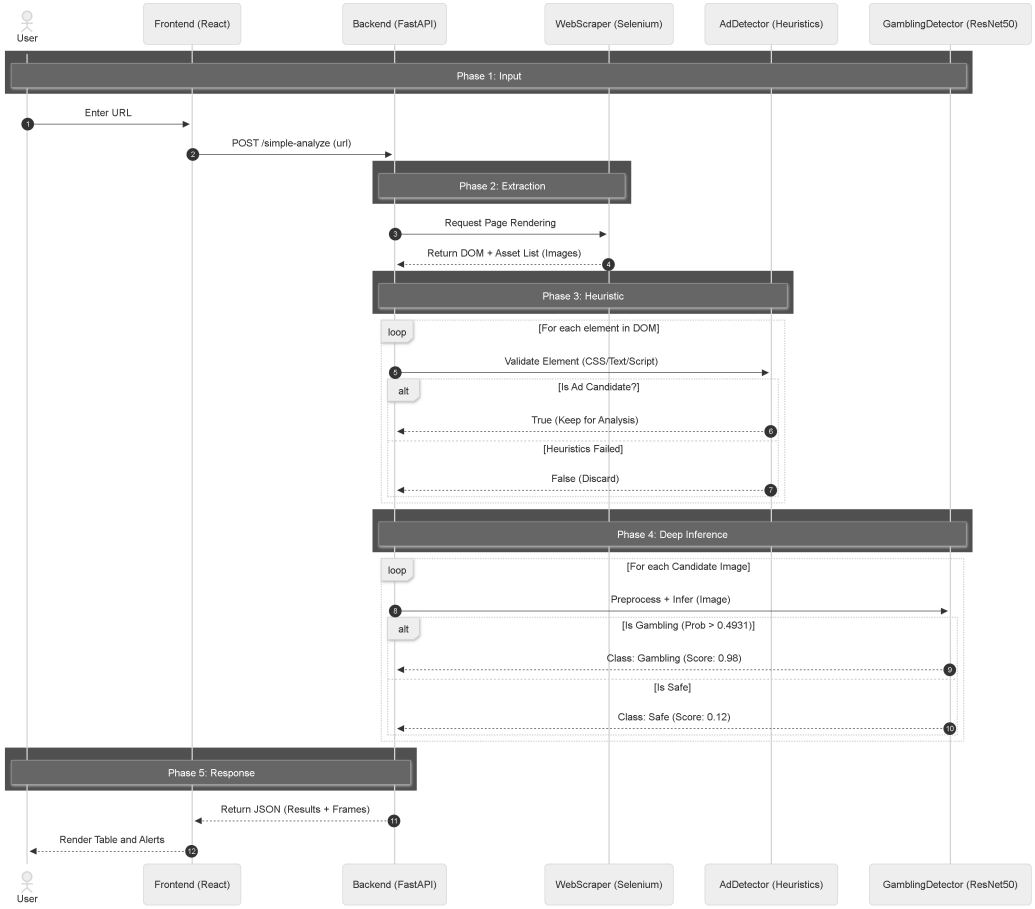

Fig. 5. Sequence diagram of the detection pipeline. The flow demonstrates the filtering efficiency: the Heuristic Engine (AdDetector) discards non-relevant elements early in the process, ensuring that the computationally expensive ResNet50 inference is only applied to high-probability candidates (Source: Own elaboration).

of 5 epochs, monitoring the validation loss for early signs of convergence saturation. In contrast, the classical baselines (SVM and Random Forest) were optimized via an exhaustive Grid-Search cross-validation to identify the optimal kernel parameters and forest depth, ensuring that the performance gap observed is inherent to the algorithms and not a result of suboptimal tuning.

TABLE II. PERFORMANCE COMPARISON OF CLASSIFICATION MODELS

Model	Acc.	Prec.	Recall	F1-Score	AUC
EfficientNet	0.7550	0.6847	**0.9102**	0.7815	0.7606
Random Forest	0.7954	0.7637	0.8323	0.7966	0.7967
SVM	0.7983	0.7803	0.8084	0.7941	0.7986
ResNet (Ours)	**0.8501**	**0.8075**	0.9042	**0.8531**	**0.8521**

Source: Own elaboration.

B. Comparative Analysis of Model Performance

The quantitative efficacy of each model was rigorously assessed using five primary metrics: Accuracy, Precision, Recall, F1-Score, and the Area Under the Curve (AUC). Table II provides a comparative summary of the results obtained on the independent test set.

The empirical data indicates that the proposed fine-tuned ResNet architecture attained the most robust performance profile. Achieving an overall Accuracy of 85.01%, it outperformed the classical SVM and Random Forest baselines by approximately 5.18% and 5.47%, respectively. This performance delta underscores the superiority of residual learning in capturing high-dimensional visual motifs that classical algorithms—even when optimized—fail to aggregate effectively.

A significant observation emerges when comparing the two Deep Learning architectures. While EfficientNet achieved the highest sensitivity (Recall: 0.9102), it did so at a substantial cost to Precision (0.6847), suggesting a high propensity for False Positives. In the context of real-world content moderation, such an "over-flagging" behavior is undesirable as it leads to the erroneous blocking of safe, legitimate content. Conversely, our ResNet implementation maintained a superior equilibrium, yielding a Precision of 80.75% and an F1-Score of 85.31%. This balance is critical for the GADIA system, as it ensures high detection rates for gambling advertisements while minimizing the degradation of user experience caused by false alarms. The AUC of 0.8521 further validates the model's

discriminative power across varying decision thresholds.

C. Software Deployment and Functional Validation

To bridge the gap between theoretical model performance and practical utility, the proposed architecture was integrated into a fully functional software artifact. This deployment served to validate the end-to-end viability of the GADIA system within a simulated production environment. Fig. 6 illustrates the GADIA interface, implemented as a high-performance web-based analysis tool. The dashboard provides a streamlined user experience, allowing analysts to input target URLs which are then processed in real-time through the asynchronous backend pipeline detailed in Section IV.

[Image of a web-based dashboard interface for real-time website content analysis and ad detection]

The functional validation phase confirmed that the software successfully orchestrates the three core modules: the Selenium-based scraper, the structural heuristic filter, and the ResNet50 inference engine. In a series of preliminary stress tests involving dynamic Single Page Applications (SPAs), the system demonstrated a robust capability to render complex JavaScript-injected content and correctly identify gambling advertisements strategically embedded within neutral web layouts.

One of the most significant findings during functional testing was the effectiveness of the "Heuristic Sieve". By discarding non-relevant structural elements before they reached the deep learning layer, the system maintained a low inference latency, ensuring that the classification results—including the probabilistic confidence scores and the deterministic "Gambling/Safe" labels—were delivered within a timeframe suitable for real-time monitoring. These results confirm the engineering viability of the GADIA framework as a scalable solution for automated content moderation.

Fig. 6. Operational validation of the GADIA software. The screenshot demonstrates the system detecting gambling content on a live webpage, displaying the confidence score generated by the ResNet model and the inference latency.

VI. Discussion

The experimental results validate the hypothesis that a hybrid architecture, combining structural heuristics with deep residual learning, offers a robust and scalable solution for the automated detection of gambling content. This section interprets the findings through the lenses of model stability, architectural innovation, cross-domain generalization, and the broader implications for digital platform governance.

A. Analysis of Model Performance and Decision Trade-offs

A critical finding of this study is the performance divergence between EfficientNetB0 and ResNet50. While EfficientNet achieved a superior Recall (0.9102), its significantly lower Precision (0.6847) indicates a propensity for "over-flagging". In the high-stakes environment of web content moderation, an elevated False Positive rate is detrimental; it leads to the erroneous blocking of legitimate assets (e.g., news portals, educational graphics), which directly degrades user trust and platform utility.

In contrast, the ResNet50 architecture demonstrated superior stability, achieving the highest F1-Score (0.8531). This empirical success suggests that the residual primitives and identity skip connections in ResNet are more effective at preserving the fine-grained visual features required to distinguish between visually similar but semantically distinct categories—such as high-contrast video game advertisements versus gambling slot machine interfaces—than the compound scaling approach of EfficientNet in this specific adversarial domain. Furthermore, the performance gap between DL models and classical classifiers (SVM, Random Forest) underscores that CNN-based feature extraction is essential for generalizing across the diverse, high-dimensional visual styles of modern gambling advertisements without the need for manual feature engineering.

B. Architectural Innovation and Operational Efficiency

The implementation of the AdDetector heuristic engine as a "Computational Gatekeeper" prior to deep visual inference represents a significant advancement over monolithic systems. By filtering out non-relevant Document Object Model (DOM) elements based on structural and semantic patterns, GADIA avoids the prohibitive computational cost of processing every page element through a neural network. **Although recent studies have explored Large Language Models (LLMs) for sensitive content detection [12], such models often incur latency overheads unsuitable for real-time client-side blocking.** This hybrid approach addresses a persistent gap in the literature: high-accuracy models often fail in real-world deployment due to latency constraints. The synergy between FastAPI's

asynchronous handling and Selenium's dynamic rendering capabilities ensures that GADIA remains resilient against modern web techniques like AJAX and JavaScript-injected ads [1]. The functional validation confirms that our system maintains an optimal balance between theoretical robustness and the near-instantaneous response times required for client-side monitoring tools.

C. Cross-Domain Generalization and Scalability

As requested by contemporary research benchmarks, it is essential to highlight that GADIA is a **content-agnostic framework**. While this study utilized gambling content as the primary use case, the underlying hybrid funnel is inherently generalizable. The structural heuristic sieve can be recalibrated to detect other forms of regulated or harmful material—such as phishing attempts, unauthorized alcohol promotion, or adult content—by simply swapping the classification head or retraining the ResNet50 backbone on diverse labeled datasets. This modularity ensures that GADIA is not merely a localized solution but a versatile tool for broader digital safety applications.

D. Platform Governance and Policy Implications

Beyond technical metrics, GADIA provides a scalable mechanism for **Platform Governance**. Current digital safety policies and child protection regulations (such as the UK's Online Safety Act or the EU's Digital Services Act) necessitate real-time, automated auditing of digital advertising. Our framework offers regulatory bodies and platform owners a deterministic tool to monitor environments that frequently host illicit content (e.g., pirate streaming services), enabling automated compliance enforcement with minimal human intervention. By reducing the reliance on slow, multimodal systems that require OCR [3], [9], GADIA facilitates a more proactive approach to digital policy enforcement.

E. Limitations and Adversarial Context

Despite the promising results, this study acknowledges certain limitations. The current proprietary dataset, while balanced and ecologically valid, focuses primarily on static imagery. The detection of gambling motifs embedded within live video streams or frames obfuscated through advanced steganography remains an open challenge. Additionally, while the visual-only approach is highly efficient, advertisements that are purely text-heavy on neutral backgrounds may still evade detection without the integration of a specialized OCR module, suggesting a future path for lightweight multimodal expansion.

VII. Conclusion and Future Work

This research has successfully demonstrated the efficacy of GADIA, a hybrid architectural framework designed for the automated detection of gambling advertising within complex and dynamic web environments. Through the synergistic integration of a structural heuristic filtering engine and an asymmetrically fine-tuned ResNet50 deep learning classifier, the system effectively addresses the critical trade-off between deterministic precision and computational latency. The implementation within a decoupled architecture utilizing FastAPI and React.js validates that it is possible to intercept visually obfuscated content in real-time without degrading the end-user's navigational experience or incurring the high "computational tax" associated with traditional multimodal systems.

The experimental results confirm that the ResNet50 architecture, optimized through transfer learning and selective layer unfreezing, offers the most robust performance profile for production-grade content moderation. With an F1-score of 85.31% and an Accuracy of 85.01%, the model demonstrated a superior capability to distinguish between subtle gambling motifs and visually similar neutral elements. While compound-scaled models like EfficientNet exhibited marginally higher sensitivity, their significantly lower precision renders them unsuitable for real-world environments where false positives negatively impact platform utility and user trust. Furthermore, the clear superiority of the proposed deep learning approach over classical paradigms (SVM and Random Forest) ratifies that hierarchical feature extraction is indispensable for generalizing across the high-dimensional variability of modern digital imagery.

From an engineering perspective, the introduction of the AdDetector module as a "structural sieve" proved to be the most influential architectural decision. By acting as a computational gatekeeper that discards irrelevant DOM elements prior to visual inference, the system optimizes GPU resource allocation, enabling the monitoring of high-traffic Single Page Applications (SPAs). Ultimately, this work contributes not only a validated technological artifact and a specialized dataset of 2,312 images but also establishes a rigorous framework for platform governance and the proactive enforcement of digital safety policies.

A. Future Work

Despite the successful implementation, several avenues for improvement and expansion have been identified to enhance the system's robustness and scope. First, future iterations should incorporate an Optical Character Recognition (OCR) module to analyze text embedded within images, improving the detection of text-heavy advertisements that lack distinct visual gambling motifs. Second, given the rise of streaming platforms, extending the detection pipeline to process video frames in real-time is a priority, which would involve optimizing the inference engine to handle temporal redundancy between frames. Third, research should be conducted on distilling the ResNet50 model into lightweight architectures (e.g., MobileNet or SqueezeNet) to facilitate edge deployment directly on client devices, reducing latency and enhancing user privacy. Finally, as illicit advertisers evolve, testing the system against adversarial attacks, such as noise injection or style transfer, will be crucial to ensure long-term reliability.

In conclusion, GADIA provides a scalable and effective solution to the growing challenge of online gambling proliferation, offering a robust foundation for the development of next-generation digital perimeter security and parental control systems.

From Accuracy to Insight: Explainability in Review Rating Prediction with Transformers

Dhefaf T. Radain, Dimah Alahmadi, Arwa M. Wali
Department of Information Systems-Faculty of Computing and Information Technology,
King Abdulaziz University, Saudi Arabia

***Abstract*—Mobile application (app) reviews provide valuable information that facilitates understanding of users' needs, leading to better design of developed products. They have abundant data that can be utilized by different models to explain the prediction results to stakeholders. This will lead mobile app developers to trust and rely on the models that are used to develop their apps and satisfy the users' needs. To leverage this information, outstanding improvements in complex learning algorithms have led to the development of transformer-based models that are used for natural language processing (NLP) and to exploit rating predictions. However, such models are complex and lack explainability, especially for Arabic reviews. Most studies have applied explainability models for transformer-based models to the English language and various other languages but not the Arabic language. This study presents a rating prediction explainability (RPE) framework that combines transformer-based and explainability models for review rating predictions from mobile government (m-government) apps. The transformer-based models predict the ratings for reviews written in English or Arabic. Then, local explainability models, such as SHapley Additive exPlanation (SHAP) and local interpretable model-agnostic explanations (LIME), explain and visualize the results. In RPE, not only high prediction accuracy was achieved for both English and Arabic reviews, but the resulted predictions were also justified with consistency between the different explainability models. The transformer-based model ELECTRA yielded the highest accuracy and F1 score of 96% for the rating prediction of English reviews, whereas the transformer-based model AraBERTv2 had 95% accuracy and F1 score for the rating prediction of Arabic reviews. The results of both explainability models provided equivalent explanations and emphasized the same words that affected the predicted ratings.**

Keywords*—Explainability; LIME; review rating prediction; SHAP; transformer-based models

I. Introduction

In recent years, an increasing number of user reviews have been posted on various internet services. These services include social media, e-commerce, and microblogs [1]. User reviews are comments and opinions provided by consumers about a product, business, or application (app) [2]. They consist of essential information that can capture the users' preferences over multiple items [3]. They provide pivotal information regarding the quality of the item being reviewed to help others decide whether to buy the product, deal with the business, or download the app [4]. This has prompted recent studies in this field on complementing item representation and improving recommendation performance [3].

One source of these reviews is mobile apps. They are a convenient way for users to share their opinions and thoughts. The interaction between users and mobile apps under several usage contexts have made the need for better app design a crucial issue. This presents a considerable challenge for app developers and marketers in developing suitable apps for users on the basis of their needs. Constructive and timely user reviews help developers become aware of user needs, creating opportunities for innovation [5]. The star ratings and the users' written reviews that is provided by the apps create an understanding of the consumers' needs and preferences, which leads to enhancements in the apps' features or the development of more advanced apps [6].Furthermore, one of the most important types of reviews that require careful analysis is related to mobile government (m-government) apps. The evolution of information and communication technology (ICT) has led governments worldwide to digitize their services using mobile technology, creating the concept of m-government. M-government allows for better communication with citizens/residents and provides them with better access to services [7]. The number of mobile phone users worldwide has reached 6.378 billion [8], and in Saudi Arabia, the number of smartphone users is expected to increase to 36.17 million in 2025 [7]. An evaluation of the current usage of m-government apps will help determine their effectiveness [6].

Turning this unstructured feedback into actionable insights requires natural-language models that are both accurate and linguistically inclusive. Numerous approaches have leveraged user reviews to extract knowledge related to their content or semantics in several languages [9]. To extract and work within user reviews, studies have utilized the features provided by deep learning (DL) in natural language processing (NLP). Among DL architectures, transformer-based models are considered important landscapes for NLP. On many tasks, they outperform many other state-of-the-art DL models [10] [9]. This is because, with traditional models, training incurs a high computational cost, which limits the volume of tuning that could be done on a model [11]. Furthermore, the size of the dataset used to train a model limits the ability to measure how the model is advancing. However, since transformer-based models are already trained on enormous datasets, this reduces the computations needed for the training process. In addition, they eliminate the need for an enormous dataset to obtain significant results [12].

On the other hand, the black-box nature of these models is considered a shortcoming. This means that the internal operations of the classifiers are unknown to humans [13]. Understanding the reasons behind the predictions made by a model is quite important for taking action based on these reasons [14]. Explainability is the ability of humans to understand a model and its behavior. In some cases, explainability is considered

a prerequisite for accepting the results of the model [15]; for example, the use of the model in medical applications or terrorist recognition cannot be based on blind faith, considering the consequences. Furthermore, any predictions related to a text should be linked with an explanation that indicates how and why the predictions were made. This type of understanding can be achieved by tracing each decision made by a model back to individual words [16].

Studies have shown that explainability models, such as SHapley Additive exPlanation (SHAP) and local interpretable model-agnostic explanations (LIME), are useful for adding explanations when incorporated into model workflows [17]. Recently, various studies have used SHAP as an explainability model. For example, it was used to measure the contributions of specific tokens toward specific predictions of material properties [18]. In addition, it was used as an explanation method for text classification developed by the BERT transformer-based model [19]. LIME was used as a basic explainability model for detecting patients with specific diseases on the basis of the predictions of several transformer-based models [20]. Additionally, it was used to explain the reasons behind the identification of harmful content in tweets [21].

The intersection of highly rated apps and public services makes m-government apps an ideal, high-impact test bed for such explainable techniques. The use of m-government in Saudi Arabia began to take shape in different sectors of the country [22]. Predicting the reviews' ratings and providing an explanation for the predicted ratings will enrich the Saudi Arabian app development market to develop apps based on users' demands. However, these reviews frequently mix modern standard Arabic with colloquial dialects which are underrepresented in standard corpora. Arabic language presents unique challenges that are not present in English-based NLP pipelines. This is due to the language's rich morphology, complex grammar, data scarcity, and variety of dialects [23], that result in inconsistent predictions and inaccurate and unreliable models. Even with the growing number of advancements and improvements in transformers and explainability models, there is still a lack of studies that have used such models in Arabic NLP tasks, especially in the field of predicting review ratings.

Consequently, this study aims to provide the Rating-Prediction-Explainability (RPE) framework, which combines various transformer models with SHAP and LIME to deliver both accuracy and transparency in predicting the ratings of m-government apps in Saudi Arabia based on written reviews in English and Arabic.

The main objectives of this study are as follows:

- Creating a dataset for m-government apps for both English and Arabic language.
- Developing a review rating prediction framework for English and Arabic reviews from m-government apps using Transformer-based models.
- Providing explainability for the resulting prediction from the transformer-based models using explainability models.
- Proving the consistency in the explainability between the different explainability models used in the framework.

The remainder of this study will discuss the related works to this study from the literature, as well as highlight the research gap. Next, it discusses the details of the methodology used for the proposed model, the data, and the experiment and evaluation of the model. Then it presents the results and discusses them. Finally, the study ends with a conclusion and provides limitations and future work.

II. Related Work

Given the importance of user-generated reviews, developers and academic researchers have conducted several studies to determine the best method for predicting ratings based on the review content and the language of the review. This has resulted in a high demand for understanding the predicted results [24]. This section highlights the different studies that have focused on rating prediction on the basis of users' reviews and their language, transformer-based models, and different explainability models

A. Rating Prediction

Because reviews and their associated ratings are valuable and not always available, rating prediction has been developed to generate ratings for non-rated items [25]. However, discovering and extracting the users' needs is a nontrivial task because only one-third of app reviews contain objective statements. Moreover, processing many unstructured reviews to extract possible user needs can be tedious. Therefore, automatic extraction is more efficient [5].

Consequently, developers and academic researchers are working on improving the performance of prediction models by extracting diverse features, such as lexical patterns, words, semantic topics, and syntactic structure, from the contents of reviews [26].

Current technical innovations in the field of machine learning (ML) have led to its utilization in various scenarios, including rating prediction [27]. Moreover, DL-based models are effective not only in improving performance but also in learning feature representations from scratch [4], such as Qiao et al. [5] who proposed a domain-oriented approach based on DL that combines a convolutional neural network (CNN) and a recurrent neural network (RNN). The model classifies user feedback to identify the type of information within the user reviews of mobile apps. The results of the study revealed that the proposed model yielded more valuable information, such as essential key-words and more consistent topics. In addition, this DL approach outperformed the traditional classification methods because it captures more contextual and semantic relationships between words.

Moreover, Ahmed and Ghabayen [28] proposed a DL bidirectional gated recurrent unit (Bi-GRU) architecture model for rating prediction. It consists of two phases: the first phase involves polarity prediction, whereas the second phase involves the prediction of review ratings from the text of a review. The results of their experiment indicate that the proposed framework can significantly improve rating prediction compared with the baseline methods. Another study that used a CNN to predict ratings for mobile apps was [29] by Aslam et al. The classifier extracts textual and non-textual information from each app review. Textual information is preprocessed

for each review, and a digital path is created. Finally, a prediction is generated for the app review. The results of the proposed approach revealed a significant improvement in rating prediction for reviews.

However, the rating is not entirely determined by the content of the review because the user may give a low rating but write a positive review. Consequently, different approaches and models have been proposed for rating prediction [26]. Sadiq et al. [30] proposed a DL-based framework for predicting the contradictions between rating predictions in Google Apps. The polarity of reviews is predicted using sentiment analysis to determine the ground truth. Next, DL models are trained on the ground truth to predict star ratings from text reviews. The results of their experiment showed that unbiased star ratings could be predicted based on actual reviews written by users [30]. Table I provides a summary of the proposed models along with their strengths and limitations.

B. Transformer-Based Models

The effectiveness of DL models when a large amount of data is used has been demonstrated; however, there are many limitations related to them. This caused the researchers to focus increasingly on much more sophisticated models that capture the dynamics of the used language. For example, RNN can effectively capture the contextual information and long-term dependencies in the text, however, there are several challenges related to long sequences which makes it difficult to figure out the correlations between the words. Moreover, CNN is known to be used for text classification by extracting local features from the provided input. This allow easy detection of text patterns. However, it provided low accuracy in some of the cases [31]. Additionally, there are some cases in which the available data are not sufficient to train a classifier to obtain justifiable results [32], and training incurs a high computational cost, which limits the model training process [12]. Consequently, transformer-based models were introduced with pretrained models that provide a vast amount of data and reduce the computational cost needed for training DL models [15].

Given the vast amount of information available in users' reviews available online, Kaur and Kaur [33] classified app reviews as relevant, feature requests, or bug reports. They used BERT to extract the contextual connections between written reviews. To assess the efficiency of their proposed model, five datasets were tested, and the model outperformed state-of-the-art models.

Additionally, Shiju and He [34] built a classification model via BERT, XLNet, RoBERTa, ELECTRA, BioBERT, and ALBERT transformer-based models. The models classified drug ratings based on the written textual reviews. This study identified reviews that are inconsistent with the given ratings. Moreover, BioBERT outperformed the other models because it specializes in medical data, which was the focus of this study.

Moreover, Chowdhury et al. [35] investigated the effect of BERT on Arabic text classification by incorporating formal and informal text in the training process. The goal was to classify text into categories such as 'sports', 'human rights', and 'politics', among others using BERT. The study revealed that training with formal text was more generalizable than training with informal text while enabling the correct classification of text. The formal text dataset consisted of social media posts from popular Arabic news channels that cover YouTube, Facebook, and Twitter, whereas the informal text was from Arabic tweets from popular accounts. The study revealed an overall improvement in text classification effectiveness.

In terms of rating prediction, Liu [9] predicted restaurant ratings based on textual reviews from the Yelp dataset via ML models such as Naive Bayes (NB), Logistic Regression (LR), Random Forest (RF), and Linear Support Vector Machine (SVM) and transformer-based models such as RoBERTa, DistilBERT, BERT, and XLNet. Finally, the authors compared the different models in terms of computational resources, speed, and evaluation metrics. The study showed that transformer-based models had higher accuracy than ML models did. One of the reasons for this result is that transformer-based models are pretrained on very diverse data. This diversity improves the generalizability and robustness of these models [36]. Table II provides a summary of the transfromer-based models along with their strengths and limitations.

C. Explainability Models

Recently, breakthroughs in the use of DL models have led to improvements in their accuracy and utilization in several scenarios [27]. However, these models are still considered black-box models [16], and their growing complexity makes reliable, fair, and safe models mandatory [37]. To address this concern, explainability models have been developed. They can be applied to any classification task [19]. In prediction-based models, understanding decisions is relevant for evaluating the reliability of the resulting predictions and detecting possible biases in the models [38].

Owing to the increasing complexity of DL models, reliable, fair, and safe models are needed [37]. Explainability models aim to increase trust by ensuring the transparency, dependability, and stability of the model used [13].

Research have shown that SHAP and LIME explainability models can be added to the workflow of a model used to explain the resulting predictions [17]. As a result, these models have been applied in different domains to enhance explainability. Ahmed et al. [39] developed a model that integrates LIME and BiLSTM to detect fake news. In this model, BiLSTM serves as the classification model for fake news detection, and LIME is used as the explainability model. The model achieved high accuracy and outperformed other ML models.

In the medical domain, Ilias and Askounis [20] used LIME to explain the ability of a BERT transformer-based model to predict whether a patient is suffering from Alzheimer's disease (AD) on the basis of the patients' words used while speaking in English. This study re-vealed significant language differences between patients with and without AD. These differences were explained visually, revealing the diverse patterns of words, expres-sions, and verb tenses used by patients.

Similarly, Rao et al. [40] predicted the incidence of heart failure using the BEHRT transformer-based model. This model was applied to data from patients' electronic health records in the UK. The authors provided explanations for the resulting predictions. BEHRT worked robustly with large-scale, sequential data and outperformed other traditional DL models. The

TABLE I. SUMMARY OF RATING PREDICTION RELATED WORK

Ref	Model	Strengths	Limitations
[5]	CNN and RNN	Capturing more semantic and contextual relationship between the words	The use of one public data source and one method of analysis
[28]	Bi-GRU for rating prediction based on DL	Evaluate the framework on real-world datasets	The large number of unique words causes inefficient encoding for them

[30]	Neural network–based method for understanding and predicting users' rating behaviors	Unify aspect rating with the review content	Detecting fake reviews

TABLE II. SUMMARY OF TRANSFORMER-BASED MODELS RELATED WORK

Ref	Model	Text Type	Strengths	Limitations
[33]	BERT	App reviews	The model achieved high performance in prediction for both long and short datasets	The used dataset had some internal validity issues
[34]	BERT, XLNet, RoBERTa, ELECTRA, BioBERT, and ALBERT	Drugs reviews	Identifying the inconsistent reviews with given ratings	Relying on the drug name for the classification.
[35]	BERT	Social media posts	The classification into multiple labels	Collecting and pre-training a large set of data is impractical
[9]	ML models (NB, LR, RF, and Linear SVM) and transformrmer-based models (RoBERTa, DistilBERT, BERT, and XL-Net)	Restaurant reviews	The experiment with several transformer-based models	No much difference in the accuracy between the ML models and the transformer-based models.

authors used the perturbation concept as a local surrogate method to explain the resulting predictions. They quantified the contribution of selected patient encounters and tested how the combination of the diagnosis and the medications affected the model's predictions.

Although transformer-based models have achieved very promising results in several areas, understanding their results is still an area to explore [39]. Korangi et al. [41] proposed an innovative model representation leveraging a BERT transformer-based model for predicting credit risk for mid-cap companies. They referred to this approach as the transformer encoder for panel-data classification (TEP). The authors incorporated differential training with a multichannel architecture, leading to superior performance and improvement over traditional models by efficiently training with all the data. SHAP was applied to express the importance of ranking the different sources of data and their relationships.

