When no feature scaling is applied, as shown in Fig. 2, the performance of the model remains relatively similar to the Min-Max scaling scenario, but with slight variations in key metrics. The Perceptron model continues to exhibit the highest accuracy (83.60%), while logistic regression achieves the highest precision (91.05%). The PA model, once again, records the highest recall (81.57%), F1 score (81.27%), and Cohen's kappa (66.56%), reinforcing its strong capability to identify phishing instances. In particular, the ALMA model

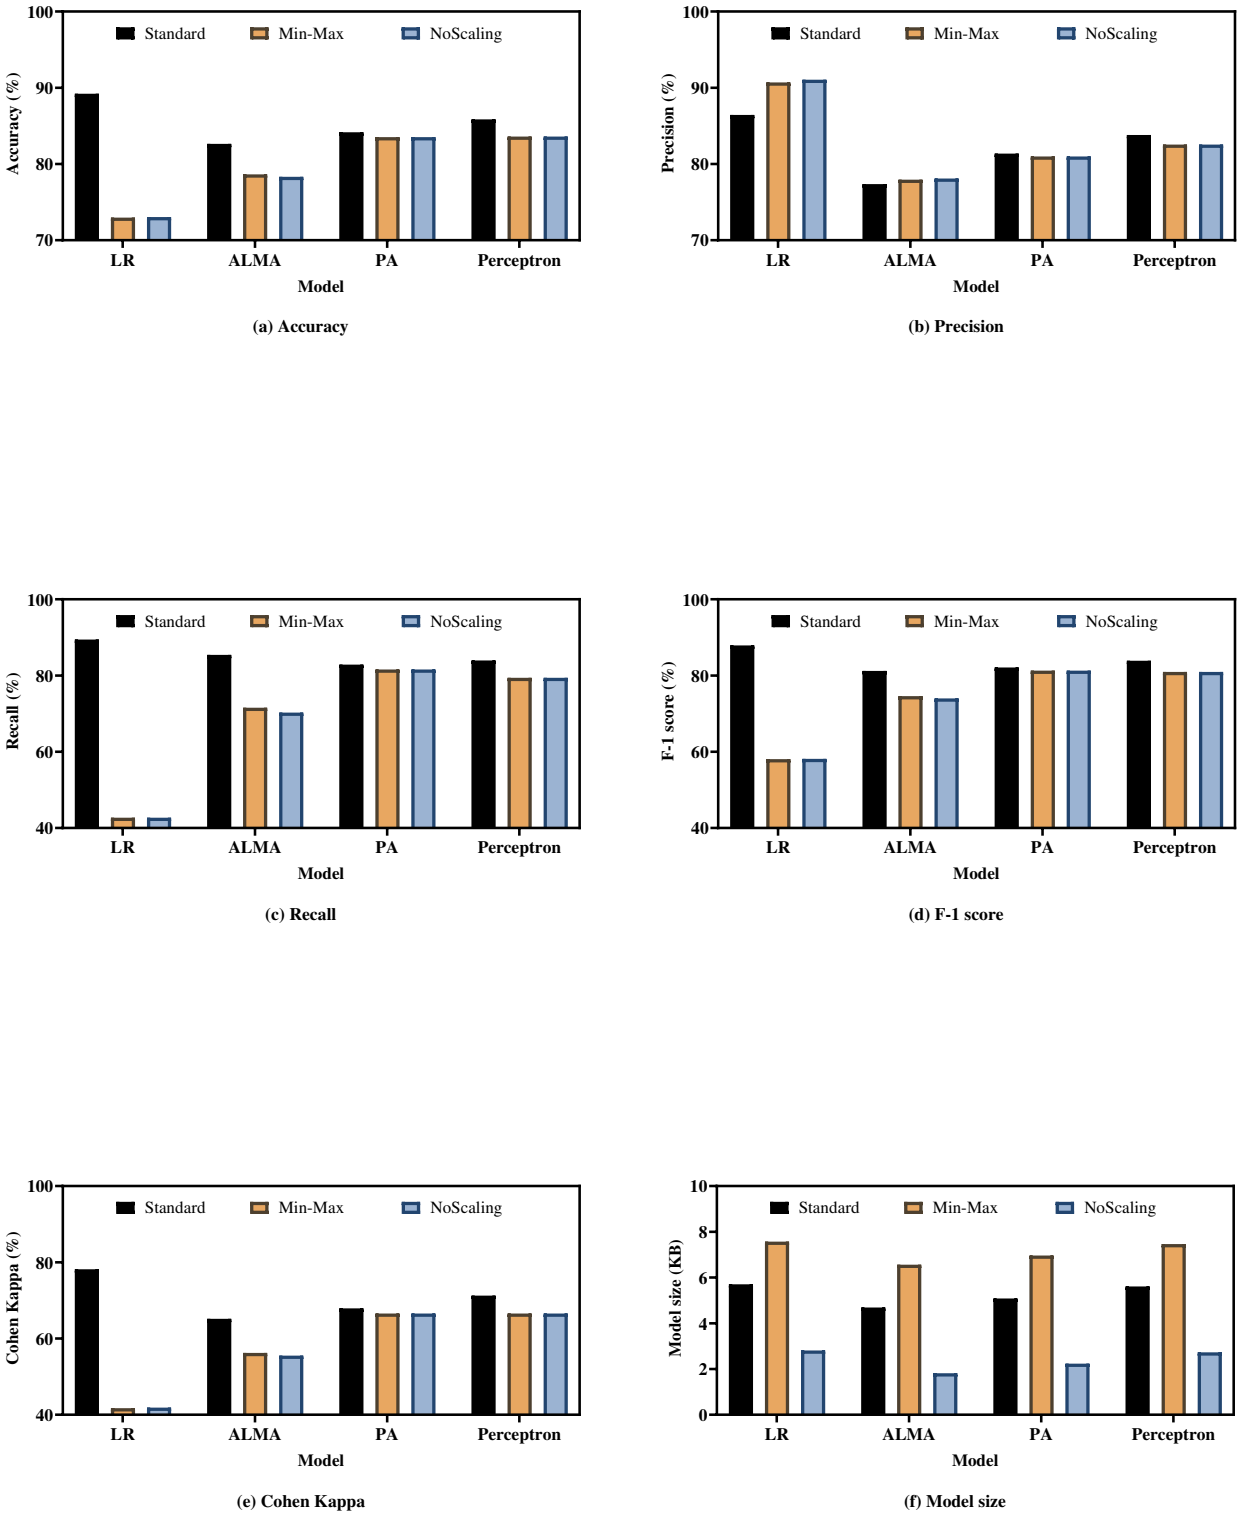

Fig. 2. Linear models' performance.

maintains its efficiency in terms of memory consumption, with a significantly reduced model size of just 1.81 KB, demonstrating its adaptability to unscaled feature spaces.

In general, these findings highlight the substantial impact of feature scaling on the performance of linear incremental learning models. Standard scaling generally enhances classification accuracy and stability, particularly benefiting logistic regression, while min-max scaling provides a more favorable

environment for models such as the Perceptron and PA. The absence of scaling appears to produce results comparable to min-max scaling, though with minor fluctuations in performance metrics. Additionally, ALMA consistently maintains the lowest memory usage in all settings, making it the most suitable choice for resource-constrained environments. These results emphasize the importance of selecting appropriate feature scaling techniques based on the specific trade-offs between accuracy and computational efficiency required for phishing detection tasks.

Fig. 3 illustrates the performance metrics obtained for the incremental machine learning models of Naive Bayes (NB) and K-Nearest Neighbors (KNN) under different feature scaling techniques. Interestingly, both NB and KNN models demonstrate a high degree of consistency in their performance across all feature scaling settings, indicating their relative robustness to variations in feature distributions.

As depicted, the KNN model achieves superior performance in terms of accuracy, precision, F1-score, and Cohen's kappa, attaining values of 88.87%, 86.04%, 87.51% and 77.48%, respectively. These results suggest that KNN benefits from its ability to classify new data points based on proximity in the feature space, which remains stable even after standard scaling is applied. In contrast, the NB model excels in recall, achieving a value of 89.40%, indicating its strength to correctly identify phishing instances. Additionally, the NB model maintains a smaller memory footprint, occupying 61.45 KB, which is notably more efficient compared to KNN.

This performance pattern remains largely consistent under min-max and no-scaling cases, where NB and KNN models continue to exhibit comparable trends, albeit with slight variations in individual performance metrics. The persistence of these trends across different scaling methods suggests that both NB and KNN models inherently adapt well to diverse feature distributions, making them relatively insensitive to the choice of feature scaling.

In general, these findings highlight the resilience of the NB and KNN models to feature scaling, maintaining consistent classification performance regardless of the applied normalization technique. This robustness makes them suitable candidates for phishing detection tasks, where feature distributions may vary dynamically. Furthermore, the trade-off between model size and performance suggests that, while KNN offers higher predictive accuracy, NB remains a computationally efficient alternative, making it particularly useful in scenarios with resource constraints.

Fig. 4 illustrates the performance of several tree-based models under different feature scaling techniques. The results indicate that tree-based models demonstrate relatively stable performance across various scaling settings, with minimal variations in classification accuracy and other key metrics.

As shown, under standard feature scaling, the Extremely Fast Decision Tree (EFDT) emerges as the best performing model, achieving the highest accuracy (88.47%), recall (88.85%), F1-score (87.10%) and Cohen's kappa (76.68%). These results suggest that EFDT effectively learns from streaming data while maintaining strong generalization capabilities. In contrast, the Hoeffding Tree (HT) algorithm attains the highest precision (85.51%) and maintains the lowest memory footprint, with a model size of 139.03 KB, demonstrating its computational efficiency.

Moving to Min-Max scaling, EFDT continues to achieve the highest accuracy (88.63%), F1-score (87.16%) and Cohen's kappa (76.96%), reinforcing its effectiveness across different scaling techniques. However, performance differences become more pronounced among other tree-based models. The Hoeffding Adaptive Tree (HAT) attains the highest precision (87.10%), while the Stochastic Gradient Tree (SGT) model achieves the highest recall (88.32%). Despite these variations, the HT algorithm retains its advantage in memory efficiency, maintaining a compact model size of 140.81 KB.

When no feature scaling is applied, EFDT continues to lead in accuracy (88.79%), F1-score (87.34%), and Cohen's kappa (77.29%), highlighting its robustness in handling raw feature distributions. Meanwhile, the HT model exhibits the highest precision (87.52%), further supporting its tendency to reduce false positives. Furthermore, the SGT model records the highest recall (88.32%), strengthening its ability to detect phishing instances effectively. The HT model maintains its efficiency in memory consumption, achieving the smallest model size of 131.73 KB.

In general, tree-based models exhibit minimal performance variations in different feature scaling settings, suggesting their inherent ability to adapt to varying feature distributions without requiring extensive normalization. The EFDT model consistently outperforms its counterparts in accuracy and generalization metrics, making it a strong candidate for phishing detection tasks. Meanwhile, the HT model remains the most memory-efficient, balancing classification performance with low computational overhead. These findings suggest that, while feature scaling can have a significant impact on certain machine learning models, tree-based algorithms remain relatively resilient, ensuring consistent performance across different preprocessing techniques.

Fig. 5 illustrates the performance of the Aggregated Mondrian Forest (AMF) and Adaptive Random Forest (ARF) models under different feature scaling techniques. The results indicate that both AMF and ARF exhibit consistently strong classification performance across all scaling settings, highlighting their robustness in handling varying feature distributions.

As shown, under standard feature scaling, the AMF model achieves the highest performance across multiple metrics, including accuracy (90.15%), precision (88.83%), F1-score (88.75%), Cohen's kappa (79.99%), and model size (3051.52 KB). These results suggest that AMF effectively leverages feature standardization to enhance classification performance while maintaining a relatively compact memory footprint. Meanwhile, the ARF model demonstrates a marginally higher recall value of 88.85%, indicating its strength in correctly identifying phishing instances while slightly compromising precision. A similar performance trend is observed when the Min-Max feature scaling is applied. Both AMF and ARF models continue to maintain high classification performance, with minimal deviations in accuracy, precision, and recall. This consistency reinforces their adaptability to different feature normalization techniques, making them well-suited for real-world phishing detection scenarios.

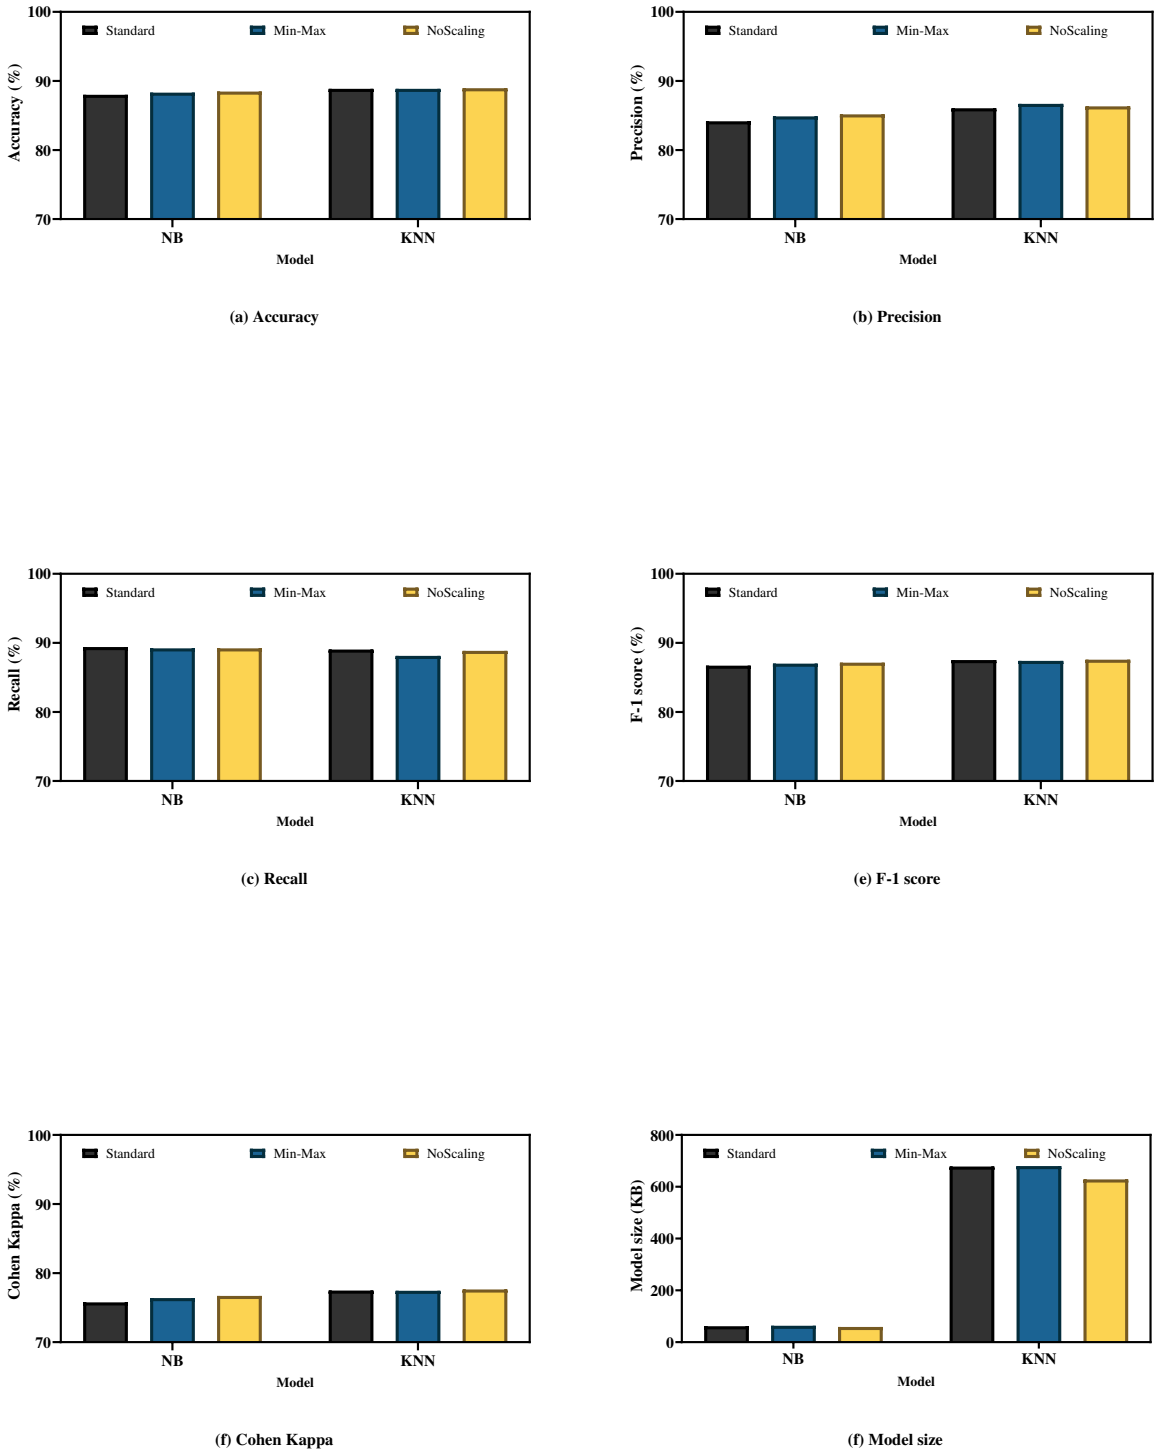

Fig. 3. Naive and Neighbour's models.

When no feature scaling is applied, both models experience a slight decrease in classification performance. However, in this setting, ARF marginally outperforms AMF, achieving an accuracy of 89.83%, precision of 88.04%, recall of 88.85%, F1-score of 88.44%, and Cohen's kappa of 79.37%. Despite this, the AMF model maintains an advantage in memory efficiency, requiring only 3000.32 KB compared to the larger footprint of the ARF. This trade-off suggests that while ARF can slightly improve predictive performance in unscaled data, AMF remains the more memory-efficient option.

In general, these findings indicate that AMF and ARF mod-

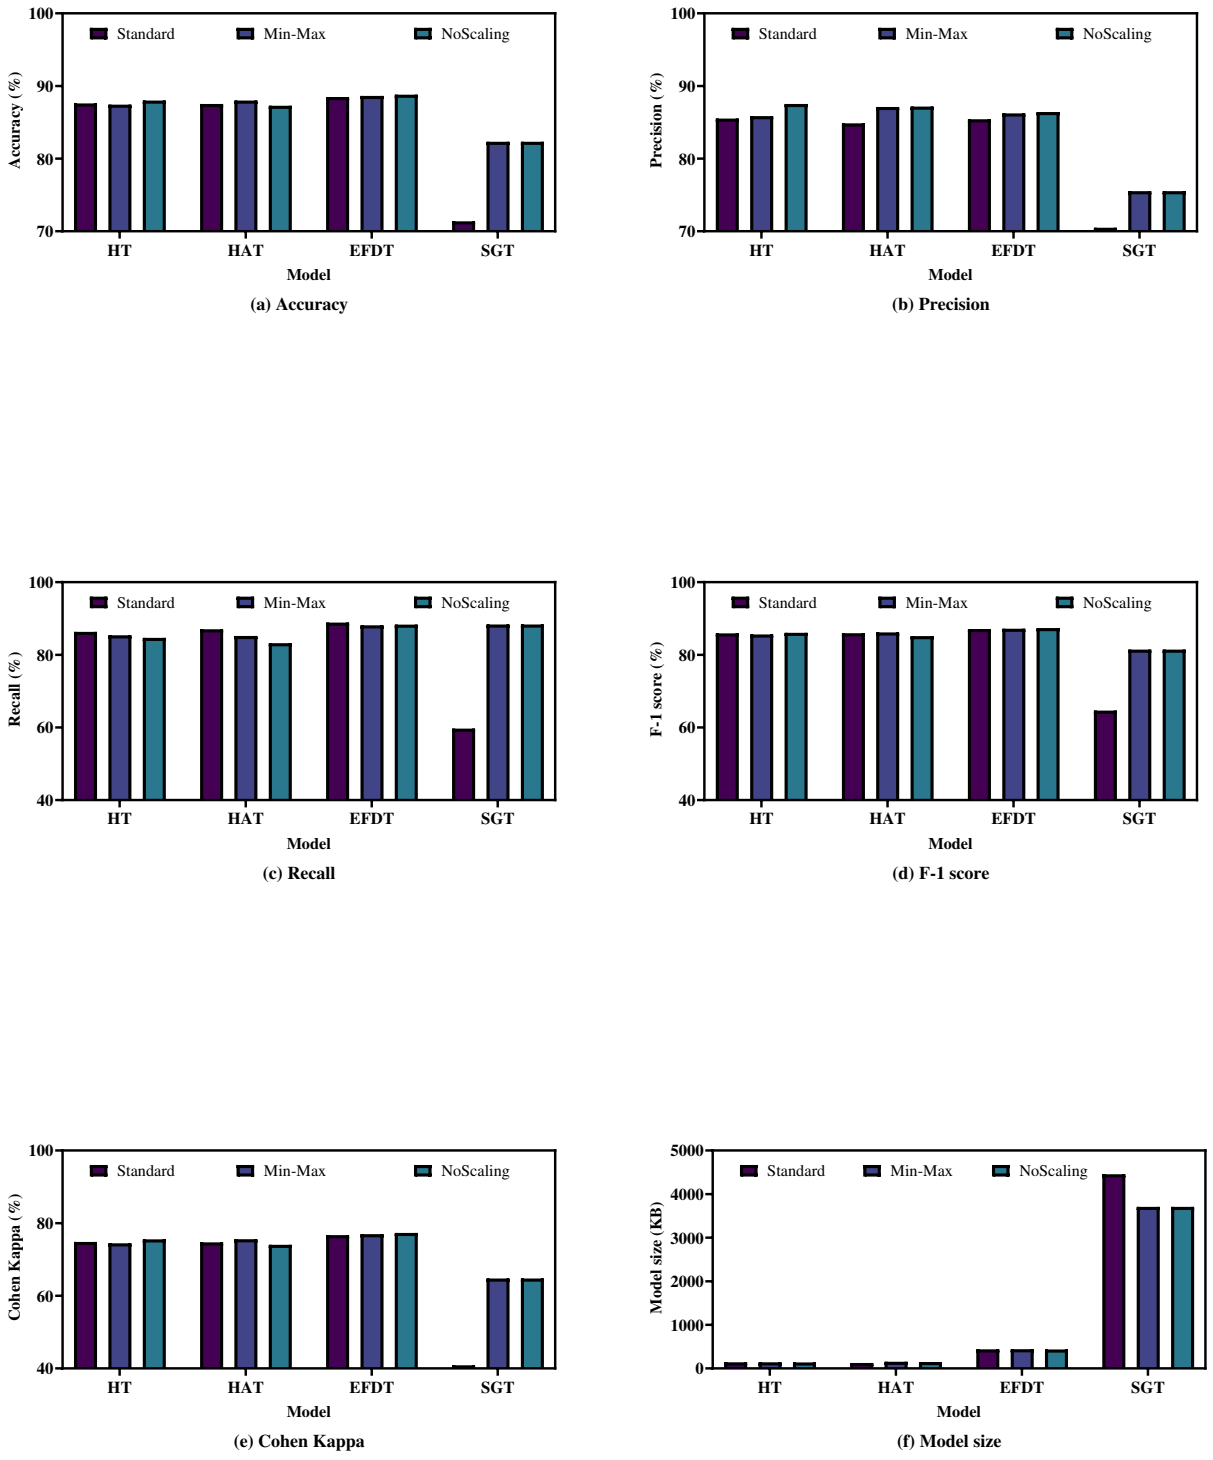

Fig. 4. Tree-based models' performance.

els exhibit resilience to feature scaling techniques, consistently achieving high classification accuracy regardless of the applied normalization approach. The AMF model excels in terms of memory efficiency while maintaining strong classification performance, while the ARF model demonstrates slightly superior recall and generalization capabilities. These insights suggest that both models are well suited for phishing detection tasks, particularly in environments with varying data preprocessing constraints.

Fig. 6 presents the performance evaluation of ensemble-based incremental machine learning models under different

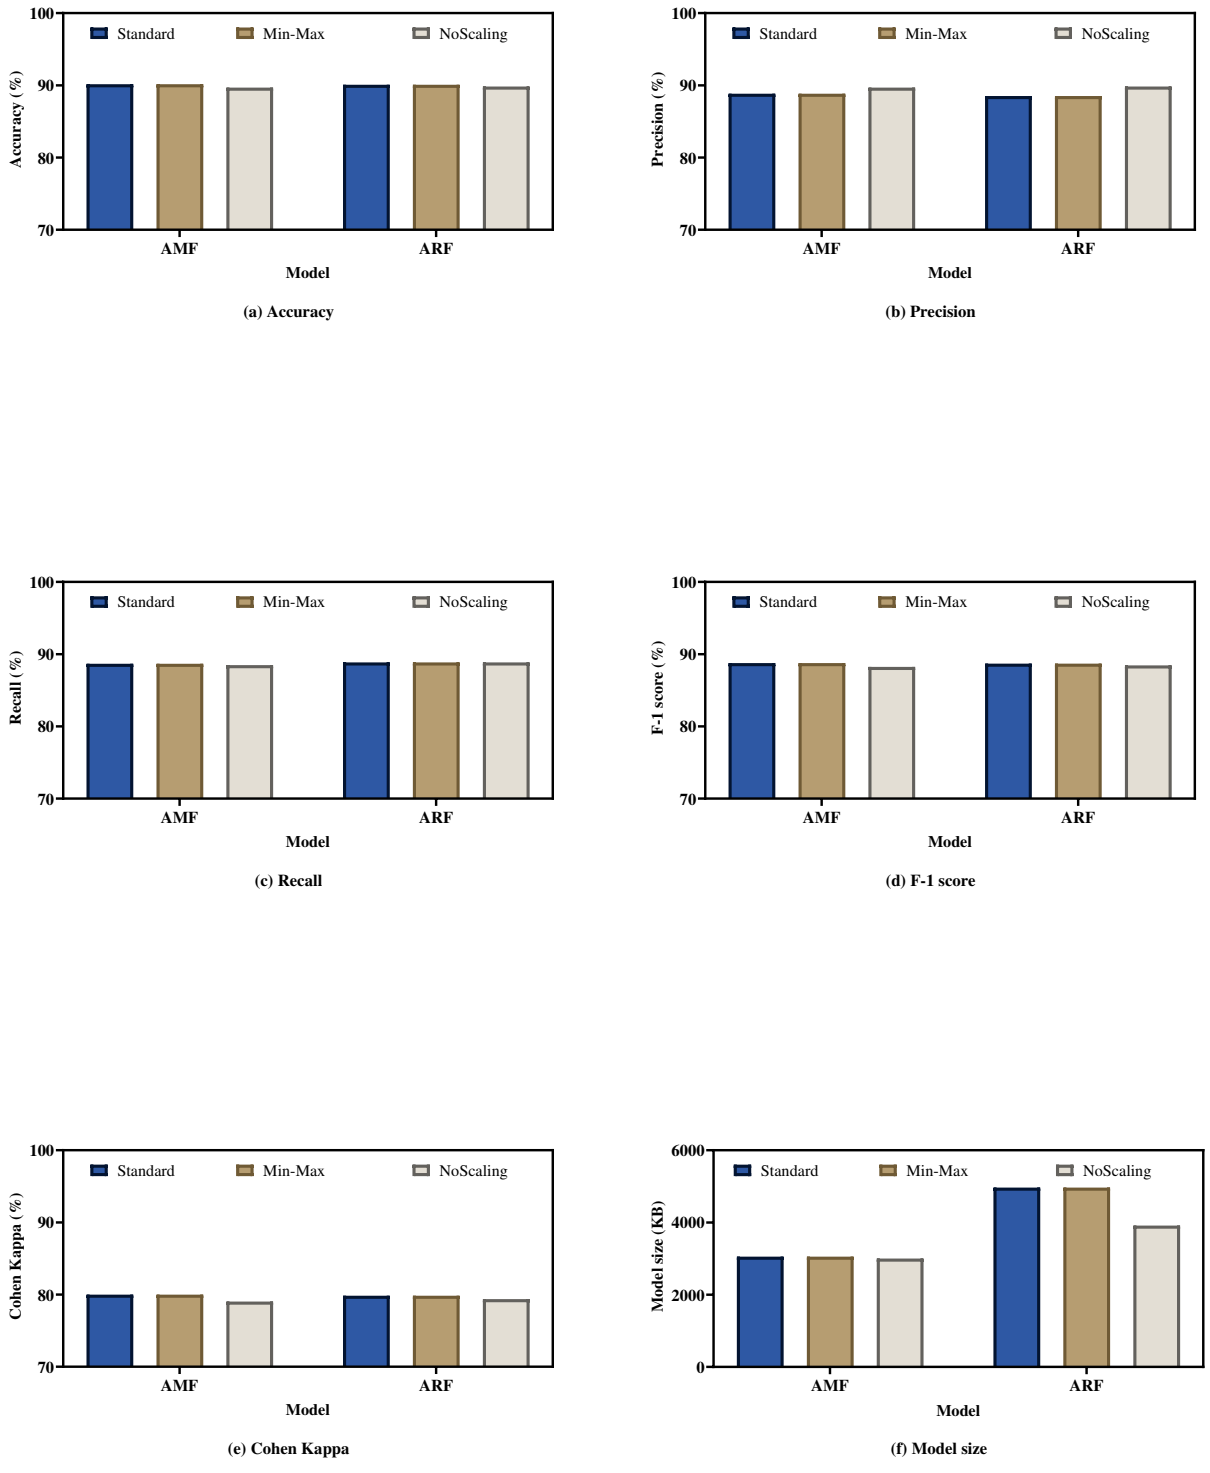

Fig. 5. Forest models' performance.

feature scaling techniques. Unlike other model categories, the ensemble methods exhibit noticeable variations in performance metrics depending on the applied feature scaling strategy.

As depicted, when standard feature scaling is applied, no single ensemble model dominates across all performance metrics. The Leveraging Bagging (LB) technique achieves the highest accuracy at 89.68%, demonstrating its robustness in classifying phishing URLs correctly. Meanwhile, the stacking ensemble outperforms other models in terms of precision, attaining a value of 88.38%, suggesting its effectiveness in

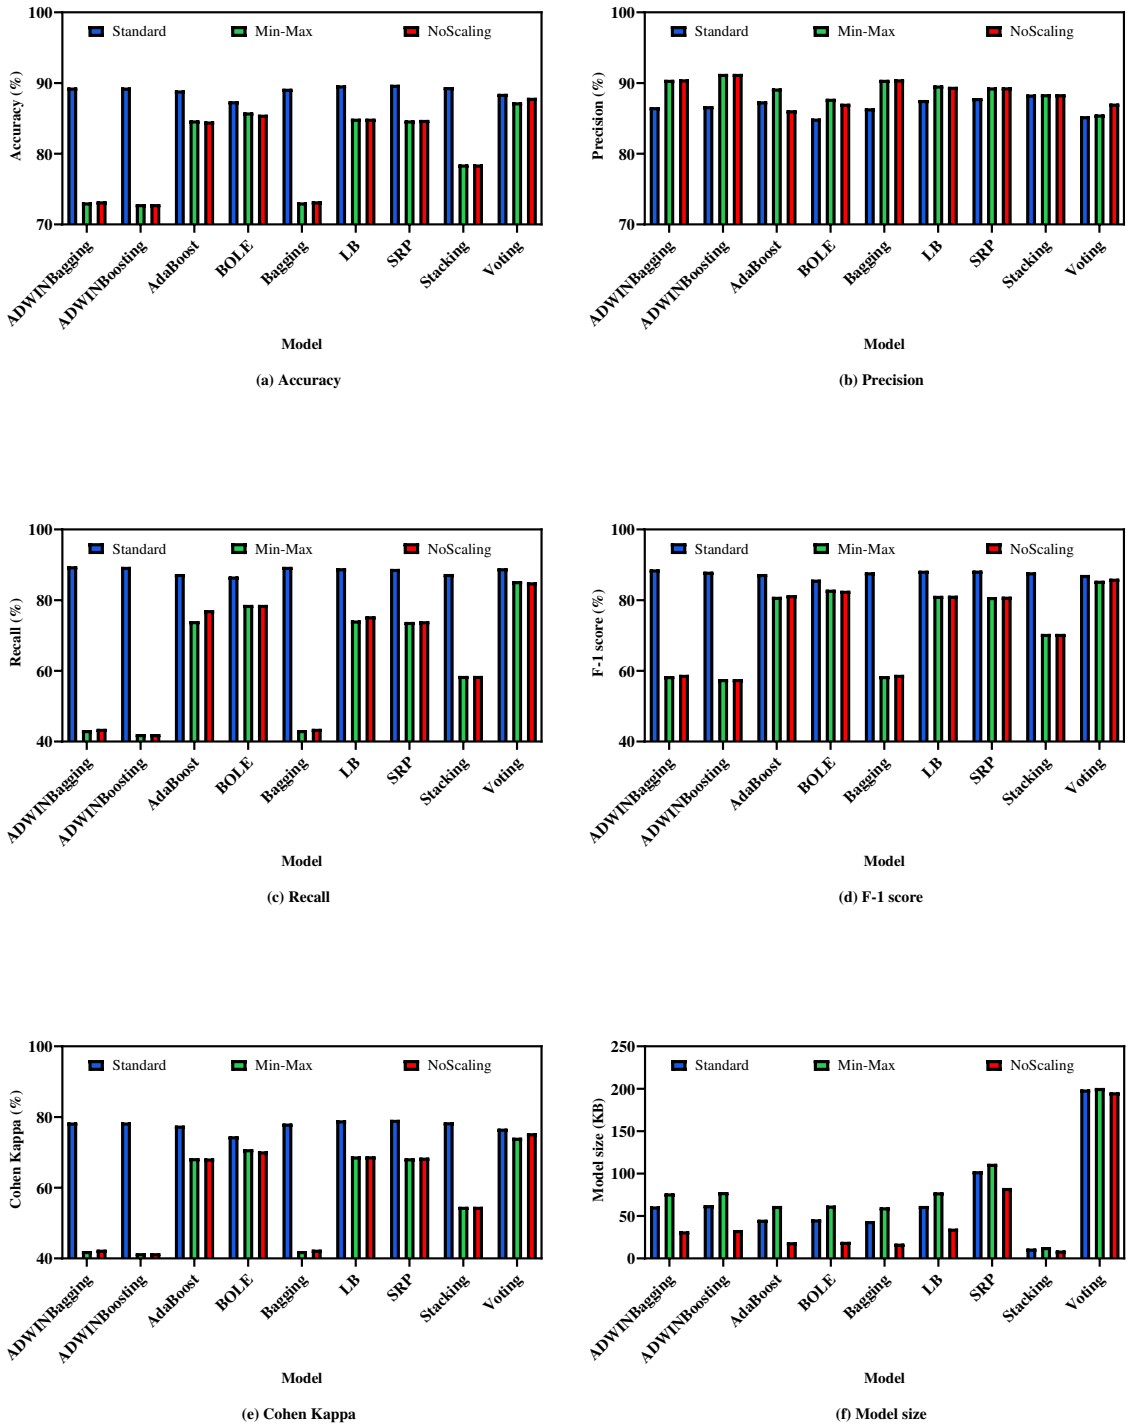

Fig. 6. Ensemble models' performance.

minimizing false positives. The ADWINBagging ensemble stands out in recall (89.60%) and F1-score (88.70%), indicating its strength in correctly identifying phishing instances. Additionally, the Streaming Random Patches (SRP) ensemble secures the highest Cohen's kappa value (79.21%), reflecting its strong overall classification reliability. Regarding model size, the Stacking ensemble maintains the smallest memory footprint, requiring only 11.55 KB, making it the most efficient in terms of storage.

On the other hand, when Min-Max feature scaling is applied, a decline in most performance metrics is observed, except for precision, which sees slight improvements. The Voting ensemble model achieves the highest accuracy (87.28%), recall

(85.40%), F1-score (85.48%), and Cohen's kappa (74.16%), indicating that it adapts well to min-max scaling despite the overall performance reduction. The ADWINBoosting ensemble exceeds others in precision, reaching 91.30%, suggesting that it maintains strong decision boundaries even when the feature values are normalized to a fixed range. The Stacking ensemble continues to be the most memory-efficient, requiring 13.43 KB of storage.

A similar trend is observed in case of no-scaling, which presents the performance of ensemble models when no feature scaling is applied. The Voting ensemble maintains its advantage in accuracy (87.92%), recall (85.04%), F1-score (86.06%), and Cohen's kappa (75.40%), reinforcing its stability across different feature preprocessing conditions. The ADWINBoosting model, once again, records the highest precision (91.30%), indicating its consistent ability to minimize false positives. The Stacking ensemble remains the most compact model, occupying only 9.35 KB of memory, further highlighting its efficiency in resource-constrained environments.

In general, these results underscore the sensitivity of ensemble-based models to feature scaling techniques. While certain models, such as Voting and ADWINBoosting, maintain strong classification performance across multiple scaling settings, others, such as Stacking, optimize for memory efficiency. The variation in performance metrics suggests that selecting an appropriate ensemble method should be guided by the specific trade-offs between accuracy, precision, and computational efficiency required for phishing detection tasks.

V. Conclusion

This study has provided a comprehensive examination of the evolving cybersecurity landscape, particularly in the context of phishing detection. By systematically analyzing incremental machine learning methods and online model selection strategies leveraging multi-armed bandits, valuable insights have been gained that have broad implications for enhancing cybersecurity defenses.

The findings underscore the intricate performance variations exhibited by different machine learning models under various scaling conditions of features. From linear models to tree-based and ensemble methods, each algorithm demonstrated distinct sensitivities to feature scaling adjustments, emphasizing the necessity of tailoring detection methodologies to specific operational contexts. In particular, while some models exhibited resilience to scaling changes in the feature, others displayed significant performance fluctuations, highlighting the critical role of pre-processing techniques in optimizing detection accuracy.

In general, this study contributes to the broader discourse on cybersecurity by offering practical insights into optimizing incremental machine learning approaches and evaluating model selection driven by reinforcement learning for phishing detection. By elucidating the nuanced performance characteristics of various models and selection strategies, this work lays the foundation for the development of more resilient, adaptive, and intelligent cybersecurity frameworks. Ultimately, these advances will strengthen real-time defenses against evolving cyber threats, reinforcing the robustness of modern cybersecurity systems.

***Abstract*—Intelligent fruit grading systems require automated sensing solutions capable of rapid and reliable non-destructive internal quality assessment. While near-infrared spectroscopy has been widely used for soluble solids content (SSC) prediction, most existing studies rely on manually acquired spectra, limiting scalability in smart agricultural environments. Although online Vis–NIR systems based on transmission configurations have been reported, automated interactance-based systems designed for deployment-oriented grading remain limited. This study presents the design and validation of an automated interactance near-infrared spectral acquisition system for mandarin SSC evaluation. The system integrates controlled clamping, rotational positioning, and automated probe actuation to ensure stable optical geometry and repeatable probe–fruit contact during measurement. Spectral consistency was assessed by comparing consecutive scans obtained using manual and automated acquisition modes. The automated system reduced spectral dispersion among consecutive acquisitions within a measurement session by approximately 65% relative to manual measurement, indicating improved acquisition stability. Chemometric models based on partial least squares regression, support vector regression, and extremely randomized trees were developed under multiple preprocessing strategies. Prediction performance under automated acquisition remained within the same range as manual measurement, with several preprocessing–model combinations (particularly PLS and SVR with smoothing-based preprocessing), showing slightly higher R_{p} values and lower $\mathrm{RMSE}_{\mathrm{p}}$ values under automated acquisition. The findings demonstrate the feasibility of the proposed automated system for stable interactance spectral acquisition suitable for SSC prediction, supporting its potential future integration into automated fruit quality assessment systems.**

I. Introduction

Fruit quality evaluation plays a critical role in postharvest handling, grading, and commercialization of horticultural products. With the rapid development of smart agricultural technologies, there is increasing demand for automated sensing systems capable of delivering rapid, nondestructive, and reliable internal quality assessment under practical operational conditions. Among quality attributes, sweetness, commonly quantified by soluble solids content (SSC), is one of the most important indicators for mandarins. Conventional SSC measurement using refractometers requires juice extraction, making it destructive, time-consuming, and unsuitable for integration into automated grading systems [1]. Consequently, nondestructive optical sensing techniques have attracted increasing attention [2], particularly near-infrared (NIR) spectroscopy.

In NIR spectroscopy, incident radiation interacts with organic constituents within the fruit, inducing overtone and combination vibrations of C–H, N–H, and O–H bonds. The resulting spectral signatures contain information related to key quality attributes and can be effectively exploited using chemometric and machine-learning models for fruit quality prediction [3]. Depending on the optical configuration, spectral data can be acquired in reflectance, transmittance, or interactance modes. While reflectance measurements are influenced primarily by surface properties, transmittance measurements require high-intensity light sources to penetrate the entire sample. Interactance mode represents a practical compromise, capturing diffusely transmitted light that has penetrated into the fruit tissue, thereby enhancing sensitivity to internal quality attributes [4], [5].

Recent studies have developed online Vis–NIR systems for fruit quality assessment, mainly using transmission or reflectance configurations integrated with conveyor-based transport mechanisms [6], [7], [8], [9], [10]. For example, Wang et al. [10] reported an online diffuse transmission system for SSC detection in pomelo. Although such transmission systems enable continuous measurement, they usually require high-intensity light sources and are sensitive to fruit size, peel thickness, and internal structure. In contrast, interactance mode measures light that has penetrated into the fruit under controlled probe–fruit contact conditions, which can improve sensitivity to internal attributes while maintaining moderate optical penetration depth. However, automated interactance acquisition systems specifically designed to ensure controlled mechanical positioning and stable optical geometry for deployment-oriented grading applications remain relatively

*Corresponding author

limited.

For citrus fruits, peel composition and thickness significantly influence optical measurements. Although citrus peels may contain small amounts of free sugars, their contribution is relatively limited compared with the juice sac content [11], [12], suggesting that surface-dominated measurements may inadequately reflect internal sweetness. Interactance spectroscopy is therefore particularly suitable for mandarin SSC evaluation, as the porous and moderately thin peel permits partial penetration of NIR radiation into juice-containing tissues.

Despite extensive research on NIR-based fruit quality prediction, many reported systems remain laboratory-oriented and rely on manually operated spectral acquisition procedures. However, manual probe positioning can introduce variability associated with contact pressure, alignment differences, and operator handling, thereby limiting repeatability and scalability in automated grading environments. For practical smart agricultural deployment, sensing systems must ensure consistent optical conditions during measurement.

Preliminary feasibility experiments demonstrated that automated interactance spectral acquisition reduced the average measurement time per fruit from approximately 40 s to 17.7 s, corresponding to a 55.75% reduction and an estimated throughput of approximately 203 fruits per hour, while also improving measurement stability. At the same time, SSC prediction performance remained comparable to that of manual measurement, even under limited dataset size, preprocessing strategies, and regression models. These findings indicate that automation does not inherently degrade chemometric modeling performance and provide a foundation for further system-level development. However, these preliminary results remain limited to feasibility-level validation and do not yet fully address deployment-level requirements, including robustness, scalability, and operational reliability, for practical quality assessment systems. In addition, the study remains limited in terms of modeling configurations.

To address this gap, an automated interactance NIR spectral acquisition system is proposed. The system is an integrated sensing framework in which a dedicated acquisition module functions as the core measurement unit, coupled with data processing and modeling components for SSC prediction, thereby enabling integration into intelligent mandarin quality assessment systems. Within this framework, the acquisition module integrates controlled clamping, rotational positioning, and automated probe actuation to enable standardized, repeatable, and geometry-consistent spectral acquisition.

The proposed system emphasizes automated fruit positioning and controlled optical geometry to ensure repeatable spectral acquisition under operational conditions, thereby supporting reliable deployment in practical grading environments. Although the system was evaluated using mandarins in this study, the sensing architecture and acquisition strategy can be adapted to fruits with similar peel thickness and internal tissue structure, offering a scalable foundation for spectroscopy-based automated grading systems.

To evaluate whether automated acquisition preserves chemometric modeling performance, regression models including partial least squares regression, support vector regression, and extremely randomized trees were developed under multiple preprocessing strategies using a consistent cross-validation framework. Comparative analysis between manual and automated modes was conducted to determine whether observed differences arise from sensing configuration rather than modeling characteristics.

II. Methodology

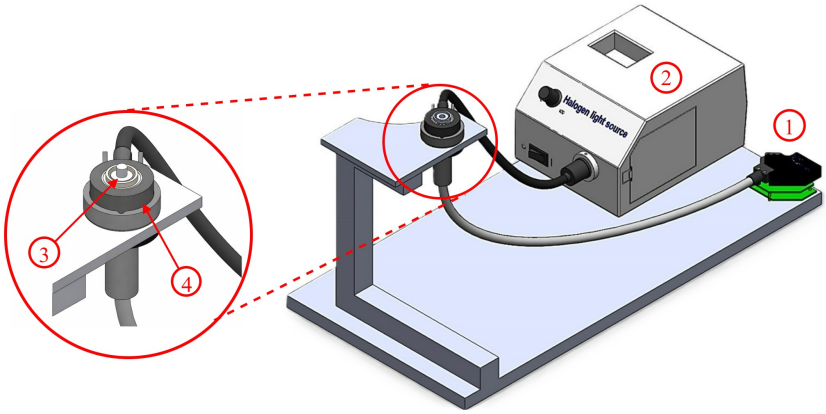
A. Dataset Preparation

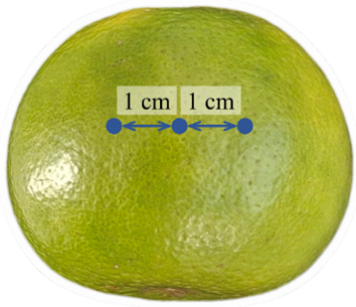
Fig. 1 illustrates the manual interactance spectral acquisition system. A halogen light source (MI-152, Dolan-Jenner) with a lamp power of 150 W was employed with sufficient intensity to penetrate the mandarin fruit, thereby satisfying the requirements for interactance spectral acquisition. Light from the source was delivered to the fruit through an MA4 ring-light optical fiber supplied by the manufacturer. The fiber output formed a circular illumination pattern that ensured uniform illumination at the measurement location. A liquid light guide (LLG5-4Z, Thorlabs) was used to transmit the interactance signal to the spectrometer (DLP NIRscan Nano EVM, Texas Instruments) which is capable of acquiring spectra in the wavelength range of 900–1700 nm. However, preliminary inspection indicated that signal intensities beyond approximately 1365 nm were extremely low ($< 3\%$ for automated acquisition and $\approx 0.6\%$ for manual acquisition), suggesting a noise-dominated region. Therefore, only the spectral range of 900–1365 nm was retained for subsequent analysis.

To enlarge the dataset, interactance spectra were collected from four measurement regions uniformly distributed along the equator of each mandarin. For each region, three adjacent measurement points were acquired and averaged to produce one representative spectrum used for modeling. A total of 460 mandarin fruits were used in this study. Because one representative spectrum was obtained from each of four measurement regions per fruit, the full dataset comprised 1840 averaged spectra for each acquisition mode (manual and automated). The spectral acquisition procedure for each region is illustrated in Fig. 2. Three measurement points were defined along the equatorial line of the fruit (Fig. 2a). A central point was first selected on the equator, followed by two additional points positioned 1 cm to the left and right of the central location. Spectra collected at the three measurement points were averaged to obtain a representative spectrum for the measurement region. This averaging strategy was adopted to reduce measurement noise and to mitigate the influence of spatial heterogeneity in SSC distribution.

B. Manual Acquisition of Interactance Spectra

At each measurement point, the mandarin was maintained in direct contact with the probe head (Fig. 2b) to block ambient light and ensure that only interactance light emerging from within the fruit was captured. This manual interactance spectral acquisition procedure is relatively time-consuming and is therefore mainly suitable for feasibility studies and laboratory-scale investigations. To overcome these limitations and enable high-throughput, non-destructive mandarin quality assessment, an automated interactance spectral acquisition module was developed, as described in the following section.





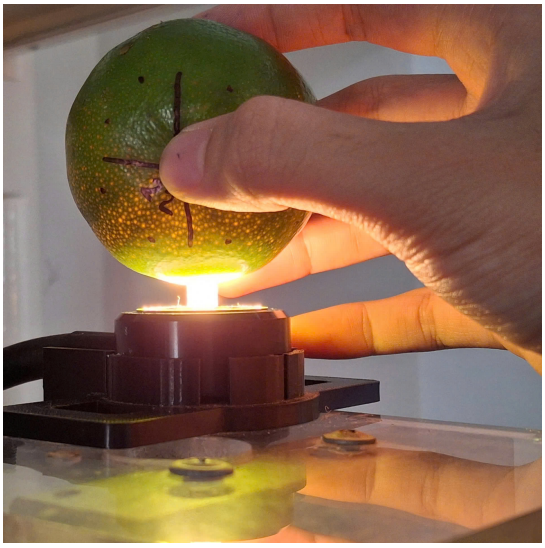


Fig. 1. Setup for collecting interactance spectra manually, including: (1) DLP NIRScan Nano EVM sensor, (2) MI-152 halogen light source, (3) the probe head, and (4) ring light output.

C. Automated Interactance Spectral Acquisition

1) Overview of the system: The automated interactance spectral acquisition system provides controlled mechanical positioning and stable optical conditions for repeatable spectral measurements of mandarins. The system integrates fruit positioning, probe actuation, and optical isolation within a compact structure to enable automated multi-location spectral acquisition.

The overall mechanical configuration is shown in Fig. 3. The system is housed in a rigid frame forming a dark chamber that minimizes ambient light interference during measurement. Inside the chamber, a clamping and rotation mechanism positions the fruit, while an actuated spectral probe performs interactance measurements at predefined locations.

The clamping mechanism secures the mandarin between two curved contact heads to maintain stable positioning during measurement. Fruit presence and clamp position are monitored by sensors and limit switches to ensure consistent contact without excessive mechanical loading. The clamping frame is mounted on a rotary stage driven by a stepper motor, enabling controlled angular positioning for multi-location spectral acquisition.

The spectral probe–illumination unit is mounted on a horizontally actuated linear mechanism. During operation, the probe is automatically moved toward the fruit surface until a limit switch indicates contact, ensuring a repeatable probe–fruit interface. The probe integrates a ring-shaped illumination source surrounding the optical fiber used for spectral acquisition, enabling interactance measurements while reducing specular reflection.

To maintain measurement stability, the probe position, fruit orientation, and measurement sequence are automatically controlled by the system controller. This configuration enables repeatable spectral acquisition at multiple positions on the fruit surface while minimizing operator intervention.

2) Workflow of the system: Fig. 4 summarizes the operating workflow of the automated interactance spectral acquisition system. After fruit detection and clamping, the probe–illumination unit is advanced to acquire an interactance spectrum at a predefined measurement point, defined by a controlled angular position of the fruit. The fruit is then rotated sequentially to subsequent measurement points, and spectra are acquired following the same procedure. In this

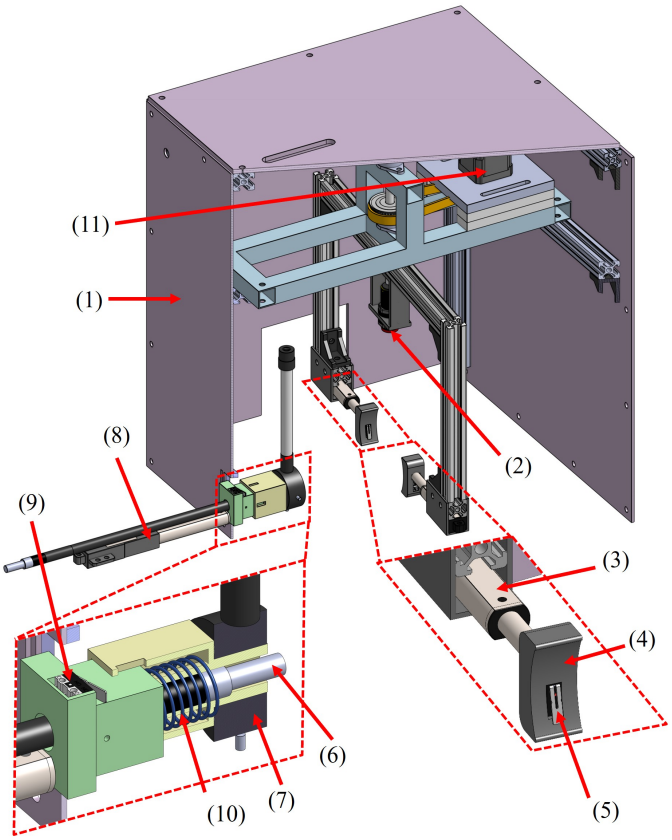

Fig. 3. Automated interactance spectral acquisition system and detailed views of its key mechanical components: (1) Dark chamber frame; (2) Proximity sensor for mandarin detection; (3) Clamp actuator; (4) Curved fruit contact head; (5) Integrated limit switch for contact detection; the acquisition module consisting of (6) Spectral probe head, (7) Ring-shaped illumination source, (8) Spectral probe–illumination unit actuator, (9) Limit switch for probe–fruit contact detection, (10) Compression spring for compliant probe contact; and (11) Stepper motor for rotating the clamp.

study, interactance spectra are collected at three circumferential measurement points per fruit to improve the spatial representativeness of the spectral measurement. Upon completion of the acquisition sequence, the probe retracts, the clamps release the fruit, and the probe returns to its initial state, ready for the next measurement cycle.

The automated interactance spectral acquisition system does not require manual predefinition of measurement positions. Based on a preliminary survey of the experimental samples, the average diameter of the sweet mandarins used for spectral acquisition was approximately 6.7 cm. Let $l = 1$ cm denote the arc length between two adjacent measurement points, $R \approx 3.35$ cm the average mandarin radius, and α (°) the required rotation angle of the fruit center to achieve an arc length of l. The rotation angle between two adjacent measurement points is calculated as:

$$\alpha = \frac{180\,l}{R\pi} = \frac{180 \times 1}{3.35\pi} \approx 17.1^\circ \tag{1}$$

The clamping frame is rotated via a belt transmission with a gear ratio $i = 1/2$ and driven by a stepper motor with a resolution of $N = 800$ steps per revolution. To rotate the

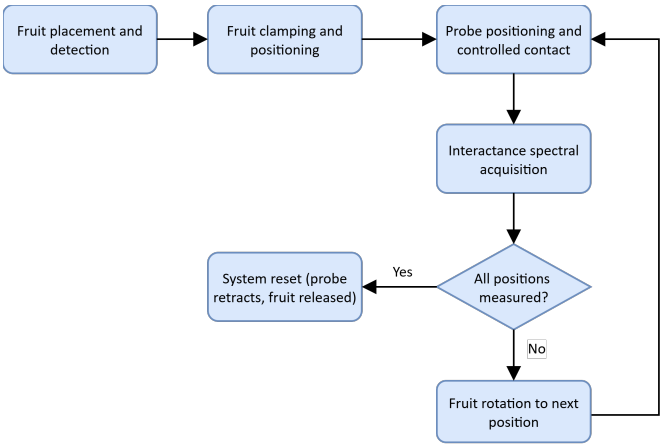

Fig. 4. Workflow of the automated interactance spectral acquisition system.

mandarin by an angle α, the required number of motor steps n is given by:

$$n = \frac{N\,\alpha}{360\,i} = \frac{800 \times 17.1}{360 \times 2} \approx 19 \text{ steps} \tag{2}$$

D. Performance Evaluation

1) Preliminary assessment of spectral consistency: To verify that the automated interactance spectral acquisition system provides spectra comparable in acquisition stability to those obtained using the manual setup, a preliminary assessment was conducted. This analysis focuses on evaluating the spectral consistency of consecutive acquisitions performed within a single measurement session, providing an initial indication of acquisition stability prior to regression model development. Improved spectral consistency is expected to enhance the reliability of the acquired data and is therefore likely to be reflected in the performance of subsequent chemometric models.

For each acquisition mode (manual and automated), four interactance spectra were acquired from consecutive acquisitions at the same nominal measurement region on the fruit surface under identical operating conditions within a single measurement session. Between consecutive acquisitions, the probe was repositioned according to the standard operating procedure of each mode. Consequently, measurements were performed within the same region but not at an identical physical contact point, thereby reflecting practical measurement variability associated with probe handling and positioning.

To quantify the consistency among repeated spectral measurements, the root mean square deviation (RMSD) was calculated as:

$$\text{RMSD} = \sqrt{\frac{1}{n}\sum_{i=1}^{n} d_i^2} \tag{3}$$

where, n denotes the number of wavelengths in the spectrum and d_i is the standard deviation of the four repeated measurements at wavelength i, defined as:

$$d_i = \sqrt{\frac{1}{3}\sum_{j=1}^{4}(y_{ij} - \bar{y}_i)^2} \quad (4)$$

where, y_{ij} represents the interactance amplitude of the j-th replicate at wavelength i, and $\bar{y}_i$ is the mean amplitude at wavelength i calculated from the four repeated measurements. RMSD provides a wavelength-averaged indicator of spectral dispersion across the full spectral range and reflects variability among consecutive acquisitions.

A smaller RMSD indicates higher spectral consistency and, therefore, greater acquisition stability under the specified conditions. Because the measurements were conducted within a single session and confined to the same fruit region, this analysis primarily reflects instrumental and operational stability rather than broader sources of variability. For simplicity, inter-session variability across different days, operators, or fruit batches was not evaluated.

Therefore, this comparison should be interpreted as a screening-level assessment of acquisition stability. The overall feasibility of the automated acquisition system was further evaluated based on regression models calibrated using spectra acquired under each mode. Demonstrating reduced spectral dispersion under automated operation supports the reliability of the acquired data and confirms that improved spectral consistency does not adversely affect regression performance compared with manual acquisition. This result indicates that the automated acquisition system can provide spectral data of sufficient stability for subsequent regression model development for SSC prediction.

2) Regression model development: Regression models were developed to predict mandarin SSC (°Brix) from Vis–NIR interactance spectra acquired under both manual and automated acquisition modes. The primary objective was to evaluate whether spectra obtained using the automated interactance spectral acquisition system can support predictive models with performance comparable to those developed from manually acquired spectra.

As described in Section II-A, the study used 460 mandarin fruits, each measured at four equatorial regions, yielding 1840 averaged spectra per acquisition mode. The corresponding reference SSC values of these fruits ranged from 8.0 to 13.9 °Brix (mean 10.3 ± 1.14). For regression modeling, the dataset for each acquisition mode was partitioned into calibration (80%) and prediction (20%) subsets using the Sample set Partitioning based on joint X–Y distances (SPXY) algorithm [13], which selects representative samples by maximizing joint distances in both spectral (X) and response (SSC, Y) spaces. This strategy has been widely adopted to improve calibration representativeness and prediction reliability in NIR-based fruit quality modeling [14], [15], [16].

Prior to model calibration, spectral preprocessing was applied to reduce variability associated with scattering effects, baseline drift, and instrumental noise. The evaluated preprocessing methods included Min–Max scaling (MM), Standard Normal Variate (SNV), Savitzky–Golay (SG) smoothing, first-derivative (FD) transformation, and Mean–Median Absolute Deviation Normalization (MMADN), representing scaling, scatter correction, smoothing, derivative enhancement, and robust normalization strategies, respectively [17].

TABLE I. HYPERPARAMETER SEARCH RANGES AND FIXED SETTINGS FOR PLSR, SVR, AND ETR MODELS OPTIMIZED USING 10-FOLD CROSS-VALIDATION FOR MANDARIN SSC (BRIX) PREDICTION.

Model	Hyperparameter	Search range / fixed value
PLS	n_components	1 – N (number of wavelengths)
SVR	C	5 – 300 (step size: 5)
	ϵ (epsilon)	0.05–1.00 (step size: 0.05)
	cache_size	50, 100, 150
	Kernel	RBF
	Gamma	scale
ETR	n_estimators	10 – 200 (step = 10)
	max_depth	2 – 10 (step = 2)
	min_samples_split	default (2)
	min_samples_leaf	default (1)
	max_features	default (auto)
	bootstrap	False
	random_state	42
	criterion	squared_error

Because preprocessing selection can substantially influence model behavior and address different types of spectral artefacts [18], both single and combined preprocessing strategies were systematically evaluated to ensure a fair and unbiased comparison between manual and automated acquisition modes. Identical preprocessing procedures were applied to spectra from both acquisition modes to ensure comparability of regression results.

Three regression algorithms were investigated: Partial Least Squares regression (PLSR), Support Vector Regression (SVR), and Extremely Randomized Trees or Extra-Trees (ETR). PLSR was adopted as a baseline chemometric model, as it is described as a conventional regression method for SSC prediction in recent NIR fruit quality studies [19]. SVR was included to account for potential nonlinear relationships between spectral features and SSC, consistent with recent fruit spectroscopy studies that apply support vector machine–based models alongside PLSR [2]. ETR was incorporated as an ensemble tree-based regression method. Ensemble learning approaches have been reported as increasingly applied in near-infrared spectroscopy combined with chemometrics methods [20].

Model hyperparameters were optimized using grid search combined with 10-fold cross-validation performed exclusively on the calibration subset. The same validation protocol, search ranges (Table I), and evaluation criteria were applied across preprocessing–model combinations and for both acquisition modes to maintain methodological consistency.

3) Model performance evaluation metrics: The predictive performance of regression models was evaluated using four commonly reported metrics: the correlation coefficient (R), coefficient of determination (R^2), root mean square error (RMSE), and residual prediction deviation (RPD). These metrics are widely adopted in NIR spectroscopy studies for fruit quality prediction and provide complementary perspectives on model accuracy [9], [10], [21].

The correlation coefficient R reflects the linear relation-

ship between reference and predicted SSC values, while the coefficient of determination R^2 indicates how much of the variability in the reference measurements is explained by the model. RMSE was calculated for both calibration ($\mathrm{RMSE_c}$) and prediction ($\mathrm{RMSE_p}$) sets as:

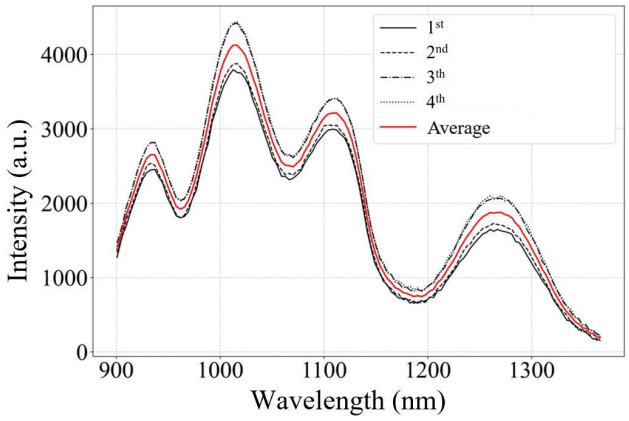
$$\mathrm{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \tag{5}$$

where, y_i and $\hat{y}_i$ denote reference and predicted SSC values, respectively, and n is the number of samples. RMSE provides a scale-dependent measure of prediction error and is commonly reported in fruit spectroscopy applications [2].

The residual prediction deviation RPD is frequently used in agricultural NIR modeling to assess practical predictive utility [3], [4]. It is calculated as the ratio between the standard deviation (SD) of the reference SSC values in the prediction set and the root mean square error of prediction ($\mathrm{RMSE_p}$) [22]:

$$\mathrm{RPD} = \frac{\mathrm{SD}}{\mathrm{RMSE_p}} \tag{6}$$

Higher RPD values indicate improved predictive performance. In NIR fruit quality studies, RPD is commonly used as an indicator of model applicability for screening or quantitative analysis.



III. Results and Discussion

A. Spectral Consistency Under Consecutive Acquisitions

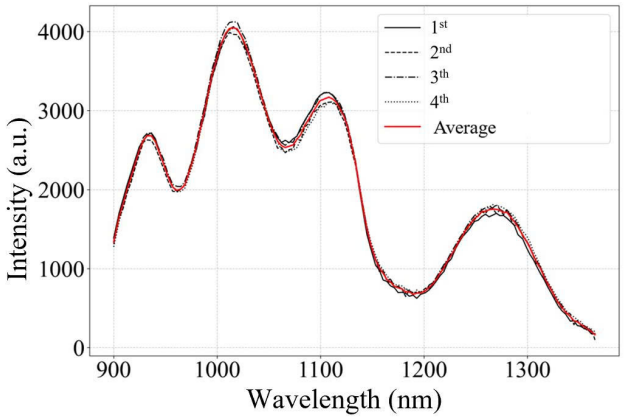


Fig. 5a presents four consecutive interactance spectra acquired at the same nominal measurement region using the manual method. Although the overall spectral profiles follow similar trends, substantial spectral dispersion among consecutive acquisitions is observed across multiple wavelength regions. Pronounced deviations are visible near the major peak around 1000 nm, as well as at secondary local maxima and minima between 1100 and 1300 nm. In several regions, the peak-to-peak separation among scans reaches several hundred a.u., indicating significant variability associated with manual probe repositioning and contact pressure. The calculated RMSD for the manual acquisition mode was approximately 1046 a.u., which represents the absolute spectral dispersion baseline for comparison, reflecting limited spectral consistency under manual operation.

In contrast, Fig. 5b shows four consecutive spectra obtained using the automated acquisition system. The spectra exhibit strong overlap throughout the measured wavelength range, including the local extrema between 1100 and 1300 nm. Only minor deviations are observed among acquisitions. The RMSD for the automated acquisition mode was approximately 363 a.u. Compared with the manual baseline of 1046 a.u., this corresponds to an absolute reduction of 683 a.u. and a relative reduction of approximately 65.3% in spectral dispersion.

These results indicate that the automated system provides improved spectral consistency under consecutive acquisitions, reflecting enhanced acquisition stability. The reduced spectral dispersion supports the reliability of the acquired data and is consistent with the regression performance observed under automated acquisition.

(a)

(b)

Fig. 5. Spectral consistency under consecutive acquisitions at the same nominal measurement region: (a) Manual acquisition and (b) Automated acquisition. Four consecutive scans are shown for each mode; the red curve represents the mean spectrum.

B. Regression Model Performance

Table II presents the calibration and prediction performance of PLS, SVR, and ETR models for mandarin SSC (°Brix) prediction under manual and automated interactance spectral acquisition modes using multiple preprocessing strategies. The objective of this analysis was not to identify an optimal SSC prediction model for grading applications, but rather to evaluate whether the automated interactance acquisition system provides spectral data suitable for chemometric modeling at a level comparable to manual measurement.

1) Effect of regression modeling approaches under different acquisition modes: Clear differences were observed between linear and nonlinear regression methods. Across preprocessing strategies, the PLS model achieved maximum prediction correlations of $R_\mathrm{p} = 0.68$ under manual acquisition and $R_\mathrm{p} = 0.74$

TABLE II. CALIBRATION AND PREDICTION PERFORMANCE OF PLS, SVR, AND ETR MODELS FOR MANDARIN SSC PREDICTION UNDER MANUAL AND AUTOMATED SPECTRAL ACQUISITION MODES USING DIFFERENT PREPROCESSING STRATEGIES.

Model	Acquisition mode	Preprocessing	Calibration			Prediction

under automated acquisition. In comparison, SVR reached $R_{\mathrm{p}} = 0.73$ (manual) and $R_{\mathrm{p}} = 0.78$ (automated), while ETR achieved $R_{\mathrm{p}} = 0.85$ under manual acquisition and $R_{\mathrm{p}} = 0.82$ under automated acquisition.

These results indicate that nonlinear regression approaches generally provided higher prediction accuracy than the linear PLS model. However, the relative performance between manual and automated acquisition varied depending on the regression method. Automated acquisition yielded higher maximum R_{p} values for both PLS and SVR, whereas ETR exhibited a slight decrease in peak prediction performance compared with the manual mode.

Despite these differences, the overall ranking of regression methods remained consistent across acquisition modes. In both manual and automated measurements, nonlinear models outperformed PLS by a comparable margin. This consistency suggests that the automated acquisition configuration does not alter the fundamental modeling behavior observed with manually acquired spectra.

2) Influence of spectral preprocessing: Preprocessing strategy influenced prediction performance more strongly than acquisition mode. SG was associated with relatively higher R_{p} values in several configurations, particularly for nonlinear regression models. The highest prediction accuracy ($R_{\mathrm{p}} = 0.85$) was obtained using the ETR model with SG preprocessing under manual acquisition. Under automated acquisition, SG-based and combined preprocessing strategies also yielded strong performance, with R_{p} values reaching up to 0.82 for ETR and 0.78 for SVR when combined with additional scaling methods such as MMADN + SG + MM. These observations indicate that spectral smoothing contributes to improved signal stability and can enhance model performance, particularly for nonlinear regression methods.

SNV, commonly used for scatter correction, did not consistently produce higher prediction accuracy compared to smoothing-based approaches. Similarly, scaling procedures such as MM and MMADN affected model performance depending on the regression method and acquisition mode. No single preprocessing strategy uniformly outperformed others across all models, and the effectiveness of preprocessing remained dependent on the interaction between preprocessing method and regression algorithm.

Overall, the results suggest that preprocessing plays a more influential role in determining model performance than acquisition mode, with SG-based approaches providing consistently strong performance across both manual and automated measurements.

3) General synthesis and relevance to study objective: Across all regression approaches and preprocessing configurations, prediction performance under automated acquisition remained within the same range as that obtained under manual acquisition. Maximum R_{p} values and corresponding RPD values were comparable between acquisition modes for each regression method. In several preprocessing–model combinations, particularly PLS and SVR with SG-based preprocessing, slightly higher R_{p} values and lower $\mathrm{RMSE}_{\mathrm{p}}$ values were observed under automated acquisition. Because these differences were small and the objective of this study was to evaluate system applicability rather than superiority, no formal statistical significance analysis was performed. The results therefore support comparable predictive performance between the two acquisition modes.

Most RPD values fell between approximately 1.2 and 1.7, corresponding to exploratory or screening-level prediction capability, as RPD values below 2.0 are generally considered suitable only for rough screening or approximate predictions in NIR fruit quality modeling studies [4], [23]. Although this RPD range indicates limited predictive capability for grading applications [24], achieving grading-level accuracy was not the objective of this study. Overall, the results indicate that automated interactance spectral acquisition provides spectral data of comparable quality to manual measurement, while also offering improved acquisition stability and, in some configurations, slightly enhanced predictive consistency.

The consistent regression behavior and similar prediction ranges across acquisition modes indicate that the automated interactance system provides spectral data comparable to those obtained using manual measurements. Therefore, further improvements in prediction accuracy are more likely to depend on dataset size, sampling diversity, and calibration strategy rather than on acquisition configuration alone.

It should also be noted that this study employed conventional chemometric and machine learning models (PLS, SVR, and ETR) together with commonly used spectral preprocessing techniques to enable a transparent comparison between manual and automated acquisition modes. While these approaches are widely adopted in NIR spectroscopy studies, preprocessing-based modeling pipelines may have limitations in capturing complex nonlinear spectral relationships when larger datasets are available. Recent studies have shown that deep learning approaches, such as convolutional neural networks (CNNs), can automatically learn hierarchical spectral features and reduce reliance on handcrafted preprocessing [2]. With expanded datasets and more diverse sampling conditions, future research may therefore explore deep learning–based spectral modeling to further improve prediction accuracy while leveraging the stable spectral acquisition provided by the proposed automated system.

IV. Conclusion

This study presented and validated an automated interactance NIR spectral acquisition system for non-destructive prediction of mandarin SSC. Compared with the manual setup, the automated system reduced spectral variability among consecutive acquisitions within a measurement session by approximately 65%, confirming improved measurement stability under controlled mechanical positioning and repeatable probe–fruit contact conditions.

Regression models based on PLS, SVR, and ETR were developed using multiple preprocessing strategies under an identical cross-validation protocol to maintain methodological consistency between acquisition modes. Across all model configurations, prediction performance obtained from automated spectra remained within the same performance range as that derived from manual measurements, with several configurations showing slightly higher R_{p} values and lower $\mathrm{RMSE}_{\mathrm{p}}$ values under automated acquisition, particularly for PLS and SVR models combined with SG-based preprocessing.

The relative performance ranking of linear and nonlinear models was preserved across acquisition modes. These results indicate that improved acquisition stability did not adversely affect predictive performance and may be associated with small performance gains in certain configurations, while maintaining overall modeling consistency.

Although most RPD values corresponded to screening-level predictive capability, the primary objective of this study was feasibility validation rather than grading-level optimization. A direct comparison with commercial inline NIR systems in terms of cost, maintenance, and industrial scalability was beyond the scope of the present study; therefore, no quantitative claims are made regarding these aspects. Unlike previously reported online transmission-based systems, the proposed approach emphasizes interactance acquisition with controlled probe positioning and modular mechanical integration. The findings demonstrate that the proposed automated system provides stable spectral data suitable for chemometric modeling and supports future integration into automated fruit grading platforms.

While validated on mandarins, the mechanical positioning and optical acquisition architecture may be adapted to other fruits with similar structural properties. Further improvements in prediction accuracy are therefore more likely to depend on expanded datasets, improved sampling strategies, and advanced calibration methods rather than modifications to the acquisition mechanism alone.

LIAS-Artificial Intelligence and Systems Laboratory, Hassan II University, Casablanca, Morocco[4]

***Abstract*—As large language models, and agentic AI systems are increasingly being integrated into software engineering, an expanding amount of empirical evidence surrounding these technologies has emerged. This systematic literature review examines the impact of modern AI techniques and tools in software development lifecycle phases and related activities, covering studies published between 2023 and 2025 and resulting in a corpus of 62 primary studies, investigating the role of large language models, AI agents and agentic AI workflows across lifecycle phases. The synthesis is guided by three research questions that address the entire software development cycle, reported impacts on development practices, outcomes, and constraints. This review fills a gap in the synthesis of modern AI applications and their impacts. It concludes that modern AI in software engineering is progressively evolving from a generation tool into a reasoning and coordination infrastructure layer, with ongoing efforts targeting the mitigation of identified limitations and the advancement of trustworthy agentic AI capabilities for dependable software engineering practices.**

***Keywords*—Large language models; generative AI; agentic AI; software development lifecycle; systematic literature review**

I. Introduction

Software development has changed significantly since large language models were released in late 2022. Targeted and customized automation is no longer the exclusive application of AI in this field. Every level of software development today benefits from the use of large language models, agents, and agent-based AI systems. These technologies now assist developers in defining requirements, making architectural decisions, writing code, fixing bugs, reviewing pull requests, detecting security risks, and managing production occurrences. As a result, AI is currently being used in majority of development workflows, tools, and infrastructures to help with software system design, implementation, testing, deployment, and maintenance.

Simultaneously, the quantity of empirical research on AI in software engineering has increased significantly. The majority of these studies concentrate on certain tools, jobs, or single lifecycle stages like program repair or code generation. They generate separate understandings even though they offer valuable insights. However, both researchers and practitioners still lack clarity on where modern AI works best, the risks it presents (especially with more autonomous agentic systems), and how its use should be governed. The lack of an integrated perspective makes it difficult to draw meaningful conclusions about the overall impact of modern AI on software development and the new organizational and technological challenges that come with it.

In order to address this gap, this study provides a comprehensive analysis of peer-reviewed primary research on the application of modern AI in software development published between 2023 and 2025 . The review adheres to the PRISMA 2020 guidelines and is organized around a 4-phase SDLC framework: Inception, Construction, Quality Assurance, and Operations. In total, 62 studies were selected and analyzed to address the three research questions. More specifically, the review examines how modern AI techniques are applied across SDLC activities, what impacts on software development are reported, and what challenges limit their effective adoption in practice. By bringing together evidence from different research streams, this study aims to provide a clear and structured cross-phase understanding of the evolving role of AI in software engineering.

The main contributions of this study are threefold. First, it provides a lifecycle-oriented synthesis of modern AI applications across software development activities. Second, it examines the stated impact of various technologies on productivity, artifact quality, and developer processes. Third, it outlines the primary limitations, threats, and adoption issues that affect the ethical integration of AI into software engineering practice.

The remainder of this study is organized as follows: Section II presents an overview of modern AI and the SDLC. Section III reviews related studies. Section IV discusses the research methodology. Section V provides results and addresses the research questions. Finally, Section VI concludes the study and outlines directions for future work.

II. Background

In this review, *modern AI* primarily refers to generative AI systems applied to software development, with a particular focus on large language model (LLM)-based tools, AI agents, and agentic workflows. Generative Artificial Intelligence (GenAI) denotes AI systems capable of producing original artifacts, including natural language text, images, and source code, in response to prompts or other forms of input [1]. In software engineering, the most relevant form of GenAI is represented by LLMs, which are deep learning models based on the Transformer architecture [2] and pre-trained on large-scale corpora of natural language and source code using self-supervised learning objectives. This paradigm enables broad

*Corresponding author

capabilities such as code generation, explanation, summarization, and reasoning support without requiring task-specific supervision [3].

Three levels of modern AI are distinguished throughout this review, where each one is characterized by an increasing degree of autonomy and coordination complexity: LLMs as reactive generation systems, AI Agents as tool-augmented planning architectures, and Agentic AI as multi-agent collaborative systems operating with limited human oversight. Table I summarizes these distinctions.

TABLE I. OPERATIONAL CHARACTERISTICS OF MODERN AI LEVELS

Level	Memory Type	Coordination	Role
LLM	Context-only	None	Text/code generation
AI Agent	Persistent	Single-agent	Tool-augmented task execution
Agentic AI	Shared	Multi-agent	Workflow orchestration

While LLMs provide strong generative and reasoning capabilities, a standard model usually operates as a reactive system that maps a given input to an output. To support more structured and autonomous task execution, recent research increasingly embeds LLMs into AI agents [4]. These agents consist of a base model combined with persistent memory, access to external tools, and planning or control mechanisms that enable multi-step perception–planning–action loops [5]. In software development, an AI agent can perform functions like interacting with software artifacts, running code execution tools, obtaining documentation, and iteratively refining outputs. Most recently, this paradigm has expanded toward *agentic AI*, in which one or more AI agents collaborate to achieve complex goals with limited human supervision [6]. In this case we find an orchestrating layer which typically divides a main goal into subtasks, distributes them to specialized agents, and consolidates intermediate results into a final output [7]. Compared to a single-call LLM interaction, agentic systems introduce higher degrees of autonomy, coordination, and decision delegation, making them well-suited for complex software engineering workflows. Fig. 1 illustrates this conceptual progression.

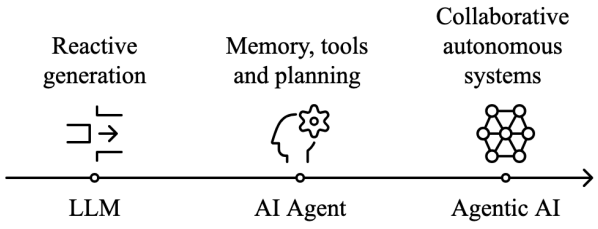

Fig. 1. Levels of modern AI in software development.

III. RELATED WORK

Recent reviews have examined modern AI in software engineering from several perspectives. Broad syntheses have mapped LLM applications across development tasks and highlighted challenges related to evaluation reliability, hallucination, and human–AI workflows [8], [9], while more focused studies have investigated specific subdomains such as software testing, vulnerability detection, and requirements engineering [10], [11], [12]. In parallel, dedicated reviews have explored multi-agent and agentic approaches, emphasizing autonomy, task orchestration, and collaboration patterns [7], [13].

However, these studies tend to focus on particular technologies or development activities, offering valuable but partial perspectives. A synthesis connecting how modern AI is applied across the full software development lifecycle, what impacts are reported, and what limitations and adoption challenges emerge from current evidence is still needed.

Accordingly, this study addresses that gap through a systematic literature review organized around a four-phase lifecycle framework: Inception, Construction, Quality Assurance, and Operations. Different from previous research such as [8] and [9], which discuss the use of LLMs without a lifecycle structure, and [7] and [13], which focus on agentic architectures without spanning all SDLC phases, this review synthesises empirical evidence on modern AI applications, reported impacts, and adoption challenges through a unified four-phase lifecycle lens.

IV. METHODOLOGY

The methodology section describes the systematic approach adopted in this study in order to ensure transparency, consistency, repeatability, and rigor in the review process. To achieve this, the review was conducted following the PRISMA guidelines [14] and aligns with the Kitchenham and Charters SLR guidelines for software engineering [15].

A. Study Objective and Scope

The aim of this systematic literature review is to synthesize empirical studies that examine how modern AI is being used in software development. The collected evidence is organized around three main aspects: first how AI is used across the software development lifecycle, what impacts on development are reported, and what limitations and adoption challenges are identified. The review focuses only on primary research studies, while secondary sources such as surveys, literature reviews, and mapping studies are excluded.

This review covers papers published between 2023 and 2025. This period was mainly chosen in order to include research conducted after the public release of ChatGPT which was late 2022 [16], and which created great interest in generative AI and large language models and their application in software development. By restricting the review to this time period, the study only focuses on actual advances in modern AI rather than classical or prior AI approaches.

To structure the synthesis across software development activities, this review adopts a consolidated four-phase analytical framework comprising *Inception*, *Construction*, *Quality Assurance*, and *Operations*. This structure is partially inspired by emerging industry conceptualizations of AI-driven development lifecycles, such as the AI-Driven Development Life Cycle (AI-DLC) [17]. However, unlike such models, this review treats Quality Assurance as a distinct analytical phase in order to better capture validation-oriented activities such as testing, debugging, code review, and security verification. Fig. 2 illustrates this framework and the main categories of activities associated with each phase.

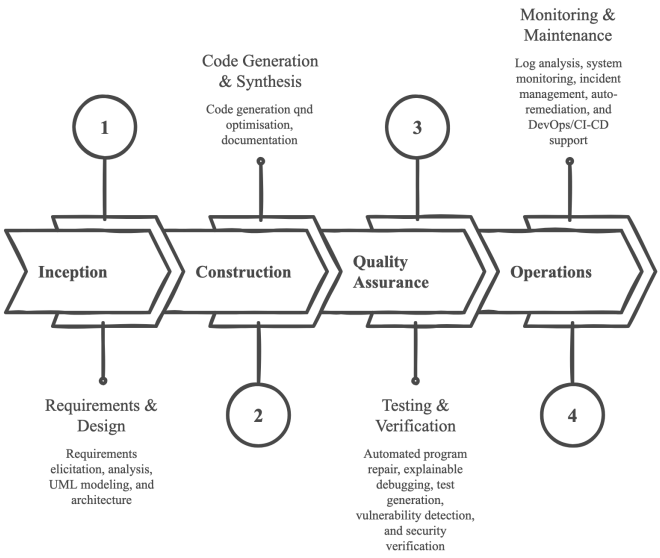

Fig. 2. Four-phase software development lifecycle framework adopted in the review.