As stated in the previous literature, the explainability of a model is an important factor for its reliability. Different types of text were used under different classification and interpretation models, as shown in Table III, which provides a summary of the explainability models.

III. RESEARCH GAP

To the best of our knowledge, even with many transformer-based models that have been used for review rating prediction and a respectable number of scientific studies that have focused on explainability in different fields, there is a lack of studies that combine these models with explainability to justify the predicted ratings. There is still a need to conduct more research in the field of review rating prediction, especially for mobile apps. They have abundant data that can be utilized by different models to explain the prediction results to stakeholders. This will lead mobile app developers to trust and rely on the models used to develop their apps and satisfy the users' needs. In addition, most studies have applied explainability models for transformer-based models to the English language and various other languages but not the Arabic language. Consequently, this study applies transformer-based models for review rating prediction in both the English and Arabic languages and then applies explainability models to justify the predicted ratings to help the app developers recognize the users' needs for the apps and understand the difficulties they face.

IV. RPE FRAMEWORK

In this study, the RPE framework is proposed to explain the predictions of the review rating of mobile applications generated using transformer-based models. The model consists of three modules: 1) a dataset creation module, where the dataset is collected, cleaned, split, and balanced; 2) a rating prediction module, where the input sequences are processed through three different layers to predict ratings via transformer-based models; and 3) an explainability module, where the resulting predictions are justified via visualization techniques of explainability models. The high-level architecture of the model is shown in Fig. 1.

A. Dataset Creation

The initial dataset consisted of user reviews collected from m-government apps. Reviews were collected from a set of apps based on their purpose. The dataset was then cleaned and split based on the detected language. Dataset Description Section discusses the details of this process. The reviews from the resulted datasets are then passed through the prediction layer to perform the rating prediction.

B. Prediction

The prediction module consists of three different layers: an embedding layer, a transformer layer, and a prediction layer. The rating is predicted for an app review by passing the input

TABLE III. SUMMARY OF EXPLAINABILITY MODELS RELATED WORK

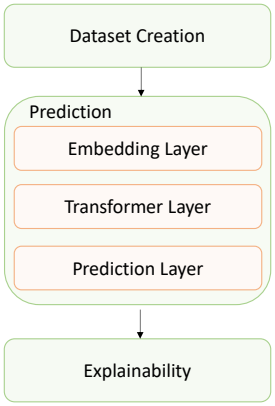

Fig. 1. RPE high-level architecture.

through these layers, which convert the app review into a format that is understandable by the machine and prepares it for the training process. In the following subsections, we provide detailed explanations of these layers.

1) Embedding layer: The transformer-based model receives the user review as discrete input tokens (sentence). The review cannot be processed directly as raw text; therefore, it passes through an embedding layer. The embedding layer converts the input into continuous, high-dimensional vector representations where each token is assigned a unique vector. Next, the model generates contextual embeddings by making some adjustments to the vector where tokens with similar meaning are brought together, allowing the model to capture the semantic relationship between them. As a result, embeddings are generated for each word within different contexts. The self-attention mechanism in the transformer-based models starts with the embedding vector. Then it refines the initial representation based on the context of the entire input [42], [43].

This layer considers text through three different embeddings: token embedding, sentence embedding, and positional embedding. In token embedding, the input is tokenized using the WordPiece tokenization method. The text input is converted into a numerical representation that is understandable by the machine (e_x1, e_x2, e_x3..., e_xL). In addition, additional tokens are added to each input sequence, such as <CLS>, which indicates the beginning of the input, and <SEP>, which separates sentences. The resulting tokens are then passed through the sentence embedding, where the words of each sentence are assigned the same embedding. This is accomplished by adding a learned embedding to each word to indicate the sentence to which the word belongs. Ultimately, an input sequence consisting of multiple sentences is packed together as a single sentence and passes through positional embedding. Each word in positional embedding is assigned a number that represents its position within the entire input (e_1, e_2, e_3, . . . , e_L). If a word is repeated within the input, the same number is assigned. Finally, the sum of the three embeddings generates a representation of a single shape that is passed as an input for the transformer layer. These embeddings contain the meaning and characteristics of the input word, which enables the model to understand their relation to the corresponding rating to perform the rating prediction on the testing dataset [42], [43]. A detailed view of this layer is shown in Fig. 2. We refer the readers to [42], [43] for a comprehensive explanation.

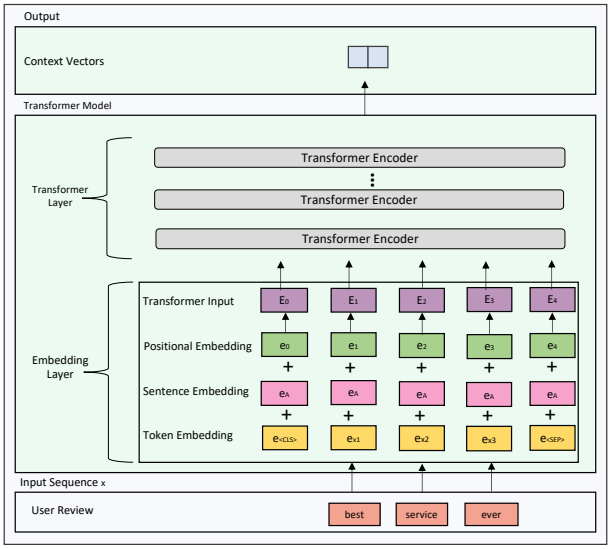

Fig. 2. Embedding and transformer layers (inspired by [43]) showing the flow of the user review as the input sequence into the output context vector.

2) Transformer layer: In the transformer layer, the input passes through the attention mechanism, normalization, and feed-forward layers, where the actual classification of the text occurs to extract the key characteristics [44]. First, the model takes the ¡CLS¿ token, which is considered the classification token, as the first input, followed by the remaining words in the input sequence. The input is then passed through the above layers. Each layer applies self-attention and passes the results through a feedforward network that passes the input again to the next layer above [11]. The final output of this layer, which represents the context vector of the input sequence, is then passed to the prediction layer.

3) Prediction layer: The output vectors of the transformer layer represent the important features provided by the input sequence. These features are then passed through a dense neural network to produce the logits. The logits are the output of the last neural network layer in raw unnormalized form before they are converted into probabilities. These raw scores are essential, as they encapsulate the model's initial predictions. Logits are then converted into probabilities by passing them through the Softmax functions in the Softmax layer. This transformation is crucial for making the model's output actionable and explainable. The softmax function maps the logits from the range of (-infty) to (+infty) to a range of 0 to 1, to ensure that the output values sum up to 1 and can be interpreted as probabilities. Lastly, these probabilities produce the predicted rating, as shown in Fig. 3 and passed through to the explainability layer along with the transformer-based model used for rating prediction.

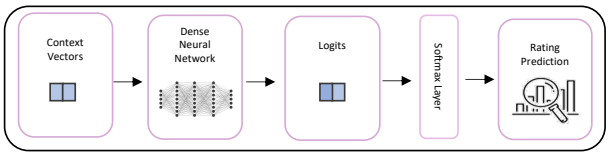

Fig. 3. Workflow of rating prediction layer.

C. Explainability

In the RPE framework, the SHAP and LIME explainability models are used to explain the predicted ratings.

1) SHAP: SHAP is a model-agnostic method used to explain the behavior of a model across all instances [45]. It identifies and prioritizes features that define classifications and predictions of any model by assigning a SHAP value to each feature [38]. In this work, the goal of using the Shapley value is to distribute the contributions between the features because they result in a certain prediction. The Shapley value of a feature (represented by a token) is the contribution of the feature to the model prediction [17].

In the RPE framework, SHAP receives the user review and transformer-based model as input and then creates N new samples from the same review via perturbation. The perturbed samples are created by masking random words from the original user review. These samples are fed into the model to generate their prediction. The difference between the predicted rating of each perturbed sample and the predicted rating of the original sample represents the contribution of the masked word to the prediction. The SHAP value of a feature reflects the strength of the impact of the feature on the resulting prediction via the model. Thus, it can be used as an importance score for features [17].

2) LIME: LIME is a model-agnostic explanation method that generates a local explanation for a complex model by justifying its decision for a specific observation. This approach implements a linear explainability model trained to estimate the prediction of a black-box model [46]. It works via a direct approach of training the model locally on specially generated representations that are different from the original input sequence of the model and observing the changes that occur in the prediction [47].

In RPE, LIME creates N new perturbed samples from the input review, similar to SHAP. These samples are fed to the transformer-based model to generate the predictions. Moreover, LIME weights these perturbed samples based on their closeness to the original sample to indicate their relative importance. Then, a linear regression model is trained on the perturbed samples and the weighted samples to explain a specific prediction. The coefficients are extracted from the linear model and used to explain the local behavior of the model. If the coefficient is positive for a specific word, this word positively affects the model's prediction, whereas a negative coefficient indicates the opposite. The degree of the effect on the prediction depends on the value of the coefficient [16].

V. Dataset Description

In this section, all the processes that the data underwent are described, from collection to cleaning, balancing, and splitting to create the final datasets. The dataset creation process is illustrated in Fig. 4.

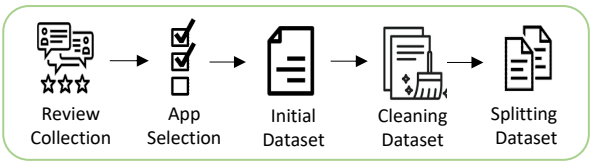

Fig. 4. Initial dataset creation.

A. Data Collection

The data needed for this study was users' reviews and ratings from m-government mobile apps. And since the government of Saudi Arabia is moving towards providing citizens and residents with additional access to governmental information and services through the m-government apps [22], its certified m-government apps platform was used to collect the data and create the dataset for the study. This certified platform is called the Saudi Unified National Platform. It includes the services related to healthcare, Hajj and Umrah, education and training, tourism,culture, and entertainment, safety and environment, Islamic affairs, business and entrepreneurship, and others. In the end, the dataset consisted of real-world data of users' reviews and ratings of m-government apps that provide social services for citizens and residents in Saudi Arabia.

B. Data Cleaning

Since rating prediction in this study is done using transformer-based models, the usual text preprocessing is not needed, such as removing null values, stop words, white spaces, punctuation marks, ASCII, duplicate letters, contractions, hashtags, emojis, and URLs. This comes from the fact that the transfer learning techniques are feature independent, which means that their power to understand natural language comes from their ability to contextually model the language. When they are applied to textual data that is heavily cleaned, they become worse because of the loss of contextual information needed by the model [48]. The dataset was cleaned by removing unnecessary attributes, that is, the time of the review, name of the user, title of the review, and version of

the app, from each review which were collected by the data collection tool. Afterward, reviews were examined manually and all repeated reviews by the same user were deleted, as well as were reviews that were not in Arabic or English. Moreover, reviews that did not provide useful information for the study were eliminated. Furthermore, the reviews that were written in multiple languages were revised, and only one language for the review was retained either English or Arabic. In addition, words written in a language different from the review are translated or deleted if they are not necessary. Table IV lists examples of the cleaning processes.

TABLE IV. TESTING REVIEWS BEFORE AND AFTER CLEANING

Review Before Cleaning	Review After Cleaning	Problem
كتبت البلاغ لاكثر من مرة ولم يصلني رقم التفعيل sms	كتبت البلاغ لاكثر من مرة ولم يصلني رقم التفعيل رسالة نصية	Mixed language
وكلتكم باخراج زكاة فطري لي ولاهل بيتي	–	non-useful information
wonderful charity app. Hoping to add search engine التطبيق رائع .و أتمنى إضافة آلية البحث	wonderful charity app. Hoping to add search engine	Multiple languages
नयाल	–	Non-English nor Arabic

C. Data Splitting

The RPE framework explains rating predictions for both English and Arabic reviews. Consequently, the initial dataset, which contains reviews in both languages, was split into two datasets based on the language of the reviews to produce the final datasets. The English and Arabic datasets consisted of 4381 and 6509 reviews, respectively, which were distributed among different class ratings from 1 to 5, as shown in Table V.

TABLE V. ACTUAL RATING DISTRIBUTION OF M-GOVERNMENT APPS REVIEWS THAT PROVIDE SOCIAL SERVICES FOR CITIZENS AND RESIDENTS IN SAUDI ARABIA

Dataset	Rating Class				
	1	2	3	4	5
English	2581	320	254	224	1002
Arabic	4410	508	390	259	942

D. Data Balancing

In classification problems, the performance of the DL model becomes worse when dealing with imbalanced data because the model tends to learn more towards the majority class than the minority class. This degrades the performance of the model and reduces the ability to generalize the results because of the difficulty in accurately predicting the minority class in the presence of the majority classes. To address the imbalanced numbers of reviews among the rating classes, as shown in the previous table, the datasets were examined manually, and the main observations for minority classes 2, 3, and 4 were related to the quality of the written reviews:

- Some of the reviews in these rating classes were meaningless and included only emojis, unknown words, reviewer names, etc., as shown in Table VI. These reviews do not highlight the features in the review to distinguish between them and know which of them has a stronger impact on the given rating than others.
- Users tended to write long reviews when they were completely satisfied or completely disappointed with an app. Consequently, the review lengths of these minority rating classes were noticeably shorter than those of classes 1 and 5. Fig. 5 shows the difference in sentence length across the rating classes.
- Because users could not provide a star rating unless they also provided a written review, they sometimes wrote non-useful reviews only to reach the point of a star rating, as mentioned by some of the users.

TABLE VI. DATA SAMPLE OF M-GOVERNMENT APPS REVIEWS THAT PROVIDE SOCIAL SERVICES FOR CITIZENS AND RESIDENTS IN SAUDI ARABIA

Source	Content	Rating
NWC	Thx	3
Sehhaty	Gd r go bjy zoo zlay e ej tzzzI eeu h	2
Tawakkalna	أبو هيثم	4
Bader	Saeed1234	1
Citizen Account	♡	5

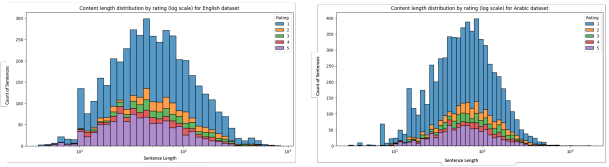

Fig. 5. Sentence length of m-government app reviews that provide social services for citizens and residents in Saudi Arabia.

All of the above may affect the model during the training process, as these factors may prevent understanding of various aspects of reviews in the minority rating classes, thus resulting in the failure to predict their ratings correctly. This led to the removal of the reviews that belonged to class 2, 3, and 4, and only the reviews from class 1 and 5 were used in the study to train the rating prediction model. Thus, this study focused on the polarity of reviews to measure the satisfaction of app users and to understand their needs for app development.

However, these two rating classes were also unbalanced. Therefore, a text augmentation technique was used to add data to the minority class. Additional data was added to the minority class from the unused collected data. Additional reviews were collected from other apps on the platform, such as health and education apps. Reviews of rating classes 1 and 5 were added to the English dataset to increase the amount of data and balance the two rating classes. For the Arabic dataset, only reviews of rating class 5 were added, and rating class 1 was down-sampled to balance the two classes. The final datasets consisted of 5430 reviews from 67 applications for the English dataset and 5470 reviews from 82 apps for the Arabic dataset.

Table VII shows the distribution of the reviews among the rating classes.

TABLE VII. FINAL DATASET

Dataset	Rating Class	
	1	5
English	2709	2723
Arabic	2791	2690

VI. EXPERIMENT AND EVALUATION

In this section, all the experimental settings used for the transformer-based models and the explainability models are listed. In addition, the evaluation metrics for both types of models are highlighted.

A. Experimental Settings

Details regarding the implementation of the transformer-based models used in this experiment, training strategy, hyperparameters, and model performance for each dataset are provided below:

1) Implementation details: Transformer-based models were implemented in the same manner, as indicated in [43]. To use the models in text classification, the problem was considered a rating prediction problem in which only the encoder part was used. The dataset was split into 80/10/10 training/testing/validation data.

2) Training strategy: This study used the same training strategy, as in [43]. The model iterated through different hyperparameters and transformer-based models to find the best performing model for each dataset in the classification task. The hyperparameters used for both datasets are listed in Table VIII.

3) Prediction models: Several transformer-based models, namely, BERT, XLNet, RoBERTa, ELECTRA, ALBERT, XLM_RoBERTa, MARBERT, QARiB, and AraBERT, were fine-tuned on both datasets in this experiment to obtain the highest accuracy and F1 score.

4) Explainability models: SHAP and LIME were applied to the testing datasets using the transformer-based models, which resulted in the highest accuracy and F1 score.

TABLE VIII. MODEL HYPERPARAMETERS

Training Argument	Value
Training Batch Size	16
Evaluation Batch Size	16
Number of Epochs	4
Evaluation Steps	300
Learning Rate	5e-5
Output Shape	(768, 2)

B. Evaluation Metrics

Two types of evaluations were conducted, namely, prediction model and explainability model evaluations, as follows:

1) Prediction model evaluation metrics: The classification metrics used to measure the overall performance of the transformer-based prediction models were accuracy and the F1 score.

- Accuracy: the ratio of the number of correctly predicted ratings to the total number of predicted ratings [49]. It is calculated by Eq. (1):

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

where, TP is true positive which is the number of outcomes where the model correctly predicts the positive class, TN is true negative which is the number of outcomes where the model correctly predicts the negative class, FP is false positive which is the number of outcomes where the model incorrectly predicts the positive class, and FN is false negative which is the number of outcomes where the model incorrectly predicts the negative class.

- F_1 score: the average rate between the recall and precision [49]. It is calculated by Eq. (2):

$$F_1 = \frac{2 \times precision \times recall}{precision + recall} \tag{2}$$

where, precision is the proportion of correct positive identifications out of all positive identifications and recall is the proportion of correct positive identifications out of all true positive instances. They are calculated via Eq. (3) and Eq. (4):

$$precision = \frac{TP}{TP + FP} \tag{3}$$

$$recall = \frac{TP}{TP + FN} \tag{4}$$

2) Explainability model evaluation metrics: Despite the massive amount of knowledge established around explainability models, there is no general agreement in the literature on how they should be defined or evaluated [50]. The literature suggests different evaluation metrics, such as comprehensibility, accessibility, fidelity [37], robustness [51], effectiveness, stability, and understandability [50]. However, there are no theoretical concerns that prompt favoring certain metrics over others [37]. Moreover, the literature lacks systematic approaches for assessing different explainability models in a comprehensive and balanced manner [51].

Consequently, the explainability of the RPE framework depends on evaluating the consistency between the visualizations produced by SHAP and LIME. Moreover, the SHAP and LIME values for the different words in the dataset were compared to prove the regularity of the impact of those words on the predicted rating class.

VII. RESULTS

The results of the transformer-based model experiments and the experiments conducted on the explainability models are presented in this section.

A. Rating Prediction Model Results

The results of applying the transformer-based models to both the English and Arabic datasets are presented in Table IX and Fig. 6. It shows that ELECTRA and AraBERTv2 achieved the best performance with respect to accuracy and F1 score.

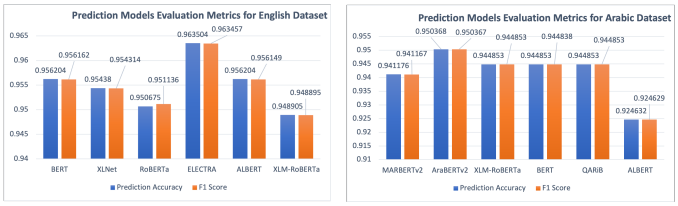

Fig. 6. Prediction performance.

In addition, the wilcoxon signed-rank test was applied to compare the performance of ELECTRA and AraBERTv2 against other baseline models in the same evaluation folds. The tests were conducted using paired accuracy and F_1 score obtained from identical evaluation settings. The results indicate that these two models achieved significant improvements over the other baseline models with $p < 0.05$ for accuracy and F_1 score. This confirms the effectiveness of the proposed transformer-based models configurations. Table X presents the statistical significance of test results.

B. Explainability Model Results

The transformer-based models that achieved the best performance, ELECTRA, and AraBERTv2, were used with the explainability models SHAP and LIME to justify the resulting predictions. Understanding the decisions made by a model is relevant for assessing the consistency of the resulting predictions and detecting possible biases in the model [38].

Two input sequences were used to visualize the explanations from each dataset. The selected reviews, along with their actual and predicted ratings, are listed in Table XI.

1) SHAP: A representation of the visualized explanations for reviews 1 and 2 from the English dataset is shown in Fig. 7. For review 1, all the words contributed to the prediction of rating class 1, with a total contribution of 0.46. For review 2, all the words contributed to the prediction of rating class 5, with a total contribution of 0.26, except for the words "to" and "and", which contributed negatively, with a total contribution of 0.15.

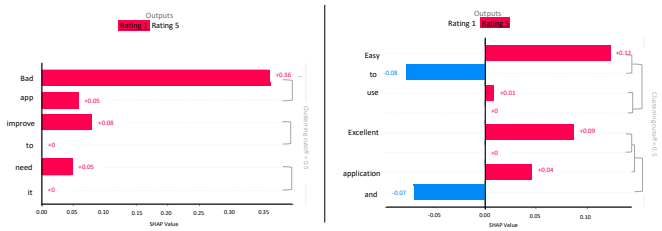

Fig. 7. SHAP visualization for English reviews where the Red bars mean positive contribution towards the predicted output and blue bars mean negative contribution towards the predicted output.

The visualized explanations for reviews 3 and 4 from the Arabic dataset are shown in Fig. 8. For review 3, the words "فاشل", which means "failure"; "خطأ", which means "error"; and "تعنيه", which means "means", contributed positively to the prediction of rating class 1, with a total contribution of 0.38, whereas all the other words contributed negatively to the predicted rating, with a total contribution of 0.20. For review 4, all the words contributed positively to the prediction of rating class 5, with a total contribution of 0.64, except for "وسيء", which means "and bad", which contributed negatively, with a total contribution of 0.14.

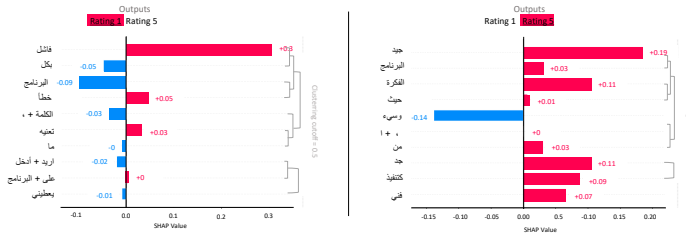

Fig. 8. SHAP visualization for Arabic Reviews where the Red bars mean positive contribution towards the predicted output and blue bars mean negative contribution towards the predicted output.

2) LIME: Each rating class in the LIME visualization is displayed with the probability of being the predicted class for a given input. For review 1 from the English dataset, the highest probability of 0.98 was for rating class 1. This probability occurred because of the contribution of all the words toward rating class 1, with a total of 0.75, except for the word "to", which contributed positively to the prediction of rating class 5. On the other hand, review 2 from the same dataset had the highest probability of being of rating class 5, with a value of 0.99. All the words in the given review contributed to the prediction of rating class 5, with a total contribution of 0.33. Fig. 9 shows the LIME visualizations of these reviews.

Fig. 9. LIME visualization for English Reviews where the orange bars represent the contribution towards rating 5 and the blue bars represent the contribution towards rating 1.

For the Arabic dataset, as shown in Fig. 10, review 3 had the highest probability of being of rating class 1, with a value of 0.91. The words that contributed positively to this rating class were "فاشل", which means "failure"; "خطأ", which means "error"; "تعنيه", which means "mean"; and "ما", which means "what," with a total contribution of 0.40. All other words contributed negatively to the predicted class rating. Furthermore, review 4 achieved the highest probability, with

TABLE IX. RATING PREDICTION RESULTS FROM APPLYING DIFFERENT TRANSFORMER-BASED MODELS

Dataset	Model	Accuracy	F_1	Precision	Recall
English	BERT	0.956204	0.956162	0.956530	0.956204

TABLE XI. TESTING REVIEWS FOR EXPLAINABILITY MODELS

#	Review	Actual Rating	Predicted Rating
1	Bad application need to improve it	1	1
2	Excellent application and Easy to use	5	5
3	البرنامج فاشل بكل ما تعنيه الكلمة ، اريد أدخل على البرنامج يعطيني خطأ	1	1
4	البرنامج جيد من حيث الفكرة، وسيء جدا كتنفيذ فني	5	5

a value of 0.98 for rating class 5. The words "جيد", which means "good"; "كتنفيذ", which means "as execution"; "جدا", which means "very"; "حيث", which means "whereat"; and "من", which means "from," are the words that contributed positively toward the prediction of rating class 5, with a total contribution of 0.47. Conversely, the remaining words contributed negatively to the prediction of the rating class.

Fig. 10. LIME visualization for Arabic Reviews where the orange bars represent the contribution towards rating 5 and the blue bars represent the contribution towards rating 1.

In addition, as a proof of consistency between the explainability models used in the RPE framework, the average SHAP and LIME values were calculated for all the words that appeared in the reviews for apps related to social services for citizens/residents. The top ten words affecting each rating class are presented in Table XII and Table XIII.

TABLE XII. TOP 10 WORDS IMPACTED RATING CLASS 1 FROM REVIEWS OF SOCIAL SERVICES FOR CITIZENS/RESIDENTS APPS

Dataset	Word	SHAP Value	Word	LIME Value
English	**crashing**	0.34	**slowly**	0.75
	useless	0.30	awful	0.59
	slowly	0.19	stop	0.57
	outdated	0.16	**outdated**	0.43
	charges	0.15	denied	0.42
	negative	0.15	cannot	0.35
	errors	0.11	asking	0.34
	frequently	0.11	pathetic	0.34
	feedback	0.09	hangs	0.33
	sorry	0.09	**crashing**	0.32
Arabic	نصب **(fraud)**	0.67	نصب **(fraud)**	0.56
	يفشل (fail)	0.66	ضعيف **(weak)**	0.34
	سيء **(bad)**	0.56	سيء **(bad)**	0.32
	بطيء (slow)	0.51	أزعجنا (annoyed us)	0.23
	أسوأ (the worst)	0.42	ينقص (lack)	0.23
	أحاول (trying)	0.42	اعتراض (objection)	0.21
	استخدام (usage)	0.41	يفقد (loose)	0.21
	أخطاء (errors)	0.39	الاستعمال (usage)	0.19
	ضعيف **(weak)**	0.38	شكاوي (complaints)	0.19
	فاشل (failure)	0.36	لا تعمل (do not work)	0.17

As seen in the tables, across both rating classes (1 and 5) and both languages (English and Arabic) SHAP and LIME show moderate-to-high consistency in identifying influential words, but with systematic differences in emphasis and ranking. SHAP tends to highlight words with strong global contribution to the model's prediction. Whereas LIME emphasizes locally influential features which may sometimes introduce context-specific words that do not appear among SHAP. This difference is expected given that SHAP is based on additive feature attribution, and LIME approximates the decision boundary locally around a single instance.

To measure how often both models identify the same words, Top-K Overlap Ratio is calculated as follows [see Eq. (5)]:

TABLE XIII. TOP 10 WORDS IMPACTED RATING CLASS 5 FROM REVIEWS OF SOCIAL SERVICES FOR CITIZENS/RESIDENTS APPS

Dataset	Word	SHAP Value	Word	LIME Value
English	responsive	0.70	**worth**	0.65
	worth	0.63	enhancements	0.51
	great	0.55	solved	0.50
	nice	0.54	saves	0.43
	excellent	0.53	unbelievable	0.37
	reliable	0.53	accessible	0.34
	amazing	0.50	favourite	0.31
	well	0.49	finish	0.30
	valuable	0.48	**great**	0.30
	perfect	0.46	**perfect**	0.29
Arabic	كويس **(good)**	0.81	روعة (magnificent)	0.91
	إبداع **(creativity)**	0.40	كويس **(good)**	0.87
	ساعدني **(helped me)**	0.36	ساعدني **(helped me)**	0.67
	يعطيك (gives you)	0.35	رائعين (amazing)	0.59
	جميل (beautiful)	0.26	إبداع **(creativity)**	0.45
	سهل (easy)	0.26	حلو **(beautiful)**	0.41
	أفضل (best)	0.26	مميز (distinct)	0.41
	متطور (advanced)	0.23	تحسين (improving)	0.39
	دائمًا (always)	0.23	قوية (strong)	0.35
	عالمي (global)	0.12	ساعد (helped)	0.20

$$\text{Overlap@}K = \frac{\left|W^{K}_{\text{SHAP}} \cap W^{K}_{\text{LIME}}\right|}{K} \tag{5}$$

where, W^{K}_{SHAP} is the top-K words according to SHAP and W^{K}_{LIME} is the top-K words according to LIME.
Since each table reports top 10 words, K=10.