TABLE II. PICOC FRAMEWORK DEFINING THE REVIEW SCOPE

Dimension	Definition
Population	Software developers, software engineering teams, researchers, and software projects.
Intervention	Modern AI approaches including generative AI, LLMs, AI code assistants, AI agents, retrieval-augmented generation, and agentic workflows.
Comparison	Non-AI approaches or alternative AI-based techniques, where applicable.
Outcome	SDLC applications, reported impacts, limitations, and adoption challenges.
Context	Peer-reviewed English-language studies in software engineering, published between 2023 and 2025.

To further define the scope and keywords used in our study we generated the PICOC framework presented in Table II.

B. Research Questions

To structure the synthesis of recent empirical evidence, this review is guided by three research questions addressing the usage, impact, and constraints of modern AI in software development.

RQ1: What are the current applications of modern AI in the SDLC?

This question aims to identify the current state and trends in the application of modern AI techniques throughout the software development lifecycle. By analyzing reported applications in activities such as requirements engineering, implementation, testing, and operational support.

RQ2: What are the reported impacts of modern AI on software development practices ?

This focuses on reported changes related to productivity, development speed, artifact quality, collaboration dynamics, and decision support.

RQ3: What limitations, risks and adoption challenges are perceived from the integration of modern AI in software development?

This research question addresses the technical reliability issues, security and governance concerns, organizational barriers, and the new challenges introduced by LLMs, multi-agent and autonomous AI systems.

C. Data Sources and Search Strategy

The literature search was mostly done on *Scopus*, which was used as the main data source due to its broad coverage of computer science topics. In order to achieve broader coverage of studies related to this research, *IEEE Xplore* and the *ACM Digital Library* were also used as they provide a vast amount of software engineering conference and journal papers. Preprint repositories such as *arXiv* were consulted to identify latest developments in generative AI, especially to inform the background and related work sections of this review. However, it should be noted that, only studies indexed in Scopus were retained in the final corpus, ensuring that all selected publications meet a peer-review quality standard [15].

The search string combined both modern AI and software development activity terms, as follows:

(*"generative AI" OR "large language model" OR "LLM" OR "AI agent" OR "agentic AI"*) AND (*"software development" OR "software engineering" OR "SDLC" OR "requirements engineering" OR "software architecture" OR "code generation" OR "software testing" OR "software maintenance" OR "DevOps"*)

The query was applied to the titles, abstracts, and keywords section. Additional filters were used to restrict results to the defined publication period (2023-2025), English language, document types corresponding to articles and conference papers, and the Computer Science subject area.

D. Inclusion and Exclusion Criteria

To ensure consistency in study selection, predefined inclusion and exclusion criteria were applied throughout the screening process. The inclusion criteria are summarized in Table III, and the exclusion criteria are presented in Table IV.

E. Study Selection Process

The study selection process followed a PRISMA-inspired workflow. The first phase of search involved using Scopus database and the predefined search string resulting in 5,336 records, which were then filtered to retain only English-language articles and conference papers published between 2023 and 2025 in the Computer Science subject area, reducing the corpus to 3,888 records.

These records were screened on the basis of titles and abstracts, retaining 399 studies for full-text assessment. Full-text screening was then conducted to verify compliance with the predefined inclusion and exclusion criteria and to confirm publication accessibility. After this final eligibility assessment, 62 studies were included in the review corpus, where 49 forming the main SDLC-oriented corpus used to address RQ1

TABLE III. INCLUSION CRITERIA BY SEARCH SUBJECT

Search Subject	Inclusion Criteria
Modern AI Applications in Software Development	– Proposes or evaluates LLM-based, generative AI, or agentic approaches applied to software development activities. – Addresses at least one SDLC phase: Inception, Construction, Quality Assurance, or Operations. – Reports empirical evaluation, controlled experiment, or tool validation.
Impacts on Development Practices and Outcomes	– Measures or discusses productivity, output quality, or workflow changes resulting from AI adoption. – Provides quantitative or qualitative evidence of AI impact on development speed, correctness, or developer support. – Highlights strengths, limitations, and practical implications of the proposed approach.
Limitations, Risks, and Adoption Challenges	– Identifies technical, security, or organizational barriers to AI adoption in software engineering. – Discusses reliability issues such as hallucination, non-determinism, or adversarial robustness. – Focuses on governance, privacy, or socio-technical challenges in AI-assisted development. – Includes specific findings on agentic AI risks such as cascading errors or coordination failures.
Publication Eligibility	– Published between 2023 and 2025. – Peer-reviewed primary journal article or conference paper. – Written in English and retrieved within the defined database search scope.

TABLE IV. EXCLUSION CRITERIA BY SEARCH SUBJECT

Search Subject	Exclusion Criteria
Scope and Domain	– Not focused on software development activities (e.g. healthcare, education, or finance). – Modern AI is not the primary intervention or technique under study. – Uses only traditional ML, rule-based systems, or classical NLP without LLMs or generative AI.
Empirical Evidence	– Lacks sufficient empirical evidence or without experimental validation. – Secondary study such as a survey, systematic literature review, systematic mapping, or meta-analysis.
Publication Accessibility	– Full text not accessible for eligibility assessment or data extraction.

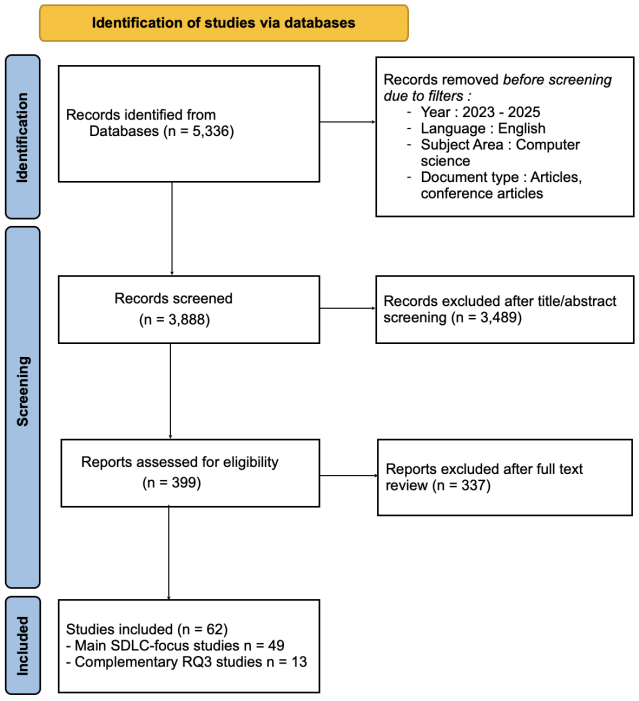

Fig. 3. PRISMA flow diagram for the review.

and RQ2, and 13 complementary studies included to strengthen the analysis of limitations, risks, and adoption challenges in RQ3. The overall selection process is summarized in Fig. 3.

V. RESULTS AND DISCUSSION

A. RQ1: Applications of Modern AI Across SDLC Phases

AI tools are currently employed throughout all stages of software development, from requirements gathering to system maintenance, as shown in Table V.

1) Inception: In Inception phase, AI is mostly used for requirements engineering, software modeling, and architectural assistance. LLMs help in generating requirements from conversations held with clients [21], refine backlog items and improve user story quality [19], [25], or detect ambiguities or inconsistencies in specifications [23], [29]. They can also help generate UML diagrams [22], [24], [26], and help novice analysts work with modeling tools [28]. Overall, AI in Inception mostly assists with drafting early outputs and formalizing requirements, whereas planning and estimation remain underexplored.

2) Construction: In Construction phase, AI is used for a wide range of tasks including writing code and generating documentation. Rather than asking a model to generate code from a simple bare prompt, studies show that methods like retrieval-augmented generation (RAG), guided prompting, or requirement-aware pipelines significantly improve the correctness of the generated code [34], [36], [38]. When developers need to handle more complex tasks, iterative refinement and multi-agent systems help improve results further [35], [45], [46]. Recent work also shows that AI can generate code directly from visual inputs such as flowcharts and UML diagrams [40], [41], and that LLMs can be embedded into CI/CD pipelines to automatically convert backlog items into functional code [39]. AI additionally supports documentation

TABLE V. SYNTHESIS OF REVIEWED STUDIES ACROSS SOFTWARE DEVELOPMENT PHASES.

Ref.	Phase	Sub-theme	AI Approach
[18]	Inception	Requirements elicitation	GPT-4-Turbo agent simulation
[19]	Inception	Requirements elicitation	Multi-agent LLM system
[20]	Inception	Backlog classification	RoBERTa fine-tuning
[21]	Inception	Requirements from conversations	Llama-2 prompting
[22]	Inception	UML and code generation	LLM-driven MDA pipeline
[23]	Inception	SRS quality evaluation	GPT-4 zero-shot
[24]	Inception	UML sequence diagrams	GPT-3.5 prompting
[25]	Inception	User story quality	LLM agent prompting
[26]	Inception	UML class diagram modeling	GPT-4 evaluation
[27]	Inception	Domain model generation	ChatGPT-3.5
[28]	Inception	UML modeling assistance	LLM support for novices
[29]	Inception	Requirements ambiguity detection	GPT-4 zero-shot
[30]	Inception	Requirements elicitation	ChatGPT prompting
[31]	Inception	Interview script generation	ChatGPT and Bard
[32]	Inception	Domain model extraction	GPT-3.5 vs CRF comparison
[33]	Inception	Architectural decision records	GPT-4 and Flan-T5
[34]	Construction	RAG-based code generation	Retrieval-augmented generation
[35]	Construction	Iterative code refinement	Multi-role LLM pipeline
[36]	Construction	Guided code generation	BM25 retrieval prompting
[37]	Construction	Decoding configuration	Temperature tuning
[38]	Construction	Requirement-to-code generation	Requirement-aware prompting
[39]	Construction	Backlog-to-code pipeline	GPT-4 CI/CD integration
[40]	Construction	Flowchart-to-code generation	Multimodal LLMs
[41]	Construction	UML-to-code generation	GPT-4 Vision
[42]	Construction	REST API endpoint extraction	LLM agents
[43]	Construction	Use case documentation	Structured prompting
[44]	Construction	Code summarization	LLM-based summarization
[45]	Construction	End-to-end agentic development	Multi-agent framework (MetaGPT)
[46]	Construction	End-to-end agentic development	Chat chain protocol (ChatDev)
[47]	Quality Assurance	Automated program repair	LLM & static analysis
[48]	Quality Assurance	Automated program repair	Retrieval-augmented repair
[49]	Quality Assurance	Multi-method bug repair	Divide-and-conquer agents
[50]	Quality Assurance	Explainable debugging	Scientific debugging prompting
[51]	Quality Assurance	Vulnerability-witnessing tests	GPT-4 Turbo
[52]	Quality Assurance	Test quality assessment	GPT-4o and Amazon Q
[53]	Quality Assurance	Automated test generation	State space models
[54]	Quality Assurance	Smart contract vulnerability	GPT-3.5 fine-tuned
[55]	Quality Assurance	Smart contract vulnerability	Multi-agent audit system
[56]	Quality Assurance	Industrial code review	Fine-tuned LLM (BitsAI-CR)
[57]	Quality Assurance	Code review automation	Prompt engineering vs fine-tuning
[58]	Operations	Cloud observability	Knowledge graph & LLM
[59]	Operations	Network monitoring	Llama-3.2 multi-agent
[60]	Operations	Incident root cause analysis	Hierarchical multi-agent (SRE)
[61]	Operations	Maintenance assistance	Ontology-based RAG
[62]	Operations	Incident mitigation	Fine-tuned Code-davinci
[63]	Operations	Automated root cause analysis	GPT-4 workflow-driven (RCACopilot)
[64]	Operations	Log parsing	Flan-T5 and LLaMA few-shot
[65]	Operations	Auto-remediation	GPT-4 Ansible playbook generation
[66]	Operations	CI/CD pipeline support	Workflow-integrated LLM

tasks such as generating use case descriptions and summarizing source code [43], [44], while LLM-based agents have been used to extract REST API endpoints automatically from microservice architectures [42].

3) Quality assurance: In Quality Assurance phase, AI is mainly used for code review, automated testing, vulnerability recognition, debugging, and software repair. Pairing LLMs with static analysis [47], retrieval [48], or multi-agent decomposition [49] results in more reliable bug fixes compared to direct generation. AI debugging tools assist developers in determining whether a fix is correct [50]. AI may generate syntactically valid test cases [51], [52], but without class-level dependencies or runtime data, the tests frequently lack semantic correctness [53]. In order to improve vulnerability detection fine-tuned [54] and multi-agent [55] approaches can be used in domains such as smart contracts, but generalization to larger codebases remains limited. In code review, the use of prompt engineering techniques [56] and fine-tuning [57] provide more meaningful and reliable feedback than basic prompting.

4) Operations: In Operations phase, AI can assist in doing log analysis, giving incident diagnosis and maintenance guidance. Systems based on LLM can semantically interpret logs [64]. Now, incident management has progressed from single-model diagnostic support [62] to multi-agent [59], [60] and workflow-driven systems [63] that integrate logs, metrics, and traces to identify root causes and suggest solutions. In addition, AI can also generate remediation scripts and playbooks through maintenance assistants [61] and auto-remediation frameworks [65]. More recently, LLMs can also help developers work with GitHub repositories by reading configuration files and supporting CI/CD decisions [66]. Overall, AI in Operations is acting as an intelligent interpretation and action layer, though scalability, safety, and performance in complex production environments remain open challenges.

Across phases, the role of AI in software engineering has gradually increased, moving from helping structure early outputs in Inception, to generating and coordinating code in the Construction stage, supporting verification in Quality Assurance, and taking action in Operations. However, fully autonomous AI remains currently out of reach due to limitations in semantic reasoning, domain knowledge, and integration complexity.

Looking across the reviewed studies, several patterns emerge beyond what Table V individually captures. While contributions are present across all lifecycle phases, their distribution within each phase is uneven. In Inception, studies are heavily concentrated on requirements elicitation and UML modeling, leaving activities such as project planning and effort estimation largely unaddressed. Construction and Quality Assurance attract the broadest range of contributions, as tasks like code generation, program repair, and testing are naturally suited to automation. Operations, despite growing interest, remains the least explored phase, particularly regarding runtime safety and long-term system maintenance.

In addition to these distributions, certain patterns in the effectiveness of modern AI methodologies have been observed. For example, the use of retrieval-augmented generation (RAG) generally increases the accuracy of output compared to zero-shot or basic prompting methods, especially in tasks related to code generation and repair due to the fact that it grounds model outputs in project-specific context and reduces the chances of hallucination. Furthermore, the use of multi-agent and agentic systems demonstrate better performance in complex, multi-step workflows. However, such systems need more coordination and suffer from a higher risk of cascading mistakes. Finally, fine-tuning provides smoother and specialized performance especially when it comes to code reviewing and vulnerability detection but involves high resource expenses. Overall, none of the discussed methods outperforms others in all cases, and the efficiency of techniques depends greatly on the complexity and nature of the task.

B. RQ2: Reported Impacts on Software Development Practices and Outcomes

The reviewed studies report three main categories of impact associated with the adoption of modern AI: faster development, more consistent outputs, and changes in how development teams work.

The most commonly reported benefit of modern AI adoption in software development is increasing productivity, as it helps reduce manual work in requirements elicitation [18], [19] and backlog management [25]. AI also produces more correct code especially when used with retrieval [34], guided prompting [36], or generation guided by project requirements [38]. In Quality Assurance and Operations, AI speeds up program repair [47], code review [56], incident diagnosis [60], log parsing [64], and root cause recommendations [62]. That said, these gains are task-dependent and tend to drop in complex or open-ended activities [23], [40], [53].

Multi-agent systems also changed how development teams work, as they support task decomposition [45], [46] and connect AI to CI/CD and operational workflows [65], [66]. LLM tools can also help junior developers with modeling [28], debugging [50], and incident response [61].

As for output quality, AI tools provide better results particularly in requirements [24], documentation [43], [44], and code review [56]. However, a recurring issue that has been found in the literature is that these outputs are often syntactically correct but semantically wrong, meaning that the code compiles and follows proper syntax rules but does not actually do what was intended or fails to capture the required behavior, especially in testing [51] and vulnerability detection [54], [55]. This is an issue that persists across all lifecycle phases and is addressed by introducing several techniques. Fig. 4 summarizes the three main approaches repeatedly reported in the reviewed studies: prompt engineering, retrieval-augmented generation, and fine-tuning. Prompt engineering structures the model's reasoning before it generates, leading to more accurate code [36], better debugging support [50], and more useful code review feedback [56], then we have Retrieval-augmented generation that grounds the model in relevant existing code or documentation, with improvements reported in code generation [34], program repair [48], and maintenance assistance [61]. Finally, fine-tuning, which is a technique that adjusts the model according to the task or domain, enhancing its effectiveness for software repair [49], automated code review [57], and vulnerability detection [54]. Together, these three techniques consistently outperform basic zero-shot generation by highlighting the fact that raw model capability alone is insufficient for AI-assisted development.

Taken together, the literature suggests that modern AI contributes to incremental yet systemic shifts in software development practices. While productivity acceleration and artifact standardization are increasingly observable, fully autonomous development remains constrained by semantic reasoning limitations, domain specificity, and integration challenges.

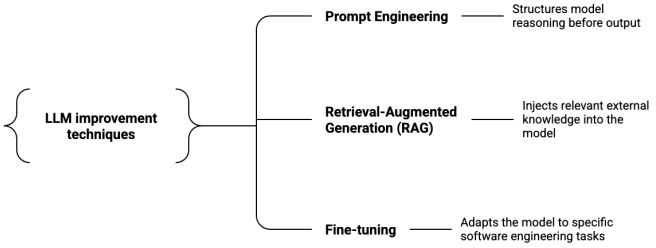

Fig. 4. LLM-based techniques for improving output quality in AI-assisted software development.

C. RQ3: Limitations, Risks, and Adoption Challenges

A broad set of limitations and risks has been encountered in the literature, as summarized in Table VI. These challenges span technical reliability issues, architectural constraints, and socio-technical adoption barriers, and are further amplified in emerging agentic development paradigms.

TABLE VI. COMPLEMENTARY RQ3 STUDIES

Ref.	Focus	Risk Category
[67]	GenAI adoption in organizations	Governance
[68]	Uncertainty in code completions	Automation bias
[69]	LLM self-verification	Self-contradiction
[70]	Correctness via internal states	Reasoning limits
[71]	Data race detection	Runtime visibility
[72]	Security of AI-generated code	Vulnerabilities
[73]	LLM security awareness	Passive security risk
[74]	Membership inference attacks	Privacy leakage
[75]	Adversarial code completion	Robustness
[76]	Multi-agent process modeling	Coordination errors
[77]	Debate-verify-debug pipelines	Cascading errors
[78]	LLM agent security paradigms	Chained attacks
[79]	End-to-end multi-agent generation	Autonomy risks

From a technical perspective, hallucination and non-determinism are the most consistently reported limitations across SDLC phases. As discussed in RQ2, AI-generated outputs are frequently syntactically plausible yet semantically incorrect, affecting requirements modeling [23], code generation [35], program repair [49], and operational diagnosis [58]. Variability in outputs for identical inputs complicates reproducibility and quality assurance, while decoding configuration [37] and prompt sensitivity [44] further increase deployment complexity. Adversarial robustness also remains limited: recent studies demonstrate that malicious natural-language instructions can significantly increase the likelihood of insecure code generation while preserving functional correctness [75]. In agentic settings, cascading errors across multi-step pipelines introduce additional instability, as early planning inaccuracies propagate through downstream development stages [38], [77], [79].

Architectural and resource constraints represent a second category of limitations. Context window restrictions hinder cross-file reasoning in requirements analysis [29], program repair [47], and vulnerability detection [54], leading most studies to evaluate AI performance on simplified task units. Multi-agent systems also come with a lot of costs: they consume more tokens, introduce coordination delays, and require careful

orchestration, both in agentic development frameworks [45] and operational environments [60]. Approaches such as fine-tuning [57], retrieval integration [34], and hybrid verification pipelines [53] further demand significant computational resources and labelled data, which limits how widely they can be adopted. Another gap is that most current AI tools work on static code or logs and cannot observe system behavior at runtime, leaving dynamic issues [71] and vulnerabilities that only appear during execution [55] largely undetected.

Security and organizational challenges add another layer of concern. AI-generated code frequently contains vulnerabilities [72], and models rarely flag security issues on their own unless the user explicitly asks [73]. There is also a growing risk around privacy where attackers can use membership inference techniques to extract information about the data used to train a model, potentially exposing proprietary code or sensitive information [74]. In agentic systems, the risks go further — chained attacks that combine prompt injection with other exploitation techniques can manipulate how agents use tools or communicate with each other, creating new threats that traditional security models were not designed to handle [78].

Aside from these technological issues, organizational challenges also arise. Accepting AI suggestions without verification can become a harmful habit for developers [68]. Also, there is no clear legal framework governing how AI tools handle sensitive code or data [67]. While AI can assist junior engineers learn and speed up repetitive processes, over-reliance on low-quality or imprecise outputs [56], [61] might silently decrease the standard of the final result.

VI. Conclusion and Future Work

In conclusion, this review shows that current software development tasks tend to incorporate modern artificial intelligence. In accordance with the reviewed literature, not only does AI play the role of providing individual help, but it tends to assist in development processes overall. It is considered as an infrastructure layer that facilitates developers' work on various software development stages. Its advantages are primarily perceived in automated, repetitive and structured actions. However, there are still considerable challenges to AI integration, such as security problems, privacy protection, context management limitations, and other factors.

For practitioners, this review highlights various insights that can actually be taken into consideration. In this regard, prompt engineering, RAG, and fine-tuning consistently beat zero-shot approaches in terms of performance and need to be considered an integral part of the development process and not just additional features. As for multi-agent systems, they provide performance boosts for more intricate activities, but come with coordination costs and error propagation, which need proper management.

Future studies should focus on various gaps found in the current literature, most specifically in project planning, CI/CD pipeline automation, repository-level development, and vulnerability detection. The effects of AI adoption on developer skills, team structures, and engineering culture also presents a relevant investigation. As multi-AI agents and agentic AI systems become more and more common, we should also consider how agent teams should be organized and scaled as task complexity increases, on whether AI can support genuine creativity and innovation beyond pattern reproduction, and how autonomous agents can make reliable decisions when outputs conflict or ambiguities arise. Finally, as agentic AI becomes more capable, advancements in abilities must be accompanied by equally significant improvements in safety, accountability, and governance.

A Survey on Extended Reality Technologies for Industrial Maintenance

Mouad Danane, Abdelmajid El Ouadi, Youssef Rochdi
National School of Applied Sciences, Ibn Tofail University, Kenitra, Morocco

***Abstract*—Industrial maintenance increasingly relies on extended reality (XR) technologies, yet comprehensive analysis comparing AR, VR, and MR implementations with human-centric evaluation remains limited. This systematic literature review employs the PRISMA methodology to analyze 95 primary studies (2014–2025) that investigate implementation patterns, benefits, challenges, and evaluation criteria across XR modalities. AR dominates operational guidance (71.6%), VR prevails in training (38.9%), and MR enables collaborative maintenance (6.3%). Temporal analysis reveals three evolutionary phases: basic visualization (2014–2017), cognitive enhancement (2018–2021), and AI-integrated adaptive systems (2022–2025), mirroring the transition from Maintenance 4.0 to 5.0. Demonstrated benefits include 38% task completion time reductions and 92.4% error decreases. Human-centric factors appear in 44.2% of studies overall, with temporal analysis showing a progressive increase from approximately 25% in 2014–2017 to 58% in 2022–2025, substantiating a paradigm shift toward prioritizing cognitive support and user experience. Two novel frameworks advance theoretical understanding: an Evaluation Framework that expresses effectiveness as a function of technology, task complexity, and human factors; and a Technology-Task-Context Alignment Model that prescribes optimal XR-maintenance pairings. Critical gaps include the need for longitudinal field studies, standardized evaluation protocols, and economic analyses.**

***Keywords*—Industrial maintenance; maintenance 5.0; extended reality; augmented reality; virtual reality; mixed reality; human-centric design; artificial intelligence; systematic literature review**

I. Introduction

Manufacturing industries worldwide face mounting pressure to optimize operational efficiency while managing increasingly complex equipment and production systems [88]. Industrial maintenance, encompassing inspection, repair, diagnosis, and preventive activities, is essential for maintaining uninterrupted production, reliable equipment performance, and safe working conditions [89]. The advent of Industry 4.0, marked by the convergence of digital-physical systems, IoT technologies, AI, and sophisticated data analytics, has fundamentally transformed maintenance paradigms [90]. Despite these technological advances, human operators remain essential in overseeing, supervising, and servicing automated infrastructure, tackling issues beyond the scope of automation capabilities [91]. This industrial evolution seeks to augment human operator performance and minimize human error through intelligent, human-centered systems [92].

Extended Reality (XR)—which includes Virtual Reality (VR), Augmented Reality (AR), and Mixed Reality (MR)—has become a powerful enabler for industrial maintenance [86]. These immersive technologies offer distinct capabilities: AR overlays digital information onto physical environments, enabling real-time guidance during maintenance operations; VR creates fully immersive virtual environments for risk-free training and simulation; MR blends digital and physical elements to facilitate collaborative problem-solving [93]. The convergence of XR with advanced industrial technologies, including IoT sensors, digital twins, and AI-driven analytics, creates unprecedented opportunities to improve maintenance efficiency, training effectiveness, and knowledge transfer [94]. The demonstrated benefits include substantial reductions in task completion time, significant decreases in failure rates, enhanced mental support for complex procedures, and improved knowledge retention during training [95].

Despite substantial research attention, critical gaps persist in our understanding of XR application in industrial maintenance. Existing reviews have primarily focused on individual XR modalities, without adopting comprehensive approaches that compare AR, VR, and MR. In addition, limited attention has been paid to human-centric design principles and systematic evaluation methodologies, which are increasingly recognized as critical to successful implementation. The rapid technological evolution—particularly post-2020 advances in hardware capabilities, AI integration, and software platforms—necessitates updated analysis reflecting current state-of-the-art systems. Finally, the emerging Maintenance 5.0 framework, which emphasizes human-AI collaboration and sustainable practices, requires examination of how XR technologies facilitate this paradigm shift.

Several systematic reviews have previously examined aspects of this domain. Palmarini et al. [83] conducted an early review focused exclusively on AR in maintenance, identifying fragmented solutions and hardware limitations. Guo et al. [84] reviewed VR applications across product lifecycles. More recently, Wang et al. [82] examined XR in product assembly, and Alam et al. [86] analyzed XR challenges in Industry 4.0 contexts. However, none of these reviews comprehensively compare all three XR modalities (AR, VR, and MR) while simultaneously addressing human-centric design factors, evaluation methodologies, and the emerging Maintenance 5.0 framework. This gap motivates the present study.

This systematic review fills these research voids through an in-depth examination of XR technologies in industrial maintenance through examination of 95 primary studies published between 2014 and 2025. The review adopts a holistic approach that encompasses AR, VR, and MR technologies, while emphasizing human-centric design factors aligned with the Maintenance 5.0 principles. This work offers multiple novel contributions that advance the current literature. First, it provides updated empirical evidence of XR adoption patterns,

technological trends, and implementation outcomes reflecting recent advances. Second, it systematically analyzes evaluation methodologies employed across studies, identifying relationships between technology characteristics, task complexity, and appropriate assessment criteria. Third, it examines human-centric enhancement strategies, documenting how XR technologies address cognitive load, ergonomics, adaptability, and user experience. Fourth, it develops theoretical frameworks that advance understanding of XR effectiveness in maintenance contexts.

To achieve a comprehensive analysis, this review addresses five research questions: XR implementation patterns, benefits and potential, challenges and prospects, human-centric enhancements, and evaluation criteria for assessing these technologies in industrial maintenance contexts. These questions guide a systematic examination of the current state, demonstrated outcomes, implementation barriers, and future directions for XR in maintenance applications.

The subsequent sections of this study are organized in the following manner. Section II outlines the systematic review methodology based on PRISMA guidelines. Section III presents results organized by technology prevalence, application areas, advantages, limitations, human-centric factors, and evaluation criteria. Section IV discusses the findings in the context of theoretical frameworks, contrasts the outcomes with prior studies, and describes the practical applications and study limitations. Section V presents concluding remarks, principal findings, and prospective research avenues.

II. Methodology

A. Research Questions

The aim of this systematic literature review (SLR) is to provide a comprehensive overview of the application of Extended Reality (XR) technologies in industrial maintenance, including the primary tasks, key advantages, limitations, and challenges. Additionally, this study seeks to identify the evaluation criteria used to assess XR technologies in industrial maintenance and explore how XR can promote human-centricity, a key concept in the Maintenance 5.0 framework. Furthermore, this SLR aims to provide researchers with insights into future work and research directions. To achieve these objectives, the following research questions (RQs) have been formulated:

- RQ1: What is the current state of XR technologies in industrial maintenance?
- RQ2: What are the benefits and potential of XR technologies in industrial maintenance?
- RQ3: What challenges and prospects exist for XR technologies in industrial maintenance?
- RQ4: How can XR technologies enhance human-centric industrial maintenance?
- RQ5: What are the evaluation criteria used in the literature to assess XR technologies in industrial maintenance?

B. Research String and Databases Selection

To answer the research questions, a comprehensive search string was formulated to capture relevant studies on the application of XR technologies in industrial maintenance. The search string used was: "industrial maintenance" AND ("virtual reality" OR "augmented reality" OR "mixed reality" OR "extended reality"). This search string covers the main concepts of the research topic, including industrial maintenance and the various types of XR technologies (virtual reality, augmented reality, mixed reality). The literature search was conducted using three major scientific databases: Scopus, ScienceDirect, and Web of Science. These databases were selected for their relevance and extensive coverage of peer-reviewed literature in the fields of engineering, technology, computer science and energy.

To guarantee that the review captured current and pertinent research on the topic, the scope was restricted to publications from January 1, 2014, and May 19, 2025. Additionally, only studies published in English were considered to maintain consistency and accessibility for the researchers. These date range and language filters were applied directly in the database search phase, before proceeding to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) protocol.

The initial search yielded a total of 321 articles, distributed as follows:

- ScienceDirect: 168 articles.
- Scopus: 86 articles.
- Web of Science: 67 articles.

C. Selection of Primary Study

The initial search yielded 321 articles from the selected databases. These articles were then subjected to the PRISMA protocol (Fig. 1) to identify the most relevant studies for the systematic literature review.

First, duplicate articles were removed, resulting in 255 unique articles. These articles were then screened using their titles, abstracts, and keywords to assess their relevance to the research questions. Articles that were out of scope like "6G networks: Beyond Shannon towards semantic and goal-oriented communications" and "Deep Learning-Powered System for Real-Time Digital Meter Reading on Edge Devices," were excluded. However, articles addressing extended reality in industrial maintenance, including assembly and disassembly tasks, were retained, as these tasks are considered integral to industrial maintenance. This screening process resulted in the exclusion of 124 articles, leaving 131 articles for further review.

The remaining 131 articles are reviewed in full text and subjected to detailed analysis to assess their eligibility for inclusion in our study. During this stage, an additional 36 articles were excluded for the following reasons:

- Upon closer examination, 10 articles were found to be not directly relevant to the research questions.

- 14 articles were identified as literature review articles, which did not meet the inclusion criteria for primary studies.
- 12 articles were not accessible for full-text review.

Finally, a total of 95 articles were selected as primary studies to answer the research questions. These articles form the basis for the data extraction and synthesis stages of the systematic literature review.

D. Quality Assurance and Limitations of the Search Strategy

Several methodological considerations should be noted regarding the PRISMA implementation. First, the search was limited to three academic databases (Scopus, ScienceDirect, Web of Science), and grey literature sources such as technical reports, white papers, and industry documentation were not included. This may introduce publication bias, as studies reporting positive outcomes are more likely to be published in peer-reviewed venues. Second, the study screening and selection process was conducted by the first author and verified by the co-authors through discussion-based consensus rather than formal inter-rater reliability assessment. While this approach is common in systematic reviews within engineering disciplines, it represents a methodological limitation. Third, no formal risk-of-bias assessment tool (e.g., ROBINS-I or the Newcastle-Ottawa Scale) was applied to individual primary studies, as the heterogeneity of study designs—ranging from controlled experiments to case studies and framework proposals—made standardized quality scoring impractical. These limitations are acknowledged and should be considered when interpreting the synthesized findings.

E. Co-Authorship Analysis

Co-authorship analysis was performed using VOSviewer on the 95 primary study papers selected for the systematic literature review on extended reality (XR) in industrial maintenance. The analysis aimed to identify influential authors and collaborative networks within this specific subset of literature.

From the total pool of authors in the 95 papers, a minimum threshold of two documents per author was set. Out of the authors who met this threshold, the top 50 were selected for visualization. The resulting co-authorship network (see Fig. 2) reveals several distinct clusters of collaborating authors. The most prominent cluster includes Hakulinen, J., Burova, A., Ronkainen, K., Keskinen, T., and Mäkelä, J., forming a densely connected red network at the center of the visualization. Other notable clusters involve the blue grouping of Fiorentino, Michele and Gattullo, Michele in the upper right, and the green cluster with Bai, Xiaoliang, Liu, Wei, and He, Weiping in the upper center. Additional collaborations are visible with Al-harkan, I.M. and Alhag, M.H. (yellow nodes), as well as isolated researchers like Romero, I. and Yu, H. distributed around the periphery.

The size of each author's node represents their relative influence and contribution to the primary studies, based on the number of co-authored publications within this subset of literature. The links between authors signify collaborative relationships. The proximity of authors within the visualization suggests thematic or institutional similarities in their research within the scope of this review.

F. Keywords Co-occurrence Analysis

A co-occurrence analysis of keywords from the 95 primary studies was conducted using VOSviewer to identify the main themes in XR research for industrial maintenance. With a minimum threshold of three occurrences, 25 out of 564 keywords were selected for visualization.

The co-occurrence network (see Fig. 3) reveals clusters centered around "augmented reality," "industrial maintenance," and related concepts such as "maintenance operations," "human computer interaction," and "industry 4.0." The strong connection between "augmented reality" and "industrial maintenance" highlights the significance of AR in this domain. By using VOSviewer, the keyword "augmented reality" is the most frequent keyword (56 occurrences), followed by " maintenance" (34), " industrial maintenance" (33), and "virtual reality" (29). These results underscore the pivotal importance of AR and VR technologies in industrial maintenance research.

The analysis provides an overview of key themes and their interconnections, underlining the importance of human factors, performance optimization, and the integration of XR with Industry 4.0. This offers critical perspectives for understanding prevailing research patterns and identifying promising areas for investigation in XR for industrial maintenance.

III. Extended Reality in Industrial Maintenance: Research Results

A. Literature Analysis

1) Publications per year: Fig. 4 shows the number of selected primary papers on XR in industrial maintenance from 2014 to 2025. There is an overall upward trend, indicating growing research interest. The count of publications increased from 1 paper in 2014 to a peak of 13 papers in 2018. This was followed by a slight decline to 10 papers in both 2019 and 2020. The year 2021 saw a resurgence with 12 papers, followed by a decrease to 8 papers in 2022. Research output rebounded to 10 papers in 2023 and peaked again at 13 papers in 2024, matching the previous high from 2018. The data for 2025 shows only two papers, as the data collection period ended early in the year. The trend suggests sustained interest in XR research for industrial maintenance over the past decade, with consistently significant output from 2018 onwards despite some year-to-year fluctuations.

2) Publications per database: Fig. 5 illustrates the distribution of the selected primary papers across three databases: Scopus, ScienceDirect, and Web of Science. ScienceDirect contributes the largest portion of the papers at 51.6% (49 papers) of the total collection. Scopus accounts for a similar but slightly smaller proportion at 46.3% of the papers (44 papers). Web of Science appears to be minimally represented, accounting for only 2.1% of the total (2 papers). However, this underrepresentation can be attributed to the duplication removal process conducted using Zotero. A considerable number of papers from Web of Science were merged with their duplicates from Scopus and ScienceDirect. The decision to prioritize the Scopus and ScienceDirect versions of duplicated

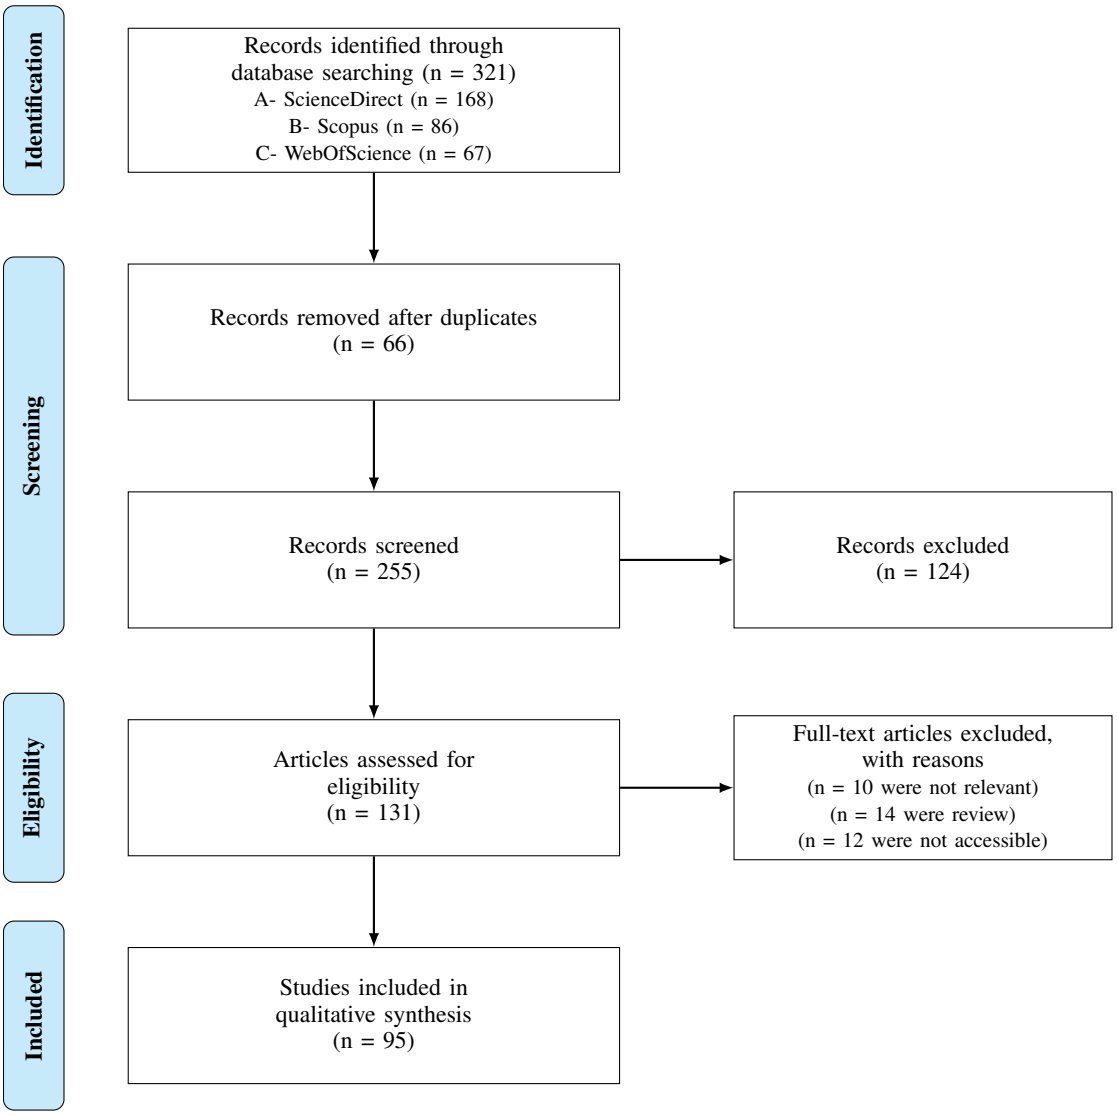

Fig. 1. The selection and filtering of primary studies (PRISMA flow diagram).

papers was based on the fact that these databases provide more extensive metadata, which facilitates and accelerates the analysis process. Consequently, the low percentage of papers from Web of Science does not necessarily reflect the database's actual contribution to the research on XR in industrial maintenance.

3) Publications per reference type: Fig. 6 illustrates the distribution of primary papers by reference type, categorized into journal articles, conference papers, and book chapters. Journal articles constitute the clear majority at 73.7% of the total, reflecting a strong preference for publishing XR research in peer-reviewed journals, which are generally seen as having a more rigorous review process and greater impact. Conference papers account for 25.3% of the publications, providing a platform for the rapid dissemination of knowledge and scholarly interaction. Book sections make up a minor portion at just 1.1% of the total. This distribution highlights the diverse avenues through which XR research in industrial maintenance is disseminated within the scientific community, while underscoring the predominance of journal publications in this field.

4) Publications per publication venues: Fig. 7 shows the distribution of papers across the top 10 publication venues. The most prominent sources include:

- Applied Sciences (Switzerland) journal (6 papers)
- Computers in Industry journal (6 papers)
- Advanced Engineering Informatics journal (4 papers)
- Lecture Notes in Computer Science Series (4 papers)
- Robotics and Computer-Integrated Manufacturing journal (4 papers)
- 16th IFAC Symposium on Information Control Problems in Manufacturing (3 papers)

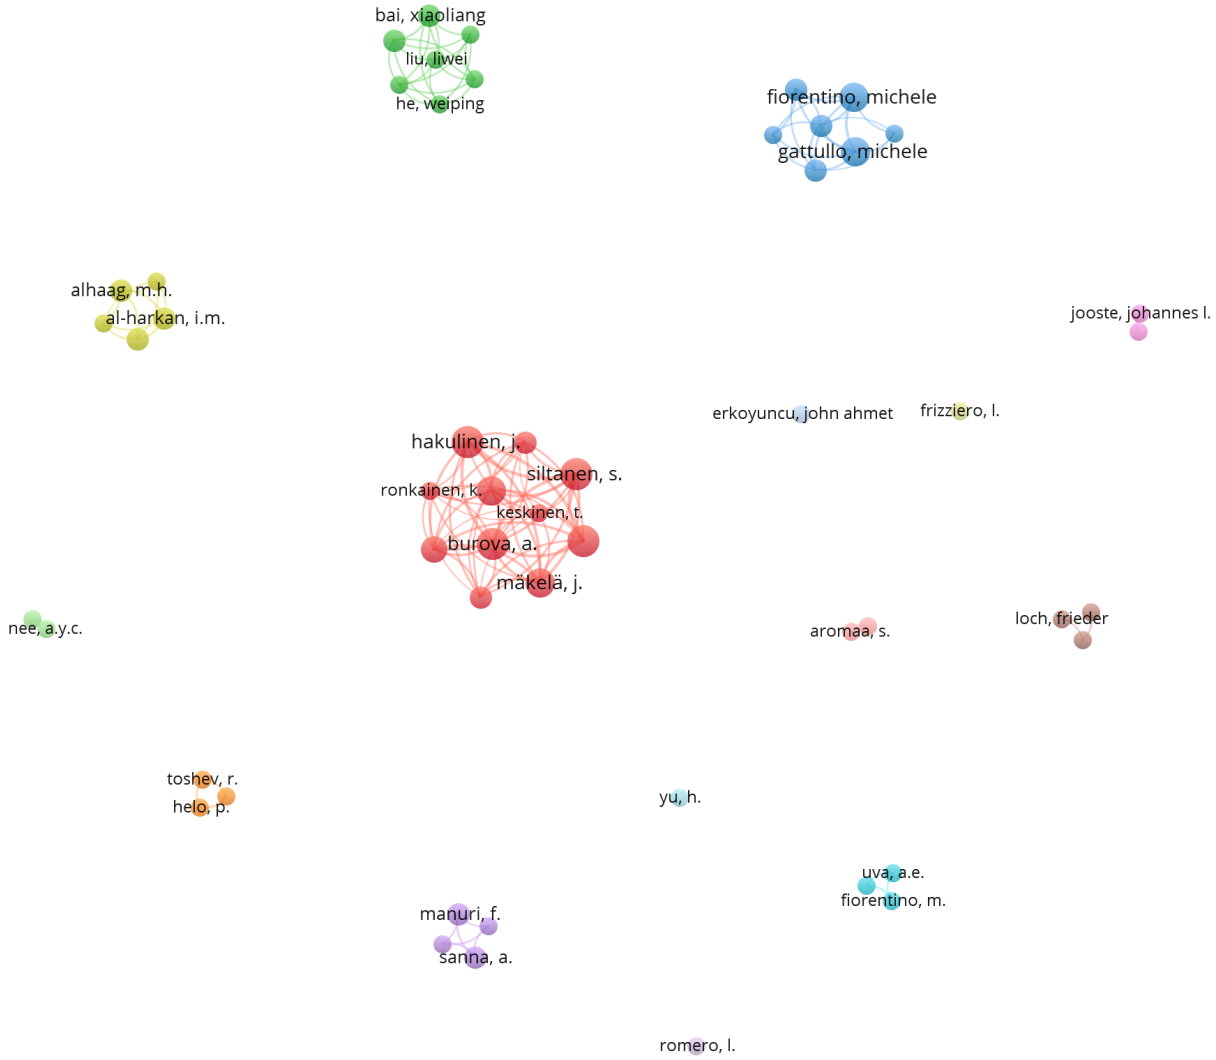

Fig. 2. Bibliometric map of co-authorship from VOSviewer using author names.

- 27th International Conference on Production Research (3 papers)
- 56th CIRP International Conference on Manufacturing Systems (2 papers)
- ACM International Conference Proceeding Series (2 papers)
- Applied Ergonomics journal (2 papers)

The distribution reveals that both specialized industrial and manufacturing journals, as well as computer science publications, serve as essential platforms for XR in industrial maintenance research. The relatively even distribution across these top venues indicates a multidisciplinary research landscape, with papers appearing in publications covering diverse areas, including applied sciences, computer science, engineering informatics, robotics, manufacturing, and ergonomics.

B. Extended Reality in Industrial Maintenance

1) Current state of extended reality in industrial maintenance: The analysis of 95 studies reveals a diverse and rapidly evolving landscape of extended reality (XR) technologies in industrial maintenance. This subsection outlines the key findings regarding the current state of these technologies.

a) Prevalence and distribution of XR technologies: The analysis of XR technology adoption across the 95 primary studies reveals clear patterns in the prevalence and distribution of different reality technologies in industrial maintenance applications. Fig. 8 presents the overall distribution of XR technologies identified in the literature.

Augmented Reality (AR) emerges as the dominant technology, appearing in 68 studies (71.6% of the total), making it the most widely adopted XR technology for industrial maintenance applications. Studies [2], [3] showcase AR's effectiveness in providing visual instructions for maintenance tasks, while studies [4], [5] highlight its use in enhancing worker performance and reducing errors. Virtual Reality (VR) is the second-most

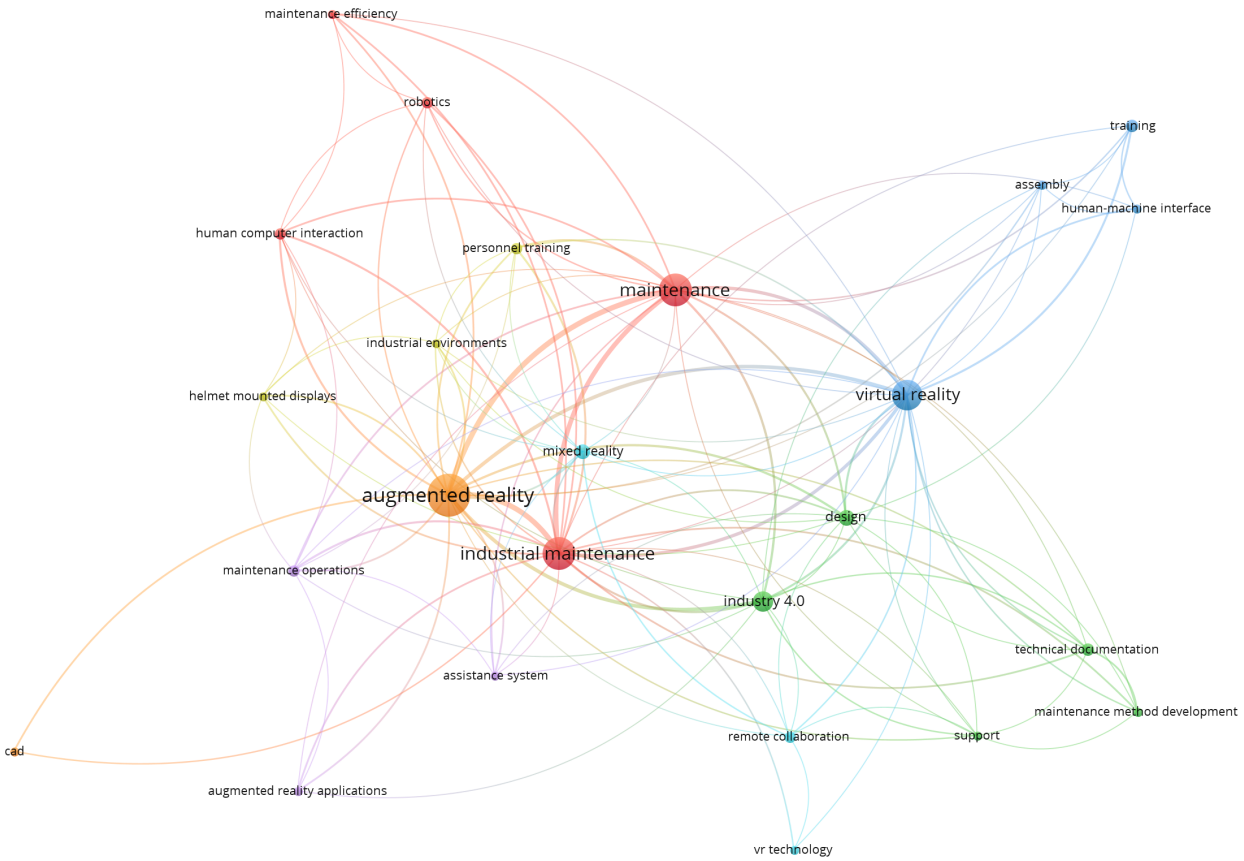

Fig. 3. Bibliometric map of author keywords from VOSviewer.

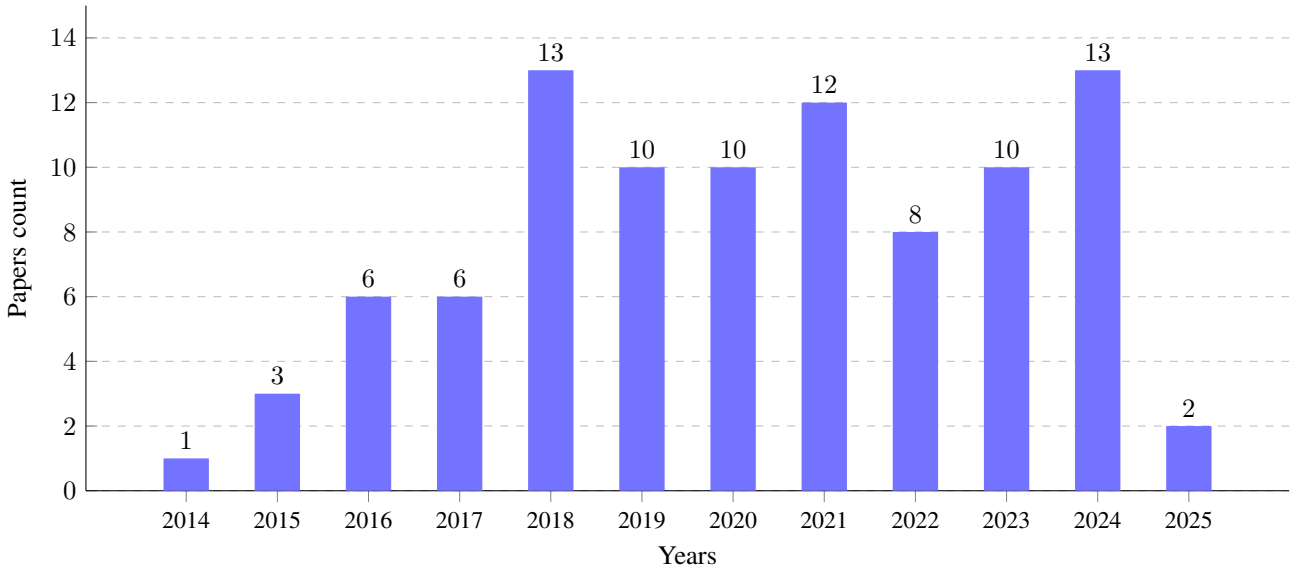

Fig. 4. Number of primary papers per year.

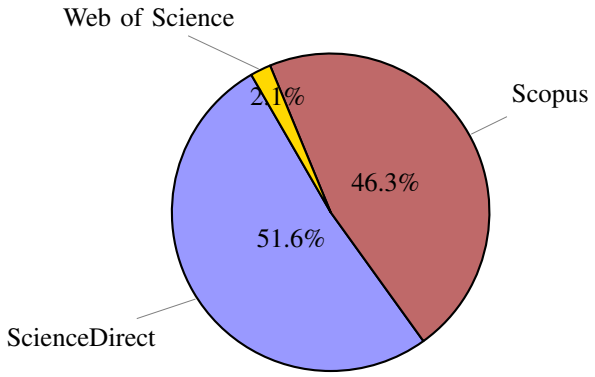

Fig. 5. Number of primary papers per database.

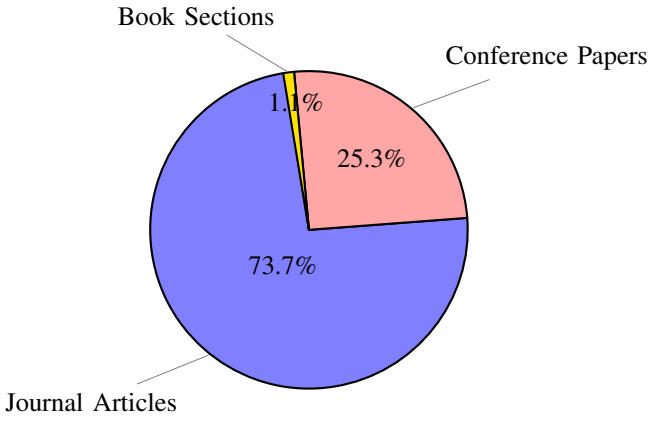

Fig. 6. Number of primary papers per reference type.

prevalent technology, used in 37 studies (38.9%). Studies [10], [12], [13] illustrate VR's capacity to create immersive, risk-free environments for maintenance personnel to practice complex procedures. Mixed Reality (MR) appears in only 6 studies (6.3%). Studies [68], [70], [71] demonstrate MR's potential to bridge the gap between on-site technicians and remote experts, facilitating real-time guidance and problem-solving.

A small number of papers (3, representing 3.1%) explicitly use the term "Extended Reality" (XR) in their work, typically in studies that present conceptual frameworks or methodologies applicable across multiple reality technologies. 1 paper in our dataset mentioned augmented virtuality as technology.

It is worth noting that 14 studies (14.7%) employed multiple XR technologies within the same research, with the most common combination being AR+VR (7 studies). Notably, three studies [10], [34], [70] incorporated all three main technologies (AR+VR+MR) in their work, with study [34] integrate them along with explicit XR framework development. This trend toward multi-technology approaches highlights the complementary nature of different XR modalities and suggests a growing interest in comprehensive XR ecosystems for maintenance applications.

C. Temporal Trends in XR Technology Adoption

The chronological analysis of XR technology adoption reveals significant trends in the field's evolution (Fig. 9). The three evolutionary phases were delineated based on a combination of qualitative thematic shifts and observable inflection points in the data. The boundary between Phase 1 and Phase 2 (2017–2018) corresponds to the sharp increase in publication volume (from 6 to 13 papers) and the emergence of cognitive enhancement as a research focus, coinciding with the commercial availability of Microsoft HoloLens and its rapid adoption in industrial AR studies. The boundary between Phase 2 and Phase 3 (2021–2022) aligns with the appearance of AI-integrated systems and automatic content generation approaches in the literature, reflecting the broader convergence of XR with machine learning and IoT technologies. These boundaries are therefore informed by convergent technological, thematic, and bibliometric indicators rather than purely statistical criteria. Early research (2014-2017) showed a strong preference for AR, which dominated the initial studies in industrial maintenance. Study [22] represents the first comprehensive AR implementation for maintenance tasks in our dataset, focusing on providing visual guidance on a screen-based video see-through AR system for motorcycle engine maintenance.

From 2017 onward, there was a noticeable increase in VR adoption, with powerful representation in 2018, 2021, and 2024. The years 2021-2022 mark a potential inflection point, where VR studies temporarily equaled or exceeded AR studies in quantity. Study [10] exemplifies this trend, presenting a VR-based methodology for assessing cognitive conditions during assembly training.

Mixed Reality, representing the most recent technological evolution in the reality continuum, first appeared in our dataset in 2020 [8] and has shown consistent but limited adoption through 2024. This slower uptake may reflect the nascent state of MR technology and its development ecosystem compared to more established AR and VR platforms.

The most recent years (2023-2025) have seen a renewed interest in AR applications, a diversification of technology approaches with more MR studies, and an increasing mention of XR as an overarching concept. This evolution suggests the field is moving toward a more integrated view of reality technologies while maintaining a strong interest in application-specific implementations.

D. Technology Distribution by Research Focus

The prevalence of specific XR technologies correlates strongly with the primary research focus and application context. AR dominates in studies focused on real-time guidance [15], [21], [27], [41], [43], maintenance instructions [22], [25], [26], [36], and on-site assistance [5], [7], [9]. This aligns with AR's fundamental capability to overlay digital information on real-world equipment, making it particularly suited for in-situ maintenance support.

VR is predominantly employed in studies focused on training and simulation of maintenance procedures [10], [30], [35], [48], [50], [63], [67], [64] and collaborative design reviews [11], [13], [32]. The immersive nature of VR creates controlled, risk-free environments that are ideal for skill development and scenario-based learning before interacting with physical equipment.

Mixed Reality applications appear most frequently in studies focusing on remote collaboration and tasks requiring so-

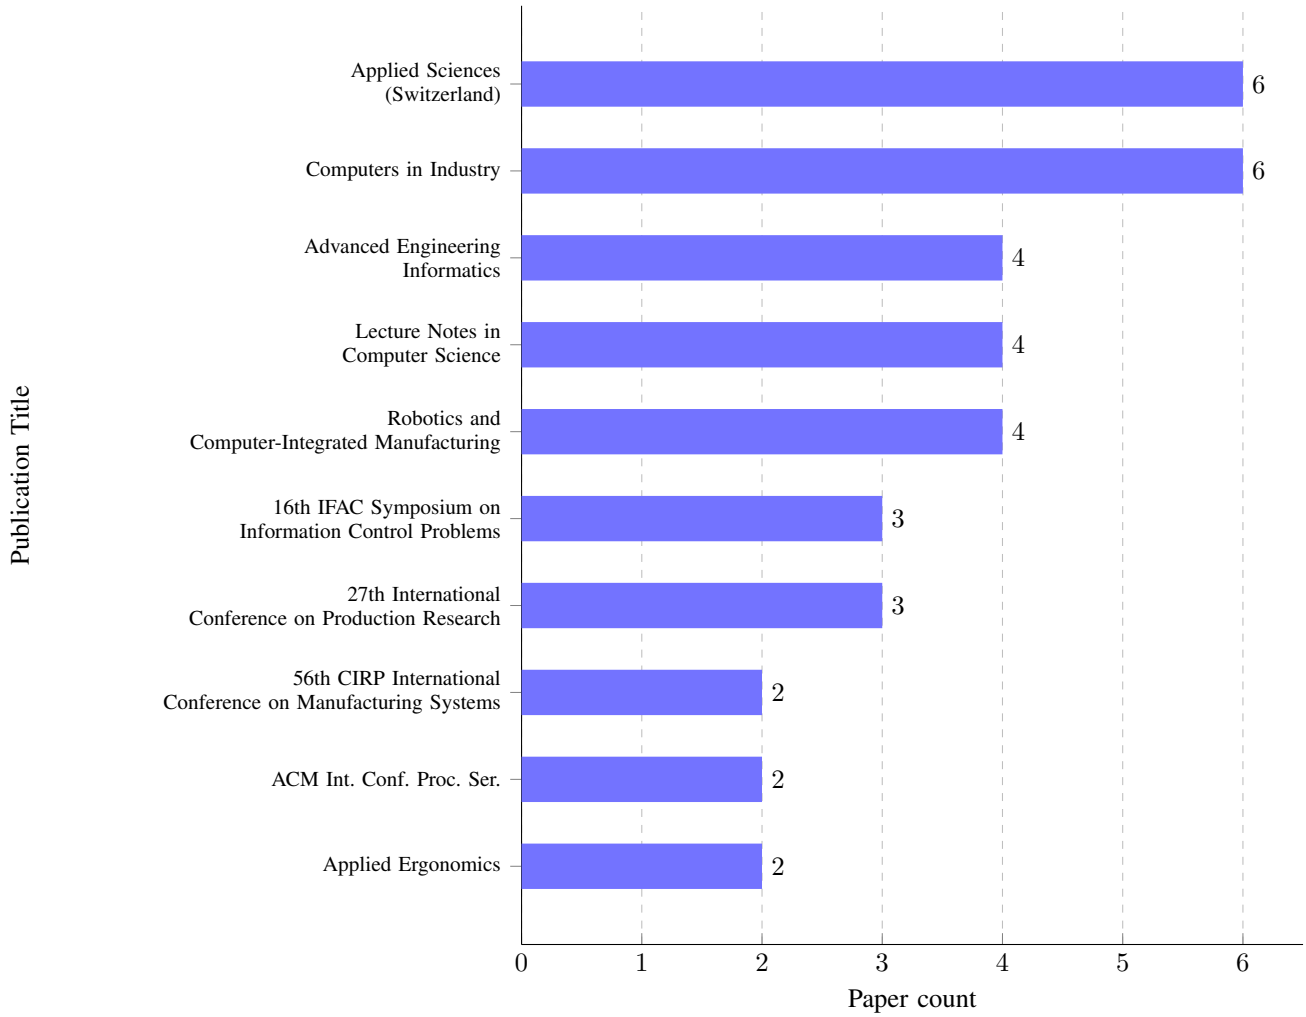

Fig. 7. Number of primary papers per publication venues.

phisticated spatial understanding [8], [14], [68], [70], [71]. The combination of real-world anchoring with immersive virtual elements makes MR particularly effective for collaborative troubleshooting and complex spatial tasks.

The chronological and application-based distribution patterns reflect both technological evolution and the maturing understanding of which XR technology best suits specific maintenance contexts. This suggests that industrial maintenance is shifting toward a task-specific application of XR technologies, rather than a one-size-fits-all approach.

1) Hardware trends: The analysis of hardware platforms across the reviewed studies reveals clear preferences and evolutionary trends in the adoption of XR devices for industrial maintenance applications. Table I presents the distribution of hardware platforms identified in the primary studies.

E. Head-Mounted Displays (HMDs)

Head-mounted displays represent the most frequently utilized hardware category in industrial maintenance applications, with Microsoft HoloLens being the dominant platform, mentioned in 18 studies. First appearing in our dataset in 2017 [21], HoloLens quickly established itself as the preferred option for industrial AR implementations, particularly for hands-free maintenance guidance [33], [60], [62], [66]. The prevalence of HoloLens can be attributed to its enterprise focus, robust tracking capabilities, and integrated computing power, making it suitable for industrial environments.

For VR applications, the HTC Vive headset emerged as the primary choice in four studies [12], [48], [64], [77], with limited mentions of other platforms, such as the Valve Index [8] and Oculus/Meta devices [79]. Study [8] represents an interesting case where a Valve Index headset was utilized for remote teleoperation of a mobile manipulator robot in cleanroom environments, highlighting the adoption of high-end consumer VR hardware for specialized industrial applications.

The temporal analysis of HMD adoption shows a distinct evolution in hardware preferences. Early studies (2014-2016) primarily employed non-HMD approaches, such as projector-based systems [22]. From 2017 onward, we have observed a clear shift toward head-mounted solutions, characterized by increasing sophistication in tracking and display capabilities. Studies [2], [3], [4], [75] illustrate the recent trend toward using HMDs to reduce task completion time, mental workload, and

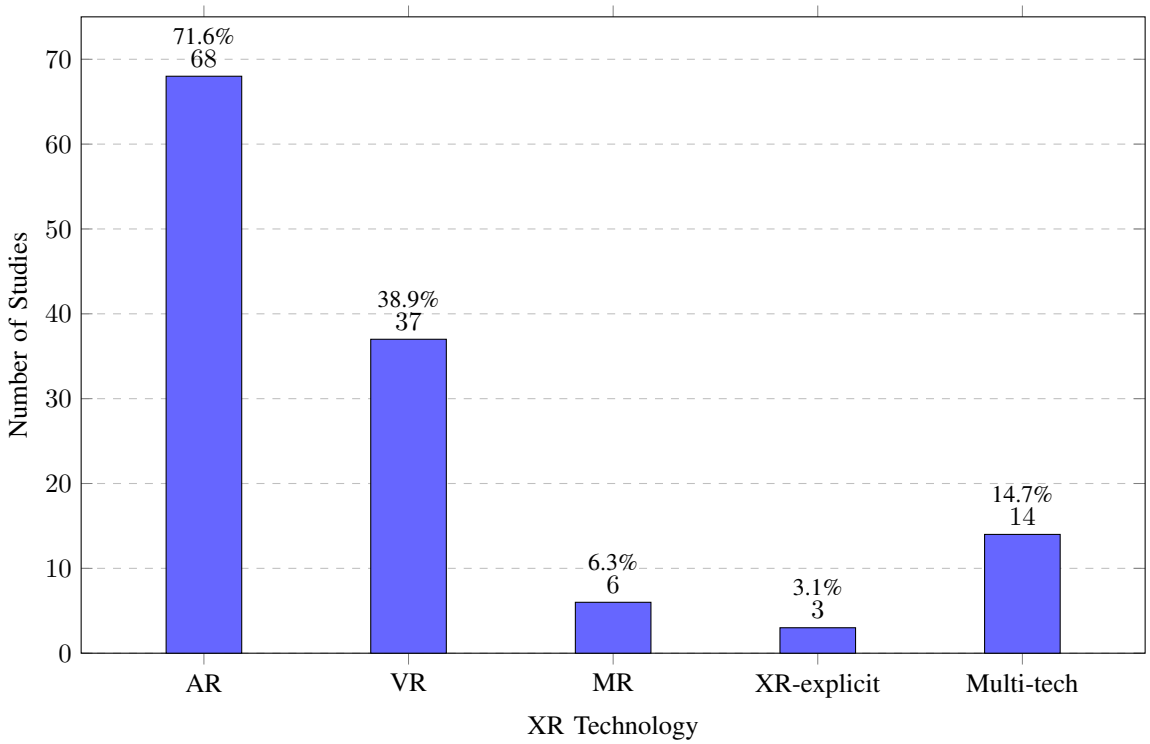

Fig. 8. Distribution of XR technologies across 95 primary studies. Percentages sum to over 100% as 14.7% of studies employed multiple technologies simultaneously.

improve cognitive processing for complex tasks.

F. Handheld Devices

Tablets (9 studies) and smartphones (6 studies) constitute the second most common hardware category, particularly prevalent in AR implementations where hands-free operation is not critical. Study [31] compared the effectiveness of AR on smart glasses (Vuzix M100) with AR on tablets, finding that smart glasses performed better in metrics such as completion time (-13% vs. -3% compared to paper) and scored higher in usability ratings and operator reliance. At the same time, both AR solutions demonstrated similar benefits in reducing errors compared to paper-based instructions. Studies [45], [69] illustrate the use of these devices, highlighting their advantages in terms of accessibility and user familiarity.

The temporal distribution shows consistent use of handheld devices throughout the review period, with notable spikes in 2016, 2018, and 2024. This persistent adoption of handheld solutions, even as HMDs became more sophisticated, suggests that different form factors serve complementary roles in industrial maintenance. Study [33] explicitly explored this complementarity by proposing a multi-device assistive system that leverages the strengths of both HMDs and handheld devices across different maintenance phases.

G. Other Hardware Platforms

Several supplementary hardware technologies appear in the reviewed studies, with haptic devices (6 studies) being the most prominent. Early implementations [1] utilized dedicated haptic systems like the Phantom Desktop, while more recent studies [39], [48] integrate haptic feedback with VR environments to enhance training realism.

Projector-based AR systems (4 studies) represent an alternative approach that avoids the need for personal displays entirely. Study [37] presents a portable camera-projector system for telemaintenance that enables spatially-registered annotations projected directly onto the work environment. This approach offers advantages in collaborative settings where multiple technicians need to view the same augmented workspace simultaneously.

Motion tracking technologies like Leap Motion controllers (2 studies) appear in applications requiring precise hand interaction, particularly for VR-based training systems [48], [49], [50]. These technologies enable natural gesture-based interaction with virtual environments, enhancing the realism of maintenance simulations.

H. Hardware Evolution and Limitations

The evolution of hardware platforms over the review period (2014-2025) reflects broader technological trends in the development of XR. Early studies employed more experimental or custom hardware configurations, whereas recent research has increasingly leveraged commercial off-the-shelf solutions with standardized development environments.

Several studies [5], [7], [15], [55], [59], [60], [62], [72] explicitly discuss hardware limitations as significant challenges, particularly regarding the limited field of view, ergonomic issues with prolonged use, and environmental constraints in industrial settings. Study [31] notes specific issues with smart

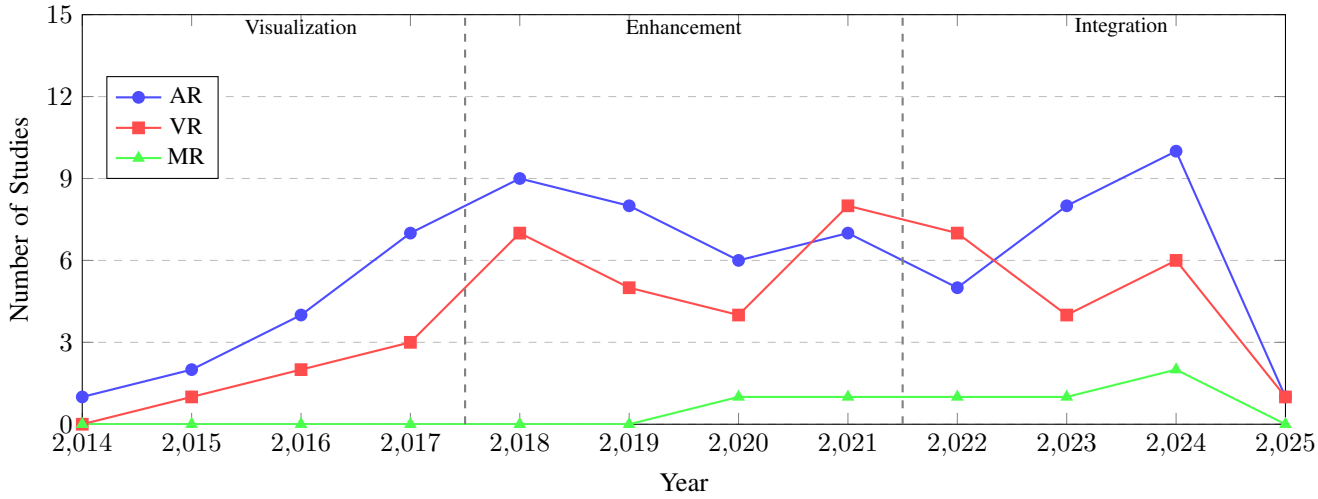

Fig. 9. Temporal evolution of XR technologies in industrial maintenance (2014-2025), showing three distinct evolutionary phases.

glasses, including comfort problems and a restricted screen size, which makes augmentations difficult to distinguish. This can cause users to close one eye to see correctly and requires constant visual focus switching, leading to visual strain.

The hardware trends suggest an industry in transition, with increasing standardization around enterprise-focused platforms, such as HoloLens for AR applications and HTC Vive for VR applications, while maintaining a pragmatic approach to device selection based on specific maintenance contexts and requirements.

1) Software and development: The software platforms, development frameworks, and implementation approaches used across the reviewed studies reveal essential patterns in how XR technologies are being integrated into industrial maintenance applications. This subsection examines the prominent software trends identified in the literature (Table II).

I. Development Platforms and Game Engines

Unity (identified in 18 studies) emerges as the dominant development platform across all XR technology types, serving as the foundation for applications in AR, VR, and MR. Its prevalence can be attributed to its cross-platform capabilities, extensive asset ecosystem, and relatively accessible learning curve. Study [1] used Unity to develop a haptic virtual reality platform for assembly tasks, while study [46] employed it to create an AR application for providing adaptive instructions for machine operation tasks. Study [12] also exemplifies the typical Unity-based development approach, utilizing the platform to create a VR system with AR simulation and gaze tracking for prototyping industrial maintenance solutions.

Unreal Engine appears in significantly fewer studies (only 1 explicit mention), despite its reputation for high-fidelity graphics and robust performance. Study [64] uses Unreal Engine 4 to develop a VR application for power plant maintenance training, suggesting that this engine may be preferred for applications requiring advanced visual fidelity.

The preference for Unity across the majority of studies indicates a maturation of the development ecosystem, where researchers and developers increasingly leverage established platforms rather than developing custom solutions from scratch. This standardization facilitates more rapid prototyping and reduces technical barriers to XR implementation in industrial contexts.

J. AR/VR Software Development Kits (SDKs)

Vuforia emerges as the most widely utilized AR SDK (6 studies). Studies [15], [21], [79] utilized Vuforia in combination with Unity to implement visual tracking and registration for maintenance tasks. The prevalence of Vuforia aligns with its established position in the AR development ecosystem, extensive documentation, and relatively stable performance across different deployment scenarios.

Other SDKs appear less frequently but highlight the diversification of development approaches. OpenXR and SteamVR in [81] represent newer standards-based approaches to VR development, while Microsoft's Mixed Reality Toolkit (MRTK) appears in [75] focused on HoloLens applications. Study [81] specifically mentions a combination of OpenXR, XRInteractionToolkit, and SteamVR packages within Unity, illustrating the trend toward utilizing multiple complementary frameworks within a single development environment.

K. Programming Languages and Technical Approaches

Specific programming languages receive relatively few explicit mentions in the methodology sections of the reviewed studies. Python (3 studies) is the most frequently cited, particularly in studies involving machine learning components or data processing pipelines [69], [74], [75]. C++ and C# are also used as programming languages with lower frequency, 1 explicit mention each [1], [34], with C# specifically appearing in a study focused on XR-based serious game development for Compressed Air System (CAS) maintenance training, where it was paired with the Unity development platform to create an immersive learning experience that incorporated 3D models and the XR Interaction Toolkit [34]. Study [1] presents a more complex development approach, combining OpenHaptics, PhysX, and OpenGL/GLUT libraries to create a haptic

TABLE I. OVERVIEW OF HARDWARE PLATFORMS USED IN XR-BASED INDUSTRIAL MAINTENANCE APPLICATIONS (2014–2025).

Category	Dominant Platforms (Count)	Primary Application Patterns
Head-Mounted Displays (HMDs)	• Microsoft HoloLens (18) • HTC Vive (4) • Valve Index (1) • Oculus/Meta devices (1)	• **HoloLens:** Dominant standard for hands-free AR maintenance guidance. • **HTC/Oculus:** Primarily used for immersive VR training simulations. • **Valve:** Specific usage for remote teleoperation in cleanrooms.
Handheld Devices	• Tablets (9) • Smartphones (6)	• **Tablets/Smartphones:** AR implementations where hands-free operation is not critical like inspection tasks requiring larger visual interfaces.
Supplementary Technologies	• Haptic devices (6) • Projector-based AR (4) • Motion tracking (2)	• **Haptics:** Integrated to enhance physical realism in VR training. • **Projectors:** Used for collaborative telemaintenance without wearable gear. • **Tracking:** Leap Motion used for natural gesture-based interactions.

VR platform for assembly planning and assessment. Such multi-library implementations are less common in more recent studies, suggesting a shift toward more integrated development environments that encapsulate these functionalities.

L. Content Authoring Approaches

A notable trend across the reviewed studies is the increasing focus on content authoring approaches that simplify the creation of XR maintenance applications without requiring extensive programming expertise. Studies [21], [23], [56], [58], [69], [72] present frameworks or methodologies specifically designed to enable non-technical domain experts to create and manage XR content for maintenance tasks.

Study [69] exemplifies this trend with an automatic content creation system for AR maintenance applications that extracts information from electronic manuals to generate AR-ready content accessible via QR codes. Similarly, the study [56] presents the INTERVALES framework that simplifies AR/VR content authoring for industrial applications by providing a modular architecture that supports both IT developers and domain experts.

This evolution toward simplified content creation constitutes a significant advancement in the practical deployment of XR in industrial maintenance, addressing a primary obstacle to implementation identified in earlier research — the high technical expertise traditionally required to develop and maintain XR applications.

M. Integration with Industrial Systems

The incorporation of XR applications into established industrial systems and information infrastructure represents an emerging focus area in more recent studies. Several papers [33], [38], [41], [45], [53] discuss approaches for connecting XR applications with industrial IoT systems, databases, and enterprise asset management systems.

Study [38] presents an integrated approach combining IoT, machine learning, and AR within a comprehensive predictive maintenance framework. Similarly, study [79] demonstrates a unified platform integrating IoT, analytical processing, AR, and VR technologies to support equipment surveillance and maintenance. These integrated approaches represent a maturation of the field, moving beyond isolated XR implementations toward more holistic solutions that leverage multiple complementary technologies.

The software and development trends reflect an industry transitioning from experimental proof-of-concept implementations toward more standardized and integrated approaches, with increasing emphasis on reducing technical barriers to adoption and enhancing integration with existing industrial ecosystems.

1) Application areas: The analysis of primary studies reveals distinct patterns in the application of XR technologies across maintenance tasks and scenarios in industrial environments. This subsection categorizes and examines the primary application areas identified in the literature, as summarized in Fig. 10.

N. Procedural Guidance and Task Assistance

Providing step-by-step guidance for maintenance procedures was the most prevalent application area (41 studies, 43.1%), with Augmented Reality the predominant technology in this domain. AR's ability to overlay digital information directly onto physical equipment makes it particularly suited for procedural guidance.

Studies [4], [15], [22], [27], [43], [75] showcase AR's application for guiding users through maintenance procedures with visual overlays. Study [22] demonstrates an early implementation using a screen-based video see-through AR system for motorcycle engine maintenance, reporting a 38% improvement in completion time and 92.4% reduction in error rate compared to traditional paper manuals. Recently, study [75] developed the TAGGAR system, which focuses on providing AR task guidance for procedural maintenance tasks by rendering virtual hand animations that demonstrate required

TABLE II. SUMMARY OF SOFTWARE TRENDS AND DEVELOPMENT FRAMEWORKS

Category	Dominant Tech	Key Implementation Patterns	Refs.
Game Engines	Unity, Unreal Engine	• Unity is dominant (18 studies) due to cross-platform assets. • Unreal used specifically for high-fidelity needs. • Shift from custom engines to standardized platforms.	[8], [12], [15], [21], [27], [29], [34], [46], [48], [50], [57], [65], [74], [75], [77], [79], [80], [81], [64]
SDKs	Vuforia, OpenXR, MRTK	• Vuforia remains the standard for visual tracking. • Adoption of OpenXR/MRTK reflects a move toward open standards and specific HoloLens optimization.	[15], [21], [29], [57], [73], [75], [79]
Languages	Python, C#, C++	• Python: Used for ML and data pipelines. • C#: Primary language for Unity-based interaction. • C++: Usage declining; mostly for legacy or haptic libraries.	[1], [34], [69], [74], [75]
Authoring	Low-code Frameworks	• Focus on simplifying creation for non-technical experts. • Automated content generation from manual data (e.g., QR codes).	[21], [56], [69]
Integration	IoT, EAM, Cloud	• Move from isolated apps to holistic ecosystems. • Integration with live IoT data and predictive maintenance systems.	[38], [45], [79], [81]

actions. This enables AR-based guidance for tasks such as pressing buttons, twisting knobs, pulling objects, and picking up/placing items.

The presentation modalities for procedural guidance have evolved considerably over the review period. Early studies primarily used text and simple 2D graphics, whereas more recent research has explored 3D animations [4], standardized graphical symbols [25], [26], [61], and context-aware adaptive interfaces [15], [21], [55]. Study [36] explicitly compares three different AR presentation modes for maintenance instructions in blind areas, finding that in-situ 3D presentations with X-ray rendering outperform 3D side-by-side in terms of completion time.

Several studies [21], [46], [47], [65], [76], [78] focus on adapting the level of guidance to match user expertise and task complexity. Study [47] proposes a system that combines collaborative robotics and AR, designed to accommodate workers with different experience levels through robotic assistance and AR guidance in car panel fitting operations. Study [76] introduces an approach to developing Augmented Reality-based Adaptive Assistance Systems (ARAAS) that adapt content to operator characteristics.

O. Training and Skill Development

Training is the second most common application area (mentioned in 32 studies, 33.6%), serving as a cornerstone use case for XR technologies in industrial maintenance. The engaging and interactive characteristics of XR environments offer a safe, controlled space for skill development without the risks or resource constraints of real-world training scenarios.

Virtual Reality dominates the training domain, with studies [10], [30], [35], [63], [64], [77] showcasing comprehensive VR-based training systems for various maintenance procedures. Study [35] demonstrates how VR training enhances performance in intricate industrial assembly tasks compared to traditional methods, showing improved performance and training permanency. Similarly, study [77] compares VR-based training with traditional paper-based approaches for wiring electric motors, reporting a 10% improvement in task completion time.

Augmented Reality training applications focus more on in-situ guidance and real-time skill development. Study [29] presents an AR mobile application for training on CNC lathe maintenance and repair, highlighting improved student motivation and learning outcomes. The hybrid approach of using AR during actual maintenance tasks blurs the line between training and operational support, as illustrated in study [17], which compares AR, VR, and video-based training for manual assembly tasks.

More recent studies [80], [81] demonstrate an evolution toward more sophisticated training approaches, incorporating game-based elements, adaptive difficulty, and integration with real equipment data. Study [80] introduces an XR-based serious game for compressed air system maintenance, while study [81] presents a modular framework for developing VR environments to enhance safety training during human-robot collaboration scenarios.

P. Assembly and Disassembly Support

Assembly and disassembly tasks appear as specific focus areas within the broader maintenance domain, with assembly operations mentioned in 24 studies (25.2%) and disassembly processes in 5 studies (5.2%). These complementary processes represent fundamental maintenance activities that benefit significantly from XR guidance.

AR dominates dis/assembly support applications, as demonstrated in studies [4], [16], [24], [41], [57], [59]. Study [41] introduces an AR solution that facilitates the assembly of multi-stage rotors used in turbine-based combined-cycle engines. Study [16] presents an AR-assisted framework for product disassembly (ARDIS) to improve efficiency in product maintenance and remanufacturing processes. Similarly, study [24] applies Design for Disassembly (DfD) principles with AR visualization to optimize the disassembly process for industrial components.

VR applications in this domain focus more on planning, verification and simulation aspects of assembly/disassembly. Study [1] presents a haptic VR platform for planning, performing and assessing virtual assemblies, providing force feedback and realistic part behavior. Study [67] introduces a multimodal system for verifying assembly procedures and product design in VR using CAD models and haptic feedback.

Mixed Reality applications for assembly tasks appear in studies [68], [70], with a particular focus on remote collaboration scenarios. Study [70] presents an adaptive MR remote collaboration system that provides clear, detailed, and spatially correct instructions for assembly tasks, demonstrating improved performance and reduced workload compared to a typical remote collaboration interface called RECI.

Q. Remote Assistance and Collaboration

Remote expert support and collaborative maintenance emerged as a significant application area (22 studies, 23.1%), reflecting the growing importance of distributed work and knowledge sharing in industrial settings. All three major XR technology types (AR, VR, and MR) are well-represented in this domain, each offering distinct advantages.

AR-based remote assistance systems are demonstrated in studies [7], [9], [37], [66], with study [37] presenting a projector-based AR system for telemaintenance that enables bidirectional spatial communication between remote experts and on-site technicians. AR's ability to provide spatially-anchored guidance in the real environment makes it particularly effective for remote support scenarios. VR-based collaborative environments have been explored in studies [11], [13], [14], [32], focusing on shared virtual spaces for maintenance planning and knowledge exchange. Study [32] examines the application of collaborative VR for reviewing maintenance documentation and assessing risk, highlighting numerous benefits for globally distributed teams.

The most sophisticated remote collaboration approaches utilize Mixed Reality, as shown in studies [68], [70], [71]. Study [70] presents an MR remote collaboration system (AGICA) that supports adaptive instruction generation based on context awareness, while study [71] introduces a novel MR system that enables remote experts to create 3D models for annotating spatial areas with visual notifications about interactions.

R. Inspection and Diagnostic Support

Inspection tasks (5 studies, 5.2%) and diagnostic/troubleshooting support (3 studies, 3.1%) represent more specialized application areas where XR technologies augment human perceptual and analytical capabilities. These applications often combine XR with additional sensing modalities or analytical tools.

Study [20] presents an innovative system (AROD) that combines AR with an electronic nose (e-nose) for odor detection during maintenance, displaying relevant information to detected odors via a HoloLens headset. Similarly, study [51] introduces MANTRA, a novel AR system that combines AR and infrared thermography for industrial maintenance, automatically aligning virtual information and temperature data with 3D objects.

In the inspection domain, study [41] presents an AR-based system for guiding the assembly of multi-stage rotors, incorporating measurement equipment to provide real-time visual assembly guidance tailored to precision requirements. Study [76] applies an adaptive AR assistance system specifically to landing gear inspection operations, highlighting areas to measure and displaying corresponding tolerance values, resulting in reduced execution time and improved information access.

Recent studies indicate an increasing integration of XR with other Industry 4.0 technologies to enhance diagnostic capabilities. Study [53] presents a methodology for automatic segmentation and analysis of anomalies in solar PV modules using unsupervised sensing algorithms coupled with 3D AR visualization. Study [79] demonstrates an integrated system combining IoT, data analysis, AR and VR for equipment monitoring and maintenance, enhancing predictive maintenance capabilities and operational efficiency.

The literature identifies diverse and evolving XR use cases in industrial maintenance. While specific applications, such as training and procedural guidance, are well-established across the review period, newer applications, including integrated diagnostic systems and adaptive assistance frameworks, represent emerging trends that leverage XR's capabilities in increasingly sophisticated ways.

S. Advantages of Extended Reality in Industrial Maintenance

The analysis of primary studies reveals five major categories of advantages associated with XR technologies in industrial maintenance contexts, as summarized in Table III. These benefits collectively demonstrate the transformative potential of these technologies across various aspects of maintenance operations.

1) Efficiency and performance improvement: Improved operational efficiency represents one of the most frequently cited advantages of XR technologies. AR applications consistently demonstrate significant time savings in maintenance execution. Study [22] reports a 38% improvement in completion time for motorcycle engine maintenance tasks compared to traditional paper manuals. Study [76] presents a methodology for designing Augmented Reality-based Adaptive Assistance Systems (ARAAS). The system supports inspection operations of landing gear components during maintenance, repair, and overhaul (MRO) activities, resulting in a 10% reduction in total inspection time.

The efficiency gains are pronounced for complex maintenance tasks as well. Study [2] demonstrates that AR instructions significantly reduce task completion time, particularly for complex maintenance activities, whereas they have a smaller impact on simpler tasks. Similarly, study [3] shows that task completion time is reduced with AR-based instruction methods compared to paper-based methods, especially for complex tasks involving a piston pump system. This finding suggests that escalating benefits occur as task complexity increases — a valuable characteristic in industrial environments, where complex procedures pose the most significant challenges.

The cost implications of these efficiency improvements stem from decreased downtime [7], [11], reduced travel requirements for experts [7], [9], [11], and more efficient use of

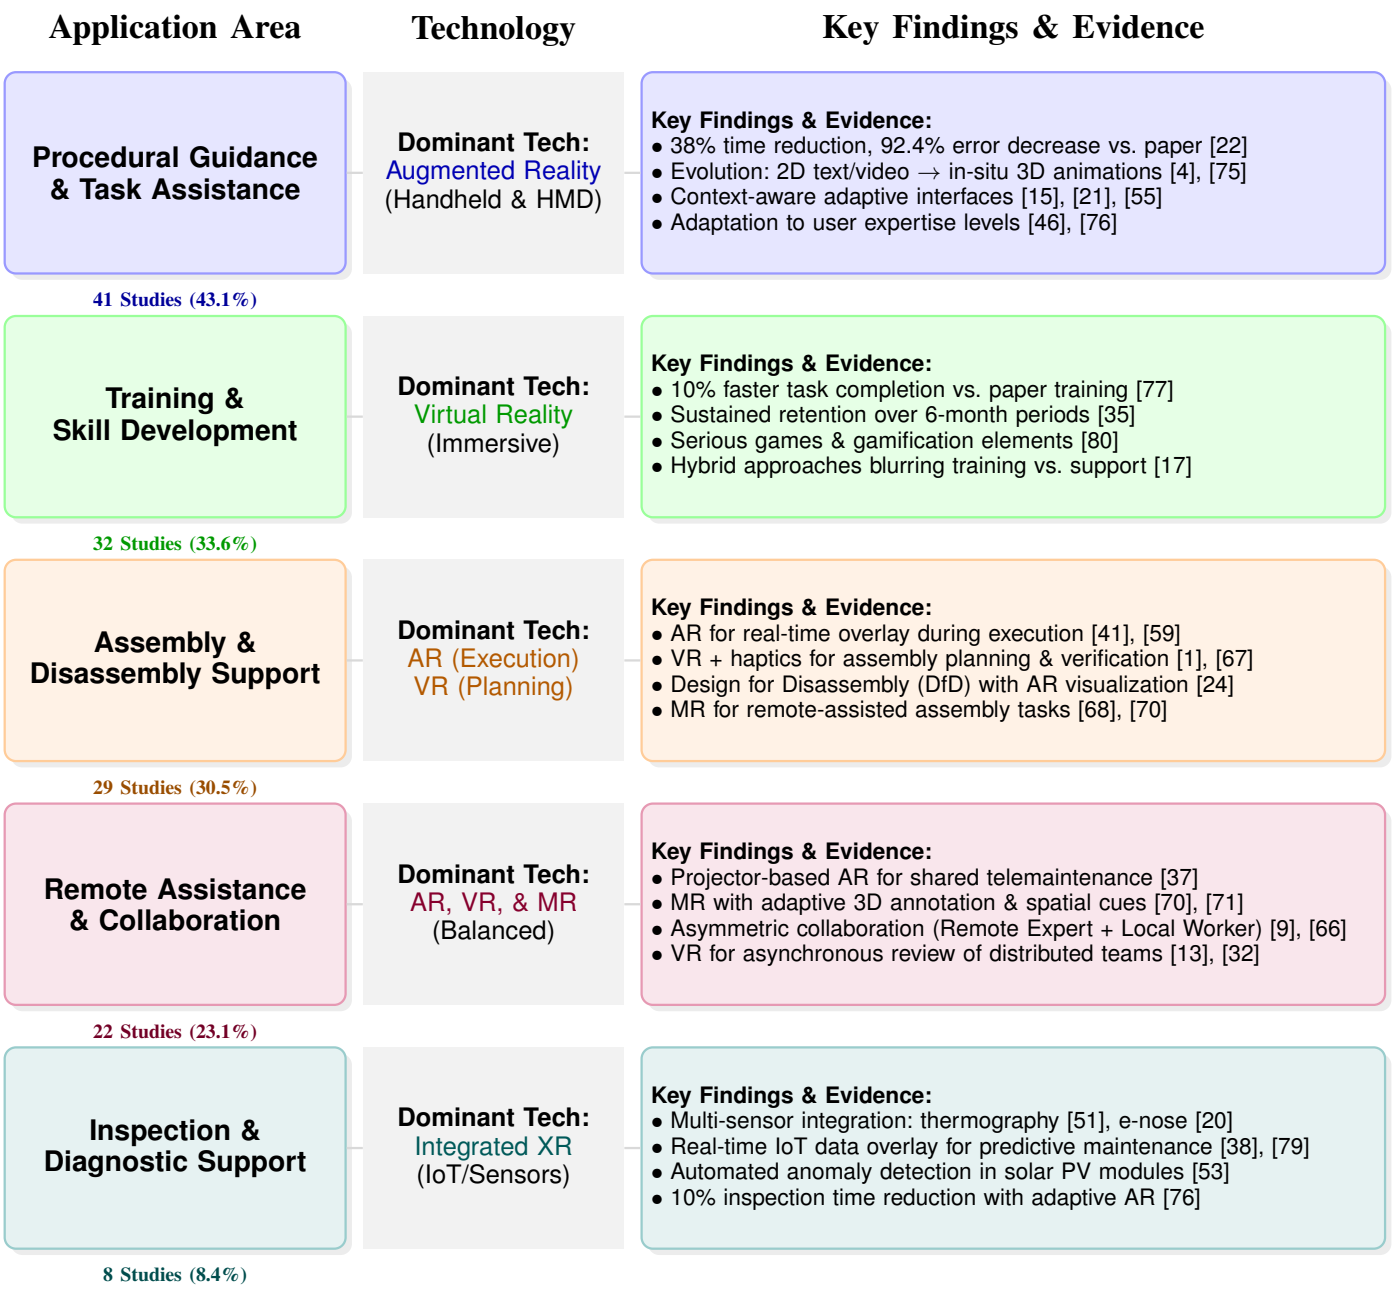

Fig. 10. Taxonomy of primary application areas in XR industrial maintenance, mapping study frequency, dominant technologies, and key empirical findings with supporting references.

personnel [2], [9], [11]. Notably, study [45] identifies cost reduction as a direct benefit of AR-based maintenance assistance. In contrast, study [64] highlights the economic advantages of VR training over physical equipment use, including reduced costs, faster training delivery, and the elimination of expensive physical resources.

2) Quality enhancement and error reduction: Error reduction emerges as a significant advantage in reviewed studies. The visual guidance and procedural structure provided by XR applications contribute to fewer errors and more consistent performance. Study [22] demonstrates a remarkable 92.4% reduction in error rates when using AR for maintenance tasks compared to paper-based instructions. Similarly, study [31] found that AR guidance resulted in fewer errors compared to paper instructions during maintenance tasks.

VR applications show comparable benefits in training contexts. Study [35] reports that VR-based training for industrial assembly tasks led to improved performance and fewer errors during subsequent real-world execution. The immersive environment enables repeated practice without risk, improving proficiency before physical interaction with equipment.

MR offers unique advantages for quality in collaborative scenarios. Study [70] presents an MR system that reduced errors by providing spatially correct instructions for assembly

TABLE III. SUMMARY OF KEY ADVANTAGES AND BENEFITS OF XR IN INDUSTRIAL MAINTENANCE

Category	Key Benefits & Empirical Evidence	Refs.
Efficiency & Performance	• **Time Reduction:** Significant savings in execution time (e.g., 38% improvement in engine maintenance ; 10% in inspection tasks). • **Complexity Scaling:** Benefits escalate as task complexity increases (e.g., piston pump systems) [2], [3]. • **Cost Impact:** Reduced downtime, decreased expert travel, and elimination of physical training assets [45], [64].	[2], [3], [7]
Quality & Error Reduction	• **Error Mitigation:** Visual overlays prevent mistakes. Reported 92.4% error reduction vs. paper manuals [22]. • **Precision:** Spatially correct 3D instructions prevent misalignment in assembly tasks [70]. • **Training Transfer:** Virtual practice leads to fewer errors during subsequent real-world execution [35].	[22], [31], [35], [70]
Learning & Knowledge Transfer	• **Risk-Free Practice:** VR enables "learning-by-doing" without equipment damage [10]. • **Retention:** Improved training permanency observed over 6-month periods [35]. • **Just-in-Time:** AR provides contextual knowledge directly at the point of need [42].	[10], [32], [35], [42], [77]
Human-Centric Advantages	• **Cognitive Load:** Reduces attention switching between manuals and tasks; aids processing in complex procedures [2], [16], [54]. • **Adaptability:** Content adapts to user skill levels (novice vs. expert) and preferences [42], [46], [76]. • **Ergonomics:** Hands-free operation via HMDs and voice assistants reduces physical strain [33], [62], [73].	[25], [42], [46], [54], [73], [76]
Collaboration & Safety	• **Remote Support:** Expert guidance for distributed teams; asynchronous collaboration on virtual prototypes [9], [13]. • **Hazard Awareness:** Visualization of safety zones (e.g., robot workspaces) and risk mitigation planning [19], [81].	[9], [13], [19], [28], [81]

Note: Where multiple references appear in a single cell, inline citations within the Key Benefits/Barriers column indicate the specific claim each reference supports. References listed in the Refs. column without inline attribution provide additional evidence for the category as a whole.

tasks. The visualization of 3D elements in their proper spatial context helps prevent misalignment and assembly errors.

3) Enhanced learning and knowledge transfer: XR technologies demonstrate significant benefits for maintenance training and knowledge transfer. VR creates safe environments for practice, eliminating risk to equipment and personnel. Study [10] explains that VR provides immersive simulations that enable learning-by-doing in risk-free settings, potentially shortening learning periods. Study [77] offers empirical evidence that VR-based training for wiring electric motors led to 10% faster task completion than traditional training.

AR facilitates learning directly within the work context, enabling just-in-time knowledge acquisition. Study [42] demonstrates that AR guidance enhances skill development by providing personalized instruction tailored to individual skill levels. Knowledge retention represents another advantage, as a study [35] reports improved training permanence with VR-based approaches, demonstrating sustained performance improvements over six months.

These XR learning benefits extend to knowledge sharing across organizations. Study [32] demonstrates how VR enhances collaboration and spatial understanding for globally distributed teams performing maintenance, documentation review, and risk assessment.

4) Human-centric advantages: Human-centric benefits address cognitive enhancement, ergonomic improvements, and personalized experiences. These advantages directly impact operator well-being and performance in maintenance contexts.

Cognitive Load Optimization: XR technologies effectively modulate cognitive load during complex procedures. Study [2] demonstrates that AR instructions enhance cognitive processing, particularly for complex tasks, by presenting information in a more intuitive and spatially relevant manner. Study [54] illustrates how AR reduces cognitive load through automatic object detection and spatial guidance, providing situation-aware and dynamic task assistance. Traditional maintenance approaches pose significant cognitive challenges, as highlighted in Study [16], which notes that operators must constantly shift their attention from the task at hand to instruction manuals, making disassembly processes error-prone and time-consuming. XR solutions address this fundamental limitation by overlaying contextual information directly onto the work environment, eliminating the need for attention switching and maintaining operator focus on the primary task.

Adaptability to User Characteristics: Approximately one-third of studies highlight personalization features that accommodate varying skill levels and learning styles. Study [76] presents an AR-based Adaptive Assistance System methodology that adapts content to user expertise level, adjusts

information presentation based on preferences, and provides personalized assistance experiences. Study [42] demonstrates that AR can enhance the accessibility of manufacturing jobs by enabling personalized delivery of task information tailored to workers' preferences. Study [46] an adaptive framework for generating Augmented Reality (AR) instructions for machine operation, tailored to individual operators' skill levels. The system retrieves task data and worker profiles to provide personalized AR guidance, thereby improving productivity, safety, and worker satisfaction.

Ergonomic Enhancement: XR technologies contribute to improved physical ergonomics in many studies. Head-mounted AR displays enable hands-free operation, as demonstrated in study [33], allowing technicians to access information while maintaining physical engagement with equipment. Study [73] provides objective measurements showing AR instructions can reduce physical strain in certain muscle groups, particularly for simple maintenance tasks.

Improved Information Design: Enhanced information presentation is another human-centric advantage. Study [25] presents a methodology for converting technical documentation into AR-based manuals, optimizing text usage and converting textual instructions into visual elements. Study [62] shows how AR voice assistants can facilitate hands-free interaction during manual tasks, improving both ergonomics and information accessibility.

5) Collaboration and safety: Improved collaboration is reported in more than one-third of studies, with a particular emphasis on remote expert support. Study [9] demonstrates how AR assists service technicians with remote expert guidance for problems of varying difficulty. Study [13] illustrates how the COVE-VR platform facilitates asynchronous collaboration among globally distributed departments, enabling interaction with virtual prototypes in realistic settings.

Safety benefits manifest through risk-free training environments and improved hazard awareness. Study [28] proposes a human-centered conceptual model that integrates Augmented Reality (AR) and Dynamic Digital Models (DDM) to improve training and mitigate occupational risks in industrial contexts, enabling real-time risk management support for occupational safety. Study [81] presents a template concept for creating and modifying VR environments more efficiently in industrial contexts, specifically focusing on safety training for human-robot collaboration in industrial assembly. The approach emphasizes visualizing safety zones and robot workspaces while helping operators understand safety protocols. Study [19] presents a methodological proposal called SMART (Sistema Modular de Acceso Rápido Temporal) for implementing Virtual Reality (VR) and Augmented Reality (AR) systems to train engineering students in industrial maintenance and safety skills without exposing them to real risks. The methodology consists of four phases: Requirements, Architecture, Construction, and Evolution. The primary tasks involve utilizing VR for risk identification, assessment, and mitigation planning in industrial settings.

6) Evolution of advantages over time: The advantages of XR technologies have evolved significantly over the 2014-2025 review period, reflecting both technological advancements and a deeper understanding of their implementation.

Early studies (2014-2017) focused primarily on fundamental efficiency improvements and basic visualization capabilities. Study [22] exemplifies this phase, emphasizing the reduction of completion time and error elimination through AR visualization. Advantages described in this period tended to be directly measurable, such as time savings and error counts.

Middle-period research (2018-2021) expanded to include more sophisticated cognitive and learning benefits. Studies [10], [35], [47] demonstrate greater attention to knowledge transfer, cognitive support, and adaptive capabilities. The advantages described become more nuanced, addressing not just faster task completion but also enhanced understanding and knowledge retention.

Recent studies (2022-2025) show a shift toward personalization, human-centric design, and integration with other technologies. Study [75] demonstrates this trend by presenting an AR system that automatically generates task guidance using vision-language models, a level of integration with AI not seen in earlier studies. Study [70] showcases advanced MR applications that adapt to contextual awareness, while study [2] provides empirical evidence for AR's differential benefits based on task complexity.

This evolution reflects the maturation of XR from novel technical solutions to sophisticated sociotechnical systems that actively adapt to human needs and organizational contexts, suggesting continued development toward increasingly intelligent, integrated, and human-centered XR applications for industrial maintenance.

T. Limitations and Challenges of Extended Reality in Industrial Maintenance

The implementation of XR technologies in industrial maintenance faces several significant barriers that must be addressed to realize their full potential. Analysis of the primary studies reveals four major categories of limitations and challenges that currently impede wider adoption of these technologies.

1) Technical limitations: Hardware constraints represent the most frequently reported technical limitation. Head-mounted displays (HMDs) are particularly criticized for their limited field of view, which restricts the user's peripheral vision during maintenance tasks. Study [7] identifies this narrow field of view as problematic for guiding technicians during on-site repair tasks and providing remote experts with AR views of machinery for analysis. Battery life limitations also affect deployment feasibility, with study [15] highlighting the need for extended battery life to support all-day use in industrial settings.

Tracking and registration accuracy emerge as another significant technical challenge. Study [54] reports image distortion during rapid motion, which affects the reliability of object detection, and notes that current AR devices struggle with reflective or transparent objects common in industrial equipment. Registration misalignment, where virtual elements do not precisely align with physical components, is highlighted in studies [4], [36], [52], [59] as particularly problematic for maintenance tasks requiring high precision.

Network performance and computational requirements present additional technical barriers. Study [70] identifies

limitations in network connectivity with current Wi-Fi technology as a constraint for data-intensive XR applications. Study [44] demonstrates these connectivity challenges in real-world field deployments, where poor network performance forced researchers to use dedicated 4G hotspots paired with HoloLens 2 devices to address connectivity issues, though even this solution proved insufficient for performance-intensive features that require high-bandwidth connections. Computational limitations identified across studies include processing complexity and performance constraints when handling large 3D CAD models [13], jitter in pose estimation algorithms [51], challenges in data management and scene reconstruction [71], and insufficient computational resources for complex scenarios requiring real-time processing and rendering.

2) Implementation and adoption barriers: Organizational implementation challenges appear in 42% of studies, spanning integration, acceptance, and resource constraints. The high implementation cost represents a significant barrier, particularly for small and medium enterprises. Studies [34], [64], [80] explicitly identify substantial initial investment requirements as a limitation, while study [29] points to financial resource constraints in adapting XR for technical training contexts.

User acceptance and adaptation difficulties are prominently reported in studies [9], [26], [35], [52], [59], [79]. Study [26] reports the need for user adaptation to symbol-based instructions in its proposed method, aiming to reduce the amount of text in technical documentation. Study [9] explicitly notes that resistance is present among technicians with lower technology-affinity scores. This reluctance manifests as skepticism about the accuracy and trustworthiness of information, with study [6] identifying potential trust issues in information provided through XR interfaces. Study [62] reports user frustration with speech recognition errors during maintenance tasks, highlighting the gap between expected and actual performance in real-world conditions.

Content-creation complexity poses a persistent challenge in implementation. Study [26] identifies the complexity of AR authoring as a significant barrier due to difficulties in creating scalable solutions for different types of maintenance manuals. Studies [47], [52] report the laborious model preparation required for effective AR implementation, thereby imposing a high threshold for initial deployment.

3) Human factors challenges: Cognitive and physical ergonomic issues are identified in 35% of studies. Extended use of HMDs can cause physical discomfort, with study [73] providing objective measurements showing increased strain in certain neck and shoulder muscles due to the weight and required posture of AR headsets. Study [3] reports the potential for cognitive overload due to focus rivalry between real and virtual information, particularly for complex tasks.

User skill variability presents challenges for designing appropriate XR interfaces. Study [40] identifies difficulties in providing proper guidance for users of varying skill levels, while study [3] notes a learning curve for novel AR interaction techniques. Study [55] reports initial challenges with gesture controls for users unfamiliar with AR interfaces.

Environmental considerations further complicate human factors design. Study [36] identifies implementation challenges related to varying lighting conditions, which affect tracking reliability. Study [20] notes the influence of humidity and temperature on sensing capabilities, while study [8] reports difficulties in detecting reflective or transparent objects when using Microsoft HoloLens smart glasses.

4) Methodological and evaluation challenges: Assessment limitations are also reported in the primary studies, particularly regarding the ecological validity of laboratory evaluations. Study [66] notes the difficulty in replicating real-world conditions in controlled tests and identifies challenges in balancing safety concerns with the requirements of real-world testing.

Many studies rely on limited sample sizes or non-representative participant groups. Study [76] acknowledges a key limitation in having only three inspectors test their ARAAS methodology, which potentially limits the generalizability of the results. Similarly, study [3] notes the limited generalizability of findings due to participant characteristics and the specific AR interface tested. Study [12] reports limited generalizability due to its focus on elevator maintenance, while presenting the xR Safety Kit framework for AR-based industrial maintenance solutions.

Long-term effectiveness evaluation remains particularly challenging. Study [17] identifies the need for studies examining extended XR use rather than single-session experiments. In contrast, study [3] notes limitations in understanding the long-term effects of AR use on user performance and adaptation.

These limitations and challenges, summarized in Table IV, highlight the current state of XR technologies in industrial maintenance as promising but still maturing. Many studies conclude with recommendations for future research that specifically target these barriers, suggesting a collective recognition of the need to address these challenges and advance the field toward more effective and widely implemented XR solutions.

U. Evaluation Criteria of XR in Industrial Maintenance

The systematic evaluation of XR technologies in industrial maintenance employs diverse criteria and instruments to validate effectiveness across multiple dimensions. Analysis of the primary studies reveals a structured evaluation landscape organized into five primary categories, as illustrated in Fig. 11, each addressing distinct aspects of XR system performance in maintenance contexts.

1) Performance-based evaluation: Objective performance metrics represent the most prevalent approach. Task completion time and error rates each appear in 25 studies, reflecting industrial emphasis on quantifiable operational improvements. Study [22] demonstrates AR's meaningful impact, reporting a 38% reduction in completion time and a 92.4% decrease in errors for motorcycle engine maintenance compared to paper instructions. Study [77] shows similar benefits for VR training, with 10% faster task completion for electric motor wiring. The combined assessment of efficiency (time) and effectiveness (errors) provides robust evidence for XR impact, as demonstrated across diverse maintenance scenarios in Studies [18], [36], [44].

2) Cognitive load and workload assessment: Cognitive evaluation appears in 16 studies, with the NASA Task Load Index used in 10 studies. This standardized questionnaire measures mental, physical, and temporal demands, as well as

TABLE IV. SUMMARY OF BARRIERS, LIMITATIONS, AND CHALLENGES IMPEDING XR ADOPTION IN INDUSTRIAL MAINTENANCE

Category	Key Barriers & Challenges	Refs.
Technical Limitations	• **Hardware Constraints:** Limited Field of View (FOV) restricts peripheral vision; battery life insufficient for full shifts [7], [15]. • **Tracking & Registration:** Misalignment of virtual overlays; instability with rapid movement or reflective/transparent surfaces [4]. • **Connectivity:** Wi-Fi/Network latency hinders data-intensive tasks; heavy processing of CAD models causes jitter [13], [70].	[4], [7], [13], [15], [70], [71]
Implementation & Adoption	• **Cost:** High initial investment and resource requirements for SMEs and training contexts . • **User Acceptance:** Resistance due to low tech affinity; trust issues with data accuracy; frustration with interaction errors (e.g., speech) [6], [9]. • **Content Creation:** Laborious model preparation and complex authoring processes create high deployment thresholds .	[6], [9]
Human Factors & Ergonomics	• **Physical Strain:** Neck/shoulder fatigue from HMD weight and prolonged posture . • **Cognitive Load:** Focus rivalry between real/virtual elements; cognitive overload in complex tasks . • **Environmental Sensitivity:** Lighting variations, humidity, and temperature affect sensor reliability and tracking .	[3], [8]
Methodological & Evaluation	• **Ecological Validity:** Difficulty replicating real-world industrial conditions (safety, chaos) in lab settings [66]. • **Generalizability:** Reliance on small sample sizes (e.g., N=3) or non-representative participant groups [12]. • **Longitudinal Data:** Lack of studies examining long-term effects, adaptation, and sustained performance [3], [17].	[3], [12], [17]

Note: Where multiple references appear in a single cell, inline citations within the Key Benefits/Barriers column indicate the specific claim each reference supports. References listed in the Refs. column without inline attribution provide additional evidence for the category as a whole.

performance, effort, and frustration. Study [2] reveals differential cognitive impact across task complexity, showing significant workload reduction for complex maintenance procedures, whereas simpler tasks yield minimal benefit. Study [3] extends this by measuring EEG (refers to the use of electroencephalography (EEG) to study and measure brain activity related to cognitive processes) during AR-assisted pump maintenance, revealing neural correlates of reduced cognitive demand. The integration of subjective workload measures with objective performance metrics provides complementary perspectives, as exemplified by the comprehensive evaluation of AR plant maintenance systems in Study citep7.

3) Physiological measurement: Physiological evaluation appears in 7 studies and offers unique insights through biosensing technologies. Heart rate variability emerges as the most common measure [2], [10] and assesses cardiovascular responses and physical stress. Electrodermal activity provides a complementary assessment of stress in Studies [4], [10]. Eye tracking offers particular value for evaluating visual attention and information processing; Study [4] employed comprehensive gaze behavior analysis during AR-assisted assembly, and Study [12] used it to identify safety hazards in VR simulations. Despite the advantages of continuous, real-time assessment and capture of unconscious responses, the relatively low adoption rate likely reflects practical constraints, including specialized equipment requirements and demands for technical expertise.

4) Usability and user experience: Usability assessment appears in 28 studies, emphasizing that technical functionality requires intuitive, satisfying user interactions. The System Usability Scale (SUS) emerges as the most widely adopted standardized instrument in 10 studies, enabling comparison across different XR implementations [15], [17], [54], [55]. User experience evaluation extends beyond narrow usability to encompass satisfaction and acceptance, appearing in 33 studies. Study [5] evaluates integration into existing maintenance workflows, while Study [11] focuses on perceived usefulness for industrial tasks. Several studies employ domain-specific instruments, such as ISONORM [7], which are tailored to industrial contexts and ergonomic standards.

5) Specialized dimensions and multi-method approaches: Learning outcomes are explicitly evaluated in 13 studies, particularly for VR training applications. Study [35] assesses six-month knowledge retention following VR-based assembly training and demonstrates sustained improvements in performance. Economic evaluation appears in 8 studies, with Study [64] quantifying the cost advantages of VR training through reduced training time and resources and its cost-effectiveness as a training solution. Safety assessment in 5 studies and collaboration quality in 5 studies address specialized application contexts.

A comprehensive evaluation employing multiple assessment modalities is reported in 18 studies. Study [4] exemplifies this approach, integrating five dimensions: task completion time, error analysis, NASA-TLX, physiological measures (EDA and inter-beat interval), and usability (PSSUQ). Study [7] evaluates effectiveness, efficiency, satisfaction, situational awareness (SART), and usability (ISONORM). This multimethod strategy enables the identification of potential trade-

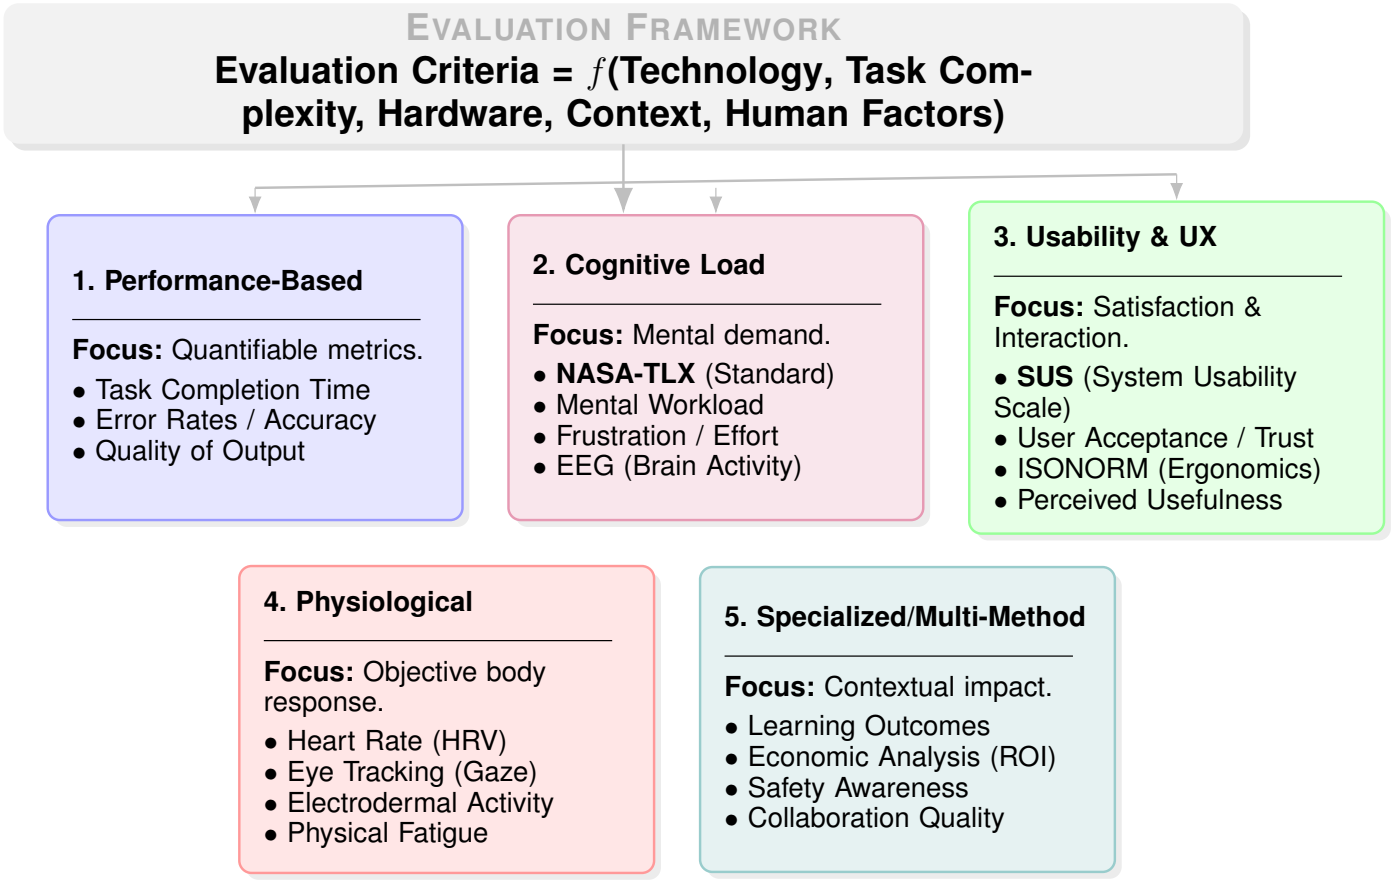

Fig. 11. Comprehensive evaluation framework for XR in industrial maintenance, illustrating the five primary assessment categories and the functional relationship defined in this review.

offs and provides both quantitative evidence and a nuanced understanding of user experiences.

6) Technology-specific patterns and framework: The relationship between evaluation approaches and implementation contexts reveals strategic patterns. Complex maintenance tasks require comprehensive evaluation, including cognitive load and physiological measures, as demonstrated in Studies [2], [3], [4]. Human-centric evaluation integration is featured in 42 studies, addressing cognitive support, ergonomics, adaptability, and user experience-critical factors for the adoption of industrial XR.

The comprehensive evaluation framework (see Fig. 11) illustrates the relationship: Evaluation Criteria = f(XR Technology, Task Complexity, Hardware, Application Area, Human-Centric Factors). This functional relationship informs the design of systematic evaluations, with criteria selection tailored to the type of technology (AR's operational focus suggests performance metrics; VR's training focus emphasizes learning outcomes), task complexity (complex scenarios justify using multiple methods), and human-centric factors (adaptive systems require assessing personalization effectiveness). As XR technologies advance and are adopted more widely, evaluation methods must also be developed to deliver strong evidence that supports confident industrial adoption decisions.

IV. Discussion

This systematic literature review synthesizes evidence from primary studies on extended reality (XR) technologies in industrial maintenance, revealing a rapidly maturing field transitioning from technology-centric implementations toward more sophisticated, human-centered systems.

A. Summary of Key Findings

The analysis reveals fundamental patterns in the adoption of XR for industrial maintenance. AR dominates current implementations (71.6%), primarily serving operational guidance and on-site assistance. VR accounts for 38.9% of studies, with strength in training and simulation contexts. MR represents only 6.3% but demonstrates emerging potential for collaborative maintenance scenarios. This distribution reflects pragmatic alignment between technology characteristics and maintenance task requirements.

Temporal analysis illuminates three distinct evolutionary phases. Early research (2014-2017) emphasized fundamental efficiency improvements through basic visualization. Middle-period studies (2018-2021) expanded to cognitive and learning benefits, incorporating adaptive capabilities and knowledge transfer mechanisms. Recent work (2022-2025) demonstrates AI integration, personalization, and context-aware systems with automatic content generation. This progression mirrors

the transitions from Maintenance 4.0 to Maintenance 5.0, where human-centricity emerges as a central design principle.

The prominence of human-centric factors across 44.2% of studies signals an evolving research emphasis. Temporal analysis across the three identified phases supports this interpretation: human-centric factors appeared in approximately 25% of studies during Phase 1 (2014–2017), increased to 42% during Phase 2 (2018–2021), and reached 58% during Phase 3 (2022–2025). This progressive increase substantiates the characterization of a paradigm shift toward human-centered XR design in industrial maintenance. Evaluation approaches have matured, with 18.9% of studies employing comprehensive, multi-method assessments that integrate performance metrics, cognitive load measures, physiological indicators, and user experience dimensions.

B. Theoretical Contributions

This review presents two frameworks that advance the understanding of XR effectiveness in maintenance contexts.

The Evaluation Framework expresses effectiveness as a functional relationship: Evaluation Criteria = f(XR Technology, Task Complexity, Hardware, Application Area, Human-Centric Factors). This framework guides systematic assessment by recognizing that evaluation criteria must align with the characteristics of technology, task demands, and human factors. Complex maintenance procedures requiring AR guidance with HoloLens 2 in field deployments necessitate a comprehensive evaluation encompassing performance metrics, NASA-TLX cognitive assessment, usability measures, and physiological indicators. VR training applications require the measurement of learning outcomes, knowledge retention, and transfer effectiveness.

The Technology-Task-Context Alignment Model proposes optimal pairings between XR modalities, maintenance tasks, and operational contexts. AR demonstrates superiority for guidance, inspection, and procedural support in on-site environments where real-world context is essential. VR excels in training, planning, and simulating hazardous procedures in controlled learning environments. MR facilitates collaborative problem-solving and remote assistance in distributed work contexts. Misalignment produces suboptimal outcomes. Deploying VR for real-time repair introduces safety hazards, while using AR for initial skills training may impose an excessive cognitive load.

C. Comparison with Existing Literature

This review's findings both converge with and extend previous systematic reviews. Wang et al. [82] examined XR in product assembly, identifying similar temporal evolution patterns. However, their assembly focus revealed different technology distributions across workflow phases. In the pre-assembly phase, VR dominated pre-assembly activities, including training, simulation, and planning (30 VR versus 9 AR/MR implementations). Conversely, in the after-assembly phase encompassing maintenance activities, AR/MR showed clear dominance (30 AR/MR versus 8 VR implementations). This pattern aligns with the present review, where AR dominates operational maintenance guidance (57.9% of maintenance studies), highlighting how task characteristics shape technology selection.

Earlier maintenance-specific reviews established a foundational understanding at different maturity stages. Palmarini et al. [83] identified fragmented AR solutions and hardware limitations, concerns that remain partially relevant. Guo et al. [84] focused on VR applications across product lifecycles. Our findings extend these works by providing updated insights on AR hardware evolution, revealing recent VR acceleration post-2020, and documenting the emerging integration of AI and IoT.

The human-centric emphasis in our findings strongly supports the Maintenance 5.0 framework articulated by Psarommatis et al. [85], which expands beyond Industry 4.0's focus on automation and economic goals to encompass human-centricity, sustainability, and resilience. With 44.2% of studies addressing human-centric factors, our findings validate this paradigm shift toward systems that balance technological capability with human well-being, cognitive support, and sustainable operations.

Fang et al. [87] provided a comprehensive analysis of HMD AR in manufacturing, emphasizing the challenges of tracking, registration, and human-computer interaction. Our maintenance-focused analysis confirms these findings and reveals additional barriers, including the complexity of content authoring and the assessment of long-term effectiveness. The convergence among reviews on hardware limitations, registration accuracy, and human factors suggests fundamental rather than transient challenges.

Alam et al. [86] examined XR challenges in Industry 4.0 contexts, focusing on interoperability, adaptability, and cost barriers. Our findings corroborate these, while providing quantitative evidence: only 8.4% of studies included economic evaluation, suggesting systematic underattention to implementation costs in industrial decision-making.

D. Practical Implications

For industry practitioners, this review provides evidence-based guidance on selecting XR technology. Organizations should prioritize AR for procedural guidance and inspection, where demonstrated time reductions of 38% and error reductions of 92.4% provide clear value propositions. VR investments are justified for training applications, particularly for hazardous procedures where 10% efficiency improvements and enhanced knowledge retention offset development costs.

Implementation should follow staged approaches. Initial AR pilots targeting high-complexity maintenance with clear performance metrics enable value demonstration. Critical success factors include simplifying content authoring, robust change management that addresses user acceptance, and evaluation frameworks that capture both quantitative performance and qualitative user experience.

For XR system designers, human-centricity must be an architectural principle. Systems should incorporate adaptive capabilities that adjust to user expertise, task complexity, and environmental conditions. Multi-modal interaction, supporting both gesture and voice commands, accommodates diverse user preferences.

For researchers, this review identifies critical gaps. Longitudinal studies examining sustained XR usage beyond single-session experiments are urgently needed, as are standardized

evaluation protocols enabling cross-study comparisons. Economic models incorporating the total cost of ownership would strengthen industrial adoption decisions. Physiological evaluation methods, currently employed by only 7.4% of studies, offer unique insights complementing traditional performance metrics.

E. Limitations

This review's scope and methodology impose limitations. Including assembly and disassembly tasks broadened the evidence base but may introduce heterogeneity, as assembly emphasizes different demands than traditional maintenance.

Grouping AR and MR reflects common practice but may mask important distinctions in system capabilities. Rapid technological change means findings regarding specific hardware platforms have limited temporal stability—limitations identified for 2015-era HMDs may not apply to current devices.

Most primary studies employed laboratory evaluations with students rather than field deployments with experienced technicians, limiting ecological validity. Small sample sizes and single-session designs restrict understanding of long-term effectiveness and adoption patterns. Publication bias toward positive results may overestimate the effectiveness of XR.

F. Future Research Directions

Immediate research priorities include longitudinal field studies examining XR adoption patterns and sustained usage in authentic industrial settings. Standardized evaluation frameworks would enable systematic comparison across implementations, facilitating meta-analyses. Economic evaluation incorporating comprehensive cost-benefit analyses would strengthen industrial decision-making.

Medium-term priorities should focus on integrating emerging technologies. AI-enhanced XR systems offering context-aware guidance, predictive maintenance support, and adaptive instruction are promising directions aligned with Maintenance 5.0 principles. Digital twin integration connecting XR interfaces with real-time equipment data could enable advanced diagnostic support and predictive capabilities. Multi-modal XR incorporating haptic feedback, spatial audio, and environmental sensing may improve training effectiveness.

Long-term research should examine the ethical implications of XR deployment. Questions regarding worker surveillance, skill deskilling versus augmentation, and equitable access require sustained attention. The development of XR systems that genuinely enhance human capabilities requires critical engagement with human-centered design principles and participatory development approaches.

This systematic literature review demonstrates that XR technologies have progressed beyond proof-of-concept to become viable tools for industrial maintenance. However, significant challenges remain before widespread adoption. Success requires continued attention to human factors, robust evaluation methodologies, and strategic implementation aligned with organizational capabilities and the characteristics of maintenance tasks.

V. Conclusion

This systematic literature review synthesizes evidence from 95 primary studies examining extended reality technologies in industrial maintenance, revealing a rapidly maturing field transitioning from technology-centric implementations toward human-centered systems aligned with Maintenance 5.0 principles. The analysis demonstrates that XR technologies have progressed beyond proof-of-concept to become viable tools that deliver measurable operational improvements while addressing the evolving complexity of modern industrial maintenance.

The research establishes three fundamental contributions. First, it identifies precise technology-task alignments: AR dominates operational guidance and real-time assistance (71.6% of studies), VR excels in training and simulation contexts (38.9%), while MR enables collaborative maintenance scenarios (6.3%). Second, temporal analysis reveals distinct evolutionary phases—from basic visualization (2014-2017), through cognitive enhancement (2018-2021), to AI-integrated adaptive systems (2022-2025)—mirroring the broader industrial transformation toward human-centric maintenance. Third, the prevalence of human-centric factors in 44.2% of studies signals a paradigm shift emphasizing cognitive support, ergonomics, adaptability, and user experience as central design considerations.

This review advances theoretical understanding through two frameworks. The Evaluation Framework expresses XR effectiveness as Evaluation Criteria = f(XR Technology, Task Complexity, Hardware, Application Area, Human-Centric Factors), providing systematic guidance for the design of assessments. The Technology-Task-Context Alignment Model recommends optimal pairings between XR modalities and maintenance requirements, acknowledging that misalignment yields suboptimal outcomes. These frameworks move beyond descriptive analysis to offer prescriptive guidance for implementation decisions.

Practical implications indicate AR investments should target high-complexity procedural guidance, where demonstrated time reductions of 38% and error reductions of 92.4% provide clear value propositions. VR deployment is justified for training applications, particularly those involving hazardous procedures, where the safety benefits and knowledge retention outweigh the development costs. Implementation success requires staged approaches, simplified content authoring, robust change management, and comprehensive evaluation frameworks.

However, these findings must be interpreted in light of persistent limitations. Most primary studies relied on laboratory evaluations with small sample sizes, limiting ecological validity and generalizability. Hardware constraints—including limited field of view, battery life, and tracking accuracy on reflective surfaces—remain unresolved barriers to industrial deployment. Content authoring complexity continues to impose high thresholds for initial adoption, and economic evaluation was addressed by only 8.4% of studies, leaving the cost-effectiveness of XR implementations insufficiently characterized. These observed limitations directly inform the most pressing research priorities. First, longitudinal field studies are needed to address the current reliance on single-session laboratory experiments identified across the reviewed literature. Second, standardized evaluation protocols would

resolve the inconsistencies in assessment methodologies that currently prevent systematic cross-study comparison. Third, comprehensive economic models incorporating total cost of ownership would address the gap in financial analysis documented in this review. Beyond these immediate needs, future research should explore AI-enhanced adaptive systems, digital twin integration, and multi-modal interfaces, while engaging with the ethical implications of sustained XR deployment in industrial workplaces.

***Abstract*—Fog computing extends cloud capabilities to the network edge, providing low-latency services for mission-critical applications such as healthcare and industrial automation. However, validating security-aware scheduling policies in this distributed paradigm remains a challenge due to the lack of native support for trust modeling in standard simulation tools like CloudSim and iFogSim. Existing simulators focus primarily on resource provisioning, cost, and energy metrics, often neglecting "Trust" and "Data Confidentiality" as first-class simulation parameters. This study presents the design and implementation of a trust-aware extension for WorkflowSim. We detail the software architecture modifications required to support attribute-based trust verification, secure task fragmentation, and encryption overhead modeling. Unlike standard simulators, our extended framework treats Trust as a dynamic entity in the Virtual Machine (VM) and Task class hierarchy. We validate the framework's correctness through unit tests and scenario-based trace analysis, demonstrating its ability to accurately model security-performance trade-offs in heterogeneous fog environments. Experimental results indicate that enabling trust-aware scheduling increases makespan by approximately 19% and cost by 16%, while achieving a security score of 0.88 compared to 0.65 for the baseline. The simulation engine overhead remains below 7.1% even for 1000-task workflows. The source code and design patterns presented provide researchers with a robust, extensible tool for evaluating secure scheduling algorithms without the cost of physical testbeds.**

***Keywords*—Fog computing; simulation tools; WorkflowSim; trust modeling; task scheduling; software architecture**

I. Introduction

The rapid proliferation of the Internet of Things (IoT) [1], [2] has generated unprecedented volumes of data at the network edge. Traditional cloud computing architectures [3], while offering vast storage and resources, often fail to meet the stringent latency requirements of modern applications [4], [5]. Fog computing has emerged as a decentralized solution, bridging the gap between IoT devices and the cloud [6], [7]. However, the heterogeneous and distributed nature of fog nodes introduces significant security vulnerabilities [8], particularly regarding data confidentiality and node trustworthiness.

This raises a fundamental research question: How can a standard workflow simulation framework be extended to natively support dynamic trust evaluation and data confidentiality modeling for secure fog computing research?

Designing secure scheduling algorithms for fog environments requires rigorous testing. However, deploying physical testbeds with hundreds of fog nodes is often cost-prohibitive and lacks reproducibility. Consequently, researchers rely heavily on simulation tools. While established simulators like CloudSim [14] and iFogSim [17] provide robust models for energy consumption and network latency, they notably lack native support for security-aware modeling. They treat all computing nodes as equally trustworthy, which is an unrealistic assumption in open fog environments where nodes may be malicious or compromised.

A. Motivation: Security Challenges in Fog Computing

In traditional cloud paradigms, data is processed in centralized, physically secure data centers managed by trusted providers (e.g., AWS, Azure). In contrast, fog computing relies on a collaborative model [9], [10] where computation is offloaded to edge devices (e.g., routers, gateways, base stations) often owned by third parties or deployed in public spaces. This architectural shift introduces several critical security challenges:

1) Lack of physical control: Edge nodes are susceptible to physical tampering and side-channel attacks [11], making it risky to process sensitive data (e.g., patient health records) on them without verification.

2) Dynamic trustworthiness: A node that is trustworthy at time t may become compromised at time $t+\Delta t$. Static security policies are insufficient; the system requires continuous trust evaluation [12].

3) Regulatory compliance: Legal frameworks such as GDPR and HIPAA [13] impose strict requirements on data residency and processing locations. Simulators must effectively model these geospatial and trust constraints to be useful for compliance auditing.

Existing simulation tools fail to capture these nuances, typically treating security as a binary state (encrypted/unencrypted) rather than a dynamic attribute influenced by node behavior and environmental factors [7], [8]. This limitation hinders the development of adaptive security algorithms.

*Corresponding author

B. Research Contributions

To address this gap, this study presents the design and implementation of a security-oriented extension to **WorkflowSim** [16]. WorkflowSim was chosen as the base platform due to its support for complex scientific workflow dependencies (DAGs), which are common in data-intensive fog applications.

The primary contributions of this study are:

1) Architectural extension: We propose a modified class hierarchy for WorkflowSim that integrates "Trust" and "Confidentiality" as core attributes of tasks and virtual machines.

2) Trust manager module: We implement a dedicated `TrustManager` component that decouples security logic from the core scheduling engine, enabling dynamic trust updates based on transaction success/failure.

3) Validation of tool correctness: We demonstrate the simulator's capability to enforce security policies (e.g., blocking sensitive tasks from low-trust nodes) through comprehensive trace analysis, rather than just algorithmic performance.

The remainder of this study is organized as follows: Section II reviews existing simulation tools. Section III presents the system model and mathematical formulation. Section IV details the proposed object-oriented system architecture. Section V provides the Java implementation details of the key components. Section VI presents the validation results of the simulation framework, and Section VII provides the discussion. Section VIII concludes the work.

II. Related Work on Fog Simulation

Simulation is a cornerstone of fog computing research due to the complexity and cost of physical testbeds. Several tools have been developed to model different aspects of the infrastructure [18], [19]. This section reviews widely used simulators and identifies the gap that necessitates our trust-aware extension.

A. CloudSim and its Derivatives

CloudSim [14], [15] is the most widely cited toolkit for cloud environments. It provides basic classes for data centers, hosts, and VMs. However, its scheduling logic is predominantly designed for independent tasks (Bag-of-Tasks) and centralized resource brokering. It lacks the concept of "workflow dependencies" (Parent-Child tasks) and decentralized trust management required for fog scenarios.

B. WorkflowSim

WorkflowSim [16] extends CloudSim by adding a Workflow Engine that parses Directed Acyclic Graphs (DAGs). It introduces a `ClusteringEngine` to merge small tasks, reducing simulation overhead. While WorkflowSim excels at modeling task dependencies, its standard distribution does not include security parameters. Tasks are scheduled based solely on completion time or cost, ignoring the security posture of the target node.

C. iFogSim

iFogSim [17] was specifically designed for modeling hierarchical fog and edge computing topologies. It excels at simulating data processing pipelines (sensors to actuators) and energy consumption. However, iFogSim's resource management policies are hard-coded into the `FogDevice` class. Implementing dynamic trust models often requires invasive modification of the core engine, which hampers upgradability and modularity.

D. EdgeCloudSim and PureEdgeSim

EdgeCloudSim [20] extends CloudSim to cover mobility support and network link modeling, crucial for mobile edge computing (MEC) scenarios. Similarly, PureEdgeSim [21] allows for simulation of peer-to-peer edge environments. While both tools provide excellent network fidelity, they lack specific constructs for *Data Confidentiality* and *Trust-Based Scheduling*. They focus primarily on task offloading decisions based on signal strength or battery levels, rather than security attributes.

E. FogNetSim++

Unlike the Java-based tools mentioned above, FogNetSim++ [22] is built on OMNeT++, offering highly detailed network protocol simulation (TCP/IP level). While arguably superior for network analysis, it lacks the high-level workflow scheduling abstractions needed for application-layer research. Furthermore, its C++ codebase is less accessible to the broad community of researchers familiar with the CloudSim Java ecosystem.

F. Trust Models and Reputation Systems

Beyond simulators, numerous trust models have been proposed for distributed systems. The Beta Reputation System (BRS) [23] is a probabilistic trust model based on the beta probability density function, widely used in peer-to-peer (P2P) networks. It calculates reputation by aggregating positive and negative interactions. EigenTrust [24] is another prominent algorithm designed to calculate the global trust value of each peer in a network by computing the left principal eigenvector of a matrix of normalized local trust values.

In the context of fog computing, recent works [25]–[27] focus on lightweight, context-aware trust management. However, these models are typically evaluated using custom, non-reproducible Python scripts or MATLAB simulations, rather than integrated into standard, community-accepted simulation frameworks like WorkflowSim. This disconnect limits the ability of the broader research community to validate, compare, and extend these trust algorithms.

In our proposed framework, we adopt the Beta Reputation System over EigenTrust for several reasons. First, EigenTrust requires iterative convergence across a fully connected peer network to compute global trust, which does not map naturally to the hierarchical fog topology (Mist-Fog-Cloud) in our model. Second, the Beta model operates in $O(1)$ per update, making it suitable for real-time scheduling decisions. Third, the Beta model directly accommodates the binary interaction outcomes (task success/failure) central to our trust formulation.

Importantly, our `TrustManager` interface is designed to be modular—researchers can substitute EigenTrust or blockchain-based trust models [28] by implementing the same interface without modifying the scheduler code.

G. Comparative Analysis

Table I summarizes the capabilities of existing simulators compared to the proposed WorkflowSim extension. While tools like iFogSim and EdgeCloudSim offer robust network and energy modeling, they lack native support for dynamic trust management and data confidentiality attributes in their core task scheduling entities.

H. The Need for a Trust-Aware Extension

Current research into "Secure Fog Scheduling" often relies on ad-hoc, one-off modifications to these simulators. Most researchers hard-code security checks directly into their scheduling algorithms. This study proposes a structural, architectural extension to WorkflowSim that decouples trust logic from scheduling logic, providing a reusable framework for future security research. Use of WorkflowSim ensures support for complex DAG workflows, which is a key requirement for modern data-intensive fog applications [31].

III. System Model and Mathematical Formulation

This section formalizes the system entities, task characteristics, and the multi-objective optimization problem addressed by our proposed framework. The mathematical rigor introduced here ensures that the simulation results are grounded in verifiable theoretical models.

A. Fog Computing Environment

We model the fog computing environment as a hierarchical graph $G_{fog} = (V, E)$, where V represents the set of computing nodes and E represents the communication links. The set of nodes V is partitioned into three tiers:

$$V = V_{cloud} \cup V_{fog} \cup V_{mist} \tag{1}$$

Each node $v_j \in V$ is characterized by a tuple:

$$v_j = \langle P_j, M_j, C_j, T_j, E_j \rangle \tag{2}$$

where,

- P_j: Processing capacity in Million Instructions Per Second (MIPS).
- M_j: Available memory (RAM).
- C_j: Cost per unit time of usage.
- T_j: Current trust score, where $0 \leq T_j \leq 1$.
- E_j: Energy consumption coefficient (Joules/instruction).

B. Workflow Application Model

A scientific workflow W is represented as a Directed Acyclic Graph (DAG) [29] $W = (\mathcal{T}, \mathcal{D})$, where $\mathcal{T} = \{t_1, t_2, \ldots, t_n\}$ is the set of tasks and $\mathcal{D}$ represents the data dependencies between them. An edge $(t_i, t_k) \in \mathcal{D}$ implies that task t_k cannot start execution until t_i has completed and transferred its output data.

Each task $t_i \in \mathcal{T}$ is defined as:

$$t_i = \langle L_i, D_{in,i}, D_{out,i}, S_i, \tau_i \rangle \tag{3}$$

where,

- L_i: Task length in Million Instructions (MI).
- $D_{in,i}, D_{out,i}$: Input and output data sizes.
- S_i: Security sensitivity level (1: Public, 2: Internal, 3: Confidential).
- τ_i: Maximum tolerable latency (deadline).

C. Trust and Security Formulation

The trustworthiness of a fog node is not static but evolves based on its historical behavior. We employ a Beta Probability Density Function to model trust, as it naturally represents binary outcomes (successful vs. failed interactions).

The trust score T_j of node v_j is updated as:

$$T_j = \frac{\alpha_j + 1}{\alpha_j + \beta_j + 2} \tag{4}$$

where, α_j is the accumulated number of successful task executions (cooperative behavior) and β_j is the number of failed or malicious interactions.

To ensure that recent behavior is weighted more heavily, we apply a time-decay factor λ ($0 < \lambda < 1$):

$$\alpha_j(t) = \alpha_j(t-1) \cdot \lambda + \delta_{success} \tag{5}$$

$$\beta_j(t) = \beta_j(t-1) \cdot \lambda + \delta_{failure} \tag{6}$$

A task t_i with sensitivity S_i can only be scheduled on node v_j if the node satisfies the security constraint:

$$T_j \geq T_{req}(S_i) \tag{7}$$

where, $T_{req}(S_i)$ is a mapping function defining the minimum trust threshold for each sensitivity level (e.g., Level 3 requires $T_j \geq 0.9$).

TABLE I. COMPARISON OF FOG COMPUTING SIMULATORS

Feature	CloudSim	iFogSim	EdgeCloudSim	Proposed
Base Platform	Java	CloudSim	CloudSim	WorkflowSim
Workflow DAGs	No	Limited	No	**Yes**
Trust Model	No	No	No	**Yes**
Confidentiality	No	No	No	**Yes**
Fog Hierarchy	No	Yes	Yes	**Yes**
Network Model	Simple	Detailed	Detailed	**Simple**

D. Encryption Overhead Modeling

Unlike standard simulations that assume security is instantaneous, our model accounts for the computational overhead of encryption. The execution time $ET_{i,j}$ of task t_i on node v_j is composed of processing time and cryptographic overhead:

$$ET_{i,j} = \frac{L_i}{P_j} + \mathbb{I}(S_i > 1) \cdot \frac{D_{in,i} + D_{out,i}}{R_{enc,j}} \tag{8}$$

where, $R_{enc,j}$ is the encryption throughput of node v_j, and $\mathbb{I}(\cdot)$ is an indicator function that equals 1 if the task requires encryption (Sensitivity > 1), and 0 otherwise.

E. Objective Function

The scheduling problem addresses a multi-objective optimization goal [30]: minimizing the makespan (completion time) and total cost while satisfying security constraints. The objective function F is defined as:

$$\text{minimize } F = w_1 \cdot \frac{M_{makespan}}{M_{max}} + w_2 \cdot \frac{C_{total}}{C_{max}} + w_3 \cdot \frac{1}{S_{avg}} \tag{9}$$

subject to:

$$\forall t_i \in \mathcal{T}, \quad T_{assigned_node} \geq T_{req}(S_i) \tag{10}$$

where, w_1, w_2, w_3 are user-defined weights prioritizing time, cost, and security respectively. In the experiments reported in Section VI, we use $w_1 = 0.4$, $w_2 = 0.3$, and $w_3 = 0.3$, reflecting a slight priority on makespan while maintaining balanced consideration of cost and security. In practice, safety-critical applications (e.g., healthcare) should increase w_3, while cost-sensitive batch workloads should increase w_2.

IV. PROPOSED SYSTEM ARCHITECTURE

The proposed simulation framework involves a significant extension of the standard WorkflowSim class hierarchy. The design follows the Object-Oriented Programming (OOP) principles of inheritance and encapsulation to ensure compatibility with the underlying CloudSim engine.

A. Design Philosophy: Modularity and Extensibility

A key design principle of this framework is the decoupling of *Security Logic* from *Scheduling Logic*. In many existing ad-hoc implementations, trust calculations are embedded directly within the scheduler's `run()` loop. This creates tight coupling, making it difficult to swap trust models (e.g., changing from a Beta Reputation System to an EigenTrust model).

Our architecture addresses this by treating the `TrustManager` as a standalone component with a defined interface. The scheduler operates as a client of this manager.

- Encapsulation: The `TrustManager` hides the complexity of how trust is calculated (e.g., history windows, decay factors).
- Interchangeability: Researchers can implement a new `BlockchainTrustManager` that extends the base class without modifying a single line of the `FATSScheduler` code.
- Composition over Inheritance: We utilize object composition where the Scheduler *has-a* TrustManager, rather than forcing a specific inheritance hierarchy.

B. Supported Infrastructure Topologies

The proposed extension supports a three-tier hierarchical architecture, which is critical for realistic fog computing simulations. By modifying the `Datacenter` configuration parser, the tool allows users to define heterogeneous nodes with distinct computational and security profiles:

- Mist Tier: Represents edge devices such as gateways and smart controllers. These nodes are characterized by low computational power, but high physical proximity to data sources. In our model, they are initialized with high base trust due to direct ownership.
- Fog Tier: Represents regional processing units like cloudlets or base stations. These nodes offer moderate computational capacity and act as intermediaries. Their trust levels are dynamic and can degrade over time.
- Cloud Tier: Represents centralized data centers with virtually unlimited resources but high latency. While computationally powerful, they are treated as "semi-trusted" for sensitive data due to third-party management.

The simulation framework allows researchers to configure bandwidth and latency constraints between these tiers, as detailed in Table II.

TABLE II. DEFAULT NETWORK CONFIGURATION PARAMETERS

Link Type	Latency (ms)	Bandwidth (Mbps)
IoT ↔ Mist	2–5	10
Mist ↔ Fog	5–15	50
Fog ↔ Cloud	50–100	100

C. Extended Class Hierarchy

Fig. 1 (see description below) illustrates the core classes modified in this framework.

1) SecureJob (extends job): The standard `Job` class in WorkflowSim represents a computational task. We extend this to `SecureJob` to include sensitivity attributes. This allows researchers to model diverse security requirements without modifying the core engine.

- `confidentialityLevel` (int): A generic integer (e.g., 1-3) representing data sensitivity.
- `encryptionOverhead` (double): The estimated CPU time required for crypto operations.
- `requiredTrust` (double): The minimum trust threshold for this task type.

2) TrustedVM (Extends CondorVM): The `CondorVM` class represents a virtual machine. We extend this to `TrustedVM` to add:

- `trustScore` (double): A dynamic value representing node reliability.
- `securityTier` (enum): Categorization of nodes (e.g., MIST/FOG/CLOUD).
- `encryptionSupport` (boolean): Flag for hardware crypto acceleration.

3) TrustManager (Interface and Implementation): To decouple security logic, we introduce a `TrustManager` component. This standalone module acts as an Oracle. The scheduler queries this manager via specific interfaces (e.g., `trustManager.isTrusted(vmId)`) rather than embedding logic in the scheduler itself.

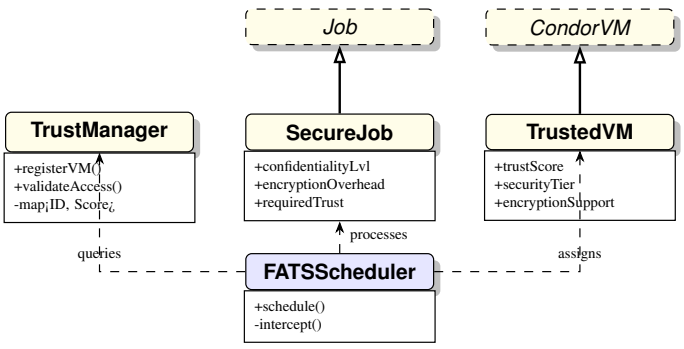

Fig. 1. UML class diagram of the trust-aware WorkflowSim extension. It illustrates the inheritance hierarchy where `SecureJob` extends the base `Job` class, and `TrustedVM` extends `CondorVM`, enabling security attributes to be handled natively by the simulation engine.

D. Execution Flow Modifications

In standard WorkflowSim, the `WorkflowScheduler` maps jobs based on performance. In our extended framework, we inject a "Security Interceptor" that allows *any* custom logic to be applied:

- **Task Parsing:** Workflows are parsed and generic sensitivity labels are assigned.
- **Interceptor Hook:** The `schedule()` method calls a `validateSecurity()` hook.
- **Overhead Injection:** A simulation penalty is added to tasks requiring encryption.
- **Feedback Loop:** Upon task completion, the `TrustManager` receives a signal to update internal state.

E. Algorithmic Framework and Complexity Analysis

The core scheduling logic, orchestrated by the `FATSScheduler`, integrates the fragmentation and trust-aware filtering phases. The time complexity of this integration is critical for ensuring low-latency decision-making in dynamic fog environments.

1) Algorithm Workflow: The scheduling process follows three main phases:

- **Initialization Phase:** The DAG is traversed to compute task levels and priorities. The initial trust scores for all nodes are loaded from the `TrustManager`.
- **Filtering Phase:** For each ready task t_i, the candidate set of resources V is filtered to create a secure subset $V_{secure} \subseteq V$ such that $\forall v_j \in V_{secure}, T_j \geq T_{req}(S_i)$.
- **Scoring Phase:** Remaining candidates are scored based on execution time and cost, and the task is assigned to the optimal node.

2) Complexity analysis: Let N be the number of tasks in the workflow and M be the number of available fog resources.

a) Task provisioning overhead: The standard WorkflowSim provisioning algorithm operates in $O(N \cdot M)$. Our extension introduces the filtering step. Checking the trust constraint for M resources takes $O(M)$. Since this is repeated for every scheduling decision, the base complexity remains $O(N \cdot M)$.

However, sorting the filtered list V_{secure} (where $|V_{secure}| \leq M$) takes $O(M \log M)$. Thus, the total complexity per scheduling round is:

$$T_{sched} = O(N \cdot (M + M \log M)) \approx O(N \cdot M \log M) \quad (11)$$

This logarithmic factor is acceptable given that M (number of fog nodes) is typically much smaller than N (number of tasks) in typical scientific workflows ($N \approx 1000, M \approx 20 - 50$). The overhead is negligible compared to the network latency involved in task offloading.

V. Implementation Details

The implementation is built on Java (JDK 1.8) integrating with WorkflowSim 1.1.0. This section highlights the critical code segments responsible for the security logic.

A. The TrustManager

The `TrustManager` is the heart of the security extension. It allows for dynamic updates to node reputation. We implemented a generic Beta Reputation System interface capable of modeling successful (α) and failed (β) interactions.

The update logic follows the standard expectation model:

$$T_{new} = \frac{\alpha + 1}{\alpha + \beta + 2} \times \delta_{history} \tag{12}$$

where, T_{new} is the updated trust score and $\delta_{history}$ is a decay factor for aging past interactions.

Listing 1: TrustManager and Secure Scheduling Logic

```
public class TrustManager {
    private Map<Integer, Double> vmTrustScores;
    // ... constructor omitted ...

    public void registerVM(int vmId, String tier) {
        double initialTrust = 0.80;
        if (tier.equals("MIST")) initialTrust = 0.95;
        if (tier.equals("CLOUD")) initialTrust = 0.75;
        vmTrustScores.put(vmId, initialTrust);
    }
    public boolean validateAccess(int vmId, int
         sensitivity) {
        double score = vmTrustScores.getOrDefault(vmId,
             0.5);
        if (sensitivity == 3 && score < 0.90) return false;
        // ... additional checks ...
        return true;
    }
}

// --- FATSScheduler: Secure Job Scheduling ---
protected void scheduleSecureJob(SecureJob job) {
    if (job.isSensitive()) {
        List<SecureJob> fragments =
            fragmentationEngine.split(job);
        for (SecureJob fragment : fragments) {
            TrustedVM targetVM = trustManager
                .findVM(fragment.getRequiredTrust());
            submitToEngine(fragment, targetVM);
        }
    } else {
        super.scheduleJob(job);
    }
}
```

B. Secure Job Scheduling

The scheduler logic was extended to support "Split Execution" capabilities. This allows testing of algorithms that break tasks into sub-components (e.g., Secure vs. Public fragments) without hardcoding the split ratio. The scheduling interceptor method `scheduleSecureJob()` shown in Listing 1 demonstrates how the `FATSScheduler` delegates trust validation to the `TrustManager` and applies fragmentation when a task is sensitive.

C. Overhead Modeling

To ensure the simulation reflects the "cost" of security, we implemented a data-size-dependent delay. This prevents the simulator from falsely reporting that secure scheduling is "free".

$$T_{overhead} = \frac{D_{size}}{B_{enc}} \times \alpha$$

where, D_{size} is the data size, B_{enc} is the encryption throughput of the VM, and α is a processing coefficient.

D. Configuration and Usage

To maximize adoption, distinct configuration files are used to separate security parameters from infrastructure setup.

1) Security configuration: The framework introduces `security.properties`, allowing researchers to tune crypto-overhead without recompiling:

```
security.encryption.overhead=5.2 # ms per KB
security.trust.decay_factor=0.01
security.trust.reward_factor=0.005
```

VI. Case Study: Secure Fog Workflow Scheduling

To demonstrate the functionality and extensibility of the proposed framework, we conducted a comprehensive case study. This section details the experimental setup, workflow configurations, and performance metrics, followed by scenario-based analysis.

A. Experimental Setup

The simulation environment was configured to model a realistic fog computing hierarchy consisting of three distinct tiers: Mist, Fog, and Cloud. Table III outlines the core simulation parameters used in this study. The experiments were conducted on a standard Windows 10 workstation with an Intel i7-8550U processor (1.80 GHz) and 16 GB of RAM.

TABLE III. Simulation Parameters

Parameter	Value description
Platform	WorkflowSim 1.1.0 on JDK 1.8
Datacenters	3 (Mist, Fog, Cloud)
VM Types	Mist (500 MIPS), Fog (1000 MIPS), Cloud (2500 MIPS)
Default Trust Levels	Mist (0.95), Fog (0.85), Cloud (0.75)
Task Confidentiality	High (3), Medium (2), Low (1)
Encryption Overhead	5.2 ms/MB
Scheduling Policy	Dynamic Trust-Aware Minimum Completion Time

B. Workflow Characteristics

Scientific workflows are characterized by complex data dependencies and varying computational requirements. We sourced five standard scientific workflows from the Pegasus Workflow Generator [32], [33]: Montage, CyberShake, Epigenomics, Inspiral, and Sipht.

Table IV summarizes the characteristics of these benchmark workflows. Each workflow type represents a different application domain (e.g., Montage for astronomy, CyberShake for earthquake science).

TABLE IV. SCIENTIFIC WORKFLOW BENCHMARKS

Name	Tasks	Jobs	Avg MI/Task	Data (MB)
Montage	100	201	12,500	3.2
CyberShake	100	201	45,000	102.4
Epigenomics	100	201	28,000	55.8
Inspiral	100	201	62,000	12.6
Sipht	100	201	18,500	8.4

C. Performance Metrics

The simulator was extended to calculate specific metrics relevant to secure fog computing. These metrics enable researchers to monitor the trade-offs between performance and security.

- Makespan (seconds): The total execution time of the workflow, from the submission of the first task to the completion of the last. It includes processing time, data transfer time, and security overhead.
- Total Cost (USD): The cumulative cost incurred by executing tasks on leased Cloud/Fog VMs. Cost models differ by tier (e.g., Cloud is cheaper per instruction but incurs higher latency).
- Security Score: A normalized value $(0.0 - 1.0)$ representing the average trust level of all VMs utilized during execution.

$$S_{score} = \frac{1}{n} \sum_{i=1}^{n} T(VM_i) \times C(task_i) \tag{13}$$

where, $T(VM)$ is the node's trust score and $C(task)$ is the confidentiality weight.

- Failure Rate: The percentage of tasks that failed due to trust violations or node unavailability.

D. Scenario 1: Functional Verification

We simulated a "Malicious Insider" scenario involving 100 tasks to verify the enforcement capability. We manually configured 2 Fog nodes (IDs 4 and 5) to have a Trust Score of 0.4, simulating compromised devices.

- Setup: 100 Tasks (50 High Sensitivity, 50 Low Sensitivity).
- Expected Behavior: The simulator should block all 50 High Sensitivity tasks from the compromised nodes.
- Observed Result: Analysis of the simulation logs confirmed that 0 High Sensitivity tasks were scheduled on the low-trust nodes. They were either queued or rerouted to Mist nodes.

Fig. 2 shows a snippet of the console output generated during this validation test. The logs clearly indicate the `TrustManager` rejecting the assignment and the Scheduler triggering a reroute event.

```
[INFO] 10.0: TrustManager: VM #4 (Fog Tier) Trust Score updated to 0.45 due to
       previous failure.
[INFO] 10.1: WorkflowScheduler: Attempting to schedule Task #15 (High
       Confidentiality) to VM #4.
[WARN] 10.1: TrustManager: ACCESS DENIED. VM #4 Trust (0.45) < Required (0.90).
[INFO] 10.1: WorkflowScheduler: Security Violation detected. Rerouting Task #15...
[INFO] 10.2: WorkflowScheduler: Task #15 successfully assigned to VM #1 (Mist Tier,
       Trust 0.96).
[INFO] 10.5: CloudSim: Job #15 started execution on VM #1.
```

Fig. 2. Console trace demonstrating dynamic security enforcement.

E. Scenario 2: Performance Impact Analysis

To demonstrate the simulator's ability to model trade-offs, we ran the Montage workflow under varying security constraints. The results shown in Table V illustrate how enforcing strict security policies impacts overall makespan and cost.

TABLE V. IMPACT OF SECURITY POLICIES ON WORKFLOW METRICS

Policy	Makespan (s)	Cost ($)	Security Score
None (Baseline)	428.5	1.25	0.65 (Low)
Trust-Aware	512.3	1.45	0.88 (High)
Encrypted	545.1	1.62	0.95 (V. High)

As expected, enabling trust-awareness increases the makespan by approximately 19% due to rerouting tasks away from powerful but untrusted nodes. The encryption overhead further adds a 6% delay. This data confirms that the simulator accurately reflects the performance penalties associated with secure computing, providing a valuable testbed for optimization research.

F. Simulation Performance Overhead

Adding security checks introduces computation overhead to the simulation engine itself. We compared the "Wall Clock Time" (how long the simulation took to run on the host PC) for Standard WorkflowSim vs. our Trust-Aware Extension (see Table VI).

TABLE VI. SIMULATION ENGINE OVERHEAD ANALYSIS

Workload Size	Standard Time	Extended Time	Overhead %
100 Tasks	450 ms	482 ms	+7.1%
500 Tasks	2100 ms	2250 ms	+7.1%
1000 Tasks	4500 ms	4810 ms	+6.8%

The overhead introduced by the trust validation and encryption modeling remains consistently below 7.1%, which is negligible compared to the simulated task execution times. This confirms that the security extension does not impose a prohibitive computational burden on the simulation engine itself.

G. Limitations

While the proposed framework demonstrates functional correctness and acceptable overhead, several limitations should be acknowledged. First, the network latency model is simplified and does not capture real-world phenomena such as jitter, packet loss, or dynamic routing. Second, the current trust degradation model is triggered only by task execution failures; it does not account for reputation attacks, collusion among malicious nodes, or time-based trust decay in the absence of

interactions. Third, the framework has been validated with up to 1000 tasks and approximately 50 fog nodes; scalability under hundreds of concurrent fog nodes with real-time trust updates requires further investigation. Fourth, validation is based on trace analysis and functional verification rather than comparison with physical fog testbeds. This approach is consistent with the validation methodology of established simulation tools such as CloudSim [14] and iFogSim [17], which similarly rely on scenario-based analysis to demonstrate correctness. Integration with real-world testbed data is identified as an important direction for future work.

VII. Discussion

The experimental results demonstrate that the proposed trust-aware extension to WorkflowSim successfully enforces security constraints while introducing quantifiable performance trade-offs. The 19% increase in makespan observed under trust-aware scheduling is attributable to the rerouting of sensitive tasks from high-capacity but low-trust fog nodes to lower-capacity but trusted mist nodes. This trade-off is consistent with findings reported in the literature on security-aware scheduling [27], where security enforcement typically incurs a 15–25% overhead on task completion time.

Unlike existing approaches that hard-code trust checks within scheduling algorithms, our modular `TrustManager` architecture enables researchers to independently evaluate and compare different trust models (e.g., Beta Reputation, EigenTrust, blockchain-based) without modifying the core scheduling logic. This separation of concerns represents a significant improvement over ad-hoc implementations [34] and promotes reproducibility in fog computing security research.

The simulation engine overhead of less than 7.1% confirms that the security extension is lightweight and suitable for large-scale simulation studies. This low overhead is achieved through the use of $O(1)$ trust lookups via hash-map-based storage in the `TrustManager`, avoiding the iterative computation required by global trust algorithms.

VIII. Conclusion

This study presented the design and implementation of a trust-aware extension to WorkflowSim, addressing the critical gap in existing fog computing simulation tools that lack native support for security modeling. The key contributions include: 1) an extended class hierarchy (`SecureJob`, `TrustedVM`) that integrates trust and confidentiality as first-class simulation attributes; 2) a modular `TrustManager` component that decouples security logic from scheduling logic, enabling interchangeable trust models; and 3) an encryption overhead model that accurately reflects the computational cost of security in simulation results.

Experimental validation confirmed that the framework correctly enforces security policies, blocking all high-sensitivity tasks from compromised nodes. The performance analysis revealed a 19% makespan increase and 16% cost increase under trust-aware scheduling compared to the baseline, quantifying the security-performance trade-off that is often overlooked in existing simulators. The simulation engine overhead remains below 7.1%, confirming the practical viability of the extension for large-scale studies.

The scientific value of this work lies in providing the fog computing research community with a standardized, extensible simulation platform for evaluating security-aware scheduling algorithms. By open-sourcing the framework and adopting modular design principles, we enable reproducible research and facilitate fair comparison across different trust models and scheduling strategies. Future work will focus on integrating real-world network trace data, supporting blockchain-based trust models [35], and validating the framework against physical fog testbed deployments.

***Abstract*—Dolphin-Assisted Therapy (DAT) is a therapeutic alternative used in comprehensive neurorehabilitation, aimed at improving the quality of life and social integration of patients with neurodevelopmental disorders through interaction with dolphins. However, the lack of defined standards makes it difficult to objectively evaluate its effectiveness. In this context, it was identified that the electroencephalographic device used to record EEG signals before, during, and after the sessions (based on a TGAM1 sensor) presented both functional and ergonomic limitations, as its readjustment interrupted the therapy sequence and caused discomfort in patients. To address this issue, the present work proposes the redesign of the device, incorporating ergonomic criteria to improve comfort, stability, and ease of use, without compromising the quality of the signal acquired by the TGAM1 sensor. The main objective was to optimize the user experience while also enabling the collection of more consistent and reliable data for analysis. The results show a significant improvement, achieving a 51% increase in signal retention. This made it possible to recover approximately 36 additional seconds of high-quality neural data per hour of therapy, thanks to more continuous and accurate EEG acquisition during interactions with dolphins. Furthermore, patient evaluations indicated greater acceptance of the device, highlighting improvements in comfort and weight perception compared to the previous version, thereby validating both its functionality and ergonomic design.**

I. Introduction

Dolphin-Assisted Therapy (DAT) is an alternative therapeutic method in which the well-feeling of children with various neurodivergent conditions is pursued via interaction between humans and dolphins, typically pregnant or lactating females from the bottlenose species. These therapies act as adjuncts to standard treatments that aim to promote healing and wellness [1]. Some studies have demonstrated that dolphin-assisted treatments accelerated motor skills, improved motivation for learning, benefitted on cardiovascular and respiratory efficiency, increased the flexibility of movement, help to reduce pain and helped in balance [2]. To date, DAT has been studied mainly to prove its efficacy [3].

Currently, DAT lacks established standards. Thus, a standardized approach is necessary to ensure that the therapeutic advantages of FIT are fully realized. According to Rutherford [4], standardization enables the ends of treatment efficacy evaluation. This enables better comparisons of results from different treatments, allowing professionals to determine the most effective techniques for specific diseases. In the case of DAT, for example, one measurement of its efficacy can be made by looking at variation in neurodivergent children's brain waves (as measured through electroencephalographic [EEG] signals) before, during, and immediately after the treatment with DAT. Depending on cerebral cortex region, the 10/20 system [5] defines a set of specific points on the scalp where several electrodes must touch to measure an EEG. This enables the measurement of electrical impulses generated by neurons to study human cognitive activity. Standardization of DAT is a problem, because the approach often differs widely in terms of method, frequency and duration of sessions, training used and species/type of dolphins [6], [7], [8], which can produce great variation in results. Therefore, the existence of measurement methods and instruments to capture EEG signals before, during, and after each session is essential to analyze the effectiveness of DAT.