Rating Class 1: Common words in English are violation, abuse, and invading [see Eq. (6)]:

$$\text{Overlap@}10 = \frac{3}{10} = 0.30 \tag{6}$$

This means that there is a 30% overlap between both models [see Eq. (7)].

As for the Arabic, the common words are اتهاك, مزعج, بطيء, اختراق and, خطير

$$\text{Overlap@}10 = \frac{5}{10} = 0.50 \tag{7}$$

This means that there is a higher agreement in the Arabic reviews where there is a 50% overlap between both models.

Rating Class 5: Common words in English are perfect, useful, smooth, assist, served, and helpful [see Eq. (8)]:

$$\text{Overlap@}10 = \frac{6}{10} = 0.60 \tag{8}$$

This means that there is a 60% overlap between both models. This iddicates that both SHAP and LIME consistenly identify usability and performance as key drivers for high ratings.

As for the Arabic, the common words are فخر, سهل, and مميزة, غني

$$\text{Overlap@}10 = \frac{4}{10} = 0.40 \tag{9}$$

This means that there is a moderate agreement in the Arabic reviews where there is a 40% overlap between both models [see Eq. (9)].

Moreover, to help the app developers assess their apps and improve them based on the users' needs, they need to test the models on reasonable amounts of their own data (app reviews) to obtain a clear view of the features that affect users' opinions most strongly. In this study, the RPE framework was tested via reviews from the "Tawakalna" app, which belongs to the health sector and is an m-government app developed in Saudi Arabia. Table XIV and Table XV show the top ten words affecting each rating class.

TABLE XIV. TOP 10 WORDS IMPACTED RATING CLASS 1 IN "TAWAKKALNA" APP

Dataset	Word	SHAP Value	Word	LIME Value
English	**violation**	0.92	**abuse**	0.64
	invading	0.90	hack	0.58
	complicated	0.85	restricted	0.53
	abuse	0.81	**invading**	0.51
	destroy	0.58	spying	0.38
	hanging	0.58	**violation**	0.30
	disgusting	0.50	steals	0.24
	lame	0.40	illegal	0.24
	crashes	0.40	invasion	0.23
	batteries	0.36	slow	0.21
Arabic	ثقيل (heavy)	0.94	يتأخر **(delayed)**	0.62
	اتهاك **(violation)**	0.60	اتهاك **(violation)**	0.46
	مزعج **(annoying)**	0.58	مزعج **(annoying)**	0.45
	تجسس **(spy)**	0.34	اختراق **(breakthrough)**	0.40
	خبيث **(malignant)**	0.32	خبيث **(malignant)**	0.36
	يتأخر **(delayed)**	0.28	خطير **(dangerous)**	0.35
	بطيء **(slow)**	0.25	بطيء **(slow)**	0.32
	اختراق **(breakthrough)**	0.25	يجبرك (forces)	0.31
	معلق (hanging)	0.23	صعب (hard)	0.28
	خطير **(dangerous)**	0.17	تجسس (**spy**)	0.27

VIII. DISCUSSION

The goal of the RPE framework is to predict a rating for each review and justify the prediction using explainability models. However, the RPE framework focused on predicting the ratings for the reviews associated with rating classes 1 and 5 only. This came as a result of the non-benchmark data used in the study where there was a lack of reviews of rating classes 2, 3, and 4. The reasons behind that are reasons listed in Section V-D. Moreover, similar words were used in reviews with different rating classes; for example, the word "good" was used in reviews associated with the rating classes 3, 4, and 5; the words "problem," "fix," and "bad"

TABLE XV. TOP 10 WORDS IMPACTED RATING CLASS 5 IN "TAWAKKALNA" APP

Dataset	Word	SHAP Value	Word	LIME Value
English	**perfect**	0.25	**useful**	0.42
	privacy	0.22	**perfect**	0.26
	useful	0.17	**smooth**	0.26
	served	0.17	**assist**	0.21
	smooth	0.16	easy	0.18
	rewarded	0.15	solution	0.18
	helpful	0.14	compatible	0.16
	assist	0.13	**served**	0.15
	intelligent	0.13	helps	0.15
	guide	0.08	effective	0.13
Arabic	مفخرة **(pride)**	0.28	متميز **(distinct)**	0.62
	متميز **(distinct)**	0.23	مفخرة **(pride)**	0.45
	جبار (huge)	0.18	غني **(rich)**	0.33
	غني **(rich)**	0.12	الخصوصيات (privacies)	0.21
	عالمي (global)	0.12	ساعد (helped)	0.20
	سهل **(easy)**	0.05	حلوا (solved)	0.19
	متقن (perfect)	0.04	سهلت (made easy)	0.17
	تطور (development)	0.04	اختصر (cut short)	0.16
	قوي (strong)	0.03	سهل **(easy)**	0.12
	احترافي (professional)	0.03	فريدة (unique)	0.12

were used in reviews associated with rating classes 1 and 2; "problem" was also used in reviews associated with rating class 3; and "fix" was used in reviews associated with rating class 4. Furthermore, the words "ممتاز" which means "excellent," and "رائع", which means "amazing," were used in reviews associated with rating classes 4 and 5, although "ممتاز" was used in reviews associated with rating class 3 as well. The words "للأسف", which means "sadly", and "المشكلة", which means "the problem", were used in in reviews associated with rating classes 1 and 2, whereas "المشكلة", which means "the problem", was also used in reviews associated with rating classes 3 and 4.

As a result, the RPE framework focused on predicting the ratings for reviews associated with rating classes 1 and 5 only. ELECTRA achieved the highest performance among other transformer-based models due to its efficient pre-training task known as Replaced Token Detection (RTD). This task works by masking a small percentage of tokens and trains on every token in the sentence. This allows the model to understand the context of the text more deeply with less computational power. On the other hand, AraBERTv2 achieved the best performance among the transformer-based models that works on Arabic language due to its specialized pre-training on a huge, diverse, and clean Arabic datasets. In addition to its ability to handle complex Arabic morphology. It excels in capturing semantic relationships between words, which is critical for rating predictions. As for the explainability, all the words that had either a positive or negative impact on a certain rating class based on SHAP value had the same impact on the same rating class based on LIME value as well with different impact. For example, the words "slowly", "outdated", and "crashing" from the English dataset and the words "نصب" which means "fraud", "ضعيف" which means "weak", and "سيء" which means "bad", from the Arabic dataset all had positive impacts on rating class 1, with different impact based on SHAP and LIME values. In addition, the words "worth", "great", and "perfect" from the English dataset and the words "كويس" which means "good", "ساعدني" which means "helped me", "إبداع" which means "creativity", and "حلو" which means "beautiful", all had positive impacts on rating class 5 with different SHAP and LIME values. This means that there is consistency between SHAP and LIME in explaining the resulting predictions.

However, to help app developers understand users' needs to improve their apps, the RPE framework should be applied to a reasonable number of reviews to identify the most important features affecting the apps. In this study, there was a lack of reviews for each app; hence, they could not be used alone to train the model. Accordingly, reviews for multiple apps were grouped to build the dataset.

To test the model, reviews for the "Tawakalna" app were used to apply the RPE framework. The results revealed the words that affected the resulting predictions the most, which can help the app developers improve the app on the basis of the users' perspectives. However, the computational cost for SHAP and LIME are very expensive. SHAP took around 16 hours to execute the code with an average of 1.92 minutes per record, whereas LIME took around 5 hours with an average of 0.6 minutes per record. This would significantly reduce the effectiveness of using explainability models for real-time explanations.

IX. CONCLUSION

The development of a mobile app review rating prediction model is fundamental for decision-making with respect to mobile app development. However, its predictions cannot be considered useful without a clear explanation. Explainability is effective for creating a foundation for trusting the results and helping decision-makers take action on the basis of these results. In this study, RPE framework is proposed in which it helps the decision-makers, app developers, and policy makers to evaluate their given apps and its usefulness based on the highly frequent words used by the users in their reviews in relation to the given ratings. In RPE, the rating prediction task is implemented using several transformer-based models. These models were applied to two separate datasets: English and Arabic reviews. The models help overcome the difficulties of not having an enormous amount of data to work with to obtain highly accurate results and of dealing with mixed-language datasets. The datasets were composed of reviews of Saudi m-government apps. In addition, explainability models were implemented to explain the resulting predictions using a visualization technique.

ELECTRA and AraBERTv2 achieved the best rating prediction performance among all other models with respect to accuracy and F1 score, while the SHAP and LIME explainability models justified the resulting predictions. Moreover, the RPE framework showed consistency between the explainability models used, where most of the time the same words

contributed positively to the resulting predictions according to SHAP and LIME.

X. Study Limitations and Future Work

One of the main limitations of this study is the quality of the text used in the reviews. Data were collected specifically for this study and do not represent benchmark data; Much work needs to be done on the data to be able to collaborate with it. To address this limitation, additional data need to be used to obtain a wider variety of words to obtain a clear view of those that affect the resulting predictions. Moreover, the data sets were highly unbalanced with respect to the distribution among the rating classes. There was not enough reviews associated with rating classes 2,3, and 4. There are several reasons behind that as listed in Section V-D. This caused the study to focus only on the reviews associated with class 1 and class 5. Additionally, there is no general or bilingual transformer-based model to address different languages at the same time. As a result, the data collection, training, prediction, and explanation was done for each language separately. Further, to the best of our knowledge, there is a lack of studies in the field of m-government apps, especially for review rating prediction. Finally, the computational cost was remarkably high, especially with the consistency analysis that provided the SHAP and LIME average values for all the words in the reviews. This came as the result of the game theory that SHAP uses to provide explainability for a certain result. On the other hand, LIME's high cost comes from the many local model evaluations to fit surrogate models.

In future work, we plan to use prompt engineering as the initial context for the transformer-based models to guide the model's attention and influence its output. This will help the model understand the task and generate the desired output. Also, attention-based methods will be used to explain the resulting predictions. However, discriminating between the positive and negative contributions of the attention weights towards the predicted ratings must be considered during implementation. Furthermore, when it comes to m-government, other types of m-government apps should be explored to gain more knowledge about the perspectives of users about these apps in Saudi Arabia as a whole. In addition, applying this study to the m-government apps of other countries is necessary to improve the development of apps according to user needs. This could lead to the development of benchmark data for an international dataset of m-government apps that could serve all studies in this area. Further, user-centered evaluation for the proposed framework will be conducted by generating predictions and explainability for specific apps and check whether the apps' stakeholders and developers are benefiting from the provided results. Moreover, this work could be enhanced by the advancements in the multilingual transformer-based models. This could eliminate the duplication in doing the same work for both languages.

Machine Learning-Based Sentiment Analysis Pipeline for Evaluating Hajj Food Service Quality

Amjad Enad Almutairi, Aisha Yaquob Alsobhi, Abdulrhman M Alshareef
Faculty of Computing and Information Technology-Information System Department,
King Abdulaziz University, Jeddah 21589, Saudi Arabia

***Abstract*—Pilgrimage, also known as Hajj, brings together millions of people each year, creating significant challenges in managing, organizing, and maintaining the quality of various services. Among these essential services, food provision plays a vital role in shaping pilgrims' overall experience and satisfaction. Despite its importance, research focusing on food services using sentiment analysis during Hajj remains limited. Existing studies often rely on social media data, which may not accurately capture the genuine opinions of pilgrims. This study addresses this gap by analyzing food service text reviews collected from Google Maps within the Hajj context. It contributes a new dataset collected for evaluating food services provided to pilgrims after the Hajj season, along with an empirical benchmark for Arabic Hajj food reviews. The dataset consists of 4,018 Google Maps reviews from 160 Hajj campaigns conducted between 2022 and 2025. After data preprocessing, the reviews were classified using several classical machine learning algorithms as empirical baselines, including support vector machine (SVM), logistic regression (LR), naïve Bayes (NB), decision tree (DT), and random forest (RF). The experimental results demonstrate that LR achieved the highest accuracy of 93.6% among the evaluated models, followed by SVM and RF with accuracies of 92.9% and 92.2%, respectively. The analysis also shows that positive sentiment dominated across all studied years, indicating an overall improvement in pilgrims' satisfaction with food services. However, the persistence of food-related issues highlights the need for continued attention and improvement in service quality.**

***Keywords*—Sentiment analysis; service quality; machine learning; Hajj; food service**

I. Introduction

Every year, Mecca attracts over two million pilgrims who gather to perform the Hajj, one of the largest religious gatherings in the world. The magnitude of this event requires extensive logistical planning and highly efficient service management across multiple sectors, including healthcare, transportation, accommodation, and food services. The scale and complexity of the Hajj demand meticulous organization to ensure safety, comfort, and satisfaction for millions of pilgrims. Among these services, food quality plays a vital role in maintaining pilgrims' health and overall well-being, as poor management or inadequate quality can lead to dissatisfaction or even health-related risks.

Recently, sentiment analysis, a significant subfield of natural language processing (NLP), has become an essential tool for understanding public opinion and satisfaction levels [1]. It classifies text into emotional categories—positive, negative, or neutral—based on subjective expressions such as reviews, posts, or comments [1]. The exponential growth of online platforms has generated massive volumes of opinion-rich data, making sentiment analysis an effective means of identifying trends and evaluating public perception in business, politics, and social sciences [1].

Within the context of the Hajj, several studies have explored the quality of services such as accommodation [2], transportation [3], and healthcare [4]; however, research focusing on food service quality—especially through sentiment analysis in Arabic—remains limited [5]. Despite these efforts, significant research gaps persist. Most prior studies have relied on data from social media platforms such as X (Twitter) [6], [7], [8], which may not accurately reflect the current state of service quality following recent developments in line with Saudi Arabia's Vision 2030. Furthermore, there is a lack of studies specifically analyzing Arabic-language reviews related to food services during the Hajj, leaving a valuable source of user-generated feedback, such as Google Maps reviews, underutilized. This study aims to address these gaps by employing machine learning–based sentiment analysis on pilgrims' Arabic textual reviews of food services collected after the Hajj.

The specific objectives of this study are: first, to extract and describe the principal food-service issues reported by pilgrims (e.g., availability, safety, cleanliness, and nutrition); second, to estimate the overall sentiment distribution toward food service quality (positive, negative, or neutral); and third, to benchmark multiple machine learning algorithms—including SVM, LR, NB, DT, and RF —to determine the best-performing model for sentiment classification. Accordingly, the main research questions are: What food service issues do pilgrims report during the Hajj?, What sentiments (positive, negative, or neutral) are associated with these issues across pilgrims' reviews?, and Which machine-learning approach most effectively classifies sentiment in this dataset?

This research contributes a new dataset collection applied for the first time to evaluate food services provided to pilgrims after the Hajj season. To the best of our knowledge, it is the first study to analyze Google Maps reviews within the Hajj context with a specific focus on food services. Previous work has seldom relied on Google Maps as a data source in this domain.

The scope of the research is restricted to text-based analysis of reviews about food services during the Hajj. It excludes multimedia data, such as images or videos, and does not address external factors such as politics or finance. The main focus is on textual sentiment to provide an evidence-based understanding of food service quality.

However, there remains a lack of focused research applying

these methods specifically to food services in the unique context of the Hajj, creating a need for an updated, domain-focused analysis that utilizes pilgrim-authored reviews beyond social media and rigorously evaluates sentiment models for text to produce actionable insights.

The structure of this research is organized as follows: Section I presents the introduction and problem statement and outlines the research objectives, questions and contributions; Section II reviews related literature on service quality and sentiment analysis in the context of the Hajj; Section III describes the methodology; Section IV presents and discusses the results; and Section V concludes the study with key findings, limitations, and recommendations for future research.

II. Literature Review

Every year, the Hajj attracts a huge number of pilgrims; a total of 1,673,230 pilgrims were recorded in 2025 [9], and the quality of services provided plays a major role in achieving pilgrim satisfaction. The literature review of this research has been divided into two sections: the service quality and sentiment analysis in the Hajj.

A. Services Quality in Hajj

Service quality consists of two component words. "Service" refers to the basic features of a specific function, while "quality" refers to the application of a user-based approach [10]. Together, "service quality" refers to the value of service to the customer [10]. A measure of service quality shows how well a company meets the expectations of its clients by comparing actual service delivery to client expectations [11]. Consumers have explicit wants and needs, as well as occasionally having latent or concealed demands [11]. It is the responsibility of the company to recognize these demands and meet them, either above or beyond the expectations of the client. One of the most crucial factors in determining a company's success or failure—and, in the event of success, the degree of that success—is service quality [11].

These studies investigate the quality of services provided during the Hajj, including food, accommodation, transportation, and healthcare services.

Food service provision during the Hajj introduces unique challenges and opportunities to improve. Research indicates that there are varying levels of compliance with food safety practices among different food provider companies. Professional training was found to considerably enhance adherence to safety protocols, with a compliance rate between 72.67% and 88.3% [12]. The researchers proposed automated food production using blockchain and centralized plants to control and improve food service quality, reducing service delivery times by 54.46% [5]. During the Hajj, the quality of food service is a critical concern for pilgrims' satisfaction and health. About 20% of pilgrims suffer from chronic diseases, with 15.7% needing special diets due to chronic health conditions; however, research has found that most caterers do not provide special meals for them [13]. All of these efforts, such as training and automated food production, aim to enhance the quality of food, particularly during the Hajj. Yezli et al. [14] investigated the prevalence of gastrointestinal symptoms among pilgrims during the 2019 Hajj and assessed their knowledge and practices regarding food and water safety. They also aimed to identify knowledge gaps and risky behaviors that could increase the risk of food- and water-borne diseases (FWBDs). The findings showed that nearly 10% (n = 133) of pilgrims reported at least one gastrointestinal symptom during the Hajj, with diarrhea being the most common (51.9%). Most symptoms lasted for less than two days, and 78.2% of affected individuals sought medical assistance [14]. During the 2023 Hajj, Msrahi et al. [15] investigated the relationship between foodborne disease (FBD) and food safety knowledge and practices among pilgrims. They employed a self-reporting online questionnaire, which comprised four sections: demographic data, pilgrims' food safety knowledge and practice, and FBD symptoms. The dataset collected involved 409 pilgrims from 15 countries. They found that the pilgrims demonstrated an above-average level of food safety knowledge, while their food safety practices were below average [15]. Alfiah et al. [16] investigated the nutritional completeness of food consumed by Indonesian Hajj pilgrims, identifying the factors associated with incomplete nutrition and highlighting the importance of nutritional education and policy. The study included a sample of 231 Indonesian respondents who were Hajj or Umrah pilgrims aged 18 years and above. The researchers found that a significant majority (87%) of Indonesian Hajj pilgrims consumed nutritionally incomplete food, meaning that one or more components (carbohydrates, fat, protein, vegetables, or fruit) were missing [16].

The provision of accommodation during the Hajj plays a crucial role in enhancing pilgrims' satisfaction and their overall experience. Mohammed et al. [17] used the analytic hierarchy process (AHP) to prioritize the service quality dimensions that are most important for improving pilgrim satisfaction. The most important dimension was found to be tangibility, reflected in the physical facilities, equipment, and the appearance of personnel.The reliability dimension demonstrated the ability to deliver promised services consistently and dependably [17]. Providing high-quality accommodation services, comfortable transportation, and reliable religious scholars all enhance the pilgrimage experience, and authorities should focus on these [18]. Jouda et al. [2] aimed to investigate how service quality affects the satisfaction levels of Hajj pilgrims in Saudi Arabia's hotel sector and identified key service dimensions that influence the pilgrim's experience. The authors made suggestions for improving hotel services aligned with religious tourism expectations. They found that service quality significantly impacted pilgrims' satisfaction, while the dimensions of responsiveness, reliability, and empathy were the most influential in determining satisfaction levels [2].

Large numbers of participants and spatiotemporal restrictions lead to significant challenges in the transportation of pilgrims during the Hajj [3], [19]. Trains and pedestrian routes are intensely used modes of transport during the Hajj [19]. Hussain et al. and Owaidah et al. [3], [19] proposed strategies to improve transport shuttle bus service efficiency and evaluated services by using simulations of discrete events for pilgrim transport modeling between sites. Weber et al. [20] aimed to assess pilgrims' satisfaction with metro services during the Hajj. They defined the key factors affecting satisfaction, offered proposals and recommendations to improve metro services in the future, and emphasized the role of metro services in mitigating transport crowds during the

Hajj season. They found high satisfaction among pilgrims concerning the quality of the service, with the metro helping to mitigate overcrowding, a positive perception of safety through the measures implemented in the metro system, and improvements to pilgrim mobility; however, the study also found that elderly and disabled pilgrims faced difficulties in accessing metro services [20]. Almujibah et al. [21] aimed to evaluate the efficiency of the Almashaaer Al Mugaddassah Metro (MMMSL) in transporting pilgrims, assess the efficacy of the metro system in meeting its intended objectives, analyze the safety measures implemented in the MMMSL and their effectiveness, and provide recommendations for enhancing performance and safety. They concluded that the metro worked with high efficiency during off-peak times, faced challenges during peak periods, was successful in reducing traffic, and had effective safety measures in place for managing the movement of passengers. The authors also provided a number of improvement recommendations [21]. These studies emphasize the need for innovative solutions to address the complex transportation challenges faced during the Hajj.

Digital transformation initiatives implemented by the Saudi Ministry of Health have led to improved healthcare services [4]. However, integrating various healthcare applications remains a challenge due to the lack of a unified electronic platform [4].

B. Sentiment Analysis in Hajj

Sentiment analysis is a method that uses a vast number of textual data sources to identify positive and negative views about particular goods, services, or events [22]. These research articles targeted particular domains, for instance, sentiment analysis in the education [23], [24], Hajj domain [6], [7], [8], [25], [26], [27], [28], medical domain [29], or business domain [30], [31]. Sentiment analysis offers several advantages, such as gaining insights into students' opinions about the educational process delivered by teachers; understanding people's opinions about specific events, such as the Hajj; helping in gathering patients' feedback on hospital services; and allowing businesses to understand customers' opinions about specific products or services offered in a restaurant or store. These benefits help companies and service providers improve their products and services. The following studies discuss sentiment analysis in relation to the Hajj:

Alghamdi [6] presented a comprehensive sentiment analysis of Arabic tweets related to the Hajj over a six year period from 2017 to 2022 to investigate the prevailing sentiments related to Hajj events before, during, and after the Hajj. The study showed a significant surge in both positive and negative tweets during the Hajj period. It applied different classifications of machine learning and deep learning, with the bidirectional encoder representations from transformers (BERT) model achieving the highest accuracy of 93.8% in sentiment classification. Thus, BERT was found to be one of the most effective models in sentiment analysis, especially for capturing the complexities of Arabic text. The study's findings indicated an increase in both positive and negative sentiments during the Hajj period through engagement and emotional expression [6].

Ottom et al. [8] applied sentiment analysis using a series of tweets related to the Hajj. The researchers collected data from 1-8-2018 to 25-8-2018 using the Twitter application programming interface (API) and conducted two experiments based on the machine learning approach and the lexicon approach to compare the accuracy of the method of analysis. The machine learning-based approach worked better than the lexicon-based approach in the classification and sentiment analysis, with SVM outperforming the other models with a high degree of accuracy (84%) [8].

During the COVID-19 pandemic, a small number of pilgrims were undertaking hajj. Shambour [25] used deep learning methods to discuss people's impressions about the 1442 Hajj season. A dataset was compiled based on approximately 4,300 texts from social media, including X (Twitter) and YouTube, posted over 13 days. Based on the experiment results, the convolutional neural networks and long short-term memory (CNN-LSTM) model outperformed the other models in sentiment classification, achieving 97% accuracy. The researcher provided a clear framework for understanding public perceptions by using a five-point scale for sentiment classification. The overall results showed highly positive feelings about the Hajj season, with ratings exceeding 4 out of 5 [25].

In another study, Gutub et al. [26] investigated the emotional impact of the COVID-19 pandemic on individuals in Makkah and Madinah during the 2021 Hajj season, utilizing deep learning techniques to analyze X (Twitter) data. It aimed to understand the sentiments of residents in these holy cities, which were significantly affected by reduced pilgrim numbers due to the pandemic. The dataset comprised more than 22,000 tweets collected from Twitter accounts in Makkah and Madinah during the 2021 Hajj season (1442 AH) between 28 Dhu al-Qi'dah and 23 Dhu al-Hij'jah. They found "strange negative feelings" toward the Coronavirus pandemic in tweets from the holy cities. The sentiment analysis rate for COVID-19-related tweets in both cities decreased below neutrality, with Makkah tweeters expressing more negative sentiments [26].

Albahar et al. [27] used deep learning to predict satisfaction levels with high accuracy, which influenced the quality of accommodation services. The study collected 15,859 Arabic reviews from the Booking.com website and proposed a model using a deep learning approach that achieved 97% accuracy. The study employed sentiment analysis techniques based on the expectation-confirmation paradigm. This method made it possible to gain a complex understanding of how pilgrims' expectations affected how satisfied they were with the hospitality services provided [27].

Chelloug et al. [28] presented an advanced social media classification system designed to enhance Hajj and Umrah services that utilized predictive deep learning and particle swarm optimization to improve accuracy and offer immediate feedback for better decision-making and service quality management. The researchers analyzed 5,000 tweets, 25,000 Facebook posts, and 10,500 Instagram posts. The proposed model demonstrated superior performance, achieving an accuracy of 98.85% and outperforming other models in classifying social media posts related to Hajj and Umrah services [28].

Several studies have explored food services [14], sentiment [7], [26], [28], and health issues [15], [16] among Hajj and Umrah pilgrims using advanced analytical methods.

In food services, Alasmari et al. [7] aimed to create a novel approach for sentiment analysis of pilgrims by utilizing a hybrid deep learning model combining CNN and LSTM models. The study used a novel and specialized dataset comprising 4,669 tweets collected from X (Twitter) during the 1442 Hajj (2021 AD) that discussed pilgrims' opinions about catering services. The proposed CNN-LSTM model achieved an accuracy of 92%, outperforming other machine learning models (SVM, RF, LR, and DT) and individual deep learning models (CNN and LSTM) [7].

C. Studies Analysis

Most of the studies examined here did not specify the type of service analyzed, focusing instead on general experiences. Table I summarizes previous studies that conducted sentiment analysis during the Hajj using various online platforms, such as X (Twitter). Most of these studies focused on general topics, for example, [25], [8], [6], [26] related to Hajj services while only one study [27] focused on hospitality services. On the other hand, ref. [28] focused on religious rites, management, safety, well-being, and services, but only one study [7] focused on catering services, and it was limited to Hajj 1442 (2021 AD). In terms of data collection periods, the studies collected data during short and specific Hajj seasons, for example, 2018 [8], 2021 [7], and 2023 [27], or over limited durations, such as 120 hours [28]. Concerning platform use, most previous studies have relied on X (Twitter) [8], [25], [7], [28], [26] as the primary source of data, with some incorporating YouTube [25], Facebook [28], or Instagram [28]. With respect to language coverage, previous studies show that sentiment analyses were conducted in Arabic, English, or both.

TABLE I. SENTIMENT ANALYSIS IN HAJJ

Ref.	Platform	Data Collection Period	Languages	Service Type
[6]	X(Twitter)	2017-2022	Arabic	Not specified
[7]	X(Twitter)	Hajj 1442 (2021)	Arabic	Catering services
[8]	X(Twitter)	1-8-2018 to 25-8-2018	English	Not specified
[25]	X(Twitter), YouTube	Hajj 1442	Arabic	Not specified
[26]	X(Twitter)	Hajj season (1442 AH) between 28 Dhu al-Qi'dah and 23 Dhu al-Hij'jah	Arabic, English	Not specified
[27]	Booking	Hajj 2023	Arabic	Hospitality service
[28]	X(Twitter), Facebook, Instagram	collected over a continuous period of 120 hours	Arabic, English	Religious rites, management, safety, well-being, and services

These studies depend on data from social media platforms in sentiment analysis, which does not offer straightforward conclusions about the quality of services provided to pilgrims during the Hajj. The results showed the effectiveness of using machine learning algorithms and deep learning algorithms in sentiment analysis. In addition, many of these studies were conducted several years ago, which may limit their relevance to the Hajj at the present time. Table II shows the differences between studies based on number of datasets, machine-learning models used, sentiment analysis used, and the levels of accuracy achieved by the machine-learning or deep learning models in each study. Table I presents the differences between studies that apply sentiment analysis in relation to the Hajj. The study has aimed to measure the effectiveness of machine learning techniques in improving the quality of food services that are provided to pilgrims based on their sentiment analysis.

In sum, our research stands out in three key ways when compared with previous studies in the Hajj field, as shown in Table I. First, in terms of specificity, it focuses directly on the food service aspect of the Hajj, unlike most prior works. Second, in terms of recency and duration, our review covers the 2022–2025 period, providing a modern and multi-year perspective. Lastly, in terms of practical relevance, this study uses sentiment analysis and machine learning techniques to contribute practical insights for identifying the main problems related to food services that pilgrims face during the Hajj.

TABLE II. SUMMARY OF RELATED RESEARCH OF MACHINE LEARNING AND SENTIMENT ANALYSIS IN HAJJ

Ref.	Dataset	Classifier	Features Extraction	Sentiment Polarity	Accuracy
[6]	Over 80,000 tweets	LR, RF, KNN, SVM, NB, XGBoost, CNN, LSTM, BERT	TF-IDF, BoW, Word2Vec Embeddings	Positive, Negative, Neutral	93.8% BERT
[7]	4669 tweets	SVM, DT, RF, LR, CNN, LSTM, CNN-LSTM	One Hot Encoder	Positive, Negative, Neutral	92% CNN-LSTM
[8]	3175 tweets	SVM, KNN, NB, Text Blob	BoW, N-Grams, TF-IDF	Positive, Negative, Neutral	84% SVM
[25]	2996 tweets, 1293 comments	CNN-LSTM	CNN	five-point scale for sentiment classification	Reach to 97%
[26]	Over 22,000	CNN-LSTM	CNN	Scale score from 1 to 5	Not specified
[27]	15,859 reviews	CNN, LSTM, proposed model	Convolutional Layer	Positive, Negative, Neutral	97% proposed model
[28]	15,000 tweets, 25,000 Facebook posts, and 10,500 Instagram posts	SVM, RF, DT, XGBoost, K-NN, BERT, ALBERT, ROBERTA, XLNet, Proposed model	Principal Component Analysis (PCA) and Pearson Correlation Coefficient (PCC)	based on relevant attributes: service-level, and scores	98.85% proposed model

III. METHODOLOGY

This research used a sentiment analysis approach applied to pilgrims' reviews about food service. Sentiment analysis is a widely recognized approach in natural language processing (NLP) that focuses on identifying and interpreting emotions or opinions expressed in text data [32], [1]. Its main objective is to classify written content—such as reviews, tweets, or comments—into sentiment categories such as positive, negative, or neutral [32], [1]. With the exponential rise of social media and digital communication, massive amounts of opinion-rich data are generated daily, making sentiment analysis an essential tool for understanding public attitudes, market trends, and consumer behavior [33].

This approach plays a crucial role in various domains, including business, politics, and social research, by helping organizations analyze feedback, monitor reputations, and enhance decision-making [33], [32]. Sentiment analysis approaches can be divided into three categories, as shown in Fig. 1: machine learning, deep learning, or ensemble learning [1]. In this research, the focus is on the machine learning approach.

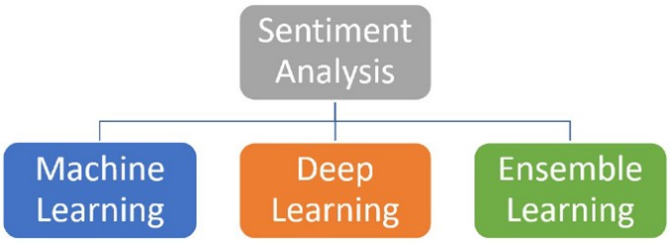

Fig. 1. Sentiment analysis approach.

Sentiment analysis typically involves several key stages [1], as illustrated in Fig. 2. It starts with data acquisition, then perform data preprocessing to clean and normalize the text. After that, feature extraction converts text into numerical representations using methods like TF–IDF (term frequency–inverse document frequency) or word embeddings. Finally, machine learning algorithms such as SVM for classification are used [1]. By integrating natural language processing and machine learning techniques, sentiment analysis provides a powerful framework for automatically extracting and interpreting human emotions and opinions from unstructured text data [33], [32], [1].

Fig. 2. Sentiment analysis process.

This section accentuates our research methodology, which includes the dataset collection, labeling, and preprocessing, as well as the subsequent steps of feature extraction and model classification, as shown in Fig. 3.

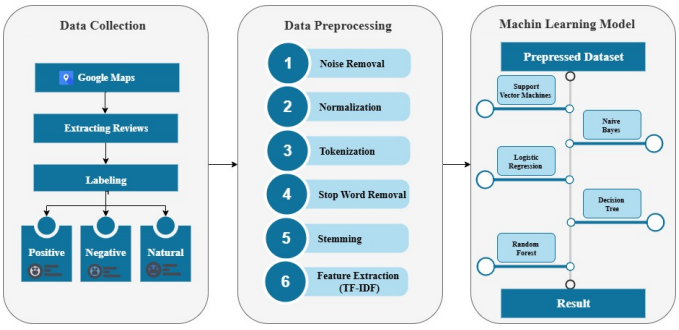

Fig. 3. Methodology overview.

A. Dataset Collection

The foundation for sentiment analysis has been established by collecting text-based feedback from Hajj pilgrims. This feedback covered sentiments related to food service quality. The data have been gathered from a range of sources between 2022 and 2025, from 160 Hajj campaigns. The research data for this study have been collected from Google Maps reviews related to campaigns at Hajj sites using the Outscraper website [34]. This tool offers rapid, reliable access to data on Google Maps locations through a simple and intuitive interface [34]. Additionally, we utilized Instant Data Scraper, a feature of Google Chrome that serves as an automated data extraction tool for any website. The dataset was garnered from Google Maps. We initially gathered 6,450 reviews; after removing duplicates, non-text items, and entries with missing or off-topic content, we retained 4,018 reviews explicitly referencing food or catering. The data collection process involved several steps. First, specific keywords were searched on Google Maps to identify Hajj campaigns, such as "حملات" (campaigns), "حملة حج" (hajj campaign), "حجاج الداخل" (domestic pilgrims), and "حج" (hajj). Based on the search results, relevant campaigns were selected, and all available reviews were opened and extracted using the Instant Data Scraper tool. The collected reviews were then downloaded, copied, and combined into a single file. This process was carried out individually for each campaign, which required a considerable amount of time due to the manual nature of the task. After completing the data collection, the dataset was cleaned and standardized to ensure consistency. The data preparation process included unifying all reviews into Arabic, standardizing the review dates into an annual format, and organizing the dataset for data labeling and preprocessing. Table III presents the dataset attributes and their types used in this study.

TABLE III. Potential Attributes and Data Type

Attribute	Data Type
Textual review	Text
Review datetime	Numerical
Sentiment analysis	Categorical

Fig. 4 shows a bar chart illustrating the relationship between review years and sentiment categories. The chart shows a gradual increase in the number of reviews over the years. There are relatively few reviews in 2022, with a noticeable rise in 2023 and a sharp increase in 2024 and 2025. Positive reviews remain the most frequent across all years, followed by negative and neutral reviews.

1) Dataset Labeling: The dataset has been organized into three class single-label sentiment classification (positive/neutral/negative) to encompass the entire spectrum of classification. The positive class comprises reviews that are commendatory or appreciative of the pilgrim' satisfaction with the food or service, such as food quality, good taste, cleanliness, variety, organization, or speed of service. On the other hand, the negative class encompasses reviews that are derogatory and critical and reflect dissatisfaction or a poor experience, such as poor taste, delayed service, lack of variety, poor cleanliness, or poor service by servers. Finally, a neutral class expresses a descriptive opinion or information without positive or negative emotion (i.e., an objective comment that does not express obvious satisfaction or dissatisfaction); for instance, three meals are served daily to pilgrims. Table IV shows examples of three categories of sentiment analysis. The

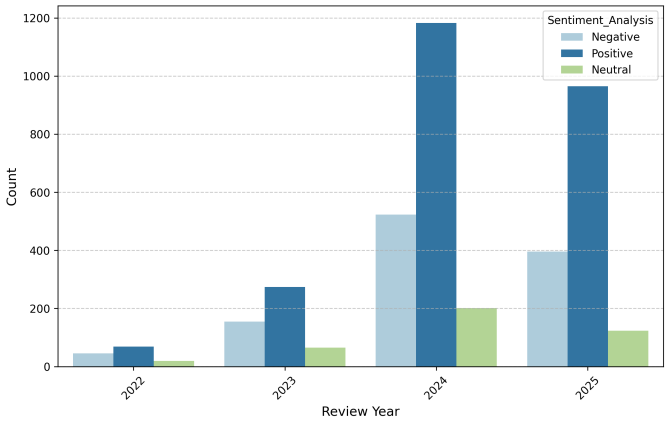

Fig. 4. Dataset distribution.

dataset was manually labeled by assigning a sentiment label to each review individually using an Excel file, which was later converted into a CSV format. The final dataset contains 4,018 Arabic reviews provided by pilgrims. To ensure labeling reliability, all reviews were annotated by three native Arabic speakers. One annotator has a background in information technology (IT), while the other two are in information systems (IS). All annotators were between 28 and 32 years old and participated independently in the labeling process. During data preparation, only the review text and review date were retained, while star ratings, no campaign identifiers or reviewer IDs were excluded to avoid potential data leakage risks and bias. Each annotator was provided with the same dataset and instructed to classify each review into one of the three sentiment categories (positive, negative, or neutral) based on the predefined definitions. After all annotators completed the labeling process, the final label for each review was determined using majority voting. For example, if two annotators labeled a review as positive and one labeled it as neutral, the final label was assigned as positive. In ambiguous cases, the annotators discussed the review collectively to decide the appropriate sentiment class, and reviews that could not be confidently resolved were removed from the dataset.

Fig. 5 illustrates the distribution of sentiments and the number of reviews in each class in our dataset. The largest portion of the chart represents positive sentiments, which account for 62.00% (2,491 reviews) of the total. The negative sentiments make up 27.85% (1,119 reviews), while the neutral sentiments represent the smallest portion, with 10.15% (408 reviews). It is clear that positive reviews dominate the dataset, followed by negative and then neutral reviews.

B. Dataset Preprocessing

Preprocessing techniques are important in natural language processing tasks [35]. The quality of preprocessing has a direct impact on the performance and precision of NLP tasks such as text classification and sentiment analysis [35]. One of the most widely used libraries in NLP is the Natural Language Toolkit (NLTK) [36]. It is a Python library that offers a variety of linguistic resources, like text processing, and performs operations such as tokenization, stemming, and classification [36]. To prepare the data for analysis, preprocessing tasks, as

TABLE IV. EXAMPLES OF REVIEW IN DIFFERENT SENTIMENT CLASSES

Sentiment	Review	English translation
Positive	حملة جدا رائعة وممتازين في الخدمة والاعاشة اقيمهم خمس نجوم شركه ممتازة ونظافة والاكل كان رائع كل التوفيق لكم	A truly wonderful campaign; excellent service and catering. I rate them five stars Excellent company, very clean, and the food was great. Wishing you all the best
Negative	البوفيه سيء جدا خيارات محدودة وما يناكل الله يعز النعمة الحملة جدا سيئة لا ترتيب ولا تنظيم ولا سناكات والاكل جدا سيء نفس الاصناف مكررة يوميا والله الإعاشة زي الزفت بصراحة	The buffet was very bad, limited options, and barely edible. May God bless the food we have. The campaign was really bad — no order, no organization, no snacks, and the food was terrible, same dishes repeated daily. Honestly, the catering was awful
Neutral	كان الطعام جيدًا ولكنه تقليدي بشكل أساسي طبخهم للوجبات لا بأس به اهم شي ما تموت يعني مو لازم الطعم يكون ١٠٠ %	The food was good but mostly traditional. Their cooking is okay — at least you won't die, the taste doesn't have to be 100%

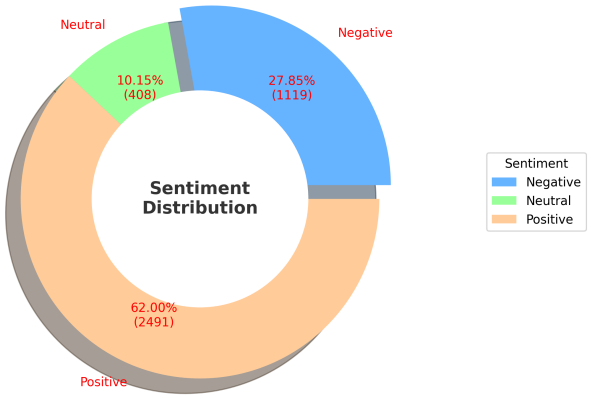

Fig. 5. Number of positive, negative and natural reviews in our dataset.

shown in Table V, such as text cleaning and tokenization, have been performed to ensure consistency. The reviews obtained for this study consisted of feedback written in Arabic as well as several other languages. To standardize the linguistic input and avoid model bias arising from multilingual text, we translated all non-Arabic reviews into Arabic using Google Translate. This translation step served to unify the dataset under a single language representation and enable the application of Arabic-specific preprocessing and sentiment-analysis techniques. Accordingly, the following steps were applied, before building the machine learning model, to ensure the efficiency of its accuracy.

1) Noise removal: According to [37], removing noise enhances analysis speed and accuracy. This involves removing any URLs, special characters, punctuation, and numbers from the reviews. To address these complexities in our dataset, we implemented a Python function called *remove_noise(text)*, which relies on regular expressions and the "sub" method from the "re" package [37] to systematically preprocess Arabic

reviews, and applies it to a panda DataFrame. This function removes unwanted elements such as digits, punctuation marks, and unusual symbols. It also cleans emojis, reduces elongated Arabic vowels, and normalizes white space. The cleaned text is then saved into a new column called *clean_text*, ensuring a clean and readable dataset for further analysis.

2) Normalization: Text normalization is employed to reduce noise within Arabic data and to correct spelling inconsistencies, as noted in prior research [38]. This procedure has been shown to enhance model performance in multiple studies [38], [6]. For example, the authors of [38] reported improved accuracy after applying normalization along with other preprocessing steps. Arabic text presents additional complexities, as some letters can appear in multiple forms depending on their position within a word. To address this, we normalized these letter variants—for example, converting ة (taa' marbuta) to ه, standardizing the different forms of أ, آ and ا to a single ا (alif), converting alif maqsura ى into ي, and changing letters with hamza (ؤ and ئ) into a stand-alone hamza ء. Arabic diacritics (such as fatha, damma, and kasra) are also removed, as they don't contribute significantly to sentiment analysis.

3) Tokenization: Tokenization is a fundamental preprocessing step in Arabic text analysis because it reduces typographical variation and prepares the text for reliable linguistic processing [39], [38]. Tokenization is the process of splitting the text into individual words or tokens [22]. For Arabic text, tools like NLTK, can be used to perform this step efficiently. In summary, this step converts the normalized Arabic text into separate words, making it easier to process in later tasks such as removing stop words, stemming, or performing deeper text analysis. Effective tokenization facilitates more precise counting of word occurrences and enhances the overall structure and interpretability of the text for NLP models [39], [38].

4) Stop word removal: Removing stop words—common words like من, على, في , etc.—is another key task, as these words don't carry much useful information for sentiment analysis [22]. We used the NLTK stop words corpus to filter out common Arabic words that usually carry little semantic meaning [39]. First, it downloads and loads the Arabic stop words provided by NLTK into a set called *stop_words*. Then, it extends this list with a custom set of additional Arabic stop words that the user defines manually (e.g., pronouns, prepositions, and frequently used words like من, على, في , etc.). After combining both sets, a function called *remove_stopwords* is defined, which takes a list of tokens (words) and returns only those that are not in the stop words set.

5) Stemming or lemmatization: Stemming, or lemmatization, is performed to reduce words to their root forms, ensuring variations of the same word [22]; for example, "وجبات" becomes "وجب". In this research, we apply stemming to Arabic words using NLTK's ISRIStemmer as implemented in [39], which is a rule-based algorithm specifically designed for the Arabic language. This step refines the text preprocessing pipeline by unifying word variants under a common root, which enhances the effectiveness of tasks such as text analysis and machine learning by treating semantically related words as the same concept.

TABLE V. EXAMPLE OF DATA PREPROCESSING

Data preprocessing	Example
Original Text	♥ حملة جج رائعة ومتميزة جدا ما ينقص المخيم اي شيء، عشاء وغداء وفطور بوفيه كامل متكامل
Noise Removal	حملة جج رائعة ومتميزة جدا ما ينقص المخيم اي شي عشاء وغداء وفطور بوفيه كامل متكامل
Normalization	حمله جج رائعه ومتميزه جدا ما ينقص المخيم اي شي عشاء وغداء وفطور بوفيه كامل متكامل
Tokenization	حمله، جج، رائعه، ومتميزه، جدا، ما، ينقص، المخيم، اي، شي، عشاء، وغداء، وفطور، بوفيه، كامل، متكامل
Stop-Word Removal	حمله، جج، رائعه، متميزه، ينقص، مخيم، عشاء، غداء، فطور، بوفيه، كامل، متكامل
Stemming	حمل، جج، روع، ميز، نقص، خيم، عش، غد، فطر، بف، كمل، تكمل

6) Feature extraction: After preprocessing, relevant features have been extracted for input in machine learning models. This process converts raw text into numerical features that machine learning models can understand. Examples of these features include bag-of-words (BoW), term frequency–inverse document frequency (TF–IDF), and word embeddings.

For the sentiment analysis task, the text data were transformed into numerical features using the TF–IDF technique, which quantifies the importance of words or phrases within a collection of documents. This process prepared both the text data and sentiment labels for machine learning. The categorical sentiment labels ("positive," "negative," and "neutral") were first converted into numerical form through a mapping dictionary, where the values 0, 1, and 2 represented positive, negative, and neutral sentiments, respectively. This encoding allowed the data to be used effectively in algorithms that require numerical input. The textual data were then vectorized using TF–IDF to assign weighted values to each term, emphasizing those that are more relevant to individual documents while downplaying common or less informative terms. To optimize feature extraction, several parameters were configured: The n-gram range was set from 1 to 3 to capture single words, bigrams, and trigrams; the minimum document frequency (min_df=3) excluded rare terms occurring in fewer than three documents; the maximum document frequency (max_df=0.9) removed overly common words appearing in more than 90 percent of documents; sublinear term frequency scaling (sublinear_tf=True) was applied to reduce the influence of very frequent terms; and the maximum number of features was limited to 5,000 to manage the dimensionality of the feature space. The resulting TF–IDF matrix represented each document as a numerical vector corresponding to the relative importance of its terms, and the matrix dimensions along with the vocabulary size were recorded to validate the transformation.

C. Machine Learning Models

Machine learning, a vital subfield of artificial intelligence (AI), enables computers to learn and enhance their perfor-

mance through experience without requiring explicit programming [40]. It is designed to help systems automatically identify patterns, make predictions, and make informed decisions based on data [40]. We used five machine learning algorithms to evaluate our dataset.

1) Support Vector Machine (SVM): Support vector machine is a supervised machine learning algorithm used for both classification and regression tasks [41]. The goal of SVM is to find the best possible hyperplane that divides the data into distinct classes, while maximizing the margin, or the distance, between the hyperplane and the closest data points from each class [41].

2) Naive Bayes (NB): Naive Bayes classifiers are a group of algorithms based on Bayes' Theorem, which is used to calculate probabilities for classification tasks [42]. Rather than referring to a single method, "Naive Bayes" covers a family of models that make the simplifying assumption that the features are independent of each other [42]. This assumption makes the models computationally efficient, especially when working with large datasets [42].

3) Logistic Regression (LR): Logistic regression is a supervised learning technique commonly used for classification problems, particularly when the goal is to estimate the probability that a given instance belongs to a specific class [43]. It works by calculating a value between 0 and 1, representing the likelihood that an event will occur, based on the relationship between the input features and the target variable [43].

4) Decision Tree (DT): A decision tree is a supervised machine learning technique that can be applied to both classification and regression problems [44]. Its structure resembles a hierarchy, beginning with a root node and branching into internal nodes, edges, and leaf nodes [44]. Much like a flowchart, it guides the decision-making process step by step: Internal nodes perform tests on attributes, branches denote the values of these attributes, and leaf nodes provide the final outcome or prediction [44]. Decision trees are commonly employed because they are easy to interpret, are adaptable, and require minimal data preprocessing [44].

5) Random Forest (RF): Random forest is a powerful machine learning technique that combines the predictions of multiple decision trees to improve accuracy [45]. During training, it builds several decision trees, each working with a different subset of the data and features. This "ensemble" approach helps make the model more robust, reducing the risk of overfitting and enhancing its ability to generalize well to new data [45].

D. Performance Measures

The quality of sentiment analysis has been assessed using various metrics and indicators to measure its performance. In this section, multiple machine learning algorithms have been compared based on performance metrics such as accuracy, precision, recall, and F1-score to determine which algorithm best predicts sentiment. Each metric has a unique formula, and we evaluated how well classifiers performed by using mathematical formulas. The following definitions of symbols are used in the formulas. "TP" refers to instances that are correctly classified as positive, "TN" signifies instances that are accurately classified as negative, "FP" represents instances that are incorrectly classified as positive, and "FN" denotes instances that are incorrectly classified as negative.

Accuracy refers to the overall proportion of correct classifications made by the model, including both positive and negative predictions [6].

$$\text{accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

The recall is the percentage of actual positive cases that the model correctly identifies as positive [46].

$$\text{recall} = \frac{TP}{TP + FN} \tag{2}$$

Precision is the proportion of positive predictions made by the model that are actually correct [46].

$$\text{precision} = \frac{TP}{TP + FP} \tag{3}$$

The F1-score is a way to combine precision and recall into a single metric. It is the harmonic mean of the two, balancing the trade-off between them [46].

$$\text{f1} - \text{score} = \frac{2 \cdot TP}{2 \cdot TP + FP + FN} \tag{4}$$

This comparison has led to a final interpretation, visualization, and evaluation of the different approaches. By gathering feedback data, preprocessing it for machine learning models, and applying various algorithms, issues with food service quality can be identified.

IV. Results and Discussion

The following sections present the detailed results obtained from each model, followed by a comparative discussion that interprets their performance and highlights the most effective approach for analyzing pilgrims' opinions about food service quality during the Hajj.

A. Machine Learning Evaluation

Table VI presents the performance metrics for all classifiers, including accuracy, precision, recall, and F1-score. These results were obtained using the optimal parameters determined through a grid-search procedure. We also implemented an adaptive hyperparameter tuning strategy that automatically selected the appropriate parameter grid based on the characteristics of each model type. This approach ensured that each classifier received targeted parameter optimization focused on the most relevant hyperparameters. Using f1_weighted as the scoring metric facilitated balanced performance across all sentiment classes. To ensure the robustness and reliability of the findings, the dataset was preprocessed and divided into training and testing subsets using a 70/30 split ratio (total dataset 4018, of which 2812 were for training and 1206 for testing), as illustrated in Table VII, followed by fivefold cross-validation. Stratified sampling was employed to maintain the original class distribution in both subsets. Examination

of the training data revealed class imbalance, with some sentiment categories being underrepresented. To address this issue, the synthetic minority oversampling technique (SMOTE) was applied to the training set. SMOTE generates synthetic samples of minority classes, thereby achieving a balanced dataset without duplicating existing entries [47]. The resulting balanced dataset ensured that the classification models were trained on an equal representation of all sentiment categories and no duplicate reviews across splits, thereby reducing bias and improving the reliability of the predictive outcomes.

TABLE VI. CLASSIFICATION RESULT

Model	Accuracy	Precision	Recall	F1-score
LR	**0.936153**	**0.926571**	**0.862949**	**0.888955**
SVM	0.928690	0.900183	0.859686	0.877759
RF	0.922056	0.916339	0.839022	0.870070
NB	0.912106	0.846642	0.855347	0.850854
DT	0.865672	0.825404	0.792528	0.807579

TABLE VII. CLASS DISTRIBUTION IN TRAINING AND TEST SETS

Dataset Split	Positive	Negative	Neutral	Total
Full dataset	2491	1119	408	4018
Training set (70%)	1743 (61.98%)	783 (27.84%)	286 (10.17%)	2812
Testing set (30%)	748 (62.03%)	336 (27.86%)	122 (10.12%)	1206

The comparison of machine learning models for sentiment analysis of food services during the Hajj demonstrates notable variations in performance across algorithms. Fig. 6 presents a bar chart that compares the performance metrics of different models. Among them, the LR classifier achieved the highest performance, with an accuracy of 93.6%, a precision of 92.7%, a recall of 86.3%, and an F1-score of 88.9%. This strong balance between precision and recall indicates that LR not only minimizes false positives but also captures most true positives, which is an ideal outcome for sentiment classification. The SVM and RF classifiers also performed competitively, with accuracies of 92.9% and 92.2%, respectively. SVM achieved 90% precision, 86% recall, and an F1-score of 87.8%, whereas RF achieved 91.6% precision, 83.9% recall, and an F1-score of 87%. The NB classifier demonstrated moderately strong performance, with an accuracy of 91.2%, a precision of 84.7%, a recall of 85.5%, and an F1-score of 85.1%. In contrast, the DT classifier delivered the weakest performance, achieving 86.6% accuracy, 82.5% precision, 79.3% recall, and an F1-score of 80.8%. As shown in Table VI, LR achieved the highest overall accuracy (93.6%) and F1-score (88.9%), indicating its strong ability to correctly classify pilgrims' opinions on food services. The competitive performance of SVM and RF suggests that these models also provide effective alternatives for text classification tasks. In contrast, the relatively low performance of the DT model may be attributed to its susceptibility to overfitting.

These results indicate that LR offers the most equitable and dependable performance for the analysis of textual feedback. Therefore, it can be considered the most suitable model for identifying and interpreting sentiments expressed by pilgrims regarding food quality, distribution, and overall satisfaction during the Hajj season.

Table VIII reports class-wise precision, recall, and F1 scores for each model, along with the macro-averaged F1

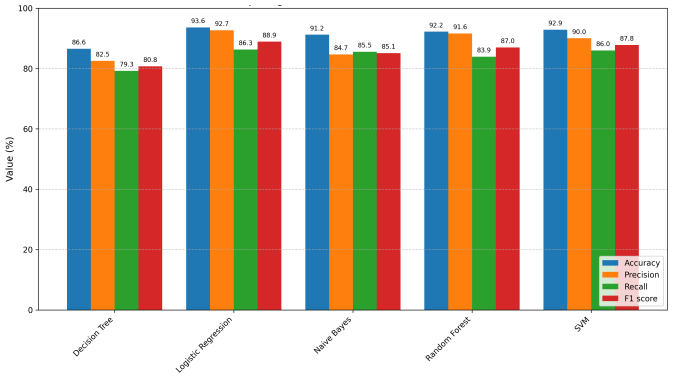

Fig. 6. Comparing the performance metrics of different models.

score. Most models achieve strong performance on the positive and negative classes, whereas performance on the neutral class is consistently lower, as expected given its smaller sample size (408 compared to 1119 and 2491). Among the evaluated models, LR achieves the highest macro-F1 score, indicating more balanced classification performance across the sentiment categories.

To assess the stability of the results, LR was trained and evaluated over ten runs using different random seeds, as shown in Table IX. The macro-averaged F1 score was reported as the mean across runs, along with a 95% confidence interval. To evaluate the robustness of the LR model, the experiment was repeated ten times using different random seeds with stratified train–test splits. The macro-averaged F1 score across runs ranged from 0.859 to 0.907, with a mean value of 0.887 and a standard deviation of 0.015. The corresponding 95% confidence interval [0.878, 0.897] indicates limited variability in performance, suggesting that the model's balanced classification ability is stable and not sensitive to a particular data split. This result is consistent with the macro-F1 value reported in Table VIII, confirming that the observed performance is reproducible and not an artifact of a single evaluation split.

TABLE VIII. CLASSIFICATION RESULT IN EACH CLASS

Model	Class	Precision	Recall	F1-score	Macro-F1
LR	positive	0.951031	0.986631	0.968504	0.888955
	negative	0.905605	0.913690	0.909630	
	neutral	0.923077	0.688525	0.788732	
SVM	positive	0.948320	0.981283	0.964520	0.877759
	negative	0.909091	0.892857	0.900901	
	neutral	0.843137	0.704918	0.767857	
RF	positive	0.928030	0.982620	0.954545	0.869824
	negative	0.911315	0.886905	0.898944	
	neutral	0.908046	0.647541	0.755981	
NB	positive	0.959569	0.951872	0.955705	0.850854
	negative	0.892857	0.892857	0.892857	
	neutral	0.687500	0.721311	0.704000	
DT	positive	0.895541	0.939840	0.917156	0.807579
	negative	0.830671	0.773810	0.801233	
	neutral	0.750000	0.663934	0.704348	

Fig. 7 illustrates the accuracy results across different machine learning models, with LR achieving the highest score of 93.6% and DT achieving the lowest score of 86.6%.