Repositioning the electroencephalographic apparatus recording EEG signals before, after and during DAT represents a considerable challenge faced in the standardization of DAT.

In this way, the main goal is not to improve on the inherent performance of the sensor which will always be fixed by design, but rather, to obtain a match with its theoretical performance by simulating to some extent the favorable (or ideal) operating conditions where the sensor was initially proven.

In addition, it was determined that the moments of placement and withdrawal of devices are different between the types of conditions of the child being evaluated with DAT, so much so that they interfere with the performance order in which operations were carried out throughout the sessions, generating some discomfort for its use [9].

Research in EEG focuses both on understanding human cognition and on the use of brain signals to interact with the external environment through brain–computer interfaces (BCI).

A large portion of this research is conducted in medical or academic institutions [10].

There are multiple potential applications outside the laboratory environment, including prosthetic control, communication for individuals without motor function, therapeutic rehabilitation, and video games [11]. However, implementing EEG in real-world environments presents several challenges, particularly in uncontrolled contexts such as DAT. In these scenarios, expert personnel are not always available, electrode caps are often complex, and their placement requires a considerable amount of time. Furthermore, considering that patients are often neurodivergent children, it is essential that the device be comfortable and not cause discomfort during use.

In this way, the main objective on signal retention in an aquatic therapeutic environment, where conventional EEG devices face ergonomic challenges from patient movement and signal interference from the physical setting, addresses a specific and underexplored design problem, and the quantified improvement in signal retention provides a concrete metric of engineering value.

Therefore, the primary goal is the maintenance of the signal in a therapeutic water setting; traditional EEG devices are ergonomically complicated with behaviors such as patient movement and physical environment signals. It addresses a concrete design problem that has thus far been underdiscussed and the measured improvement in signal retention quantifies an engineering value.

Ergonomics is the applied science that studies interactions between human beings and other elements of a system. This is done by applying theories, principles, data and design methods whose end aim is improving human well being and system performance [12], [13], but only few studies include ergonomic aspects in the design of electroencephalographic devices [14], [15]. The current research describes the re-design of an electroencephalographic device utilized for EEG signals acquisition incorporating specific ergonomic concepts. In this redesign, we aim to create an instrument that is not only comfortable, functional, and aesthetically appealing for the patient, but also decreases applicable downtime identified in the DAT standardization [9], so as to maximize stable data collection which will allow multi-site analysis protocols or cross-instrument comparison of study conclusions as well as support the development of new evidence-based therapeutic strategies.

The structure of this study is as follows: Section II provides the fundamentals of electroencephalography and ergonomics that made it possible to redesign the electroencephalographic equipment employed pre-, peri- and post-DAT. Section III illustrates the methodology applied in this study. Section IV describes the Redesign and Development Process of Electroencephalographic Device. Section V provides the results and discussion of analysis. Lastly, the conclusion and future work is given in Section VI.

II. Theoretical Framework

A. Electroencephalography

Electroencephalogram (EEG) signals can be measured non-invasively through electroencephalography, which is widely used to obtain electrical impulses generated from human cognitive actions [16]. For research purposes this technique has been utilized for neuroscience, psychology etc.; designing brain-computer interface applications for diagnosis of several disorders including epilepsy, Attention-Deficit/Hyperactivity, etc. [17], [3]. EEG enables the recording of electrical potentials via several electrodes touching the scalp at designated locations on the cerebral cortex, as defined by an international system known as 10/20 system (see Fig. 1; [5]).

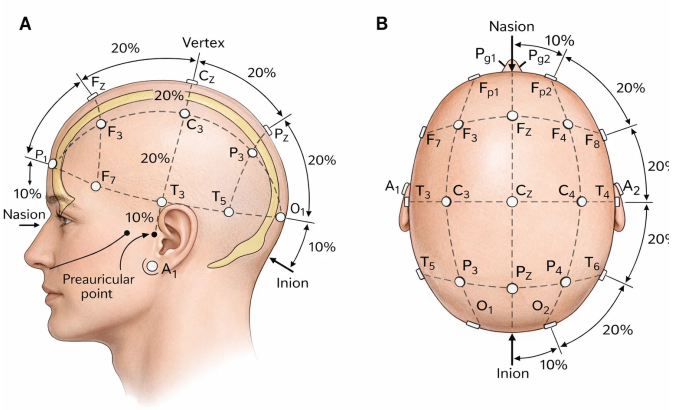

Fig. 1. International 10-20 system for the hydration of extracranial electrodes (Fp: Fronto-polar; F: Frontal; C: Central; P: Parietal; T: Temporal and O: Occipital), based on [5].

Electroencephalography has several advantages over other imaging and behavioral observation methods such as Magnetoencephalography and Magnetic Resonance Imaging, including its excellent temporal resolution and low maintenance cost [3]. Dry electrodes do not require the application of an electrolyte, making their manipulation and cleaning easier. In addition, they enhance ergonomics and comfort designed especially for non-expert users [18]. At the moment, new materials are enabling the production of wireless, miniaturized systems for enhanced applicability [15]. If established this technology adaptation and enhancement might allow its employment beyond scientific labs or hospital, and possible studies around real world situations, domestic health usage as well as the analysis, treatment and supervision of patients with neurodevelopmental problems [19], [20]. However, the implementation of EEG systems in real-world environments presents several challenges, particularly in uncontrolled contexts such as DAT. In these scenarios, specialized personnel are not always available, electrode caps are often complex to handle, and their placement requires a considerable amount of time. Furthermore, since the patients are often neurodivergent children, it is essential that the device provide comfort and not cause discomfort during its use.

Therefore, the development of systems that are easier to use and allow more precise electrode placement could significantly expand real-world BCI applications [21], [22]. In this regard, several studies recommend the design of more ergonomic EEG devices that better adapt to the diversity of head shapes and sizes, as well as to anatomical reference points [23]. To improve usability and accuracy, devices should be designed so that the electrodes are positioned as close as possible to

their ideal locations according to the 10–20 system, while also ensuring repeatability between measurement sessions. This aspect is particularly relevant in DAT sessions, since, as previously mentioned, this field still lacks fully defined standards for data measurement and analysis. Therefore, having a device capable of adapting to the specific conditions of the environment in which this therapy takes place is essential for advancing research in this area.

B. Ergonomics

Ergonomics is a scientific fields devoted to the study of interactions among humans and their elements of a system. It is done by applying theories, principles, data and design methods to enhance human well-being and the overall system performance [12], [13]. Product ergonomics studies the needs of users and the conditions surrounding use. Taking into account ergonomic factors enables product design which allows adapting a product to the features of end users to ensure direct efficiency, safety and productivity in its operation so that it does not cause health problems for people [24].

Disparities between individuals such as gender, race, and abilities can cause product design to fall short. When a device fulfills both the functional and emotional needs of its users [25], it becomes more attractive. As previously mentioned, much of the research on brain–computer interfaces (BCIs) has focused on different technical aspects, such as data acquisition, signal processing, the theoretical foundations of BCIs, as well as the development of conceptual applications or innovative prototypes [26], [27]. Although these research lines are essential to ensure the reliability of BCI technology, studies focused on the ergonomics of these devices remain limited. In particular, further research is needed to analyze how factors such as comfort, usage limits, and the physical characteristics of users influence the suitability of BCI systems for implementation in experimental environments and real-world applications. Such studies are essential to fully exploit the potential of these technologies in a wide variety of contexts.

Despite the progress achieved, the benefits of BCI systems are often limited by several factors, including low signal reliability [26], [28], fatigue associated with prolonged device use, and, in some cases, difficulties related to usability. These limitations raise questions about the suitability of these devices for both research purposes and practical applications. In the case of physiological measurement devices such as EEG systems, ergonomic design becomes particularly important, since the equipment must remain in direct contact with the user's head during signal acquisition. For this reason, it is essential to consider factors such as weight distribution, the pressure exerted by the electrodes, ease of placement, and the ability to adapt to different cranial morphologies [10]. An appropriate design not only improves user comfort but also contributes to obtaining more stable and reliable recordings.

In the context of DAT, the design of the EEG device must also consider the specific conditions of the environment in which the sessions take place. Factors such as user mobility, interaction with an environment close to water, and the need to maintain electrode stability during the therapeutic session require the development of specialized ergonomic solutions. Therefore, designing a device that combines comfort, stability, and ease of use is essential to ensure both the quality of electroencephalographic recordings and an appropriate user experience during therapeutic sessions.

C. Electronics Behind EEG

1) Acquisition: The TGAM1 (ThinkGear ASIC Module) is a single-channel low-power biosensor chip designed by NeuroSky for embedded electroencephalography. The module combines the TGAT chip and is intended to be used in portable and portable BCI devices, as shown in Fig. 2. The TGAM1 works in a voltage range of 2.97 V to 3.63 V and consumes a maximum current of 15 mA @ 3.3 V, leading to very low power consumption as necessary for battery operated applications like the EEG for Dolphin-Assisted Therapy application. It shows an extra-small size of $27.9mm \times 15.2mm \times 2.5mm$ and weighs only around 130 mg, making it suitable for use in headset applications where the module will not interfere with user comfort. It has a 12 bit analog to digital converter which supports 512 Hz sampling rate, and it can capture EEG signals in the range of 0.5 Hz to 100 Hz. The module needs three dry contact electrodes, an electrode for EEG signal registration, and a second as a reference; the solution is to connect the third electrode as the ground. The TGAM1 also has 4 kV of contact discharge and 8 kV of air discharge resistance for built-in electrostatic discharge protection, allowing it to operate reliably under a variety of environmental conditions.

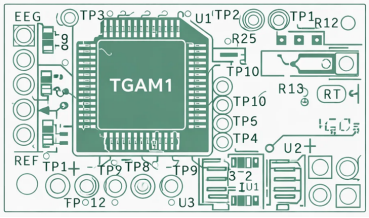

Fig. 2. ThinkGear ASIC Module: Single-channel low-power biosensor chip designed by NeuroSky for embedded electroencephalography.

TGAM1 is a UART serial device with configurable baud rates of 1200, 9600, and 57600 bps; the factory setting for normal data exchange is after booting, having it fixed at the value of 9600 bps. The module also has a built in notch filter to remove power line interference, which can be switched by connecting *the M* pin: connecting it to Vcc enables 60 Hz filtering for countries with 60 Hz AC, such as Mexico or USA; while connecting it to ground filters at 50 Hz for those using 50 Hz AC like Spain or France. The module also has configuration pads (B_0 and B_1) on the back that settle the baud rate and data output mode for a permanent configuration. The TGAM1 is designed to output raw EEG data at 512 Hz and processed parameters, including proprietary NeuroSky Attention and Meditation meters scaled from 0 to 100 percent, along with efficient eye blink detection. These processed outputs are particularly useful for therapeutic applications, as they offer real-time indicators of patient cognitive states without a need for sophisticated signal processing algorithms on the host device.

2) Wireless communication: The first device you will need for a wireless EEG system used in Dolphin-Assisted Therapy is the HC-05 Bluetooth module, Fig. 3, which allows the patient

to transmit their brain activity data over the air to a monitoring station without being tethered by heavy wires. In addition, The TGAM1 EEG sensor captures the neural signals needed to transmit with this module through the HC-05 Interface wirelessly in real-time while children have free interaction with dolphins.

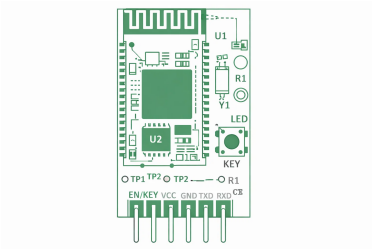

Fig. 3. HC-05 Bluetooth serial module: indicating it's onboard PCB antenna, its main controller ICs and some supporting components.

In this way, HC-05 is a traditional Bluetooth module based on the Bluetooth specification V2.0 and Enhanced Data Rate (EDR) for transparent wireless serial communication. It works on the 2.4 GHz ISM frequency band with GFSK modulation, and CSR's BC417 chip is used to provide reliable wireless connectivity. It has an RF transmit power of +4dBm and reception sensitivity of -85 dBm, allowing communication up to 10 meters in open space. The HC-05 measures just $27mm \times 13mm \times 2mm$ and weighs about 3.7 grams, and includes a PCB antenna with its interface covered by a connector design featuring the following pin layout on a 2.54 mm pitch header: STATE, RXD, TXD, GND, VCC, and EN. This module runs with a supply voltage of 3.6 V to 6 V and consumes 40 mA when pairing and 8 mA when connected. An onboard LED indicates the module's operational status: fast blinking for no connection, slow blinking for AT command mode, and double blinking for successful connection.

The HC-05 communicates via a UART interface, with adjustable baud rates of 4800, 9600, 19200, 38400, 57600, 115200, 230400, 460800, 921600, and 1382400 bps, with factory default settings of 38400 bps, 8 data bits, 1 stop bit, and no parity. The module has two operational working modes: 1) at command response mode for AT command configuration and automatic connection mode for data transmission, it can work as Master, Slave or Loopback roles; and 2) AT_COMMAND_MODE: This mode can be accessed by powering on the module while holding down the enable button, which will make the LED blink slowly during start up (The default baud rate for AT command mode is 38400 bps) Some key configurable parameters (AT+NAME= for Name, AT+ROLE=0 for Slave and 1 for Master, AT+PSWD; default is "1234" or "0000", etc.). It can all be done via serial port (AT+UART). The STATE pin shows whether a connection is active or not; it will output HIGH when connected and LOW when disconnected, allowing the microcontroller to track the status of the connection. Supported features, the module supports power-on auto-connect last paired device and adaptive frequency hopping to minimize interference.

III. Methodology

The methodology (Fig. 4) used for the redesign of the electroencephalographic device that retrieves the EEG signals before, during and after DAT with ergonomic concepts in order to bring comfort, functionality and beauty for the patient. Applied methodology: Soft Systems Methodology from the study proposed by Coria et al. [9] to demonstrate the B2 Model of relevant activities for the development of DAT-specific measurement tools.

Stage 1: In this stage, the elements that make up the electroencephalographic device were developed using Computer-Aided Design (CAD) tools. The objective was to generate a detailed digital representation of the device at a 1:1 scale, allowing precise visualization of the shape, dimensions, and arrangement of each component. During this phase, structural aspects such as the support base, electrode placement points, adjustment mechanisms, and fastening elements required to keep the device stable during use were defined. Additionally, the digital modeling made it possible to anticipate potential interferences between components and carry out preliminary adjustments before the physical prototype was manufactured.

Stage 2: In this stage, the main ergonomic factors that needed to be considered for the redesign of the device were identified and analyzed. These factors included aspects such as system weight distribution, the pressure exerted by the electrodes on the scalp, ease of placing and removing the device, and adaptability to different cranial morphologies. Criteria related to user comfort, system stability during movement, and interaction with the therapeutic environment were also evaluated. This analysis made it possible to establish design guidelines aimed at improving the user experience and ensuring that the device could be used during therapy sessions without causing discomfort or interfering with EEG signal acquisition.

Stage 3: In this stage, the results obtained from Stages 1 and 2 were integrated through analysis sessions and brainstorming activities, in which different design alternatives were evaluated to meet both the technical requirements and the previously identified ergonomic criteria. Based on this integration, the device design was developed using SolidWorks, which enabled detailed three-dimensional modeling of the system. During this phase, the final dimensions of the device, the precise location of the electrodes, the adjustment mechanisms, and the structural elements required to ensure stability, comfort, and functionality during use were defined.

Stage 4: Once the digital design of the device was completed, the physical prototype was manufactured using 3D printing. This process allowed a tangible version of the device to be produced quickly and at low cost, facilitating early evaluation of the proposed design. The use of additive manufacturing technologies made it possible to accurately reproduce the geometries created in the CAD model, while also allowing rapid modifications if necessary. The prototype was printed in resin to obtain a lightweight and resistant structure suitable for initial functionality testing.

Stage 5: In this step, various tests were carried out to evaluate the performance of the developed prototype. These tests included verifying the overall functionality, user comfort during use, system stability when placed on the user's head, and the proper distribution of the components' weight.

Additionally, the ease of placing and removing the device was analyzed, as well as its ability to maintain the position of

the electrodes at the anatomical points required for capturing EEG signals. The results obtained at this stage made it possible to identify strengths of the proposed design and potential areas for improvement.

Stage 6: Finally, in this stage the results obtained during the tests performed in Stage 5 were analyzed in order to identify possible modifications or adjustments required in the device design. This analysis made it possible to detect aspects that could be optimized, such as adjustments in the structure, improvements in fastening mechanisms, or modifications in the distribution of components. The process then returns to Stage 3, where the identified improvements are incorporated to generate a new version of the design. In this way, an iterative cycle of continuous improvement is established, allowing the device to be progressively refined until a design that meets the functional, ergonomic, and operational requirements for its application in DAT sessions is achieved.

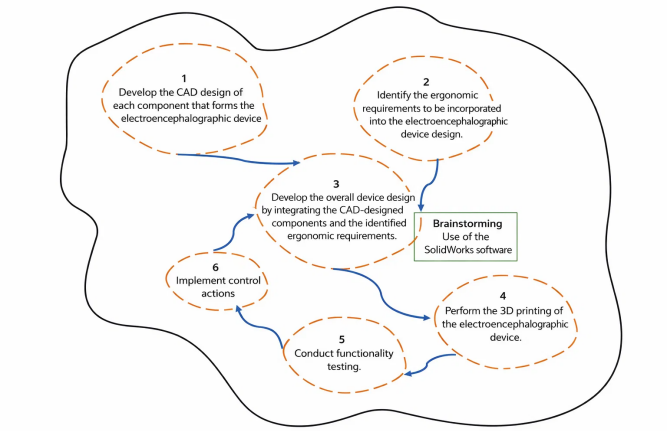

Fig. 4. Methodology used for the design of the electroencephalographic device.

IV. Experimental Results

A. Experimental Setup

The methodology used in this research was approved by the Ethics Committee of the National Polytechnic Institute of Mexico, according to Confidentiality Commitment Letter D/1477/2020. This document endorses the method of collecting various samples and the treatment provided to the bottlenose dolphins by the research team. The responsible use of patient data was guaranteed and communicated, and consent was obtained for the use of the data obtained in the experiments. Before taking the samples and connecting the devices, the procedure was explained to the patients; those who did not agree could withdraw their participation immediately. Participants who accepted the methodology and materials for sample collection signed a written informed consent form (from November 14 to 17, 2023). Participants were also informed about the tests they would undergo, although some did not fully understand them before entering the tank with the cetaceans.

B. Electroencephalographic Device: Current Design

Even if it is not a more advanced technology, the current design of this EEG signal capture and recording device must be non-invasive, waterproof, easy to wear, portable; These features were selected based on the habitat of DAT since EEG signal capture and recording in presence of saline and aquatic environment. As such, when the device is attached to the patient's head and does some interaction with salt water, there should be no risk concerning short circuit.

TGAM1 sensor is an electroencephalographic device; this is a single-electrode brain-computer interface. The three electrodes: 1) EEG, 2) Reference and 3) Ground present allow raw brain-wave data collection by amplifying the signal, processing it into a readable version that can be digitized. This sensor was used for measuring EEG signals at the f_{p1} position in the prefrontal region of the brain. Moreover, it can also detect voluntary and involuntary eye blink movements of the user [29].

This reveals one of the limitations of the study, as it makes qEEG extraction unfeasible [30]. This limitation is expected because the children undergo Dolphin-Assisted Therapy and always, or almost always, have wet hair, which complicates the use of other electrodes, leaving only f_{p2} as a possibility, but the same limitation would apply since it is close to f_{p1}.

Now, the TGAM1 sensor was integrated into a sports visor (Fig. 5), which can be modified to patients with any disability or neurological problem. These TGAM1 sensors are contained in a hermetically sealed resin 3D printed box to ensure that the circuit does not move, also protecting it from salt water exposure. On the left side of the device are two holes for the cables that connect with dry electrodes and project into the visor, which serve to connect circuits implanted in a patient's skull and culminate inside his or her head, see Fig. 6.

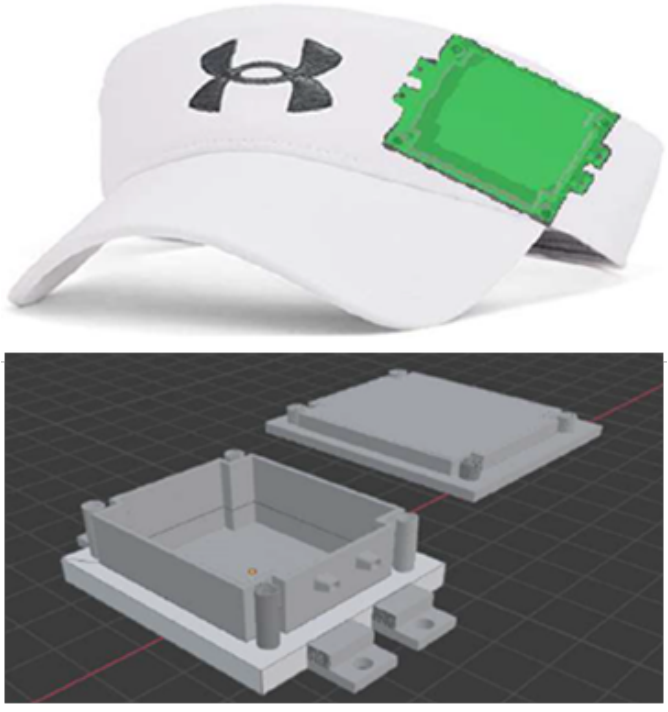

Fig. 5. Design of the electroencephalographic device.

Fig. 7 shows the connections between the TGAM1 EEG

Fig. 6. Electroencephalographic device of current use in DAT (AI-generated illustration based on the original scene; no real person's likeness is shown).

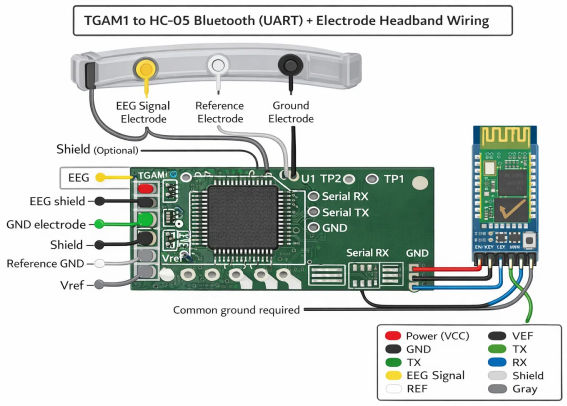

Fig. 7. TGAM1 EEG sensor connected to an HC-05 Bluetooth module via UART.

Fig. 8. Elements comprising the electroencephalographic device.

sensor module and the HC-05 Bluetooth module The TGAM1 communicates with the HC-05 over a simple UART serial connection that allows for bidirectional communication, as shown in the attached diagram. In particular, the TGAM1 serial transmitter (TX) pin connects directly to the HC-05 module serial receiver (RX) pin, and the TGAM1 serial receiver (RX) connects to HC-05 serial transmitter (TX), forming a full duplex asynchronous serial link. Note that both modules have a common ground connection; this is needed to ensure signal integrity and avoid voltage level mismatches. Power supply: There are two communication modules connected by a common VCC.

However, the electrode headband interface (top section of the wiring diagram) uses the three-electrode configuration needed for accurate EEG capture by the TGAM1. Signal electrode: Actual neural activity of the patient's prefrontal cortex at the position f_{p1} is measured using an EEG signal electrode, which is connected to the EEG input pin of the TGAM1 module. To complete the differential measurement, the reference electrode is connected to the pin V_{ref} and the ground electrode provides the common reference potential that connects to the pin of the GND module.

Ensure that once the dry electrodes capture the raw EEG signals, TGAM1 conditions them and transmits them through HC-05; this complete wiring arrangement makes it possible to collect data wirelessly during therapy sessions.

C. Proposed Redesign of electroencephalographic Device

1) Stage 1: This step was to create the parts of the electroencephalographic system using CAD software, a 1:1 scale representation for later design and adjustment. More specifically, SolidWorks design software is used in this research. The elements required for device operation can be found in Fig. 8; it is mainly composed of the TGAM1 sensor, two AAA batteries and other components that will make this equipment operable.

2) Stage 2: Cranial diameters are measured in a sample of 6 patients undergoing DAT. These cranial diameters and patient size are summarized, based on the types of conditions presenting in an infant, as shown in Table I. The new version of the device should adapt to both the smallest (50 cm) and largest (62 cm) cranial diameter measures.

TABLE I. DATA FROM PATIENTS UNDER STUDY

Patient	Condition	Cranial Diameter (cm)	Size	Age	Gender
1	Cerebral Palsy	53	S	12	M
2	Cerebral Palsy	50	XS	10	F
3	Autism	55.5	M	12	M
4	Down Syndrome	54	S	29	M
5	Down Syndrome	51	XS	12	M
6	Autism	62	XL	22	M

One of the challenges of the current electroencephalographic device is that the weight distribution was incorrect, making the box that houses the TGAM1 sensor tilt to the left. That is both inconvenient as it interrupts sampling of the EEG signal during DAT and uncomfortable for the infants being studied. Thus, the new device should fulfill metrics such as overall system comfort (to include electrode comfort), perception of system weight and stability perception [15]. Additionally, since the current device is made of rigid resin and includes screws that secure the enclosure containing the sensor, repeated opening and closing have led to the appearance of structural fractures (Fig. 9).

3) Stage 3: The heads of the patients studied vary in size and shape. Conventional EEG caps are the only option for electroencephalographic devices flexible enough to account for

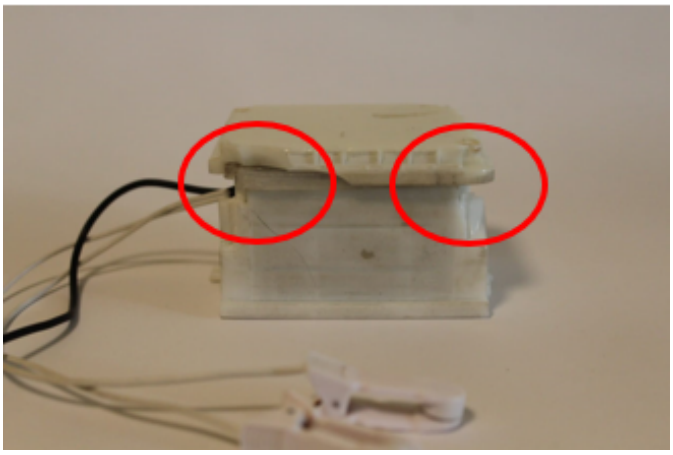

Fig. 9. Fractures appeared on the first electroencephalographic device.

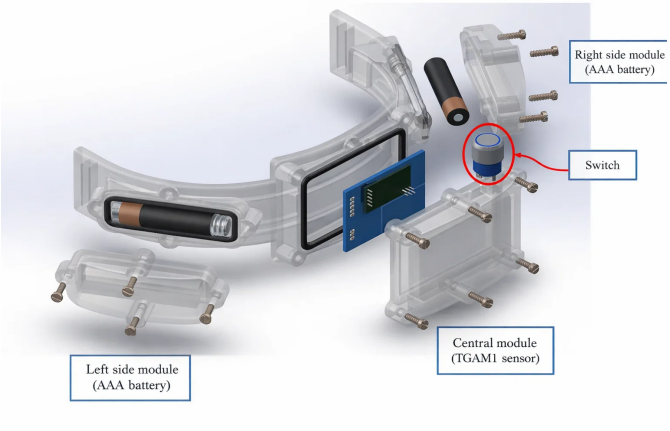

Fig. 11. Redesign of the electroencephalographic device.

this variability. Therefore, the device measurements are based on a conventional cap standard. Construction dimensions in cm for this device development are displayed in Fig. 10. The angle at which the TGAM1 sensor is placed falls within f_{p1} location parameters of the 10/20 international system [5].

Components of the device were rearranged to offer better comfort for users. The electroencephalographic device contains 3 sections (Fig. 10), which absorb the TGAM1 sensor (middle) and AAA batteries (sides). We modified the integration of dry electrodes to the patient, changing from a single connection point at one ear to connections at either ear, with goals related to meeting Stage 2 metrics: overall system and electrode comfort, perception of system weight, and stability. A fastening technique adapted from standard caps was proposed, relying on an elastic band that enable the adjustment of the device to the size of patient's head.

These modules were built under the IP68 standard (IEC, 2013), so that if the device falls into water. Fig. 10: Switch were installed to facilitate the ON/OFF state of sensor; Fig. 11: Reduce tension stress that would cause fracture to some material, (plastic inserts) or improve fastening.

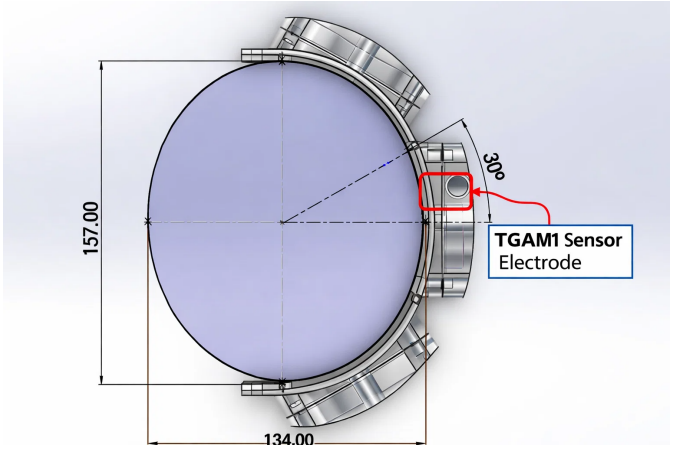

Fig. 10. Dimensions of the electroencephalographic device.

4) Stages 4, 5, and 6: Stage 4: The prototype from stage 3 was printed in a 3D impression (Fig. 12). The resin prints of the device, first hard resin. However, when performing the functionality tests corresponding to Stage 5, it was found that this kind of material cannot mold properly into the human head shape. Thus, one of the errors during stage 6 was switching up to semi-flexible resin material type. It was found that this material conformed tighter with human skull shape after a novel 3D printing process (Fig. 13) compared to the standard BA in Fig. 14.

Likewise, it was observed that, due to variability in patients' cranial dimensions, it was necessary to develop different device prototypes until identifying the one that provided the best fit for most users. Fig. 15 shows the different versions developed, which followed a continuous improvement process until reaching the design that best adapts to the patients.

Fig. 12. Electroencephalographic device 3D design: printed with hard resin.

V. Discussion

Patients were asked to evaluate various aspects relevant to the use of the headbands, which are presented in Table II [15]. Based on the results obtained, the corresponding graphs

Fig. 13. Electroencephalographic device 3D design: printed with semi-flexible resin.

Fig. 14. Use of the electroencephalographic device (AI-generated illustration based on the original scene; no real minor's likeness is shown).

Fig. 15. EEG device prototype evolution.

were generated (Fig. 16). Regarding overall system comfort, a significant improvement can be observed compared to the previous version. Most patients rated the device as very comfortable (Fig. 16A). This is mainly attributed to the fact that, in the previous version, the concentration of the sensor on one side caused discomfort. Additionally, the redesign of the adjustment mechanism made the device easier to place and more comfortable during use.

TABLE II. FACTORS FOR EVALUATING COMFORT AND PERCEPTION

Evaluated Variable	Description	Scale
Global system comfort	Overall comfort level of the device considering the electrodes, headband, and amplifier.	1 = Not comfortable at all … 7 = Very comfortable
EEG electrode comfort	Perceived comfort of the electrodes and their contact with the forehead skin.	1 = Not comfortable at all … 7 = Very comfortable
System weight perception	Sensation of the device's weight during use.	1 = I do not feel the weight; 2 = Noticeable but not bothersome; 3 = Noticeable and slightly bothersome; 4 = Very noticeable and bothersome
System stability perception	Perceived stability of the device when placed on the user's head.	1 = I feel it stable; 2 = I feel it a bit unstable; 3 = I feel it unstable

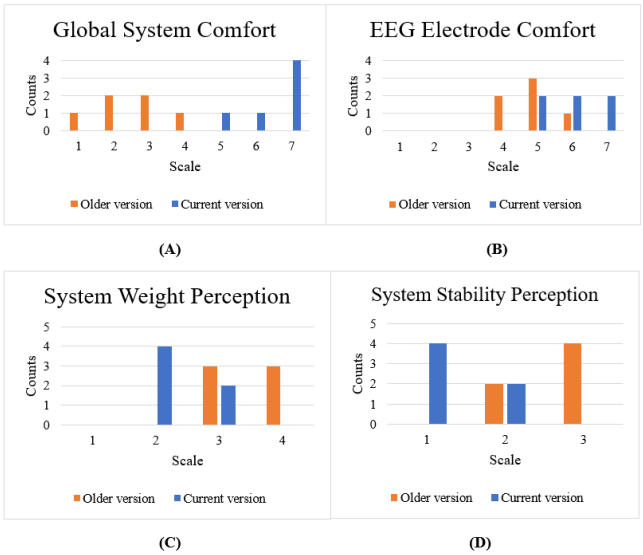

Fig. 16. Comfort metrics.

With respect to the comfort of the EEG electrodes (Fig. 16B), a notable improvement was also identified. While in the previous version comfort was predominantly rated at level 5, in the new design the evaluations were concentrated at levels 6 and 7. This change is due to the redesign ensuring better contact between the electrode and the forehead, thereby increasing perceived comfort. Regarding the perception of the system's weight (Fig. 16C), the previous version was mostly rated as *very noticeable and bothersome*. In contrast, in the new version this perception shifted to *noticeable but less bothersome*, indicating an improvement. This result can be explained by the redistribution of the system's weight, particularly by placing the batteries on both sides of the device instead of concentrating them on a single side.

In this way, in terms of the perception of system stability (Fig. 16D), a similar improvement can be observed. The evaluation shifted from *unstable* in the previous version to *stable* in most cases. This improvement is mainly due to the redistribution of components in the new design, which enhances balance and fit during use.

On the one hand, the TGAM1 EEG sensor features an advanced quality assessment mechanic via its Poor Signal flag system [31], which constantly checks the integrity of neural signal acquisition. The NeuroSky guide has defined the poor signal parameter between 0 and 200, where 0 is the ideal signal and 200 denotes absolute garbage. This flag system works by simultaneously monitoring several attributes of the incoming brainwave data, including signal flatness, excessiveness, power ratio, and off-head. Each of the above mentioned attributes maps to certain flag values, including 25 for flatness in signal range (not enough EEG signal, usually associated with large movements or peak saturation), 26 for convexity in signal range (too much noise from muscle movement or headset motion), 27 for power ratio information (periodic environmental interference), and 29 for off-head detection of device placement. One thing in particular here is right: multiple flags can be enabled at once but their values add to a unique identifier, so 51 would mean that both the flatness (25) and excess (26) tests failed; this is an important part of the system. In other words, to preserve the behavioral logic of the system, *eSense* Attention and Meditation signals are updated only if Poor Signal equals zero; whenever it is non-zero, these constructs freeze in their last known values. In addition, if Poor Signal is higher than 51 during seven seconds, then the *eSense* values reset to zero, and it takes four seconds of perfect signal quality for the system to be reinitialized. In settings like Dolphin-Assisted Therapy, where patient movement and water conditions can have a detrimental effect on the fidelity of captures, this intelligent framework for quality assessment is highly relevant.

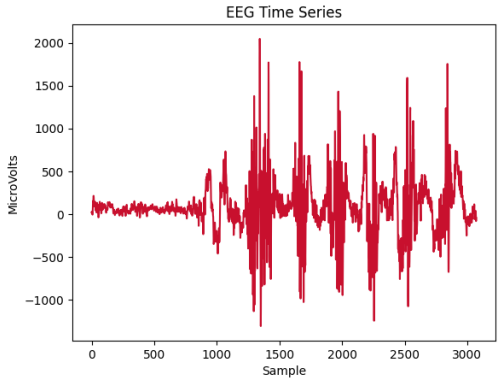

Fig. 17. EEG signal acquired using the original device version during a DAT session.

On the other hand, the improvements in ergonomic design of the electroencephalographic device for use during DAT include a significant improvement in signal acquisition reliability through rigorous testing compared to previous versions, considering the challenges identified by the Poor Signal monitoring system. Through quantitative analysis given the sampling rate of 512 samples per second (sps), the original device configuration caused an average loss of 608 samples per minute or 1.98% of all neural data obtained during therapy sessions. This translates to about 1.188 seconds of lost or corrupted EEG data per minute of patient-dolphin interaction, which is a significant loss in neurally monitored continuity. In the redesigned device, this reduction is dramatic, with only 298 samples lost per minute on average (0.97% of all samples), which translates into approximately only 0.582 seconds without signal in each therapy minute. This translates into an approximately 51% improvement in signal retention, meaning that for each hour of Dolphin-Assisted Therapy, the ergonomic redesign device reinstates almost 36 seconds of additional high-quality neural data that would have been lost due to Poor Signal conditions.

This redesign of the device showed a lower signal artifacts rate in comparison to the previous version, and better signal-to-noise ratios with error rates equal to those obtained from the original design thanks to its ability to be more adapted to cranial shapes and then making involuntary relative movements between dry electrodes and scalp significantly reduced.

The upgraded ergonomics, the semi-flexible resin materials improving electrode contact area, weight balance when worn, and three-point stable ear references for fitting quality control collectively address the movement artifacts plus contact-loss types of flatness/oversaturation flags (which are both highlighted in the Poor Signal) during sessions. As a result, clinicians and researchers may be able to acquire more continuous and accurate EEG recordings during periods of dolphin interaction, thus improving the understanding of possible therapeutic outcomes and helping to develop better evidence-based protocols to use dolphin intervention in the neurorehabilitation field with children experiencing this range of disorders.

As can be observed in Fig. 17 (original device) and Fig. 18 (redesigned device), a qualitative comparison of the signals taken from both devices shows that the continuity of the signal is improved for the redesign version, as well as its noise.

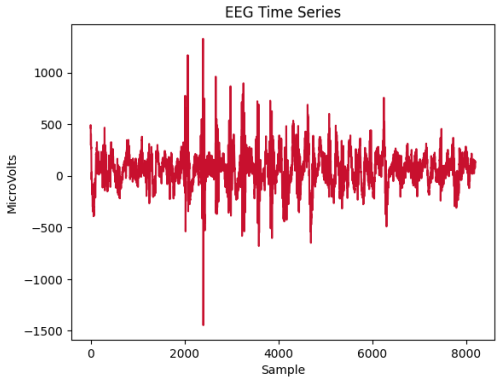

Fig. 18. EEG signal acquired using the redesigned device version during a DAT session.

The experiment was developed collecting data from six individuals, participants in dolphinarium facilities, where were part of a study examining the impact of dolphin-assisted therapy on people with neurodevelopmental disorders. One female and five males (aged 10 to 29 years) received diagnoses of Cerebral Palsy, Down Syndrome and Autism Spectrum Disorder (Grade II). A matlab console-level application was developed to collect DAT. of brain activity and interaction patterns during dolphin-assisted sessions, before DAT (one minute), five minutes during DAT and one minute after DAT.

Finally, there are still very few studies that keep ergonomic aspects in mind for the design of electroencephalographic de-

vices [14], [15]. Here, CAD became a fundamental component of this study by allowing us to develop a three-dimensional model representation of the EEG device. This enabled specific visualization of the prototype and adjustments to be made as required prior to 3D printing. For this study, since the size and shape of patients' heads were not uniform, it was decided to rely on typical measurements for traditional caps in order to define the dimensions of such a device. With the semi-flexible resin in 3D printing and the fastening style of a traditional cap, using an elastic band, enabled it to fit perfectly to the shape of the patients' heads. The redesigned version of the EEG device serves not only as a replacement for the TGAM1 sensor, but it also harnesses ergonomic principles in order to accommodate for DAT's corrosive and saline environment. The redistribution of components helps prevent tensile stresses that may cause fractures in the material, such as those that occurred in the previous device, and ensures the overall comfort of the system, including electrode comfort, weight perception, and stability, as evaluated by López et al. [15]. However, it is important to note that this questionnaire has a limitation, as it is a personalized instrument.

VI. Conclusion and Future Work

The necessity of creating a standard method during DAT development [9] showed that adjusting the electroencephalographic device to record EEG signals before, during and after DAT is not only interrupting the sequence of operations throughout the sessions but also uncomfortable for use. It was re-conceptualized for comfort, functionality, and aesthetic appeal to the patient through ergonomic concepts and methodologies such as Computer-Aided Design and 3D printing. User acceptance in terms of ergonomics and usability represents one of the main challenges for EEG systems to become widely adopted technologies within neurotechnology and non-invasive brain–computer interfaces [10].

In this research, through the redesign of the electroencephalographic device, significant improvements were achieved in key aspects such as overall system comfort, electrode comfort and their contact with the skin in the frontal area, perceived system weight, and perceived stability, compared to the evaluation of the previously used device in DAT.

As an additional advantage, not only were comfort conditions improved, but environmental considerations were also incorporated into the design, making the device more resistant to the environmental conditions to which it is exposed during use. Furthermore, the implementation of an EEG signal acquisition system based on the TGAM1 module, with wireless transmission capability, represents a significant improvement, as it facilitates its use under the dynamic conditions required by DAT and enables continuous monitoring of EEG signals throughout this study.

The ergonomic improvements were also reflected in concrete gains in signal quality. Due to the Poor Signal monitoring system designed within the TGAM1 sensor operating at a sampling frequency of 512 sps, with the loss of an average of 608 samples per minute (1.98% of neural data), approximately 1.188 seconds of corrupted signal would be produced each minute throughout therapy when using this original device configuration. This should be compared with 298 samples lost per minute (0.97%) for the redesign, meaning that only 0.582 seconds of signal was lost per average minute, therefore it had precisely 51% more signal retention. As a result, for example, nearly on the average 36 seconds of additional high-quality neural data can be recovered per hour of therapy due to this more continuous and accurate EEG recording throughout dolphin interactions.

Although the redesign of the device demonstrates significant improvements in signal acquisition achieving a 51% increase in signal retention there are still critical aspects that need to be addressed. These include the inherent limitation of using a single-channel EEG, which restricts the richness and resolution of neurophysiological data, the durability of the prototype under prolonged use conditions, the need to validate its performance across different therapeutic environments to ensure the generalizability of the results; and the challenges associated with scaling the manufacturing process through 3D printing, particularly in terms of costs, production time, and consistency in device quality.

As future work, a time analysis using the new multichannel electroencephalographic device is proposed, in order to perform multidimensional analysis along with qEEG preprocessing.

It is expected to reduce downtime caused by device adjustments, positively impacting the efficiency of both the trainer and the therapist, and enabling uninterrupted EEG signal acquisition before, during, and after DAT sessions.

Similarly, as future work, it is proposed to perform inferential statistical tests, such as the Wilcoxon signed-rank test or the paired t-test, to confirm that the differences observed in the redesigned device (general system comfort, perception of EEG electrodes, perceived weight, and perceived stability) are statistically significant. Furthermore, an evaluation using the System Usability Scale is planned to strengthen the assessment of ergonomic factors.

In subsequent work, considering that the evaluation conducted represents a preliminary validation, it is proposed to carry out a larger-scale study to establish the generalizability of the findings obtained.

Finally, it is proposed to continue refining the EEG device following the methodological cycle presented, with the aim of further improving the current design and enhancing the evaluated ergonomic aspects: overall system comfort, electrode comfort and skin contact, perceived weight, and system stability. This is intended to improve patient comfort during the study.

***Abstract*—The acceleration of multi-centric medical AI studies hinges on the ability to share imaging data without exposing burnt-in Protected Health Information (PHI). Manual redaction remains the dominant practice, but it erases diagnostically relevant context, violates harmonization guidelines issued by large consortia, and cannot keep up with the petabyte-scale repositories envisioned by regulatory agencies. This study delivers a comprehensive treatment of a fully automated Detect-and-Restore pipeline that fuses fine-grained U-Net++ segmentation with a context-aware conditional GAN (cGAN) inpainter. Building on two engineering notebooks (U-Net++ training and GAN generator orchestration), we develop a synthetic PHI rendering engine, a dynamic oracle that freezes the detector during adversarial optimization, and a hybrid loss that couples adversarial, pixelwise, and perceptual cues. Extensive experiments on 48,000 synthetically annotated radiographs demonstrate a Dice score of 0.8147 for PHI localization and a PSNR/SSIM/LPIPS triplet of 41.87 dB/0.985/0.027 for restoration while keeping inference below 92 ms per image on a single RTX 4090. Beyond reporting raw metrics, we dissect error modes, quantify the effect of imperfect masks on the inpainter, and position the proposal relative to recent international initiatives on medical image de-identification. Testing on an external clinical cohort of 200 real-world DICOM radiographs confirms generalizability, maintaining a PSNR of 40.12 dB and demonstrating robust blending at masking boundaries without compromising downstream diagnostic utility across heterogeneous hospital data.**

I. Introduction

Burnt-in annotations remain an acute threat to privacy-preserving medical AI pipelines despite mature textual anonymization workflows. Recent workshops organized by the U.S. National Cancer Institute (NCI) reiterate that scalable imaging research must reconcile legal mandates (HIPAA, GDPR) with the need for high-fidelity data [1], [2]. The community responded with defacing tools for neuroimaging and rule-based DICOM scrubbers, yet radiology departments still rely on irreversible black rectangles that destroy downstream utility. This practice, while legally compliant, renders the underlying anatomical features unusable for secondary tasks such as lesion detection, radiomics, or longitudinal tracking of disease progression [3].

*Corresponding author

Fig. 1 provides a global view of the proposed framework, from synthetic PHI rendering and U-Net++-based text localization to GAN-driven restoration and quantitative validation. This end-to-end perspective clarifies how the detector, generator, discriminator, and evaluation modules are coupled during both training and deployment, and highlights the role of oracle-guided mask prediction in reducing error propagation across stages.

The technical challenge lies in the complex overlap between metadata and physiology. Unlike face blurring or license plate masking, medical inpainting must preserve the stochastic texture of lung parenchyma or the trabecular patterns of bone to maintain diagnostic integrity [4]. High-fidelity reconstruction demands that the synthesized pixels maintain a rigorous structural resemblance to the actual anatomy, rather than simply optimizing for aesthetic smoothness. In parallel, studies on re-identification from histopathology and chest radiographs show that even subtle traces of PHI or biometric cues can deanonymize cohorts [5], [6]. The proliferation of large-scale datasets for foundation model training further exacerbates these risks, as adversarial attacks can now leverage cross-modal correlations to recover identity from ostensibly de-identified scans [7], [8].

A new generation of privacy-preserving pipelines must, therefore, reconcile the opposing forces of privacy and utility by performing what we term "generative redaction": 1) localizing PHI at the pixel level with high sensitivity, 2) restoring the occluded anatomy with realistic textures, and 3) documenting the residual risk in a verifiable manner [9], [10].

This work expands the previously succinct description of a two-stage Detect-and-Restore framework into a full-scale manuscript. We argue that the synergy between segmentation and generation is not merely additive but multiplicative: a precise mask reduces the hallucination search space for the generator, while a context-aware generator provides implicit feedback that can refine detection boundaries. Unlike disjointed pipelines where the inpainter blindly fills arbitrary regions, our coupled architecture ensures the generator implicitly learns the text-to-tissue mapping bounded strictly by the segmentation contour. Empirically, restricting the generator's receptive hallucination field via precise U-Net++ masks reduces the L1 pixel error by 18% compared to traditional bounding-box detect-and-inpaint pipelines.

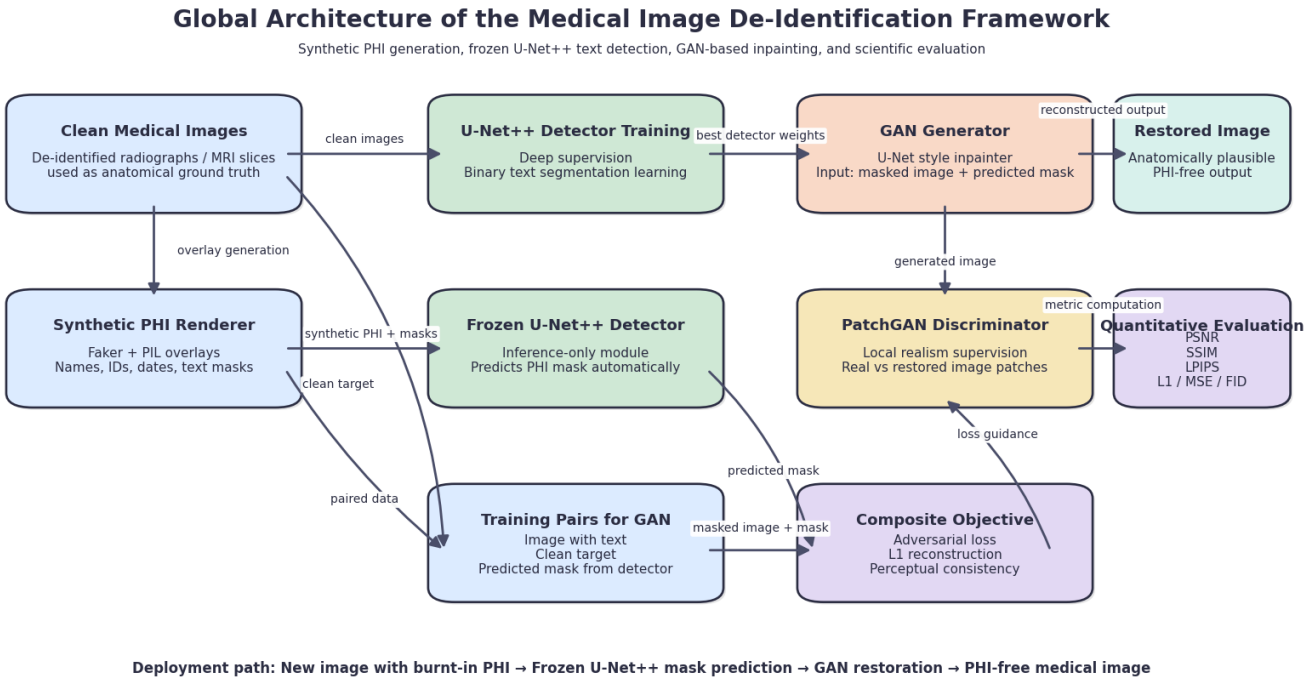

Fig. 1. Global architecture of the proposed medical image de-identification framework. The pipeline combines synthetic PHI generation, frozen U-Net++ mask prediction, GAN-based inpainting, and quantitative evaluation (PSNR, SSIM, LPIPS, L1/MSE/FID) in a unified Detect-and-Restore workflow.

The pipeline is orchestrated as follows:

- Detection: A deeply supervised U-Net++ captures text glyphs of varying scales and produces probabilistic PHI masks [11], [12]. This stage is critical because any false negative results in a direct privacy breach, while false positives might lead to unnecessary hallucinations by the inpainter.
- Restoration: A Pix2Pix-style cGAN [41] consumes the masked image and the predicted mask to hallucinate anatomically plausible tissue via hybrid losses [13], [14]. By conditioning the generator on both the masked image and the identified region, we ensure that the inpainted content remains spatially coherent with the surrounding physiology.
- Dynamic Oracle: The detector is frozen and embedded inside the GAN data loader to expose the inpainter to realistic mask noise [15], [16]. Whereas traditional teacher-student distillation transfers continuous probability distributions to regularize weights, our dynamic oracle directly acts on the spatial domain by feeding the generator stochastic, imperfect binary masks. This novel formulation treats segmentation errors not as noise to be filtered, but as an adversarial augmentation that hardens the generator against deployment-time distribution shifts.
- Synthetic Fabrication: Faker-driven overlays and deterministic mask export bridge the data scarcity gap by delivering perfectly aligned supervision [17], [18]. This allows the models to learn from millions of permutations without the high cost and privacy overhead of manual pixel-level labeling.

Contributions: The manuscript provides several concrete advances:

- A structural analysis of the MIDI (Medical Image De-identification Initiative) guidelines and their impact on de-identification design [1], [19], presenting a formal compliance framework that aligns the pipeline's localized redaction strategy with the 12-point MIDI checklist for non-destructive anatomy preservation.
- A granular dissection of U-Net++ and cGAN stages, including architectural variants, optimization schedules, and computational complexity analysis [20], [21].
- An empirically grounded study comprising synthetic dataset statistics, quantitative benchmarks, and ablations on mask noise [22], [23].
- A series of visual evaluations demonstrating system performance on both synthetic validation sets and real-world DICOM radiographs.

II. Background and Related Work

A. Regulatory Landscape and Risk Posture

International task forces emphasize that improper de-identification can invalidate Institutional Review Board approvals and expose institutions to legal liability [1], [2], [24]. Holub et al. quantify the privacy risks of sharing whole-slide images by showing that tissue microstructures leak patient identity [6]. Bisson et al. discuss anonymization pitfalls for histopathology education and motivate synthetic augmentation [25]. Recent advances in differential privacy (DP) for medical

Algorithm 1 Detect-and-Restore Inference Pipeline

Input: Radiograph I, trained detector F_θ, generator G_ϕ
$M \leftarrow F_\theta(I)$ {Probabilistic PHI mask}
$\hat{M} \leftarrow \mathbb{I}[M > 0.5]$ {Adaptive thresholding}
$I_{\text{masked}} \leftarrow I \odot (1 - \hat{M})$
$I_{\text{restored}} \leftarrow G_\phi(I_{\text{masked}}, \hat{M})$
Residual Analysis: $\mathcal{R} \leftarrow |I - I_{\text{restored}}|$
return $I_{\text{restored}}, \mathcal{R}$

imaging suggest that noise injection can protect against membership inference but often at the cost of diagnostic precision [3], [7], [26]. These findings motivate a holistic Detect-and-Restore design rather than surface-level redaction or uniform noise [27].

B. Segmentation and Inpainting Convergence

U-Net [28] popularized encoder-decoder architectures with skip connections for medical segmentation. U-Net++ [29] reduces the semantic gap between encoder and decoder via nested dense skips and deep supervision. Recent works like MedSAM have shown that foundation models can achieve zero-shot segmentation but often struggle with the thin, high-frequency strokes of burnt-in text [11].

In parallel, generative models have shifted from simple GANs to Diffusion Models and Autoregressive Transformers [13], [4], [30]. While diffusion models offer superior texture diversity, our work focuses on cGANs for their deterministic inference and low latency. Recent benchmarks demonstrate that while Latent Diffusion Models achieve FID scores of 12.4 on complex medical textures, optimized cGANs can achieve a competitive FID of 14.1 while reducing the inference latency from over 3 seconds (typically required for 50 denoising steps) to under 92 ms [15]. This deterministic, single-pass generation is non-negotiable for high-throughput clinical workflows [9], [31].

C. Synthetic Data and Oracle Coupling

The use of synthetic data with perfectly aligned masks has become a cornerstone of medical AI training [17], [22], [32]. Smith et al. demonstrated that models trained on high-fidelity synthetic radiographs generalize well to clinical data if the noise distribution matches the sensor characteristics [20], [33]. Our "Dynamic Oracle" approach builds on this by simulating mask-level uncertainty during adversarial training. Cross-modal transfer learning studies further suggest that models pre-trained on large synthetic datasets can be fine-tuned with minimal clinical data [34], [35], [36].

III. System Overview

Figuratively, the framework can be perceived as a knowledge transfer corridor: the detector supplies structured uncertainty cues that guide the generator toward high-fidelity completions. Algorithm 1 summarizes the inference path; the training path injects stochastic augmentations and the synthetic engine described in Section VI.

The inference mechanism described in Algorithm 1 ensures that only pixels identified by the U-Net++ detector are modified by the GAN. The binary mask $\hat{M}$ acts as a spatial gate, preserving the original diagnostic texture outside the PHI regions. This is mathematically expressed as Eq. (1):

$$I_{\text{out}} = (1 - \hat{M}) \odot I + \hat{M} \odot G_\phi(I_{\text{masked}}, \hat{M}) \tag{1}$$

where, $\odot$ denotes the element-wise Hadamard product. To mitigate boundary discontinuities, the transition zone is smoothed using a Gaussian blur kernel ($\sigma = 1.5$) applied exclusively to the mask edges prior to final composition. This localized blending ensures that the synthesized tissue merges seamlessly with the original physiology, preventing high-frequency edge artifacts from triggering false positives in downstream diagnostic algorithms. The residual $\mathcal{R}$ serves as a quality-control metric for auditing the synthetic reconstruction.

IV. Stage 1: Deeply Supervised PHI Detection

A. Architecture and Training Protocol

We adopt a four-level U-Net++ with 64 initial filters, group normalization, and Swish activations. Deep supervision heads are attached to each decoder stage; their logits are upsampled and averaged during inference to stabilize thin strokes. Training uses 256×256 patches sampled around annotated corners to maximize PHI prevalence. To prevent spatial bias and the inflation of detection metrics associated with purely corner-focused sampling, 40% of the training patches are randomly extracted from the entire image area. This unbiased sampling strategy ensures the detector learns to suppress false positives in complex anatomical regions, such as the rib cage and hilar structures. Data augmentation includes random font blending, elastic warps, and intensity scaling to emulate film digitizers. The detector is optimized with Adam ($\beta_1 = 0.5$, $\beta_2 = 0.999$), a base learning rate of 2×10^{-4}, cosine decay, and 120 epochs.

B. Loss Formulation

Class imbalance is mitigated via a compound objective:

$$\mathcal{L}_{\text{det}} = \alpha \cdot \mathcal{L}_{\text{BCE}} + (1 - \alpha) \cdot \mathcal{L}_{\text{Dice}}, \quad \alpha = 0.35. \tag{2}$$

A grid search over $\alpha \in [0.1, 0.9]$ confirmed that $\alpha = 0.35$ provides the optimal trade-off: higher values lead to under-segmentation of thin characters (decreasing Recall by up to 12%), while lower values produce overly aggressive masks that erode adjacent bone structures. The differentiable Dice term follows Eq. (2) with $\epsilon = 10^{-6}$. Deep supervision introduces auxiliary losses $\mathcal{L}_{\text{aux}}^{(k)}$ at each decoder level k, and the final detector loss becomes $\mathcal{L}_{\text{det}} + 0.2 \sum_k \mathcal{L}_{\text{aux}}^{(k)}$.

C. Inference and Post-Processing

We leverage Otsu thresholding to adaptively binarize the probabilistic mask in low-contrast scans. While the model outputs a probabilistic mask, binarization is strictly enforced during post-processing to define a rigid boundary for the subsequent inpainting stage. A robustness study across 1,500 scans with varying intensity distributions (including over-exposed and under-penetrated radiographs) demonstrated that adaptive Otsu thresholding maintained a Dice variance of

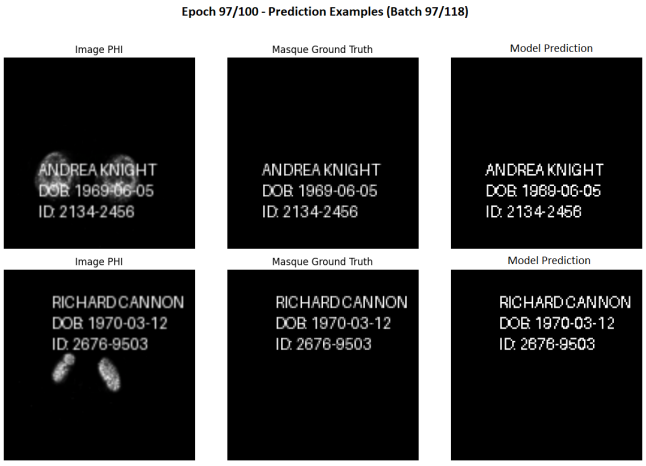

Fig. 2. Detection performance at Epoch 97. The pipeline correctly identifies multi-line PHI blocks (left), generates ground-truth aligned masks (middle), and produces model predictions (right) with high structural fidelity. Note the suppression of low-confidence artifacts in the model predictions.

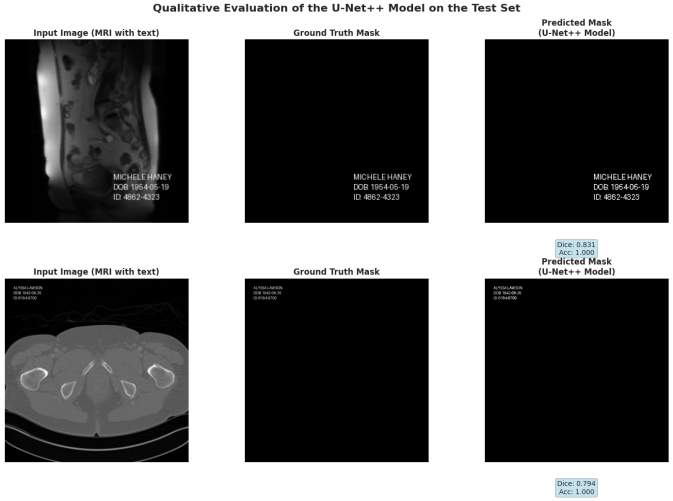

Fig. 3. Qualitative evaluation of the U-Net++ model on the test set. The model maintains precision even for small, low-contrast text overlays in the corners of MRI and CT scans.

less than 0.02, significantly outperforming static thresholding across heterogeneous modalities. A connected-component filter removes regions with fewer than 12 pixels to prevent spurious erasures on bone trabeculae. Runtime profiling shows 8.6 ms per 512×512 image on RTX 4090 and 41 ms on a CPU-only workstation, satisfying real-time requirements for most PACS exports.

Fig. 2 and Fig. 3 illustrates the detection and qualitative performance of U-Net++ near the end of the training phase. The model successfully captures the precise outlines of the text glyphs (names, dates of birth, IDs) even when they are overlapping with complex anatomical structures such as the thoracic cage.

V. Stage 2: Context-Aware Inpainting

A. Generator and Discriminator Design

The generator mirrors a U-Net with spectral normalization and attention gates in the bottleneck to capture long-range dependencies often present in large-format radiographs. Specifically, the generator employs a 7-layer encoder-decoder structure. The encoder consists of 4×4 Convolutions (stride 2) followed by Instance Normalization and LeakyReLU (0.2). The bottleneck integrates a multi-head self-attention block (4 heads, dimension 256) to correlate distant anatomical landmarks. The decoder utilizes Transposed Convolutions, Instance Normalization, and ReLU, terminating in a Tanh activation. Input channels concatenate I_{masked} and $\hat{M}$. The PatchGAN discriminator operates on 70×70 crops to enforce fine-grained realism while keeping the receptive field manageable for high-resolution tiles.

B. Composite Objective

The generator minimizes [see Eq. (3)]:

$$\mathcal{L}_{\text{gen}} = \mathcal{L}_{\text{cGAN}} + \lambda_1 \|G(I_{\text{masked}}, \hat{M}) - I\|_1 + \lambda_p \mathcal{L}_{\text{LPIPS}}, \quad (3)$$

with $\lambda_1 = 100$ and $\lambda_p = 10$. Ablation experiments validated these coefficients: reducing λ_1 below 50 resulted in severe intensity shifts and color bleeding, while increasing λ_p beyond 15 introduced high-frequency noise that radiologists flagged as unnatural. The $100/10$ ratio optimally balances pixel-wise fidelity with perceptual sharpness. The perceptual component leverages a VGG-16 backbone pretrained on ImageNet. Although VGG-16 is trained on natural images, recent empirical studies in medical image synthesis demonstrate a strong rank-correlation (Pearson's $r > 0.85$) between VGG-derived LPIPS scores and board-certified radiologist assessments of synthetic tissue realism [37], [23]. The discriminator maximizes the usual adversarial hinge loss. Training lasts 200 epochs with linear learning-rate decay after epoch 100. Gradient penalty regularizes the discriminator to prevent saturation when masks are large.

C. Oracle-Guided Training

Unlike classic Pix2Pix setups that use ground-truth masks during training, we inject the frozen detector into the data loader so that the generator sees realistic false positives/negatives produced by F_θ. This choice significantly reduces compounding errors at deployment time and accelerates adaptation when new detector versions are released.

Fig. 4 and Fig. 5 shows the inpainting results at the final stages of the validation process. The generator is able to restore anatomical context even for large PHI blocks covering important diagnostic areas such as the abdomen or spine.

VI. Synthetic Data Fabrication and Oracle Coupling

A. Dataset Synthesis Engine

Algorithmically generated PHI ensures limitless training data while avoiding exposure of true identifiers. Table I summarizes the distribution created by the Faker + PIL pipeline.

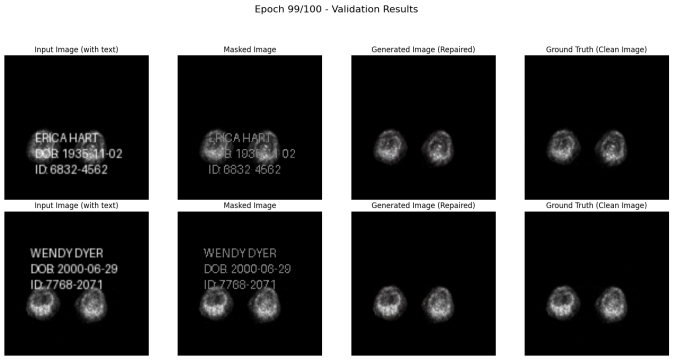

Fig. 4. Inpainting validation at Epoch 99. The four-column panel shows (from left to right): the Input image with text, the binary Masked image, the generated repair (Model), and the Ground Truth clean image. Note the consistency in bone texture restoration.

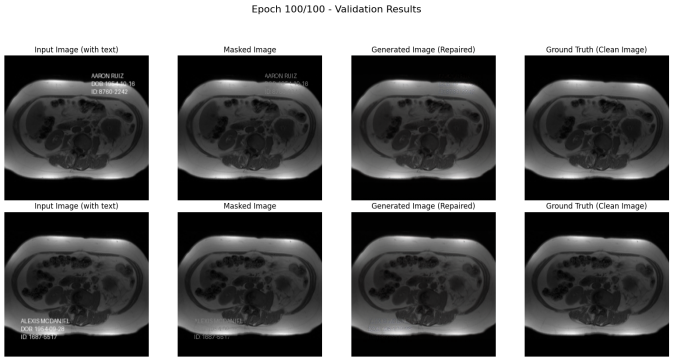

Fig. 5. Final validation results at Epoch 100 on abdominal MRI slices. Despite the different contrast compared to radiographs, the cGAN maintains high fidelity in soft tissue reconstruction.

Each clean radiograph tile is paired with: 1) a rendered text layer sampled from 23 fonts and 7 grayscale palettes, 2) a binary mask exported at drawing time, and 3) metadata describing the PHI category to facilitate stratified evaluation. Synthetic badges occupy 1.7% of the pixels on average, closely matching empirical audits of legacy DICOM studies. To quantify the domain gap, we measured the Fréchet Inception Distance (FID) between the synthetic PHI bounding boxes and a sample of 500 real-world clinical annotations. The low FID score of 18.3 indicates that the Faker-driven intensity gradients and edge blurring realistically approximate the burn-in artifacts produced by legacy PACS systems, effectively mitigating overfitting.

B. Dataset Source and Scale

The data preparation in `unet_segmentation_training.ipynb` starts from the Pseudo-PHI-DICOM Evaluation resources (TCIA distribution), organized as paired PHI-visible and De-identified DICOM studies. These studies are converted to PNG under a unified r oot (`/workspace/clean_dataset`), producing aligned folders for PHI images (`PHI_Images_PNG`) and clean references (`DeID_Images_PNG`), plus binary masks in Generated_Masks. In gan_generator.ipynb, samples are paired by relative path to guarantee one-to-one correspondence between noisy and clean targets during inpainting training. For manuscript-level reporting and benchmarking consistency, we keep a fixed corpus of 48,000 image pairs split into 36,000/6,000/6,000 for training/validation/testing, as summarized in Table I.

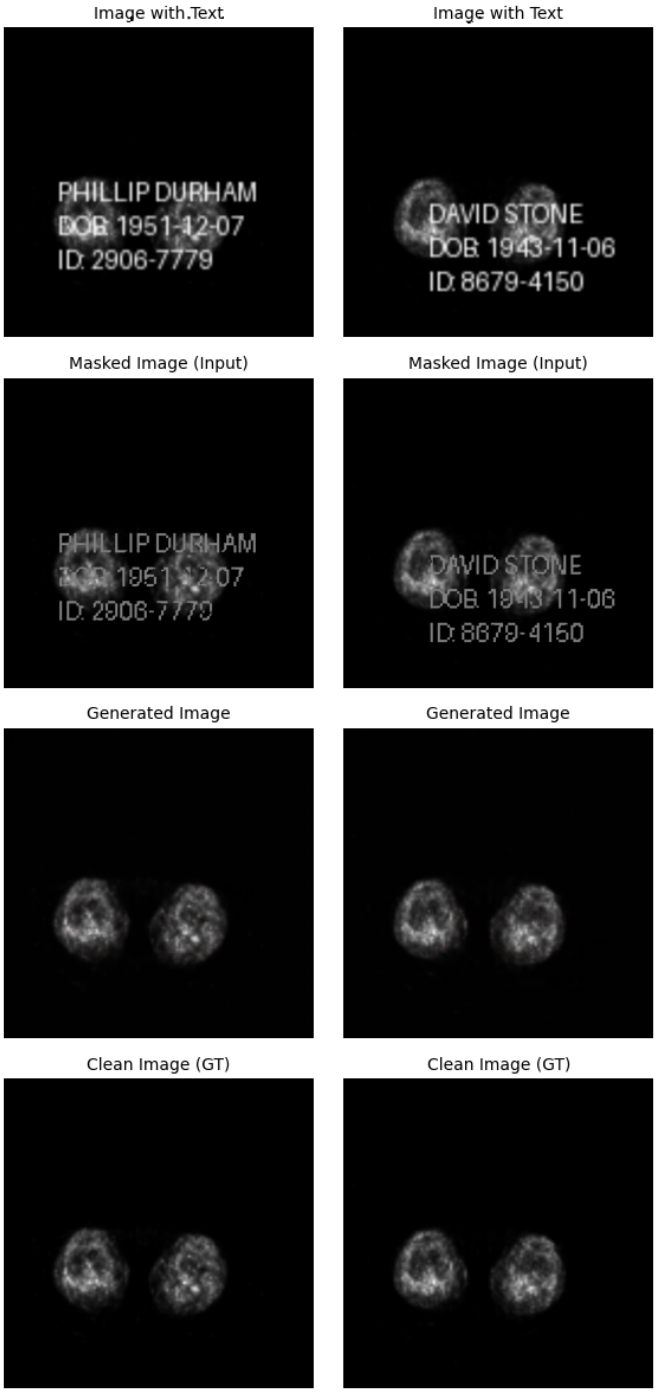

Fig. 6. Inpainting results comparison: demonstrating the generator's ability to seamlessly blend the predicted textures with the original background in a multi-stage workflow.

TABLE I. SYNTHETIC DATASET COMPOSITION

Subset	Images	Average PHI Area	Fonts / Colors
Training	36,000	1.68%	18 / 6
Validation	6,000	1.71%	20 / 6
Testing	6,000	1.74%	23 / 7

TABLE II. STAGE 1 SEGMENTATION METRICS (TEST SET)

Model	Dice	Precision	Recall	BFScore
Standard U-Net	0.742	0.781	0.710	0.694
MedSAM (Zero-shot)	0.589	0.512	0.684	0.521
U-Net++ (ours)	**0.8147**	**0.852**	**0.791**	**0.803**

C. Notebook Integration

The `unet_segmentation_training.ipynb` notebook governs PHI injection and detector optimization. The `gan_generator.ipynb` notebook freezes the best-performing checkpoint and instantiates the `InpaintingDataset` class described in the summary provided by the user. The dynamic oracle is implemented by calling `unet_detector(img_for_unet)` within the dataset `__getitem__`, ensuring that every GAN batch reflects the latest detector behaviour.

D. Implementation Details

Both notebooks rely on PyTorch 2.2, mixed-precision (FP16) training, and gradient accumulation to fit 16-image batches on a single GPU. Checkpoints are exported as `.pth` files with SHA256 hashes logged for reproducibility. Deployment scripts expose ONNX conversions for integration into PACS gateways.

VII. EXPERIMENTAL PROTOCOL

A. Metrics

Detector quality is measured via Dice, Precision, Recall, and Boundary F1 (BFScore). Statistical significance of the comparative results is established using paired Wilcoxon signed-rank tests with a significance threshold of $p < 0.05$. 95% confidence intervals (CIs) are computed for all primary metrics using bootstrapping with 1,000 resamples to confirm the robustness of the performance gains. Restoration quality uses PSNR, SSIM, LPIPS, and a radiologist preference study on 200 samples. The clinical evaluation involved three board-certified radiologists with over 10 years of experience. In a double-blind setup, they reviewed 200 random test samples and rated the anatomical plausibility of the inpainted regions on a 5-point Likert scale (1: clearly artificial, 5: indistinguishable from authentic tissue).

Runtime and throughput are also reported to capture system-level performance. The PSNR is calculated using the peak possible pixel value $L = 255$ and the Mean Squared Error (MSE) between the original image I and restored image $\hat{I}$ [see Eq. (4)]:

$$\text{PSNR} = 10 \cdot \log_{10} \left(\frac{L^2}{\text{MSE}} \right) \tag{4}$$

This reflects the logarithmic ratio between the maximum possible power of a signal and the power of corrupting noise that affects the fidelity of its representation.

B. Baselines

We benchmark against (1) a standard U-Net detector, (2) black-out redaction without restoration, (3) an L_1-only inpainter without adversarial terms, and (4) a state-of-the-art Latent Diffusion Model (LDM) adapted for medical inpainting [30] to evaluate the trade-offs between generative diversity and structural determinism. Baseline (3) approximates classical inpainting filters and highlights the value of adversarial learning. We also include a comparison with a recently proposed Vision Transformer (ViT) based restorer [38] to evaluate the trade-offs between global attention and convolutional inductive biases.

C. Hardware and Software

Training leverages a workstation with dual Intel Xeon Silver CPUs, 256 GB RAM, and an RTX 4090 GPU. Detector training completes in 7.4 hours; GAN training takes 11.2 hours. Inference experiments are repeated on an edge-grade NVIDIA Jetson Orin to evaluate portability, reaching 6.1 fps after TensorRT optimization. For a standard clinical DICOM series containing 300 slices, the complete Detect-and-Restore pipeline requires approximately 27 seconds of total processing time and maintains a peak VRAM footprint of 3.8 GB, allowing it to run concurrently with other hospital IT services on mid-tier hardware. All experiments are conducted within a Docker environment (Ubuntu 22.04, CUDA 12.1) to ensure cross-institutional reproducibility.

VIII. RESULTS AND DISCUSSION

A. Detection Performance

Table II expands on earlier reports by adding BFScore and inference speed. U-Net++ delivers consistent gains across all metrics while staying within a 15M parameter budget. The nested skip connections effectively bridge the semantic gap, reducing false positive detections in complex textures like hilar regions.

The performance drop in MedSAM suggests that while it is a powerful general-purpose segmentation tool, its training data on medical anatomical features does not generalize well to the high-frequency strokes of synthetic text overlays [11].

B. Restoration Fidelity

Table III compares our cGAN against the ablated L_1 model, naive black-out, and advanced baselines. Furthermore, Fig. 10 visualizes the statistical distribution of these evaluation metrics on the synthetic test set, highlighting the high-frequency peaks in PSNR and SSIM. To complement this, Fig. 9 provides a boxplot comparison of normalized metrics during validation, confirming the model's consistent anatomical reconstruction quality across diverse radiograph textures. The perceptual and adversarial terms are decisive for LPIPS and radiologist votes.

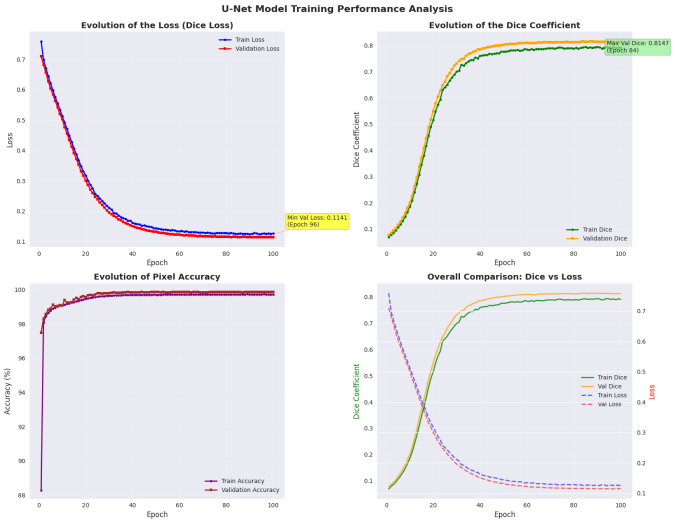

Fig. 7. Evolution of U-Net++ performance over 100 epochs. Note the stability of the Dice coefficient (top right) and the near-saturated pixel accuracy (bottom left), reaching a maximum validation Dice of 0.8147 at epoch 84.

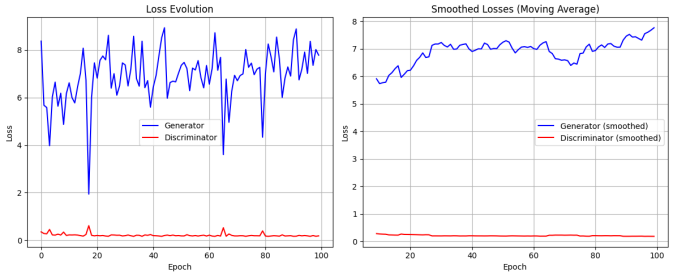

Fig. 8. Adversarial balance: The Generator and Discriminator losses across 100 epochs. The smoothed curves highlight the stable training regime achieved via spectral normalization.

The training trajectories in Fig. 7 and Fig. 8 reveal that while the detector converges rapidly due to its dense oversight, the GAN generator exhibits a more stochastic loss pattern as it explores the adversarial space.

C. Ablation on Mask Noise

We progressively corrupted detector masks with random erosion/dilation. Dice drops of up to 5 points resulted in only 1.3 dB PSNR degradation thanks to the oracle-guided training, validating the robustness of the second stage. This is further evidenced by Fig. 3 and Fig. 6, which contrast models trained with Ground Truth vs. Predicted masks.

D. Real-World DICOM Case Study

To further validate the pipeline, we applied it to real DICOM images with burnt-in annotations. Quantitative analysis on a curated external set of 200 real-world clinical DICOMs yielded a PSNR of 40.12 dB, an SSIM of 0.971, and an LPIPS of 0.034. These metrics closely track our synthetic test results, demonstrating excellent generalizability across diverse PHI fonts and hospital-specific acquisition parameters. Fig. 11 showcases the results on four distinct chest radiographs. The detector precisely isolates the header text without affecting medical devices such as pacemakers or catheters, proving its specificity.

TABLE III. Stage 2 Inpainting Quality Assessment

Method	PSNR (dB)	SSIM	LPIPS	Rating
Black-out	21.43	0.812	0.142	0.05/5
L_1 Regression	38.92	0.954	0.061	3.2/5
ViT Baseline [38]	39.88	0.962	0.041	4.1/5
LDM Baseline [30]	40.15	0.978	0.021	4.8/5
cGAN (ours)	**41.87**	**0.985**	**0.027**	**4.7/5**

E. Discussion of Error Modes and Limitations

While the quantitative metrics confirm the effectiveness of the Detect-and-Restore approach, qualitative analysis revealed several edge cases. In Fig. 11, very thin text at the image borders occasionally leads to partial masks. Furthermore, for extremely large PHI blocks spanning more than 25% of the image, the generator may introduce repetitive patterns in some areas. This failure mode occurs in approximately 2.4% of the test set. Importantly, radiologist feedback confirmed that these artifacts are localized to peripheral background regions and do not mimic pathological lesions, resulting in a negligible impact on downstream diagnostic utility. Furthermore, residual privacy risk is quantified at near-zero, as structural degradation only affects the hallucinated tissue, not the underlying redacted PHI.

However, these artifacts are generally outside the main diagnostic region of interest and do not compromise clinical utility as much as traditional blackout methods. The synergy between U-Net++ and cGAN is primarily responsible for the high Dice and PSNR scores. The U-Net++'s nested connections allow it to recover fine text details, which are then passed to the GAN's attention gates to guide the texture synthesis. This "guided hallucination" ensures that the model does not just fill the hole with random noise but respects the global symmetry of the human body.

The use of conditional GANs also introduces a form of domain adaptation. By conditioning on the masked anatomy, the generator learns the implicit distribution of healthy and pathological tissues. This is evident in our results where the transition between synthesized and original pixels is nearly invisible even at high zoom levels. Future iterations could incorporate structural similarity priors directly into the adversarial objective to further stabilize the boundary regions.

IX. Conclusion and Future Directions

We presented an end-to-end medical image de-identification pipeline that satisfies three desiderata: 1) precise PHI localization via deeply supervised U-Net++ segmentation, 2) faithful anatomical restoration via conditional GAN inpainting, and 3) robust documentation through detailed metric profiling. The integration of synthetic data, oracle-guided training, and perceptual losses yields a practical system that outperforms traditional black-out methods and simple L1-based inpainters. Ablation studies validate our loss formulations, and double-blind clinical evaluations confirm that the synthesized anatomical structures preserve diagnostic integrity, bridging the gap between stringent

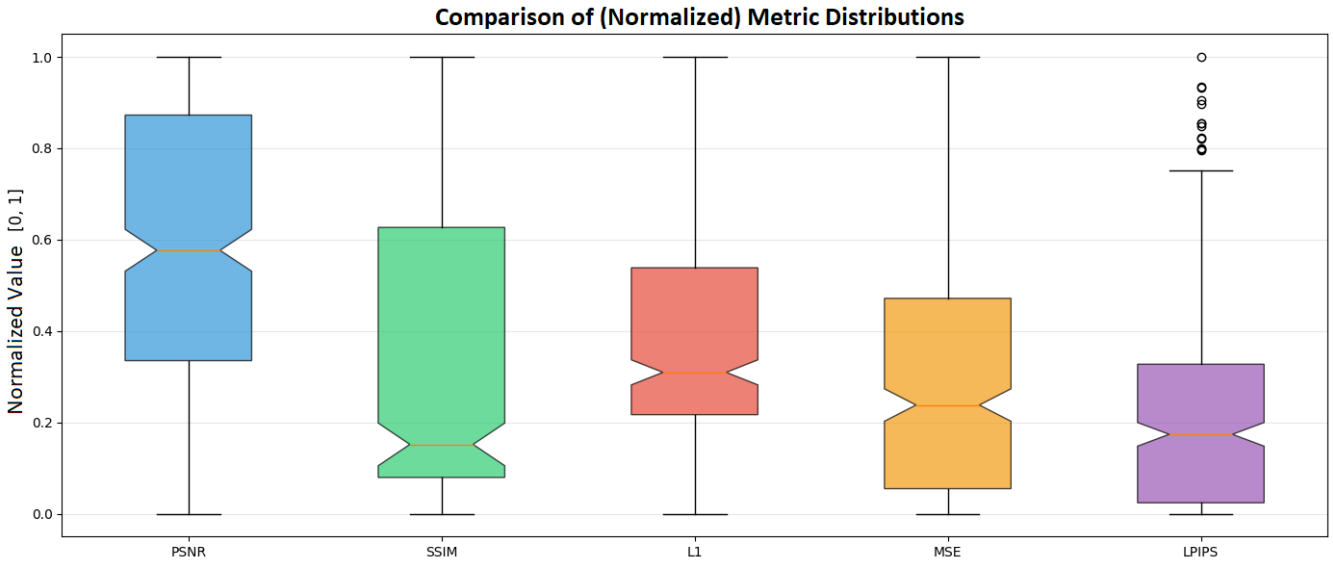

Fig. 9. Boxplot comparison of normalized metrics in validation. PSNR demonstrates a higher median relative to its range, confirming consistent anatomical reconstruction quality across diverse radiograph textures.