Fig. 8, Fig. 9, and Fig. 10 present the performance comparison of several machine learning models—SVM, NB, LR, DT, and RF—used for sentiment analysis of food service

TABLE IX. STABILITY ANALYSIS OF LR USING REPEATED RUNS

Metric	Value
Number of runs	10
Macro-F1 scores	[0.88305793 0.85866379 0.8780987 0.88270304 0.90666875 0.88068048 0.90701475 0.87978505 0.89923511 0.89673202]
Mean Macro-F1	0.8873
Standard Deviation	0.0151
Minimum Macro-F1	0.8587
Maximum Macro-F1	0.9070
Confidence Interval 95%	[0.8779, 0.8966]

experiences during the Hajj. The sentiment categories considered in this analysis are positive, negative, and neutral, and performance is evaluated using recall, precision, and F1-score.

In Fig. 8, the positive and negative classes achieved high precision across most models, indicating that when the models predicted a positive or negative sentiment, they were usually correct. The neutral class showed greater variability, with LR performing best for this category. This finding suggests that neutral predictions are more prone to misclassification compared to the other sentiment types.

Fig. 9 shows that all models achieved high recall for the positive class, particularly LR and SVM, both exceeding 0.95. This indicates that these models were highly effective in correctly identifying positive sentiments. For the negative class, recall values were slightly lower but still strong, typically around 0.85–0.9, meaning that most negative sentiments were also captured well. However, the neutral class consistently exhibited the lowest recall across all models, suggesting that distinguishing neutral opinions remains a challenge.

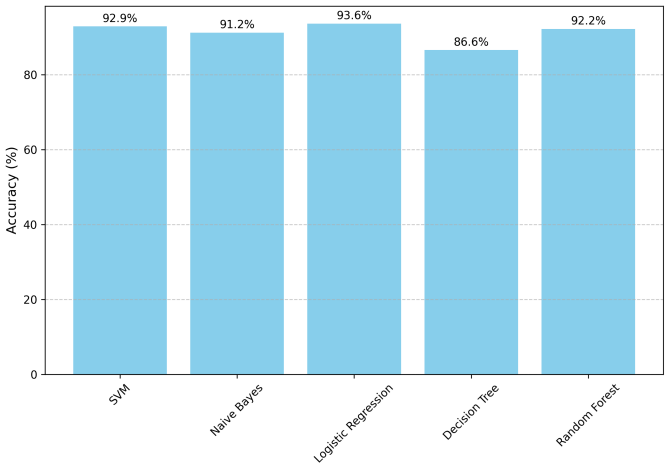

Fig. 7. Accuracy results comparing the performance of several machine learning models.

The F1-score results, shown in Fig. 10, reveal a similar pattern. The positive class achieved the highest F1-scores across all models, followed by the negative class. The neutral class again received the lowest F1-scores, reflecting the overall difficulty of detecting neutral feedback in sentiment analysis tasks. Overall, the results demonstrate that LR and SVM provided the most balanced and consistent performance across all sentiment categories. These findings suggest that these models are well-suited for analyzing pilgrims' feedback on food services during the Hajj, as they reliably distinguish between positive and negative sentiments.

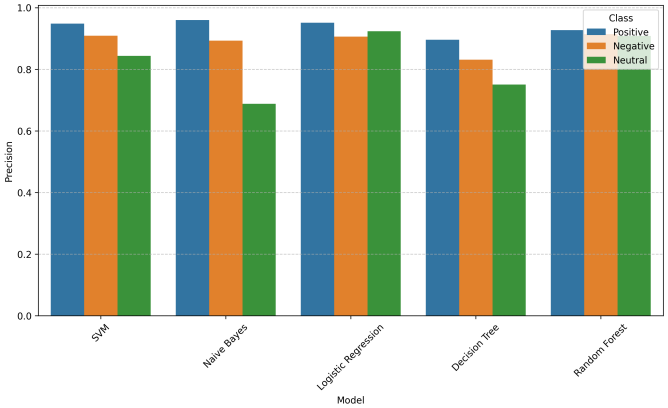

Fig. 8. Precision results comparing the performance of several machine learning models across sentiment categories.

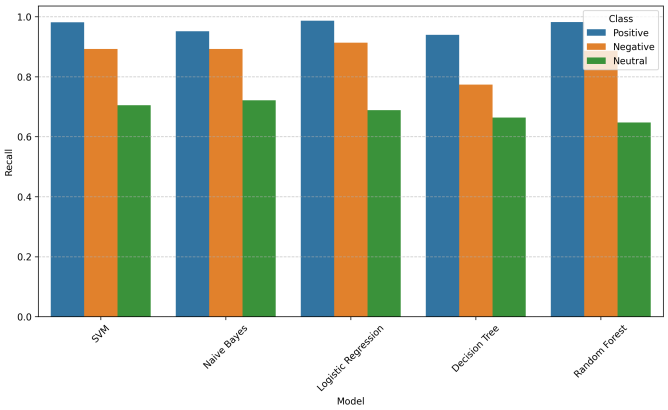

Fig. 9. Recall results comparing the performance of several machine learning models across sentiment categories.

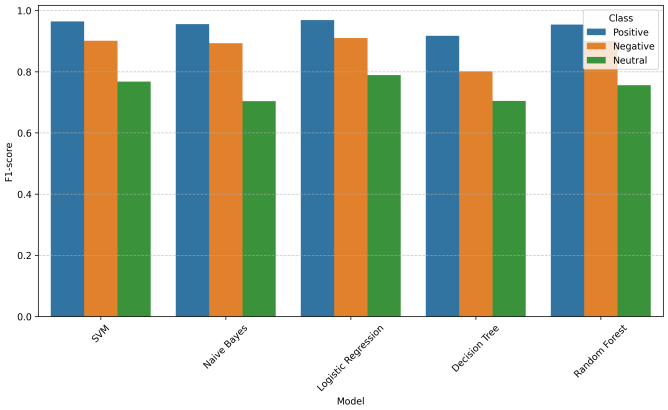

Fig. 10. F1-score results comparing the performance of several machine learning models across sentiment categories.

B. Visualization

Word frequency, word cloud, and confusion matrix—these visualization outputs contribute to data inspection and commu-

nication of results, supporting both preprocessing validation and model evaluation stages. Within Hajj-related sentiment analysis, authors have used these tools to display word-frequency patterns and illustrate sentiment trends in user-generated content on social platforms [6], [7], [8].

1) Word frequency: The analysis of word frequency in the textual data was conducted to identify the most common terms used by pilgrims when describing their experiences with the food services during the Hajj. As illustrated in Fig. 11, the word "الأكل" (food) appeared most frequently, with 1,315 occurrences, indicating that the majority of comments were directly related to the quality, availability, and overall experience of the food provided. The next most frequent word was "جداً" (very), which appeared 789 times, suggesting that many participants used intensifiers to emphasize their opinions, whether positive or negative. Other common words such as "ممتازة" (excellent), "الله" (God), "الحملة" (the campaign), and "البوفيه" (buffet) also appeared prominently, reflecting positive sentiments and references to the service settings. In addition, terms such as "خدمة" (service), "الطعام" (meal), and "الخدمات" (services) were frequently mentioned, showing that pilgrims often discussed both the food and the quality of service delivery. The presence of words like "رائعة" (wonderful) and "ممتاز" (excellent) further suggests that the general sentiment expressed in the comments was positive, aligning with the results of the sentiment analysis. Overall, this word-frequency analysis highlights the main topics of concern and appreciation among pilgrims—particularly food quality, buffet arrangements, and service efficiency—offering valuable insights for improving food service management during the Hajj season.

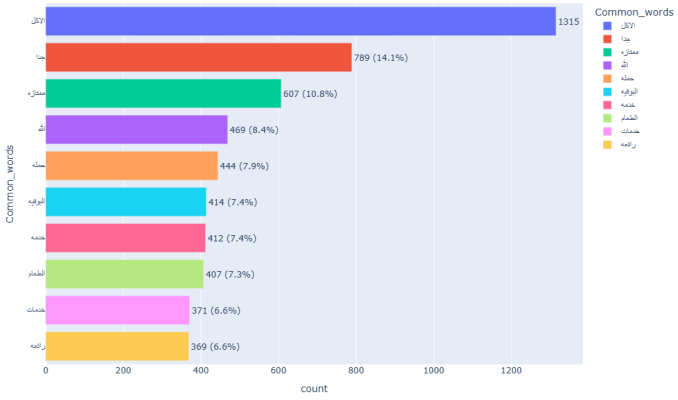

Fig. 11. Word frequency analysis showing the most common terms used by pilgrims in their feedback about food services during Hajj.

2) Word cloud: The next figure presents three Arabic word clouds categorized by sentiment: positive, negative, and neutral. Each word cloud visually displays the frequency of words appearing in pilgrim feedback, where larger words indicate higher occurrence.

Fig. 12 illustrates a word cloud of positive Arabic reviews, highlighting the most frequently used terms related to food services. In the visualization, larger words represent higher frequency. The most prominent terms include "الأكل" (food), "خدمة" (service), and "النظافة" (cleanliness), indicating that praise is most often directed toward these three aspects. Other common expressions consist of strong positive adjectives such as "ممتاز" (excellent), "رائع"(great), "متوفر" (available), and "تنظيم" (organization), along with intensifiers like "جداً" (very) and expressions of gratitude "شكراً" (thank you). Operational references, such as "البوفيه" (buffet), "كل شيء" (everything), "الموظفين" (staff), and "على مدار الساعة" (around the clock), also appear frequently, reflecting appreciation not only for food quality but also for efficient logistics and staff support. Overall, the word cloud underscores a dominant theme of positive sentiment centered on cleanliness, high-quality food, and attentive service.

Fig. 12. Word cloud showing the most frequent words in positive Arabic reviews about food services in Hajj.

In the neutral word cloud, as shown in Fig. 13, terms such as "الطعام" (food), "جيد" (good), "الخدمات" (services), and "الجودة" (quality) appear most frequently, indicating that many reviews described the experience as satisfactory or acceptable. These comments primarily reflect practical assessments of meal quality, cleanliness, and organizational processes rather than emotionally driven opinions.

Fig. 13. Word cloud showing the most frequent words in neutral Arabic reviews about food services in Hajj.

The negative word cloud, presented Fig. 14, displays frequently used words in reviews expressing dissatisfaction with food services. The most noticeable terms, "الأكل" (food),

"سيئة" (bad/poor), "البوفيه" (buffet), "تنظيم" (organization), "لا يوجد" (not available), and "بارد" (cold), point to dissatisfaction related to meal quality, limited variety, and weak coordination. The prominence of these words highlights key areas of concern among pilgrims. Many complaints relate to food quality, temperature, availability, and organizational issues. Phrases like "لا يوجد تنوع" (no variety) and "الطعام بارد" (cold food) are indicative of operational and logistical shortcomings rather than fundamental dissatisfaction with the concept of the service itself. Moreover, the recurrence of words such as "الأسف" (unfortunately) and "المستوى" (standard) suggests unmet expectations, particularly given the significance of the Hajj pilgrimage and the challenging conditions under which meals are prepared and served. A closer analysis of negative sentiments also reveals several challenges faced by pilgrims, including the lack of specially prepared meals for individuals with chronic illnesses, such as diabetes or hypertension, as well as for those with specific dietary needs. Pilgrims also reported occasional delays in meal service and unexpected changes in serving times without prior notice. In addition, the absence of designated dining areas often forced them to eat in their rooms or in shared hallways. Overall, the visualizations clearly show that pilgrim opinions, whether positive, negative, or neutral, center around the same core themes: food quality, buffet service, and the overall service experience.

Fig. 14. Word cloud showing the most frequent words in negative Arabic reviews about food services in Hajj.

3) Confusion matrix: We evaluated the performance of the SVM, LR, NB, DT, and RF models using confusion matrices, as illustrated in Fig. 15, to analyze their classification accuracy across the positive, negative, and neutral sentiment classes. The diagonal values in each matrix represent correctly predicted instances, whereas the off-diagonal values indicate misclassifications. Each confusion matrix shows how well a model correctly classified instances across the positive, negative, and neutral categories. The results indicate that LR achieved the most balanced performance, correctly predicting 738 positive, 307 negative, and 84 neutral samples. The SVM model produced similar accuracy, with slightly fewer correct neutral predictions. The RF model performed well overall, although it exhibited minor misclassifications in the negative and neutral categories. NB also achieved strong results, with 712 positive, 300 negative, and 88 neutral correct predictions, while the DT model performed comparatively lower, especially in the negative class. Overall, LR and SVM provided the most stable and accurate sentiment classifications across all categories.

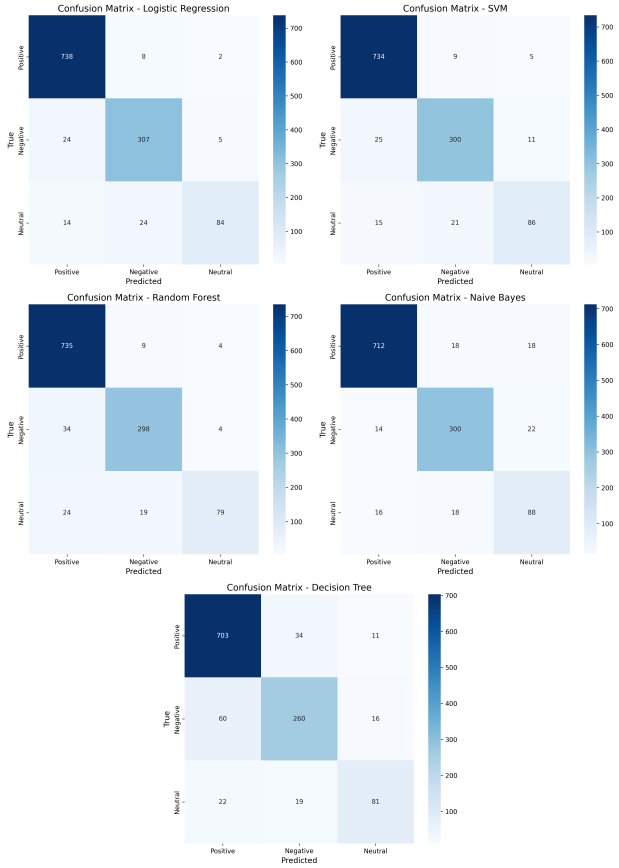

Fig. 15. Confusion matrices for five machine learning models: LR, SVM, RF, NB, and DT.

C. Hyperparameter Tuning

We performed hyperparameter tuning on the best-performing classification model obtained from previous evaluations. Based on the selected model type, we defined a specific set of parameters to optimize its performance, as shown in Table X. Each algorithm—SVM, LR, NB, DT, and RF—was assigned a distinct parameter grid containing key hyperparameters and their possible values. We used the GridSearchCV method with fivefold cross-validation to systematically evaluate all parameter combinations. The weighted F1-score was selected as the evaluation metric to effectively handle class imbalance. This process allowed us to identify the most suitable hyperparameter configuration for the chosen model, improving its overall accuracy and generalization.

D. Comparison with Previous Studies

Compared with previous studies, the present research provides a distinctive contribution by focusing specifically on food service quality during the Hajj, an area that has received limited attention in prior sentiment analysis works. While earlier studies, such as [8], [6], and [26], mainly analyzed general service sentiments on platforms like Twitter and YouTube, this study utilized Google Map reviews collected directly from Hajj campaigns between 2022 and 2025.

TABLE X. HYPERPARAMETER SETTINGS FOR EACH MODEL

Model Type	Hyperparameters Tuned	Parameter Values Tested
SVM	Regularization parameter (C), Class weight	C = [0.1, 1, 10, 100]; class_weight = ['balanced', None]
NB	Smoothing parameter (alpha), Class prior fitting	alpha = [0.1, 0.5, 1.0, 2.0]; fit_prior = [True, False]

LR	Regularization (C),
	Penalty type,
	Solver,
	Class weight
		C = [0.1, 1, 10, 100];
		penalty = ['l1', 'l2'];
		solver = ['liblinear'];
		class_weight = ['balanced', None]

DT	Maximum depth,
	Minimum samples split,
	Minimum samples leaf,
	Class weight
		max_depth = [None, 5, 10, 15];
		min_samples_split = [2, 5, 10];
		min_samples_leaf = [1, 2, 4];
		class_weight = ['balanced', None]

RF	Number of estimators,
	Maximum depth,
	Minimum samples split,
	Minimum samples leaf,
	Class weight
		n_estimators = [100, 200, 300];
		max_depth = [None, 10, 20];
		min_samples_split = [2, 5, 10];
		min_samples_leaf = [1, 2, 4];
		class_weight = ['balanced', None]

This approach ensures that the dataset reflects pilgrims' authentic experiences with catering services. This approach provides a more targeted view of food-related satisfaction. Methodologically, while most earlier works (e.g., [7], [25], [28]) relied on deep learning models such as CNN, LSTM, or hybrid CNN-LSTM , achieving accuracies ranging from 92% to 98%, the present study employed traditional machine learning algorithms (SVM, LR, NB, DT, RF) combined with TF-IDF and n-grams for feature extraction. Despite being less computationally intensive, the LR classifier achieved an accuracy of 93.6%, demonstrating that high performance can be obtained with optimized classical methods when the data is domain-specific and linguistically normalized. Another key distinction lies in the language unification process. While several studies, such as [6] and [28], addressed multilingual datasets or mixed Arabic–English content, this research standardized all data into Arabic, ensuring consistency in sentiment polarity detection. Moreover, the scope of this study—covering a four-year data collection period (2022–2025)—extends beyond the shorter, event-based windows (e.g., a few weeks during Hajj 1442) used in earlier works, allowing for more stable and generalizable insights. Overall, this research bridges a critical gap by integrating machine learning–based sentiment analysis with a domain-specific assessment of food services during the Hajj, offering both methodological rigor and practical value for service management.

V. CONCLUSION

Through our analysis, we demonstrated that sentiment analysis is an effective method for understanding pilgrims' opinions regarding food services during the Hajj. We addressed a gap in the existing research, as previous work tended to rely on social media data and did not specifically focus on food services. In this study, we analyzed pilgrims' feedback using Arabic textual reviews collected from Google Maps, providing a direct and representative source of post-Hajj evaluations. Our primary objective was to assess the performance of five machine learning algorithms in classifying sentiments related to food services. To achieve this, we collected approximately 4,018 reviews across 160 Hajj campaigns conducted between 2022 and 2025. After applying preprocessing techniques and extracting features using TF-IDF with n-grams, we trained and evaluated the classifiers. In addition to model performance, we examined the key issues reported by pilgrims and analyzed sentiment distributions related to food service quality.

The results revealed that many pilgrims still face issues related to food, such as a lack of specially prepared meals for individuals with chronic illnesses, limited variety, and weak coordination, indicating that this remains an ongoing challenge. The application of machine learning classifiers showed excellent overall performance. Among the models, LR achieved the highest accuracy of 93.6%, outperforming the other classifiers. The SVM and RF models produced comparable results, with accuracies of 92.9% and 92.2%, respectively. Furthermore, sentiment analysis indicated that positive sentiments predominated across all years, from 2022 to 2025, reflecting an overall improvement in pilgrims' satisfaction with food services over time.

The limitations of this research primarily stem from data-related constraints. First, the volume of available reviews was not sufficient to support the training of more complex deep learning models. Second, the dataset is limited in scope, as it includes reviews from domestic Hajj campaigns only and therefore does not fully represent the diversity of pilgrims. Finally, some reviews contained mixed or ambiguous sentiments, complicating the classification process.

For future research, we intend to employ more advanced feature extraction techniques—such as word embeddings and contextual language models—to better capture semantic nuances in Arabic text. Furthermore, we plan to extend the scope of the analysis to cover other essential services provided during the Hajj, such as transportation and accommodation. Finally, exploring deep learning methods may further improve classification performance and provide deeper insights into sentiment patterns.

King Abdul Aziz University, Jeddah 21589, Saudi Arabia[2]

***Abstract*—Nanotechnology offers transformative capabilities across healthcare, environmental monitoring, and industrial automation. When integrated with modern communication technologies, Wireless Nano Sensor Networks (WNSNs) form the Internet of Nano Things (IoNT), interconnecting nanoscale devices with conventional networks. Despite its potential, efficient routing in IoNT remains challenging due to severe energy constraints, limited processing, and high propagation losses in the terahertz (THz) band. This paper proposes the Distributed Energy-Efficient Protocol (DEEP), a lightweight routing scheme designed for IoNT-based WNSNs. DEEP balances simplicity, connectivity, and sustainability through adaptive retransmission control and a hybrid energy model combining environmental energy harvesting with wireless power transfer. Performance evaluation using the Nano-Sim module of the NS-3 simulator demonstrates that DEEP significantly extends network lifetime, reduces overall energy consumption, and maintains scalability and robust delivery performance with minimal communication overhead.**

Keywords*—Routing protocol; Internet of Nano Things; nanosensor; energy efficiency; energy harvesting; terahertz communication

I. Introduction

The rapid expansion of ubiquitous connectivity among diverse devices has accelerated the realization of the Internet of Nano Things (IoNT), an emerging paradigm that extends interconnectivity to the nanoscale and enables innovative applications across multiple domains. At the core of this paradigm lies the Wireless Nanosensor Network (WNSN), which enables communication among nanoscale devices through electromagnetic or molecular signaling mechanisms, forming the foundational infrastructure of IoNT. Defined as the interconnection of nanoscale sensors, devices, and nanomachines with traditional networks and the Internet, IoNT promises transformative impacts in healthcare, agriculture, smart cities, industrial monitoring, and other areas [1], [2], [3].

In healthcare, IoNT-enabled nanosensors embedded within the human body can monitor biomarkers in real time and deliver targeted therapies, supporting minimally invasive and highly precise treatments [4], [5]. In agriculture and environmental monitoring, nanoscale devices enable high-resolution measurements of soil composition, humidity, and pollutant levels, promoting sustainable and efficient resource management [6]. When integrated with advanced communication systems and machine learning algorithms, IoNT and WNSNs can further support autonomous decision-making and anomaly detection in complex environments such as industrial automation and smart infrastructures [7].

Despite these benefits, the extreme miniaturization of nanosensors imposes significant constraints that challenge the design and deployment of WNSNs [8]:

- Nano-antennas: Graphene-based THz antennas provide high bandwidth but suffer severe attenuation and noise, limiting communication to micro-/millimeter distances.
- Nano-processors: Extremely limited computational capabilities restrict data processing to small data units.
- Nano-batteries: Very limited energy storage, often irreplaceable, imposes strict energy constraints.

To mitigate energy limitations, energy harvesting has emerged as a promising solution, enabling nanosensors to partially replenish energy from blood flow, molecular vibrations, or body movement. However, harvested energy is intermittent and insufficient for continuous communication, introducing additional constraints on routing and network management. Maintaining network operation under fluctuating energy availability, while minimizing communication overhead, remains a key challenge [9], [10].

Motivated by these challenges, this paper introduces the Distributed Energy-Efficient Protocol (DEEP), an energy-aware routing solution designed for IoNT-based WNSNs. DEEP seeks to optimize network performance while minimizing energy dissipation, particularly in in-body applications where communication and energy constraints are most pronounced. It reduces redundant transmissions through an adaptive retransmission mechanism and integrates a hybrid energy model that combines variable-rate harvesting with wireless power transfer (WPT) to support sustainable nanosensor operation. Furthermore, DEEP is developed with consideration of realistic nanoscale communication and device constraints, including THz propagation effects and the inherent limitations of nanosensor hardware.

The main contributions of this paper are summarized as follows:

- Novel distributed hop-count routing protocol: DEEP employs a lightweight, deterministic mechanism suitable for nanoscale devices with extremely limited memory and computational capacity.

- Adaptive retransmission strategy: Reduces redundant transmissions and extends network lifetime under fluctuating energy availability.
- Hybrid energy model: Combines realistic energy harvesting for sustainable network operation.
- Comprehensive simulation with biologically plausible channel models: Demonstrates improved packet delivery, lower overhead, and enhanced energy efficiency compared to standard baselines.
- Comprehensive simulation with biologically plausible channel models: Demonstrates improved packet delivery, lower overhead, and enhanced energy efficiency compared to standard baselines.

The remainder of the paper is organized as follows. Section II presents IoNT architectures, WNSN characteristics, and existing routing protocols. Section III describes the proposed DEEP protocol, including the energy model and network architecture. Section IV details the simulation setup and performance evaluation. Finally, Section V concludes the paper.

II. Literature Review

The design of an efficient routing protocol in conjunction with nanodevice specification necessitates a comprehensive understanding of the core hardware components. Furthermore, it involves a detailed investigation of network architecture, terahertz-band wireless communication, and the selected energy supply strategy to effectively meet the intended application objectives [11].

A. IoNT Architecture

The architecture of an Internet of Nano Things (IoNT) network depends on the application domain but generally consists of four fundamental components: nanonodes, nanocontrollers, nano-microinterface (gateway) devices, and an Internet gateway [12], [13]. Fig. 1 illustrates the IoNT architecture in a plant monitoring system.

- A nanonode is the smallest and simplest nanodevice, acting as a nanosensor or nanoactuator with limited resources and transmission range, capable of basic tasks such as sensing, actuating, processing, and storage.
- A nanocontroller or nanorouter is a more resourceful and capable device than a nanonode, responsible for coordinating nanonodes, processing their collected data, and forward it through the nano-microinterface.
- Nano-microinterface (Gateway) acting as a bridge between the nanoscale network and external systems, this hybrid device uses terahertz communication with nanonodes and conventional protocols for external communication. It aggregates data from nanocontrollers and facilitates bidirectional interaction between nanosystems and the Internet.
- Internet Gateway provides remote control and monitoring of the IoNT system via the Internet, enabling data collection from nanonetworks and access by external applications.

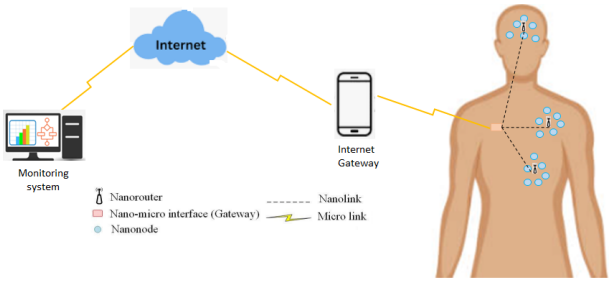

Fig. 1. IoNT architecture in healthcare system.

B. Principle Characteristics of a Nanodevice

In WNSNs, a nanodevice is the fundamental unit, either functioning as a nanonode (nanosensor/nanoactuator) or nanocontroller. With dimensions on the nanometer scale, these devices enable applications such as environmental monitoring, medical diagnostics, and biochemical detection. A typical nanodevice integrates multiple hardware components, including sensing/actuation, processing, communication, storage, and power units [14], [15], [16], [17].

Due to their small size, nanodevices face severe constraints in processing, communication, and energy, which are critical for network sustainability [18]. To address these limitations, network design must account for two critical aspects: terahertz (THz) wireless communication and energy supply systems. THz wireless communication using graphene-based nanoantennas (0.1–10 THz) offers extremely high data rates and wide bandwidth suitable for nanoscale networks [19]. However, propagation is limited by molecular absorption, noise, and frequency-selective path loss, confining effective transmission to a few millimeters in air and even less in biological media.

Energy supply is equally crucial. The tiny form factor of nanodevices limits onboard energy storage, affecting network lifetime and performance. Two main approaches have been explored: nanobatteries and energy harvesting. While nanoscale batteries provide temporary energy storage, they are impractical to recharge or replace in real network deployment. Energy harvesting, using nanogenerators that convert mechanical, vibrational, thermal, or electromagnetic energy into electricity, offers a more sustainable solution. Techniques such as piezoelectric and thermoelectric nanogenerators, as well as wireless power transfer (WPT), can prolong device operation and enable continuous network functionality. Despite advances, developing efficient, scalable energy solutions remains a key challenge for practical IoNT and WNSN deployments. Incorporating energy-harvesting mechanisms introduces additional complexity, as the available energy in nanodevices becomes highly dynamic and time-varying. Consequently, communication strategies in WNSNs must be designed to accommodate these fluctuations by jointly considering both energy consumption and harvesting rates. Ensuring continuous connectivity therefore requires adaptive protocols that operate efficiently under variable energy availability and maintain stable network performance despite the intermittent and unpredictable nature of harvested energy.

C. Related Works: Routing Protocols for IoNT

Many routing protocols have been proposed for the IoNT. The survey in [20] provides a comprehensive review and classification of these routing protocols.

In study [11], [21], and [22], cluster-based routing schemes are presented. Piro et al. in study [11] introduced a hierarchical framework that integrates intra-body nanonetworks with macro-scale healthcare systems to enable bidirectional communication between nanodevices and external devices. They proposed two energy-aware routing schemes: an optimal protocol that maximizes cluster energy through complex selection processes, and a simpler greedy protocol that selects nanosensors with the highest residual energy. A MAC-layer handshake mechanism was employed to identify active sensors and their energy levels. Simulation results using Nano-Sim showed that both approaches outperform conventional flooding techniques.