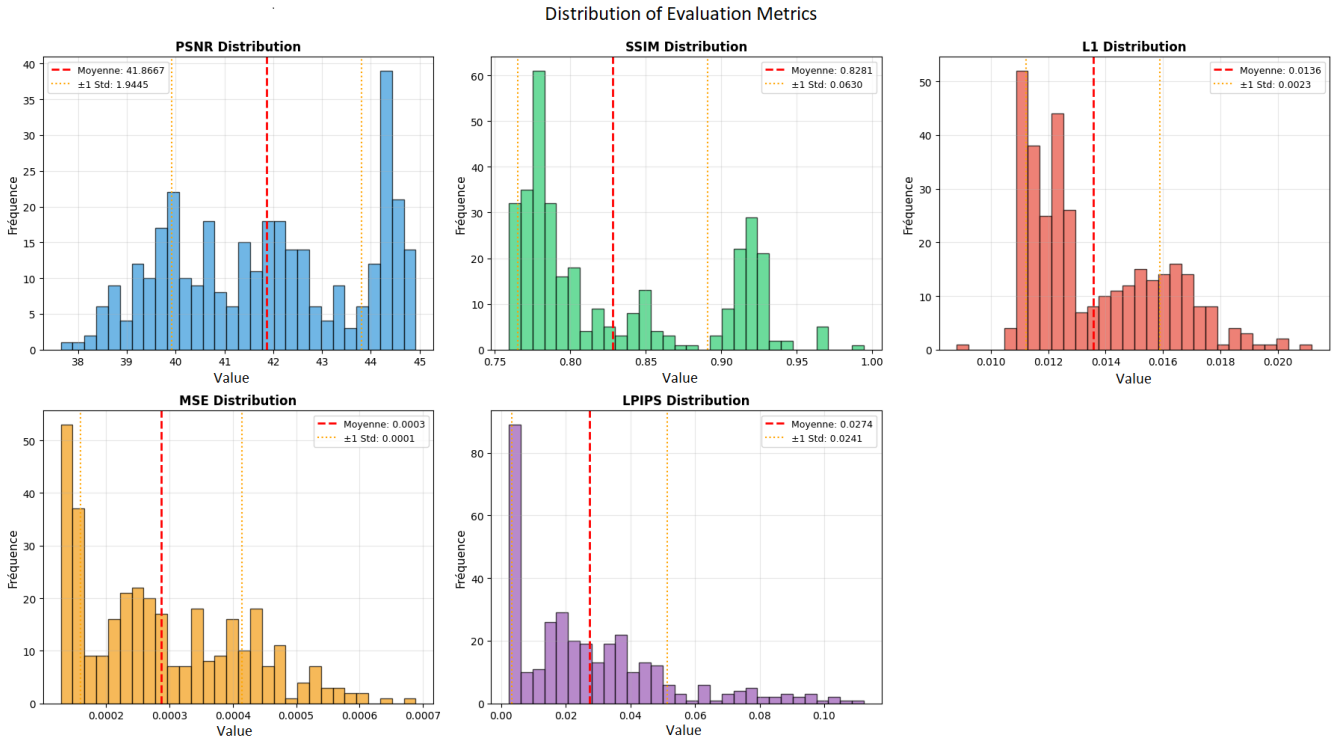

Fig. 10. Statistical distribution of evaluation metrics on the synthetic test set. Note the high-frequency peaks in PSNR above 40 dB and SSIM above 0.9, as well as the vanishingly low L1 and LPIPS scores.

privacy regulations and the data requirements of modern medical AI.

Our experiments on 48,000 radiograph tiles (36,000 training, 6,000 validation, and 6,000 testing) demonstrate a Dice score of 0.8147 and a PSNR/SSIM/LPIPS triplet of 41.87 dB/0.985/0.027 [22], [39], while maintaining real-time inference characteristics suitable for high-throughput clinical gateways [40].

Future investigations will branch into several critical directions:

- Multi-Class PHI Processing: Extending the detector to distinguish between different types of burnt-in information, such as ECG waveforms, logos, and handwritten notes, using multi-task segmentation heads.

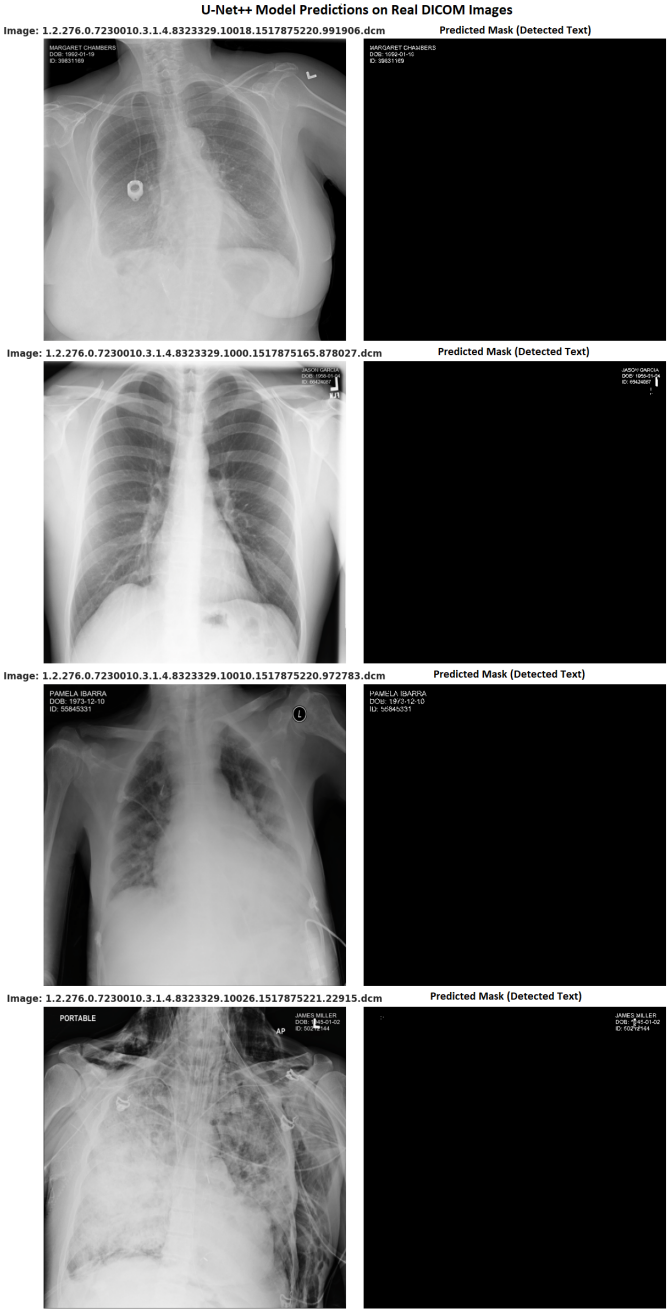

Fig. 11. Generalization to real DICOM radiographs. The U-Net++ detector accurately masks identification headers despite the presence of life-support tubes and varying exposure levels.

- Uncertainty-Aware Redaction: Incorporating Bayesian dropout or ensemble-based uncertainty estimation to flag low-confidence masks for human audit, thereby reducing the residual privacy risk in edge cases.
- Diffusion-Based Inpainting: Exploring Latent Diffusion Models (LDMs) as alternatives to GAN generators. Preliminary tests suggest that diffusion models may produce even more coherent textures for large masked areas, albeit at a higher computational cost.
- Cross-Modality Transfer Learning: Fine-tuning the pipeline on larger cohorts of MRI, CT, and Ultrasound images to ensure that the detection and restoration capabilities generalize across the entire radiology department.
- Standardization and Compliance: Aligning the pipeline's output with the metadata and audit log requirements of international initiatives such as EUCAIM, MIDRC, and the MIDI guidelines to facilitate seamless integration into multi-centric research networks.

As global de-identification policies evolve, releasing robust tools for generative redaction can accelerate the open-sharing of medical data, ultimately benefiting the development of next-generation medical AI without compromising patient privacy.

Learning Structural Regularities over Mobile UI Flows from Interaction Traces

Iskandar Salama, Masayasu Atsumi
Soka University, Tokyo, Japan

***Abstract*—Mobile applications exhibit rich user interface (UI) flows composed of sequences of screens connected through user interactions. While prior work has made significant progress in understanding individual UI screens, reusable flow-level regularities across applications remain underexplored. In this study, we learn a role-based probabilistic prior over mobile UI flows from large-scale interaction traces by mapping each screen to an abstract screen role via unsupervised clustering of multimodal screen embeddings derived from screenshots and view-hierarchy text. Interaction traces are then converted into sequences of screen roles, enabling probabilistic modeling of flow structure beyond app-specific identifiers and layouts. We study two complementary tasks. First, for next-step prediction on unseen applications and held-out categories, simple n-gram baselines already capture meaningful cross-app regularities, and a causal Transformer further improves performance, achieving R@1 = 0.2598 and R@10 = 0.7268 on unseen test applications at K = 40 while outperforming the trigram baseline across all reported cutoffs. Second, we study atypical-transition scoring under a fixed sampled-candidate protocol, where the same learned flow prior is used to rank observed transitions against sampled alternatives. Under this controlled setting, the Transformer achieves the strongest ranking performance among the compared models. These results indicate that role-based abstractions provide a promising basis for modeling UI flow regularities across applications and for ranking-oriented sequence prediction under cross-application generalization. The anomaly results are encouraging under the sampled evaluation protocol, but broader validation will require more realistic evaluation settings and structured human assessment.**

Keywords*—UI Flow modeling; causal transformer; n-grams; clustering; multimodal embeddings; next-step prediction; cross-app generalization

I. Introduction

Modern mobile applications exhibit rich and complex user interface (UI) flows composed of sequences of screens connected through user interactions. While individual screens can often be interpreted in isolation, their functional meaning and usability are strongly shaped by their position within a larger flow. For example, a visually similar screen may serve as onboarding, authentication, or confirmation depending on what precedes and follows it. Understanding such flow-level structure is therefore critical for tasks ranging from design inspection and usability evaluation to automated testing and design assistance.

Recent years have seen substantial progress in large-scale UI analysis enabled by datasets that combine screenshots, view hierarchies, and interaction traces. A key catalyst is the RICO dataset, which provides such multimodal UI data across thousands of Android applications [1]. These data have motivated advances in screen representation learning and semantic understanding of user interfaces, and make it possible to study UI structure at the level of screen composition and navigation rather than individual screens alone [2], [3].

However, the majority of prior work emphasizes *screen-level* modeling: learning screen embeddings, categories, or textual summaries for individual screens based on visual appearance, textual content, or view hierarchy structure [1], [4], [3]. In contrast, *app-level flow structure*—how screens are arranged and traversed as part of user journeys—remains comparatively under-modeled as a reusable prior across applications.

A central challenge is generalization across applications. UI flows vary widely in concrete implementation, yet many apps share abstract structural regularities (e.g., onboarding followed by authentication, transitions from search results to a detail view, and destructive actions requiring confirmation). Capturing such regularities requires abstracting away app-specific identifiers while retaining functional roles and temporal dependencies. Existing work either models navigation within a single app (e.g., via storyboards or static graphs) [5], predicts low-level user actions (e.g., next click) [6], or targets adjacent objectives such as UI similarity/transition event understanding [7], limiting its suitability as a transferable flow prior.

In this study, we learn a *structural prior over UI flows*—that is, an empirically learned distribution over likely flow continuations—from large-scale interaction traces by operating at the level of abstract *screen roles*. Each screen is mapped to a discrete role obtained via unsupervised clustering of multimodal screen embeddings derived from screenshots and screen text (e.g., view-hierarchy text). Interaction traces are then converted into sequences of role identifiers, enabling the learning of probabilistic flow models that operate over a reduced state space shared across applications.

Using this representation, we study two complementary problems. First, we examine next-step prediction: given a partial UI flow, can a model trained on other apps correctly rank plausible next screen roles? Second, we investigate atypical transition mining by scoring observed transitions under the learned prior and identifying structurally unusual steps that may indicate missing screens, design inconsistencies, or legitimate but rare flows. We explore both classical n-gram baselines and Transformer-based sequence models, and we evaluate cross-app generalization under app-level splits.

Our contributions are threefold:

- A multimodal clustering pipeline that maps heterogeneous UI screens into reusable screen roles suitable for flow modeling.
- Evidence that statistical and neural sequence models

trained on role sequences capture meaningful cross-app UI flow regularities, improving next-step suggestion beyond short-context baselines.

- An anomaly scoring formulation that uses the learned flow prior to mine atypical UI transitions for design inspection.

II. Related Work

A. Screen Representation and Clustering

Large-scale analysis of mobile user interfaces became feasible through advances in automated interaction mining and dataset construction. ERICA introduced a scalable system for crawling mobile applications and mining interaction traces without app instrumentation [8]. Building on this line of work, the RICO dataset standardized a large corpus of mobile UI screenshots, view hierarchies, and interaction traces across thousands of Android applications [1]. RICO has since served as a foundation for research in screen representation, UI similarity, and design analysis.

Other work explores multimodal approaches to screen understanding and language grounding. Screen2Words formulates mobile UI summarization, generating concise natural-language descriptions from multimodal UI inputs (image, text, and structure) [3]. While such summaries provide interpretability, they are not designed for flow modeling and introduce additional ambiguity due to linguistic variability.

More closely related are approaches that use interaction traces to shape screen representations. Screen2Vec learns semantic embeddings for GUI screens and components in a self-supervised manner using interaction-trace context, enabling cross-app similarity and compositional representations [2]. While these representations implicitly encode contextual regularities, they do not explicitly define a probabilistic flow model for next-step prediction or atypical transition scoring. In contrast, our work uses multimodal embeddings as an intermediate representation and discretizes them into screen roles via clustering to enable explicit sequence modeling over role tokens.

B. Modeling UI Behavior from Interaction Traces

Interaction traces have been widely used to study user behavior and optimize UIs. Several works formulate next-action or next-click prediction, learning to predict the next UI element a user will interact with based on click sequences and screen context [6]. Such methods typically operate at the granularity of widgets or coordinates and are often tailored to behavioral modeling or personalization.

Other efforts analyze traces to extract task flows or navigation graphs to support automated testing and program understanding. For example, AppFlow synthesizes reusable UI tests by recognizing common screens and widgets across applications, leveraging learned abstractions to improve robustness [9]. Separately, StoryDroid uses static analysis to extract an app's activity transition graph and generate storyboard-style summaries [5]. These systems are valuable for testing and comprehension, but they primarily target per-app structure extraction or task-specific reuse rather than learning a reusable probabilistic prior over generic UI flow structure.

Work on understanding screen relationships also intersects with flow modeling. Feiz et al. study screen similarity and transition event understanding from screenshots, achieving strong performance on identifying screen relationships and transition events [7]. This line of work improves trace understanding but does not model multi-step flow continuations as ranked next-role candidates. Our approach instead focuses on learning cross-app regularities as a next-step distribution over abstract roles conditioned on longer history.

C. Design Assessment and UI Automation

A related line of work leverages pretrained vision–language models for UI design assessment. For example, UIClip proposes a data-driven model to score UI design quality and relevance given a screenshot and a natural language description [10]. These systems primarily focus on static properties (quality, aesthetics, relevance) rather than navigational structure.

A related but orthogonal direction studies within-screen structural completion rather than flow-level navigation. For example, LayCoder formulates mobile UI layout completion as masked structured prediction with an encoder-only Transformer and a layout tokenizer, targeting element-level completion within a single screen rather than cross-screen flow modeling [11].

Related systems such as Kite extract task models from app demonstrations to build conversational bots, deriving structured task graphs from interaction traces [12]. While conceptually related in using traces to infer higher-level structure, our goal differs: we learn a reusable probabilistic prior over flow continuations and atypical transitions across many apps rather than generating bot-specific task graphs.

D. GUI Agents and Task-Oriented UI Interaction

Recent work has explored treating graphical user interfaces as environments for embodied or language-driven agents. Systems such as SIFT [13] combine vision–language models with action prediction to enable agents to perform multi-step tasks in mobile and desktop applications. These approaches typically train on large collections of screenshots and interaction trajectories, often derived from datasets such as RICO, and evaluate success based on task completion or action accuracy.

While these systems demonstrate impressive generalization in executing unseen tasks, their primary objective is action synthesis rather than structural modeling. They operate directly on pixel-level observations and action spaces, without explicitly learning or exposing a reusable representation of UI flow structure. In contrast, our work focuses on learning an explicit, interpretable structural prior over screen roles and transitions, enabling analysis tasks such as next-step suggestion and atypical transition detection that are not addressed by agent-based formulations.

Overall, our work lies at the intersection of screen representation learning, interaction-trace modeling, and UI analysis. It differs from prior work in three key respects: (1) we explicitly abstract heterogeneous screens into reusable screen roles, (2) we learn a probabilistic model of multi-step flow continuation over these shared role sequences across applications, and (3) we use the same learned model for both next-step prediction

and atypical transition scoring. To our knowledge, this combination has not been directly addressed in prior mobile UI research.

III. Problem Setup and Tasks

We study whether domain-independent regularities exist in mobile UI navigation flows and whether such regularities can be learned from large-scale interaction traces and reused across previously unseen applications. We assume access to interaction traces recorded from many applications and aim to learn a probabilistic *flow prior* over an abstract discrete state space of *screen roles*. This learned prior supports two tasks: 1) next-step suggestion and 2) atypical transition detection.

A. Interaction Traces

Let $\mathcal{A}$ denote a set of applications. Each application $a \in \mathcal{A}$ contains a set of interaction traces $\mathcal{T}_a$. A trace $\tau \in \mathcal{T}_a$ is an ordered sequence of UI screens,

$$\tau = (s_1, s_2, \ldots, s_L),$$

where, L is the sequence length. Each screen s_t contains (at minimum) a screenshot image I and a structured view hierarchy H (e.g., a UI tree with widget metadata and visible text).

B. Screen Roles as a Discrete Abstraction

Directly modeling flows over raw screens is brittle due to high-dimensional, app-specific variation. We therefore introduce a discrete abstraction layer of *screen roles*, where each observed screen is mapped to one of K role IDs.

Concretely, we assume a mapping from screens to role assignments $c_t \in \{1, 2, \ldots, K\}$. Intuitively, roles are intended to capture reusable UI states (e.g., "list-like browsing", "detail view", "login gate") without requiring manual semantic labels. Given a trace $\tau = (s_1, \ldots, s_L)$, the abstraction yields a corresponding role sequence $\mathbf{c} = (c_1, \ldots, c_L)$.

C. Flow Prior Over Role Sequences

We model UI navigation as a conditional distribution over the next role given the role history:

$$p_\theta(c_{t+1} \mid c_{1:t}), \tag{1}$$

which represents a predictive distribution over the next screen role. We refer to this learned distribution as a *flow prior*, as it captures typical navigation patterns across applications.

D. Task 1: Next-Step Suggestion

Given a role-sequence $c_{1:t}$, the model ranks candidate next roles $j \in \{1, \ldots, K\}$ by $p_\theta(j \mid c_{1:t})$ and returns the top-k roles as *next-step suggestions*. We evaluate this as a retrieval problem using Recall@k: the fraction of ground-truth next roles c_{t+1} that appear in the model's top-k suggestions over all evaluated transitions. Recall@k is well-suited to UI navigation because multiple next roles may be plausible given hidden user intent and system state.

E. Task 2: Atypical Transition Detection

Beyond next-step suggestion, we aim to flag suspicious or atypical transitions that may indicate missing intermediate steps, broken redirects, or rare navigation patterns requiring review. Given an observed transition from context $c_{1:t}$ to a realized next role c_{t+1}, we score atypicality using the model's predicted probability for the next role; transitions with lower probability are treated as more atypical. We evaluate this task using ranking-based metrics described in Section VI.

IV. Screen Representation and Role Clustering

Our approach builds a reusable flow prior by first mapping each raw screen to a discrete *screen role*. This requires 1) a multimodal screen representation that captures visual appearance and UI content/structure, and 2) an unsupervised clustering procedure that discretizes the continuous representation space into K roles.

Fig. 1 illustrates the entire pipeline. In this section, we focus on the first stage of the pipeline, where each screen is embedded using multimodal features and clustered into discrete screen roles. These roles serve as the abstraction used later for sequence modeling of UI flows.

A. Multimodal Screen Representation

A screen contains both visual information (layout, icons, imagery) and structured semantic information (widget types and text). We represent a screen $s = (I, H)$ by fusing an image embedding from the screenshot I with a text embedding derived from a serialization of the view hierarchy H. We deliberately avoid training a UI-specific encoder from scratch and instead rely on strong pretrained representation models.

Given a screenshot I, we compute a visual embedding using the CLIP image encoder [14]. We use the ViT-L/14 variant and extract a 768-dimensional embedding, followed by ℓ_2 normalization.

A UI view hierarchy is provided as a JSON tree describing UI elements (widget types) and their textual properties. We convert this hierarchy into a deterministic textual sequence by traversing the UI tree and extracting, for each node, a widget identifier (e.g., button, text field, text view) and an associated text attribute, such as visible text, content description, hint, or label. Each node is serialized as either `ClassName: text` when textual content is available, or simply `ClassName` otherwise. For example, a screen containing a button labeled "Login" and a text field with placeholder "Email" would be serialized as `UI_SCREEN <SEP> Button: Login <SEP> EditText: Email`, where `<SEP>` is used only for readability; in the actual implementation, entries are separated by newline characters.

The resulting sequence is then embedded using Sentence-BERT (SBERT) [15], specifically all-MiniLM-L6-v2 in our implementation, producing a 384-dimensional embedding that is again ℓ_2 normalized.

Let $v \in \mathbb{R}^{d_v}$ and $t \in \mathbb{R}^{d_t}$ denote the normalized CLIP and SBERT embeddings, respectively. We form a late-fusion representation by concatenation:

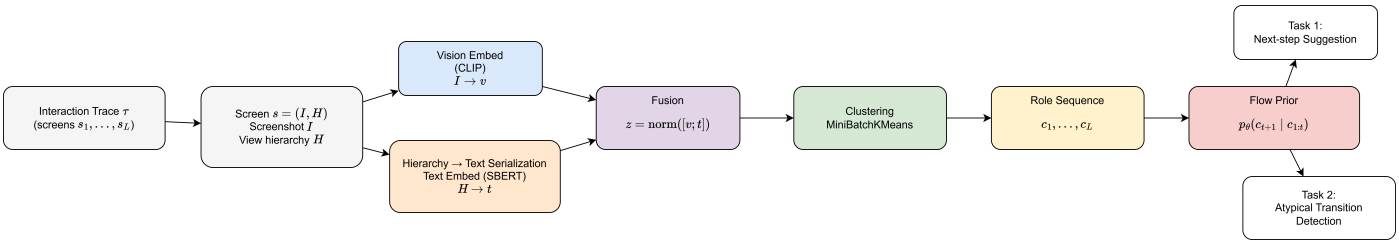

Fig. 1. Overview of the proposed pipeline. Screens are embedded using multimodal representations, clustered into discrete screen roles, converted into role sequences, and modeled with a flow prior to support next-step suggestion and atypical transition detection.

$$z = \mathrm{norm}\big([v; t]\big) \in \mathbb{R}^{d_v + d_t}, \tag{2}$$

where, $\mathrm{norm}(\cdot)$ denotes ℓ_2 normalization. Concatenation preserves modality-specific information while producing a single vector suitable for standard clustering. Intuitively, visual embeddings alone may over-emphasize template similarity, while text/structure embeddings alone may overfit app-specific vocabulary. We therefore use the fused representation as our default operating choice for the main pipeline, and we later assess this design empirically through a modality ablation at the selected operating point $K = 40$.

B. Screen Role Clustering

Given fused embeddings $\{z_i\}_{i=1}^{N}$, we cluster screens into K roles and assign each screen a discrete role ID $c_i \in \{1, \ldots, K\}$. We use MiniBatchKMeans [16], [17] for scalability on large screen corpora. Each screen is assigned to the nearest centroid under Euclidean distance (equivalently cosine distance under ℓ_2 normalization).

The choice of K controls an abstraction trade-off: small K yields coarse roles that improve statistical strength and cross-app generalization, while large K yields fine roles that increase sparsity and can reduce generalization in downstream transition modeling. We therefore treat K as a key hyperparameter and report results across multiple values (e.g., $K \in \{20, 40, 80, 120, 200\}$) in Section VI.

C. Role Cluster Diagnostics

Because screen roles are learned without labels, we assess clustering quality using complementary diagnostics rather than a single criterion. We compare standard internal validation metrics across candidate values of K, including the Silhouette score [18], Davies–Bouldin (DB) index [19], and Calinski–Harabasz (CH) index [20], evaluate stability across random seeds using repeated MiniBatchKMeans runs [16], and inspect cluster-size distributions to detect fragmentation. As summarized in Table I, no single value of K is uniformly best across all internal metrics; instead, the results suggest a trade-off between compactness, stability, and granularity.

These internal metrics are used only as heuristic diagnostics for selecting a practical range of K; they are not treated as direct evidence that the learned roles are semantically valid or optimal for downstream use. In this study, the selected operating point is justified primarily by stability, fragmentation behavior, and downstream predictive utility rather than by any single internal clustering score.

To choose a representative operating point, we prioritize two empirical criteria: 1) stability across repeated clustering runs, and 2) fragmentation behavior as reflected by singleton and very small clusters. We then use downstream next-step prediction results only as a secondary check that the selected role vocabulary remains practically useful. Additional diagnostics at $K = 10$ and $K = 15$ show that smaller values yield stronger compactness-oriented internal metrics, but produce substantially coarser partitions: the median cluster size rises from 2942.5 at $K = 20$ to 4084.8 at $K = 15$ and 6582.5 at $K = 10$, with the largest cluster at $K = 10$ containing $13{,}314$ screens on average across runs. We therefore treat $K = 20$ as the coarse-grained lower bound for downstream flow modeling. Within the practically useful range $K \geq 20$, $K = 40$ provides a substantially finer partition than $K = 20$ while maintaining comparable seed stability (ARI 0.407 vs. 0.380) and higher NMI (0.647 vs. 0.576), and it avoids the stronger fragmentation that appears at larger values of K. Normalized Mutual Information (NMI) [21] is therefore reported alongside ARI as a complementary stability reference.

We therefore use $K = 40$ in the subsequent flow-modeling experiments as the representative operating point balancing role granularity, clustering stability, and downstream predictive utility.

Fig. 2 provides a qualitative view of the fused embedding space: intra-cluster screen pairs tend to have higher cosine similarity than inter-cluster pairs.

To complement these internal diagnostics, we also provide a qualitative audit of the learned roles at $K = 40$ in the supplementary material (Appendix), where each selected cluster is illustrated using centroid-nearest representative screens from the fused embedding space. The examples suggest that several high-frequency clusters correspond to visually and functionally coherent UI states.

V. Flow Modeling with Screen Roles

Using the role assignments obtained in Section IV, each interaction trace is converted into a discrete sequence of role IDs. We then model the flow prior $p_\theta(c_{t+1} \mid c_{1:t})$ using two modeling approaches: 1) count-based n-gram priors and 2) a causal Transformer over role sequences. Both approaches output a next-role distribution that can be used for next-step suggestion and for assigning atypicality scores to observed transitions.

TABLE I. CLUSTER DIAGNOSTICS ACROSS CANDIDATE VALUES OF K

K	Silhouette↑	DB↓	CH↑	ARI↑	NMI↑	Singletons	Median size
10	0.0170	4.5768	1058.43	0.401	0.533	0.0	6582.5
15	0.0145	4.3387	785.32	0.404	0.570	0.0	4084.8
20	0.0136	4.4083	686.97	0.380	0.576	0.0	2942.5
40	0.0030	4.3292	427.74	0.407	0.647	0.0	1599.5
80	0.0077	4.2581	262.30	0.399	0.675	0.4	753.5
120	0.0013	4.0699	196.16	0.355	0.681	0.8	524.0
200	-0.0031	3.9996	134.55	0.347	0.697	1.4	296.5

$K = 10$ and $K = 15$ provide coarser role vocabularies despite stronger compactness-oriented internal metrics, while $K = 40$ serves as the representative operating point within the practically useful range $K \geq 20$. Stability is summarized across 5 MiniBatchKMeans runs with seeds 0–4.

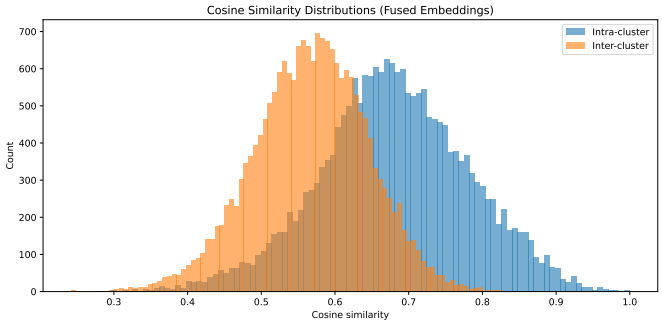

Fig. 2. Intra- vs. inter-cluster cosine similarity distributions for fused screen embeddings (illustrative example with $K = 40$). Intra-cluster pairs are shifted toward higher similarity than inter-cluster pairs, supporting that the learned roles capture consistent patterns rather than arbitrary partitions.

A. Trace-to-Role Sequence Preprocessing

Let $\tau = (s_1, \ldots, s_L)$ be a trace of screens. We map each screen to a role ID via the learned embedding-and-clustering pipeline (Section IV), yielding a role sequence $\mathbf{c} = (c_1, \ldots, c_L)$.

UI traces often contain repeated observations of the same functional state (e.g., re-rendering, minimal changes, or near-duplicate screens). To avoid overweighting self-transitions and to emphasize meaningful navigation steps, consecutive occurrences of the same role are merged. For example, a role sequence such as $(c_1, c_2, c_2, \ldots, c_2, c_3, \ldots)$ is reduced to $(\tilde{c}_1, \tilde{c}_2, \tilde{c}_3, \ldots)$, where $\tilde{c}_i \neq \tilde{c}_{i+1}$. Any trace with fewer than two roles after consecutive-duplicate merging is removed. (Additional dataset filtering and split protocol are described in Section VI.)

B. n-gram Flow Priors

We begin with count-based probabilistic priors over role sequences. These priors are strong, interpretable baselines and provide reasonable next-role probabilities for typicality scoring when the role vocabulary is moderate.

Let $N(\cdot)$ denote counts computed from training role sequences. The *unigram* prior ignores context entirely and ranks next roles by their global frequency:

$$P_{\text{uni}}(j) = \frac{N(j)}{\sum_{m=1}^{K} N(m)}. \tag{3}$$

The *bigram* prior is the first context-dependent model and corresponds to a first-order Markov assumption over role transitions:

$$P_{\text{bi}}(j \mid i) = \frac{N(i \to j)}{\sum_{m=1}^{K} N(i \to m)}. \tag{4}$$

The *trigram* prior extends this to a second-order Markov model by conditioning on the previous two roles:

$$\widehat{P}_{\text{tri}}(j \mid p, i) = \frac{N(p, i \to j)}{\sum_{m=1}^{K} N(p, i \to m)}. \tag{5}$$

Higher-order n-grams suffer from sparsity when contexts are rare. We therefore use standard interpolation/backoff from language modeling [22], [23] by mixing trigram and bigram distributions:

$$P_{\text{mix}}(j \mid p, i) = (1 - \lambda)\widehat{P}_{\text{tri}}(j \mid p, i) + \lambda P_{\text{bi}}(j \mid i), \tag{6}$$

where, $\lambda \in [0, 1]$ controls the reliance on shorter contexts. We treat λ as a tunable hyperparameter selected based on performance on the validation split (Section VI).

C. Transformer Flow Model

While n-gram priors capture local dependencies, UI navigation can depend on longer histories (e.g., multi-step onboarding or configuration flows). To model longer-range context, we train a causal Transformer [24] over role sequences to estimate the flow prior $p_\theta(c_{t+1} \mid c_{1:t})$.

We formulate next-role prediction as an autoregressive sequence modeling problem over discrete role IDs. Given a role sequence $(c_1, \ldots, c_T)$, we construct training examples by prepending a beginning-of-sequence token and predicting each next role from its preceding prefix. For a prediction step at position t, the input prefix is:

$$x_{1:t} = (\texttt{[BOS]}, c_1, \ldots, c_t), \tag{7}$$

and the target is the next role c_{t+1}. For batching, prefixes are truncated to a fixed maximum context length and right-padded with a special `[PAD]` token.

Each input token is mapped to a learned token embedding and combined with a learned positional embedding. The resulting sequence is processed by a Transformer encoder with a

causal self-attention mask, so that the representation at position t depends only on the observed prefix $x_{1:t}$. Let h_t denote the contextual representation of the last non-padding token in the prefix. The model predicts the next role by applying a linear output layer followed by a softmax over the K role IDs:

$$p_\theta(c_{t+1} = j \mid c_{1:t}) = \mathrm{softmax}(Wh_t + b)_j. \tag{8}$$

Thus, the Transformer defines a conditional next-role distribution from the encoded prefix representation.

We train the model using next-token prediction over role sequences. For each prefix-target pair $(c_{1:t}, c_{t+1})$, the objective is to maximize the model's conditional probability for the observed next role in Eq. 8, or equivalently to minimize the cross-entropy loss:

$$\mathcal{L} = -\sum_{t=1}^{T-1} \log p_\theta(c_{t+1} \mid c_{1:t}). \tag{9}$$

This objective directly corresponds to learning the flow prior in Eq. 1, since the model is trained to assign high probability to the observed next role given the preceding role sequence.

To improve generalization to unseen applications, we apply regularization through dropout, weight decay, and gradient clipping. Model selection is performed using early stopping based on Recall@10 computed on a held-out validation split constructed at the application level. Model hyperparameters (e.g., context length, depth, width) and early-stopping settings are reported in Section VI.

VI. Experimental Setup

This section describes the dataset instantiation, preprocessing pipeline, multimodal representation construction, split design, model configurations, and evaluation protocol used in all experiments.

We use the RICO mobile UI interaction corpus, in which each trace is an ordered sequence of screen observations from a single application session. Each screen observation contains 1) a screenshot image and 2) a structured view hierarchy (UI tree) with widget metadata and visible text [1], [8].

A. Preprocessing and Modality Alignment

We apply the preprocessing pipeline deterministically. A screen observation is retained only if both the screenshot and its corresponding view-hierarchy JSON are present and parsable. Alignment is performed using a derived screen identifier from the file structure and metadata.

Each view hierarchy is converted into the deterministic textual representation described in Section IV-A. In preprocessing, this representation is generated by recursively traversing the hierarchy JSON in a fixed depth-first order, extracting widget identifiers and associated textual attributes, removing duplicate `(class, text)` entries within a screen, and normalizing text by trimming whitespace and removing empty strings before SBERT encoding.

For implementation robustness, the serialized hierarchy is capped at 200 entries. This cap affects only 20 of 66,261 screens (0.03%), indicating that truncation has negligible influence on the analyzed dataset.

We also compute a near-duplicate diagnostic based on embedding similarity. Using a strict threshold (top-1 cosine similarity ≥ 0.99995), 5,868 out of 66,261 screens (8.9%) are identified as near-duplicates, consistent with repeated templates and nearly identical screens within traces. This diagnostic motivates application-wise split design but is not used as an explicit filter in the main pipeline.

B. Multimodal Embedding Construction

After extracting CLIP embeddings for all 66,261 screenshots and SBERT embeddings for their corresponding serialized view hierarchies, we identified that five screenshots lacked usable hierarchy representations, resulting in an aligned multimodal intersection of 66,256 screens. We use 768-dimensional CLIP (ViT-L/14) features and 384-dimensional SBERT (MiniLM) features. After per-modality ℓ_2 normalization, the two representations are concatenated to form a 1152-dimensional fused embedding for each aligned screen.

C. Splits and Generalization Protocols

To prevent leakage and measure generalization to unseen applications, we split by application: all traces of an application belong to exactly one split. We use an 80/20 app-wise train/test split. In our snapshot, 1,503 apps are held out for testing (corresponding to the 20% test partition). For Transformer model selection, the training apps are further divided into an inner training set and an inner validation set, where the inner validation set is used for early stopping.

In addition to this app-wise train/test evaluation, we also assess out-of-domain generalization using a leave-one-category-out protocol. In this setting, all applications from one category are held out for testing, and the model is trained on applications from the remaining categories. This protocol uses 26 categories, restricted to those with at least 50 applications each. For each held-out category, we train on all other categories and evaluate on the held-out category, reporting macro-averaged performance across categories.

D. Models and Training

Table II summarizes the key model configurations and training settings used across all experiments. We evaluate unigram, bigram, and trigram flow priors on role sequences. For the trigram model, we apply trigram–bigram interpolation/backoff (Eq. 6) following established practice in n-gram modeling [22], [23]. The interpolation weight λ is treated as a hyperparameter and selected on the validation split using Recall@10 on the trigram-subset.

We also train a causal (autoregressive) Transformer for next-role prediction [24]. Each role ID is treated as a token, and we add special tokens `[BOS]` and `[PAD]`. For a role vocabulary of size K, the full token vocabulary therefore has size $K + 2$. Prefixes are clipped to at most the chosen context length `ctx` by keeping the most recent context, and shorter prefixes are right-padded for batching. The model uses learned

token embeddings, learned positional embeddings, and masked self-attention so that each position can attend only to itself and earlier tokens. The next-role distribution is predicted from the hidden state at the last non-padding position in the prefix.

Our default Transformer architecture uses embedding dimension $d = 256$, 4 attention heads, and 4 masked self-attention layers. We optimize cross-entropy loss for next-role prediction using AdamW, apply gradient clipping with maximum norm 1.0, and train with batch size 256. Unless otherwise stated, the random seed is fixed to 42 and training is allowed to continue for up to 200 epochs with early stopping. Additional implementation details are provided in Appendix B.

For model selection, we use early stopping based on validation Recall@10 on the trigram-subset, where the validation split is constructed at the application level and is disjoint from both the training and test applications. We use this ranking-based criterion because the main task is next-role retrieval rather than calibrated probability estimation, and because preliminary experiments showed that held-out Recall@10 typically peaks early while training loss can continue decreasing. We use patience $= 8$ epochs and reset patience only when validation Recall@10 improves by more than 10^{-4}.

For the controlled context-length sweep at $K = 40$, we evaluate $\texttt{ctx} \in \{4, 8, 16, 32\}$ while keeping the remaining settings fixed, and we report the best checkpoint under the above validation criterion. For the reported multi-K Transformer runs, unless otherwise specified, we use $\texttt{ctx}= 16$, learning rate 3×10^{-5}, dropout 0.3, weight decay 0.1, batch size 256, and an application-level inner validation ratio of 0.2.

E. Evaluation Protocol

Given a test trace converted into a role sequence, we create prediction instances at each position by using the observed prefix and predicting the next role. We report Recall@k for $k \in \{1, 3, 5, 10, 20\}$.

We report two evaluation modes: 1) *all edges*, which includes all transitions with at least one preceding role, and 2) the *trigram-subset*, which restricts evaluation to transitions with at least two preceding roles for fair comparison with trigram-based methods. Unless otherwise specified, all models are evaluated on the same set of trigram-subset transition edges for fair comparison.

We evaluate atypical transition detection by converting next-step prediction into a sampled-candidate ranking problem with negative alternatives. For each true transition, we form one positive candidate (the observed next role) and $N_{\text{neg}} = 10$ negative candidates by replacing the next role with roles sampled uniformly at random from the role vocabulary $\{1, \ldots, K\} \setminus \{c_{t+1}\}$. Special tokens such as `[PAD]` and `[BOS]` are excluded from this sampling. We use a fixed random seed for reproducibility. This protocol keeps the candidate set size fixed across examples and models, while providing a lightweight approximation of anomaly discrimination without requiring exhaustive scoring over all possible next roles. Because the negatives are sampled uniformly at random, the task measures discrimination against random incorrect alternatives rather than against hardest or semantically nearest negatives. All candidates are scored using the model's assigned probability for the next role under the same observed context. We report AUROC and Precision–Recall metrics (including Average Precision) to account for the resulting class imbalance.

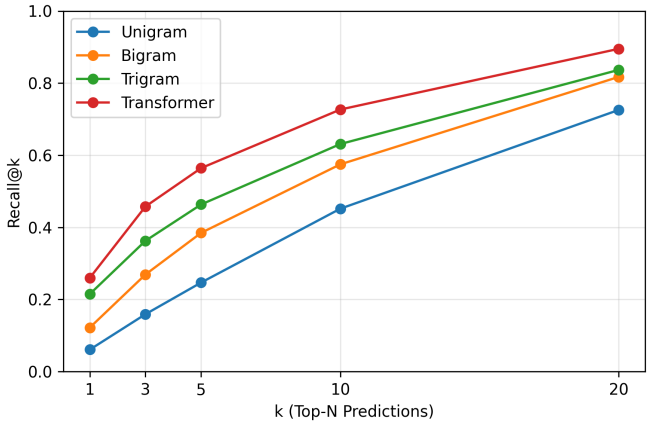

Fig. 3. Recall@k curves for next-step prediction on applications in the test split ($K = 40$), comparing unigram, bigram, trigram, and Transformer priors.

Accordingly, these metrics should be interpreted as measuring relative ranking performance under sampled alternatives, not as a direct estimate of real-world anomaly-detection accuracy under unconstrained deployment conditions.

VII. Results

We report results for the two tasks defined in Section III: 1) next-step suggestion via Recall@k and 2) atypical transition detection via ranking/classification metrics under negative sampling. Unless otherwise stated, results use the primary cross-app protocol (Section VI-C) and matched-edge evaluation for fair comparison.

A. Task 1: Next-Step Prediction Performance

Table III compares unigram, bigram, trigram, and the Transformer flow prior on the same matched set of 6,058 transition edges. The Transformer achieves the strongest Recall@k at every reported cutoff. Relative to the trigram baseline, the absolute improvements are +0.0449 at R@1, +0.0952 at R@3, +0.1009 at R@5, +0.0957 at R@10, and +0.0585 at R@20. Thus, the improvement is not simply monotonic in k; rather, the largest absolute gains occur in the shortlist range from R@3 to R@10, which is particularly relevant for shortlist-based design-assistance settings.

Fig. 3 visualizes the Recall@k curves and makes the differences in top-k ranking behavior easier to compare than the tabulated values alone.

Additional Transformer ablations over context length and regularization are reported in Appendix A.

To assess robustness to neural training randomness, we repeated the main $K = 40$ Transformer experiment with three random seeds while keeping the data split and model recipe fixed. As shown in Table IV, performance remains stable across seeds, with low standard deviation at all reported

TABLE II. KEY EXPERIMENTAL SETTINGS USED ACROSS MODELS

Component	Setting
Role vocabulary size	$K \in \{20, 40, 80, 120, 200\}$ (reported per experiment)
Duplicate collapsing	collapse consecutive identical roles; drop traces < 2
n-gram backoff	trigram–bigram interpolation (Eq. 6)
n-gram λ	tuned on validation split (maximizing Recall@10 on matched subset)
Transformer architecture	causal/autoregressive Transformer with masked self-attention
Transformer width/depth	$d = 256$, 4 heads, 4 layers
Transformer objective	cross-entropy next-role prediction
Transformer optimizer	AdamW
Transformer context length	ctx $\in \{4, 8, 16, 32\}$ (controlled sweep at $K = 40$)
Model selection	early stop on validation Recall@10 (trigram-subset), best checkpoint chosen
Training epochs	up to 200 with early stopping
Gradient clipping	max norm $= 1.0$
Transformer reported multi-K recipe	ctx $= 16$, lr $= 3 \times 10^{-5}$, dropout $= 0.3$, weight decay $= 0.1$, batch size $= 256$
Random seed	42 for the primary reported run; additional multi-seed robustness results are reported in Appendix E
Anomaly protocol	primary setting uses $N_{\text{neg}} = 10$; see App. F and App. G

TABLE III. RECALL@K FOR NEXT-STEP PREDICTION

Model	R@1	R@3	R@5	R@10	R@20
Unigram	0.0609	0.1591	0.2469	0.4518	0.7257
Bigram	0.1220	0.2692	0.3848	0.5748	0.8173
Trigram	0.2149	0.3627	0.4635	0.6311	0.8367
Transformer	**0.2598**	**0.4579**	**0.5644**	**0.7268**	**0.8952**

Recall@k for next-step prediction on unseen test applications with $K = 40$. All models are evaluated on the same 6,058 matched transition edges for fair comparison.

cutoffs: 0.2671 ± 0.0066 at R@1, 0.4691 ± 0.0097 at R@3, 0.5817 ± 0.0152 at R@5, 0.7436 ± 0.0146 at R@10, and 0.9032 ± 0.0071 at R@20. This indicates that the Transformer advantage is not tied to a favorable initialization, but persists across independent runs. Seed-specific results are provided in Appendix E.

1) Modality ablation at $K = 40$: To assess the contribution of each screen-representation modality, we repeated the $K = 40$ pipeline using three alternatives for screen-role induction: CLIP-only visual embeddings, SBERT-only hierarchy-text embeddings, and the fused CLIP+SBERT representation used in the main experiments. For each representation, we re-ran clustering, trace-to-role conversion, and downstream next-step modeling under the same application-level split and evaluation protocol. Table V shows that no single modality dominates uniformly across all models and recall cutoffs. For the Transformer, the fused representation yields the strongest top-ranked performance at $R@5$ and is effectively tied with SBERT-only at $R@1$, while CLIP-only slightly outperforms fused at $R@10$. This pattern suggests that fusion is best interpreted as a balanced representation choice rather than as a universally superior modality under all retrieval cutoffs.

We use $K = 40$ as the primary operating point in the remainder of this section. This choice is not based on raw next-step recall alone, since smaller values of K make the prediction problem easier by construction. Instead, $K = 40$ was selected in Section IV-C using clustering stability and fragmentation as the primary criteria, with downstream prediction used as a secondary check that the resulting role vocabulary remains predictive on held-out applications. Additional low-granularity diagnostics at $K = 10$ and $K = 15$ show that, although smaller values yield higher raw Recall@k, they also produce substantially coarser role vocabularies with much larger cluster sizes. We therefore use $K = 20$ as the coarse-grained lower bound in the downstream sweep and $K = 40$ as the representative operating point because it provides finer role granularity while still maintaining strong downstream performance.

Table VI reports next-step prediction performance across cluster granularities $K \in \{20, 40, 80, 120, 200\}$ under the same unseen test-application evaluation protocol; additional low-granularity results for $K = 10$ and $K = 15$ are reported in the Appendix. At $K = 20$, the $R@20$ column is saturated (1.0000 for all models) because the evaluation cutoff equals the role vocabulary size. This is a limitation of the current evaluation protocol at this granularity: with a coarse role space, $R@20$ no longer provides discriminative evidence about model quality and instead becomes a trivial upper bound. In other words, the task at this granularity is too coarse for $R@20$ to be informative under the current setup. Accordingly, the meaningful comparisons at $K = 20$ are $R@1$, $R@3$, $R@5$, and $R@10$.

As expected, raw Recall@k decreases as K increases, because the prediction task becomes harder when the role vocabulary is larger and the transition distribution becomes sparser. Across all K, the Transformer consistently outperforms the n-gram baselines.

To test out-of-domain generalization beyond application identity, we additionally evaluate leave-one-category-out with $K = 40$. Macro-averaged results over 26 held-out categories are shown in Table VII. The Transformer achieves the best macro-averaged Recall@k across all reported cutoff values, indicating stronger average category-level generalization than the n-gram baselines.

TABLE IV. MULTI-SEED TRANSFORMER NEXT-STEP PREDICTION RESULTS ($K = 40$)

Model	R@1	R@3	R@5	R@10	R@20
Transformer (3 seeds)	0.2671 ± 0.0066	0.4691 ± 0.0097	0.5817 ± 0.0152	0.7436 ± 0.0146	0.9032 ± 0.0071

Results are reported as mean $\pm$ standard deviation over three random seeds on unseen test applications.

TABLE V. MODALITY ABLATION ACROSS NEXT-STEP MODELS AT $K = 40$

Representation	Model	$R@1$	$R@5$	$R@10$
CLIP-only	Unigram	0.0668	0.2974	0.4797

Each representation is used to induce screen roles, after which the same downstream application-level split and evaluation protocol are applied.

B. Task 2: Atypical Transition Detection

We evaluate atypical transition detection by ranking the true next role against $N_{\text{neg}} = 10$ randomly sampled incorrect roles per transition (Section VI-E). On the unseen test set, the Transformer achieves strong ranking performance, with AUROC = 0.83 and Average Precision (AP) = 0.42 under this protocol. These values indicate how well the model ranks observed transitions against sampled random alternatives under a fixed candidate set, and should not be interpreted as direct evidence of real-world anomaly-detection performance.

We compare n-gram baselines and the Transformer under an identical evaluation protocol: The same 6,058 test transitions, fixed negative sampling with $N_{\text{neg}} = 10$ (positive rate ≈ 0.0909), and the same sampled negatives reused across models. Table VIII reports AUROC, Average Precision (AP), and recall at a precision-constrained operating point (precision ≥ 0.8).

We also examined sensitivity to the number of sampled negatives in the anomaly protocol. Table IX shows that AUROC remains essentially unchanged across $N_{\text{neg}} \in \{5, 10, 20, 50\}$, varying only from 0.8317 to 0.8328. This suggests that the Transformer's relative ranking quality is robust to the size of the sampled candidate set. In contrast, Average Precision and recall at precision ≥ 0.8 decrease substantially as N_{neg} increases. This is expected, since larger N_{neg} makes the sampled task more imbalanced and pushes the high-precision operating point toward increasingly conservative thresholds. The result therefore strengthens the interpretation that the Transformer's anomaly advantage is robust as a ranking result, while threshold-dependent operating points remain sensitive to the difficulty of the sampled protocol. Additional results are reported in Appendix F.

To test whether the sampled-candidate protocol materially overstates anomaly-ranking performance, we additionally re-evaluated the main Transformer checkpoint against the full role vocabulary at $K = 40$ on the same 6,058 matched test transitions. Under this stricter setting, AUROC remains essentially unchanged (0.8320, versus 0.8323 under sampled negatives with $N_{\text{neg}} = 10$), while Average Precision decreases from 0.4231 to 0.1943 and recall at precision ≥ 0.8 decreases from 0.0568 to 0.0028. This indicates that the Transformer's relative ranking quality is robust beyond the sampled-negative setting, but that threshold-dependent anomaly screening becomes substantially more conservative when each context is evaluated against the full vocabulary.

To examine threshold behavior under different precision constraints, Table X reports thresholds selected to maximize recall while maintaining a target precision level. The strictest settings (e.g., target precision 0.95 or 0.90) achieve extremely low recall, indicating that these thresholds should be interpreted as highly conservative operating points rather than broad anomaly-screening regimes.

These results show that, although the Transformer provides the strongest overall ranking performance under the sampled evaluation protocol, very high precision comes at a substantial cost in recall. At target precision 0.95 and 0.90, only a very small fraction of atypical transitions is recovered. Lower precision targets such as 0.70, 0.60, or 0.50 provide substantially higher recall, but this comes at the expected cost of admitting more false positives.

Accordingly, Table X should be interpreted as illustrating the precision–recall trade-off under the fixed negative-sampling protocol rather than as establishing a deployment threshold for real-world anomaly detection.

Fig. 4 visualizes the full precision–recall curve and highlights the operating points in Table X.

C. Qualitative Analysis of Detected Redirect Failures

To complement quantitative ranking metrics, we report qualitative examples of high-confidence anomalies detected by the Transformer. Examples are selected from cases in which the observed transition is assigned low probability and there is a large margin between its probability and that of the top predicted continuation.

Fig. 5 shows an example from the KAYAK application. After a system permission request, the observed transition redirects the user to a hotel sharing interface that is unrelated to the permission context. The model assigns low probability to the observed continuation ($p_{\text{obs}} \approx 0.0035$) while ranking an account login/linking screen as the most likely continuation ($p_{\text{exp}} \approx 0.34$).

Fig. 6 shows an example from a transportation-related application. From a tariff configuration screen, the observed transition navigates to a driver configuration page without an apparent authentication step. The model instead predicts a login screen as the most likely continuation, assigning substantially higher probability than the observed transition.

Transformer	0.832	0.423	0.0568

Atypical

transition detection under a fixed protocol (same 6,058 transitions; fixed negative sampling with $N_{\text{neg}} = 10$; positive rate ≈ 0.0909). We report AUROC, Average Precision (AP), and recall at precision ≥ 0.8.

TABLE IX. SENSITIVITY OF TRANSFORMER ATYPICAL-TRANSITION METRICS TO THE NUMBER OF SAMPLED NEGATIVES N_{neg} ($K = 40$)

N_{neg}	AUROC ↑	AP ↑	Recall@Precision ≥ 0.8 ↑
5	0.8317	0.5626	0.1720
10	0.8323	0.4231	0.0568
20	0.8319	0.2957	0.0102
50	0.8328	0.1654	0.0012

TABLE X. PRECISION-RECALL TRADE-OFFS FOR TRANSFORMER-BASED ATYPICAL TRANSITION DETECTION

Target Precision	Threshold	Achieved Precision	Recall
0.95	0.9114	1.0000	0.00033
0.90	0.8618	0.9231	0.00396
0.70	0.3774	0.7003	0.1354
0.60	0.1904	0.6000	0.2565
0.50	0.1030	0.5000	0.3760

Thresholds are chosen to maximize recall while satisfying a target precision constraint. Very high target precision yields highly conservative operating points with limited recall.

VIII. DISCUSSION

Our results support the central hypothesis of this work: after abstracting screens into reusable role IDs, mobile UI navigation exhibits domain-independent regularities that can be learned from large-scale traces and transferred to unseen applications and categories. We discuss implications for next-step suggestion and atypical transition detection, analyze the effect of role granularity, and outline limitations and future directions.

A. Next-Step Prediction on Unseen Applications

Across unseen test applications, the Transformer flow prior consistently outperforms count-based n-gram baselines, with the largest absolute gains occurring in the shortlist range from R@3 to R@10 (Table III, Fig. 3). For a fixed shortlist size, this means that the Transformer more often places the true next role among the top-ranked candidates, which is compatible with shortlist-based design-assistance settings in which a small set of plausible continuations is presented to the user.

A plausible interpretation is that role sequences contain recurring multi-step patterns (e.g., transitions from entry to browsing to detail to confirmation states) that benefit from sequence models able to condition on longer histories, whereas n-gram baselines are limited to fixed-order local context. However, the present experiments establish the empirical advantage of the Transformer rather than the exact mechanism responsible for it.

The sensitivity study across K (Table VI) further clarifies the role of abstraction. As K increases, the next-role classification problem becomes harder because the role vocabulary is larger and the transition distribution becomes sparser. This trend affects all models, but the degradation is steeper for frequency-based baselines that rely directly on repeated transition counts. In contrast, the Transformer maintains stronger performance across the full range of tested granularities, indicating that it is better able to preserve useful ranking quality as the role abstraction becomes finer.

Throughout the main results we report $K = 40$ as the primary operating point. This choice is not based on raw next-step recall alone, since smaller values of K make the prediction task easier by construction. Instead, $K = 40$ was selected as a practical trade-off between representational granularity,

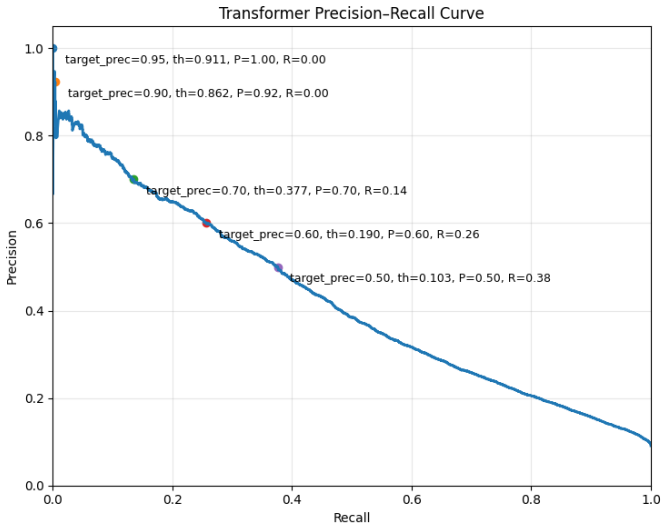

Fig. 4. Precision-recall curve for Transformer-based atypical transition detection under negative sampling. Markers correspond to selected precision-constrained operating points.

clustering stability, and downstream predictive performance, supported by the diagnostics in Section IV-C together with the sensitivity analysis in Table VI. We nevertheless report results across multiple values of K and treat role granularity as a tunable design parameter rather than a fixed constant.

B. Generalization Beyond Applications: Cross-Category Behavior

The leave-one-category-out protocol tests a more challenging distribution shift than cross-application splits, since the held-out category may involve different UI conventions, vocabulary, and navigational patterns. The n-gram results (Table VII) show that the role abstraction retains predictive value even under this stronger shift. The Transformer further improves macro-averaged Recall@k under the same protocol, providing evidence of stronger average generalization across held-out categories than the count-based baselines.

At the same time, these results should be interpreted conservatively. Categories in RICO are not perfectly disjoint in UI structure, and some categories may still share common design conventions such as list-detail patterns or authentication flows. The full per-category breakdown confirms that the macro-average masks meaningful heterogeneity rather than uniform behavior across held-out categories. In the present experiments, Transformer R@10 ranges from 0.5446 on *Sports* and 0.5843 on *Food & Drink* to 0.7666 on *Education*, 0.7455 on *Weather*, and 0.7452 on *Beauty*. Thus, the leave-one-category-out result should be read as evidence of strong average cross-category generalization together with substantial variation in category difficulty. Full per-category results are reported in Appendix H.

A plausible explanation for the weaker held-out results on *Sports* and *Food & Drink* is that these categories often involve more heterogeneous and content-driven flows than the strongest held-out categories. Sports applications may combine news, live scores, video, team pages, betting- or fantasy-like features, and account flows within the same app family, while Food & Drink applications may mix restaurant discovery, menus, ordering, reservation, delivery, and loyalty flows. Such mixtures can produce more branching continuations from visually similar intermediate states and therefore reduce next-role predictability under a shared role vocabulary. By contrast, stronger categories such as Education, Weather, and Beauty may rely more heavily on recurring template-like flows such as onboarding, settings, browsing, and detail views, which transfer more readily across applications. These explanations are interpretive rather than directly annotated in the present dataset, but they are consistent with the heterogeneity visible in the full leave-one-category-out breakdown.

C. Interpreting Atypical Transition Detection Metrics

The atypical-transition results in this study should be interpreted within the scope of the evaluation protocol. Specifically, the task is defined through fixed negative sampling, so the reported metrics measure how well each model ranks observed transitions against sampled alternatives under this controlled setting. They therefore support comparison of relative ranking performance across models, but do not by themselves establish real-world anomaly-detection effectiveness under unconstrained deployment conditions.

In particular, the protocol does not test whether low-probability transitions correspond to naturally occurring defects in deployment, since sampled negatives may differ substantially from realistic alternative continuations.

At the same time, an additional full-vocabulary re-evaluation at $K = 40$ shows that AUROC remains nearly unchanged relative to the sampled protocol, whereas Average Precision and precision-constrained recall drop substantially, indicating that sampled negatives preserve relative ranking comparisons reasonably well but understate the difficulty of strict high-precision anomaly screening. Even with this stricter full-vocabulary comparison, the evaluation remains an offline atypical-transition ranking task rather than a direct benchmark of naturally occurring deployment anomalies.

Within this fixed protocol, the Transformer achieves the strongest ranking performance among the compared models (Table VIII), indicating better discrimination between observed transitions and sampled negative alternatives than the n-gram baselines. Relative to the trigram baseline, this result suggests that atypical-transition scoring may benefit from information beyond short local context, although the present experiments do not directly establish the underlying mechanism.

At the same time, the precision-constrained analysis (Table X, Fig. 4) highlights an important limitation. At very high precision targets such as 0.95 or 0.90, recall becomes extremely low. These operating points should therefore not be interpreted as evidence of broad practical usefulness; rather, they show that only a very small fraction of positives can be recovered when false alarms are tightly constrained. Lower precision targets provide substantially higher recall, but this comes at the expected cost of admitting more false positives.

Overall, the anomaly results are best understood as evidence that the Transformer provides the strongest relative ranking performance under the sampled evaluation protocol, while also revealing clear practical limitations in strict high-precision regimes. A more realistic assessment of deployment

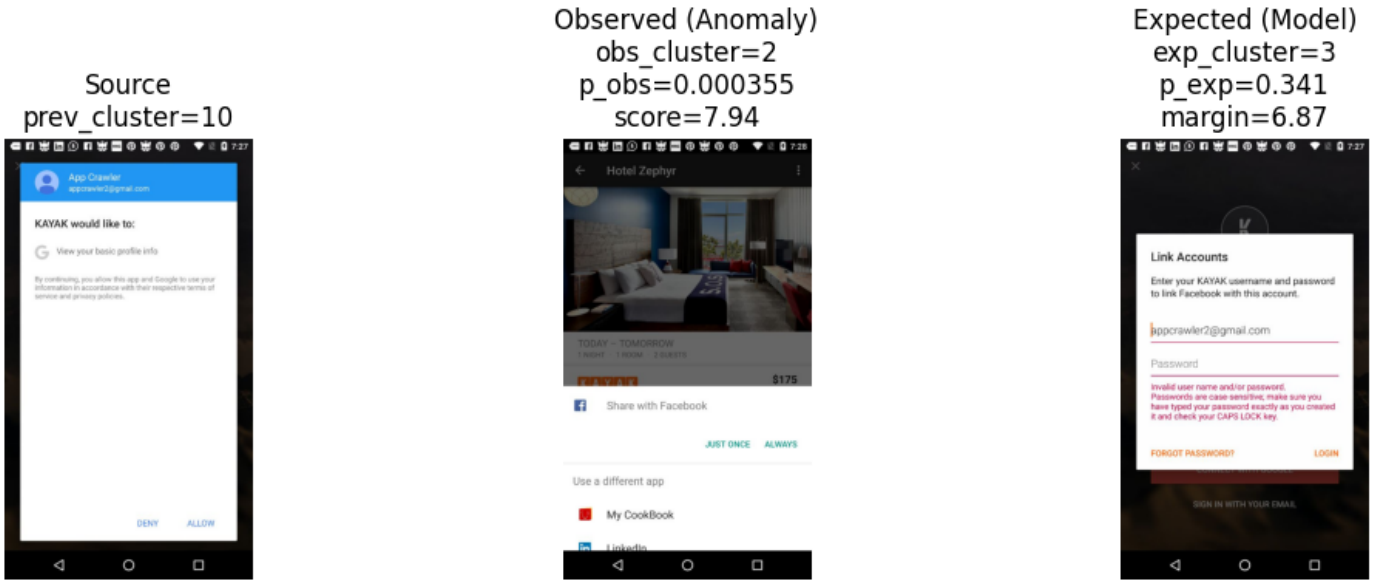

Fig. 5. Detected redirect failure in the KAYAK application. After a permission request (left), the observed transition leads to an unrelated sharing interface (middle), while the model predicts an account login screen as the expected continuation (right).

Fig. 6. Detected configuration flow anomaly. From a tariff configuration screen (left), the application navigates to a driver settings page without authentication (middle). The model instead predicts a login screen as the expected continuation (right).

utility would require evaluation settings that go beyond sampled negatives and better reflect naturally occurring atypical transitions.

D. Qualitative Inspection of High-Scoring Transitions

The qualitative case studies (Fig. 5 and 6) are interpreted as illustrative examples rather than as a general validation of the anomaly score. In the presented cases, high anomaly scores coincide with transitions that appear questionable or unusual from a design perspective, while the model assigns substantially higher probability to an alternative continuation that is more consistent with the preceding flow context (e.g., an authentication or account-linking step). These examples therefore suggest that the score can highlight potentially design-relevant irregularities in at least some cases, but they do not establish that this holds broadly beyond the illustrated examples.

The contrast between the observed continuation and the model-preferred alternative can nevertheless provide a qualitative basis for inspection. A designer can examine both what actually occurred and what the model ranked as more probable under the learned flow prior. This comparison may

help interpret why a transition was flagged, although the present qualitative evidence is not sufficient to claim general diagnostic usefulness.

A limitation is that qualitative selection can be biased toward visually obvious failures. To mitigate this, future qualitative evaluation should include a structured sampling strategy (e.g., top anomalies stratified by application/category, plus a random sample of mid-score transitions) together with human annotation to estimate how often low-probability transitions correspond to true flow defects versus legitimate but rare paths.

E. Role Granularity and the Choice of K

The experiments do not support selecting K from next-step prediction accuracy alone. Smaller values of K produce higher Recall@k, but also correspond to coarser role vocabularies in which more heterogeneous screens are merged together. Conversely, larger values of K preserve finer distinctions but lead to increased sparsity and weaker transition modeling performance.

On this basis, we use $K = 40$ as the main operating point in the study. This choice is supported by two considerations grounded in the reported experiments: 1) downstream predictive behavior on held-out applications, where $K = 40$ retains strong next-step prediction performance without relying on the overly coarse abstraction induced by smaller K values; and 2) clustering diagnostics in Section IV-C, where $K = 40$ shows favorable stability while avoiding the stronger fragmentation observed at larger values of K. We therefore treat $K = 40$ not as a universally "natural" constant, but as a practically selected operating point supported by the present evidence.

More generally, the experiments suggest that role granularity should be treated as a tunable design parameter whose preferred value depends on the balance one wants between semantic specificity and statistical reliability.

F. Limitations and Future Work

This study has several limitations. First, the primary atypical-transition evaluation uses negative sampling, which provides a controlled quantitative protocol but does not fully capture real-world anomalies. We complement this with a full-vocabulary re-evaluation at $K = 40$, but both settings remain offline ranking evaluations rather than direct measurements of naturally occurring deployment failures. In practice, unusual transitions may depend on latent application or user state, such as authentication status, granted permissions, network conditions, or prior interaction history, none of which is explicitly modeled in the current setup. As a result, the anomaly results should be interpreted as evidence of ranking quality under controlled candidate-comparison settings rather than as a complete evaluation of real deployment conditions.

Second, we added four robustness analyses to reduce dependence on a single reported configuration: multi-seed evaluation for the Transformer, sensitivity analysis with respect to the number of sampled negatives N_{neg}, an exhaustive full-vocabulary evaluation at $K = 40$, and a full per-category breakdown under leave-one-category-out. Together, these analyses show that the main next-step gains are stable across random seeds, that anomaly-ranking performance remains stable in AUROC across different sampled-negative settings, that exhaustive comparison is substantially harsher than sampled evaluation while still preserving useful ranking quality, and that cross-category generalization remains strong on average despite substantial heterogeneity across held-out categories. The remaining limitation is therefore not the absence of these checks, but the fact that anomaly evaluation is still defined primarily through sampled negatives rather than naturally occurring deployment anomalies. An additional full-vocabulary re-evaluation at $K = 40$ shows that AUROC is largely unchanged relative to the sampled protocol, but that Average Precision and precision-constrained recall decrease substantially, so the sampled setting appears to preserve relative ranking comparisons better than it preserves realistic high-precision screening difficulty.

Beyond these limitations, several research extensions are promising. One direction is to design more realistic anomaly benchmarks that better account for latent state, for example by constructing negatives within matched application/session contexts or by incorporating human-labeled subsets of truly atypical transitions. Another is to expand the comparison set beyond n-gram baselines and a causal Transformer, for example by evaluating recurrent models, structured probabilistic sequence models, or retrieval-augmented priors, in order to better understand which sequence-modeling assumptions are most suitable for UI flow data. Finally, because the current role abstraction is unsupervised and intentionally label-free, an important direction is to generate lightweight role descriptors (e.g., by summarizing common hierarchy tokens or nearest-neighbor exemplars) to improve interpretability and debugging without requiring manual role annotation. While this qualitative audit improves interpretability, it does not replace a formal human evaluation of cluster semantics. A larger-scale annotated study remains an important direction for future work.

IX. Conclusion

We presented a role-based formulation of mobile UI navigation in which screens are mapped to discrete, unsupervised *screen roles* using multimodal representations and clustering, allowing raw interaction traces to be modeled as role sequences across applications. This abstraction supports cross-application sequence modeling while preserving enough structure to study downstream navigation behavior.

Across unseen test applications, both n-gram baselines and a causal Transformer capture nontrivial regularities in role transitions, with the Transformer consistently achieving the strongest next-step prediction performance. Under the fixed negative-sampling protocol used for atypical-transition evaluation, the Transformer also achieves the strongest ranking performance among the compared models. Sensitivity analysis across role granularities further shows that the choice of K should be treated as a practical design parameter rather than a fixed constant; in this study, $K = 40$ serves as a representative operating point supported by clustering diagnostics and downstream predictive behavior.

The qualitative examples illustrate that some high-scoring atypical transitions can correspond to potentially design-relevant irregularities, although broader validation would require more realistic anomaly benchmarks and structured hu-

man evaluation. More generally, the results indicate that role-based abstractions provide a promising basis for studying UI flow regularities and for ranking-oriented tasks such as next-step suggestion under cross-application generalization.

The robustness analyses further indicate that these conclusions are stable across random seeds, across multiple negative-sampling settings, under a stricter full-vocabulary comparison, and across detailed held-out-category breakdowns. Future work should therefore focus less on basic stability verification and more on richer latent-state information, improved interpretability through lightweight role descriptors, and more realistic anomaly-evaluation protocols.

ACKNOWLEDGMENT

The authors would like to thank the creators of the *Rico* dataset for making it publicly available, which made this research possible.

CODE AVAILABILITY

The source code implementing the models and training procedures used in this study is available at: https://github.com/salsik/trico. The repository also includes the exact application-level split manifests used in the main experiments, including the train/validation/test app partitions for the cross-application protocol and the held-out category lists for the leave-one-category-out evaluation.

APPENDIX

This appendix provides additional experimental details and supplementary results that support the main work.

A. Transformer Ablations for Next-Step Prediction

We conducted a broad hyperparameter sweep for Transformer-based next-step prediction under the cross-application protocol, using $K = 40$ as the main operating point. In total, the sweep comprised 120 training runs. The goal of this search was to verify that the reported Transformer

results are stable under reasonable variations in sequence context and training hyperparameters, and to select the checkpoint used in the main experiments.

Across the sweep, we varied maximum context length, learning rate, dropout, and the application-level inner validation ratio. Specifically, the explored values were $\texttt{ctx} \in \{4, 8, 16, 32\}$, learning rate $\in \{3 \times 10^{-5}, 10^{-4}, 3 \times 10^{-4}\}$, dropout $\in \{0.1, 0.2, 0.3\}$, and validation ratio $\in \{0.05, 0.1, 0.2\}$. All runs used label smoothing 0.0, a maximum training budget of 200 epochs, and patience $= 8$. Table XI reports the strongest configurations from this 120-run sweep rather than listing all runs individually.

The best validation checkpoint used throughout the main experiments is obtained with context length 16, learning rate 3×10^{-5}, dropout 0.3, weight decay 0.1, batch size 256, and validation ratio 0.2, achieving a best validation score of 0.7187. Two general patterns are visible in the sweep. First, context length 16 consistently outperforms shorter context (8) and remains preferable to the longer setting (32), suggesting that moderate-length history is sufficient for most predictive gains in the role-sequence setting. Second, mild regularization improves selection performance, with dropout 0.3 and weight decay 0.1 appearing more reliably among the strongest runs than weaker regularization settings.

Because this selected checkpoint is the one used in all downstream experiments, the sweep serves both as a model-selection record and as evidence that the reported Transformer gains are not tied to a single arbitrary hyperparameter choice.

B. Transformer Implementation Details

The Transformer next-role model is implemented in PyTorch as a causal sequence model over discrete role IDs. Given a role vocabulary of size K, we reserve two additional token IDs for `[PAD]` and `[BOS]`, yielding a total token vocabulary of size $K + 2$. During training, each trace is converted into prefix–target pairs by prepending `[BOS]` and predicting each next role from its observed prefix.

Batch construction uses variable-length prefixes clipped to at most the selected context length `ctx`. Within each mini-batch, the effective sequence length is the minimum of `ctx` and the longest prefix in that batch. Prefixes longer than this limit are truncated to the most recent context, while shorter prefixes are right-padded with `[PAD]`. The attention mask marks valid tokens and is used both as a padding mask and to recover the last non-padding hidden state for prediction.

The model is implemented as a stack of Transformer encoder blocks equipped with a causal triangular mask, so that token representations depend only on the observed prefix despite using the encoder-layer primitive. The final hidden state at the last valid prefix position is passed through a linear output layer to obtain logits over the next-role vocabulary.

Training uses AdamW optimization, gradient clipping with maximum norm 1.0, shuffled mini-batches of size 256, and a fixed random seed of 42. The script allows up to 200 training epochs and selects the best checkpoint using early stopping on validation Recall@10 computed on the trigram-subset, with patience 8 and minimum improvement threshold 10^{-4}. The training, validation, and test partitions are all constructed at the application level.

The implementation also evaluates two edge sets for next-step prediction: *all edges*, which begin from the first prediction after `[BOS]`, and the *trigram-subset*, which includes only transitions with at least two preceding real roles in the observed sequence. The latter is used for checkpoint selection and for comparisons intended to align with higher-order context baselines.

The final checkpoint used in the main experiments corresponds to context length 16, learning rate 3×10^{-5}, dropout 0.3, weight decay 0.1, batch size 256, and validation ratio 0.2.

C. Additional Evaluation Details

We also evaluated a 4-gram baseline as a diagnostic of whether increasing Markov order improves atypical-transition ranking under the same fixed negative-sampling protocol. The 4-gram model did not outperform the trigram baseline (AUROC $= 0.752$, AP $= 0.309$), consistent with increased sparsity at higher orders.

For clarity, the atypical-transition results reported in the study are based on a fixed sampled discrimination setting rather than a fully natural anomaly benchmark. Accordingly, the reported AUROC, AP, and precision–recall values should be interpreted as measuring relative ranking quality under this controlled protocol.

D. Additional Low-Granularity Results for $K = 10$ and $K = 15$

To assess whether the downstream granularity sweep should extend below $K = 20$, we additionally evaluated $K = 10$ and $K = 15$. Table XII reports the corresponding next-step prediction results. These smaller values yield higher raw Recall@k, but correspond to substantially coarser role vocabularies, as reflected by their much larger median cluster sizes in Table I. For these low-granularity Transformer runs, checkpoint selection used validation Recall@5 rather than Recall@10, since Recall@10 becomes trivial at $K = 10$.

E. Multi-seed Transformer Results

Table XIII reports the seed-specific Transformer results underlying the summary in Table IV. These runs use the same $K = 40$ setting, data split, and model recipe as the main experiment, differing only in random seed. The low variation across seeds supports the stability of the reported Transformer gains.

F. Sensitivity to the Number of Sampled Negatives

We evaluated Transformer-based atypical-transition detection under four negative-sampling settings, $N_{\text{neg}} \in \{5, 10, 20, 50\}$. As shown in Table XIV, AUROC remains nearly constant across all settings (0.8317–0.8328), indicating stable relative ranking quality. In contrast, Average Precision decreases from 0.5626 at $N_{\text{neg}} = 5$ to 0.1654 at $N_{\text{neg}} = 50$, and recall at precision ≥ 0.8 decreases from 0.1720 to 0.0012. This behavior is expected because increasing N_{neg} makes the sampled evaluation more imbalanced and yields increasingly conservative high-precision thresholds. Table XIV additionally reports the selected decision threshold and the achieved precision for each setting.

TABLE XI. TOP-PERFORMING CONFIGURATIONS FROM TRANSFORMER SWEEP FOR NEXT-STEP PREDICTION AT $K = 40$

ctx	lr	dropout	val ratio	Best val. score
16	3×10^{-5}	0.3	0.2	**0.7187**
16	3×10^{-5}	0.3	0.1	0.7179
16	3×10^{-5}	0.2	0.2	0.7159
16	3×10^{-4}	0.3	0.2	0.7157
16	3×10^{-5}	0.1	0.2	0.7146
8	3×10^{-5}	0.3	0.2	0.7144
16	10^{-4}	0.3	0.2	0.7144
32	3×10^{-5}	0.3	0.2	0.7141

Top-performing configurations from the 120-run Transformer sweep for next-step prediction at $K = 40$ under the cross-application protocol. All runs used label smoothing 0.0, 200 training epochs, and patience $= 8$. The first row is the checkpoint used in the main experiments. For brevity, only the strongest configurations are shown.

TABLE XII. LOW-GRANULARITY NEXT-STEP PREDICTION RESULTS FOR $K = 10$ AND $K = 15$

K	Model	R@1	R@3	R@5	R@10
10	Unigram	0.1935	0.4698	0.6788	1.0000
10	Bigram	0.2472	0.5455	0.7780	1.0000
10	Trigram	0.3747	0.6476	0.8299	1.0000
10	Transformer	**0.4022**	**0.6976**	**0.8650**	**1.0000**
15	Unigram	0.1237	0.3672	0.5451	0.8835
15	Bigram	0.1732	0.4283	0.6196	0.9189
15	Trigram	0.3207	0.5519	0.7125	0.9305
15	Transformer	**0.3516**	**0.6193**	**0.7745**	**0.9440**

Additional low-granularity next-step prediction results used to assess whether the downstream granularity sweep should extend below $K = 20$. As expected, smaller values yield higher raw Recall@k, but correspond to substantially coarser role vocabularies. For the Transformer runs at $K = 10$ and $K = 15$, checkpoint selection used validation Recall@5 rather than Recall@10, since Recall@10 becomes trivial at $K = 10$.

TABLE XIII. SEED-SPECIFIC TRANSFORMER NEXT-STEP PREDICTION RESULTS FOR $K = 40$

Seed	R@1	R@3	R@5	R@10	R@20
42	0.2598	0.4579	0.5644	0.7268	0.8952
43	0.2729	0.4741	0.5928	0.7514	0.9054
44	0.2686	0.4754	0.5880	0.7527	0.9089
Mean $\pm$ Std	0.2671 ± 0.0066	0.4691 ± 0.0097	0.5817 ± 0.0152	0.7436 ± 0.0146	0.9032 ± 0.0071

TABLE XIV. SENSITIVITY OF TRANSFORMER ATYPICAL-TRANSITION METRICS TO THE NUMBER OF SAMPLED NEGATIVES N_{neg} ($K = 40$)

N_{neg}	AUROC ↑	AP ↑	Recall@Precision ≥ 0.8 ↑	Threshold	Achieved Precision
5	0.8317	0.5626	0.1720	0.3053	0.8003
10	0.8323	0.4231	0.0568	0.5935	0.8000
20	0.8319	0.2957	0.0102	0.8060	0.8158
50	0.8328	0.1654	0.0012	0.8986	0.8750

G. Full-Vocabulary Re-Evaluation

The full-vocabulary result in Table XV shows that the sampled-negative protocol does not materially inflate AUROC, but it does make the anomaly task appear less severe in terms of Average Precision and high-precision recall. This supports the interpretation that sampled negatives are acceptable for comparing relative ranking quality across models, while still understating the difficulty of precision-constrained screening under exhaustive candidate evaluation.

H. Full Leave-One-Category-Out Breakdown

Table XVI reports the full per-category leave-one-category-out results for the Transformer-based model at $K = 40$. The breakdown shows substantial heterogeneity across categories. The strongest held-out categories by Transformer R@10 are *Education* (0.7666), *Weather* (0.7455), and *Beauty* (0.7452), whereas the weakest are *Sports* (0.5446) and *Food & Drink* (0.5843). This supports the interpretation that the macro-average reported in the main text reflects strong average transfer, but not uniform difficulty across all UI domains.

I. Qualitative Audit of Representative Screen Roles

To assess whether the learned role abstraction at $K = 40$ corresponds to semantically coherent UI states rather than arbitrary visual partitions, we qualitatively inspected representative screens from selected high-frequency clusters. For each cluster, screens were ranked by proximity to the cluster centroid in the fused embedding space, and the nearest examples were retained while applying simple diversity constraints to reduce near-duplicate screens from the same app or trace.