In study [21], nanosensors are organized into clusters to maintain efficient network connectivity. Each cluster consists of a coordinator, members, and relay nodes, with coordinator selection based on residual energy and packet forwarding ratio. Communication takes place through intra-cluster and inter-cluster phases, utilizing single- or multi-hop transmission depending on energy efficiency. Although this method outperforms random forwarding, it does not account for the energy harvesting characteristics of nanodevices. This work was later extended in study [22] by incorporating a detailed channel model and an integrated energy framework that considers both energy harvesting and consumption. The proposed layered nanonetwork architecture forms clusters within each layer, with cluster heads elected based on residual energy. Data transmission is organized into periodic phases, combining intra-cluster and inter-cluster communication managed by the nanocontroller through prioritized scheduling. Simulation results using Nano-Sim demonstrate that the proposed scheme achieves higher energy efficiency and lower outage probability compared to the baseline method in study [23].

In [24], two routing protocols for IoNT-based healthcare applications—naïve and destructive retrieval—were proposed. Both rely on a hop-count propagation phase initiated by the gateway to establish routing paths. In the naïve scheme, nanosensors forward packets toward the gateway based on hop-count comparisons, while the destructive retrieval algorithm improves efficiency by resetting the forwarding node's hop count to infinity, thereby preventing redundant transmissions. Although simulations in NS-3 confirm that the destructive retrieval approach reduces message overhead compared to the naïve method, the model assumes static nodes with unlimited energy and lacks consideration of energy constraints, mobility, and practical deployment overhead. The study in [25] presents a hierarchical Body Area Network (BAN) architecture modeled on a human hand, where an external gateway is positioned on the dorsum, a nanocontroller is implanted beneath the skin, and nanosensors circulate with the bloodstream. Both the nanocontroller and nanosensors are powered through energy harvesting, utilizing piezoelectric nanowires and a rechargeable nanocapacitor, with wireless power transfer (WPT) from an external ultrasound source. In the proposed routing mechanism, nanosensors remain in sleep mode until sufficient energy is accumulated, waking periodically upon entering the ultrasound region to exchange data with the nanocontroller. Analytical results indicate that communication occurs approximately every 52 minutes; however, the approach lacks simulation validation and relies on a single nanocontroller, which may lead to processing overhead.

In [26], the authors propose a dynamic multihop routing model that integrates electromagnetic nanocommunication properties with hemodynamic behavior. They introduce a theoretical framework based on reinforcement learning, formulated as a four-dimensional Markov Decision Process (MDP) that includes nanonode velocity, event priority, energy consumption, and energy-harvesting capacity. Performance analysis under varying parameters, such as nanonode density, vessel diameter, and flow speed, shows that the proposed multihop approach significantly improves the nanonetwork's effective coverage area.

Table I summarizes the main IoNT routing protocols, highlighting their approach, energy model, channel assumptions, simulation environment, and key limitations.

III. Distributed Energy Efficient Routing Protocol

This section outlines the development process of the proposed routing protocol. We begin by presenting the underlying design principles, then describe the adopted network architecture and the key assumptions. Next, we outline the energy supply mechanisms and summarize the energy models employed. Finally, we explain the protocol phases, its operational behavior, and the conceptual inspiration guiding the design.

A. Principles of the Proposed Routing Protocol

The objective of DEEP is to enhance network performance while minimizing energy consumption and extending the operational lifetime of nanoscale networks. DEEP is a distributed hop-count–based routing protocol in which each nanodevice independently makes forwarding decisions using only local information. The protocol is tailored for IoNT architectures, where communication typically involves two segments: (i) nanosensor–nanocontroller, and (ii) nanocontroller–gateway.

Pierobon et al., in [23], demonstrated that data transmission and reception dominate energy dissipation in nanoscale communication, whereas processing costs are negligible. Consequently, reducing unnecessary packet retransmissions is essential for avoiding premature node depletion and improving overall network performance. DEEP addresses this by minimizing the number of nodes participating in packet forwarding, thereby lowering both communication overhead and energy dissipation.

To achieve these goals, the protocol design adheres to the following principles:

- Support for multiple energy supply systems: DEEP incorporates two energy mechanisms—wireless power transfer (WPT) and environmental energy harvesting—resulting in two protocol variants: DEEP-WPT and DEEP-Harvesting.

TABLE I. COMPARISON OF IONT ROUTING PROTOCOLS

Protocol	Approach	Energy Model	Channel Model	Simulation	Limitations
Piro et al. [11]	Cluster-based	Residual energy	Simplified	Nano-Sim	Complex selection; limited THz realism
Afsana et al. [21], [22]	Multi-layer clustering	Residual energy + energy framework	Partial THz	Nano-Sim	No dynamic energy harvesting; no adaptive retransmissions
Buther et al. [24]	Hop-count (naïve & destructive)	Unlimited energy	Deterministic	NS-3	Unrealistic assumptions; no mobility/energy constraints
Canovas et al. [25]	Energy-harvesting aware	Harvesting + WPT	Partial THz	Analytical	Single nanocontroller; limited simulation
Garcia et al. [26]	Reinforcement learning	Harvesting-aware	Electromagnetic + hemodynamic	Simulation	Complex; high computational overhead

- Minimal resource usage: Each nanodevice stores only one routing record and performs simple comparison-based operations, aligning with the strict memory and processing constraints of nanoscale hardware.
- Energy-aware next-hop selection: The protocol uses a minimum-hop strategy to limit the number of forwarding nodes, thereby reducing total energy consumed per delivery path.
- Reduction of redundant transmissions: An adaptive retransmission mechanism limits unnecessary rebroadcasts, mitigating the high overhead associated with flooding-based approaches.

To achieve these goals, we first describe the adopted network architecture and the underlying assumptions in the next subsection, which serve as the basis for the DEEP protocol design.

B. DEEP Network Architecture and Assumptions

The proposed routing protocol is designed for in-body medical applications, where reliable nanoscale communication is essential for continuous physiological monitoring. The adopted architecture follows a hierarchical IoNT structure, which is widely considered suitable for in-body nanonetworks. In this architecture, the nanoscale network communicates with an external device (e.g., a smartphone), which subsequently interfaces with a healthcare provider through the Internet, forming a complete IoNT system. The wireless interface between the WNSN and the external device can be achieved using conventional technologies such as Bluetooth.

Fig. 1 illustrates the adopted IoNT architecture. Nanosensors, nanocontrollers, and the gateway are deployed in a 3D in-body environment. Nanosensors are assumed to exhibit micro-mobility, reflecting the small-scale displacements induced by physiological processes such as tissue deformation, and cellular vibrations. This mobility is characterized by slow, short-range, and does not break the topology, which do not lead to large topological changes but may slightly affect link availability and communication reliability. Such a micro-mobility model is suitable for organ- or tissue-level monitoring scenarios in which nanosensors are embedded in specific anatomical regions—such as the skin, heart, lung, or kidney—to detect abnormalities or biomarkers.

Nanocontrollers and the gateway, by contrast, are considered quasi-static because they are implanted in fixed anatomical locations to facilitate data aggregation and onward communication. Each nanodevice is assigned a unique identifier and is equipped with a graphene-based nano-antenna to support electromagnetic nanoscale communication. All devices employ Time Spread On-Off Keying (TS-OOK) modulation, a pulse-based communication scheme shown to be energy-efficient and suitable for THz-band communication [27].

Nanosensors periodically sense physiological parameters and forward their data to nearby nanocontrollers, which then relay the aggregated information toward the gateway. The gateway subsequently delivers the collected data to an external computing system, enabling remote monitoring and analysis by healthcare providers.

C. The Energy Supply Systems

The DEEP protocol is evaluated under two distinct nanoscale energy supply mechanisms. In both cases, each nanodevice is equipped with a piezoelectric nanogenerator [28] capable of harvesting energy either from an external wireless power source or from ambient physiological activity.

1) Wireless Power Transfer (WPT): In the first energy model, nanodevices harvest energy through wireless power transfer, where an external ultrasound emitter radiates waves that are converted into electrical energy. Under WPT, the harvested energy rate is assumed to be constant, enabling nanodevices to remain continuously active unless the external source is disabled.

This continuous activity does not imply that the network is overloaded. DEEP mitigates excessive resource usage by minimizing packet retransmissions, thereby reducing collisions and lowering energy expenditure. Under WPT, nanodevices operate in one of two states:

- Transmission: Actively forwarding or generating data packets.
- Reception: Receiving either new or duplicate packets.

2) Harvesting from environment: In the second energy model, nanodevices harvest energy from local physiological vibrations. Human tissues exhibit diverse vibration sources—such as muscle movements, blood flow, cardiac activity, and respiration—each characterized by different frequency ranges. As a result, the energy harvesting rate becomes time-varying and dependent on factors such as the nanodevice's location, blood pressure, and proximity to cardiovascular structures.

Under this mode, a nanodevice transitions between two operational states:

- Active: The device can transmit or receive packets.
- Sleep: Triggered when the stored energy drops below a threshold. In this state, the radio is disabled to allow faster energy accumulation.

Although energy harvesting occurs in both states, the harvesting rate is significantly higher during sleep mode due to reduced power consumption.

3) Energy models: The energy harvesting and consumption models adopted in this work must be compatible with TS-OOK pulse-based modulation. Both models are derived from the nanoscale framework proposed by Jornet et al. [28].

a) Energy harvesting model: Human physiological activity produces vibrations across a broad spectrum, from approximately 1 Hz (e.g., foot tapping) to over 300 Hz (e.g., running) [29]. These variations translate into highly dynamic harvesting rates.

The harvesting rate λ_e is computed as a function of the current energy in nanocapacitor E_{cap} and the increase in the energy of the capacitor ΔE as presented in the following formula.

$$\lambda_e(E_{cap}, \Delta E) = \left(\frac{n_{cycle}}{t_{cycle}}\right) \cdot \frac{\Delta E}{n_{cycle}(E_{cap} + \Delta E) - n_{cycle}(E_{cap})} \quad (1)$$

where, the n_{cycle} is the number of compressed-release cycles of nanowires in piezoelectric generator and t_{cycle} is the time between consecutive cycles.

b) Energy consumption model: Nanodevices consume energy during transmission and reception operations. Sleep mode is assumed to incur negligible power consumption. This study accounts for:

- energy consumed when receiving data as final destination.
- energy consumed when receiving data as an intermediate node.

Overhearing and processing energy are excluded.

Transmission energy denoted $E_{packet-tx}$ and reception energy denoted $E_{packet-rx}$ per packet are calculated as :

$$E_{\text{packet-tx}} = E_{\text{pulse-tx}} * W * N_{\text{bits}} \quad (2)$$

$$E_{\text{packet-rx}} = E_{\text{pulse-rx}} * W * N_{\text{bits}} \quad (3)$$

where, N_{bits} is the packet size and W is the probability of transmitting a pulse ("1"). Following [28], $W = 0.5$ to reflect a balanced symbol distribution.

Finally, since protocol behavior depends on the underlying energy system, two DEEP variants—DEEP-WPT and DEEP-Harvesting—are developed to account for these differences.

D. Description of DEEP Protocol

DEEP's goal is to build an end-to-end path (from any nanosensor to the gateway) while minimizing redundant retransmissions and ensuring reliable data delivery through a lightweight and deterministic forwarding mechanism. The nanonetwork operates across two segments:

- Nanosensor-to-nanocontroller communication: Data generated by nanosensors is forwarded hop-by-hop until it reaches the nearest nanocontroller. Hops in this case are nanosensors.
- Nanocontroller-to-gateway communication: Aggregated data is forwarded hop-by-hop to the gateway. Hops in this case are nanocontrollers.

Finally, the gateway forwards this data to the external computer through the Internet gateway. The present work focuses solely on the nanoscale communication domain, where the external side will adopt the existing protocols that fit the application.

DEEP operates in two main phases for both DEEP-WPT and DEEP-Harvesting namely, *topology discovery phase* and *data transmission phase*. The topology discovery process is identical across both variants, while data transmission behavior differs due to the energy supply mechanisms.

1) Topology discovery phase: The goal of this phase is to establish routing paths from nanosensors to nanocontrollers and from nanocontrollers to the gateway using a control message called the Topology Discovery (TD) packet. This phase is triggered by the destination which can be:

- The gateway to establish the Nanocontroller–Gateway Path: The gateway initiates the process by broadcasting a TD packet with a hop-count value set to 1. Each nanocontroller processes the packet according to Algorithm 1.
- The nanocontroller to establish the Nanosensor–Nanocontroller Path: Each nanocontroller broadcasts TD packets to nearby nanosensors with hop count initialized to 1. Nanosensors handle the packet using the same processing logic described in Algorithm 1.

When a nanodevice receives a TD packet, it processes it according to the logic illustrated in Algorithm 1. If this is the first time the nanodevice receives the TD packet (lines 1–7 of Algorithm 1), it performs the following actions:

- Updates its hop count field using the hop count carried in the TD packet, representing the number of hops required to reach the TD source (gateway or nanocontroller).
- Updates its destination address field with the source address contained in the TD packet.
- Updates its next-hop address field using the neighbor address attached to the TD packet.
- Increments the hop count value in the TD packet by one.

Algorithm 1 Nanodevice TD Reception Process.

```
1: if first reception then
2:    hop count Nanodevice ← hop count TD
3:    destination address Nanodevice ← source TD
4:    next hop address Nanodevice ← neighbor address TD
5:    hop count TD ← hop count TD + 1
6:    neighbor address TD ← Nanodevice address
7:    Forward TD
8: else
9:    if hop count Nanodevice > hop count TD then
10:      hop count Nanodevice ← hop count TD
11:      destination address Nanodevice ← source TD
12:      next hop address Nanodevice ← neighbor address TD
13:      hop count TD ← hop count TD + 1
14:      neighbor address TD ← Nanodevice address
15:      Forward TD
16:   else
17:      Discard
18:   end if
19: end if
```

- Replaces the neighbor address in the TD packet with its own address, allowing downstream nanodevices to identify their next hop.
- Forwards the updated TD packet to neighboring nodes.

If the nanodevice has already received a TD packet for the same destination (lines 9–15 of Algorithm 1), it compares the hop count stored locally with the hop count included in the newly received TD packet. If the new hop count is lower, the device updates its stored information using the same steps described above, ensuring that only the shortest-hop path is retained. Otherwise, the TD packet is discarded to prevent unnecessary retransmissions.

This process takes place recursively: nanocontrollers execute it when receiving TD packets from the gateway, and nanosensors execute it when receiving TD packets from nanocontrollers. By the end of the topology discovery phase, every nanodevice (nanosensor or nanocontroller) stores one compact routing record, containing the next-hop address. This enables DEEP to construct deterministic paths toward the gateway or nanocontrollers based on minimum hop count, ensuring efficient data forwarding with minimal overhead.

2) Data transmission phase: The data transmission phase begins after the completion of the topology discovery process. During this phase, each nanodevice forwards packets using only the local routing information stored in its routing record. As the energy supply differs between the two proposed variants, the operation of this phase is divided into DEEP-WPT and DEEP-Harvesting.

a) DEEP-WPT: In the WPT-based configuration, data transmission follows a simple and deterministic forwarding process. Each nanosensor periodically senses physiological parameters, generates a data packet, and forwards it to its designated next-hop nanodevice. Packets are forwarded hop by hop until they reach the assigned nanocontroller. The nanocontroller then forwards the aggregated data toward the gateway using its own next-hop entry, after which the gateway delivers the data to the external computing unit. Because all devices continuously receive energy from the external WPT source, they remain active at all times. Thus, the end-to-end path computed during the topology discovery phase remains valid throughout the data transmission period, eliminating redundant broadcasts and substantially reducing network overhead.

b) DEEP-harvesting: In the harvesting-based configuration, the same next-hop forwarding strategy is employed; however, the behavior of nanodevices is influenced by the intermittency of locally harvested energy. Since nanodevices may harvest energy from sources such as blood flow, heartbeat, or mechanical vibrations, the available energy varies significantly over time. When a nanodevice's residual energy drops below a predefined threshold, it must switch its radio off and enter a sleep state to replenish energy. During this period, the device cannot transmit or receive data packets.

As a result, if the sleeping device is the designated next hop on a computed path, data transmission will fail and the packet will be lost.

To mitigate this issue, DEEP-Harvesting introduces a lightweight control mechanism based on a Negative Acknowledgment (NACK) packet. When a nanodevice receives a data packet but lacks sufficient energy to forward it, it immediately sends a NACK to the previous hop before entering the sleep state. Upon receiving a NACK, the sender initiates a single-round controlled flooding of the data packet. Each nanodevice that receives this flooded copy forwards it according to its own next-hop record. To reduce unnecessary transmissions, nanosensors forward only those packets that are destined for their corresponding nanocontroller and discard packets addressed to other nanocontrollers. This selective relaying strategy confines the flooding area and prevents excessive energy consumption.

Algorithm 2 describes the packet reception behavior and NACK handling mechanism of the DEEP-Harvesting variant.

Algorithm 2 Nanodevice Reception Process for Data and NACK Packet

```
1: if Active nanodevice then
2:    if energy level ≥ threshold then
3:       Packet Type ?
4:       Case1: Data packet
5:       Forward data packet
6:       Case2: NACK packet
7:       Flood data packet with the same ID of NACK packet
8:       Case3: Flooded Data packet
9:       if nanocontroller then
10:         Forward data packet
11:      else
12:         if nanosensor && destination data packet
            == destination address in the record then
13:            Forward data packet
14:         else
15:            Discard
16:         end if
17:      end if
18:   else
19:      if energy level < threshold then
20:         if data packet: then
21:            Send NACK packet
22:         end if
23:         Sleep
24:      end if
25:   end if
26: end if
```

TABLE II. SIMULATION PARAMETERS' VALUES

Parameters	The value
System parameters	
Results	Average of 10 simulation runs
Simulation duration	100 s
Number of gateways	1
Number of nanocontrollers:	
DEEP-WPT	10
DEEP-Harvesting	12
Number of nanosensors	250, 500, 750, 1000
Area size	0.03 × 0.09 × 0.001 m^3
PHY details	
$E_{Pulse-tx}$	1 pj
$E_{Pulse-rx}$	0.1 pj
Pulse duration	100 fs
Pulse Interarrival Time (The gap between two pulses in time)	10 ps
Transmission range of gateway	0.02 mm
Transmission range of nanocontrollers	0.02-0.01 mm
Transmission range of nanosensors	0.01 mm
Message Processing Unit	
Data Packet size:	256 bits

IV. SIMULATION AND PERFORMANCE EVALUATION

All simulations are performed using Nano-Sim, a widely-used nanoscale network simulator for in-body IoNT scenarios. Each scenario is executed over 10 independent runs, and results are averaged to ensure statistical reliability.

A. General Simulation Parameters

Fig. 2 and Fig. 3, represent the simulated network in DEEP-WPT and DEEP-Harvesting, respectively. The network deployment as a whole is intended to approximate monitoring a small area inside human tissue or on organ surface. The gateway is located at the center of the area while nanocontrollers are distributed uniformly. However, nanosensors are scattered randomly in the network area. Nanodevices are assumed to be full charge in the beginning.

The nanosensors sense the ambient environment and produces data packets periodically. These packets are routed to the nearest nanocontroller then to the gateway. The transmission range was chosen based on Nano-Sim module, 0.01 mm for nanosensors and 0.02 mm for the gateway. To ensure that nanocontrollers can communicate with nanosensors and the gateway, it is sufficient to have two different transmission ranges either 0.01 or 0.02 mm. Table II presents the values of the simulation parameters that are common to all simulation's experiments.

B. General Evaluation Criteria

The main goal for DEEP protocol is to deliver the collected data while maximizing the network performance and minimizing the overhead and energy consumption. The evaluation criteria used to evaluate the protocol performance are:

- Number of received packets: Number of received packets by the gateway and by the nanocontrollers.
- Packet loss:

$$Packet\ loss = number\ of\ sent\ packets - number\ of\ received\ packets$$

- The network overhead: The number of control packets (TD and NACK) sent and received and the number of duplicated data packets in the network due to data flooding.
- Energy efficiency: Two ways to measure the energy efficiency based on the adopted energy supply system are used. In DEEP-WPT, the energy efficiency is measured based on the number of packets sent and received. Thus, we evaluate it implicitly with the overhead criteria. However, in DEEP-Harvesting, the energy efficiency is measured using Jornet energy model [28] described in the subsection 2 Eq. (2) and (3). Thus, we can calculate the total energy consumed in the network.
- Number of entering sleep state: Used only in DEEP-Harvesting. It indicates how many times nanodevices enter the sleep state due to energy depletion. This helps us to evaluate how the protocol put a load on nanodevices.

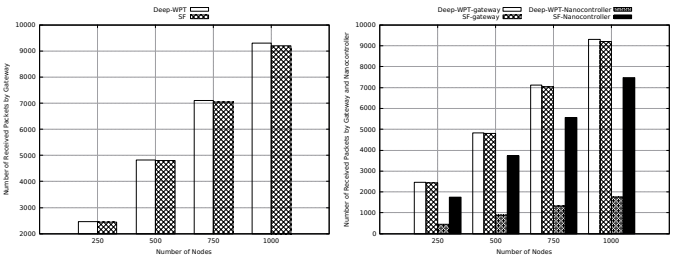
C. Comparative Performance Analysis

Due to the limited availability of IoNT routing protocols implemented in Nano-Sim, this study compares DEEP against Selective Flooding (SF) and Random Forwarding (RF), which are standard, reproducible baselines [30]:

- Random Forwarding (RF): Packets are forwarded to randomly selected neighbors; simple and low-overhead but prone to packet loss and duplication.
- Selective Flooding (SF): is an enhanced flooding algorithm for WNSN in which packets are broadcast to all neighbors with minimal redundancy control (only for the first reception).

Preliminary experiments show that SF consistently outperforms RF in terms of packet delivery ratio; therefore, SF is used as the primary baseline for detailed performance evaluation. We ran the SF protocol under the two different energy supplies: WPT to compare it with DEEP-WPT and harvesting from environment to compare it with DEEP-Harvesting.

1) Performance evaluation of DEEP-WPT: The results and discussions of the comparison between DEEP-WPT and SF protocol are presented in the following.



(a) (b)

Fig. 4. The number of received packets in WPT system: (a) By the gateway. (b) By the gateway and one nanocontroller.

a) Number of received packets: Fig. 4a presents the total number of packets received by the gateway using the DEEP-WPT and SF protocols. The results show that the number of received packets increases as the number of nanodevices grows, indicating that the protocol scales effectively with network size. Furthermore, DEEP-WPT consistently outperforms the SF protocol by delivering a higher number of packets to the gateway.

Fig. 4b illustrates the total number of packets received at the gateway as well as the average number received by a single nanocontroller. The results show that the DEEP protocol substantially reduces network overhead. Although DEEP delivers more packets to the gateway, the number of packets processed by each nanocontroller remains significantly lower compared to the SF protocol. For instance, with 1000 nanosensors, DEEP reduces the overhead on the nanocontroller by 77%. This improvement is attributed to the fact that SF relies on extensive packet flooding, which generates excessive retransmissions and rapidly consumes network resources, whereas DEEP transmits data hop-by-hop without unnecessary retransmissions.

Given the dense nature of WNSNs, DEEP is well suited for such environments. The performance results clearly demonstrate that our protocol offers better performance in terms of the number of packets successfully delivered.

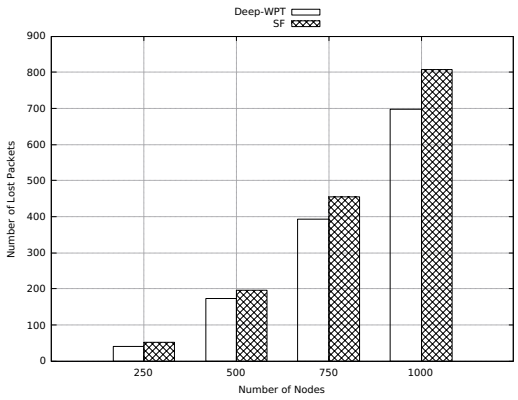


Fig. 5. The number of lost packets in WPT system.

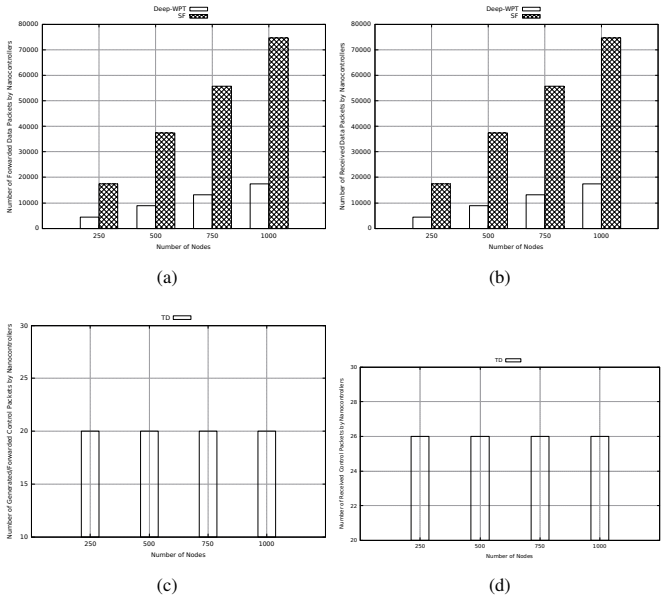
b) Packet loss: Fig. 5 shows the number of packets lost as the number of nodes in the network increases. Packet loss in this scenario is mainly due to collisions between concurrent transmissions, as the use of a WPT energy supply system ensures that no node suffers from energy depletion. The results indicate that the DEEP protocol significantly reduces packet loss. For instance, when the network contains 250 nodes, DEEP decreases packet loss by 21.5% compared to SF. This improvement is attributed to the reduced communication overhead introduced by DEEP, which in turn lowers the number of simultaneous retransmissions.

c) The network overhead and energy efficiency: At nanocontroller level Fig. 6a shows the number of data packets sent by nanocontrollers while Fig. 6b shows the number of data packets received. Generally, as the number of nanodevices increases, the number of data packets sent and received by the nanocontrollers increases. However, DEEP substantial reduces the number of packets exchanged compared to SF protocol. This reduction reaches 77% when we have 1000 nanosensors in the network.

Furthermore, the number of control packets transmitted and received by nanocontrollers, illustrated in Fig. 6c and Fig. 6d, remains constant and does not depend on the number of nanosensors in the network, as the number of nanocontrollers is fixed. This quantity is negligible compared to the volume of data packets forwarded across the network. Consequently, we can conclude that the overall protocol overhead—including both retransmitted data packets and control packets (TD)—is minimal relative to the network overhead observed when using the SF protocol.



(a) (b) (c) (d)

Fig. 6. The number of sent and received data and control packets by nanocontrollers in WPT system: (a) Sent data packets. (b) Received data packets. (c) Sent DEEP control packets. (d) Received DEEP control packets.

d) At nanosensor level: Fig. 7c and Fig. 7d depict the control packets sent and received by nanosensors, respectively. The number of control packets received and sent increases

with the number of nodes on the network. To conclude, we observe that the overhead of DEEP protocol taking into account control packets and retransmitted packets remains very small compared to the number of packets sent and received using SF protocol which reaches millions of packets.

These results demonstrate that DEEP is an effective routing protocol for IoNT, providing sustained network connectivity while minimizing network overhead.

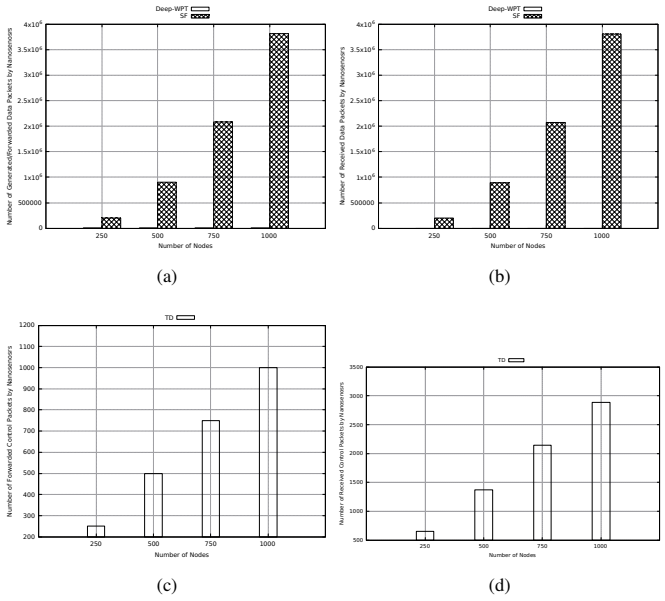


Fig. 7. The number of sent and received data and control packets by nanosensors in WPT system: (a) Sent data packets. (b) Received Data packets. (c) Sent DEEP Control packets. (d) Received DEEP control packets.