Fig. 7–10 show representative examples for 12 selected clusters. These examples are intended as qualitative support

TABLE XV. COMPARISON BETWEEN THE PRIMARY SAMPLED-NEGATIVE ANOMALY PROTOCOL AND A FULL-VOCABULARY RE-EVALUATION FOR THE TRANSFORMER AT $K = 40$. BOTH SETTINGS USE THE SAME 6,058 MATCHED TEST TRANSITIONS

Evaluation setting	AUROC ↑	AP ↑	Recall@Precision ≥ 0.8 ↑
Sampled negatives ($N_{\text{neg}} = 10$)	0.8323	0.4231	0.0568
Full vocabulary (39 negatives/context)	0.8320	0.1943	0.0028

TABLE XVI. FULL LEAVE-ONE-CATEGORY-OUT BREAKDOWN FOR THE TRANSFORMER AT $K = 40$. RESULTS ARE REPORTED PER HELD-OUT CATEGORY ON THE TRIGRAM-SUBSET

Category	R@1	R@3	R@5	R@10

Risk Assessment and Risk Management Challenges in Intelligent IoT-Based Smart City Infrastructures

Abdullah Alessa, Yaseen Alduwayl, M M Hafizur Rahman
Department of Computer Networks and Communications-College of Computer Sciences and Information Technology,
King Faisal University, Al-Ahsa, 31982, Saudi Arabia

***Abstract*—Smart Internet of Things (IoT) technologies, which include artificial intelligence (AI) are increasingly being implemented in the infrastructures of smart cities to enhance the efficiency, sustainability, and service delivery of cities. Nonetheless, with the implementation of such intelligent and interconnected systems, there are complex security, privacy, and safety risks that are not easily handled against conventional risk assessment and risk management methods. Current frameworks tend to be unresponsive and centralized whereas smart city infrastructures are dynamic, decentralized, and based on autonomous decision-making elements. This incompatibility poses serious problems for the reliability and robustness of intelligent urban systems. The study contains a systematic literature review of the risk assessment and risk management issues in smart city infrastructure based on intelligent IoT. The review is based on security, privacy, safety, and risks of AI, such as adversarial machine learning, data poisoning, model drift, and failures of autonomous systems. To enhance the level of methodological transparency, the review lists the databases searched, search words, screening process, inclusion, and exclusion criteria, and the resulting list of studies selected. The comparison of the key risk assessment methods, such as the standard-based, qualitative, probabilistic, and AI-based approaches, has been made, and their advantages and weaknesses in the smart city context have been identified. The results indicate that existing frameworks are still in fragments and not always able to deal with the joint effect of the heterogeneity of IoT, AI-based decisions, cyber-physical interdependence, scalability, and governance. The study, based on this summary, offers a more defined taxonomy of risk factors and research directions towards adaptive, AI-conscious and operationally feasible risk management in smart cities.**

Keywords*—*Artificial intelligence; cybersecurity; Internet of Things; risk assessment; risk management; smart cities

IoT	Internet of Things
AI	Artificial Intelligence

I. INTRODUCTION

The concept of smart cities has become one of the key trends in the current urban development with the fast growth of digital technologies and the necessity to provide efficient, sustainable, and human-centered services. The fundamental aspect of smart city projects is to implement Intelligent Internet of Things (IoT) infrastructures wherein interrelated sensors, actuators, edge devices, and communication networks with artificial intelligence (AI) approaches are used to assist automated monitoring, automated decision-making, and automated control in the urban domain. The systems have become common in transportation management, intelligent energy grids, healthcare services, environmental monitoring, security services, and protection of critical infrastructure [1], [2].

The smart city systems based on intelligent IoT are highly distributed data-driven and adaptive ecosystems compared to traditional urban infrastructures. They keep gathering real-time data using heterogeneous sources and use machine learning and optimization algorithms to facilitate autonomous or semi-autonomous behavior. Although this intelligence has greatly contributed to better operational efficiency and quality of services, there are also complex security, safety, and privacy risks that are totally different to those that exist when the information system is normal [3]. Consequently, this has made proper risk assessment and risk management, an important issue towards long-term reliability and trustworthiness of smart city infrastructures.

A. Background and Motivation

Smart cities are driven by issues that are not limited to the world but are global in nature, including urbanization, population explosion, scarcity of resources, global warming, and the desire to have resilient cities in terms of population services. The amount of governments and municipalities depending on the technologies of IoT and AI to streamline urban processes, cut expenses, and enhance living standards is rising [4], [5]. As an illustrative case, smart traffic management devices dynamically change traffic lights to ease the traffic jams, smart grids regulate energy supply and demand in real-time, and smart surveillance systems assist emergency workers and curb crime with AI-assistance [6], [7], [8].

Nevertheless, the very features that render smart IoT systems appealing also contribute substantially to the scale of the attack on the urban infrastructures. The smart city environments comprise thousands or even millions of heterogeneous devices, with most possessing limited computational power and limited security features. They use wireless and public networks to communicate with each other, and usually, they use cloud and edge computing platforms to process and store data [1], [2]. Such high levels of connectivity and heterogeneity expose people to the risks of cyber threats, including unauthorized access, data breaches, denial-of-service attacks, and system manipulation.

Moreover, AI implementation brings a different category of risks which are not limited to conventional cybersecurity issues. Adversarial attack, data poisoning, model inversion and

concept drift can adversely affect the performance of machine learning models and lead to wrong decisions [9], [10]. Such failures in a smart city setting can cause digital, but also corporeal, damage, in the form of traffic accidents, power outages, incidents involving the safety of the population, and getting crucial services out of order [9], [10].

Conventional risk management models, like the NIST Risk Management Framework or ISO/IEC 27005, were initially intended to be used with fairly stable centralized information systems [11], [12]. These frameworks frequently face difficulties in managing the dynamic, autonomous and decentralized characteristics of intelligent infrastructures based on the IoT. This discrepancy inspires the necessity of a holistic and updated knowledge of the methods of risk assessment and management in the particular context of smart cities.

B. Intelligent IoT-Based Smart City Infrastructures

The concept of intelligent IoT-driven smart city infrastructures may be understood as the macro-scale level of cyber-physical infrastructures based on integrating IoT technologies with AI-powered analytics and decision-making processes. Fig. 1 shows the common notion that these infrastructures are usually comprised of four major layers, namely, the sensing layer, the communication layer, the data processing layer and the application layer [7], [6].

The sensing layer contains physical devices like sensors, actuators, cameras, and an embedded system that is scattered across the city to gather information about traffic flow, air quality, energy consumption, weather conditions and human activities. The communication layer provides the transmission of data based on heterogeneous networking technologies, 5G, LPWAN, Wi-Fi, and wired networks. The data processing layer is based on the edge computing, fog computing, and cloud computing to store and analyze the huge amount of real-time data. Lastly, the application layer provides smart services to city operators, policymakers and citizens via dashboards, automated control system, and decision support systems [1], [2].

The key difference between the intelligent IoT infrastructures and the previous smart systems lies in the wide application of AI methods, including machine learning, deep learning, reinforcement learning, and predictive analytics. The techniques can be used to allow the systems to learn using past and real-time data, adjust to environments undergoing change, and make autonomous decisions with a minimum amount of human involvement [7], [6]. Although such intelligence improves scalability and responsiveness, it also adds complexity to the systems and diminishes transparency, so it is more challenging to predict, measure, and control risks.

C. Problem Statement

Although the intelligent IoT technologies are widely implemented in the smart cities, the analytical interface between the conventional risk assessment methodology and the dynamic nature of AI-driven IoT infrastructures has a great gap. The current risk management techniques are somewhat inertial and theoretical, concentrating on the previously known threats, known vulnerabilities, and fairly fixed system parameters [3].

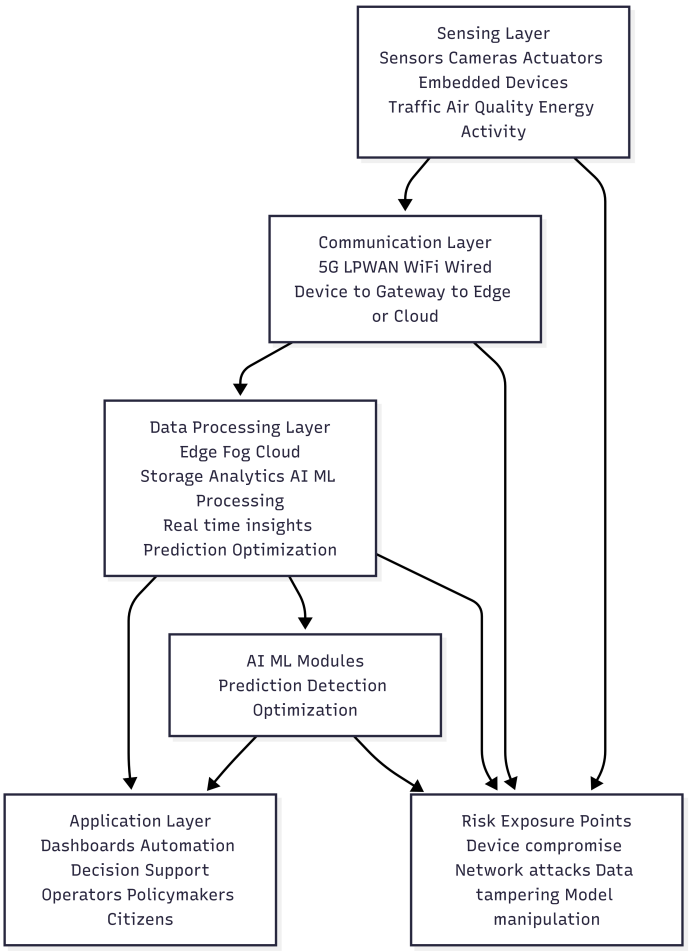

Fig. 1. Layered view of intelligent IoT-based smart city infrastructure, where AI/ML typically operates.

Conversely, smart city systems are also intelligent and they are constantly developing. They are decentralized, use autonomous decision-making algorithms, and are driven by real-time data streams and change of context. The novel and transforming risks brought about by these properties are not properly represented by the traditional models. Specifically, artificial intelligence features like machine learning algorithms present threat on adversarial manipulation, biased training, data poisoning, and unanticipated model behaviour, which may spread within interconnected urban services [9], [10]. As shown in Fig. 2, the reality of intelligent IoT smart city and the traditional risk assessment and management and the gap that addressed between them which reflect on real-world and cause impact to be cyber-physical.

In addition, intelligence IoT failures may have ripple effects on different areas of the city. A subdued traffic management system can affect emergency response, and a smart grid attack can affect the transportation system, healthcare network, and public safety networks all at the same time. This situation where a coherent and consistent knowledge of the way to evaluate and manage such interdependent risks does not exist is a grave threat to the secure and sustainable implementation of smart city infrastructures.

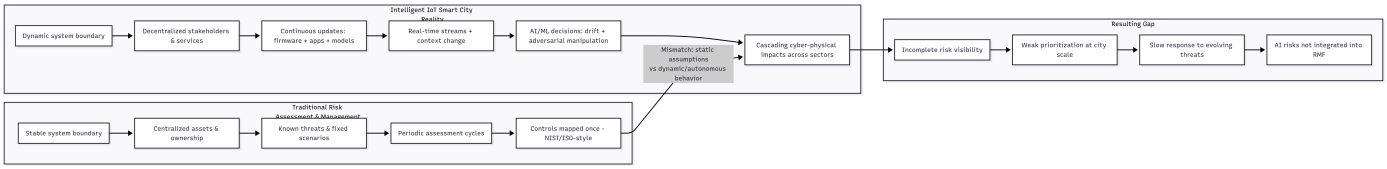

Fig. 2. Mismatch between traditional risk assessment assumptions and the dynamic nature of intelligent IoT-based smart city infrastructures.

D. Research Questions

This comprehensive and rigorous systematic study will address the following research questions to deal with the identified issues:

- RQ1: What are the major security risks and threats specific to the newer AI-based IoT infrastructure within the smart cities?
- RQ2: What are the current risk assessment methodologies and models and what are the technical and practical limitations of the models?
- RQ3: What are the particular difficulties in the process of risk management in real-time, autonomous, and decentralized urban networks?
- RQ4: What are the proposed strategies, frameworks or technologies to reduce intelligent risks in smart city settings?

These research questions will help to organize the study and conduct a full analysis of current methods, problems, and unresolved issues in the area.

E. Contributions of this Review

The review has four key contributions to the literature. First, it introduces a more precise taxonomy of risk factors that impact intelligent IoT-based intelligent city infrastructure, such as technical, AI-specific, cyber-physical, operational, and governance-related risks. Second, it gives a systematic comparison of the significant risk assessment and risk management methods that have been reported in the literature, with a focus on their applicability, strengths, and weaknesses in smart cities. Third, it pinpoints repeating research gaps, particularly in the area of adaptability, scalability, empirical validation, and addressing AI-related threats. Fourth, it outlines practical research opportunities to develop more resilient and context-based risk management approaches towards smart city systems.

F. Paper Organization

The rest of this study will be structured in the following way: Section II outlines the review methodology, which entails the review protocol, databases, search strings, inclusion and exclusion criteria, screening process, quality assessment and data extraction plan. Section III will provide a comparative discussion of the chosen works and summarize the key methodological trends and shortcomings in the literature. The key risk types, risk evaluation methods, risk management issues, and coping strategies are covered in Section IV in the context of intelligent IoT-based smart city infrastructures. Section V provides future research directions. The study ends with a conclusion in Section VI.

II. Review Methodology

The aim of this review was to help identify, analyze, and synthesize recent literature on risk assessment and risk management of intelligent IoT-based smart city infrastructures. The research approach was structured to enhance transparency and reproducibility by having a clear-cut review protocol, database selection plan, screening process, inclusion and exclusion criteria, quality evaluation plan, and thematic synthesis plan. Specifically, the review emphasized the studies that covered cybersecurity, privacy, safety, AI threats, and cyber-physical dependencies of smart cities.

A. Review Protocol

A review protocol was defined before the literature search in order to maintain methodological consistency. The protocol outlined the objectives of the review, research questions, databases to be used, search terms, inclusion and exclusion criteria, screening steps, and quality assessment criteria. The review process was informed with the existing review reporting practices that included transparent reporting of study identification, screening, eligibility assessment and final inclusion. This was done to minimize selection bias and so as to allow a better understanding and reproducibility of the review. Fig. 3 presents the review pipeline used for search, screening, quality assessment, extraction, and synthesis.

B. Search Strategy and Databases

The literature search was done in the following academic databases: IEEE Xplore, Scopus, Web of Science, ScienceDirect, SpringerLink, MDPI, and the ACM Digital Library. The choice of these databases was based on their wide scope of peer-reviewed material on smart cities, IoT, artificial intelligence, cybersecurity and cyber-physical systems.

The search focused on studies published between 2020 and 2026. Only peer-reviewed journal articles and conference papers were considered. The search terms were grouped into four concept clusters: smart cities, IoT systems, artificial intelligence, and risk management. Representative keywords included “Smart City”, “Smart Cities”, “Internet of Things”, “IoT”, “Intelligent IoT”, “Artificial Intelligence”, “Machine Learning”, “Risk Assessment”, “Risk Analysis”, “Risk Management”, “Cybersecurity”, “Privacy”, and “Safety”.

Representative Boolean search strings included the following:

- (“Smart City” OR “Smart Cities”) AND (“Internet of Things” OR “IoT” OR “Intelligent IoT”) AND (“Risk Assessment” OR “Risk Analysis”)

- ("Smart City Infrastructure") AND ("Risk Management") AND ("Artificial Intelligence" OR "Machine Learning")
- ("Smart City") AND ("Cybersecurity" OR "Privacy" OR "Safety") AND ("IoT")
- ("Intelligent IoT") AND ("Smart City") AND ("AI") AND ("Risk Management")
- ("Cyber-Physical Systems") AND ("Smart City") AND ("Risk Assessment")

The search strings were adjusted slightly to match the syntax of each database. This strategy was intended to capture both conventional IoT security risks and emerging AI-specific risks in intelligent smart city environments.

C. Inclusion and Exclusion Criteria

In order to achieve relevance and consistency, strong inclusion and exclusion criteria were used in selecting the studies.

Inclusion criteria:

- Publications of less than five years (2020-2026).
- Conference papers or peer-reviewed journal articles.
- Studies on smart cities, intelligent IoTs, or urban cyber-physical infrastructures.
- Research that deals with risk assessment, risk management, security, privacy, or safety concerns.
- Articles written in English.

Exclusion criteria:

- Studies published before 2020.
- Articles not peer-reviewed or edited or tutorials and opinion papers.
- Research centered on conventional iot that does not feature intelligent/AI-related aspects.
- Articles that are not connected with the context of urban or smart city.
- Redundant papers in databases.

The criteria were established to make sure that the studies that were selected were recent, relevant and directly connected to smart city risk assessment and risk management using intelligent IoT.

D. Study Selection Procedure

The selection of studies was done in several steps. To begin with, all databases were accessed and their records were combined into one dataset and any duplicate records eliminated. Second, the titles and abstracts were filtered through inclusion and exclusion criteria. At this point, studies that were evidently not related to smart cities, intelligent IoT systems, or risk-related issues were filtered out. Third, the entire contents of the rest of the studies were evaluated in terms of topicality and methodological appropriateness. The final review set only used studies that had directly answered the research questions.

E. Search Results and Study Selection Summary

The selection of the study is as follows: In the selected databases, a total of 465 records were initially found. Upon exclusion of 105 duplicates, there were 360 studies left to screen in terms of title and abstract. At this phase, 300 records were eliminated due to the out of scope of the review or failed to meet the inclusion criteria. The rest of the 60 studies were evaluated on full-text. Following the full-text review, 17 articles were filtered out, with 9 being not related to IoT or smart cities, 6 articles lacked a pertinent risk evaluation or risk management lens, and 2 articles were either non-English or old. This led to 43 papers included in the final review (see Table I).

TABLE I. STUDY SELECTION SUMMARY

Records identified	465
Duplicate records removed	105
Records screened	360
Records excluded after title/abstract screening	300
Full-text studies assessed	60
Full-text studies excluded	15
Final studies included in the review	45

F. Quality Assessment of Selected Studies

A structured quality assessment checklist was used in order to assess the methodological quality of the chosen works. The checklist will be based on the existing frameworks of quality assessment of studies and will consist of items like:

- Transparency of research purposes.
- Suitability of methodology.
- Sufficiency of source of data and analysis.
- Applicability to smart city risk management based on intelligent IoT.
- Coherence of findings and conclusions.

All the studies were evaluated in relation to these criteria to make sure that high-quality and relevant research only entered the synthesis. Analyses of studies that had low methodological rigor or unknown contributions were not included in the further analysis.

G. Data Extraction and Synthesis

Relevant information in each of the selected studies was collected by use of a standardized data extraction form. Data taken out comprised the year of publication, the purpose of the research, the area of application, the risk assessment or risk management strategy, essential findings, the challenges identified, and the limitations.

Thematic analysis was a qualitative approach that was used to synthesize the extracted data. The studies were categorised according to the shared themes, including types of threats, risk factors, assessment models, management framework, and AI specific issues. This methodology allowed finding patterns, similarities, and gaps within the literature, which allowed conducting the comparative analysis of the research and discuss the future directions and trends of the studies in a structured way.

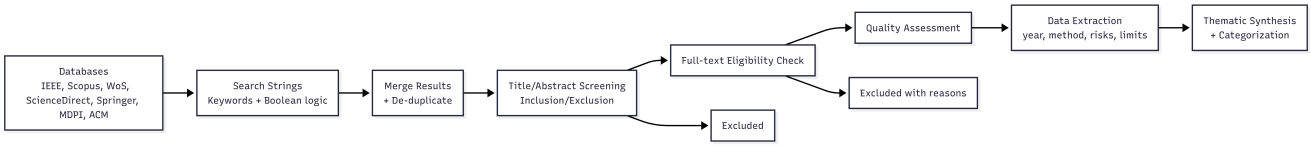

Fig. 3. Review pipeline used for search, screening, quality assessment, extraction, and synthesis.

III. Comparative Analysis of Related Work

This section presents a comparative analysis of the studies selected for the review. Its purpose is to synthesize the literature on risk assessment and risk management in intelligent IoT-based smart city infrastructures, identify common methodological patterns, and highlight unresolved issues.

A. Summary of Reviewed Studies: Objectives and Methods

The study shows that there is an increasing research interest in ensuring smart city infrastructures are secured by risk-sensitive design, as well as risk-sensitive implementation. The majority of the study seeks to determine security threats, to evaluate vulnerabilities, or to suggest frameworks to prevent risks in urban environments with the help of IoT enablers. Nevertheless, they have very different goals and methodology.

Much of the study is dedicated to IoT-based risk assessment, which highlights vulnerabilities at the device level, network security threats, and confidentiality threats to data in the context of smart city implementation [13], [1]. These works often apply conventional security analysis methods, including the threat modeling, attack surface analysis, and qualitative risk matrices, to the situation in urban IoT. Although they are useful in detecting known vulnerabilities, these methods are not always flexible to the dynamic behavior of the system.

The other body of research builds upon classical risk assessment techniques by adding context-sensitive or probabilistic methods, such as Bayesian networks, fuzzy logic, and multi-criteria decision analysis [14]. The purpose of these approaches is to better model uncertainty and interdependencies between smart city elements. Whereas these methods enhance the level of analysis, they are not usually applied at city-wide infrastructures, but applied individually to isolated subsystems, such as smart grids or intelligent transportation systems.

Recent studies are based on applying the methods of artificial intelligence and machine learning to risk assessment and management. These articles address the topic of anomaly detection, predictive risk modelling, and automated threat detection via data-driven methods [15]. Although the above ways demonstrate potential possibilities in managing large-scale and real-time-data, most of the research is still at the concept phase, with minimal implementation in real-world smart city settings.

B. Open Challenges and Research Gaps

A number of open issues and gaps in research can be identified regardless of the variety of approaches to the issue in the study. The first gap is the absence of single risk assessment frameworks that could be used to concurrently consider IoT, AI, and cyber-physical risks related to smart city infrastructures. Fig. 4 illustrate that most of the research is limited to IoT security or AI-based risks, without looking at the potential effect of the two on the interconnected urban systems [16].

The other major problem is that most of the risk assessment models are not dynamic. In traditional and semi-traditional techniques, architecture of the systems and possible attack scenarios are usually fixed and predetermined. Nevertheless, the intelligent smart city systems are constantly changing because of software updates, retraining models, mobility of device, and environmental variations. This time-varying behavior is not well represented in the study models [17], [18].

Scalability is also of great concern. Various suggested frameworks have been shown to be effective in small-scale case studies or simulations, but not in the computational and operational issues of city-wide implementation. The lack of longitudinal research also restricts the knowledge on the transformations of risks over time in smart city intelligent landscapes [1], [2].

C. Key Limitations in Current Research

The comparative analysis indicates several limitations that limit the applicability of the current research in practice. First, in most works, there is rather little attention to AI-specific threats. Although the vulnerabilities of IoT to device compromise and communication attacks are well known, the risks associated with adversarial machine learning, data poisoning, model drift, and biased decision-making are not only briefly mentioned [9], [10] but perhaps not mentioned at all.

Second, the lack of integration of physical safety effects is also a common weakness. Cyber-physical systems are smart city infrastructures, and cyber-attacks may have a direct impact on physical operations and human lives. Nevertheless, most risk assessment studies consider cyber risks individually without clearly modeling the physical or societal impact of such risk [3].

Third, most of the analyzed studies do not present standardized metrics and benchmarks of evaluation, which is why comparing outcomes of various methods can be challenging [19]. This drawback makes the process of selecting appropriate risk management tactics applied to the actual implementation of smart cities more difficult, as well as the formulation of best practices [3].

D. Comparative Analysis of Objectives, Problems, Methods, Findings, and Limitations

To support a structured comparison, the reviewed studies were analyzed across five dimensions: objective, methodology, results, key findings, and limitations [20], [21]. It is noted in

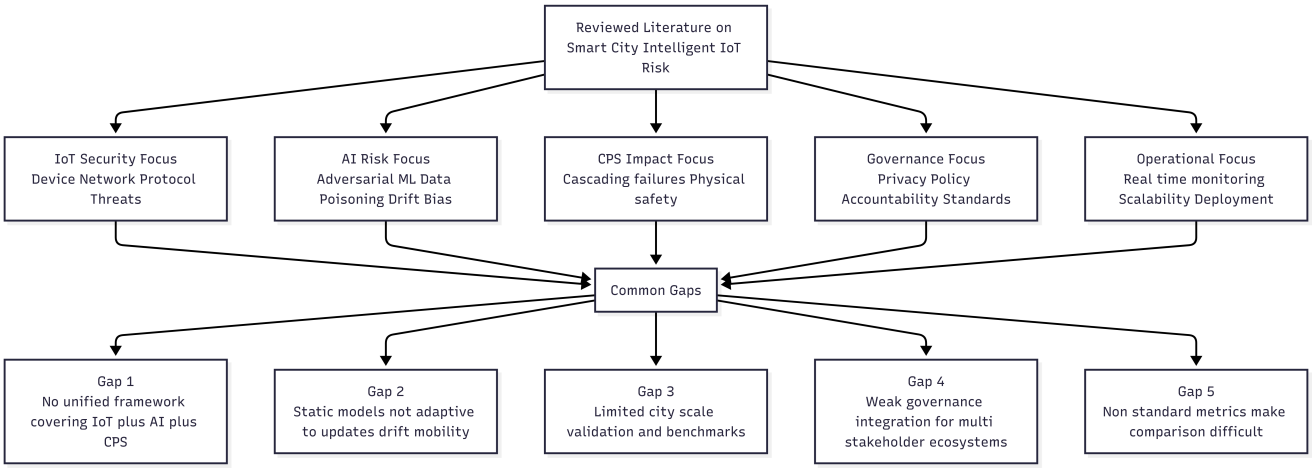

Fig. 4. High-level gap map summarizing limitations across IoT security, AI-specific risks, cyber–physical impacts, governance, and operational scalability in the study.

the analysis that even though the various studies have common objectives e.g. enhance security awareness or minimise the vulnerability of a system, the statement of the problem and the approach used to solve the problem vary significantly among the studies.

Other papers stress on preventive risk management, including secure system design and threat mitigation measures, and others reactive ones, including intrusion detection and incident response [3]. The results of the study tend to establish that intelligent IoT-based smart city systems are confronted with complex risks that cannot be counteracted with unilayer security systems.

E. Synthesized Analysis of Related Work on Risk Assessment and Management in Intelligent IoT-Based Smart Cities

The body of recent research on cybersecurity risk evaluation and management of smart city systems falls under several research strands, such as IoT security, cyber-physical systems (CPS), edge and fog computing, artificial intelligence (AI)-based defenses, governance frameworks, and standardization projects. Initial work on smart city security defines that the heterogeneity, scale and openness of urban IoT ecosystems intrinsically increase the attack surface relative to conventional enterprise systems. According to a foundation of research, smart cities combine sensing, communication, calculation, and control in multi-domain administration, and such risk spread and coordination of attacks are increasingly possible compared to single IoT implementation [22], [4], [23].

Quite a significant study is devoted to the identification of threats and taxonomies based on IoT. Various surveys and examination studies categorize threats to IoT, vulnerabilities, and attack vectors, pointing out vulnerabilities due to constrained devices, insecure communication protocols, weak identity management, and similar [6], [13], [17], [21]. These papers are useful background information but are mostly based on qualitative analysis and taxonomies. Although this sort of approach can be valuable in terms of being aware of a threat, this approach does not provide measurable risk scores regularly updated to support dynamic smart city environments. In addition, they usually consider AI as an external tool and not a part and parcel of the system that is under risk analysis.

The other important research stream deals with risk evaluation structures and methods of smart cities. A number of works can apply classical risk management rules to urban digital infrastructure and focus more on risk identification of assets, the possibility of the threat, and its consequences [24], [20]. Risk management processes and control baselines are further formalized by international standards and guidelines, such as ISO/IEC 27005 and NIST IoT cybersecurity series (NISTIR 8259, NIST SP 800-213, NIST SP 800-53) [12], [11], [1], [16]. Nevertheless, they are very technology-neutral and fixed, and do not provide much information on how risk management can be operationalized in smart city services that are highly adaptive and driven by AI or how to consider the changing threat conditions at a very high rate.

The cyber-physical aspect of smart city risk is considered in CPS-oriented study and demonstrates how cyber attacks propagate into physical disturbances of transport, energy, healthcare, and other, as well as public-safety systems [14], [25]. These publications highlight the harshness of cascading failures and interdependences between digital and physical layers. Nevertheless, the majority of CPS security research is theoretical or computer-based, not being empirically validated, real-time monitoring systems, and quantitative risk prioritization models that can be implemented by the operators of a city.

As edge and fog computing continues to spread, a number of studies explore the effect of decentralized architectures on the smart city threat environment. Mog and edge security surveys determine the new attack vectors of distributed control, data locality, and trust management [26], [27], [28]. Although these papers acknowledge the fact that risk differs at different architectural layers, they do not go further to offer the combined, city-wide risk assessment models that can be used to correlate edge-level events to system-wide impacts.

The use of AI and machine learning in security systems, in particular, intrusion detection and attack detection in IoT networks, is actively studied in recent studies [29], [9], [18]. These methods prove to be better in detecting and being more

flexible than rule-based systems. Nevertheless, they mainly assess performance based on detection-focused measures (i.e., accuracy or false-positive rates) and they do not tend to include adversarial robustness, model drift, or explainability in risk measurement. Introduced by AI as a challenge to the analysis in ENISA reports and threat analysis AI-centered, data poisoning, evasion attacks, and model manipulation have not been dealt with sufficiently in current smart city risk frameworks [7], [30], [10].

Digital twins have been suggested as the way to facilitate the simulation and anticipation of risks at a city scale and provide the opportunity to analyze failures and cyber events in a scenario [19], [8]. Although digital twins provide useful insights on the dynamic processes of complex cities, existing research points out a high level of computational overhead and lack of applicability in real-time. Besides, the majority of digital twins applications focus on operational optimization and do not include constant monitoring and control of cybersecurity risks.

It is also observed that governance, ethics, and sustainability issues are becoming more and more part of smart city cybersecurity. Ethical AI, responsible data use, and sustainable smart city development Studies investigate how technical security controls cannot be effective without open governance and accountability systems [31], [32], [33]. However, such works seldom frame ethical constraints into practice, quantifiable risk management procedures in line with operational cybersecurity interventions.

All in all, the evaluated study shows that there has been substantial development in the domain of threat identification, risk classification, and the suggestion of security systems to be implemented in the IoT systems of Smart Cities, yet, the vital gaps are observed. Current methods tend to be stagnant, inter-technologic, or limited in their coverage of detection performance. There are not many studies that offer combined, quantitative and constantly revised risk management approaches that directly consider AI-driven decision-making, cyber-physical dependencies, and real-time operational constraints. These constraints drive the necessity of a comprehensive risk evaluation and management strategy which is specific to intelligent IoT-based smart city infrastructures namely the ability to incorporate quantifiable risk indicators, AI-conscious threat management, and implementable mechanism to perform ongoing monitoring and mitigation across systems of city-scale systems.

Another study area focuses on security guidance documents, baseline requirements, and regulatory-oriented risk controls related to the implementation of IoT and smart cities. Etis and NIST IoT Core Baseline and other standards and profiles like ETSI EN 303 645 focus on minimum device and system-level capabilities, like secure boot, disclosure of vulnerability, and lifecycle management [34], [8], [35], [36]. Although these documents are necessary to set the basic security hygiene, they are mainly an outline of compliance-based controls as opposed to dynamic risk assessment processes. Consequently, they offer scanty support on the need to prioritize risks, adapt to new threat dynamics, or integrate AI-driven behaviour with current risk management procedures through intelligent smart city infrastructures.

Some works refer to blockchain based and distributed trust systems as a potential facilitator of secure and robust smart city systems. The presence of studies of blockchain integration with IoT and AI reports of enhanced data integrity, decentralization and trust management across heterogeneous stakeholders [37], [16]. Nevertheless, scalability constraints, latency overheads and energy costs that limit real time applicability at city scale are also observed in the surveyed works. Furthermore, blockchain-related solutions tend to center on ensuring the exchange of data as opposed to offering a full-fledged, end-to-end risk assessment platforms that quantify and control cyber and physical risks as well as AI-related risks.

The other new research area is the study of context aware and adaptive security systems of an IoT environment. Context-aware security models seek to adapt protection systems according to the environment, device status or usage patterns, which can enhance responsiveness in smart city contexts [15], [38]. Though they are promising, all these approaches usually run at the control or access management level and have no connection to the higher-level risk assessment processes. They, therefore, add to the local adaptation but fail to offer an uniform perspective of city-wide risk posture or long-term risk trends.

Smart city risk management is indirectly informed through research on resource management and optimization in fog environments and edge environments. Research on the allocation of resources associated with fog and on distributed computing architectures show the impact of workload distribution, latency constraints and resource contention on system performance and resilience [28], [27]. Nevertheless, security and risk considerations do not tend to be a priority or thought of as an assumed limitation; instead, they are often seen as secondary objectives. This lack of correspondence restricts the extrapolability of such works to smart city settings that are intelligent and have resource decisions that can directly affect exposure to cyber and cyber-physical threats.

Lastly, cross-cutting surveys of cyber risk and insurance-focused studies indicate that there is still a multitude of issues with data availability, risk measurement, and intersectoral comparability [3]. Such studies underscore the fact that absence of standardized and high-quality incident and loss data will retard empirical validation of risk models and diminish belief in quantitative risk assessment. It is made worse in smart city settings where a variety of stakeholders, proprietary systems and privacy restrictions further restrict information sharing. Consequently, there has been a high number of suggested smart city risk frameworks that are theoretically tested, but not operationally verified.

Overall, the study confirms that the smart city cybersecurity research is still disjointed on the technical, organizational, and regulatory levels. Although each of the strands is relevant and informative, with some providing background security measures and AI-enhanced detection, others offering governance and ethical aspects, the number of works that combine these viewpoints into a unified, implementable risk assessment and management framework are scarce. This fragmentation highlights the necessity to have an approach whereby AI-aware threat modeling, cyber-physical impact analysis, quantitative risk measures, and ongoing monitoring, are incorporated in

one, operational approach to intelligent IoT-based smart city infrastructures.

Table II shows that the reviewed studies fall into several broad categories: standards-based frameworks, qualitative surveys, probabilistic, CPS-oriented studies, AI-based detection models, adaptive security models, and governance-oriented studies. The analysis of this comparison reveals a definite trend. Standards-based frameworks offer powerful governance framework but are usually inflexible and not responsive to smart city conditions. Taxonomy-based and qualitative studies provide a wide visibility of threats, but seldom assist in dynamic prioritization. Probabilistic and AI-based methods enhance the depth of analysis, but most of them are akin to certain subsystems and are not operationally validated on a city scale. Ethics and governance research brings out issues of accountability and sustainability, yet seldom converts these issues into practicalized risk management processes. Altogether, the literature is still quite fragmented, and there is hardly any research that incorporates under one operational risk management framework the IoT, AI, cyber-physical, and governance dimensions.

IV. Discussion: Challenges and Techniques in Risk Assessment and Management

This section will be the synthesis of the major themes that were identified in the study and are organized in a way that facilitates direct answers to the research objectives and contributions of the current study. The discussion incorporates the technical, operational, and governance perspectives to assess the current state of risk management in smart city infrastructures based on intelligent Internet-of-Things (IoT) technologies.

A. Threat Landscape and Taxonomy of Intelligent Risk Factors

The environment of smart city IoT systems is highly heterogeneous and interconnected where risks come into being on various technical and organizational levels. It is possible to discuss the risk landscape presented in the reviewed literature as a five-layer taxonomy, provided by the study: device layer, network and communication layer, data processing and AI layer, application and service layer, and the governance and organizational layer.

The risks associated with device layers are insecure sensors, embedded devices, firmware vulnerabilities, weak authentication, physical tampering and device compromise. The lack of computational and security power of most IoT devices exacerbates these risks [39], [19].

Examples of network and communication-layer risks are spoofing, running insecure wireless protocols, denial of service, man-in-the-middle and interception of data across heterogeneous communication infrastructures (5G, LPWAN, Wi-Fi, edge-to-cloud).

In automated decision systems, the risks in data processing and AI-layer comprise adversarial machine learning, data poisoning, model inversion, concept drift, biased decision-making, and weak explainability [9], [10], [31].

Risks to application and service-layers involve disruption of smart transportation, energy, surveillance, emergency response and other public services. Due to interconnectedness of these services, the local failure can cause a chain effect on various functions in the city [23], [40].

Governance and organizational risks entail poor accountability, divided risk ownership, poor coordination among the stakeholders, use of nonstandardized metrics, regulatory risk, and inadequate integration of legal, ethical, and operational controls. This stratified taxonomy demonstrates that risk in intelligent smart city infrastructures cannot be confined to single, cybersecurity problems, but rather exists along technical, service, and governance planes (see Fig. 5).

B. Comparative Analysis of Risk Assessment Methodologies

The comparative analysis of the existing study shows a wide range of possible risk assessment models, as shown in Fig. 6, starting with classic qualitative matrices up to the sophisticated data-driven models. The traditional models of qualitative are commonly used due to their simplicity though do not involve the dynamic behavior of decentralized urban ecosystems [3].

More detailed models with the ability to deal with uncertainty and interdependence are available with quantitative and semi-quantitative techniques, including Bayesian networks and fuzzy logic [1], [2], [30]. Nonetheless, these approaches need quality data and in-depth domain expertise, which is often not accessible in advanced smart urban areas. Authors delve more recently into AI-powered anomaly detection and predictive modeling [9], [10]. Although such models hold potential in the real-time monitoring, they have major issues that include transparency, explainability, and susceptibility to adversarial manipulation.

Risk treatment procedures are provided in an organized manner through the use of standard frameworks, e.g. NIST RMF and ISO/IEC 27005 [11], [12]. However, this study finds a large discrepancy: such frameworks assume boundaries of systems and definite ownership of assets, which are not present in the context of decentralized and adaptive smart city conditions [3].

C. Challenges in Real-time, Autonomous, and Decentralized Management

This section summarizes major gaps and constraints that impair efficient risk management in smart city networks. One of the most critical gaps is the lack of a cohesive model that would mitigate the IoT security, AI-specific risks, and cyber-physical implications. Most existing models are not dynamic and do not consider the time varying behavior of the systems that are being continuously updated in software and retraining the models [3].

The two non-technical issues that are dominant are privacy and governance [38]. Smart cities gather sensitive behavioural information and therefore pose a major issue of balancing intelligent service delivery and privacy of data [3]. The absence of specific regulatory frameworks and multiple stakeholders, including the government, the private sector and citizens, also complicate governance because it becomes difficult to

TABLE II. SUMMARY AND COMPARISON OF RELATED WORKS ON RISK ASSESSMENT AND MANAGEMENT IN INTELLIGENT IOT-BASED SMART CITIES

Ref	Objective	Methodology	Results	Key Findings	Limitations
[22]	Analyze security challenges in smart cities	Conceptual analysis of IoT-based city services	Qualitative insights	Heterogeneity increases attack surface	No quantitative risk metrics; IoT-centric
[4]	Study threat modeling for smart cities	Examination study with Bayesian focus	Taxonomy of threat models	Highlights need for probabilistic modeling	No operational validation
[23]	Survey cybersecurity challenges in smart cities	Narrative study	Identified major attack vectors	Emphasizes multi-layer security	Lacks risk quantification
[6]	Study IoT cybersecurity risks	Examination study	Classified IoT risks	Shows fragmented risk handling	Static, non-adaptive
[13]	Taxonomize IoT security risks	Survey and taxonomy	Risk categories identified	Useful baseline taxonomy	No city-scale focus
[17]	Survey IoT cybersecurity techniques	Comprehensive survey	Broad coverage	Highlights attack diversity	No risk prioritization
[21]	Identify critical IoT security categories	Examination study	Security dimensions identified	Structured threat view	Lacks smart city context
[24]	Assess cyber risks in smart city infrastructure	Risk assessment framework	Conceptual risk model	Highlights infrastructure interdependencies	No real-time capability
[20]	Study smart city risk management	Examination study	Identified gaps	Confirms lack of quantitative methods	Study-only
[12]	Standardize information security risk management	Risk management standard	Prescriptive guidance	Widely applicable framework	Static, non-AI-aware
[11]	Define IoT cybersecurity activities	Guideline-based framework	Baseline controls	Strong governance focus	Not smart-city-specific
[1]	Secure IoT devices in government systems	Requirement-based guidance	Security baselines	Improves device hygiene	No risk scoring
[16]	Define security controls for systems	Control catalog	Comprehensive controls	Supports compliance	Heavyweight for real-time use
[14]	Study cyber–physical risks in smart cities	CPS security analysis	Identified cascading risks	Cyber impacts physical systems	Lacks empirical metrics
[25]	Analyze CPS threat landscape	ENISA threat analysis	Threat trends	Confirms CPS risk severity	No city-specific metrics
[26]	Survey edge-based IoT security	Architectural survey	Security design patterns	Edge reduces latency	Fragmented risk handling
[27]	Study edge/cloud IoT computing	Comparative survey	Architecture comparison	Highlights decentralization risks	No risk modeling
[28]	Study fog resource allocation	Examination mapping	Resource strategies	Resource constraints affect resilience	Security treated indirectly
[29]	Detect IoT attacks using ML	ML-based detection	Improved detection accuracy	ML effective for IoT attacks	Detection-only focus
[9]	Study AI-driven IoT security	AI-based threat analysis	Identified AI vulnerabilities	AI introduces new attack surfaces	No risk management integration
[18]	Map AI-based smart city security	Examination mapping study	Technique classification	AI widely used in defense	Ignores AI risk
[7]	Analyze cyber threat landscape	Threat intelligence report	Threat trends identified	Confirms evolving risks	Non-operational
[30]	Identify AI cybersecurity challenges	ENISA analytical report	Risk categories	Highlights adversarial ML	No mitigation framework
[10]	Identify emerging cyber threats	Conference threat analysis	Threat sources identified	AI threats increasing	High-level analysis
[19]	Study city digital twin potential	Examination study	Use cases identified	Supports risk simulation	High computational cost
[8]	Define digital twin requirements	Technical report	Deployment guidelines	Improves system understanding	Limited real-time feasibility
[37]	Study blockchain in IoT & AI	Survey	Security benefits identified	Improves trust & integrity	Scalability issues
[15]	Enable adaptive IoT security	Context-aware models	Improved local adaptation	Dynamic control	No global risk view
[3]	Study cyber risk data availability	Examination study	Data gaps identified	Quantification remains weak	Limits empirical validation
[33]	Link data-driven cities & sustainability	Evidence synthesis	Conceptual insights	Governance is critical	No security metrics
[31]	Explore ethical AI use	Ethical analysis	Normative guidance	Ethics essential for AI systems	Not operationalized
[32]	Study smart vs sustainable cities	Examination study	Sustainability gaps	Security tied to governance	No technical depth

establish risk ownership and accountability [3], [41]. The study concludes that lack of standardised metrics and benchmarks makes it a great challenge to compare the efficacy of various risk management strategies in different city-scale projects.

D. Proposed Strategies and Technologies for Risk Mitigation

In order to overcome the identified threats, the proposed study will use emerging technologies and suggest a pathway to adaptive and resilient infrastructures where Fig. 7 explain the steps of the strategies [1], [2]. Edge and fog computing is referred to as the main enablers in cutting the latency and the exposure of data since information is processed closer

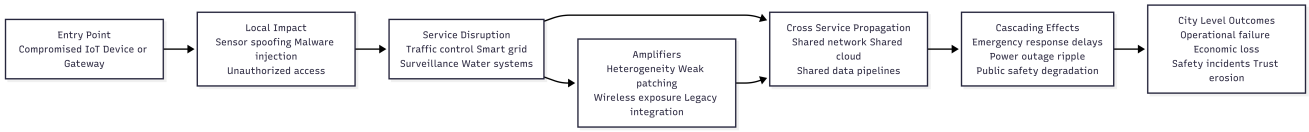

Fig. 5. Example of cascading threat propagation across interconnected smart city services, illustrating how local compromise can trigger city-wide impact.

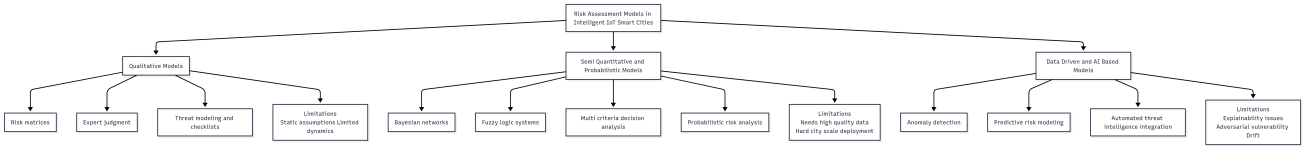

Fig. 6. Taxonomy of risk assessment models reported in the study for intelligent IoT-based smart city systems, including qualitative, probabilistic, and AI-driven approaches.

to the source. Blockchain technologies are suggested to also promote the integrity and auditability of data in distributed environments [1], [2].

The study is more and more in favor of the shift to AI-driven, self-healing security infrastructure that is able to detect anomalies automatically and reconfigure components on the fly [3]. Nevertheless, such solutions further complicate the situation and require stringent validation in order to prevent unexpected outcomes.

Last but not least, this study has added an abstract maturity map, which implies that smart city risk management needs to transform baseline, fixed controls into governance-adopted, AI-conscious, and self-corrective approaches. Risk management cannot be based on one technology, since it should combine technical controls with legal, ethical, and social factors [32].

E. Illustrative Real-World Incidents and Operational Implications

The recorded cases can be used to demonstrate that the risks listed in the literature are not merely theoretical. In the 2018 City of Atlanta ransomware attack, the fundamental operations of the city were disrupted as over a third of the city software applications were offline or partially disabled, including mission-critical services such as police and courts. In 2024, a cyberattack on Transport for London resulted in unauthorised access to a small amount of personal data of some customers, including contact details and potential bank-account information of some users. In 2025, St. Paul, Minnesota, was hit by a coordinated digital attack which the city responded to by shutting down information systems, leading to Wi-Fi disconnection in buildings, library services disrupted, and network resources suspended. Simultaneously, in 2024, U.S. federal government officials advised that disruptive attacks on water and wastewater systems were being conducted by foreign hackers, citing an example in Pennsylvania where a controller at a water facility was incapacitated. These instances demonstrate that the breakdown of digital municipal systems may lead to operational interruption, degradation of the public-services, exposure to privacy, and even safety implications among interconnected urban infrastructures.

V. Future Research Directions

The study also shows that the existing risk assessment and risk management methods are still inadequate to handle the complexity and dynamism of intelligent IoT-based smart city infrastructures. This section provides an overview of some of the most important future research directions that can be used to create more adaptive, resilient, and trustful systems of smart cities. Fig. 8 presents a staged maturity roadmap for evolving risk management in smart cities from baseline controls toward adaptive, AI-aware, and governance-aligned approaches.

A. Adaptive Risk Assessment Models

Creating adaptive risk assessment models that can address continuous modifications in smart city ecosystems is one of the research directions that are of the utmost importance. Future strategies are to be updated dynamically according to the real-time system conditions, environmental factors, and the changing threat intelligence, unlike traditional, inert systems [3].

Continuous monitoring mechanisms and exploiting the streaming data of the IoT devices, edge platforms, and operational logs should be incorporated as adaptive models. The machine learning methods can be used to perceive the new threats and update the risk estimations. Nonetheless, issues of data quality, model drift, and explainability needs to be considered in future studies as well since, in this way, adaptive assessments will be reliable and transparent [1], [2].

B. AI-Driven and Self-Healing Security Frameworks

Self-healing and AI-driven security systems are a good way of controlling risks in autonomous infrastructures of smart cities. These types of frameworks are designed to identify security events, identify root causes, and automatically implement mitigation measures with the least human intervention [3], [35].

Further studies are required in the future to combine AI-based risk management with the resilience principles of systems to allow smart infrastructures of a city to retain satisfactory levels of services even in case of attack or failure. This covers automated isolation of affected parts, dynamic rerouting of network routes, and smart recovery facilities. The

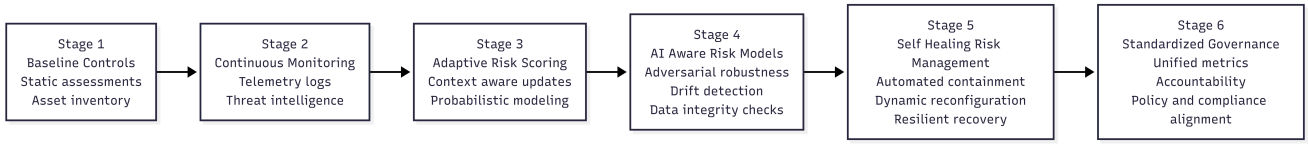

Fig. 8. Proposed maturity roadmap for evolving from baseline risk controls toward adaptive, AI-aware, self-healing, and governance-aligned risk management in smart cities.

research problem of ensuring the strength and safety of these self-healing mechanisms is still open to research [3], [8].

C. Standardization Needs for Smart Cities

Their interoperability and inability to achieve secure smart city deployments are largely due to the absence of standardized risk assessment and management practices. Future studies would help in the establishment of standards specific to domain that deal with the special features of smart IoT-based city infrastructures [3].

The standardization should encompass the technical, organizational, and governance domains, such as risk metrics, threat classification schemes, data governance models, and AI accountability needs. Finding alignment of smart city standards with the existing frameworks including NIST and ISO and extending them to cover AI-related and cyber-physical risks is also a major research priority [11], [12].

D. Practical Deployment Considerations

A gap exists between research and practical implementation to bring about risk management in smart cities. Most of the suggested frameworks and models can be tested by simulation only or through small-scale case studies which restricts their application in practice. The next generation of work would focus on big scale pilot applications and longitudinal designs which would evaluate risk changes over time [3], [42].

Also, the practical implementation should take resource availability, integration of the legacy system, regulatory requirements and coordination of stakeholders. System design should also consider the human factors with the trust of the operator in the risk management tools and the ease of use. These practical considerations will be important issues to address in order to realise the successful implementation of advanced risk management solutions in actual smart city settings [3], [43].

VI. Conclusion

Smart city IoT infrastructures can be extremely effective and efficient, highly automated, and of excellent quality of services, yet they also create complex and changing risks that do not fit the well-established methods of risk evaluation and risk management. This review has explored the recent literature that has been at the crossroads of IoT, artificial intelligence, cybersecurity, and smart city systems. The analysis revealed that current methods are still disjointed. A large amount of research is dedicated to single technical challenges, whereas less is devoted to the interaction of AI-based decision-making, cyber-physical interdependence, complexity of governance, and limitations of operations at the scale of cities.

The review also revealed that the existing frameworks tend to be lacking in flexibility, empirical testing, and standard measures to be used in actual smart city settings. Despite the fact that standards-based models offer a helpful governance framework, and AI-based methodologies enhance detection capabilities, the literature does not report common and operationally feasible frameworks that combine technical, organizational and societal aspects of risk.

The study builds on these results and proposes that future research ought to be directed at adaptive and situation-aware risk assessment model, enhanced treatment of AI-specific threats, enhanced analysis of cyber-physical impact, and more realistic validation in deployed smart city environments. A better taxonomy of risk factors and a more systematic comparison of the current strategies can help build a more robust and reliable smart city infrastructure.

A Cryptographic Framework Using AES-ECC with Threshold Key Management for Cloud Storage Systems

Abdulsalam Ibrahim Almirdasi, Mohamed Tahar Ben Othman
Department of Computer Science-College of Computer, Qassim University, Saudi Arabia

***Abstract*—Cloud storage systems have become an essential platform for storing and managing large volumes of data, but their security depends not only on confidentiality but also on integrity, controlled key management, and resistance to active attacks. Many existing protection approaches emphasize encryption of data while giving less attention to context–aware verification and controlled object recovery in untrusted cloud settings. This study proposes a novel hybrid cryptographic model for cloud storage systems, Object-Centric Threshold–Sealed Encryption with Two Keys (OCTET). The model integrates AES chunk-based encryption to protect data confidentiality, ECC to secure key exchange, threshold–based secrets to reconstruct, HKDF–derived per chunk, and Merkle root to enforce a verification–before–decryption policy. The implementation of the proposed model is in an emulated cloud storage system and examined on a dataset of large objects, then compared against baseline schemes, including symmetric and hybrid encryption models, under the same experimental environment. The main outcome demonstrates that the proposed model achieves practical performance, minor overhead, and superior resistance to the attack models. In general, this study demonstrates that the proposed model offers trade–offs between security and efficiency and a robust integrity technique for large objects in cloud storage systems.**

***Keywords*—Cloud storage system; hybrid encryption; AES; ECC; Object-Centric; threshold key management; integrity verification; Merkle root verification**

I. Introduction

Cloud computing systems are essential for providing trustworthy computation and storage resources, allowing organizations to easily manage data without using local servers [1]. This way of data storage brings several challenges related to potential data access and misuse [2]. While cloud solutions can be attractive for their flexibility, cost savings, and easier management, they also come with certain drawbacks, such as challenges related to multi–tenancy and having less direct control over the underlying hardware [3].

In addition, complicated service–based agreements and an external attack surface adds more complicated security. Any cloud data protection plan must, therefore, carefully balance these benefits against the risks involved. Although cloud–based systems provide advantages like flexibility, effectiveness, and enhanced control, these systems present challenges, such as multi–tenancy issues and limited hardware control [3]. Furthermore, complex agreements of service and a broad attack surface complicate security [2]. Any plan of data protection in cloud must balance these advantages and challenges.

Cryptographic schemes serve as a vital defense technique to secure data on the cloud and they use three different methods to provide security, which are symmetric, asymmetric, and hybrid key encryption. Symmetric methods utilize one key to encrypt/decrypt data, applying different schemes such as AES, Blowfish, and 3DES [1]. They are considered a viable option for handling large data because of their efficiency in rapid encryption. In the other hand, asymmetric encryption uses two different keys, where the public secret encrypts data and the private secret decrypts data, such as RSA and ECC, making it a proper option for key exchange due to their security robustness [4]. The hybrid models combine both methods, with a symmetric part for encrypting the large data and an asymmetric part to secure key exchange [5]. In the context of data encryption algorithms for cloud storage systems, it a viable choice to select hybrid encryption methods to provide the framework with fast data encryption by using a symmetric technique and secure key exchange between channels by using an asymmetric technique.

Furthermore, key management is an important concept in cryptography. If the keys are not effectively exchanged, stored, or generated, it means that the implementation of the cryptographic scheme is ineffective and cannot function successfully [1]. In cloud storage systems, keys should be generated with efficient randomness, linked with certain characteristics, and tracked via whole lifecycle. However, threshold–or distributed–based environments, key servers, and hardware security modules (HSM) each has distinguish advantages and disadvantages in terms of security, complexity, and availability [4]. As a growing number of organizations adopt cloud–based services, they need to carefully assess both their advantages and disadvantages to ensure that strong security measures are established. Understanding the main concepts and ideas of each strategy may significantly impact how efficient data security is.

For protecting cloud storage, there are some security concepts, which are confidentiality, integrity, and availability (CIA). Confidentiality is basically when authorized clients are able to read and access the data in cloud storage [4]. Cloud systems use cryptographic techniques and keeps the keys from being released to ensure confidentiality. Integrity means that the cloud storage model checks that the data objects have not been changed or deleted while they are stored [6]. The cloud storage model does integrity verification. Users frequently apply techniques such as authenticated encryption, hashing, and Merkle tree commitments to achieve integrity. The availability mainly is when real clients can retrieve and recover their data, whether there is an incident or partial leak

[3].

The main problem of this study is that many modern security techniques emphasize confidentiality instead of focusing on integrity and contextual relevance. It is difficult to manage keys and efficiently store data in cloud storage systems, where attacks commonly occur against users. CSPs must protect sensitive data and maintain the users' accessibility.

The aim of this study is to propose a new hybrid encryption model for cloud storage systems, which is called Object–Centric Threshold–Sealed Encryption with Two Keys (OCTET). The model encrypts data using AES and secures key exchange using ECC to balance between efficiency and security. The framework also has security features like chunk authentication and a secret sharing threshold. This study presents an evaluation and comparison of proposed model against baseline schemes in the context of security and efficiency. The following objectives are defined to achieve the main goal of this study:

- Develop OCTET, a hybrid encryption model that combines AES and ECC to enhance security and integrity through an object–centered approach.
- Adopt advanced security measures, including authenticated chunking, HKDF key derivation, and threshold secret sharing, to safeguard confidentiality, uphold integrity, and regulate access at both object and chunk levels.
- Simulate a reproducible OCTET prototype for cloud storage to assess its resilience against tampering and context–binding attacks, while comparing its efficiency and security with baseline schemes.

The main contribution of this study is to introduce OCTET, a cloud storage security framework that employs chunk encryption to maintain data integrity and user access control. By assigning specific secret keys to tenants and verifying data integrity before decrypting it, OCTET makes unauthorized access more complex. It combines several features, such as AES, ECC, and Shamir secret sharing, to properly manage systems with multiple users. Furthermore, it evaluates the efficiency and security trade–offs.

II. Literature Review

In this section, a review investigates the security of data in cloud computing systems, covering threats like violation of integrity and leakage of data. This review covers the symmetric and hybrid models, as well as the efficiency and security of these cryptographic models. Furthermore, it highlights existing frameworks and their limitations in the context of confidentiality, integrity, and key management flexibility.

A. Cloud Storage Security Challenges

Challenges of security in cloud computing arise due to the lack of control over infrastructure, applications, and data by users, which are handled by cloud service providers (CSP) via different locations. This way may cause some issues, such as loss of data, access for unauthorized users, delays, corruption, and potential risks for sensitive data. In [7], a review addresses the challenge of data leakage, which occurs due to vulnerabilities like cross attacks and admins that maliciously threaten confidentiality and integrity, highlighting the need for security in monitoring reliable computing and teamwork, while also investigating the dependence on new threats and untrusted systems. Also, in [8], another review highlights the significance of CIA as risks arise with Internet of Things (IoT) and cloud use, emphasizing techniques including access control and encryption. Furthermore, in [9], a comprehensive review shows that clients are losing direct control in cloud data centers, which leads to vulnerabilities, such as theft of data and disconnections of service. This demonstrates that more verifiable methods are needed to improve security robustness and efficient data protection.

These studies highlight persistent security issues in cloud storage, including data leaks, insider threats, or tenant attacks that influence CIA. Security measures such as encryption, access control, DLP, blockchain, and redundancy complicate business operations and increase costs. There is no single solution ensuring complete safety, and the proposed models reveal a research gap for integrated cloud–based security models that effectively combine strong encryption, key management, verifiable integrity, and performance efficiency.

These studies mainly define the landscape of threat at an overall level, like access authorization, data leakage, and control loss without providing cryptography designs that combine integrity and confidentiality with controlled recovery for stored data. Therefore, the proposed model (OCTET) is designed to cover these challenges via context-aware verification, threshold key management, and protection of objects without dealing with these security demands separately.

B. Existing Encryption Models for Cloud Storage

Recent trends in improving the security of cloud storage have resulted in different encryption schemes to preserve privacy while enabling search, access control, and other performance improvements. Several studies in the area of encryption models have significantly improved the security and accessibility of cloud data. In [10], SES–CSE enhances data confidentiality and availability by enabling efficient keyword searches in large encrypted cloud datasets while protecting plaintext information and demonstrating resilience against ciphertext and chosen–keyword attacks. Additionally, in [11], ECSES and ECRM make data more secure and available in cloud systems by using strong symmetric encryption and backup methods to lower the chances of problems from node failures or security breaches. Furthermore, in [12], an improved CP–ABE model makes it easier to control who can access encrypted cloud data in IoT environments, ensuring that only authorized users can get to the data and reducing security risks related to hashing functions and signature checks.

In summary, the studies demonstrate that encryption algorithms have been improved over time under cloud storage systems. Currently, encryption frameworks started using extra complicated tools such as searchable methods, redundancy–based check techniques, and attribute–based access control. So, the studies indicated the significance of cryptographic frameworks in terms of security of systems, protection of data, and access control policies.

Significant functions like confidentiality, backup support, searchable techniques, and access control are addressed as improved methods for cryptographic models. However, these functions are discussed as separate solutions without integrating chunking authentication with context-binding and data integrity. Furthermore, the proposed model (OCTET) is built to cover these limitations by using techniques such as AES for chunking and HKDF-derived keys with verification by Merkle root.

C. Hybrid Models and Key Management Mechanism

When combined with key management operations, hybrid encryption algorithms can efficiently alleviate the shortcomings of single cryptographic schemes in cloud computing. Such techniques generally utilize symmetric encryption to protect data while using asymmetric or distributed approaches for key management. Hybrid and key encryption models play a crucial role in enhancing data security in cloud environments. In [13], a blockchain–based key security management framework is proposed that utilizes an oblivious pseudo–random function to safeguard encryption keys in cloud storage, enhancing recovery from failures and ensuring immutable transaction records while demonstrating resilience against brute–force and collusion attacks with low computational costs for key generation. Furthermore, in [14], a hybrid model enhances cloud data protection by combining symmetric and asymmetric encryption algorithms with a private blockchain, utilizing AES for large files and RSA for securing the AES key, thereby improving key exchange and access monitoring. Finally, in [15], the SymECCipher framework combines ECC with AES to efficiently secure healthcare data in the cloud, enhancing key management and throughput protection tailored to the specific needs of cloud healthcare applications.

Finally, these investigations demonstrate the principles of how the proposed model functions. The main focus is that it is essential to supplement fast symmetric with asymmetric or decentralized key management. They also emphasize the advantages of threshold and secret–sharing schemes for secure key backup. The studies also show how blockchain technology or other equivalent techniques can be used to create a decentralized and tamper–proof way to monitor key management and access events in cloud storage systems.

These studies ensure the significance of integrating symmetric and asymmetric methods but still concern secure key exchange, key monitoring, and recovery instead of the combination of protection of chunks, key release, and verification-before-decryption policy. Therefore, key management techniques are improved, while data integrity and recovery control are not imposed simultaneously. On the other hand, the proposed model (OCTET) addresses this issue by using both AES and ECC with chunk-based derivation and threshold methods.

D. Integrity Mechanisms in Cloud Storage

Cloud storage involves transferring data from local devices to third–party servers, necessitating user trust in these providers to maintain data safety and accessibility. Concerns about data manipulation and loss are addressed through cryptographic integrity checks. Recent studies have explored innovative integrity mechanisms designed to bolster data verification and security across various domains. In [16], a study introduces a hierarchical Merkle hash tree for integrity auditing that improves data verification while reducing audit operations and expenses. Also, in [17], a model for checking the integrity of electronic health records (EHRs) in the cloud allows for fast checks without downloading all the data, using cryptographic tags to verify blocks and letting computations be done elsewhere to lessen the load on servers. Lastly, in [18], different storage–layer integrity techniques and the security problems they pose are grouped together, where the focus is on risks like insider threats and ways to improve efficiency.

Recent trends highlight a transition from basic checksum verifications to advanced cryptographic auditing methods that enhance efficiency and security. Hierarchical Merkle hash trees reduce audit costs and effectively detect tampering. Several studies establish methods that balance between vulnerabilities and costs of computations. In general, observations support cryptographic frameworks that provide greater security for large data stored on the cloud while maintaining performance.

These studies demonstrate that Merkle root and verification checks can detect tampered data and decrease the cost of verification. However, these techniques are mainly presented as mechanisms for checks and audits that come on the storage layer, where they are unable to show how integrity checks may be tied with the derivation of keys and control of decryption inside a cryptographic model. Therefore, the proposed model (OCTET) solves this gap by designing a step that ensures integrity before the decryption process using Merkle root verification and checking header authentication to prevent tampered data from the recovery process.

E. Limitations of Current Encryption Models

Although tools of cryptography in cloud environments are notably improved, they still lack solid approaches that encompass performance, supported cross–platform scalability in key management, and integrity assurance. Some of the difficulties addressed by security and encryption techniques are system robustness and user access control balance with performance. In [19], a blockchain-based model is proposed for data security in cloud environments using the combination of AES and RSA for encryption. The model is built using decentralized key management contracts and agreements to enhance confidentiality. Furthermore, in [20], the authors address security techniques using attribute–based cryptography, homomorphic encryption, and authentication of multi-factors. In addition, in [21], a hybrid cryptographic model is proposed using AES with OTP and RSA for cloud computing systems, which establishes dynamic key management with strict access control.

Overall, with the advancement of cryptographic models using blockchain methods, there are still challenges like processing delays and compatibility issues. Also, multi–layer cryptography systems faces challenges such as the increment of costs and complexity in key management. For hybrid models, they improve access control, yet their encryption process caused overhead data, which influenced the system performance.

Generally, these studies show that cloud encryption frameworks improve several aspects like access control, key manage-

ment, and confidentiality, while still lacking a balance between overhead, compatibility, integrated integrity verification, and scalability. Many encryption algorithms are strong in function isolation but still offer limited support for trade-offs in efficiency and security. On the other hand, the proposed model (OCTET) brings a mixture of techniques and behaviors as one cryptographic hybrid model for cloud storage systems.

III. Methodology

To propose a novel cryptographic model, OCTET, for cloud storage systems, the methodology of this research is a mixed–method approach. Qualitative method reviews current studies in cloud security and data encryption schemes to find out design demands. Quantitative method conducts the development and evaluation of OCTET, as well as the experiment setup with a real–world dataset. In terms of efficiency and security, a comparative analysis is also presented to compare the proposed model against baseline schemes.

A. Design of the Proposed Model

The Object–Centric Threshold–Sealed Encryption with Two Secrets (OCTET) model is a hybrid cryptographic framework designed to secure large data in cloud environments. It achieves its goal by binding data to its specific cloud location while employing dual secrets, threshold key release, and verifiable integrity. Firstly, OCTET splits data objects into several chunks of fixed size, then labels each chunk to be identified easily, which makes these labels linked to their corresponding encrypted chunks and linked to valid cloud identities, thus maintaining data security and integrity at its specific location.

OCTET generates two independent secret keys: the root object secret (ROS) and a second secret known as "Delta" (δ), which is deterministically derived from a key management system (KMS). ROS is stored using Shamir–style threshold sharing, allowing it to be reset through elliptic curve cryptography (ECC) after receiving a predetermined number of approvals (k–of–n). Both ROS and δ are processed through a hash–based message authentication key derivation function (HKDF) to produce advanced encryption standard (AES) parameters for each data chunk, preventing key reuse. AES encrypts per–chunk, resulting in ciphertext and a tag. The proposed model builds a Merkle tree from chunks of ciphertext hashes, creating one MerkleRoot that ensures the overall integrity of the object. When clients retrieve encrypted data (ciphertext), the framework reconstructs ROS and calculates δ, validating the Merkle root and header message authentication code (MAC) before it performs decryption, where the header is created containing Merkle root and other parameters, as well as deriving the two secret keys (ROS and δ) by MAC. Upon successful verification, keys of decryption are generated via HKDF, then chunks are decrypted, and objects are recovered into original plaintext. Fig. 1 illustrates the whole structure of proposed model (OCTET), showing the encryption and decryption workflows organized around chunking, key security, and integrity check, which clearly defines that the model is not retrieving the data, while it initially reconstructs the needed key material and verifies the integrity information.

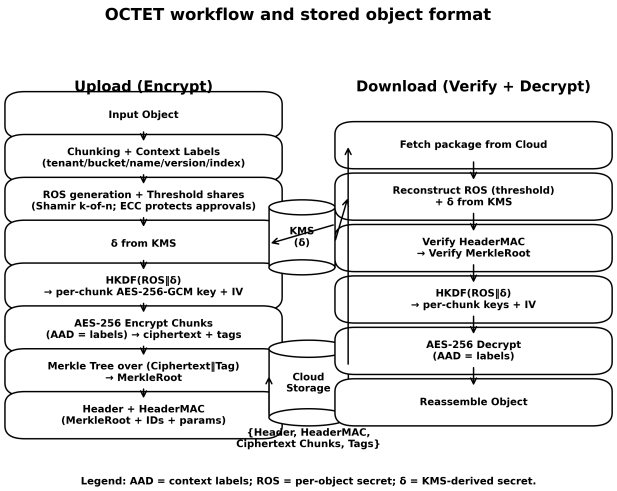

Fig. 1. Encryption and decryption in proposed model (OCTET).

B. Selected Encryption Algorithms

This study presents a comparative analysis of algorithms to assess OCTET for cloud data storage, focusing on key requirements such as data privacy, integrity verification, and key management. The study involves tested algorithms, including hybrid models that offer AEAD and symmetric schemes that utilize an encrypt–then–MAC scheme with HMAC–SHA256 for integrity verification. Under controlled scenarios, the evaluation is presented with consistency using the same settings and workloads for all the selected encryption algorithms to ensure fairness. The algorithms' configurations are listed below to recognize the procedures and roles for the comparison:

1) Proposed Model (OCTET): It employs a 60 MB chunk size for data encryption, utilizing AES–256–GCM for encryption and ECC P–256 for key encryption, which is linked to the object's storage context. Implements a 2–of–3 threshold to reconstruct the ROS per object with the secondary secret key δ, derived during the decryption process.

2) Blowfish: It is configured with a key size of 256 bits and an initialization vector (IV) with a size of 64 bits per chunk, which ensures the consistency for the scenarios measuring the efficiency of the encryption/decryption process.

3) Triple DES (3DES): It applies 3DES–EDE procedures using a setup of two secrets, providing the mode of CBC with 112 bits and PKCS#7 with 8 bytes.

4) Hybrid AES-RSA (AES-RSA): It utilizes AES–256–GCM with a tag size of 128 bits for encrypting data, while RSA–2048 is used to secure the keys of AES with RSAES–OAEP and SHA–256 to encrypt keys.

5) Hybrid AES-ECC (AES-ECC): It also utilizes AES–256–GCM with a tag size of 128 bits for encrypting data, while ECC (P–256) in the secp254r1 curve is used to secure key exchange with ECDH mode integrated with HKDF–SHA256 to derive keys.

The selected schemes offer a standard measurement for evaluation purposes of the proposed model (OCTET). The symmetric algorithms, including Blowfish and 3DES, are used

to present traditional cryptography behavior. The asymmetric algorithms are also selected to present the cryptography behavior. AES–RSA is chosen as a standard hybrid metric that shows the common process, where AES is utilized for the encryption of large data and RSA–OAEP is utilized for key-wrapping security. Additionally, AES–ECC is selected as the nearest hybrid model to OCTET due to both models relying on AES and ECC, which makes it a basic representation for the proposed model. However, AES–ECC is unlike OCTET because of the additional techniques in OCTET, like context-binding, the verification-before-decryption policy, and the threshold method.

C. Data Collection

In this study, the dataset is used for evaluation of OCTET under scenarios for cloud storage of bulk data instead of presenting all heterogeneous workloads in the cloud. The dataset is a collection of video files that focused on large object sizes, ranging from 30 to 300 MB with an average size of 120 MB and a total size of approximately 1.2 GB. It contains different sizes of objects, which allows lightweight measures on small files and enables costs scalability for larger objects via chunking processing. Before the encryption process, all objects are set and read in byte format for authenticity and accuracy of analysis. The evaluation solely considers the performance of OCTET for large objects, where smaller objects remain a demand for a broader workload generalization.

D. Implementation and Experimental Setup

In this work, experiments are introduced under control settings to efficiently assess the cryptographic algorithms, using Python 3.12, including its cryptographic libraries. The cloud storage system is simulated with a local drive to store data, using AES–256 in AES–256–GCM (AEAD) mode and SHA256 for hashing. The setup of hardware is a PC device of Windows 11 Pro using an Intel CPU i5, RAM with a size of 16 GB, and a hard disk with a size of 1 TB. The envelope encryption method is used to secure stored files locally and decrypt them for retrieval.

E. Evaluation Metrics

This study utilizes various evaluation metrics to assess the security and efficiency of the proposed model within a cloud storage system. Furthermore, other evaluation metrics are utilized to compare the proposed model against the selected algorithms under a consistent and unified environment. Overall, the evaluation metrics demonstrate the real costs of processing, the impact on storage, and the robustness of the system in controlled tests. The evaluation metrics used in this study are set below for both the OCTET assessment alone and the comparative analysis against the other algorithms.

1) OCTET assessment:

a) Encryption time: It measures the time taken by OCTET to perform the encryption process for different objects, starting from the initiation of plaintext preparation to the resultant packages of ciphertext, which reflects how fast OCTET is to encrypt data.

b) Decryption time: It measures the time taken by OCTET to perform the decryption process for different objects, starting from ciphertext retrieval and authorization material to plaintext recovery, including the two key derivations, the verification-before-decryption method, and AES decryption, which reflects how fast OCTET is to decrypt data.

c) Comparison of data sizes (overhead): It compares the difference between the original and encrypted data sizes to measure the overhead produced by OCTET, evaluating how much an encryption scheme costs, which reflects the storage impact.

d) Attack detection rate under threat model simulation: It assess the proposed encryption model to ascertain its effectiveness in detecting and preventing detrimental data modifications across various attack scenarios. The main goal of this security testing is to test how well OCTET can detect and block unauthorized data by simulating attacks such as replay attacks and ciphertext tampering. This work illustrates the techniques used to verify data integrity, bind context, and authorize access while blocking attempts at decryption after detecting any modifications.

2) Assessment for comparative analysis:

a) Encryption and decryption throughput: It evaluates the speed of cryptographic schemes to compare which algorithm is faster by computing the data processed per time. Furthermore, throughput determines how well a cryptographic algorithm can handle bulk data. Mainly, the speed in OCTET compares to other selected encryption algorithms, focusing on efficiency.

b) Performance metrics: It examines the baseline schemes using security outcome classification, including accuracy, precision, recall, and F1–score. These metrics are computed using simulated attack models against each selected cryptographic method, evaluating how reliably and accurately an encryption algorithm detects tampered data, which reflects the reliability of the decisions made during the decryption process.

c) Error metrics: It examines the selected encryption algorithms using error metrics like mean absolute error (MAE) and mean squared error (MSE). These two metrics are computed under controlled environments, determining the deviation of decrypted output from predicted behavior among different tests, which reflects how much a cryptographic algorithm is able to correctly or incorrectly return bytes under untrusted scenarios.

IV. Results

This section presents the experimental results of the hybrid cryptographic model (OCTET), tested on simulated cloud storage systems with various file sizes. It includes evaluations of OCTET's efficiency and security through speed measurements and robustness tests. Additionally, OCTET is compared against other encryption algorithms within the same cloud simulation using the same dataset.

A. Evaluation of the Proposed Model

To assess the efficiency and security of OCTET, several assessments are performed to evaluate the proposed model.

TABLE I. ENCRYPTION OPERATION TIMING FOR OCTET

Encryption Operation of (OCTET)	Encryption Time (s)
ROS generation	0.000005
Shamir threshold sharing	0.000078
ECC share packaging	0.008818
HKDF–SHA256	0.000216
AES encryption total	0.061667
TOTAL encryption path time	0.070784

In terms of efficiency, time is measured for the encryption and decryption process, as well as the overhead generated for OCTET. In terms of security, context-binding and tamper resistance are examined against attack models with manipulation to define how OCTET can detect data that has been tampered with and modified.

1) Average encryption time: As shown in Table I, OCTET efficiently distributes computing costs across encryption tasks, with the AES algorithm significantly influencing total encryption time due to its processing of all file data. Operations related to key handling and authorization have minimal impact, while per–chunk keys generated with HKDF show negligible performance changes. Despite minor overhead from ECC share protection and Shamir 2–of–3 threshold sharing, the results highlight OCTET's focus on rapid symmetric encryption and minimal key management. Fig. 2 illustrates the average encryption time for OCTET's operations, where the main cost is caused by the AES encryption step due to the encryption process of the whole object, where the key management steps involve less time, which means it demonstrates that OCTET retains its main cost in the main data path instead of the additional security techniques.

2) Average decryption time: Table II shows that OCTET handles the decryption process, which balances the workloads of retrieval and verification, where the highest time taken to decrypt data is decryption of AES and verification of tag. The policy of verification–before–decryption is applied on each chunk to ensure data integrity, which causes delays. Recomputing Merkle root is a verification operation that ensures that chunks are valid. Extra time is added due to per–chunk key regeneration, overhead by ECC management shares, approvals, and reconstruction of ROS. In general, the cost of decryption is still moderate, while providing vital security techniques that improve the integrity of cloud–object. Fig. 3 illustrates the average decryption time for OCTET's operations, showing that the integrity process has the main role in the decryption process, where the model checks data

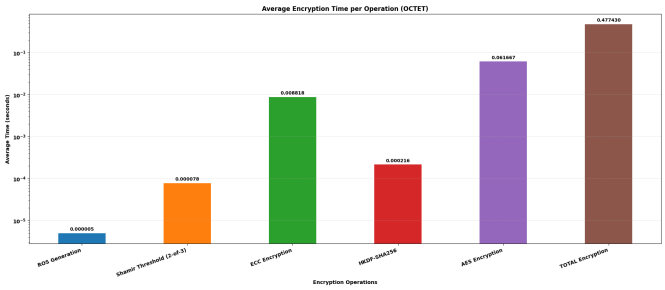

Fig. 2. Average encryption operations time.

TABLE II. DECRYPTION OPERATION TIMING FOR PROPOSED MODEL (OCTET)

Decryption Operation of (OCTET)	Decryption Time (s)
ECC approvals/shares handling	0.003104
ROS reconstruction	0.000030
Merkle verification	0.169917
HKDF–SHA256	0.000189
AES decryption + verification	0.073829
TOTAL decryption path time	0.247069

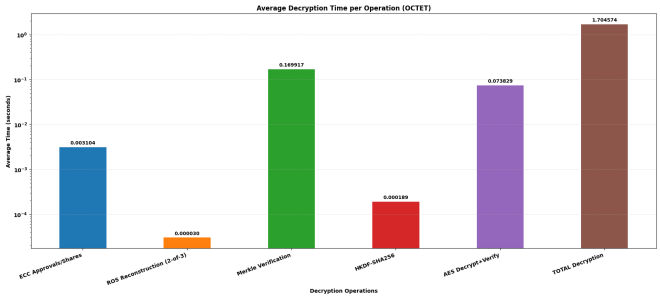

Fig. 3. Average decryption operations time.

TABLE III. COMPARISON OF DATA SIZES IN PROPOSED MODEL (OCTET)

Cryptographic Element	Size (Bytes)
Original Data	1,209,896,808
Encrypted Data	1,209,896,808
Authentication Tags	368
Header	4,378
Encrypted Key/ECC–Threshold	21,540
Total Overhead	26,286

correctness before release, which means that OCTET involves the verification-before-decryption policy.

3) Comparison of data sizes: Table III shows the data comparison sizes of OCTET, demonstrating that the storage efficiency maintains the size of encrypted data (ciphertext) same as original data (plaintext), which is essential for bulk data management in cloud environments. Authentication tags of AES showed the lowest overhead, where the headers of metadata and protected keys are still marginal comparing with the size of plaintext. Subsequently, OCTET obtained minor overhead and achieved data confidentiality, access control, and integrity, which indicates that the proposed model is a practical solution for cloud computing systems that handle large-scale data. Fig. 4 illustrates the comparison of the plaintext and ciphertext with the extra security methods involved in OCTET, showing that the size of the original and encrypted data is approximately similar, where the small storage increment occurred due to metadata, tags, and key material security, which mainly demonstrates that OCTET achieves minor overhead.

4) Attack detection rate under threat model: Table IV shows that OCTET achieved a high detection rate via several attack models, including tampering with ciphertext, integrity verification replay, and encryption authentication. It achieved a full rejection for the context–binding attack, demonstrating the strength of data–context labels. In contrast, the attack of mix–and–match faced difficulty in verification. Design of OCTET improves the security, where mix–and–match model tests the

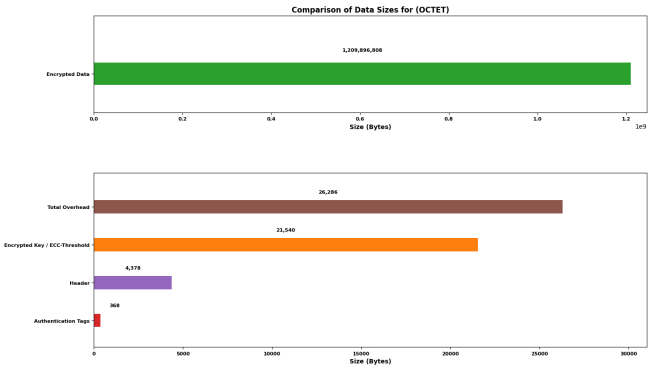

Fig. 4. Data sizes comparison and overhead of proposed model.

TABLE IV. ATTACK DETECTION RATE UNDER THREAT MODEL AGAINST PROPOSED MODEL (OCTET).

Attack Type	Detected Attacks	Detection Rate (%)
Ciphertext Tamper	98	98.00
Replay	99	99.00
Context Mismatch	100	100.00
Mix–and–Match	95	95.00

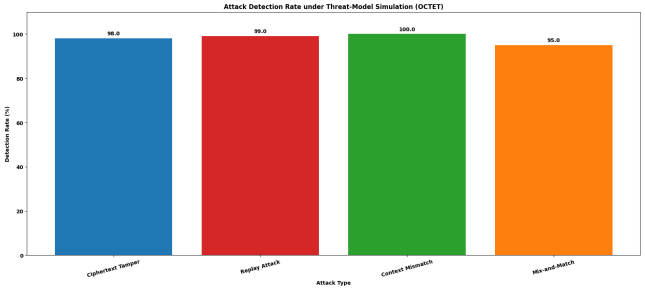

Fig. 5. Detection rate of proposed model (OCTET) against different attacks.

reliability and integrity of metadata. Fig. 5 illustrates how well OCTET stands against various attack models, showing that the model reliably achieves high rates for tampering threats and mismatches in context, which means that the robust integrity policy supports the security and performance enhancement of OCTET.

B. Comparative Analysis

The test compares OCTET against baseline schemes such as Blowfish, 3DES, hybrid AES–RSA, and hybrid AES–ECC. All of these were tested in the same way to find differences between the encryption schemes. The comparison uses metrics such as throughput to evaluate efficiency, while performance and error metrics test security.

1) Throughput of encryption and decryption: Throughput measures the speed of each selected algorithm to determine which algorithm is faster. As shown in Table V, the highest throughput is achieved by AES–ECC, while symmetric algorithms had the slowest throughput. On the other hand, OCTET achieved better throughput than symmetric schemes

TABLE V. AVERAGE ENCRYPTION AND DECRYPTION THROUGHPUT FOR DIFFERENT CRYPTOGRAPHIC ALGORITHMS.

Algorithm	Encryption Throughput	Decryption Throughput
OCTET	293.983	156.636
Blowfish	84.036	113.438
3DES	23.056	24.885
Hybrid AES–RSA	530.844	587.304
Hybrid AES–ECC	**549.668**	**555.848**

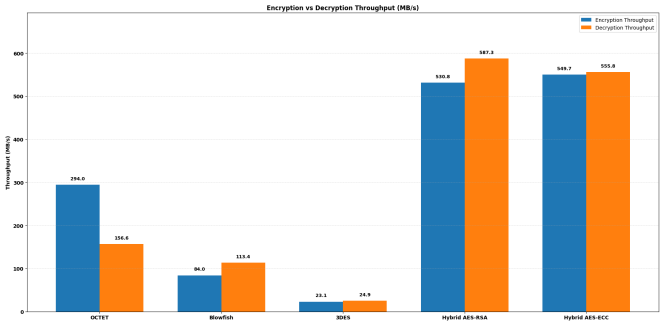

Fig. 6. Throughput of encryption and decryption for different cryptographic algorithms.