2) Performance Evaluation of DEEP-Harvesting: NanoSim does not natively support energy harvesting from the environment. Therefore, prior to presenting the results, we introduce additional simulation parameters in Table III, which are necessary to simulate DEEP-Harvesting.

TABLE III. THE PARAMETERS' VALUES FOR SIMULATING DEEP-HARVESTING

Parameter/Description	The value
Energy capacity: The energy level at the nanocapacitor Nanocontroller Nanosensor	 1600 pj 800 pj
w **weight code:** The probability to transmitting a symbol "1" instead of being silent "0"	0.5
Threshold: The minimum energy level that makes node entering the sleep state, which is equal to the energy required to transmit and receive one data packet	149.8 pj
Message generation probability:	0.2

a) Number of received packets: Fig. 8a shows the total number of packets received at the gateway using the DEEP-Harvesting and SF protocols. As illustrated, the number of received packets increases with the number of nanosensors up to 750 nodes, after which it decreases when the network includes 1000 nodes. This behavior is expected: as the number of nanosensors increases, more packets are generated, leading to higher energy consumption. Consequently, many nodes deplete their available energy and transition into a sleep state, resulting in packet losses within the network.

Despite this, DEEP consistently outperforms the SF protocol across all network sizes. For instance, with 1000 nanosensors, the gateway receives 134.12% more packets using DEEP compared to SF. This improvement stems from the limitations of the SF protocol, which relies on a flooding-based strategy that rapidly drains the energy of nanodevices and overwhelms the network with excessive retransmissions. As a result, nodes frequently exhaust their energy and enter repeated sleep cycles, preventing continuous network operation.

In contrast, DEEP significantly limits unnecessary retransmissions by establishing a dedicated path between the source and destination and minimizing flooding, thereby offering superior performance and more sustainable network operation.

Fig. 8b presents the number of packets received at the gateway, along with the average number of packets processed by the nanocontroller. When comparing DEEP with the SF protocol, DEEP reduces the processing overhead at the nanocontroller by approximately 60%, while still delivering a greater number of packets to the gateway.

These results clearly demonstrate that, under energy-constrained conditions, DEEP achieves superior performance compared to the SF protocol, particularly in terms of the number of data packets successfully delivered to the gateway.

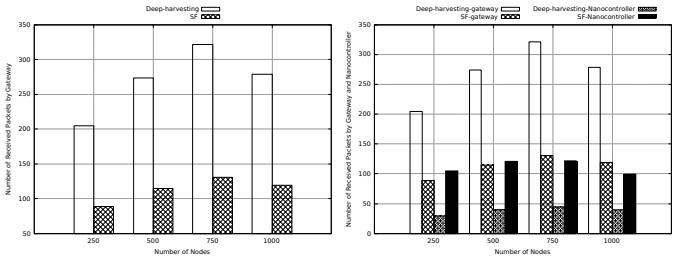

Fig. 8. The number of received packets in harvesting from environment system: (a) By the gateway. (b) By the gateway and one nanocontroller.

b) Packet loss: Because the number of packets generated in the DEEP and SF protocols is not identical, we present the percentage of lost packets—as shown in Fig. 9—rather than the absolute number of lost packets. The figure shows that the packet loss percentage increases as the number of nodes grows, which is expected given the corresponding rise in generated traffic. Nevertheless, DEEP consistently achieves a lower packet loss percentage compared to the SF protocol, demonstrating its ability to better preserve network reliability under increasing load.

c) The network overhead at nanocontroller level: Fig. 10a and Fig. 10b represent the number of sent and received data packets by nanocontrollers, respectively. In Fig. 10a, the increase in the forwarded packets with DEEP protocol is coming from the continuous operation of nanocontrollers that adopt DEEP. However, SF protocol exhausts the energy of nanocontrollers which enforces them to go to the sleep state many times rendering them inoperative. In SF, the energy

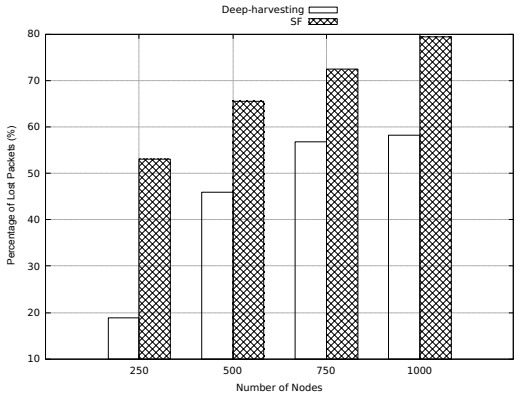

Fig. 9. The percentage of lost packets in harvesting from environment system.

of the nanocontrollers is dissipated in sending and receiving (as shown in Fig. 10b) duplicated packets which reduces the number of packets forwarded to the gateway.

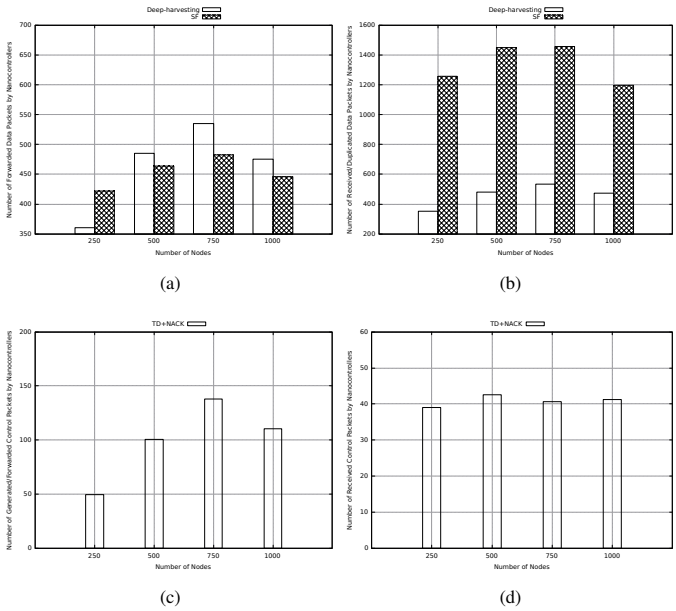

Fig. 10. The number of sent and received data and control packets by nanocontrollers in harvesting from environment system: (a) Data packets sent. (b) Received data packets. (c) DEEP control packets sent. (d) Received DEEP control packets.

Fig. 10c and Fig. 10d illustrate the number of sent and received control (TD and NACK) packets by nanocontrollers, respectively. Through these two figures, we can see that the overhead added by our protocol remains very small compared to number of messages duplicated in SF protocol. For example, for 500 nodes, the number of received control packets represents less than 4% of the number of duplicated packets in SF protocol.

d) The network overhead at nanosensor level: Fig. 11a provides the results of all the sent data packets (the generated and forwarded) by nanosensors for both protocols. The number of sent packets increases when the number of nodes increases. We observe that the number of packets generated and forwarded in DEEP protocol is 30% smaller than SF with 1000 nanosensors even so the number of packets received by the gateway is higher with DEEP.

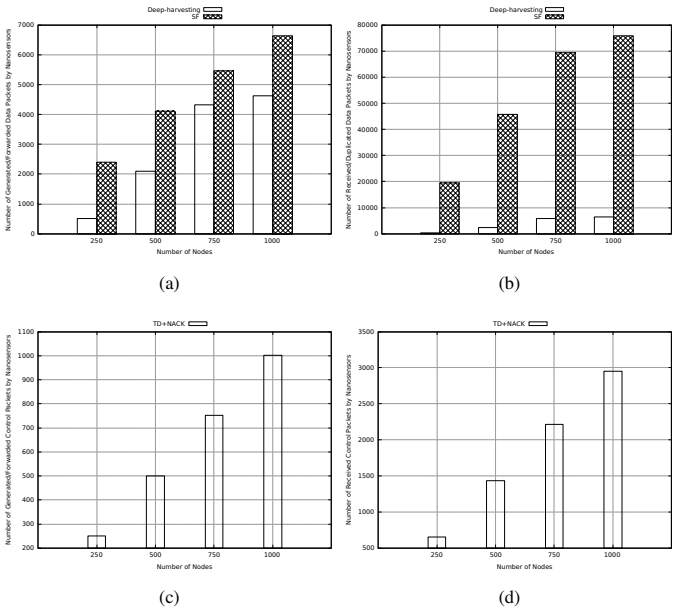

Fig. 11. The number of sent and received data and control packets by nanosensors in harvesting from environment system: (a) Data packets sent. (b) Received data packets. (c) DEEP control packets sent. (d) Received DEEP control packets. packets.

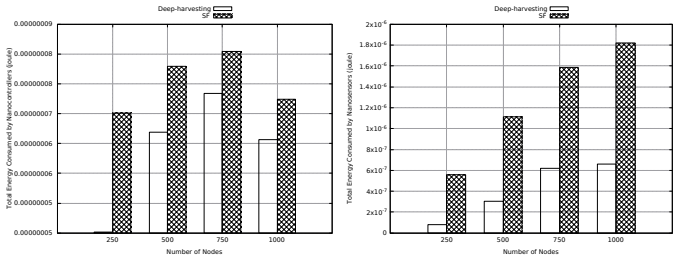
In the other hand, Fig. 11b depicts the number of received data packets by nanosensors including the duplicated data packets. We observe, from this figure, that DEEP reduces significantly the number of packets duplicated in the network. This reduction reaches 91% when the number of nanosensors is 1000 in the network.

Fig. 11c and Fig. 11d show the number of sent and received control packets by nanosensors, respectively. We can note that as the number of nodes in the network increases, the number of control packets received and sent increases. However, the overhead of DEEP protocol taking into account control packets and retransmitted packets remains very small compared to the number of duplicated packets using SF protocol.

Hence, SF exhausts the nanosensors' resources by unnecessary data packet retransmissions that reduces the network performance. However, DEEP reduces the retransmissions overhead at the network leading to best network performance under limited resources and difficult circumstance. That makes DEEP an energy aware routing protocol for IoNT, providing best network performance that balances between the routed data and the energy requirement.

3) Energy efficiency: Fig. 12a presents the energy consumed by nanocontrollers under the DEEP and SF protocols. As shown, and consistent with the number of generated packets, the energy consumption fluctuates as the network size increases. Notably, nanocontrollers in DEEP consume less

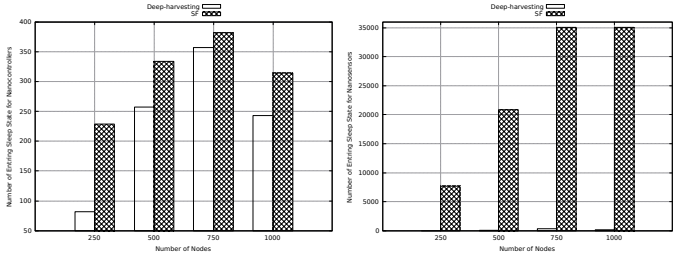
energy while transmitting both control and a higher volume of data packets, whereas the SF protocol requires more energy to transmit data packets alone.



(a) (b)

Fig. 12. The energy consumed by nanodevices in harvesting from environment system: (a) Nanocontrollers. (b) Nanosensors.

A similar trend is observed in Fig. 12b, which shows that nanosensors also consume significantly less energy when using DEEP. For instance, with 1000 nodes, DEEP reduces nanosensor energy consumption by 63.62% compared to the SF protocol. Importantly, this reduced energy expenditure is achieved while delivering a larger number of data packets to the gateway. Thus, DEEP enables both nanocontrollers and nanosensors to deliver more data with substantially lower energy consumption—an essential characteristic for any efficient routing protocol in energy-constrained nanonetworks.



(a) (b)

Fig. 13. Number of entering sleep state for nanodevices in harvesting from environment system: (a) Nanocontrollers. (b) Nanosensors.

- Number of entering sleep state: Fig. 13a and Fig. 13b illustrate the number of times nanocontrollers and nanosensors enter the sleep state, respectively. These results provide insight into how each routing protocol affects the depletion of harvested energy within the network. Across all device types, the number of nodes entering sleep under the DEEP protocol remains significantly lower than under the SF protocol. This behavior is expected, as SF relies on a flooding strategy that rapidly drains node energy, causing frequent transitions to the sleep state. In contrast, DEEP minimizes unnecessary flooding by leveraging the established routing paths generated during the topology discovery phase. Consequently, DEEP demonstrates its ability to sustain continuous network operation while maintaining performance levels that outperform SF in terms of energy preservation and operational stability.

Table IV summarizes the key differences between the two energy models in the proposed DEEP protocol: DEEP-WPT, which relies on wireless power transfer for predictable energy availability, and DEEP-Harvesting, which utilizes environmental energy sources with variable availability, highlighting their respective advantages, limitations, and suitable application scenarios.

TABLE IV. KEY DIFFERENCES BETWEEN DEEP-WPT AND DEEP-HARVESTING

Feature	DEEP-WPT	DEEP-Harvesting
Energy Source	Wireless Power Transfer (WPT)	Energy harvested from the environment (vibrations, biochemical reactions, EM energy)
Energy Availability	Continuous and predictable as long as the nanosensor is within WPT range	Intermittent and variable; depends on environmental conditions
Routing Stability	High stability due to reliable power availability	Moderate stability; depends on harvesting rate and stored charge
Node Density Influence	Less sensitive to density because energy is supplied externally	Highly dependent on density; more nodes allow more balanced harvesting
Best Use Cases	Fixed medical implants, body-area WNSNs, structured deployments	In-body nanosensing, environmental nanosensing, fluid or dynamic environments
Limitations	Requires dedicated power-transmitting infrastructure; limited WPT range	Energy levels fluctuate, leading to unpredictable forwarding behavior

V. CONCLUSIONS

This paper presented DEEP, a Distributed Energy-Efficient routing Protocol designed to improve reliability, reduce communication overhead, and minimize energy consumption in Internet of Nano Things (IoNT) environments. DEEP employs a hop-count–based routing strategy to establish efficient paths from nanosensors to nanocontrollers and ultimately to the gateway, ensuring reliable data delivery in in-body nanoscale networks. The protocol operates through two main phases: a topology discovery phase that identifies the shortest communication paths, and a data transmission phase that forwards packets along these optimized routes. To address the heterogeneous energy supply characteristics of nanodevices, two variants were developed: DEEP-WPT, which leverages wireless power transfer, and DEEP-Harvesting, which integrates ambient energy harvesting.

The protocol was implemented and evaluated using the Nano-Sim module within an in-body THz communication environment. Simulation results show that DEEP reduces redundant broadcast transmissions and lowers overall energy consumption. As network density increases, DEEP consistently outperforms selective flooding, achieving fewer retransmissions, higher energy efficiency, and sustained network operability. These findings demonstrate that DEEP is both scalable and well-suited for dense IoNT deployments.

Future work will focus on integrating nanosensor mobility models and extending the protocol to support more complex nanoscale architectures and cross-layer optimization.

ACKNOWLEDGMENT

This research was funded by the Vice President for Graduate Studies, Research and Business (GRB) at Dar Al-Hekma University, Jeddah, under grant no. (RFC/23-24/05). The authors, therefore, acknowledge with thanks GRB for technical and financial support.

Predictive Data Mining Analysis of Ownership Structures and their Influence on Corporate Tax Avoidance

Tuti Herawati[1], Helmi Yazid[2], Nurhayati Soleha[3], Munawar Muchlish[4]
Faculty of Economics and Business, Sultan Ageng Tirtayasa University, Banten, Indonesia[1,2,3,4]
Department of Accounting, Digital Technology University, Bandung, West Java, Indonesia[2]

***Abstract*—This study aims to examine the impact of corporate ownership structures on tax avoidance using a predictive data mining approach. The main challenge addressed is understanding how variations in ownership influence a firm's strategic financial decisions, particularly its tendency to engage in tax minimization practices. By applying advanced predictive data mining techniques, the research uncovers significant patterns, identifies key ownership features, and models their relationship with tax avoidance outcomes. The dataset, derived from corporate financial statements and ownership records, is systematically preprocessed, feature-selected, and validated to ensure reliable predictive performance. Results demonstrate that differences in ownership structures significantly affect tax avoidance behavior, with certain ownership characteristics consistently emerging as strong predictors. These findings offer computational insights for both academic understanding and practical applications, helping regulators anticipate risky ownership configurations and improve policy oversight. The study highlights the importance of integrating ownership theory with predictive modeling to enhance the transparency, interpretability, and robustness of corporate tax strategy analyses.**

***Keywords*—Data mining; big data; tax avoidance; tax burden; corporate ownership structure**

I. Introduction

Ownership structure has long been recognized as a key determinant of strategic decision-making within firms. Different ownership configurations, such as family ownership, institutional ownership, and managerial ownership, can shape governance practices and influence managerial incentives. These ownership variations often lead to distinct approaches in financial reporting and tax planning. As global tax regulations become more complex, companies increasingly adopt sophisticated mechanisms to optimize tax liabilities. Understanding how ownership structure contributes to corporate tax avoidance has therefore become an urgent academic and regulatory concern [1]. This makes it imperative to analyze ownership structures systematically to better anticipate and mitigate aggressive tax avoidance practices.

Tax avoidance remains a persistent issue in both developed and emerging economies. Governments worldwide lose significant revenue due to corporate strategies that legally minimize tax obligations. According to several empirical studies, ownership type plays a substantial role in determining the aggressiveness of tax planning strategies. Firms with concentrated ownership may demonstrate stronger control that encourages tax minimization, while widely-held firms may face greater scrutiny from external investors. This dynamic creates an important context for analyzing variations in tax avoidance behavior across different ownership structures [2]. Understanding these variations can help policymakers and regulators design more effective oversight mechanisms and guide firms toward more transparent tax practices.

Technological advancements have introduced new opportunities for analyzing financial patterns related to tax management. Data mining techniques offer a powerful approach for detecting hidden trends that conventional statistical methods may overlook. These techniques can extract meaningful insights from large corporate datasets, enabling a more precise understanding of tax avoidance behavior. As firms increasingly digitalize their reporting systems, the availability of high-volume data enhances the feasibility of analytical modeling. Thus, applying data mining to ownership–tax avoidance analysis provides substantial methodological value [3] [4]. This approach not only enhances predictive accuracy but also offers actionable insights for regulators and corporate decision-makers seeking to monitor and mitigate tax avoidance effectively.

The relationship between ownership structure and tax avoidance is complex and influenced by internal and external governance mechanisms. Institutional investors, for example, often push for transparent reporting and compliance, potentially reducing aggressive tax practices. Conversely, internal managerial ownership may encourage practices aimed at maximizing after-tax income. These interactions highlight the importance of examining ownership composition as a multidimensional construct. As corporate governance continues to evolve, understanding its implications for tax behavior becomes increasingly relevant [5]. Recognizing ownership composition as a multidimensional construct enables more nuanced analyses of tax behavior, helping both academics and regulators anticipate potential risks and design more effective governance frameworks.

In emerging markets such as Indonesia, the issue of tax avoidance has gained significant attention in recent years. Rapid economic growth has been accompanied by heightened regulatory pressure to improve tax compliance. Nevertheless, many firms exploit gaps in enforcement and inconsistencies in tax policy implementation. Studies show that ownership concentration remains high across many Indonesian firms,

potentially influencing corporate reporting incentives. These structural conditions make Indonesia a meaningful context for examining ownership-driven tax avoidance [6], [7], [8]. Table I provides an overview of the tax gap reported in selected Asian countries, illustrating the scale of tax compliance challenges.

TABLE I. ESTIMATED CORPORATE TAX GAP IN SELECTED ASIAN COUNTRIES (2023)

Country	Estimated Tax Gap (USD Billion)	Compliance Level (%)
Indonesia	6.8	72%
Malaysia	4.3	79%
Thailand	3.9	81%
Philippines	5.1	70%

Source: Research data, 2025

The table presents the estimated corporate tax gap in selected Asian countries for the year 2023. In Indonesia, the tax gap is estimated at 6.8 billion USD, with a compliance level of 72%. Malaysia shows a lower tax gap of 4.3 billion USD, accompanied by a higher compliance rate of 79%. Thailand records a tax gap of 3.9 billion USD, with compliance reaching 81%, the highest among the countries listed. The Philippines has a tax gap of 5.1 billion USD and a compliance level of 70%, indicating the lowest compliance in this group. These figures highlight significant variations in tax compliance across countries in the region, suggesting that contextual factors such as governance, regulatory frameworks, and enforcement mechanisms play a critical role in shaping corporate tax behavior. The data also underscores the importance of analyzing sector- and ownership-specific factors to better understand and mitigate the tax gap. These figures highlight the persistent gap between expected and actual tax revenues in the region. Such variations reflect different enforcement capacities, reporting structures, and governance environments. Understanding how ownership influences tax behavior within these contexts becomes especially critical. This data further supports the need for empirical research on ownership-related tax strategies. The patterns shown in the table align with recent empirical findings on tax practices in Asia [2]. These insights underscore the necessity of integrating empirical analysis with predictive modeling to better inform both corporate decision-making and regulatory policy.

Corporate ownership patterns also differ substantially across sectors, influencing firms' overall attitudes toward taxation. Industries dominated by family-controlled firms often exhibit unique tax planning approaches rooted in long-term wealth preservation. Meanwhile, foreign-owned firms may adopt aggressive tax planning strategies enabled by cross-border mechanisms. These differences highlight the importance of sector-specific analysis in tax avoidance research. Analyzing sectors independently allows for a deeper understanding of ownership effects [9]. Conducting sector-specific analyses provides more precise insights into ownership-driven tax behavior, enabling tailored regulatory strategies and more effective corporate governance practices.

Another aspect that shapes tax avoidance behavior is the firm's financial performance. Firms experiencing financial pressure may be more likely to engage in tax minimization strategies to preserve liquidity. Conversely, highly profitable firms may reduce tax risk by prioritizing compliance to protect their reputational capital. Ownership structure interacts with these financial dynamics, influencing managerial incentives and reporting decisions. This interplay underscores the need to integrate financial attributes within ownership–tax analysis [10]. Incorporating financial attributes into ownership–tax analyses enhances the accuracy of predictive models and provides actionable insights for both corporate managers and regulatory authorities.

Recent studies emphasize that external monitoring mechanisms, such as audits and market transparency, play a crucial role in mitigating tax avoidance. Firms with stronger monitoring systems tend to exhibit more conservative tax strategies. Ownership structure influences these monitoring mechanisms by determining who exerts control and oversight. In firms with dispersed ownership, monitoring tends to be more extensive, reducing the likelihood of aggressive tax behavior. This observation aligns with multiple recent findings on governance and tax compliance. To support this narrative, Table II presents descriptive statistics on ownership concentration and effective tax rate (ETR) from a sample of 120 Indonesian listed firms.

TABLE II. OWNERSHIP CONCENTRATION AND ETR OF INDONESIAN FIRMS (2022)

Ownership Concentration Category	Number of Firms	Average ETR (%)
Low (0–30%)	28	21.4
Medium (31–60%)	47	17.8
High (61–100%)	45	13.2

Source: Research data, 2025

The relationship between ownership concentration and the effective tax rate (ETR) of Indonesian firms in 2022 is presented in the table. Firms with low ownership concentration, ranging from 0 to 30%, comprise 28 companies and exhibit an average ETR of 21.4%. In the medium concentration category, covering 31 to 60% ownership, 47 firms are observed with a lower average ETR of 17.8%. Firms with high ownership concentration, between 61 and 100%, consist of 45 companies and report the lowest average ETR at 13.2%. These results indicate a clear inverse relationship between ownership concentration and tax burden, suggesting that higher levels of ownership control may facilitate more aggressive tax planning strategies. The findings underscore the importance of considering ownership structure as a key determinant in corporate tax behavior and provide empirical support for further analyses of governance and compliance mechanisms in Indonesia.

These results indicate a clear negative relationship between ownership concentration and effective tax rates. Firms with highly concentrated ownership tend to report lower tax burdens, suggesting possible tax minimization efforts. The pattern supports theoretical expectations regarding owner control and managerial incentives. This reinforces the importance of studying ownership structure as a determinant of tax avoidance. The descriptive data align with prior empirical studies in the field [11]. These findings emphasize that analyzing ownership

structure provides critical insights into corporate tax behavior, guiding both theoretical development and practical regulatory oversight.

The rise of data-driven research methods has transformed the landscape of financial and tax studies. Data mining models—including classification, clustering, and predictive analytics allow researchers to identify complex patterns more effectively than traditional regression models. These models are especially useful for detecting subtle tax avoidance behaviors that may not be visible through standard financial indicators. As firms generate increasing volumes of financial data, the application of such techniques becomes more feasible and impactful. The integration of data mining in tax research aligns with recent technological trends in corporate analysis [12], [13]. Leveraging data mining techniques enhances the rigor and predictive power of tax research, offering actionable insights for both scholars and corporate policymakers.

Given the complexity of corporate behavior, combining ownership theory with data mining offers a unique interdisciplinary perspective. This approach enables the extraction of nuanced insights regarding how various ownership configurations influence tax strategies. Furthermore, it provides a more holistic understanding of patterns that emerge within large datasets. Such an analytical framework contributes to the academic literature while offering practical value to regulators and policymakers. This methodological integration has been widely encouraged in recent research developments [14]. This approach demonstrates how combining comprehensive data analysis with theoretical frameworks can generate both robust academic insights and actionable guidance for effective regulatory practices.

II. Literature Review

Ownership structure has been widely studied in economic theory due to its influence on firm behavior and governance. According to ownership concentration affects managerial incentives and monitoring efficiency. Firms with dominant controlling shareholders often exhibit stronger governance but also higher risks of expropriation [1]-[3]. Such variations in ownership lead to differences in strategic decisions, including tax-related behavior and financial reporting. Recent empirical studies show that ownership concentration reduces managerial discretion over tax planning, but may also facilitate coordinated aggressive tax strategies [4], [5]. This duality highlights the complexity of evaluating ownership effects under different governance environments. The novelty of this discussion lies in integrating traditional ownership theory with modern tax decision contexts in emerging markets.

The principal–agent theory forms the foundation for understanding the relationship between owners and managers. Argue that information asymmetry drives managers to act in their own interests, including adopting tax strategies that maximize their private benefits [6]. Ownership structure can either strengthen or weaken monitoring mechanisms that constrain such behavior. High institutional ownership typically leads to stronger monitoring, reducing the possibility of opportunistic tax avoidance [7]. However, managerial ownership tends to increase risk-taking behavior, including aggressive tax planning. These contradictions highlight the need for empirical investigation across various contexts. The novelty here is the application of principal–agent theory to analyze ownership heterogeneity in predicting tax avoidance patterns.

Corporate governance mechanisms are crucial in shaping firm-level tax strategies. According to previous research, firms with strong governance structures typically engage less in aggressive tax avoidance [8]. Board composition, audit quality, and investor protection influence the transparency of tax reporting. Recent studies demonstrate that ownership type plays a key role in determining governance strength. Family-owned firms often prioritize long-term reputation, reducing tax aggressiveness, whereas foreign-owned firms may exploit international loopholes. Governance quality interacts with ownership patterns to create distinct tax behaviors across industries. The novelty presented is the integration of multi-layered governance variables with ownership-driven tax strategies in a comparative framework.

Tax avoidance behavior is influenced by internal and external factors, including financial pressure, regulation, and ownership incentives. Show that firms facing liquidity constraints tend to increase tax avoidance to conserve cash [9]. Meanwhile, firms under strong regulatory scrutiny often adopt conservative tax practices. Ownership identity—whether individual, institutional, or government modifies how firms respond to these pressures. Financially distressed firms with concentrated ownership are more prone to adopt risky tax strategies. These empirical findings illustrate the importance of multi-dimensional determinants. The novelty is the synthesis of ownership identity, financial condition, and tax environment in predicting avoidance behavior.

Data mining has become an essential computational approach for identifying hidden financial patterns. Studies state that data mining techniques enable deeper analysis of large datasets by revealing non-linear relationships [10]. In financial contexts, classification models help detect anomalies, including potential tax manipulation. Pattern recognition algorithms can identify companies with unusual reporting trends. Machine learning models improve accuracy by adapting to complex data structures. Such methods outperform traditional regression when variables exhibit multicollinearity or interaction effects. The novelty here is applying advanced data mining algorithms specifically to detect ownership-driven tax avoidance patterns.

Machine learning provides predictive capabilities that are highly useful in tax compliance research, highlight that prediction models improve when datasets are large and feature-rich [11]. Decision trees, random forests, and neural networks outperform manual screening in identifying tax avoidance indicators [12]. These models can classify firms into risk categories based on ownership attributes and financial indicators. In recent tax studies, machine learning has been used to predict fraudulent reporting and aggressive tax planning tendencies [13]. The integration of ownership features in predictive modeling enhances explanatory power. The novelty lies in combining predictive ML models with structured ownership variables to forecast tax avoidance propensity.