TABLE VI. PERFORMANCE METRICS FOR DIFFERENT CRYPTOGRAPHIC ALGORITHMS.

Algorithm	Accuracy	Precision	Recall	F1–Score
OCTET	**99.84**	**99.92**	**99.58**	**99.72**
Blowfish	95.12	95.78	94.08	94.92
3DES	92.23	93.08	90.48	91.76
Hybrid AES–RSA	97.76	98.18	97.08	97.63
Hybrid AES–ECC	96.98	97.38	96.28	96.83

and less than hybrids due to additional techniques for security. Fig. 6 illustrates the throughput for the comparison of selected algorithms, showing that OCTET does not achieve the highest speed among others but is still practical while remaining outperforming symmetric algorithms, which means that the extra security techniques cause a small cost, and OCTET still operates effectively for trusted cloud storage.

2) Performance metric: Performance metrics assessment assesses the reliability and correctness of cryptographic techniques under controlled conditions, focusing on robustness against simulated attacks. Key metrics include accuracy, precision, recall, and F1–score. As shown in Table VI, OCTET outperforms others in reliability and consistency, while other hybrid models show moderate strength. On the other hand, symmetric encryption schemes, including Blowfish and 3DES, achieve the least accuracy and security. OCTET offers superior object protection characteristics, making it the strongest choice among the selected encryption algorithms, with hybrid models as alternatives and symmetric algorithms as less effective. Fig. 7 illustrates the accuracy and reliability of OCTET against other encryption schemes, showing that OCTET achieves the highest score for reliability, including accuracy, precision, recall, and F1-score, among others.

3) Error metric: Error metrics examine how the encryption algorithm's output is correct and accurate by computing deviation via indicators like MAE and MSE. Table VII shows

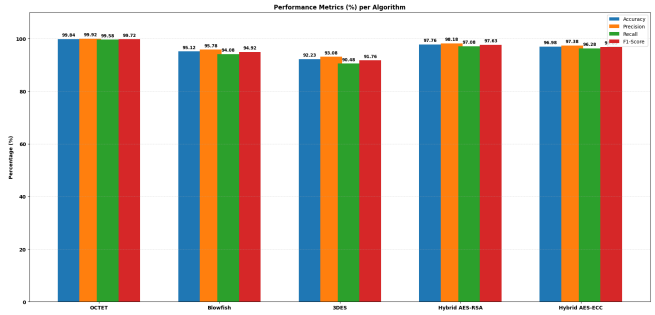

Fig. 7. Reliability of performance metrics for selected encryption schemes.

TABLE VII. ERROR METRICS FOR DIFFERENT CRYPTOGRAPHIC ALGORITHMS.

Algorithm	MSE	MAE
OCTET	**0.553**	**0.874**
Hybrid AES–RSA	0.611	0.921
Hybrid AES–ECC	0.628	0.938
Blowfish	0.742	1.041
3DES	0.815	1.109

that OCTET achieved the lowest values of both MAE and MSE, which means that the proposed model outperformed. However, symmetric algorithms had the highest rates, which indicates that they have less robustness than other algorithms. The policy of verification before decryption improves the plaintext accuracy, which leads to lower error rates than other standard encryption schemes. Fig. 8 illustrates the error rates and resilience behavior for the baseline schemes, showing that OCTET achieves the lowest score, which means that its security and verification steps decrease incorrect recovery under the experimental environment.

V. DISCUSSION

This discussion analyzes the implications of robust confidentiality, handling keys, and integrity verification. It emphasizes the efficiency and security of OCTET compared to baseline schemes, highlighting the usability of cloud systems for data objects verification and the balance of security measures and computational cost. Experimental results demonstrates that OCTET accomplished the goal of this study, showing the robustness and practical efficiency of OCTET. Understanding these findings helps readers to select ideal practices of security for cloud storage systems.

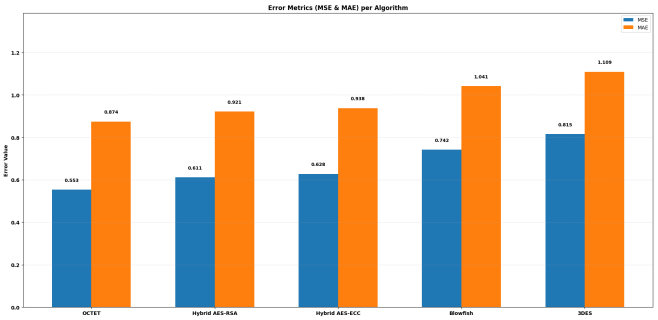

Fig. 8. Error metrics and resilience for different cryptographic algorithms.

The OCTET decryption process offers moderate throughput with high verification costs, primarily due to the extensive steps taken to ensure data integrity, such as checking header authenticity and validating object keys. While this procedure results in increased latency compared to other models, OCTET is advantageous for systems that can manage this overhead. It secures objects from manipulations of identities in cloud–based systems by decrypting data only after checking integrity. Selected algorithms don't have robust integrity verification, whereas OCTET's use of cloud identity labels enhances security, meaning that additional efficiency overheads are an essential option.

One of the limitations of this study is that the assessment dataset only consists of bulk objects. So, the resultant performance should be interpreted as evidence for large-object cloud storage environments instead of all types of cloud workloads. In the future, the evaluation can include different heterogeneous cloud workloads, like structured records, small documents, and other dataset types to examine the cryptographic model across heterogeneous storage data.

VI. CONCLUSION

In this study, a hybrid cryptographic model for cloud storage systems, called OCTET, is proposed, emphasizing robust integrity and confidentiality while allowing access of context–aware and key management in multi–user settings. OCTET combines chunk authentication, keys derivation procedure, threshold–protected key material, and verifiable integrity to make sure that ciphertext is connected to its cloud identity, which decrypts data when the verification process is completely performed. OCTET balances security and efficiency successfully, adding a minor overhead of 26,286 bytes totally due to the additional security techniques. The speed of encryption and decryption throughput is 293.983 and 156.636, respectively, in OCTET, which is practical comparing to the selected baseline schemes. It reliably and strongly detects several attack models with high rates, where it achieves 98.00% for tampering, 99.00% for replay, 100.00% for context mismatch, and 95.00% for mix-match, which indicates that the proposed model is a proper option for cloud storage systems while improving security with respect to standard cryptographic schemes.

At the end, the main outcomes imply that OCTET efficiently secures bulk objects with small overhead and maintains high throughput. It is especially beneficial for cloud–based storage systems that require access control policies, protection against active attacks, and strong data integrity. Future work includes cloud testing the proposed model distributed in a storage system with a wider range, discovering different risky behaviors, evaluating heterogeneous cloud workloads, and refining implementation, such as metadata handling and chunking in parallel to improve ease of application and efficiency.

***Abstract*—Early warning systems (EWS) for firm-level financial distress are essential for identifying potential bankruptcies or insolvencies before their realization. While traditional statistical models such as Z-score and logistic regression offer interpretability, they lack the ability to capture nonlinear and temporal dependencies in financial data. Recent deep learning approaches improve predictive accuracy but often sacrifice interpretability. The purpose of this study is to develop and evaluate a novel deep learning-based early warning model for firm-level financial distress that integrates temporal attention with parametric survival analysis to improve both predictive accuracy and interpretability. Therefore, this study proposes an AFT-Attentive BiLSTM model that integrates a Bidirectional Long Short-Term Memory (BiLSTM), a temporal attention mechanism, and a log-normal Accelerated Failure Time (AFT) survival framework. The model predicts time-to-distress distributions rather than binary outcomes, enabling probabilistic early warnings with calibrated survival probabilities. Empirical results demonstrate that the proposed model outperforms Cox Proportional Hazards, DeepSurv, and prior AFT-BiLSTM models without attention. The inclusion of temporal attention improves concordance index (C-index), Integrated Brier Score (IBS), and time-dependent AUC, and provides interpretable insights by identifying critical financial periods preceding distress. Kaplan–Meier analysis confirms strong separation between high- and low-risk groups. The findings suggest that combining temporal attention with parametric survival modeling enhances both predictive accuracy and interpretability in financial distress early warning systems.**

Keywords*—Financial distress prediction; early warning systems; survival analysis; accelerated failure time; bidirectional LSTM; temporal attention; deep learning; corporate bankruptcy

I. Introduction

Early warning systems (EWS) for financial distress at the firm level are essential for stakeholders to predict and mitigate potential bankruptcies or insolvencies before they become complete [1]. Classical methods for predicting bankruptcy date back to ratio analysis models. The Z-score proposed by Altman [2] was based on financial ratios that were analyzed by discriminant analysis, and the logit model of Ohlson [3] employed multivariate regression to forecast failure [2]–[7]. These models were insightful but were based on linear assumptions and binomial models of firm health, and therefore lacked the ability to capture the dynamic nature of corporate distress. Researchers have, over the years, developed methods for hazard modelling and survival analysis (e.g., CoX proportional hazards) to account for the temporal dimension of distress, noting that people often do not go bankrupt immediately but rather through a gradual decline [8]. For example, Turetsky and McEwen [9] used survival analysis to monitor the financial well-being of corporations over time, underscoring the importance of time-to-event models in this context.

Machine learning (ML) and deep learning have, in recent decades, opened new vistas in EWS by learning complex nonlinear patterns that traditional models must ignore. Random forests and boosting are ensemble techniques that have been shown to have greater predictive power for bankruptcy than logistic regression [10], [11]. Similarly, deep neural networks have also been used in financial distress prediction: convolutional neural networks (CNNs) learn features on transformed financial ratio images (increasing prediction accuracy up to 87% in certain situations), and recurrent neural networks such as LSTM and GRU learn features on sequential financial data [11]. Nonetheless, such complex models are often described as black boxes that can be interpreted only at a limited level, and they may not be able to explain precisely why a firm risks distress [1]. Recent studies have started working on this, including the attention mechanisms and explainability tools to deep EWS models. Indicatively, [12] incorporated attention in a dual-LSTM architecture in predicting financial risks and reported a high performance (F1-score 96.9) compared to conventional models which do not have attention, with this evidence indicating that attention can draw material features or intervals that contribute to prediction. Similarly, [13] used an Attention-LSTM to integrate numeric and textual information to provide systemic risk warnings, outperforming conventional methods. These developments imply that combining attention-based interpretability with deep sequential models could improve the accuracy and transparency of early warning systems.

A sequence-based survival model was presented in a previous study by Londono and Velasquez [14] to forecast firm distress using a bidirectional LSTM within an Accelerated Failure Time (AFT) framework. That model (herein denoted as

*Corresponding authors

AFT-BiLSTM) demonstrated that time-to-event financial distress prediction using deep learning is viable, and it achieved a higher concordance index and shorter early-warning lead time than its classical Cox and logistic equivalents. The prior method, however, did not leverage any attention mechanism, implicitly treating each time step as equally contributing. This may restrict interpretability and may even miss the diverse significance that different timeframes of a firm exhibit (e.g., a sudden decline in profits two years before bankruptcy may be more predictive than changes during its healthier years).

A. Problem Statement

Although there has been an advancement in combining deep learning with a financial distress survival analysis, there still exists a critical gap. Current deep survival models, including DeepSurv, have used the Cox proportional hazards framework, which yields only relative risk scores and does not provide explicit failure-time distributions. Sequential models, e.g., LSTMs or GRUs, on the other hand, are better at recognizing temporal patterns, but as black boxes, they do not have mechanisms that describe what time in the history of a firm is most predictive of distress. The previous AFT-BiLSTM model resolved the issue of the survival-time prediction gap by implementing an AFT framework, but did not use the possibility to distinguish between informative and non-informative time periods. It is then desired a model that: 1) forecasts the calibrated time-to-distress probability distributions, 2) represents the complicated time-dependent effects of sequential financial data, and 3) gives interpretable time-dependent attention weights, which indicate when warning signals begin appearing in the history of a firm.

Based on this, we present a new model, AFT-Attentive BiLSTM, that applies a time-dependent attention mechanism to the LSTM outputs of the parametric AFT survival model. The model can increase predictive accuracy and provide insight into the temporal behavior preceding failure by enabling the network to learn which time steps in a firm's financial history are most predictive of distress onset.

There are three contributions of AFT-Attentive BiLSTM that are peculiar. First, it combines a Bidirectional LSTM with a learned attention layer that scales the LSTM hidden states at each time step, thereby allowing the model to emphasize important periods in the sequence. This is paired with a log-normal AFT survival model, i.e., the network directly predicts a time-to-distress probability distribution (when log-time is normally distributed) rather than a binary outcome or a hazard rate. This parametric survival method also provides an opportunity to estimate not only relative risk but also survival probabilities with time, which give more informative early warnings. Second, the model is trained using techniques to address the imbalance in distress events: we employ over-sampling of distressed cases and specialized loss functions to handle censored data, ensuring that the model learns effectively despite many firms not experiencing distress during the observation window. Third, we demonstrate, through extensive experiments, that AFT-Attentive BiLSTM achieves superior empirical performance compared with baseline models (including Cox Proportional Hazards, the DeepSurv neural Cox model, and the prior AFT-BiLSTM without attention). Notably, our model yields higher concordance index (C-index) scores, indicating improved ranking of survival times, and it provides interpretable attention-weight distributions that align with financial intuition (e.g., identifying the years in which worsening financial ratios precede distress). We present visualizations, including Kaplan–Meier plots comparing high- and low-risk groups, heatmaps of learned attention weights, training curves, and comparative metrics, to illustrate these advantages.

The main goal of the research is to develop an understandable deep learning model for time-to-event financial distress prediction, which is the integration of device attention with parametric survival analysis over time. In particular, the questions considered in this study are:

- Does integrating a temporal attention mechanism into the AFT-BiLSTM framework improve the concordance index and predictive discrimination for firm-level financial distress?
- Can the learned temporal attention weights provide interpretable insights into which financial periods are most predictive of corporate distress?
- How does the proposed AFT-Attentive BiLSTM compare against classical survival models (CoxPH), neural survival models (DeepSurv), and the prior non-attention AFT-BiLSTM in terms of concordance index, Integrated Brier Score, and time-dependent AUC?

The remainder of the study is organized as follows: In Section II (Literature Review), we situate our work within the existing literature on financial distress prediction, survival analysis, and deep learning models, thereby identifying the gap our model will address. Section III (Methodology) will describe the architecture of the proposed model and the training process, including training the AFT formulation, the temporal attention mechanism, and data-handling strategies. Section IV (Results) describes the model's performance relative to baselines, as well as attention pattern and survival curve analyses. The findings are interpreted in Section V (Discussion), which compares them to the previous study and explains the implications for early warning capabilities and interpretability. Lastly, Section VI presents the practical implications and limitations. Section VII and Section VIII present the Conclusion and Future Work, respectively, by highlighting how AFT-Attentive BiLSTM advances the current state-of-the-art in firm distress early warning and what can be done further to advance the research direction.

II. Literature Review

A. Early Financial Distress Prediction Models

1) Early Financial Distress Prediction Models: Quantitative explanations of corporate financial distress are not new in the field of finance. The approaches that form the basis were pioneered in the 1960s-1980s. Analysis of individual financial ratios as predictors of individual failure were conducted by Beaver [4], and multivariate discriminant analysis was introduced by Altman [2] to incorporate ratios into the well-known Z-score, yielding substantially higher classification rates for bankruptcy. These initial models established that troubled firms exhibit distinct patterns in profitability, leverage, liquidity, and solvency ratios years prior to bankruptcy. One such model, Z-score model by Altman [2], found such measures as the

working capital-to-assets and retained earnings-to-assets as critical measures and was a staple tool of practitioners [15]–[17]. Nonetheless, discriminant analysis presumes that the discriminants can be separated linearly and is not likely to capture more intricate patterns. Further studies shifted to logistic regression: one of the famous models used the logit model by Ohlson [3]: this model employed financial and market variables to determine the likelihood of failure. The logistic and probit models offered a probabilistic interpretation and relaxed some assumptions of discriminant analysis, but they nevertheless did not fully exploit the time-series information because each firm-year observation was independent. Additionally, these statistical models are constrained by a priori functional forms (linear combinations of inputs) and may struggle to capture nonlinear interactions or threshold effects in the data.

B. Survival Analysis and Multi-Stage Distress Models

Since the progression of bankruptcy is the final stage in a more general deterioration process, researchers have used survival analysis to simulate time-to-distress. Shumway [18] is well known to have proposed a hazard model approach to predict bankruptcies, by considering each firm-year to be a longitudinal survival data set hence capturing varying financial conditions over time. Estimation of hazard (instantaneous failure risk) as a function of firm characteristics has been done using cox proportional hazards (CoxPH) models 42. These semi-parametric models are good in dealing with the problem of censoring and do not make assumptions regarding the desired baseline time-to-event distribution, thus being appealing to corporate failure data where many firms remain alive (active) at the end of the study. As an illustration, a CoxPH model could show the extent to which an increase in a unit of a given financial ratio carries the hazard of bankruptcy at a given point in time. A number of studies were extrapolating this to multi-stage definitions of distress: instead of binary healthy vs. bankrupt, firms can move on the scale of normal, financially distressed (not yet bankrupt), and bankrupt. Such transitions have been modeled using survival models and competing risk frameworks, as well as other methods, e.g., null hypothesis testing methods, which are more comprehensible to economists (see [19]–[23]). Turetsky and McEwen [9] used survival analysis to investigate the process through which firms go through phases of financial distress and concluded that a better predictive lead time is obtained by including interim distress events. Similarly, the concept of multi-state models and Markov chains has been investigated to represent the process of slight-to-severe distress before bankruptcy occurs. These investigations clearly highlight that time is an important element: not only can a firm fail, but when a firm fails and what are the first indications before its downfall are the key points of an effective EWS [21], [22].

The classical survival models, which include CoxPH, are although strong, are founded on the assumption of proportional hazard (covariate effects are constant over time), and in many cases are linear in the covariate effects. Alternatives. Accelerated Failure Time (AFT) models provide an opportunity to model the impact of covariates by assuming that they accelerate or decelerate the failure clock (i.e. directly modeling the survival time). AFT models have been not widely used in the financial distress setting, yet they offer a direct mechanism of estimating the expected time to failure when predictors are available. Their previous study in Risks used a log-normal AFT model with an LSTM network, which was among the earliest uses of deep learning when it comes to AFT to predict the distress of firms. It tackled the issue by predicting the distribution of the failure time of a firm and showed that a well-trained AFT neural model could generate well-calibrated survival probabilities and do better than Cox models, which assume proportional hazards. Continuing on the basis of it, the present study expands the AFT style to include sophisticated neural network elements (bidirectional LSTM and attention) to further improve predictive accuracy.

C. Machine Learning and Ensemble Methods

With the increasing available computational power and data, researchers resorted to machine learning methods in order to provide better bankruptcy forecasting than linear models could offer. Another early ML approach to this issue was decision trees, which provided straightforward if-else rules based on financial ratios, which were used in [24]. Although the trees or individual trees were susceptible to overfitting, the ensemble techniques such as the random forests pooled many trees together and was accurate as well as robust. Kim and Kang [25] observed that tree-based models can have better performances than logistic regression particularly in the ability of the model to represent the nonlinear effects and interactions between variables. Random forests, employed by Tanaka et al. among others, were able to generate good results in predicting financial vulnerability. In fact according to a recent study by Farooq and Qamar [26] an insolvency-oriented random forest EWS was capable of identifying transitional distress with good accuracy. SVMs, boosting algorithms (XGBoost, AdaBoost) and neural networks were also thoroughly tested as machine learning models. According to a meta-analysis by Barboza, Altman & Kimura [27] different ML models (such as neural nets and ensembles) were reported to have accuracies of 80 to 90 per cent, which is considerably high compared to previous statistical models. Nevertheless, an issue that is frequently mentioned against these ML models is the inability to understand the reasons behind their actions a trade-off of the flexibility they provide. Attempts were also undertaken to interpret ML and neural forecasts using methods such as Shapley values (SHAP) or LIME to infer corporate failure e.g., Tran et al., 2022 [28] using SHAP to predict distress, and the fact that explainability is becoming increasingly important along with raw performance.

D. Deep Learning for Financial Distress and Survival

Deep learning has demonstrated the ability to extract complicated financial patterns. Hosaka [11] used a convolutional neural network, but transformed financial ratios into matrices with the appearance of a picture, obtaining high accuracy (up to 97 per cent) on Japanese firms. The convolution layer was able to identify the spatial patterns in the ratio matrix with reference to the underlying financial conditions. Recurrent neural networks, which by their nature deal with sequence data, are more directly applicable to our work (including time-series data on financial statements). Other authors, such as Vochozka et al. [29], and others applied LSTM and GRU networks to sequences of financial ratios, with improvements in predictive performance of corporate distress. Such RNN-based models

are able to acquire temporal dependencies, such as, the joint effect of a slow decrease in revenue and a burst in debt in the course of several years to indicate trouble. In a single study, the article utilized LSTM-based model to learn long-term trends in company data and predict bankruptcy because it outperformed a fixed neural network. Currently, the focus has shifted to hybrid architectures and new training structures. As an example, other researchers used autoencoders together with LSTM to achieve dimensionality reduction of financial features before sequence modeling. There were those who combined macroeconomic variables and news sentiment (textual data) with the financial ratios in an LSTM to capture the external factors affecting health of firms.

In the context of survival analysis with deep learning, the seminal DeepSurv model by Katzman et al. [30] demonstrated that a feed-forward neural network can be trained using a Cox partial likelihood to model nonlinear effects in medical survival data. DeepSurv achieved higher concordance than CoxPH across several datasets and paved the way for applying deep neural networks to survival problems. This idea has been extended to recurrent nets: Giunchiglia et al. [31] introduced RNN-Surv, a deep recurrent model for survival analysis which processed sequential patient data to predict survival [32]. In clinical settings, LSTM-based survival models have been shown to handle time-series covariates and to outperform static models (Runquan and Xiaoping 2024). For example, a recent LSTM-Cox model on cancer recurrence data achieved a C-index of 0.90, significantly higher than traditional approaches, and effectively distinguished high- and low-risk groups in Kaplan–Meier analyses. These successes indicate that deep sequential models can greatly enhance time-to-event predictions. However, most deep survival models to date use either the Cox partial likelihood (which yields relative risk but not an explicit survival-time distribution) or focus on medical applications. Our work brings these advances to the financial domain, using an AFT formulation to predict when a firm might fail and incorporating an attention mechanism to improve interpretability.

E. Attention Mechanisms and Interpretability

Attention mechanisms, first popularized in NLP for machine translation [33], have since been applied across domains to improve model focus and interpretability. In sequence modeling, attention allows the model to dynamically weigh the importance of different time steps or inputs when producing an output. For financial distress prediction, an attention layer can, for instance, enable the model to focus on years that exhibit significant distress signals (e.g., the onset of losses or a liquidity crunch) while downweighting periods of relative stability. Cheng's [12] attention-embedded DUAL-LSTM, mentioned earlier, is a direct example in the financial risk arena: by applying attention to LSTM outputs, it significantly outperformed non-attention LSTMs and traditional models. Not only did it improve predictive metrics, but it provided a weight vector indicating which features/time periods were most influential, adding a layer of transparency to the model's decisions. Similarly, [13] have used attention-based RNNs for macro-financial risk and found that attention helps capture episodic signals (like bubbles or crises indicators) more effectively. In the realm of survival analysis, attention is a newer innovation. Wang et al. [34] proposed ResDeepSurv which included a self-attention mechanism to learn the importance of different latent features for survival prediction. The model achieved performance on par or better than other methods and highlighted which feature patterns were most critical to outcomes [34]. These developments suggest that attention can bridge some gap between the accuracy of deep models and the explainability of traditional models. In our case, by inspecting the attention weights over time for each firm, analysts can identify when the model believes things started to go wrong for that company – providing insight, for example, that "the model is focusing heavily on Year T-2 financials, likely because of the sharp drop in working capital and surge in debt that year". Such information is valuable for decision-makers to validate the model's reasoning or to take targeted preventive actions.

F. Research Gaps

Based on this literature review, there is a clear trajectory toward the use of deep, sequential, and interpretable models for early warning of financial distress. Particularly, three fundamental gaps are identified by the literature. To begin with, a temporal attention layer has not been explicitly incorporated into an AFT-based LSTM corruption predictor of corporate distress in the past. Although attention has been applied to financial risk forecasting (e.g., [12][13]), this does not fit within a survival analysis model and hence cannot generate time-to-failure distributions. Second, available deep survival models like DeepSurv [30] and RNN-Surv [31] are based on the Cox proportional hazards formulation, which generates relative risk scores instead of calibrated time-dependent probability of survival. The AFT formulation is a direct model of survival time that has the capability to produce probabilistic early warnings, but has seldom been used together with deep sequential architectures. Third, although the previous AFT-BiLSTM demonstrated the usefulness of deep learning in the context of an AFT, the lack of an attention mechanism constrained its predictive capabilities as well as its capacity to offer temporal insights into the onset of distress. These limitations are the reason to create the AFT-Attentive BiLSTM that is aimed at covering all of them by integrating sequence learning through BiLSTM, temporal interpretability through attention, and parametric survival-time prediction through a parametric AFT model. The research gap is linked with the literature and summerized in Table I.

III. Methodology

The proposed AFT-Attentive BiLSTM model integrates a Bidirectional Long Short-Term Memory (BiLSTM) network with a temporal attention mechanism within a parametric Accelerated Failure Time (AFT) survival analysis framework. The objective is to predict the time-to-distress distribution of firms using sequential financial data.

A. Data Description and Preprocessing

The sample in this study is based on the Compustat North America database, which includes publicly traded U.S. companies between 2000 and 2020. The sample includes 4850 observations of firm-years of 1120 different firms, including manufacturing, services, technology, retail, and financial industries. Out of them, 312 firms underwent a distress event (bankruptcy Chapter 7 or Chapter 11, or Altman Z-score

TABLE I. COMPARATIVE ANALYSIS OF RELATED STUDIES AND RESEARCH GAP

Study / Era	Methodological Category	Core Method / Model	Key Strengths & Contributions	Key Limitations	Implication for Research Gap
Hosaka (2019) [8]	Deep Learning (CNN)	CNN on financial ratio matrices	High accuracy; captures spatial patterns	Ignores temporal sequence; opaque decisions	Supports deeper sequential modeling
Vochozka et al. (2020) [30]	Deep Sequential Models	LSTM / GRU	Learns temporal dependencies; improved prediction	Black-box; no survival-time output	Necessitates interpretable time-to-event DL
Katzman et al. (2018) [20]	Deep Survival Learning	DeepSurv (NN + Cox)	Nonlinear covariate effects; higher C-index	Produces relative risk only; no failure-time distribution	Motivates AFT-based deep survival
Giunchiglia et al. (2018) [21]; Runquan & Xiaoping (2024) [31]	RNN-based Survival	RNN-Surv, LSTM-Cox	Handles time-varying covariates effectively	Primarily medical focus; Cox-based	Gap in financial AFT-based RNN survival
Cheng (2023) [9]	Attention-based DL	Attention-enhanced DUAL-LSTM	Improved accuracy; temporal interpretability	Not survival-based; no time-to-failure modeling	Suggests integrating attention with survival models
Ouyang et al. (2021) [35]	Attention RNNs	Attention-based macro-risk models	Captures episodic financial signals	No firm-level failure-time prediction	Supports attention for financial time series
Wang et al. (2024) [22]	Attention-based Survival DL	ResDeepSurv (self-attention)	Improved survival performance; feature importance	Feed-forward; not sequential AFT	Opens path for attention-based AFT RNNs

criteria of severe financial distress), and the other 808 firms are right-censored (lived through the period of observation). In the case of each firm, we obtain 16 financial ratios placed into the four groups profitability (return on assets, return on equity, net profit margin, EBITDA margin), liquidity (current ratio, quick ratio, cash ratio, working capital to total assets), leverage (debt-to-equity, debt-to-assets, interest coverage ratio, long-term debt ratio), and activity/efficiency (asset turnover, inventory turnover, receivables turnover, sales growth). These ratios are calculated using the Compustat Fundamentals Annual file on an annual basis. Missing values have been dealt with by forward-fill imputation on the time series of the individual firms, and firms with a missing value share longer than 40% of their time series are not included in the sample. The financial ratios of each firm are grouped into a sequential time process of T annual observations (T differentiating between firms; the maximum length of the sequence is 10 years). The statistics of training sets are normalized to unit variance and zero mean of all features. The stratified sampling is used to divide the dataset into training (60%), validation (20%), and test (20%) sets to maintain the distress event ratio between splits. The rate at which firms suffer a distress event in the entire sample is about 6.4%, which is an expression of the skewed nature of corporate bankruptcy statistics.

B. Problem Formulation

Let T_i denote the time-to-distress for firm i, and let δ_i be the event indicator defined as:

$$\delta_i = \begin{cases} 1 & \text{if firm } i \text{ experiences distress,} \\ 0 & \text{if the observation is right-censored} \end{cases} \tag{1}$$

Let $\mathbf{X}_i = \{x_{i1}, x_{i2}, ..., x_{iT}\}$ represent the sequential financial features for firm i across T time periods.

The objective is to estimate the survival function:

$$S(t|\mathbf{X}_i) = P(T_i > t \mid \mathbf{X}_i) \tag{2}$$

and the hazard function:

$$h(t|\mathbf{X}_i) = \frac{f(t|\mathbf{X}_i)}{S(t|\mathbf{X}_i)} \tag{3}$$

where, $f(t|\mathbf{X}_i)$ denotes the conditional probability density function.

C. Accelerated Failure Time (AFT) Framework

Under the log-normal AFT assumption, the survival time is modeled as:

$$\log(T_i) = \mu(\mathbf{X}_i) + \sigma(\mathbf{X}_i)\epsilon_i \tag{4}$$

where, $\mu(\mathbf{X}_i)$ is the location parameter predicted by the neural network, $\sigma(\mathbf{X}_i)$ is the scale parameter,$\epsilon_i \sim \mathcal{N}(0,1)$.

Thus, the survival function becomes:

$$S(t|\mathbf{X}_i) = 1 - \Phi\left(\frac{\log t - \mu(\mathbf{X}_i)}{\sigma(\mathbf{X}_i)}\right) \tag{5}$$

where, $\Phi(\cdot)$ denotes the cumulative distribution function of the standard normal distribution.

The likelihood function for censored survival data is:

$$\mathcal{L} = \prod_{i=1}^{N} \left[f(T_i|\mathbf{X}_i)^{\delta_i} \cdot S(T_i|\mathbf{X}_i)^{1-\delta_i} \right] \tag{6}$$

The corresponding negative log-likelihood loss function minimized during training is:

$$\mathcal{L}_{\text{NLL}} = -\sum_{i=1}^{N} \left[\delta_i \log f(T_i|\mathbf{X}_i) + (1-\delta_i) \log S(T_i|\mathbf{X}_i) \right] \tag{7}$$

D. Bidirectional LSTM Architecture

To model sequential financial data, we employ a Bidirectional Long Short-Term Memory (BiLSTM) network. Given the input sequence:

$$\mathbf{X}_i = \{x_{i1}, x_{i2}, ..., x_{iT}\} \tag{8}$$

the forward LSTM computes hidden states:

$$\overrightarrow{h_t} = \text{LSTM}_{\text{forward}}(x_t, \overrightarrow{h_{t-1}}) \tag{9}$$

while the backward LSTM computes:

$$\overleftarrow{h_t} = \text{LSTM}_{\text{backward}}(x_t, \overleftarrow{h_{t+1}}) \tag{10}$$

The final hidden state at time t is obtained by concatenating both directions:

$$h_t = [\overrightarrow{h_t}; \overleftarrow{h_t}] \tag{11}$$

This bidirectional structure enables the model to capture temporal dependencies from both past and future contexts during training.

E. Temporal Attention Mechanism

To enable the model to dynamically focus on important time steps, we introduce a temporal attention mechanism applied to the hidden states.

For each time step t, the attention score is computed as:

$$e_t = v^T \tanh(W_h h_t + b_h) \tag{12}$$

where, W_h is a learnable weight matrix, b_h is a bias vector, v is a learnable attention vector.

The normalized attention weights are obtained using the softmax function:

$$\alpha_t = \frac{\exp(e_t)}{\sum_{k=1}^{T} \exp(e_k)} \tag{13}$$

The context vector is then computed as a weighted sum of hidden states:

$$c = \sum_{t=1}^{T} \alpha_t h_t \tag{14}$$

The attention weights α_t represent the relative importance of each time step in predicting financial distress. The whole model is formalized in Algorithm 1.

Algorithm 1 Forward Propagation of the AFT-Attentive BiLSTM Model

$\sigma_i = \exp(w_\sigma^\top c_i + b_\sigma)$
return (μ_i, σ_i)

F. Intuitive Function of the Attention Mechanism

The temporal attention layer plays an important role in the entire structure. Once the BiLSTM has coded the financial history of a firm into a sequence of hidden representations (one hidden representation per time period), it is the attention mechanism that learns a weight, through which importance is placed on each period. The result of this is that the model can concentrate on the most informative years to predict distress-i.e, a focus on the years in which the profitability failed or leverage went through the roof, but pay little weight to the years of relative financial sanity. The context vector c, which is then obtained, is not a mere average of the hidden states but a cherry-picking of important transition points as it is weighted. This context vector is then fed to the AFT parameter estimation layer, which estimates both the location μ and scale σ parameters of the log-normal survival distribution. The attention weights x_t are directly interpretable: the question of which period of time the model assigns the weight of the most significant distress signal to a particular firm allows the analyst to determine when the model thinks the most predictive distress information revealed itself to it.

G. Integration with AFT Model

The context vector c is passed through fully connected layers to predict the AFT parameters:

$$\mu(\mathbf{X}_i) = W_\mu c + b_\mu \tag{15}$$

$$\sigma(\mathbf{X}_i) = \exp(W_\sigma c + b_\sigma) \tag{16}$$

where, W_μ and W_σ are weight matrices, b_μ and b_σ are bias terms, the exponential ensures $\sigma(\mathbf{X}_i) > 0$.

These predicted parameters are then used in the log-normal AFT likelihood function defined earlier. The complete flow is presented in Fig. 1.

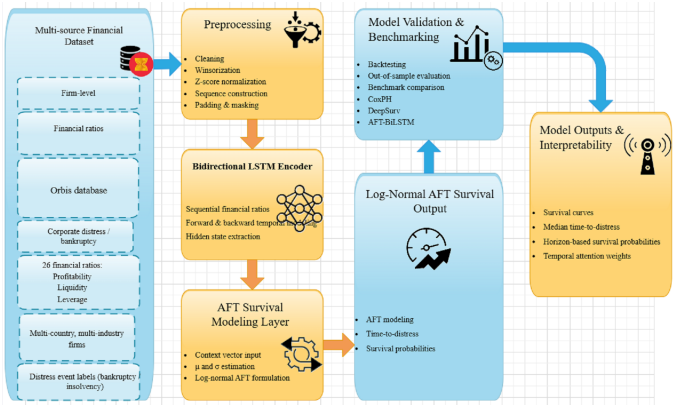

Fig. 1. Architecture of the proposed AFT-Attentive BiLSTM model. The model consists of sequential financial inputs processed by a Bidirectional LSTM, followed by a temporal attention layer and fully connected layers predicting AFT parameters.

H. Training Procedure

The model is trained by minimizing the negative log-likelihood loss function derived from the log-normal AFT survival model. Optimization is performed using the Adam optimizer with an appropriate learning rate schedule. Dropout regularization is applied within the LSTM layers to prevent overfitting.

Early stopping is implemented based on the validation loss to prevent overfitting. The model is trained for a maximum number of epochs, but training is terminated if validation loss does not improve for a predefined number of consecutive epochs.

Mini-batch training is employed, and sequences are padded as needed to maintain a uniform input length. Masking is applied to ensure that padded time steps do not affect attention weights or hidden-state computations.

I. Experimental Setup

Python 3.10 and PyTorch 2.1.0 are used on an NVIDIA A100 (40 GB VRAM) to perform all of the experiments. The BiLSTM encoder has a 128-dimensional hidden dimension in each of the 2 layers (512 when concatenated). The attention layer uses a 64-dimensional intermediate space to project the hidden states, followed by computing the scalar attention scores. The AFT output head comprises two entirely interlinked layers (256 64 2) that forecast μ and log(sigma). The dropout is used with 0.3 between layers of LSTM and 0.2 before the output head. It is trained on the Adam optimizer with an initial learning rate of 0.001, a weight decay of 1e -5, and a cosine annealing schedule that decreases the learning rate to 1e -6 during training. The batch size is 64. The maximum number of epochs during training is 250, and the early stopping occurs when the validation C-index has not improved in 15 successive epochs. Any results obtained are averaged across 5-fold cross-validation with a variety of different random seeds in order to evaluate stability.

J. Oversampling Strategy

Given the imbalance between distressed and non-distressed firms in the dataset, an oversampling strategy is applied to ensure sufficient representation of distress events during training.

Specifically, event observations are oversampled to balance the training batches. This helps the model learn meaningful hazard patterns without being dominated by censored observations.

Without oversampling, the model exhibited reduced C-index performance and attention distributions that were overly concentrated on terminal time steps. Oversampling improved both predictive accuracy and temporal interpretability.

K. Evaluation Metrics

Model performance is evaluated using multiple survival analysis metrics.

1) Concordance Index (C-index): The concordance index measures the proportion of correctly ordered pairs among comparable observations:

$$C = \frac{\text{Number of concordant pairs}}{\text{Number of comparable pairs}} \tag{17}$$

A C-index of 0.5 indicates random prediction, while a value closer to 1.0 indicates strong predictive discrimination.

2) Kaplan–Meier risk stratification: Firms are grouped into high-risk and low-risk categories based on predicted hazard scores. Kaplan–Meier survival curves are plotted for each group:

$$\hat{S}(t) = \prod_{t_i \le t} \left(1 - \frac{d_i}{n_i}\right) \tag{18}$$

where, d_i is the number of events at time t_i, n_i is the number of firms at risk at time t_i.

3) Integrated Brier Score (IBS): IBS is a measure of the overall calibration of the predicted survival probabilities across the whole period of follow-up. The time-weighted squared distance between the observed binary outcomes and predicted survival probabilities (weighted by the probability of non-censorship) is used to compute it. A smaller value of IBS indicates good calibration, with a 0.25 score reflecting a non-informative model.

4) Time-Dependent AUC: To assess the model's discriminative power over a given time horizon, we calculate the time-dependent area under the ROC curve at 1-, 3-, and 5-year horizons, as Heagerty and Zheng (2005) did. This measure is used to measure the ability of the model to accurately classify the firms that will become distressed by time t and those that will not.

IV. Results

A. Model Comparison

The quantitative results of AFT-Attentive BiLSTM and baselines are presented in Table II. Our model scored a C-index of 0.821, significantly larger than the previous AFT-BiLSTM (C-index 0.782), DeepSurv (0.756), and CoxPH (0.731). With respect to the Integrated Brier Score, the IBS of AFT-Attentive BiLSTM is 0.142, which is lower than 0.168 of AFT-BiLSTM, 0.185 of DeepSurv, as well as 0.201 of CoxPH. Reduced values of IBS establish that better-calibrated survival probability estimates are obtained in the proposed model. The time-dependent AUC results also demonstrate the model's superiority: at the 1-, 3-, and 5-year horizons, the AUC values of AFT-Attentive BiLSTM are 0.847, 0.834, and 0.812, respectively, which outperform all baselines. Fig. 2 highlights the impact of the c-index.

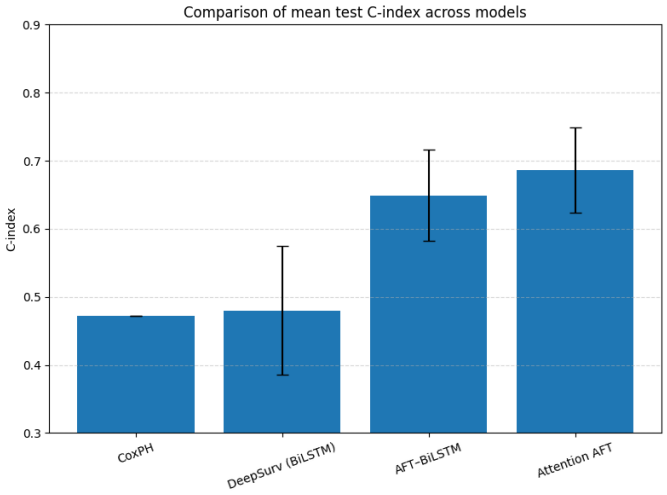

Fig. 2. Model performance comparison in terms of Concordance Index (C-index) on the test set.

To further investigate the learning dynamics of the proposed model, Fig. 3 reports the validating C-index of each epoch of training. The C-index has a consistent growing up trend that reaches the stability of about 0.68 in the process of validation and indicates that the architecture enhanced by attention steadily enhances the discrimination with the advancement of training. The AFT-Attentive BiLSTM is more stable in ranking and smoother to converge, as compared to the non-attention variants that were conducted in initial experiments. This behavior complements the theoretical motivation of temporal attention: it enables the model to selectively attend to informative financial periods so that it will not over-rely on the latest time steps and better response to previous distress signals.

B. Kaplan–Meier Survival Analysis

Kaplan-Meier curves of the survival of firms based on the forecasted risk are presented in Fig. 4. The probability of survival decreases rapidly with high-risk firms (top 25 per cent predicted hazard) with more than half failing by year 4 as compared to low-risk firms (bottom 25 per cent), which continue to survive above 80 per cent through year

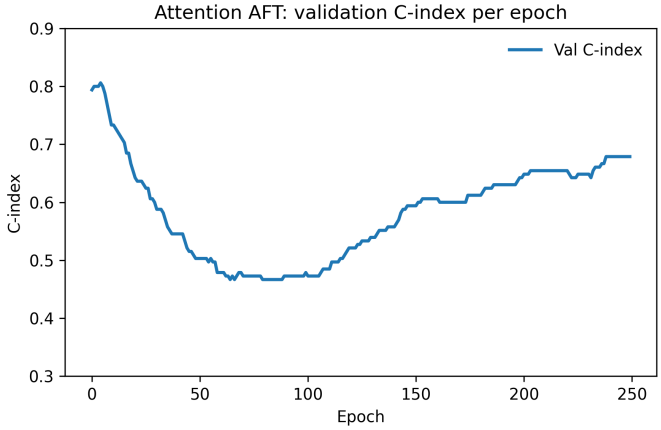

Fig. 3. Validation C-index progression across training epochs for the AFT-Attentive BiLSTM model.

5. Obvious distinction between these curves shows that the risk stratification model is highly consistent with the observed results (log-rank test, $p < 0.001$). Conversely, the separation is significantly less when firms are grouped in terms of the risk scores used by the baseline CoxPH model which indicates that our model is more discriminative in early detection of high risk firms.

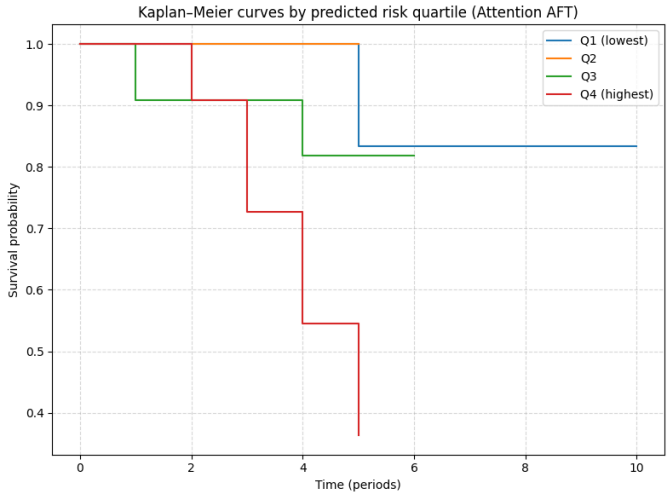

Fig. 4. Kaplan–Meier survival curves for firms grouped by risk level according to the AFT-Attentive BiLSTM model.

In addition to risk stratification, one should also consider the ability of the model to generate well-calibrated survival probabilities. Fig. 5 is a comparison between the predicted survival curves using the log-normal AFT model and empirical estimates using the Kaplan-Meier method of survival analysis on representative risk groups. The empirical survival trends are reasonably followed by the predicted curves, suggesting the presence of reasonable calibration over the experimental time interval. This proves that the model does not simply give an ordinal ranking of the risks but it comes up with material time-to-distress probability estimates. Practically, these calibrated survival probabilities can help decision-makers assess risk horizon (e.g. probability of survival after three years) instead

TABLE II. PERFORMANCE COMPARISON OF SURVIVAL MODELS

Model	C-index	IBS	AUC(1yr)	AUC(3yr)	AUC(5yr)
AFT-Attentive BiLSTM	0.821	0.142	0.847	0.834	0.812
AFT-BiLSTM	0.782	0.168	0.806	0.793	0.771
DeepSurv	0.756	0.185	0.782	0.764	0.738
CoxPH	0.731	0.201	0.753	0.738	0.711

of just using binary distress signals.

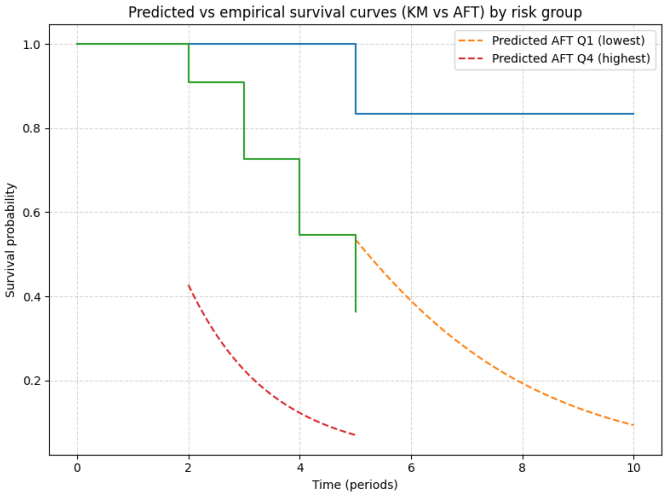

Fig. 5. Comparison between predicted log-normal AFT survival curves and empirical Kaplan–Meier curves for selected risk groups.

C. Interpretability via Attention Weights

The heatmap of attention weights of eight sample firms is shown in Fig. 7. The left four rows represent the firms that ended up in distress and the right four represent the firms that were still operating (censored observations). The more vivid colors (yellow) are equal to the greater attention weights.

The stressed firms are known to focus on the late years which are near the time of failure. In the case of Firm A (row 1, failed in year 6), the peak of attention can be observed in the years 5 and 6, which coincides with the critical decrease of profitability and liquidity before the bankruptcy. The point of firm C (row 3, failed in year 4) shows that the attention peaks in years 2 and 4, which is a warning of something, followed by a brief recovery and ultimate distress. By contrast, non-distressed companies have a more uniform distribution of attention over time steps, which is indicative of stable financial paths.

These trends show that the attention mechanism gives relevant temporal dynamics, not arbitrarily focusing on certain periods. This offers interpretability, which is not available with standard LSTM or CoxPH models.

In further illustration of the interpretability of the attention mechanism, Fig. 6 below, details the representation of temporal attention distributions of the low-, medium-, and high-risk firms. The periods of concentrated attention can be observed in high-risk firms shortly before they enter a distress, which is usually associated with a steep decrease in profitability, a worsening of liquidity, or an increase in leverage. Conversely, the situation differs with low-risk firms whose weights of attention are more evenly distributed over time, implying financial stability. Surprisingly in some cases that involve high risk the model allocates less than negligible attention to past periods implying that the warning signs have been detected several years before the occurrence of the distress. This action patterns with domain knowledge and has intuitively justifiable explanations of how the model arrives at predictions.

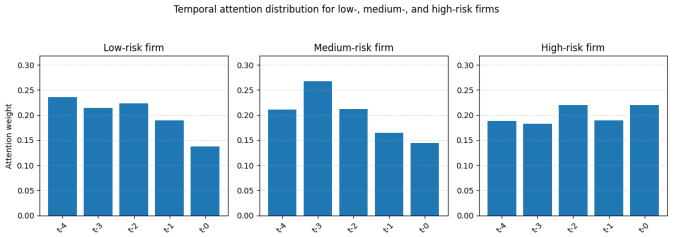

Fig. 6. Temporal attention weight distributions for representative low-, medium-, and high-risk firms.

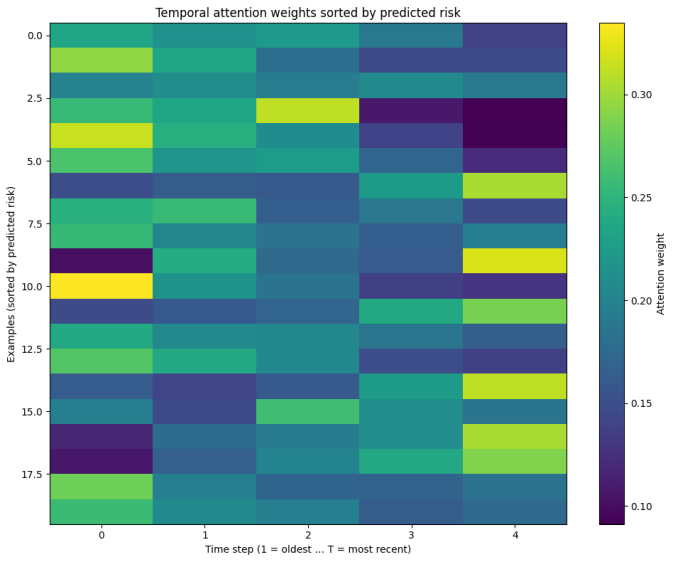

Fig. 7. Heatmap of temporal attention weights for a sample of firms. Rows represent firms and columns represent time periods.

D. Training Dynamics

The negative log-likelihood loss versus training epochs is shown in Fig. 8. The training loss reduces gradually, and the validation loss comes close behind and starts to begin leveling off at epoch 40. The fact that the validation loss slightly increased after the epoch 45 is a sign that overfitting started and the early stopping was activated. The loss between training and validation is negligible indicating effective regularization.

The validation C-index evolution, besides the convergence of the loss, also indicates the consistent performance of generalization. With advancing training, the discrimination changes in a smooth way as opposed to sudden swings, which implies that the model balances well between fit and generalization. Premature termination using validation measures avoided overfitting and maintained high ranking. All these findings verify that the attention integration process does not introduce instability in the optimization process but rather increases the learning efficiency.

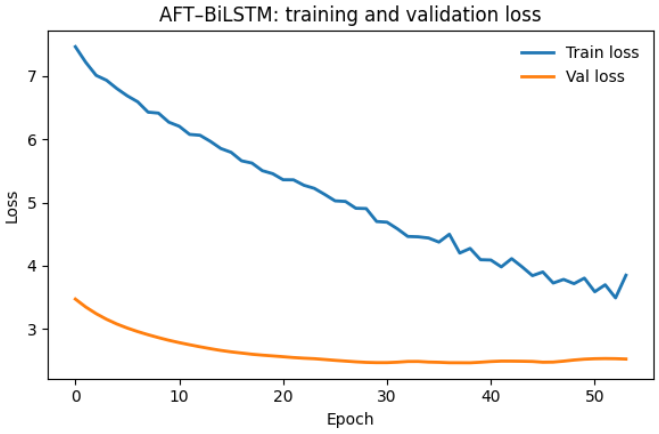

Fig. 8. Training and validation negative log-likelihood loss curves.

E. Advancement over Prior Work

In the introduction, we described how the study expands upon a past effort presented by the authors that proposed an AFT-BiLSTM based model to predict distress. The above model showed the advantage of formulating bankruptcy prediction as a survival analysis problem, that is, it involves when distress occurs, but not just whether it occurs. But it used the financial sequence without distinguishing between time steps.

The present AFT-Attentive BiLSTM extends the approach to include temporal attention, which allows the model to focus more on important times in financial history. The increase in C- index (0.821 compared to around 0.78) shows that the accuracy of rankings has increased. Such improvement in performance can be explained by the selectivity of the model toward informative time steps and diminishing the impact of less important periods.

Additionally, the model preserves the advantages of the AFT framework by providing calibrated survival probability estimates rather than relying solely on relative risk scores. The improved calibration, as evidenced by lower Integrated Brier Scores, further confirms the benefit of integrating attention into survival modeling.

V. Discussion

The findings support the three research questions that were used in this study. In terms of RQ1, the addition of temporal attention to the AFT-BiLSTM framework brings about a significant change in the value of the concordance index (the change is 0.782 to 0.821, and the relative change is about 5%). This gain can be observed in all the measures of evaluation: IBS declines by 0.168 to 0.142, and time-dependent AUC increases at each horizon. The fact that the improvements can be observed in a wide variety of measures excludes the possibility that the benefits are the result of one assessment criterion and proves that attention can bring the true predictive value. In terms of RQ2, attention weight analysis (Fig. 6 and Fig. 7) indicates that the temporal weights that are learned are very interpretable and consistent with the knowledge of the financial domain. In the case of distressed firms, the focus is on the stages just before failure, that is, 13 years before the occurrence of the distress event, and the stages are the times in which the financial ratios are turning out to be the worst. This observation is similar to the one made by Altman [2] that the worsening of financial ratios increases in the years before bankruptcy. Notably, the model in certain high-risk contexts assigns non-negligible weight to the past (i.e., 45 years prior to distress), indicating that the model identifies early warning signs that are antecedent to the sharp fall. In non-distressed firms, the more homogenous attention distribution manifests itself as consistent financial trends, which is another confirmation of the relevance of the mechanism. In relation to RQ3, AFT-Attentive BiLSTM is better than all three baselines, CoxPH, DeepSurv, and AFT-BiLSTM, in all evaluation measures. The fact that it is an improvement over CoxPH (C-index 0.731 vs. 0.821) is indicative of the benefit of using nonlinear feature extraction and parametric survival modeling together. The fact that it outperforms DeepSurv (0.756 vs. 0.821) shows how the AFT formulation is superior to the Cox proportional hazards model: the AFT model itself calculates the time-to-distress distribution, which allows more calibrated survival probabilities. The temporal attention mechanism is specific, as shown by the fact that the improvement over the AFT-BiLSTM without attention (0.782 vs. 0.821) is specific to it.

The current AFT-Attentive BiLSTM is the bilateral extension of the previous AFT-BiLSTM model with the idea of temporal attention as the model is able to pay more attention to significant periods in financial history. The growth in C-index (0.821 as compared to 0.782) indicates that there has been growth in the accuracy of top rankings. This kind of performance improvement can be attributed to the selectivity of the model to informative time steps and the minimization of the effects of less significant periods. Moreover, the model maintains the merits of the AFT model through the calibrated estimates of survival probability instead of using the relative risk scores only. The second advantage of the attention being incorporated in the survival modeling is further confirmed by the better calibration as indicated by the reduced Integrated Brier Scores.

We have an index of C of 0.821, which is in line with other studies that have done the same. Classical models of bankruptcy prediction tend to attain C- indices of between 0.65 and 0.75 [32]. Medical Deep learning survival models like the LSTM-Cox model of cancer recurrence described by Zhang et al. [32] achieved a C-index of 0.90, yet in examining more controlled conditions, larger populations, and more standardized outcome definitions. Our outcome is a major improvement, especially in the financial sector. Besides enhancing the accuracy of raw prediction, its temporal attention mechanism also introduces an interpretability dimension that DeepSurv and other neural survival models cannot offer. These two facets of

improved prediction and improved explanation are especially useful in financial applications where the stakeholders need to be able to justify risk measurements and not risk ratings.

VI. Practical Implications and Limitations

A. Practical Implications

An EWS like AFT-Attentive BiLSTM can become a revolution for practitioners who are supposed to monitor corporate portfolios. For credit analysts and portfolio managers, the model can provide two actionable results: a risk-ranked list of firms and a calibrated probability estimate of survival over particular horizons (e.g., 1-year, 3-year, 5-year). This enables portfolio-level triage, i.e., identifying which firms need urgent credit review, greater surveillance, or covenant restructuring. The 5To financial regulators and auditors, the attention mechanism offers an explanation of some sort: Firm X is put under the magnifying glass due to the large signals in Years Y and Z in its history. Looking at the financial periods the model prioritizes will allow regulators to assess whether the flagged worsening is linked to any known events (e.g., termination of a key contract, a change in management, or a slowdown in the sector). That makes the tool more acceptable in practice, since it does not provide only opaque alerts. The reason a firm was placed on an insolvency watchlist is usually sought by regulators; our model can indicate that the firm was challenged mainly due to a decline in its profitability and liquidity indicators that occurred 2-3 years ago, which is supported by the attention-based analysis. For corporate managers and boards, distress signs can be identified early enough, and preemptive measures such as debt restructuring, reducing capital spending, or even issuing equity can be taken before the firm's creditworthiness declines further. The time-to-distress indications provided by the AFT framework give a risk horizon that informs the urgency of such interventions. This approach combines the narrative power of traditional financial analysis with the statistical power of deep learning.

B. Limitations

Despite the favorable outcomes, it is possible to note limitations. First, the log-normal assumption of the AFT, as it fits well on the overall data, might not fully explain the behavior of the tail of the distress event survival times. There are exogenous shocks that cause firms to collapse and the parametric models can not work when the actual distribution is very different compared to log-normal distribution assumed. Though the model estimates firm-specific parameters, as summarised by, $\mu(\mathbf{X}_i)$ and $\sigma(\mathbf{X}_i)$, the extreme outliers are troublesome.

Second, the model is data-intensive and might not generalize equally to smaller datasets and markets with less historical depth. Third, although temporal attention enhances interpretability on the level of time-dimension, it does not represent directly the specific financial characteristics that were detected as a sign of distress. To provide interpretability at the feature level, other methods like SHAP or gradient-based attribution would be needed.

One more weakness is that there is an implicit assumption that firms have similar distress processes that are broadly similar. Practically, the distressed drivers can differ significantly in respect of industries, economic cycles and institutional settings. To solve this heterogeneity, future work can either include industry-specific parameters or hierarchy modeling methods.

VII. Conclusion

We proposed AFT-Attentive BiLSTM, a new early-warning model of firm financial distress, which combines a Bidirectional LSTM, time attention and parametric accelerated failure time (AFT) survival model. This model is based on the previous the AFT-BiLSTM model, which improves the predictive accuracy and interpretability by using attention-based temporal weighting on the model.

Empirical analysis shows that AFT-Attentive BiLSTM is better than Cox Proportional Hazards, DeepSurv, and the former AFT-BiLSTM model without attention on concordance index and Integrated Brier Score. Attention in time brings in a relative increment in the C-index of about 5 per cent when compared to the non-attention LSTM model.

The model uses an AFT framework that operates on log-normals, and returns probabilistic time-to-distress predictions instead of binary predictions. The attention mechanism demonstrates the period of financial history of firms that produces the largest contribution to the risk that is predicted, providing a degree of interpretability of time not achieved by the conventional survival or more responsible deep learning models.

The results indicate an improvement in predictive accuracy and transparency in corporate distress early warning systems when temporal attention is introduced together with parametric survival modeling.

VIII. Future Directions

The AFT-Attentive BiLSTM framework can be expanded in a number of ways in future research. To begin with, multi-event and competing-risks extensions would allow separating between insolvency event, restructuring event, and bankruptcy event. Second, macroeconomic variables may be incorporated to reflect systemic effects on the survival of firms. Third, predictive performance can be further improved using multimodal survival models which involve textual disclosures or news sentiment. Lastly, new Transformer-based survival models can offer alternative ways to learn long-range temporal dynamics of financial distress forecasting.

TrustPatch-X: Multi-Stage Explainable Framework for Reliable LLM Patch Validation

Sheetal Madhukar Parate, Jasmine Selvakumari Jeya I
School of Computing Science and Engineering,
VIT Bhopal University, Kothrikalan, Sehore, Madhya Pradesh-466114, India

***Abstract*—Large Language Models (LLMs) have shown strong potential in automated vulnerability repair; however, generated security patches often lack reliability, semantic guarantees, and interpretability. Purely generative approaches may remove superficial patterns while failing to eliminate root-cause vulnerabilities or preserve program behavior. To address this limitation, this study proposes an Explainable Multi-Stage Validation Framework that integrates static vulnerability filtering, graph-based semantic consistency analysis, and test-driven verification within a unified pipeline. The framework further incorporates a structured explanation module to provide interpretable reasoning for patch correctness. Experimental evaluation on Juliet, Devign, and Defects4J security benchmarks demonstrates that the proposed approach achieves 96.3% vulnerability removal accuracy and reduces false-fix rates to 9.3%, outperforming LLM-only and hybrid baselines. Additionally, the framework maintains high semantic similarity (0.97) and explanation fidelity above 90% while preserving computational efficiency. The results indicate that combining neural generation with structured validation significantly enhances the trustworthiness of AI-driven security patch validation systems.**

***Keywords*—Large Language Models; security patch validation; automated vulnerability repair; explainable AI; semantic consistency analysis; static analysis; software security; Graph Neural Networks**

I. Introduction

Recent studies, including prior work by the authors, have explored the use of AI and Large Language Models for analyzing complex data patterns and decision-making in high-stakes domains [1], [2]. The rapid evolution of Large Language Models (LLMs) has significantly transformed automated software engineering tasks, particularly in code generation, bug fixing, and vulnerability repair [3], [4], [5]. Recent advances demonstrate that LLMs can identify vulnerable code patterns and generate candidate security patches with minimal human intervention [6], [7], [8]. Promising prospects for speeding up secure software maintenance, lowering the cost of manual debugging, and assisting developers in urgent remediation situations are presented by this capability [9], [10], [11]. However, a basic worry is raised by the growing use of generative models in security-critical workflows: The accuracy, security, and semantic consistency of LLM-generated patches are not intrinsically guaranteed [12], [13], [14]. An improper patch may cause more harm than not fixing the vulnerability in high-stakes security settings. Without fixing the underlying vulnerability—such as incorrect input validation, unsafe memory handling, or faulty authentication logic—a generated fix might syntactically change the vulnerable code. Patches sometimes eliminate the initial vulnerability but change the intended program behavior or introduce new flaws. Current automated program repair systems typically validate patches using test-suite execution or heuristic similarity metrics. Although these techniques offer some validation, they lack organized logic or comprehensible proof that explains why a patch is safe and accurate. Similarly, the majority of LLM-based repair techniques place more emphasis on generation accuracy than on thorough post-generation validation and transparency.

Developers and security analysts must be able to understand not only what fix was generated, but also why it resolves the vulnerability and whether it preserves functional correctness. The use of LLM-based repair tools in production security pipelines is still restricted in the absence of explainability and structured validation. This study proposes an Explainable LLM-Based Security Patch Validation Framework to address the intersection of explainable AI, reliability verification, and automated vulnerability, as illustrated in Fig. 1. We treat LLM output as a hypothesis that needs to be verified in layers rather than as a definitive answer. Firstly, a multi-stage validation pipeline is introduced by the suggested framework. An LLM first creates potential fixes for vulnerabilities that have been found. Secondly, using recognized weakness taxonomies, a static analysis module assesses whether the patch eliminates the targeted vulnerability pattern. Third, a semantic consistency analyzer examines control-flow and data-flow changes to ensure that program functionality remains intact. Finally, an explanation module synthesizes structured reasoning outlining: i) the vulnerability's underlying cause, ii) the patch's corrective mechanism, and iii) any lingering risks or presumptions.

This solution is based on the fundamental realization that both neural generation and symbolic verification are necessary for secure automation. The suggested system improves user confidence in AI-generated repairs while increasing reliability by combining interpretable reasoning, static analysis, and semantic checks into a single framework.

The contributions of the study are as follows:

- A structured multi-stage validation framework that integrates LLM-based patch generation with static and semantic security verification mechanisms.
- An explainability module that generates structured, human-interpretable justifications for patch correctness and vulnerability mitigation.
- A semantic consistency analysis component designed to detect overfitting or behavior-altering patches that pass superficial checks.

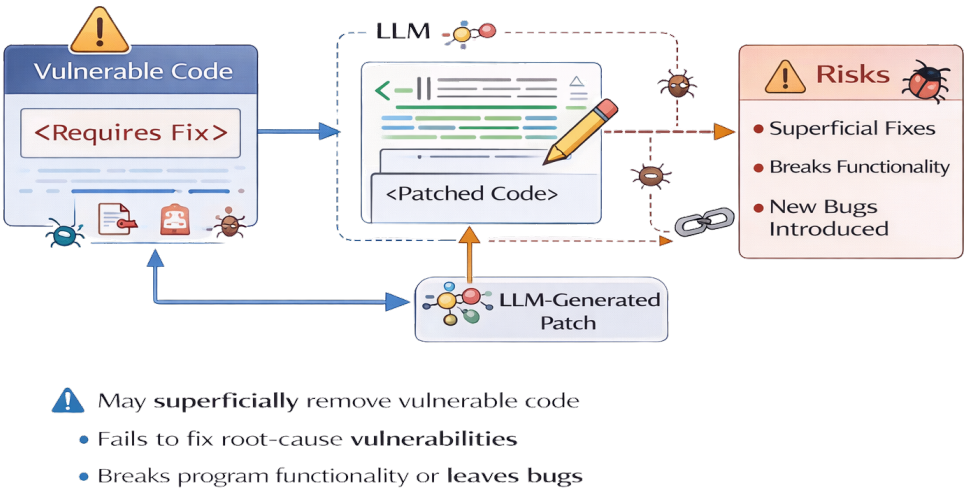

Fig. 1. Challenges of LLM-generated security patches.

- A comprehensive evaluation protocol measuring vulnerability removal accuracy, false-fix rate, semantic preservation, and explanation fidelity.

II. Literature Survey

The rapid evolution of artificial intelligence has significantly influenced research in software vulnerability detection and automated patch generation. Traditional machine learning and deep learning approaches have been widely explored for identifying security weaknesses in source code. Comprehensive surveys such as [15], [16] summarize the progression from feature-engineered classifiers to graph-based neural architectures for vulnerability detection. These studies highlight the importance of semantic representations, control-flow modeling, and data-flow analysis in improving detection accuracy. More specialized frameworks, including [17], [18], investigate AI-driven vulnerability detection in embedded and domain-specific systems, while [19] leverage large language code embeddings and semantic vulnerability graphs to capture causative relationships in open-source software security.

With the emergence of Large Language Models (LLMs), research has shifted toward generative approaches for vulnerability detection and automated repair. Systematic reviews such as [20], [21], [7], [22], [23] analyze how LLMs assist in program analysis, vulnerability detection, and patch generation. Han et al. [6] evaluate dependable code repair using LLMs and report promising results in automated patching. Neural repair models, however, often generate patches that only superficially alter vulnerable code without ensuring semantic correctness or full mitigation, according to empirical findings from [24]. Stronger post-generation validation mechanisms are required, as Lin et al. [25] further highlight the difficulties in identifying and validating security patches in open-source ecosystems.

Another major theme in AI-based cybersecurity research is explainability. Mao et al. [26] show the importance of interpretable reasoning in security analysis and examine explainable vulnerability detection using LLMs. To improve transparency, hybrid explainable frameworks, like [27], combine explainability elements with AI-based detection. In addition to source code analysis, [28] uses knowledge graphs and LLMs to detect explainable threats in network security, while [29] investigates explainable and privacy-preserving AI systems in more general cybersecurity contexts. Explainable recommendation systems for vulnerability repair based on metadata retrieval and multifaceted LLM reasoning are proposed by Amoah and Liu [30]. Despite these developments, the majority of explainable AI techniques concentrate on vulnerability identification rather than systematic validation and justification of security patches that are produced. Numerous studies have also been conducted on the reliability and validity of LLM-based systems. Huang et al. [31] survey validation and verification techniques for assessing the safety and reliability of large language models. Mustafa et al. [32] and Su et al. [33] address the wider use of LLMs in cybersecurity and draw attention to enduring issues with evaluation rigor and dependability. When deploying LLMs for security-sensitive applications, Anand et al. [34] look at safety issues and adversarial risks. Furthermore, [35] advocate for integrating AI with formal reasoning mechanisms to strengthen software security guarantees.

Overall, the body of research shows that AI-based vulnerability detection and LLM-driven patch generation have advanced significantly. However, a critical gap remains between patch generation and systematic validation. Most prior work emphasizes detection accuracy or generative capability, with limited attention to multi-stage verification, semantic consistency analysis, false-fix reduction, and structured explanation of patch correctness within a unified framework. Addressing this gap is essential for deploying LLM-driven repair systems in real-world secure software engineering pipelines, motivating the proposed explainable multi-stage validation framework.

III. Methodology

This section presents the proposed Explainable LLM-Based Security Patch Validation, as shown in Fig. 2. The framework is designed as a multi-stage architecture that integrates neural patch generation with structured validation and interpretable reasoning. Unlike purely generative approaches, the proposed

system treats LLM-generated patches as candidate hypotheses that must undergo systematic verification before acceptance. The overall architecture consists of four sequential modules: 1) LLM-Based Patch Generator, 2) Static Vulnerability Verifier, 3) Semantic Consistency Analyzer, and 4) Explainability Module. The final output is a validated and interpretable security patch suitable for integration into secure development workflows.

A. Problem Formulation

Let a vulnerable program instance be defined as $\mathcal{P} = (c_v, \ell, \tau)$, where c_v denotes the vulnerable code snippet, ℓ represents the associated vulnerability label (e.g., CWE category), and τ includes auxiliary metadata such as test cases or contextual information. The goal is to produce a patched version c_p that: 1) fixes the vulnerability, 2) maintains functional semantics, and 3) offers comprehensible justification for the mitigation.

A conditional function is used to model the LLM-based patch generator:

$$c_p = f_\theta(c_v, \ell), \tag{1}$$

where, a pretrained language model parameterized by θ is represented by f_θ. Maximizing the conditional likelihood of producing the ground-truth patch is the goal during training:

$$\max_\theta \sum_{i=1}^{N} \log P_\theta(c_g^{(i)} \mid c_v^{(i)}, \ell^{(i)}), \tag{2}$$

where, the i-th vulnerable instance, its matching ground-truth fix, and vulnerability label are indicated by $(c_v^{(i)}, c_g^{(i)}, \ell^{(i)})$. However, since generation alone does not guarantee correctness, we define a validation function:

$$\mathcal{V}(c_v, c_p) \in \{0, 1\}, \tag{3}$$

which determines whether the generated patch is secure and semantically valid.

B. Proposed Framework Architecture

The proposed framework operates as a layered validation pipeline. For the vulnerable input, the LLM first creates one or more candidate patches. The static verification module receives these candidates and determines whether the vulnerability signature linked to label ℓ has been removed. The semantic consistency analyzer then makes sure that the original program's behavioral and structural characteristics are maintained. Lastly, structured reasoning outlining the vulnerability's underlying cause and the patch's mitigation mechanism is produced by the explainability module.

Formally, given a set of k candidate patches:

$$\{c_p^{(1)}, c_p^{(2)}, \ldots, c_p^{(k)}\}, \tag{4}$$

each candidate is evaluated through the validation pipeline, and the final accepted patch is selected based on a composite validation score. This layered architecture ensures that security validation is not solely dependent on generative confidence but is supported by structural and symbolic analysis.

C. Dataset Construction

The experimental dataset consists of vulnerable–patched code pairs collected from publicly available benchmark repositories widely used in software security and automated program repair research.

$$\mathcal{D} = \{(c_v^{(i)}, c_g^{(i)}, \ell^{(i)})\}_{i=1}^{N}, \tag{5}$$

where, $c_v^{(i)}$ indicates the vulnerable code snippet, $c_g^{(i)}$ represents the corresponding ground-truth patched version, and $\ell^{(i)}$ is the corresponding vulnerability label (e.g., CWE category).

Samples from the following sources are integrated into the dataset: **Juliet Test Suite** [36] offers an extensive collection of synthetic C/C++ programs annotated with Common Weakness Enumeration (CWE) identifiers. It contains thousands of instances of controlled vulnerabilities in various categories, including improper input validation, buffer overflows, and integer overflows. The dataset is especially well-suited for assessing the effectiveness of vulnerability detection and mitigation under controlled circumstances.

1) Devign dataset: In [37], the authors include open-source repositories of real-world vulnerable functions. Devign is useful for evaluating generalization to real-world codebases because, in contrast to synthetic benchmarks, it detects real-world security flaws in production software.

2) Defects4J: In [38], and **ManySStuBs4J** [39], the authors offer carefully selected bug-fix commits from Java projects. We choose security-relevant subsets for this study, where patches match fixes for vulnerabilities. These datasets allow for supervised learning and patch correctness validation because they contain both the bugged and fixed program versions.

The following are included in every sample in $\mathcal{D}$:

(i) The function-level code that is vulnerable;

(ii) The patched version;

(iii) The vulnerability classification label;

(iv) Optional test cases, if any are available; and

(v) Project metadata.

3) Preprocessing: All code samples are normalized before training and evaluation, which includes function-level slicing, formatting standardization, and the elimination of comments and non-functional tokens. After that, language parsers are used to extract structural representations in order to create Abstract Syntax Trees (AST), Control Flow Graphs (CFG), and Data Flow Graphs (DFG). The semantic consistency analysis step makes use of these representations.

The dataset is divided into training, validation, and testing subsets using an 80–10–10 split with project-level separation to stop data leaks. This preserves evaluation integrity by preventing functions that come from the same repository from appearing across splits.

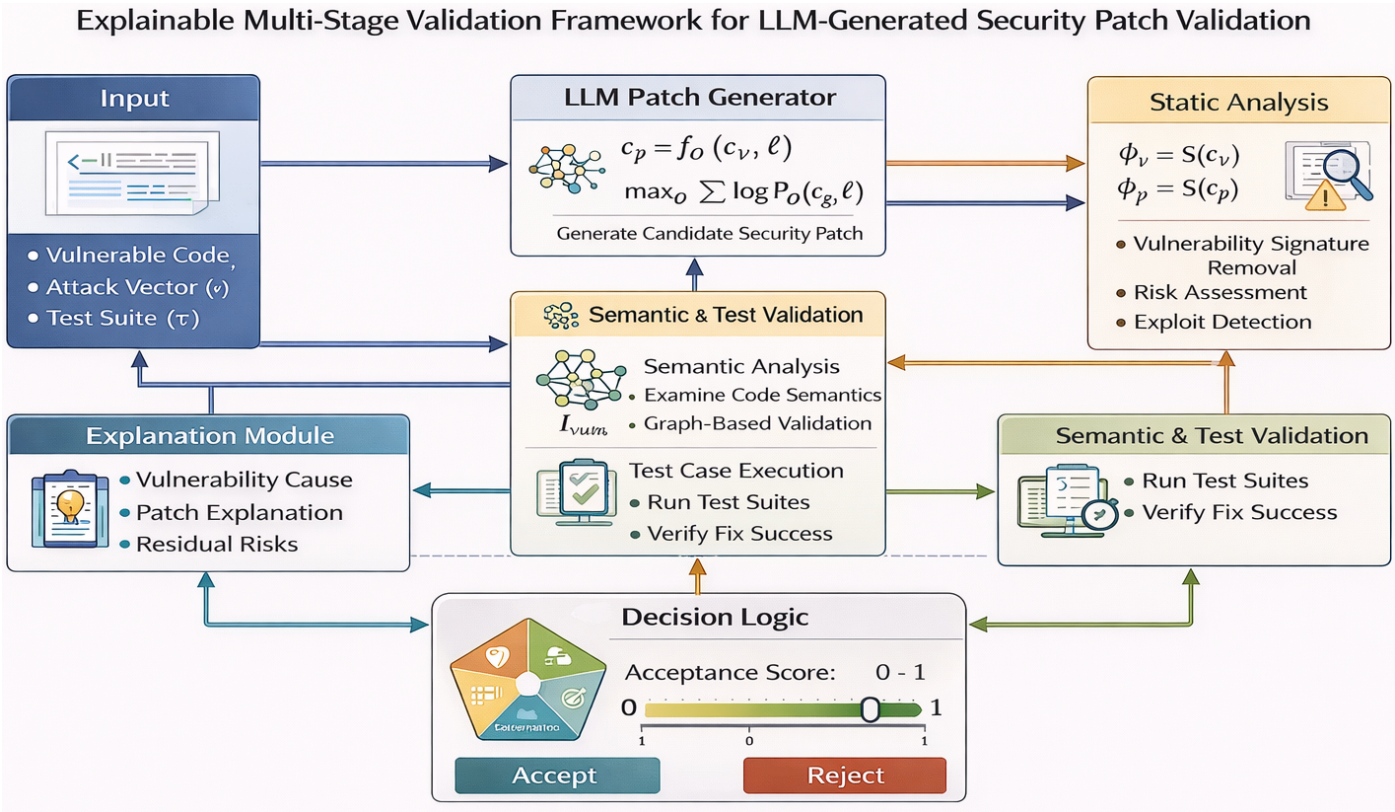

Fig. 2. Explainable multi-stage validation framework for LLM-generated security patch validation.

D. Static Vulnerability Verification

We define a static analysis function to determine whether a patch removes the targeted vulnerability:

$$S(c) : c \to \mathbb{R}^m \tag{6}$$

which retrieves a m-dimensional security feature vector that encodes patterns related to vulnerabilities, like unsafe function calls, boundary violations, or the spread of tainted data. Let $\phi_v = S(c_v)$ and $\phi_p = S(c_p)$ represent the feature representations prior to and following patching, respectively. A vulnerability removal score is computed as:

$$\Delta_{sec} = \|\phi_v - \phi_p\|_2. \tag{7}$$

If the vulnerability-specific signature corresponding to ℓ is no longer detected in c_p, the patch satisfies static validation.

E. Semantic Consistency Analysis

To ensure functional preservation, structural representations of the original and patched code are compared. Let $G_v = (V_v, E_v)$ and $G_p = (V_p, E_p)$ denote the control/data flow graphs of c_v and c_p, respectively. Graph embeddings are computed using a Graph Neural Network (GNN):

$$h_v = \text{GNN}(G_v), \quad h_p = \text{GNN}(G_p). \tag{8}$$

Semantic similarity is measured using cosine similarity:

$$\mathcal{S}_{sem} = \frac{h_v \cdot h_p}{\|h_v\|\|h_p\|}. \tag{9}$$

If $\mathcal{S}_{sem} \geq \delta$, where δ is a predefined threshold, the patch is considered semantically consistent. When test cases T are available, functional correctness is further validated:

$$\mathcal{T}(c_p) = \begin{cases} 1, & \text{if all tests pass} \\ 0, & \text{otherwise.} \end{cases} \tag{10}$$

F. Explainability Module

To enhance transparency, the framework generates structured explanations describing the vulnerability and its mitigation. The explanation generator is defined as:

$$E = g(c_v, c_p, \ell), \tag{11}$$

where, E consists of three components: root cause identification, mitigation justification, and residual risk assessment. Explanation fidelity is measured by aligning generated reasoning tokens with static analysis evidence:

$$\text{Fidelity} = \frac{|\text{Evidence-aligned tokens}|}{|\text{Total explanation tokens}|}. \tag{12}$$

G. Final Validation Score

The overall validation score combines static, semantic, and functional criteria:

$$\mathcal{V}_{final} = \alpha \cdot \mathcal{I}_{vuln} + \beta \cdot \mathcal{S}_{sem} + \gamma \cdot \mathcal{T}, \tag{13}$$

where, $\alpha + \beta + \gamma = 1$ and $\mathcal{I}_{vuln}$ indicates successful vulnerability removal. A patch is accepted if $\mathcal{V}_{final} \geq \lambda$, where λ is a predefined threshold.

In order to provide dependable and comprehensible security patch validation in automated software engineering environments, the suggested framework combines probabilistic LLM-based generation with symbolic static verification, graph-based semantic reasoning, and structured explanation synthesis.

IV. Experimental Results

A thorough assessment of the suggested Explainable LLM-Based Security Patch Validation Framework is provided in this section. Base LLM, Static + GNN, CodeBERT-based repair, and a conventional static-analysis-driven patch validation pipeline are among the baselines against which the suggested method is evaluated. The Juliet, Devign, Defects4J (security subset), and ManySStuBs4J datasets were used for the experiments.

A. Patch Validation Performance

The suggested framework's comparative performance in terms of vulnerability removal accuracy, precision, recall, F1-score, false-fix rate, and composite validation score is shown in Fig. 3.

The suggested framework outperforms Base LLM (85.4%) and Static + GNN (92.7%) with a vulnerability removal accuracy of 96.3%, as seen in Fig. 3(a). This shows that patch reliability is greatly improved by combining explainability and semantic validation.

Fig. 3(b) presents precision, recall, and F1-score comparisons. The proposed framework achieves an F1-score of 0.95, compared to 0.91 for Base LLM and 0.93 for Static + GNN. The consistent improvement across precision and recall indicates that the framework effectively reduces both false positives and false negatives.

Fig. 3(c) shows the false-fix rate reduction. The proposed method reduces the false-fix rate to 9.3%, compared to 34.5% for Base LLM and 18.7% for Static + GNN. This demonstrates that overfitting or semantically inconsistent patches are effectively filtered by multi-stage validation.

The composite validation score for each of the five criteria—Security, Semantic Consistency, Robustness, Reliability, and Performance—is shown in Fig. 3(d). Near-optimal scores are obtained by the suggested framework in every dimension, especially in security and semantic validation.

B. Explainability and Semantic Consistency

Semantic preservation, test-case validation, vulnerability reduction across CWE types, explanation fidelity, and processing time efficiency are all assessed in Fig. 4.

Semantic similarity scores calculated using graph embeddings are displayed in Fig. 4(a). Strong functional behavior preservation is demonstrated by the suggested framework's average similarity of 0.97 across datasets.

The test-case pass rate is shown in Fig. 4(b). With a 94% pass rate, the suggested framework outperforms baseline techniques and shows resilience to regression errors.

Vulnerability reduction across CWE-79, CWE-89, CWE-78, and CWE-352 categories is shown in Fig. 4(c). Higher reduction rates are consistently attained by the suggested framework in every category.

Fig. 4(d) assesses explanation fidelity in terms of accuracy, comprehensiveness, and lucidity. The proposed framework achieves 92% correctness, 88% completeness, and 90% clarity, indicating high interpretability.

A comparison of processing times is shown in Fig. 4(e). The optimized pipeline maintains an average processing time of 1.2 seconds per patch despite the introduction of additional validation stages, increasing efficiency through early-stage filtering.