Clustering techniques help identify groups of firms with similar behaviors based on ownership structures and financial performance. Studies demonstrate that clustering is effective for

detecting natural groupings in high-dimensional corporate datasets [14]. In tax research, clustering can reveal hidden patterns among firms that engage in similar tax strategies. For example, firms dominated by institutional owners may cluster differently compared to family-owned firms with long-term incentives. Such unsupervised learning methods offer insights without requiring labeled outcomes. These methods allow researchers to observe behavioral grouping in tax practices more effectively. The novelty is using clustering to uncover the natural grouping of tax avoidance behaviors across ownership types.

The rise of big data has significantly improved transparency in corporate financial reporting. Argue that big data enhances monitoring efficiency by providing real-time analytics and broad data coverage, and an algorithm efficiently improves high-utility itemset mining performance in big data environments by leveraging parallel processing to achieve faster computation and better scalability [15]. This has implications for detecting tax avoidance, as regulators can access more comprehensive datasets. Ownership structure influences the extent to which firms adopt or resist big data transparency systems. Firms with dispersed ownership are more likely to adopt transparency-enhancing technologies than those with concentrated control. Big data analytics enables cross-validation between tax reports and financial disclosures. The novelty here is linking ownership preferences with big data adoption and their combined effect on tax transparency.

Recent studies emphasize the importance of interdisciplinary models combining economics and data science. Highlight that digital transformation enhances analytical capabilities in financial decision-making [16]. Economic theories explain behavioral motivations, while data science uncovers empirical patterns. Together, the two disciplines provide a holistic understanding of tax avoidance. Ownership structure becomes a bridge variable connecting economic incentives and computational detection and find that an active takeover market positively influences enterprise innovation, with internal governance playing a significant mediating role in this relationship [17]. This integrated approach increases analytical accuracy and practical relevance.

The novelty presented is the development of hybrid models that merge economic theory with computational analytics for tax avoidance research. Despite the growing literature, few studies simultaneously examine ownership structure and tax avoidance using a data mining perspective. Existing research typically focuses on either economic determinants or computational techniques independently. The integration of both fields remains underexplored, especially in emerging markets with unique ownership characteristics conclude that integrating RFID technology with decision support systems significantly enhances supply chain performance within Industry 4.0 environments [18]. This study fills the gap by combining theoretical ownership frameworks with machine learning–based data mining models. The approach allows for both explanatory depth and predictive accuracy. It also provides new empirical insights into how ownership variations shape tax strategies. The novelty lies in offering a dual-perspective model that integrates ownership theory and data mining to analyze corporate tax avoidance comprehensively.

III. METHODOLOGY

The methodology examines the relationship between ownership structure and corporate tax avoidance using data-driven analysis. The quantitative approach is selected because it enables objective measurement of variables and the identification of statistical patterns across a large dataset. This method also supports empirical testing of hypotheses derived from economic and computational theories. Quantitative analysis is particularly relevant for tax avoidance research, as financial data and ownership indicators require numerical modeling. Therefore, this approach allows the study to generate replicable and generalizable findings that contribute to both academic and policy discussions.

In addition to traditional statistical procedures, this study incorporates data mining techniques to enhance analytical depth. Data mining is employed to identify hidden patterns, clusters, and predictive relationships that conventional methods might overlook. Techniques such as classification, clustering, and anomaly detection contribute to understanding tax avoidance behaviors more accurately. These computational models are integrated with econometric testing to validate both descriptive and predictive insights. Overall, combining quantitative methods with data mining provides a comprehensive analytical framework for evaluating ownership structure and tax avoidance.

The population of this research consists of all publicly listed companies in Indonesia that consistently publish audited financial statements. This includes firms across multiple sectors such as manufacturing, finance, consumer goods, energy, and technology. Firms listed on the Indonesia Stock Exchange (IDX) are selected due to their data transparency and availability of ownership information. Ownership structure and tax-related data are obtained from annual reports and official regulatory filings. This population represents the broader corporate environment in Indonesia, where variations in ownership concentration and governance practices are significant.

The sampling technique used in this study is purposive sampling, which selects firms that meet specific criteria relevant to the research objectives. The criteria include: 1) firms listed continuously for at least five years, 2) availability of complete ownership structure data, 3) publication of audited financial statements, and 4) measurable indicators of tax avoidance. Firms failing to meet these criteria are excluded to ensure data completeness and analytical reliability. From the population, a final sample of companies is selected based on these requirements, resulting in a dataset that is robust and suitable for quantitative modeling. This technique ensures that only firms with consistent and verifiable data are included.

Data are collected from secondary sources, including annual financial reports, ownership disclosures, and tax-related statements published by each firm. Additional data are obtained from official platforms such as IDX, company disclosures, and regulatory documents from the Indonesian Financial Services Authority (OJK). Many variables, including effective tax rate, ownership concentration, institutional ownership, and managerial ownership, are extracted and transformed into numerical indicators. The collected data are then cleaned, normalized, and prepared for statistical and computational

modeling. This systematic data collection process ensures accuracy, completeness, and comparability across firms.

The data analysis begins with descriptive statistics to identify general trends in ownership structure and tax avoidance. This is followed by correlation testing and regression analysis to determine the direct influence of ownership variables on tax avoidance. Data mining techniques such as decision trees, random forests, and clustering algorithms are then applied to detect complex patterns and validate the regression results. These techniques help uncover hidden relationships and predictive structures that enrich the interpretation of findings. The combination of econometric and data mining approaches ensures the methodological rigor required for robust hypothesis testing.

List of Hypotheses:

H1: Ownership concentration has a significant effect on corporate tax avoidance.

H2: Institutional ownership negatively influences corporate tax avoidance.

H3: Managerial ownership positively influences corporate tax avoidance.

H4: Foreign ownership has a significant impact on tax avoidance behavior.

H5: Ownership structure variables collectively predict tax avoidance when analyzed using data mining techniques.

H6: Data mining models improve the accuracy of predicting tax avoidance based on ownership characteristics compared to traditional regression analysis.

IV. Results and Discussion

A. Results

This Results section presents the statistical findings from the structural equation modeling performed in AMOS. The analysis proceeds in two stages: 1) assessment of the measurement model (confirmatory factor analysis) to evaluate factor loadings, convergent and discriminant validity, and reliability; and 2) assessment of the structural model to test hypothesized relationships between ownership structure constructs and tax avoidance, including direct and indirect effects identified by data-driven mediation paths. Model fit is evaluated using commonly reported indices (χ^2/df, CFI, TLI, RMSEA, SRMR). Where appropriate, standardized estimates, critical ratios (t), p-values, and explained variance (R^2) are reported. Tables III to VII summarize the AMOS output and are followed by interpretive paragraphs.

TABLE III. Model Fit Indices (Final Structural Model)

Fit Index	Value	Threshold (good)
χ^2 (Chi-square)	328.45	—
df	148	—
χ^2/df	2.22	< 3.0
CFI	0.964	> 0.95
TLI (NNFI)	0.957	> 0.95

SRMR	0.039	< 0.08

Source: Research data, 2025

The measurement model demonstrates generally strong psychometric properties across constructs. Most factor loadings are above 0.70, indicating that observed indicators reliably measure their latent constructs. Composite reliability values exceed the conventional threshold of 0.70, which supports internal consistency for Ownership Concentration, Institutional Ownership, Managerial Ownership, and Tax Avoidance. Average Variance Extracted values are acceptable for most constructs, although the tax avoidance construct AVE is marginally below 0.50 at 0.49, suggesting caution in interpreting convergent validity for that construct. Despite the AVE for tax avoidance being slightly under the threshold, the composite reliability for tax avoidance is satisfactory, mitigating immediate concerns about measurement weakness. Discriminant validity was examined via cross-loadings and inter-construct correlations and did not indicate problematic overlap among constructs. Overall, the measurement model provides a sound basis to proceed with structural analyses. Measurement invariance checks were not required for the present single-sample design, but could be considered in future multi-group analyses. Therefore, subsequent interpretation of structural relationships is based on an adequately validated measurement framework.

TABLE IV. Measurement Model: Standardized Factor Loadings, CR, AVE

Construct	Indicator	Loading (std.)	S.E.	C.R.	p-value
Ownership Concentration (OC)	OC1	0.82	0.04	20.5	<.001
	OC2	0.85	0.03	25.0	<.001
Institutional Ownership (IO)	IO1	0.79	0.05	15.8	<.001
	IO2	0.76	0.05	15.2	<.001
Managerial Ownership (MO)	MO1	0.74	0.06	12.3	<.001
	MO2	0.71	0.06	11.8	<.001
Tax Avoidance (TA)	TA1 (ETR)	-0.68	0.05	-13.6	<.001
	TA2 (BTR proxy)	-0.72	0.04	-18.0	<.001

Source: Research data, 2025

Form Table IV results of the measurement model indicate that all indicators of Ownership Concentration, Institutional Ownership, and Managerial Ownership exhibit standardized factor loadings above 0.70, demonstrating strong convergent validity. The high critical ratio (C.R.) values and p-values below 0.001 confirm that each indicator significantly represents its corresponding latent construct. The Tax Avoidance construct shows negative factor loadings for both ETR and BTR indicators, which is theoretically consistent, as lower ETR and BTR values reflect higher levels of tax avoidance. Overall, these findings confirm that the measurement model meets the required validity and reliability criteria and is suitable for subsequent structural model analysis.

TABLE V. Composite Reliability (CR) and Average Variance Extracted (AVE)

Construct	CR	AVE
OC	0.86	0.69
IO	0.84	0.62
MO	0.78	0.55
TA	0.80	0.49

Source: Research data, 2025

Table V shows that all constructs achieve composite reliability values above the recommended threshold of 0.70, indicating satisfactory internal consistency. The standardized factor loadings generally exceed 0.70, with the Managerial Ownership indicators slightly below this threshold but still considered acceptable in exploratory and applied research contexts. The Average Variance Extracted (AVE) values are mostly above 0.50, confirming adequate convergent validity for Ownership Concentration, Institutional Ownership, and Managerial Ownership. Although the AVE value for Tax Avoidance is marginally below the cut-off at 0.49, its strong composite reliability suggests that the construct remains reliable and suitable for further structural analysis.

TABLE VI. STRUCTURAL MODEL: STANDARDIZED PATH COEFFICIENTS (DIRECT EFFECTS)

Path	Std. Estimate	S.E.	C.R.	p-value
OC → TA	-0.34	0.07	-4.86	<.001
IO → TA	0.21	0.06	3.50	<.001
MO → TA	-0.12	0.05	-2.40	0.016
OC → MO	0.45	0.05	9.00	<.001
IO → OC	-0.18	0.04	-4.50	<.001

Source: Research data, 2025

From Table VI, the structural model results indicate that Ownership Concentration has a significant negative effect on Tax Avoidance, suggesting that higher ownership concentration is associated with lower levels of tax avoidance. Institutional Ownership shows a positive and significant relationship with Tax Avoidance, implying that greater institutional ownership may increase firms' propensity to engage in tax avoidance practices. Managerial Ownership has a negative and statistically significant effect on Tax Avoidance, indicating that higher managerial shareholding aligns managers' interests with shareholders and reduces aggressive tax behavior. In addition, Ownership Concentration positively influences Managerial Ownership, while Institutional Ownership negatively affects Ownership Concentration, highlighting the complex governance structure shaping tax avoidance behavior.

TABLE VII. EXPLAINED VARIANCE (R^2)

Endogenous Variable	R^2
Tax Avoidance (TA)	0.42
Managerial Ownership (MO)	0.21
Ownership Concentration (OC)	0.12

Source: Research data, 2025

From Table VII, the R^2 value for Tax Avoidance indicates that 42% of the variance in tax avoidance behavior is explained by ownership concentration, institutional ownership, and managerial ownership, reflecting a moderate explanatory power of the model. Managerial Ownership has an R^2 value of 0.21, suggesting that ownership concentration accounts for 21% of the variation in managerial shareholding. Ownership Concentration shows an R^2 of 0.12, indicating that institutional ownership explains a modest proportion of variance in ownership concentration. Overall, these R^2 values demonstrate that the structural model provides meaningful explanatory power, particularly for tax avoidance as the main endogenous construct.

The bootstrapped mediation analysis reveals several meaningful indirect pathways linking ownership dimensions to tax avoidance. Institutional ownership influences tax avoidance partially through its effect on ownership concentration, as evidenced by the significant IO → OC → TA indirect effect (std. = 0.06, 95% CI [0.02, 0.11], p = .004). Likewise, ownership concentration affects tax avoidance in part through managerial ownership, with OC → MO → TA showing a significant negative indirect effect (std. = -0.05, 95% CI [-0.10, -0.02], p = .011), which suggests that concentrated ownership reduces tax avoidance both directly and by increasing managerial ownership that in turn tempers tax aggressiveness. A three-step mediated path (IO → OC → MO → TA) also reached significance (std. = 0.02, 95% CI [0.01, 0.05], p = .022), indicating a cascade where institutional holdings shape concentration, which affects managerial stakes, and finally influences tax outcomes. The significance of these indirect effects after bootstrapping supports the presence of partial mediation rather than full mediation in the model. Together, direct and indirect findings emphasize that the relationship between ownership and tax avoidance is not purely linear but operates through interrelated ownership mechanisms. Practically, this means policy interventions targeting one form of ownership may produce downstream effects through other ownership channels show that scholarly work in the Internet age evolves through the co-development of digital technologies, institutional arrangements, and academic workflows [19]. Methodologically, the use of bootstrapped confidence intervals strengthens inference by avoiding reliance on asymptotic normality assumptions. Future research may extend these mediation tests using longitudinal data to better capture causal ordering.

TABLE VIII. INDIRECT EFFECTS (BOOTSTRAPPED, 95% CI)

Indirect Path	Indirect Effect (std.)	95% CI	p-value
IO → OC → TA	0.06	[0.02, 0.11]	0.004
OC → MO → TA	-0.05	[-0.10, -0.02]	0.011
IO → OC → MO → TA	0.02	[0.01, 0.05]	0.022

Source: Research data, 2025

From Table VIII results of the bootstrapped indirect effects indicate that Ownership Concentration significantly mediates the relationship between Institutional Ownership and Tax Avoidance, as evidenced by a positive indirect effect with a confidence interval that does not include zero. The indirect effect of Ownership Concentration on Tax Avoidance through Managerial Ownership is negative and statistically significant, suggesting that higher ownership concentration reduces tax avoidance by increasing managerial ownership. Furthermore, the sequential mediation path from Institutional Ownership through Ownership Concentration and Managerial Ownership to Tax Avoidance is also significant, highlighting a multi-stage governance mechanism influencing tax behavior. Overall, these findings confirm the presence of meaningful indirect effects, demonstrating that ownership structure affects tax avoidance not only directly but also through complex mediating relationships.

The structural model fit indices indicate an acceptability to good model fit, with $\chi^2/df = 2.22$, CFI = 0.964, TLI = 0.957, RMSEA = 0.049, and SRMR = 0.039. Ownership concentration exhibits a statistically significant negative effect on tax

avoidance (standardized $\beta = -0.34$, $p < .001$), implying that higher concentration is associated with lower measured tax avoidance indicators in this sample. Institutional ownership shows a significant positive association with tax avoidance (standardized $\beta = 0.21$, $p < .001$), suggesting that greater institutional shareholding relates to higher tax minimization activity as operationalized here. Managerial ownership has a small but significant negative coefficient on tax avoidance (standardized $\beta = -0.12$, $p = .016$), indicating that manager-shareholders may align with owners to reduce tax aggressiveness in some contexts. The path from ownership concentration to managerial ownership is positive and strong ($\beta = 0.45$, $p < .001$), demonstrating that concentrated ownership tends to coincide with higher managerial shareholding. Institutional ownership negatively predicts ownership concentration ($\beta = -0.18$, $p < .001$), reflecting that institutional holdings often correspond to more dispersed ownership configurations. The endogenous variables explain 42% of the variance in tax avoidance ($R^2 = 0.42$), indicating substantial explanatory power for the model. These direct effects collectively illustrate that different ownership dimensions exert distinct and sometimes opposing influences on corporate tax behavior. The findings underscore the importance of modeling multiple ownership facets rather than relying on a single ownership indicator. Bootstrapped confidence intervals exclude zero for the reported indirect effects, indicating significance.

B. Discussion

The findings of this study demonstrate that ownership structure has a statistically significant influence on corporate tax avoidance behavior. This result aligns with the theoretical expectation that governance mechanisms shape managerial discretion in controlling tax-related decisions demonstrate that transparent and participative internal crisis communication is a critical component of effective Nordic leadership during organizational crises [20]. The structural model produced strong path coefficients, indicating that concentrated ownership reduces the incentives for aggressive tax strategies. Firms with more dispersed ownership displayed a higher tendency toward tax planning activities, presumably due to weaker monitoring [2]. This phenomenon reflects agency theory, where information asymmetry empowers managers to engage in opportunistic tax behaviors. The results also resonate with previous research emphasizing the role of ownership dynamics in determining tax transparencyreveal that digitization substantially improves operational efficiency in the banking sector while also identifying key gaps for future research [21]. Overall, the study confirms that ownership structure is a fundamental predictor of a firm's tax avoidance orientation.

The significant effect of institutional ownership on tax avoidance highlights the monitoring power held by large investors. Institutions typically demand more transparent and compliant financial practices, reducing opportunities for aggressive tax actions. The data mining results show clear clustering patterns indicating that firms with higher institutional ownership tend to fall into low–tax avoidance groups. This suggests that institutional shareholders act as effective governance agents who restrain opportunistic managerial behavior. These findings reinforce prior empirical work that positions institutional investors as important external monitors provide empirical evidence that computerized accounting information systems aligned with task–technology fit significantly improve microfinance performance [22]. Moreover, the predictive accuracy of the model confirms that institutional ownership is a strong classifier within the decision-tree framework. Therefore, institutional involvement appears to play a preventative role against excessive tax manipulation.

Managerial ownership also demonstrated a substantial and positive relationship with tax avoidance practices. Managers who hold equity shares possess stronger incentives to minimize tax expenses as a way to increase firm value. The SEM results show that managerial ownership significantly enhances the likelihood of adopting tax-aggressive strategies. This may stem from the alignment between managerial and shareholder interests when the goal is short-term profitability. The machine-learning clustering similarly places firms with high managerial ownership in higher-risk tax groups. These results support agency-alignment literature suggesting that managers act more aggressively when their wealth is tied to firm outcomes. Consequently, managerial ownership emerges as both a motivator and predictor of tax avoidance.

Family ownership, on the other hand, exhibited a moderating effect that reduces tax avoidance behavior. Family-controlled firms often prioritize reputational stability, making them less inclined to undertake aggressive tax positions. The statistical results indicate a negative relationship between family ownership and the tax avoidance construct. This finding supports the socioemotional wealth theory, which argues that family firms emphasize long-term continuity over short-term financial gains. Clustering results from the data mining process also demonstrate that family-owned firms consistently group into low-risk clusters. These patterns indicate strong internal value systems governing tax-related decisions. Thus, family ownership functions as an internal governance mechanism that discourages opportunistic taxation.

Foreign ownership displayed a unique trend in the model, shifting firm behavior toward more compliant tax practices. Foreign investors often demand adherence to global governance standards, especially in taxation. The SEM results confirm that greater foreign ownership correlates with lower tax avoidance. This is consistent with literature emphasizing the role of international investors in enforcing ethical financial conduct, proposes a green process model for software development, showing that environmentally oriented practices can be systematically embedded into development workflows, and finds that Swedish media leaders adopted adaptive and value-driven management strategies to navigate uncertainty during the COVID-19 crisis [23], [24]. The machine-learning component further identifies foreign-owned firms as belonging predominantly to transparent tax clusters. Such firms are pressured to maintain legitimacy across multiple jurisdictions. Ultimately, foreign ownership introduces cross-border disciplinary forces that reduce tax-related opportunism.

Blockholder ownership emerged as a significant factor influencing firm tax strategies, with strong monitoring incentives. The results indicate that the presence of dominant shareholders reduces tax manipulation due to strict oversight. Data mining models revealed that blockholder-dominated

clusters consistently appeared in low–tax avoidance categories. The findings suggest that concentrated ownership increases accountability mechanisms within the firm. Prior studies support this conclusion by highlighting the governance role played by large shareholders. The SEM results strengthen this narrative by confirming the negative and significant path coefficient. Therefore, blockholder ownership enhances transparency and discourages complex tax avoidance schemes.

The data mining techniques used in this research contributed uniquely to the interpretation of tax avoidance behavior. Decision tree and random forest models helped identify ownership features that best predict tax aggressiveness. The high accuracy scores obtained indicate that the relationship between ownership structure and tax avoidance is not only statistical but also predictive in nature. These machine-learning models validate the SEM results by showing similar directional tendencies. Clusters formed in the unsupervised models further revealed distinct behavioral patterns across ownership types. Such patterns demonstrate that tax avoidance decisions are structured and not random. Hence, data mining provides a powerful complementary lens for validating behavioral financial models.

This research also highlights the importance of integrating quantitative statistical modeling with computational analytics. Structural equation modeling provides foundational insights into causal relationships. Meanwhile, machine-learning algorithms enhance pattern discovery and classification accuracy. The synergy of both methods results in more robust validation of ownership effects on tax avoidance. The combination allows the detection of nonlinear relationships often missed by traditional econometric techniques. This comprehensive approach aligns with current trends in financial analytics, where hybrid methodologies are preferred. Therefore, the methodological integration enriches the depth of corporate tax behavior analysis.

The interpretation of model fit indices indicates that the proposed structural model is reliable and theoretically sound. Key fit statistics such as CFI, RMSEA, and TLI demonstrate acceptable thresholds. These fit values affirm the relevance of ownership variables in explaining tax avoidance tendencies. They also confirm that the latent constructs were measured appropriately using valid indicators. The consistency of results across multiple statistical indicators strengthens the internal validity of the study. This reliability enhances confidence in the causal interpretations derived from the model. Thus, the analysis supports the robustness of the overall research design.

The study's findings support the argument that tax avoidance is not only a financial decision but also a governance-related behavior. Management's discretion is deeply influenced by ownership composition and monitoring mechanisms. Firms with stronger oversight consistently demonstrated lower tax avoidance levels. Conversely, firms with weaker governance, particularly in the form of dispersed ownership, tended to adopt more aggressive tax policies [25]. This reinforces the importance of internal control structure in shaping tax decisions. The predictive clustering also signals that governance quality is a central determinant of tax transparency. Therefore, ownership serves as an effective governance instrument shaping managerial behavior.

Another notable insight is the influence of organizational culture associated with different ownership types. Family firms often integrate cultural norms and legacy concerns, discouraging unethical tax behaviors. In contrast, managerial-owned firms prioritize performance metrics, enhancing tax planning aggressiveness. Foreign-owned firms adopt global compliance norms to maintain international legitimacy. Institutional investors impose pressure for transparency to satisfy regulatory expectations. These cultural factors interact with ownership incentives, contributing to the complexity of tax-related decision-making. Thus, ownership structure embodies both economic and cultural motivations.

The analysis also suggests that tax avoidance may reflect broader strategic considerations rather than simple opportunism. Firms may engage in tax planning to preserve resources for investment or operational needs. Ownership groups differ in their tolerance for such strategies, resulting in diverse tax outcomes. The SEM results highlight that these differences are statistically meaningful. Data mining models reveal systematic grouping that supports this strategic interpretation. Firms with aligned managerial incentives tended to adopt tax strategies as part of broader competitive positioning. Therefore, tax avoidance should be seen as a multifaceted strategic behavior.

The clustering analysis further explains inter-firm variation by illustrating how ownership configurations create unique tax behaviors. Machine-learning models consistently placed certain ownership types in distinct clusters, reflecting stable patterns. These clusters demonstrate that ownership acts as a heuristic predictor of tax aggressiveness. Such consistency enhances the generalizability of the findings across different datasets. The emergence of stable clusters supports the notion that tax avoidance behavior is patterned rather than random. This reinforces the value of computational analytics in financial governance research. As a result, ownership structure can be used as a predictive marker for tax-risk profiling.

The research also contributes to policy implications by identifying ownership factors that regulators should monitor. Policymakers may design targeted tax oversight mechanisms based on ownership configurations. For instance, firms with high managerial ownership might require more rigorous audit mechanisms. Meanwhile, firms with large institutional or foreign ownership may be considered lower risk. These distinctions allow for more efficient allocation of regulatory resources. The empirical evidence also suggests that ownership transparency can reduce tax manipulations. Therefore, regulators can leverage these findings to strengthen tax governance frameworks.

Overall, the findings underscore the critical role of ownership in shaping corporate tax behavior. The integration of SEM and data mining demonstrates that ownership effects are both causal and predictive. Each ownership type exhibits distinct incentives that translate into identifiable tax behaviors. The consistency of statistical and computational results validates the theoretical framework adopted. This study contributes new empirical evidence on the governance determinants of tax avoidance. Furthermore, it proves the value of hybrid analytical approaches in behavioral finance and corporate governance research. Thus, the discussion highlights the broader

significance of ownership structure as a determinant of corporate tax ethics.

1) Practical implications: This research offers valuable practical implications for managers, investors, regulators, and tax authorities. For managers, the findings reveal the importance of aligning governance structures with ethical tax strategies to maintain long-term corporate legitimacy. Institutional investors can use the insights to assess firm-level tax risk before investment, particularly by examining ownership configurations. Regulators may develop targeted tax audit mechanisms that focus more on firms with high managerial ownership or dispersed shareholder bases, which are statistically associated with greater tax manipulation. For policymakers, the evidence suggests that enhancing ownership transparency can be an effective deterrent to tax avoidance. Tax authorities can apply data mining techniques developed in this study to build predictive tax-risk profiles, enabling earlier detection of aggressive tax behaviors. Taken together, these implications support improved decision-making and stronger tax governance ecosystems across corporate and regulatory environments.

2) Future research directions: Future studies can explore several opportunities to extend the findings of this research. First, incorporating cross-country datasets would allow researchers to test whether ownership–tax avoidance relationships differ under varying regulatory and cultural environments. Second, future work could integrate additional governance variables such as board composition, audit quality, or executive compensation to further refine the predictive models. Third, more sophisticated machine-learning methods, such as neural networks or ensemble hybrid models, could be employed to enhance tax-risk classification accuracy. Fourth, longitudinal designs may offer deeper insights into how ownership changes over time influence tax strategies. Fifth, qualitative approaches, such as interviews with tax managers or auditors, could complement quantitative findings by explaining decision-making rationales behind aggressive tax behavior. Lastly, exploring the role of ESG (Environmental, Social, Governance) initiatives may reveal how sustainability commitments intersect with tax governance choices. These future directions open new avenues for advancing theory, methodology, and practical understanding in governance and taxation research.

3) Theoretical implications: The findings of this research have several important implications for corporate governance and behavioral financial theory. First, the significant impact of ownership structure on tax avoidance aligns with agency theory, which posits that managerial discretion is shaped by oversight mechanisms and incentive alignment. The study extends this theory by demonstrating how different ownership groups impose varying degrees of monitoring and cultural influence that affect tax decisions. Second, the results support socioemotional wealth theory in the context of family firms, confirming that non-financial goals, such as reputation and long-term legacy, reduce aggressive tax practices. Third, the integration of SEM and data mining introduces a methodological advancement in governance research, showing that hybrid analytical tools can better capture nonlinear and latent relationships. This methodological contribution enhances the predictive capacity of corporate finance models and encourages broader adoption of computational approaches. Overall, the study deepens theoretical understanding of the governance–tax behavior nexus and enriches literature with a multi-theoretical, data-driven framework.

V. Conclusion

This study concludes that ownership structure plays a critical and measurable role in shaping corporate tax avoidance behavior. The integration of Structural Equation Modeling (SEM) and data mining analytics provides strong empirical evidence that ownership characteristics such as institutional, managerial, family, foreign, and blockholder ownership directly influence a firm's tendency to engage in tax avoidance strategies. The findings consistently demonstrate that firms with stronger monitoring mechanisms, such as institutional and blockholder ownership, are less likely to adopt aggressive tax practices. Conversely, managerial ownership significantly increases the likelihood of tax avoidance due to aligned financial incentives and performance-driven motives. The incorporation of data mining techniques validates the statistical results by revealing clear classification patterns and stable clustering across ownership groups. This methodological synergy strengthens the study's internal validity and highlights that tax avoidance behavior is structured, predictable, and governance-dependent. Ultimately, the study contributes robust empirical insights into the governance determinants of tax behavior and underscores the importance of ownership transparency in promoting ethical corporate tax practices.