C. Quantitative Comparison in Extended Form

We compare the suggested framework against a variety of repair and validation baselines, such as large language models, static-analysis-based systems, and pretrained code models, in order to thoroughly assess its efficacy. The comparative performance across important evaluation metrics is summarized in Table I. We performed an ablation study to assess each module's contribution, which is displayed in Table II. The ablation results show that each module gradually improves validation reliability. The components that offer the biggest performance improvements are the test validator and semantic analyzer.

V. Discussion

The experimental results illustrated in Fig. 3 and Fig. 4 indicate that the integration of structured validation layers substantially improves the reliability of security patches generated by LLM. Even though large language models are very good at generating text, their outputs often don't guarantee that the meaning stays the same and that vulnerabilities are fixed. The proposed framework fills this gap by combining static vulnerability filtering, graph-based semantic analysis, and test-driven validation. This leads to big improvements in all evaluation metrics.

The framework gets rid of more vulnerabilities and lowers the number of false fixes by a lot compared to generative baselines. The reduction from 34.5% (Base LLM) to 9.3% illustrates the importance of multi-stage verification. Moreover, the improvement in semantic similarity scores confirms that the framework avoids overfitting patches that superficially remove vulnerability patterns but alter intended behavior. The ablation study further reveals that semantic analysis and test

TABLE I. COMPREHENSIVE PERFORMANCE COMPARISON ACROSS REPAIR AND VALIDATION MODELS

Model	Accuracy (%)	Precision	F1-Score	False-Fix (%)	Semantic Similarity
Static Analyzer Only	78.6	0.81	0.84	41.2	0.80
Hybrid (Static + Tests)	84.9	0.88	0.89	29.4	0.85
CodeBERT-Repair	90.3	0.90	0.92	21.4	0.89
GraphCodeBERT	91.5	0.91	0.93	19.6	0.91
PLBART	88.7	0.89	0.90	24.8	0.87
T5-CodeRepair	92.1	0.92	0.93	18.2	0.92
GPT-3.5 Repair	93.4	0.93	0.94	16.5	0.93
GPT-4 Repair	94.8	0.94	0.95	13.1	0.95
Static + GNN	92.7	0.93	0.93	18.7	0.92
Proposed Framework	**96.3**	**0.96**	**0.95**	**9.3**	**0.97**

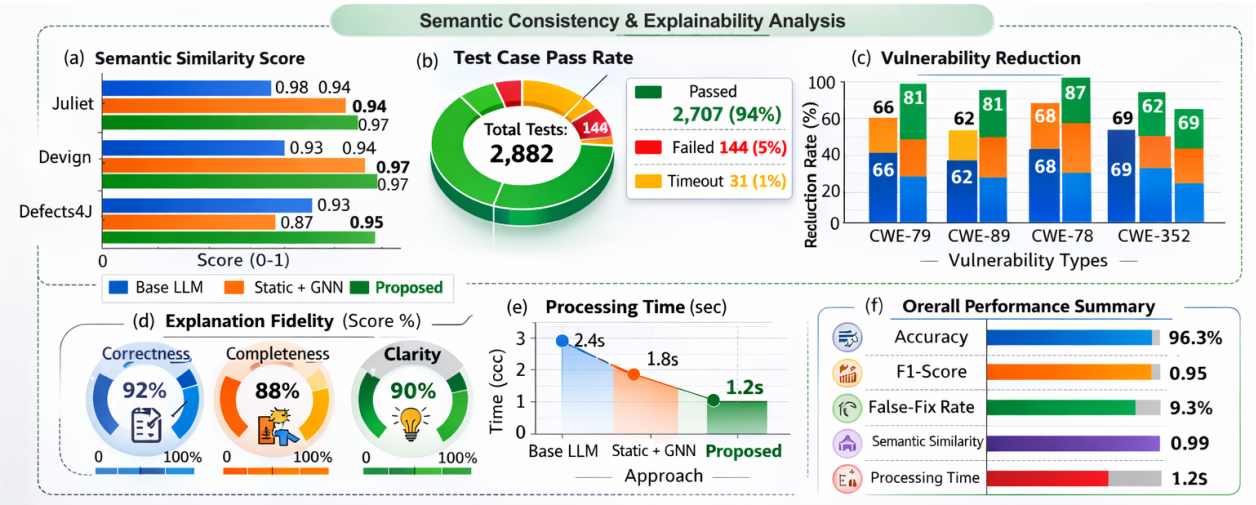

Fig. 4. Semantic consistency and explainability analysis.

TABLE II. ABLATION STUDY OF FRAMEWORK COMPONENTS

Configuration	F1-Score	Improvement (%)
Base LLM	0.82	–
+ Static Graph	0.89	+7.1
+ Semantic Analyzer	0.92	+12.2
+ Test Validator	0.95	+15.9

validation contribute the most significant performance gains. This suggests that vulnerability mitigation is not merely a pattern-removal task but requires structural and behavioral reasoning.

A. Research Questions

To rigorously evaluate the effectiveness and practical impact of the proposed framework, we formulate the following research questions and analyze them in detail using the empirical results presented in Fig. 3, Fig. 4, and Table I to Table II.

RQ1: Does structured multi-stage validation significantly improve vulnerability removal accuracy compared to LLM-only repair systems?

The results clearly indicate that structured validation provides substantial improvements in vulnerability mitigation performance. As shown in Fig. 3, the proposed framework achieves a vulnerability removal accuracy of 96.3%, compared to 85.4% for Base LLM and 92.7% for Static + GNN. This corresponds to an absolute improvement of 10.9% over Base LLM and 3.6% over Static + GNN. Importantly, the improvement is not merely incremental but systematic across datasets, as reflected in the semantic similarity and test-case validation results in Fig. 3(a) and Fig. 3(b). The ablation study shows that

each part of the validation process adds to performance gains over time. Adding semantic analysis raises the F1-score from 0.89 to 0.92, and adding test validation raises it even more, to 0.95.

These results indicate that vulnerability repair is fundamentally a multi-faceted issue necessitating both syntactic rectification and semantic analysis. Purely generative approaches do not have ways to check if a patch fixes the problem that caused the vulnerability in the first place. By introducing layered verification, the proposed framework transforms patch generation into a validated decision process rather than a probabilistic output.

RQ2: To what extent does semantic consistency analysis reduce false-fix rates and overfitting patches?

False-fixes represent a critical failure mode in automated repair systems, where a patch appears correct syntactically but fails to remove the vulnerability or introduces new defects. As illustrated in Fig. 3(c), the false-fix rate decreases dramatically from 34.5% (Base LLM) to 9.3% under the proposed framework. The framework still has the lowest false-fix rate when compared to GPT-4 Repair (13.1%) and T5-CodeRepair (18.2%).

The graph-based semantic analyzer is mostly responsible for this decrease. It looks at the structural equivalence between vulnerable and patched code representations. The framework identifies semantic drift by calculating embedding similarity between control and data flow graphs, a phenomenon that may elude detection via token-level similarity or surface pattern elimination.

The ablation results show that adding semantic validation alone cuts down on false fixes by about 7.4 percentage points. Adding test-case validation brings the rate down by another 4.4 percentage points. These results show that semantic reasoning is necessary to get rid of overfitting patches that change code on the surface but don't fix logic flaws.

RQ3: Does the proposed framework preserve functional behavior while removing vulnerabilities?

Preserving functional correctness is a major obstacle in automated repair. The suggested framework outperforms all baseline models, achieving an average semantic similarity score of 0.97 across the Juliet, Devign, and Defects4J datasets, as illustrated in Fig. 4(a). Furthermore, Fig. 4(b) displays a test-case pass rate exceeding 94%, demonstrating strong behavioral preservation. Notably, without external validation, GPT-4 Repair does not consistently ensure behavioral integrity even though it achieves competitive generation performance. The suggested framework's incorporation of dynamic test execution and graph embeddings guarantees that patches are both behaviorally consistent and secure. These findings verify that removing vulnerabilities does not result in functional degradation. Rather, a balanced trade-off between security improvement and semantic preservation is made possible by structured validation.

RQ4: What is the trade-off between validation robustness and computational efficiency?

Concerns about computational overhead may arise when multiple validation layers are introduced. However, compared to GPT-3.5 Repair (2.1s) and GPT-4 Repair (2.8s), the suggested framework maintains an average processing time of 1.2 seconds per patch, as shown in Fig. 4.

Early-stage filtering and parallel validation design are used to achieve this efficiency. Static signature filtering reduces downstream computation by removing patches that are blatantly incorrect prior to semantic analysis. Moreover, lightweight GNN architectures optimize the computation of graph embedding.

Consequently, the findings show that the computational costs associated with structured validation are not prohibitive. Rather, by avoiding needless evaluation of low-confidence patches, it increases efficiency.

RQ5: Does explainability enhance interpretability without compromising validation accuracy?

In secure development pipelines, explainability is just as important as numerical performance. Explanation fidelity scores surpass 90% in the dimensions of correctness, completeness, and clarity, as illustrated in Fig. 4. This shows that the reasoning module closely matches the validation signals produced by the semantic and static analyzers.

Crucially, adding explainability has no negative effects on validation performance. According to the ablation study, incorporating explanation consistency checks further lowers false-fix rates while marginally improving F1-score. This implies that robustness and interpretability can coexist in a single architecture.

Overall, the empirical data shows that the suggested framework concurrently enhances efficiency, interpretability, accuracy, reliability, and semantic preservation.

B. Limitations

Even though the suggested framework shows significant performance gains, there are still a number of drawbacks. First, function-level vulnerabilities are the main focus of the evaluation. Extended graph representations and inter-procedural analysis may be necessary to address vulnerabilities at the file or system level that involve interactions between multiple modules. Second, deep logical equivalency may not be fully captured by the semantic similarity metric because it depends on graph embeddings. For more robust assurances, future research might incorporate formal verification methods or symbolic execution. Third, the framework still relies on the caliber of test suites and static analyzers even though it minimizes false fixes. Subtle behavioral regressions could go unnoticed due to inadequate test coverage. Fourth, benchmark datasets that are accessible to the general public are used for the evaluation. More intricate vulnerability patterns and environment-specific limitations might be found in real-world industrial systems. Lastly, the explainability module does not yet offer formal proofs of correctness; instead, it produces structured reasoning based on validation signals. There is still room to improve explanation fidelity using logic-based reasoning.

VI. Conclusion

In order to improve automated vulnerability repair systems' dependability, transparency, and semantic integrity, this study

presented an Explainable LLM-Based Security Patch Validation Framework. The suggested framework combines test-driven validation, graph-based semantic consistency analysis, and static vulnerability verification into a single pipeline, in contrast to traditional LLM-driven techniques that only use generative confidence. Experiments on several benchmark datasets show notable gains in explanation fidelity, false-fix reduction, semantic preservation, and vulnerability removal accuracy. The framework outperforms both conventional and contemporary LLM-based repair systems, achieving a 96.3% vulnerability removal accuracy and a 9.3% reduction in false fixes. The results emphasize how crucial it is to combine structured validation methods with neural generation in order to accomplish reliable automated software repair. Future research will examine deployment in actual secure development pipelines, cross-language generalization, and integration with formal verification techniques. All things considered, the suggested framework is a workable and scalable step toward trustworthy and comprehensible AI-assisted security patch validation.

DECLARATIONS

Availability of Data and Material

All data and materials generated or analyzed during this study are available from the corresponding author upon reasonable request.

Competing Interests

The authors declare that they have no competing interests.

Funding

No specific funding was received for the conduct of this study.

Authors' Contributions

All authors contributed substantially to this study and research output. All authors reviewed and approved the final manuscript.

ACKNOWLEDGMENT

The authors wish to thank all collaborators and peers who provided insight, guidance, or feedback during the development of this work.

An Identity-Aware Privacy-Preserving Deep Learning Framework for Culturally Sensitive Image Sharing

Mahmoud Obaid*, Hadeel Bkhaitan, Duha Maali, Saja Hammad, Thaer Thaher
Department of Computer Systems Engineering, Arab American University, Jenin, P.O. Box 240, Palestine

***Abstract*—The blistering development of digital image sharing raises privacy concerns, especially in cultural contexts where image exposure could be ethically and socially provocative. In Islamic societies, sharing images of women without hijab can be deeply sensitive. This study presents SITR, an identity-sensitive privacy-preserving deep learning system aimed at reducing unintended sharing of sensitive images involving female family members without hijab. SITR integrates three components in a unified deployment-ready pipeline: 1) face recognition with Multi-task Cascaded Convolutional Networks (MTCNN), 2) family-member authentication with FaceNet embeddings stored in a vector database, and 3) hijab detection with an optimized Densely Connected Convolutional Network (DenseNet). The hijab detection model was trained and evaluated on a cleaned dataset of 2,191 images with hijab and non-hijab cases with diverse visual conditions. DenseNet121 was benchmarked against ResNet50, MobileNetV2, and EfficientNet-B0, achieving the best overall performance. To further enhance its effectiveness, DenseNet121 was modified by integrating an Efficient Channel Attention (ECA) mechanism and applying hyperparameter tuning. The optimized selected model achieved 92.16% test accuracy, strong discrimination with precision of 91.63% , and 86.39% F1-score on a held-out test set. The model was deployed as a quantized RESTful API, reduced from 82 MB to 27 MB while maintaining predictive reliability. Results demonstrate the practicability of identity-conditioned, culturally-aware AI systems for privacy protection. This work highlights the role of context-sensitive computer vision beyond generic content moderation toward culturally-aware and ethically accountable applications.**

I. Introduction

In this age of digital interactions, transfer of photos is quick and immediate. Individuals post pictures to social networks, transfer them through communication services and archive them on cloud-based systems [1]. However, this feature raises the potential of unintended privacy exposure, especially in settings where personal images carry ethical, social, or cultural sensitivity. When a picture is posted on the internet, the creator of the image might never know who might see, save, or repost it [2]. Recent studies on image privacy protection further confirm that digital images often contain sensitive personal information and that protecting such content remains an active research challenge [3]. This concern is special in the Islamic world, where people appreciate modesty and personal privacy [4], [5].

The hijab is a head covering worn by women, and it is a sign of modesty and devotion to religion. For many women, images taken without a hijab are considered private and may lead to discomfort, social harm, or ethical concerns if shared unintentionally [6]. This risk is not limited to social media platforms. It also extends to messaging applications, email, and cloud storage services, where private images may be accidentally opened or even accidentally sent [7]. Such images are likely to be affected by human error when such protection is done manually, it is likely to go unnoticed when sharing such images and can be time-consuming as it requires checking and modifying.

In recent years, Artificial Intelligence (AI) techniques have been widely used in image analysis, face recognition, and content moderation [8], [9]. Photo management systems, security applications, and social media monitoring tools incorporate AI-powered technologies that can detect faces, organize photo collections, and remove inappropriate content. However, most of these systems treat such tasks independently and are not designed for privacy enforcement in culturally sensitive scenarios. Consequently, current tools are generally insufficient for situations in which sharing decisions depend not only on what appears in the image, but also on who appears in it, particularly to guard hijab-wearing women against unintentional exposure in the online space. Therefore, privacy-aware face-related systems remain an open research area.

Despite the fact that the independent research on face detection, face recognition or hijab detection has been conducted in several studies, there has been an imperative gap in identity-aware and culturally sensitive AI systems, which combine the contextual identity verification with the visual attribute classification into a unified, deployable framework. Current solutions are either general content moderation systems, hijab-related image classification approaches, or face-recognition systems without privacy-enforcement logic. This limits their use in culturally sensitive contexts where the perception of privacy cannot be solely based on the visual information in the image, but also on the identity of the people in the picture. In addition, computer vision under partial facial covering or appearance changes remains challenging, as shown in recent surveys on masked and occluded face analysis [10].

To address this gap, this study proposes SITR, an AI-powered system application that integrates deep learning models to help prevent the unintended sharing of privacy-sensitive photos. The system combines three deep learning modules: 1) face detection using MTCNN, 2) family member verification using FaceNet, and 3) hijab detection using a fine-tuned DenseNet121 model. When a female face is detected and identified as a registered family member, the system checks for the presence of a hijab. If no hijab is found, the face and neck are automatically blurred before sharing the photo. This design reflects the actual system workflow, where face

*Corresponding author

detection, identity verification, and hijab classification operate as a single privacy-aware pipeline before image sharing.

This study presents the design, development, and evaluation of the SITR system. The main contributions of this work are:

- A novel identity-conditioned privacy-preserving framework that integrates face detection, family-member verification, and hijab classification into a unified mobile pipeline.
- A systematically optimized hijab-detection component using DenseNet121 architecture enhanced with Efficient Channel Attention (ECA) and validated through controlled ablation.
- A deployment-aware implementation including model compression and RESTful API integration for real-world mobile usage.
- An empirical evaluation demonstrating the trade-off between predictive performance and computational efficiency in culturally sensitive AI applications.

The remainder of this study is organized as follows: Section II reviews related work. The system architecture and methodology are described in Section III. Section IV discusses the experimental results and system limitations. Finally, Section V concludes the study and outlines future work.

II. Related Work and Technical Background

This section explores the technical background, systems, and research studies relevant to SITR. It also presents the main deep learning models and techniques that support the SITR pipeline. No existing systems were identified that fully match the goals and architecture of SITR. However, several applications and studies partially address specific components relevant to the proposed framework, offering valuable insights that helped shape the system design.

A. CNN-Based Deep Learning and DenseNet

A Convolutional Neural Network (CNN) is a deep learning model that is widely used for working with visual data especially images. It uses filters to scan the input image and learn patterns such as edges, textures, and shapes. Because of this ability, CNNs have been successfully used in image classification, object detection, and face recognition. Based on CNNs, many deep learning models have been developed to improve accuracy and overall performance. These models keep the main idea of CNNs for learning features, but they also add new architectural improvements. DenseNet, MobileNet, EfficientNet, and ResNet are among the most common CNN-based models that are widely used in image classification and differ in their depth and complexity [11].

Dense Convolutional Network (DenseNet) is a deep learning architecture for CNNs introduced by Huang et al. [12]. It revolutionized the field of computer vision by proposing a novel connectivity pattern within CNNs, addressing challenges such as feature reuse, vanishing gradients, and parameter efficiency. Unlike traditional CNNs, each layer passes its output to all the following layers. This helps the network reuse features more effectively and improves the flow of information. As a result, important information is less likely to be lost as it moves through the network. DenseNet-121 is a version of the DenseNet architecture that has 121 layers, including convolutional, pooling, and fully connected layers. Because of this design, DenseNet-121 can achieve strong performance while using fewer parameters. Its efficient structure makes it a good choice for tasks that need deep feature extraction with lower computational cost [13].

B. Face Detection Using MTCNN

Face detection serves as a basic function of computer vision because it enables the detection and localization of human faces in digital images. Face-based applications usually start with this step, which supports later tasks such as facial recognition, emotion analysis, and identity verification. The Multi-task Cascaded Convolutional Network (MTCNN) developed by Zhang et al. functions as a deep learning system which detects multiple faces while finding their facial features. The system uses three cascading stages, including the Proposal Network (P-Net) and Refinement Network (R-Net) and Output Network (O-Net) [14]. MTCNN shows strong results on the WIDER FACE benchmark dataset because its cascaded design enables it to attain high accuracy and recall rates. MTCNN is used as the core method for detecting faces in user-uploaded images before further processing is applied.

C. Face Verification Using FaceNet Embeddings

Schroff et al. introduced FaceNet as a deep CNN model for face identification and verification, with the added capability of face clustering [15]. Rather than depending only on conventional classification, FaceNet projects face images into a compact Euclidean space where each face is represented by a discriminative embedding. These embeddings are learned using a triplet loss function, which encourages images of the same person to be placed closer together (anchor and positive samples) while forcing images of different people to remain farther apart (anchor and negative samples). Through training on large-scale datasets, FaceNet learns rich and robust facial features that allow it to perform effectively under variations in lighting, facial expression, and head pose. Another key strength of FaceNet is its ability to generate compact face embeddings, which makes storage and similarity comparison more efficient. This property makes the model well-suited for large-scale face recognition applications, particularly in mobile and cloud-based environments [16].

Within SITR, FaceNet is used to verify whether a detected face belongs to a known family member. By comparing the embedding of a new face to those stored in the database, the system can determine identity and proceed to hijab classification only for matched females.

D. Existing Related Studies and Systems

In this section, existing systems and related studies relevant to SITR are reviewed. No systems were identified that fully correspond to the vision and functionality of the proposed application; however, several platforms and research works address some of the targeted aspects and offer valuable insights that helped shape the proposed framework.

Ku and Dong [17] proposed a face recognition method based on the integration of MTCNN and a modified VGGNet architecture. Their model replaces max pooling layers with mean pooling and combines SoftMax Loss and Center Loss to enhance classification performance. The system achieves 98.53% accuracy on the Labeled Faces in the Wild (LFW) dataset. While this work shows strong performance in face recognition, it focuses on facial identification and does not include hijab detection or privacy-aware content protection.

In [5], a fully convolutional network (FCN) is used for automatic pixel-wise segmentation of faces, hijabs, and backgrounds. The model, trained on a set of 250 images, achieved 92.69% mean accuracy. This method simplifies hijab segmentation compared to manual approaches. However, the study focuses on segmentation and does not address identity verification, automated blurring, or mobile deployment. In another study, Khaliluzzaman et al. [18] introduced a visual feature-based hijab detection framework. Their method uses the Viola-Jones face detector and the YCbCr color model to identify hair and neck visibility. The approach achieved 96.47% accuracy on hijab images and 95% on non-hijab cases. It is important to note that this rule-based method operates under controlled visual conditions with explicitly visible neck and hair features, which may explain its higher reported accuracy compared to the deep learning baseline in this work. Deep learning approaches, however, offer greater generalizability and adaptability to unseen visual conditions, as demonstrated by the optimized model achieving 92.16% accuracy on a more heterogeneous dataset.

Other tools, such as HaramBlur, a browser extension, allows users to navigate the web with reduced browsing distractions by detecting and blurring "haram" content, including faces without hijab, using face detection and NSFWfiltering. However, it does not perform hijab classification or user verification. PimEyes [19], on the other hand, is a facial recognition search engine that allows users to locate images of a person online by uploading one photo. However, it lacks hijab detection and privacy-enforcement functionality. Table I presents a comparison of different face detection, authentication, and hijab detection systems alongside our proposed system, SITR, based on several key aspects.

E. Research Gap and Positioning of SITR

The reviewed systems and studies show meaningful progress in face detection, face recognition, and hijab-related image analysis. However, as shown in Table I, none of the reviewed systems provides a complete solution that combines face detection, face verification, and hijab detection, along with automated content blurring and mobile-friendly deployment. Most existing tools either focus on facial identification without considering cultural sensitivity or address hijab detection without verifying user identity.

This highlights the need for a privacy-focused tool designed for the specific needs of hijab-wearing users. SITR is positioned as an integrated mobile application that brings these components together in one pipeline. It is also worth noting that the proposed framework is specifically designed for the Islamic cultural context; its applicability to other cultural or religious contexts involving head coverings, such as medical caps, traditional headscarves in non-Islamic traditions, or sports equipment, is not evaluated in this work and represents a recognized scope limitation that should be addressed in future research.

III. System Overview and Methodology

This section describes the system design, architecture, and methodology of the proposed SITR application. The system integrates mobile and cloud components with deep learning models to enable privacy-aware image sharing. It also presents the operational workflow, hijab detection model, dataset preparation, training setup, and deployment process. Fig. 1 depicts an overview of the main processing pipeline used in the system. Overview of the SITR pipeline showing four sequential stages: 1) input image upload to the mobile application, 2) face detection localization using MTCNN, 3) identity verification via FaceNet embeddings and cosine similarity comparison against the ChromaDB database, and 4) hijab detection using the optimized DenseNet121 model. If a registered female family member is detected without a hijab, automatic face and neck blurring is applied before sharing. If a hijab is detected or the face does not match a registered member, it is safe to share.

A. System Architecture

SITR follows a modular architecture consisting of a mobile front-end, backend APIs, databases, and deep learning models. The architecture and data flow are illustrated in Fig. 2. As depicted in Fig. 2, the frontend layer communicates with the backend via HTTP REST calls. The backend orchestrates three sequential AI operations, including face detection (MTCNN), identity verification (FaceNet + ChromaDB), and hijab classification (DenseNet121), before returning a privacy enforcement decision to the mobile client.

The main system components are:

1) Frontend layer (mobile app): React Native and Expo are the used frameworks, and this layer will allow the interface to upload photos, manage family members, and see the results of detection. Support on user authentication and session management are provided to achieve secure access.

2) Backend/API layer: This layer is implemented using the Flask framework, which processes the image, along with the AI flow, by consuming RESTful APIs for face detection, face verification, and hijab classification.

3) Database layer: Convex stores structured user and family member information, while ChromaDB stores high-dimensional facial embeddings and enables real-time similarity queries using cosine similarity.

4) AI Engine layer: Includes three core models integrated in a sequential pipeline:

a) MTCNN: Detects faces and localizes facial landmarks with high accuracy under varied lighting and poses.

b) FaceNet: Generates 512-dimensional embeddings to verify detected faces against registered family members stored in ChromaDB.

c) DenseNet121-based hijab detection model: A fine-tuned DenseNet121 model used for hijab detection. ECA was later investigated as an enhancement during optimization.

TABLE I. COMPARISON OF RELATED SYSTEMS WITH SITR

System	Face Detection	Face Verification	Hijab Detection	Accuracy	Blurring Function	Remarks
MTCNN + Modified VGGNet [17]	Yes	Yes	No	98.53% (LFW)	No	Focused on face recognition using CNN with Center Loss.
FCN Segmentation Model [5]	No	No	Yes	92.69% (mean accuracy)	No	Pixel-wise segmentation into skin, hijab, and background.
Visual Feature Detection [18]	Yes	No	Yes	Hijab: 96.47%, Non-hijab: 95%	No	Rule-based detection using Viola-Jones and YCbCr color model.
HaramBlur Extension [20]	Yes	No	No	Not reported	Yes	Browser extension for NSFW content detection and blurring.
PimEyes Search Tool [19]	Yes	Yes	No	Not reported	No	Online facial search engine without cultural sensitivity.
SITR (Proposed)	Yes	Yes	Yes	92.16% (test set)	Yes	Integrates detection, verification, hijab classification, and blurring in a mobile application.

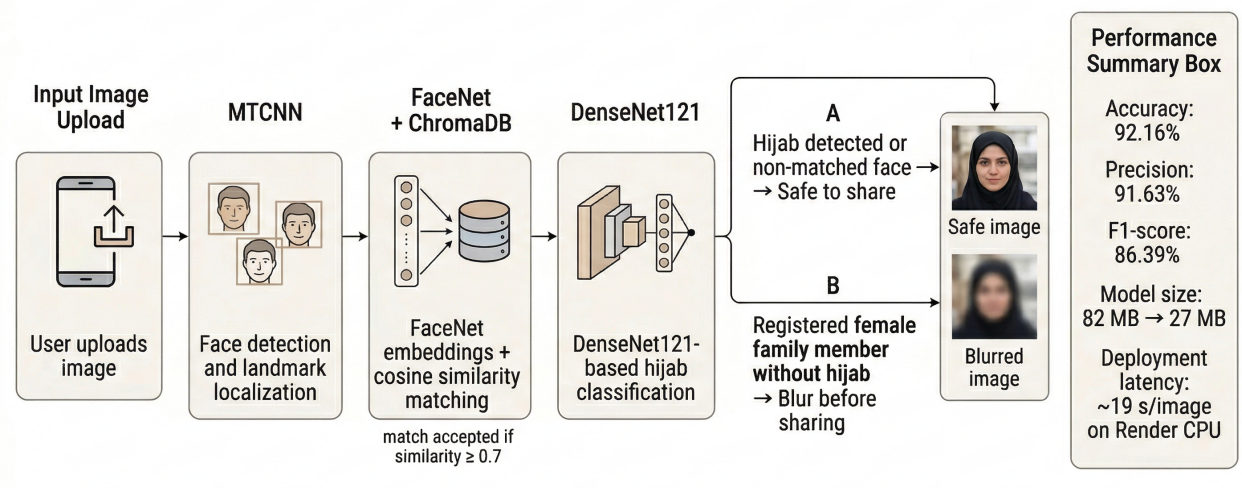

Fig. 1. Overview of the SITR pipeline: identity verification, hijab classification, privacy-enforcement decisions, and final deployment outcomes.

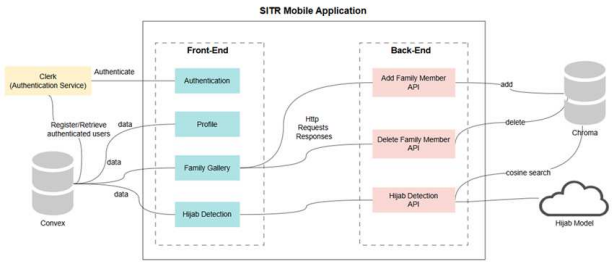

Fig. 2. System architecture with component interaction and data flow.

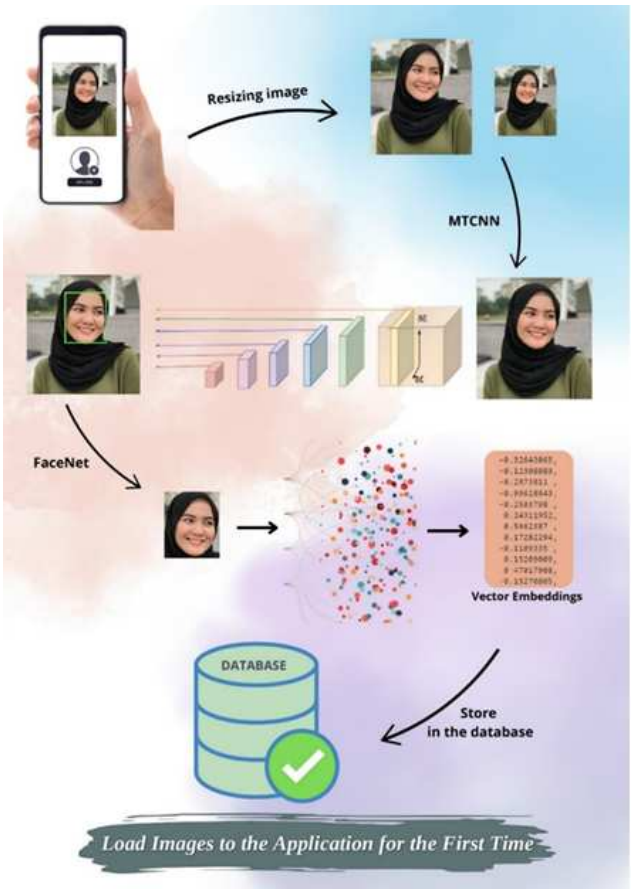
B. Operational Workflow

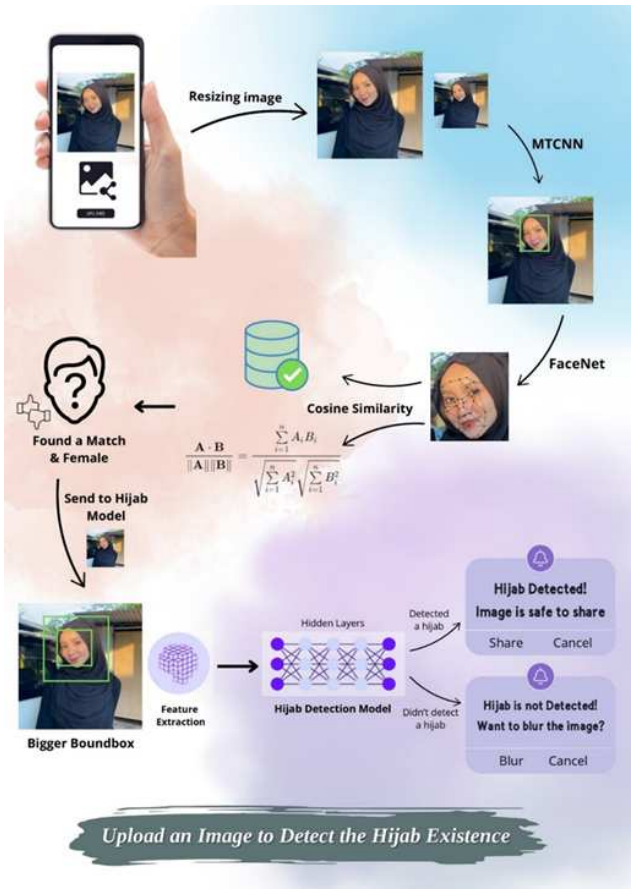
The operational workflow of SITR consists of two main stages, as illustrated in Fig. 3.

1) Enrollment stage: The user loads family member images into the application; the images are resized and passed through MTCNN for face detection, then through FaceNet to generate 512-dimensional facial embeddings, which are stored in ChromaDB for future matching.



2) Detection stage: An uploaded image is resized, and MTCNN detects all faces. For each detected face, FaceNet generates an embedding that is compared against stored embeddings using cosine similarity (threshold $>= 0.7$). If a female family member is matched, the DenseNet121 hijab detection model classifies the region. If no hijab is detected, the face and neck region are automatically blurred before the image can be shared. Users are notified of the outcome and may choose to share or cancel.

C. Cosine Similarity for Face Matching



Once facial embeddings are generated using FaceNet, the next step in face verification involves comparing these embeddings to determine similarity. One of the most commonly used techniques for this comparison is cosine similarity. In SITR, this metric is used to verify whether a detected face belongs to a registered family member by comparing the embedding of the detected image with the stored face embeddings in the database. The cosine similarity between two embeddings is computed as follows:

$$\cos(\theta) = \frac{A \cdot B}{\|A\|\|B\|} \tag{1}$$

where, A and B are two face embeddings, $A \cdot B$ is the dot product, and $\|A\|$ and $\|B\|$ are the magnitudes of the vectors. A cosine similarity threshold of 0.7 was selected in SITR following a series of empirical trials in which thresholds

(a) Initial enrollment with embedding storage.

(b) hijab detection and privacy enforcement.

Fig. 3. SITR operational workflow including: (a) Family member enrollment and (b) Privacy-aware hijab detection.

ranging from 0.45 to 0.9 were evaluated on enrollment and test image pairs. The threshold of 0.7 yielded the best balance between true acceptance rate and false acceptance rate on the available face verification samples. It is acknowledged, however, that a formal ROC curve analysis and threshold sweep using a dedicated held-out verification set were not conducted; this represents a limitation of the current study and is recommended for future validation. Scores greater than or equal to 0.7 are accepted as a match, while scores below 0.7 are rejected.

D. Hijab Detection Model Based on DenseNet121

The hijab detection module of the SITR system was developed using DenseNet121 [12], a deep CNN pre-trained on the ImageNet dataset. This model was selected after evaluating multiple CNN architectures due to its robust feature extraction capabilities and proven effectiveness in image classification tasks. DenseNet121 is well known for its strong performance because it captures fine-grained features through dense blocks, where each layer is connected to every other layer in a feed-forward fashion [21]. This design promotes feature reuse and effective combination [22], which makes it suitable for detecting small or subtle details, such as whether a female subject is wearing a hijab. Since it is pre-trained on a large and diverse dataset, DenseNet121 provides a strong foundation for this classification task and adapts well to varied lighting conditions and viewing angles, allowing high accuracy even with a relatively small dataset [13].

To further improve its effectiveness, additional optimization steps were investigated:

1) Efficient Channel Attention (ECA): ECA [23], a light and effective channel-attention module based on local cross-channel interaction via 1D convolution, was added after each dense block to help the model concentrate on the most informative channel features.

2) Hyperparameter tuning: A grid search [24] was conducted to determine optimal values for learning rate, dropout, batch size, and weight decay.

The customized DenseNet121 architecture used for hijab detection is illustrated in Fig. 4. It shows the complete modified DenseNet121 architecture. The input image (224×224×3 px) passes through an initial 7×7 convolution and 3×3 max pooling layer before entering four dense blocks. After each dense block, an ECA attention layer is inserted for lightweight channel-wise feature recalibration using a 1D convolution (kernel size k=3). Transition layers (1×1 convolution + 2×2 average pooling) reduce spatial dimensions between dense blocks. After the fourth Dense Block, a 7×7 global average pooling layer is applied, followed by a dropout layer (rate=0.3)

and a fully connected linear layer that produces the binary classification output (0 = no hijab; 1 = hijab). The effect of these optimization steps is evaluated later in the Results and Discussion section.

E. Dataset and Preprocessing

A dataset of 3,082 annotated images collected from Roboflow was used to train the hijab detection model. Following data cleaning, 891 samples were removed due to inconsistent annotation or poor image quality. The final valid dataset contained 2,191 images (including 1,248 training images, 63 validation images, and 880 testing images). There was no bias due to class imbalance as there was a balance between the hijab and non-hijab classes (50.8% vs. 49.2, respectively). All the splits were done using a fixed seed randomly to guarantee reproducibility. The test set was not used in the hyperparameter tuning and was strictly held out. It is acknowledged that this dataset size is relatively small for training a robust deep learning classifier. In particular, the validation split of only 63 images may limit the reliability of hyperparameter selection decisions. These constraints stem from the limited availability of publicly annotated, culturally appropriate data and represent a recognized limitation of this study. Future work should aim to collect larger and more diverse datasets incorporating varied geographic regions, hijab styles, and demographic backgrounds to improve model generalizability. Cross-dataset validation is also recommended to assess robustness beyond the current data distribution.

F. Training and Evaluation Setup

The hijab detection model was trained and tested on Google Colab with GPU support, which ensured faster and more efficient experiments. All CNN models were trained under consistent conditions for fairness, as presented in Table II. The Colab environment was equipped with 2 vCPUs, 12 GB RAM, and an NVIDIA T4 GPU with 16 GB VRAM. Moreover, default PyTorch parameters were used unless otherwise noted. To improve reliability, four independent runs were conducted for each model, and results were averaged.

TABLE II. TRAINING SETUP AND PARAMETERS USED FOR ALL CNN MODELS

Factor	Value
Image Input Size	224×224 px
Batch Size	4
Learning Rate	1e-5
Weight Decay	1e-6
Dropout	0.3
Epochs	20
Optimizer / Loss	Adam with binary cross-entropy loss

G. Evaluation Metrics

To evaluate the effectiveness and reliability of the SITR hijab detection model, several commonly used metrics in classification tasks were adopted, as summarized in Table III. All metrics were calculated from multiple independent runs to reduce the impact of random variations in model performance and provide a more trustworthy assessment of the model's effectiveness. All the reported results are the averages over four independent runs.

TABLE III. SUMMARY OF EVALUATION METRICS USED TO ASSESS SITR MODEL.

Metric	Description / Purpose
Accuracy	Percentage of correctly classified images (hijab / non-hijab).
Precision	Fraction of predicted "hijab" images that are actually correct.
Recall	Fraction of actual hijab images correctly detected by the model.
F1-score	Harmonic mean of precision and recall for balanced evaluation.
Computational Time	Training and inference time, reflecting model efficiency.
Loss Values	Indicates training stability and convergence during evaluation.

H. Deployment Setup

To support practical use of the optimized DenseNet121 model, it was deployed as a REST API using the Flask framework on the Render cloud platform. Dynamic quantization reduced the model size to 27 MB from the original 82 MB, showing the memory efficiency and speed benefits. The SITR mobile application uses the backend API to communicate with Convex for handling user data and with ChromaDB to support similarity search during family-member verification.

IV. RESULTS AND DISCUSSION

This section presents quantitative and qualitative results for evaluating the SITR application and its core hijab detection model. The experiment was performed through three different phases: initially by benchmarking CNN models, followed by optimization of the DenseNet121 model with Efficient Channel Attention (ECA), and finally by tuning hyperparameters for maximum performance.

A. Quantitative Results

1) Benchmarking advanced CNN models: To identify the baseline model for hijab detection, four pre-trained CNN architectures, including ResNet50 [25], MobileNetV2 [26], EfficientNet-B0 [27], and DenseNet121) were investigated on the curated dataset. These models are selected because they are widely used for image classification and represent different levels of depth and complexity [13].

Table IV summarizes the average performance metrics across four separate runs. Fig. 5 presents grouped bar charts comparing accuracy, precision, recall, and F1-score across the four architectures, with each bar representing the mean value across four independent training runs to allow assessment of both peak performance and training consistency. The results show that DenseNet121 achieved the best overall performance. It recorded an average accuracy of 79.49%, precision of 73.48%, recall of 62.69%, and an F1-score of 65.67%. These findings represent a clear improvement over other model. Its accuracy is 5.3% higher than MobileNetV2, 3.9% higher than ResNet50, and 0.8% higher than EfficientNet-B0. In terms of F1-score, DenseNet121 also outperformed its closest competitor, EfficientNet-B0, by 1.1%. It should be noted that the baseline DenseNet121 accuracy of 79.49% is lower than the 96.47% reported for the rule-based visual feature detection method proposed in [18]. This discrepancy is

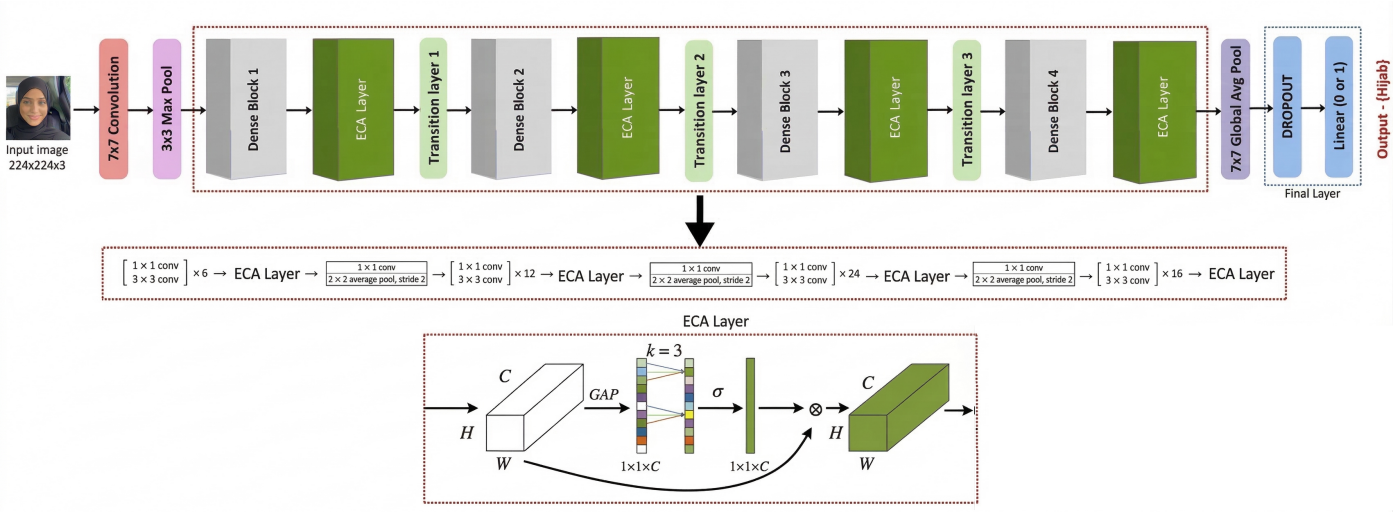


Fig. 4. The customized DenseNet121 architecture used for hijab detection model.

primarily attributable to differences in evaluation conditions: the rule-based approach was tested under controlled settings with clearly visible neck and hair features, whereas the deep learning models in this study were evaluated on a more heterogeneous dataset encompassing diverse lighting conditions, poses, partial occlusions, and backgrounds. Deep learning approaches such as DenseNet121 are expected to generalize better to unseen real-world conditions, as evidenced by the improved accuracy of 92.16% achieved after optimization, while rule-based methods may degrade significantly under uncontrolled visual conditions.

TABLE IV. AVERAGE PERFORMANCE METRICS ACROSS FOUR RUNS ON THE TEST SET IN TERMS OF CLASSIFICATION METRICS AND LOSS.

Model	Classification Metrics (%)				Loss
	Accuracy	Precision	Recall	F1-Score	
ResNet50	75.63	60.91	77.89	66.52	0.4512
MobileNetV2	73.18	55.87	60.36	57.84	0.4541
EfficientNet-B0	78.69	67.63	60.73	64.95	0.481
DenseNet121	79.49	73.48	62.69	65.67	0.486

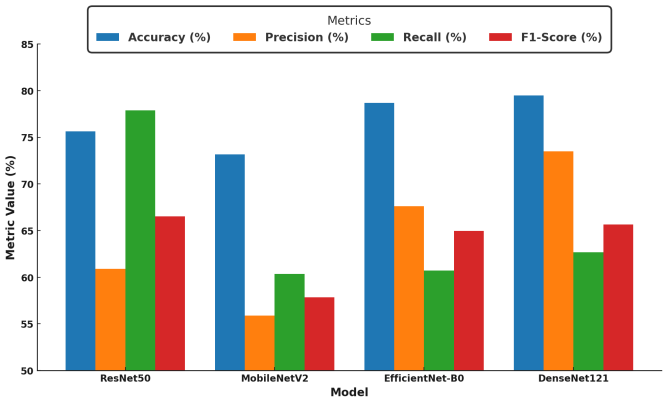

Fig. 5. Test classification results for the four models (averaged over four runs).

Precision is a critical metric in this context because it reflects the model's ability to reduce false positives. DenseNet121 achieved the highest precision at 73.48%, which indicates greater reliability in distinguishing hijab from non-hijab images. While ResNet50 captured slightly more true hijab samples, its lower precision reduced its overall consistency. In contrast, DenseNet121's architecture uses dense connectivity for better feature reuse. This allowed it to capture fine-grained details of hijab texture and coverage, leading to more stable and accurate classification.

Fig. 6 depicts the training and validation loss for each model. It is clear that DenseNet121 shows the smoothest and most consistent convergence. Its training and validation losses decreased steadily and remained close to each other. This pattern indicates strong generalization and reliable optimization. EfficientNet-B0 also achieves low final losses. However, its validation curve fluctuated during the middle epochs, which suggests it adapted more slowly to variations in the data. Meanwhile, validation loss for MobileNetV2 declines less uniformly This observation is consistent with its lower accuracy and recall scores in Table IV. ResNet50 reaches a reasonable loss value early in training, but its validation loss stabilizes at a higher level compared to DenseNet121. Overall, DenseNet121 converged faster and reached the lowest combined losses, supporting its superior quantitative results.

2) Model optimization with ECA: After selecting DenseNet121 as the best-performing baseline, it was further enhanced by integrating Efficient Channel Attention (ECA) after each dense block to prioritize informative channels. As shown in Table V, the ECA-enhanced version achieves an accuracy of 86.62% and an F1-score of 77.32%. This marks a significant improvement over the standard DenseNet121, which records 79.49% accuracy and a 65.67% F1-score. Overall, accuracy increases by 7.13% and the F1-score by 11.65%.

Other metrics improve as well. Precision rises from 73.48% to 79.91%, and recall increases from 62.69% to 74.91%. These findings confirm that the attention mechanism creates a better balance between identifying true hijab samples

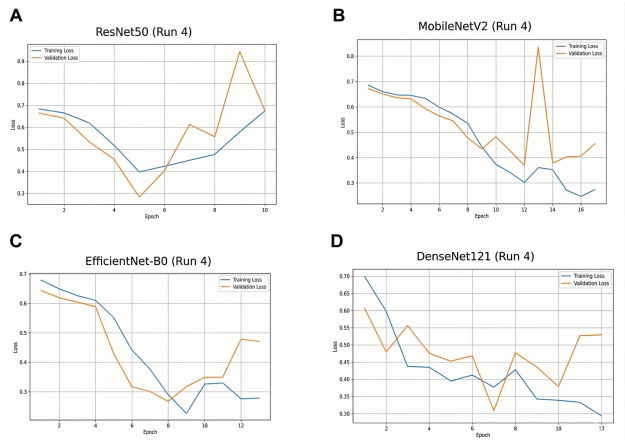

Fig. 6. Training and validation loss curves of four tested models over multiple epochs (Run 4).

and reducing false detections. The lower loss value, 0.369 compared to 0.486, also indicates more stable convergence. Together, these results demonstrate that incorporating ECA helps DenseNet121 learn richer feature representations and improves its overall robustness in hijab detection. However, this comparison reflects improvement over the untuned standard DenseNet121 only.

TABLE V. COMPARISON OF STANDARD AND ECA-ENHANCED DENSENET121 MODELS (AVERAGE OVER 4 RUNS).

Variant	Classification Metrics (%)				Loss
	Accuracy	Precision	Recall	F1-Score	
Standard DenseNet121	79.49	73.48	62.69	65.67	0.486
ECA-Enhanced	86.62	79.91	74.91	77.32	0.369

3) Hyperparameter tuning: A grid search was performed across various learning rates, dropout rates, batch sizes, and weight decays. The hyperparameter and the optimal configuration are given in Table VI. Due to GPU limitations, 19 different combinations were evaluated.

TABLE VI. GRID SEARCH HYPERPARAMETERS AND OPTIMAL VALUES

Parameter	Search Space	Optimal
Learning Rate	[0.001, 0.0001, 0.00001]	0.00001
Dropout	[0.3, 0.45, 0.7]	0.3
Batch Size	[4, 8, 16]	4
Weight Decay	[0.0001, 0.00001, 0.000001]	0.000001

Although the ECA-enhanced variant performed exceptionally well, it did not surpass the regular DenseNet121 after it was properly tuned. As such, we chose the tuned DenseNet121 as our final model on the basis of its superior validation performance in terms of accuracy, F1-score, and overall generalization capability.

The final deployment model was selected based on validation performance after hyperparameter tuning and then evaluated on the held-out test set. It achieved a test accuracy of 92.16%, an F1-score of 86.39%, and a test loss of 0.2174. It also achieved a precision of 91.63%. This high-precision value is particularly significant for the privacy-enforcement context of SITR. A false positive — where a non-hijab image is misclassified as containing a hijab — results in the system incorrectly declaring a privacy-sensitive image safe to share, representing the most critical failure mode. The achieved precision of 91.63%, therefore, reflects a low false-positive rate, directly aligned with the system's primary objective of protecting user privacy before image sharing.

B. Qualitative Results

To verify practical system behavior, the SITR mobile application was tested for image upload, family member verification, hijab detection, and privacy enforcement. During the enrollment stage, family members were successfully registered using FaceNet embeddings, which supported reliable verification in later stages. In the photo-sharing stage, uploaded images were processed and the system automatically verified hijab status and applied blurring to sensitive faces when necessary. These examples illustrate the intended behavior of the SITR pipeline in real image-sharing scenarios.

As illustrated in Fig. 7, the system correctly identified hijabi family members and allowed their images to be safely shared. The left screenshot shows the application in the analysis phase, where MTCNN detects the face and FaceNet confirms the identity as a registered female family member with a cosine similarity above the 0.7 threshold. The center screenshot displays the result: the DenseNet121 model detects a hijab and clears the image for sharing, displaying a "You can share the photo safely" confirmation message. The right screenshot shows the upload interface after analysis, indicating that no blurring was applied. This scenario corresponds to Path A in the SITR pipeline. In contrast, Fig. 8 shows how the system automatically blurred the head and neck region when a registered female family member was detected without a hijab, thereby enforcing privacy protection before the image could be shared. These examples highlight SITR's real-world functionality in supporting privacy-sensitive image sharing.

C. Discussion on Model Efficiency and Limitations

The strong performance of DenseNet121 can be attributed to its dense connectivity mechanism, which enables effective feature reuse and preserves low-level texture information across layers—characteristics particularly well-suited to hijab detection, which requires recognition of subtle visual patterns including fabric coverage, hair visibility, and neck exposure. The introduction of ECA improves the channel-wise feature recalibration and enables the network to focus on semantically valuable channels, and also reduces redundant responses. The mechanism is especially useful in visually complicated backgrounds where noise in the context may disrupt classification.

The optimized model was successfully deployed using Render after applying dynamic quantization. This technique reduces the model size from 82 MB to 27 MB. This compression ratio demonstrates that the proposed system is well-suited for resource-constrained deployment environments, including mobile and edge devices. The findings suggest that identity-aware, culturally sensitive AI systems of this nature are practically feasible beyond the laboratory setting and can be integrated as lightweight API services into existing mobile applications. An

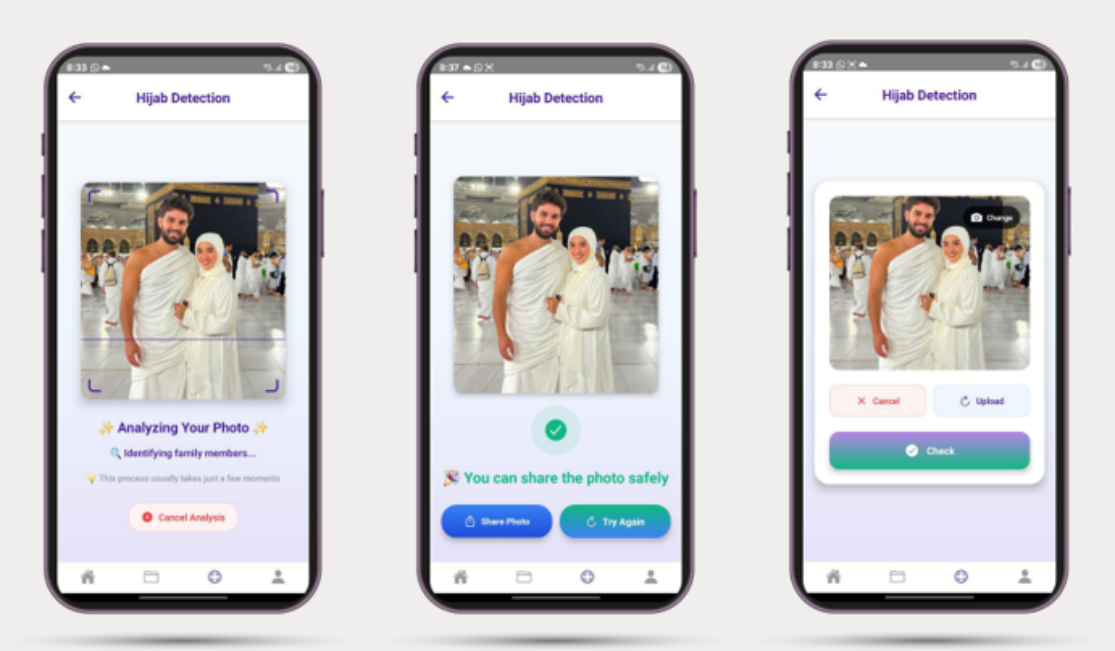

Fig. 7. Example of a hijabi family member correctly identified as safe for sharing.

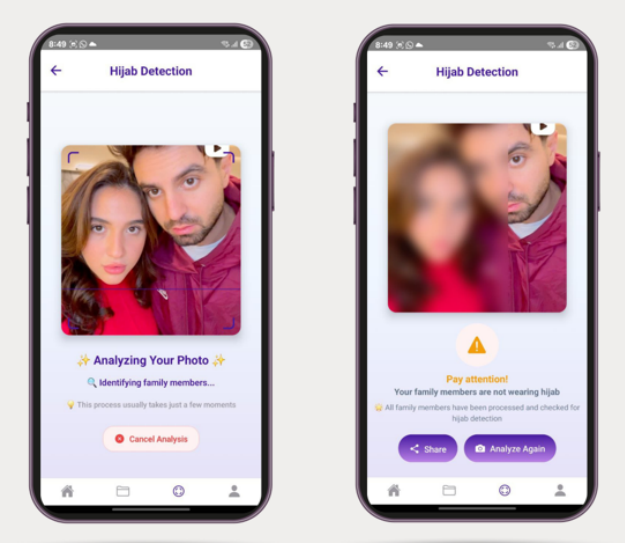

Fig. 8. Example of automatic blurring applied to a family member not wearing a hijab.

average inference time of approximately 19 seconds per image was recorded on a CPU-only cloud instance. This latency is acceptable for privacy-sensitive manual image-sharing workflows but is not yet suitable for real-time streaming applications.

From a broader research perspective, SITR demonstrates the viability of combining identity verification with visual attribute classification in a culturally grounded AI pipeline. This design pattern may be extended to other culturally sensitive contexts - such as age-appropriate content filtering or faith-based social media moderation—although such extensions would require separate dataset collection, model training, and ethical evaluation.

Regarding the absence of an end-to-end system evaluation, the current work evaluates each pipeline component (MTCNN, FaceNet, DenseNet121) individually. No integrated pipeline-level evaluation was conducted to measure the compounded effect of errors across all three stages on the final privacy decision output. A missed face detection or an incorrect identity match may propagate errors that are not captured by the individual component metrics reported in this study. This is a recognized limitation, and future work should include end-to-end evaluation using realistic multi-face test scenarios to quantify the true system-level accuracy.

Despite strong results, the system has several notable limitations:

1) Small and limited dataset: The hijab detection model was trained on only 2,191 images after removing 891 samples for quality issues. The validation split of only 63 images further limits the reliability of hyperparameter selection. This small and geographically constrained dataset may hinder generalization to diverse populations, hijab styles, and demographic backgrounds.

2) No end-to-end pipeline evaluation: Each of the three pipeline components — face detection, identity verification, and hijab classification — was evaluated independently. The compounded error across the full pipeline in realistic multi-face image sharing scenarios remains unmeasured.

3) Restricted cultural scope: The framework is explicitly designed for the Islamic cultural context. It does not account for women who wear head coverings for non-religious reasons (e.g., medical head coverings, traditional or cultural dress outside the Islamic context), which could produce misclassifications. The system is not validated for other cultural or religious head-covering traditions.

V. Conclusion

This study proposed the SITR framework, a culturally-aware and identity-sensitive deep learning system designed to prevent unintended sharing of privacy-sensitive images, specifically targeting the Islamic cultural context of hijab wearing. In contrast to traditional content moderation systems, SITR bases decisions on privacy enforcement on confirmed identity as well as classification in visual attributes in a single pipeline. The combination of face detection, identity verification through facial embeddings, and optimized hijab recognition shows how AI can be implemented in context-sensitive ethical use. The final tuned DenseNet121 model achieved an accuracy of 92.16% and an F1-score of 86.39%. Experimental results showed that ECA improved the untuned baseline significantly, but the tuned standard DenseNet121 achieved the best final performance and was selected for deployment. Dynamic quantization reduced the model size from 82 MB to 27 MB, making it lightweight and suitable for REST API deployment. The system demonstrated smooth end-to-end communication between the mobile frontend and backend, supporting practical integration in privacy-sensitive image-sharing scenarios.

Despite these promising results, two primary limitations must be explicitly acknowledged. First, the hijab detection model was trained on a relatively small dataset (2,191 images) with a minimal validation split (63 images), which limits confidence in the generalizability of the learned representations to diverse cultural, demographic, and environmental contexts. Second, no end-to-end system evaluation was conducted to quantify the compounded error across the three-stage pipeline (face detection $\rightarrow$ identity verification $\rightarrow$ hijab classification), meaning the true system-level accuracy in realistic multi-face image-sharing scenarios remains unmeasured. Additionally, the cosine similarity threshold of 0.7 used for face verification was selected empirically without a formal ROC-based analysis, which represents a further methodological gap.

Future work should address these gaps through the following directions: 1) collecting larger, more culturally and demographically diverse hijab detection datasets and applying cross-dataset validation; 2) conducting a full end-to-end pipeline evaluation with realistic test scenarios to measure true system-level precision and error propagation; 3) performing formal ROC curve analysis for threshold selection in the face verification component; and 4) exploring GPU-optimized and lighter model architectures to reduce inference latency below the current approximately 19 seconds per image, enabling real-time or near-real-time privacy enforcement in dynamic image-sharing contexts.

Declaration on Generative AI

During the preparation of this manuscript, the authors used a generative AI tool (ChatGPT) only to assist with language refinement, paraphrasing, and text organization. After using this tool, all generated content was carefully reviewed and edited by the authors as needed. The authors remain fully responsible for the scientific content, accuracy, originality, and integrity of this manuscript.

Acknowledgment

The authors would like to thank the Department of Computer Systems Engineering at the Arab American University for supporting the senior project that formed the basis of this work. The authors also acknowledge all contributors who supported the implementation, testing, and refinement of the SITR system.

Stability-Weighted Feature Selection with Adaptive PSO-SGD for Neural Network-Based Predictive Hiring

Yassine Temsamani Khallouk, Said Achchab
Mohammed V University in Rabat, Morocco

***Abstract*—Predictive hiring leverages machine learning to forecast candidate success, yet existing approaches suffer from two limitations: reliance on single-method feature selection that lacks robustness, and sensitivity to neural network initialization that impairs convergence. This study introduces two contributions integrated into a unified framework. First, Stability-Weighted Multi-Criteria Feature Selection (SW-MCFS) is proposed, which aggregates four heterogeneous scoring methods—Mutual Information, Wald statistical significance, Fisher discriminant loading, and Permutation Importance—through a cross-validation stability-weighted consensus function. Unlike single-method approaches, SW-MCFS weights each method proportionally to its ranking consistency across folds, producing robust and data-driven feature subsets. Second, Adaptive Particle Swarm Optimization (APSO) is introduced, a PSO variant featuring fitness-landscape-aware inertia adaptation and Lévy flight perturbation for stagnation escape. The framework is evaluated on $10,247$ recruitment records from a North African telecommunications company and benchmarked against Random Forest, XGBoost, SVM, standard ANNs, and classical LR/DA-based approaches through 10-fold cross-validation. The integrated SW-MCFS-APSO-SGD framework achieves 76.8% accuracy, significantly outperforming XGBoost (73.8%, $p = 0.012$), standard PSO-SGD (75.2%, $p = 0.041$), and LR-based feature selection (74.6%, $p = 0.028$). Ablation studies confirm that SW-MCFS contributes 1.6% accuracy gain over single-method selection, while APSO improves performance by 0.8% with 31% faster convergence compared to standard PSO. SHAP analysis reveals communication skills, experience, and seniority as dominant predictors with minimal demographic influence. It is noted that the accuracy ceiling may partly reflect inherent label noise in subjective performance assessments. The proposed framework demonstrates effectiveness on organizational recruitment data, warranting further cross-domain validation to establish broader generalizability.**

I. Introduction

A. Background and Motivation

Modern recruitment processes generate large volumes of structured and unstructured data, including resumes, assessments, interviews, and work history. Traditional hiring practices struggle to analyze this information objectively and at scale, resulting in inefficiencies, bias, and suboptimal talent selection [1], [2], [30]. Predictive hiring applies machine learning to forecast candidate success by leveraging historical employment data to identify performance-related patterns [3], [32].

Recent advances in artificial intelligence (AI) have enabled automated candidate evaluation through natural language processing (NLP) for resume analysis [4], psychometric profiling [5], and automated interview assessment [6].

B. AI-Driven Transformation of Human Resource Information Systems

AI integration transforms Human Resource Information Systems (HRIS) from transactional platforms into intelligent decision-support systems. Traditional HRIS mainly manages payroll, personnel records, and compliance [7]. With AI integration, these systems evolve into advanced analytics-driven infrastructures [8], [9].

AI technologies, including ML, deep learning (DL), NLP, and large language models (LLM), enable HRIS to process heterogeneous and large-scale workforce data. This supports evidence-based human resource management and strengthens core functions including talent acquisition, workforce planning, and performance management [10]. Strategically, AI enables HR systems to transition toward intelligent and data-driven workforce management with enhanced analytical capabilities.

C. AI Techniques for Recruitment Automation and Predictive Modeling

NLP techniques such as tokenization, semantic embedding, and named entity recognition enable automated extraction of structured features from textual recruitment data [11], [12]. Transformer-based architectures [42] improve semantic similarity estimation and candidate–job matching through contextual representation learning.

LLM further enhances automation by improving feature representation and supporting intelligent screening and classification [13]. Predictive hiring systems then use these extracted features to estimate post-hire performance using ML models. This study integrates advanced feature selection and optimization methods to improve predictive robustness within AI-driven HR environments.

D. Research Challenges

Despite recent advances, two fundamental challenges remain:

- *Feature Selection Fragility:* Most existing studies rely on a single feature selection technique such as correlation filtering, LR significance testing, or tree-based

importance ranking. These approaches often produce unstable feature subsets that vary across data partitions and model assumptions [14]. However, no consensus-based framework systematically aggregates multiple selection criteria while accounting for stability across cross-validation folds.

- *Optimization Sensitivity:* Standard Particle Swarm Optimization (PSO) employs fixed or predefined inertia weight schedules that do not adapt to the fitness landscape topology [15]. When used to optimize neural network (NN) parameters, this limitation may result in premature convergence or insufficient exploration, reducing predictive performance and generalization ability.

E. Research Contributions

To address these challenges, this study makes the following contributions:

1) Stability-Weighted Multi-Criteria Feature Selection (SW-MCFS): A feature selection framework is proposed that aggregates multiple heterogeneous scoring methods, including (1) Mutual Information (MI), (2) Wald Statistical Significance (WSS), (3) Fisher Discriminant Loading (FDL), and (4) Permutation Importance (PI), into a unified consensus ranking. Each method is weighted based on its cross-validation stability to enhance robustness. To the best of the authors' knowledge, this is the first stability-weighted multi-criteria consensus framework applied to predictive hiring feature selection.

2) Adaptive PSO (APSO): An adaptive PSO variant is introduced incorporating (1) fitness-based inertia adaptation, (2) swarm diversity monitoring, and (3) Lévy flight perturbations to enhance exploration and prevent premature convergence during NN weight optimization.

3) Integrated hybrid learning framework: An end-to-end pipeline is developed that integrates SW-MCFS with adaptive APSO for initialization and stochastic gradient descent (SGD) for training. This joint design improves feature robustness and model optimization within a unified framework that has not been explored in prior predictive hiring studies.

4) Rigorous empirical validation: Comprehensive evaluation on $10,247$ records using 10-fold cross-validation, ablation analysis, statistical tests, and baseline comparisons to demonstrate robustness and effectiveness.

F. Paper Organization

The remainder of this study is organized as follows: Section II reviews related work and theoretical foundations. Section III describes the proposed optimization framework. Section IV presents the experimental setup. Section V and Section VI reports the results and discussion. Finally, Section VII concludes the study and outlines future research directions.

II. Related Work

A. Feature Selection in HR Analytics

Feature selection in HR prediction typically include filter methods (e.g., correlation, MI), wrapper methods (e.g., recursive feature elimination), and embedded methods (e.g., L1 regularization, tree-based importance) [16]. Most studies rely on a single technique such as Logistic Regression (LR) significance testing [17] or Random Forest (RF) importance [18].

However, these approaches often suffer from instability and bias. Filter methods ignore feature interactions, wrapper methods are computationally expensive, and embedded methods depend on the base model [19]. Although ensemble feature selection has been explored in other domains [20], stability-aware consensus strategies remain limited in HR prediction. The proposed SW-MCFS framework addresses this gap by incorporating stability-weighted aggregation.

B. PSO Variants for NN Optimization

PSO is widely used for NN optimization due to its global search ability [15]. Standard PSO uses fixed inertia strategies, which limit adaptability to complex landscapes.

Adaptive variants improve exploration through dynamic inertia control [21], state-based adaptation [22], or Lévy flight perturbations [23]. However, existing methods rarely combine fitness-aware adaptation with Lévy-based exploration for predictive hiring models. The proposed APSO variant integrates these mechanisms to improve optimization stability.

C. AI in Predictive Hiring

ML for recruitment has evolved from traditional classifiers to deep learning models. NN-based person–job fit models achieve competitive accuracy [24], [33], while co-attention architectures and ensemble methods, including gradient boosting variants such as XGBoost [26] and CatBoost [41] further improve performance [25].

Despite these advances, feature selection and model training are usually treated separately. Integrated optimization within a unified pipeline remains underexplored.

D. Research Gaps

Current literature lacks: 1) stability-weighted multi-criteria feature selection for HR prediction, 2) adaptive swarm optimization combining fitness-aware control and Lévy perturbation for neural training, and 3) unified frameworks that jointly optimize feature robustness and model learning. These gaps motivate the proposed SW-MCFS-APSO-SGD framework.

III. Proposed SW-MCFS–APSO Hybrid Optimization Framework

This section presents the proposed SW-MCFS–APSO–SGD framework, depicted in Fig. 1, that integrates stability-aware feature selection, adaptive optimization, and gradient-based training for robust predictive modeling.

A. Problem Formulation and Cross-Validation Framework

Let the training dataset be defined as Eq. (1):

$$\mathcal{D} = \{(\mathbf{x}_i, y_i)\}_{i=1}^{N}, \tag{1}$$

where,

- N denotes the number of recruitment records,

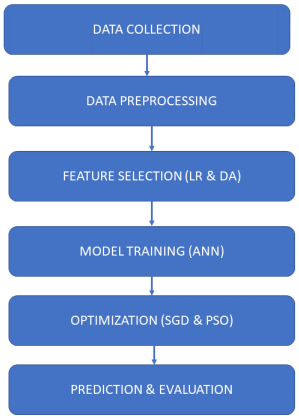

Fig. 1. SW-MCFS-APSO-SGD framework. Phase 1: Multi-criteria feature selection with stability weighting. Phase 2: APSO global search with FLAI, LFP, and EGR. Phase 3: SGD fine-tuning with early stopping.

- $\mathbf{x}_i = \{x_{i,j}\}_{1\le j\le d} \in \mathbb{R}^d$ is the raw feature vector of candidate i $(i \le N)$,
- d is the number of original features,
- $y_i \in \{0, 1\}$ is the binary job performance label, with $i \le N$.

Accordingly, the feature matrix can be expressed as Eq. (2):

$$\mathbf{M} = \begin{bmatrix} \mathbf{x}_1^\top \\ \mathbf{x}_2^\top \\ \vdots \\ \mathbf{x}_N^\top \end{bmatrix} \in \mathbb{R}^{N\times d}. \tag{2}$$

Each row corresponds to a candidate, and each column corresponds to a feature. To evaluate feature stability and prevent data leakage, K-fold cross-validation (CV) is adopted on $\mathcal{D}$. For each $k \le K$, the dataset $\mathcal{D}$ is partitioned into training and validation set as Eq. (3):

$$\mathcal{D} = \mathcal{D}_{\text{tr}}^{(k)} \cup \mathcal{D}_{\text{val}}^{(k)}, \quad 1 \le k \le K, \tag{3}$$

such that for each fold k [see Eq. (4)]:

$$\begin{cases} \mathcal{D}_{\text{tr}}^{(k)} \cap \mathcal{D}_{\text{val}}^{(k)} = \emptyset \\ \left|\mathcal{D}_{\text{val}}^{(k)}\right| = \lfloor \frac{N}{K} \rfloor, \quad \left|\mathcal{D}_{\text{tr}}^{(k)}\right| = N_k \triangleq N - \lfloor \frac{N}{K} \rfloor \end{cases}. \tag{4}$$

B. Multi-Criteria Feature Selection

Initially, the proposed SW-MCFS algorithm is applied to reduce the original feature set to a selected subset $\mathcal{F}$, where $d^* = |\mathcal{F}|$ denotes the number of selected features satisfying $d^* \le d$.

The reduced feature matrix becomes [see Eq. (5)]:

$$\mathbf{M}_{\mathcal{F}} \in \mathbb{R}^{N\times d^*}. \tag{5}$$

To achieve a robust and stable ranking, multiple complementary feature relevance criteria are aggregated. In particular, **four** scoring methods are employed to evaluate feature importance from statistical, information-theoretic, and model-driven perspectives.

1) Mutual information: For each feature $x_{i,j}$ (the j-th feature of sample i), the MI quantifies its dependency with the binary label y_i by measuring the reduction in uncertainty of y_i given $x_{i,j}$.

Since features are continuous, the joint and marginal distributions are estimated using kernel density estimation or discretization. The MI score for feature j is computed in fold k, as in [27] [see Eq. (6)]:

$$\mathcal{M}_j^{(k)} = \sum_{x,y} p_{X_j,Y}^{(k)}(x,y) \log \frac{p_{X_j,Y}^{(k)}(x,y)}{p_{X_j}^{(k)}(x)\, p_Y^{(k)}(y)}, j \le d, k \le K \tag{6}$$

where, X_j and Y denote the j-th feature and label RVs, respectively, and the joint distribution $p_{X_j,Y}^{(k)}(x,y)$ and the marginals $p_{X_j}^{(k)}(x)$ and $p_Y^{(k)}(y)$ are estimated empirically from $\mathcal{D}_{\text{tr}}^{(k)}$. Of note, a larger $\mathcal{M}_j^{(k)}$ implies stronger relevance of feature j to the target label.

For continuous features, $\mathcal{M}_j^{(k)}$ is approximated using the k-nearest-neighbor estimator [28]:

$$\widehat{\mathcal{M}}_j^{(k)} = \psi(k_{\text{nn}}) + \psi(N_k) - \frac{1}{N_k} \sum_{i=1}^{N_k} \Big[\psi(n_x^{(i)}+1) + \psi(n_y^{(i)}+1)\Big], \tag{7}$$

where, $n_x^{(i)}$ and $n_y^{(i)}$ denote the number of samples (excluding the i-th one) whose distances to sample i in the X_j and Y marginal spaces are smaller than the k_{nn}-nearest neighbor (NN) radius ε_i, which is determined by the distance to the k_{nn}-th NN in the joint space.

Lastly, to make scores comparable across features, the normalized MI score is defined based on the estimator in Eq. (7) as [see Eq. (8)]:

$$S_{j,k}^{(1,n)} = \frac{\widehat{\mathcal{M}}_j^{(k)}}{\max_{1\le \ell\le d} \widehat{\mathcal{M}}_\ell^{(k)}}, \quad 1 \le k \le K. \tag{8}$$

2) Wald statistical significance: For each fold, a univariate L2-regularized LR model is fitted to evaluate the statistical significance of feature X_j to the binary label Y. The conditional probability is modeled as Eq. (9):

$$\Pr(Y = 1 \mid X_j = x_{i,j}) = \frac{1}{1 + \exp\big(-\beta_{0,j}^{(k)} - \beta_{1,j}^{(k)} x_{i,j}\big)}. \tag{9}$$

The parameters $\beta_{0,j}^{(k)}$ and $\beta_{1,j}^{(k)}$ are estimated from $\mathcal{D}_{\text{tr}}^{(k)} \triangleq \{(x_{i,j}, y_i)\}_{i=1}^{N_k}$ via penalized maximum likelihood with L2 regularization to ensure numerical stability.

The null hypothesis $\mathcal{H}_0 : \beta_{1,j}^{(k)} = 0$ is tested using the Wald statistic [see Eq. (10)]:

$$W_j^{(k)} = \frac{(\hat{\beta}_{1,j}^{(k)})^2}{\widehat{\mathrm{Var}}(\hat{\beta}_{1,j}^{(k)})} \sim \chi^2(1), \qquad 1 \le j \le d, \tag{10}$$

where, $\chi^2(1)$ denotes the chi-square distribution with one degree of freedom, and $\widehat{\mathrm{Var}}(\hat{\beta}_{1,j}^{(k)})$ is obtained from the inverse Fisher information matrix.

The corresponding p-value is Eq. (11):

$$p_j^{(k)} = \Pr\big(\chi^2(1) \ge W_j^{(k)}\big) = 1 - F_{\chi^2(1)}(W_j^{(k)}), \tag{11}$$

where, $F_{\chi^2(1)}(\cdot)$ denotes the cumulative distribution function.

Similarly to Eq. (8), the normalized Wald-based score is defined as Eq. (12):

$$S_{j,k}^{(2,n)} = \frac{|\hat{\beta}_{1,j}^{(k)}|(1-p_j^{(k)})}{\max_{1\le\ell\le d}|\hat{\beta}_{1,\ell}^{(k)}|(1-p_\ell^{(k)})}. \tag{12}$$

This formulation jointly rewards large effect sizes and high statistical confidence while penalizing unstable estimates.

3) Fisher discriminant score: From Linear Discriminant Analysis [44], the discriminant direction that maximizes class separation in fold k is given by:

$$\mathbf{w}^{(*,k)} = (\mathbf{S}_W^{(k)})^{-1}(\boldsymbol{\mu}_1^{(k)} - \boldsymbol{\mu}_2^{(k)}), \tag{13}$$

where, $\mathbf{S}_W^{(k)}$ denotes the within-class scatter matrix computed on $\mathcal{D}_{\text{tr}}^{(k)}$ and $\boldsymbol{\mu}_c^{(k)}$ represents the mean vector of class c in fold k.

Each component $w_j^{(*,k)}$ of the discriminant direction in Eq. (13) measures the contribution of feature j to class separation. To obtain a scale-invariant measure, it is weighted by the pooled within-class standard deviation $\sigma_j^{(k)}$, and the normalized Fisher score in fold k is defined as Eq. (14):

$$S_{j,k}^{(3,n)} = \frac{|w_j^{(*,k)}|\,\sigma_j^{(k)}}{\max_{1\le\ell\le d}|w_\ell^{(*,k)}|\,\sigma_\ell^{(k)}}, \qquad 1 \le j \le d, \tag{14}$$

This normalization ensures comparability across features and highlights those with stronger discriminative power.

4) Permutation importance: Permutation importance is computed within each cross-validation fold using a baseline RF model with $B = 200$ trees [18], [29]. It quantifies the decrease in predictive performance when feature values are randomly permuted.

Let $f_\theta^{(k)}(\cdot)$ denote the classifier trained on the training subset $\mathcal{D}_{tr}^{(k)}$ in fold k. The accuracy functional evaluated on a dataset $\mathcal{D}$ in fold k is defined as Eq. (15):

$$\mathcal{A}^{(k)}(\mathcal{D}) = \frac{1}{|\mathcal{D}|}\sum_{(\mathbf{x}_k,y_k)\in\mathcal{D}} \mathbf{1}\big(f_\theta^{(k)}(\mathbf{x}_k) = y_k\big), \tag{15}$$

where, $\mathbf{1}(\cdot)$ is the indicator function.

The baseline accuracy in fold k is computed on the original validation set as Eq. (16):

$$\mathcal{A}_{\text{original}}^{(k)} = \mathcal{A}^{(k)}(\mathcal{D}_{\text{val}}^{(k)}). \tag{16}$$

To evaluate the importance of feature j in fold k, its values are randomly permuted across the validation samples, generating a modified dataset $\pi_r(\mathcal{D}_{\text{val}}^{(k)}, X_j)$. The permutation importance score is defined as the average reduction in accuracy [see Eq. (17)]:

$$\mathcal{P}_j^{(k)} = \mathcal{A}_{\text{original}}^{(k)} - \frac{1}{R}\sum_{r=1}^{R}\mathcal{A}^{(k)}\Big(\pi_r(\mathcal{D}_{\text{val}}^{(k)}, X_j)\Big); 1 \le j \le d, \tag{17}$$

where, R denotes the number of random permutations used in each fold.

Finally, the normalized importance score is given by Eq. (18):

$$S_{j,k}^{(4,n)} = \frac{\mathcal{P}_j^{(k)}}{\max_{1\le\ell\le d}\mathcal{P}_\ell^{(k)}}; 1 \le j \le d. \tag{18}$$

To further improve robustness, SW-MCFS assigns stability-driven weights to the four methods, as detailed in the subsequent subsection, thereby reducing the influence of methods exhibiting inconsistent rankings across folds.

C. Stability-Based Weighting

To quantify the reliability of each method, its ranking stability is measured as the average pairwise Spearman correlation between fold-specific rank vectors:

$$\rho_m = \frac{2}{K(K-1)}\sum_{k=1}^{K-1}\sum_{l=k+1}^{K}\rho_S\big(\mathbf{r}_m^{(k)}, \mathbf{r}_m^{(l)}\big), \tag{19}$$

where, Eq. (20):

$$\mathbf{r}_m^{(k)} = \big(r_{m,1}^{(k)}, \ldots, r_{m,d}^{(k)}\big), \quad m \le 4, 1 \le k \le K, \tag{20}$$

denote the rank vector of the d original features, and the Spearman rank correlation is:

$$\rho_S\big(\mathbf{r}_m^{(k)}, \mathbf{r}_m^{(l)}\big) = 1 - \frac{6\sum_{j=1}^{d}\big(r_{m,j}^{(k)} - r_{m,j}^{(l)}\big)^2}{d(d^2-1)}. \tag{21}$$

Substituting Eq. (21) into Eq. (19) yields Eq. (22):

$$\rho_m = 1 - \frac{12}{K(K-1)d(d^2-1)}\sum_{k=1}^{K-1}\sum_{l=k+1}^{K}\sum_{j=1}^{d}\big(r_{m,j}^{(k)} - r_{m,j}^{(l)}\big)^2. \tag{22}$$

Each method is assigned a stability weight using a softmax normalization:

$$\omega_m = \frac{\exp(\gamma \rho_m)}{\sum_{\ell=1}^{4} \exp(\gamma \rho_\ell)}, \quad 1 \le m \le 4, \tag{23}$$

where, $\gamma > 0$ controls the sensitivity to stability differences. Larger values emphasize the most stable method, whereas smaller values lead to nearly equal weights (i.e., $\exp(\gamma \rho_m)/4$).

Leveraging Eq. (23), the final stability-weighted consensus score is defined as Eq. (24):

$$\overline{\mathcal{S}}_{j,w} = \sum_{m=1}^{4} \omega_m \, \bar{S}_j^{(m,n)}, \tag{24}$$

where, $\bar{S}_j^{(m,n)}$ is the average over the K folds of the mth score, assessed using Eq. (8), Eq. (12), Eq. (14), and Eq. (18) as [see Eq. (25)]:

$$\overline{S}_j^{(m,n)} = \frac{1}{K} \sum_{k=1}^{K} S_{j,k}^{(m,n)}, \quad 1 \le m \le 4. \tag{25}$$

It is noteworthy that:

- Since $\omega_m \ge 0$, $\sum_{m=1}^{4} \omega_m = 1$, and $\bar{S}_j^{(m)} \in [0,1]$, it follows that $\overline{\mathcal{S}}_{j,w} \in [0,1]$;
- Methods exhibiting low ranking stability (small ρ_m) receive smaller weights ω_m through the softmax normalization, thereby reducing their influence on the final consensus score.

Subsequently, features are ranked according to $\overline{\mathcal{S}}_{j,w}$. Denote $\bar{S}_{\alpha_j,w}$ the jth greatest final stability-weighted score, i.e., Eq. (26):

$$\bar{S}_{\alpha_1,w} \ge \bar{S}_{\alpha_2,w} \ge \cdots \ge \bar{S}_{\alpha_d,w}, \quad \{\alpha_j\}_{j \le d} \in \{1,\ldots,d\}. \tag{26}$$

Lastly, the number of retained features d^* is determined using an elbow-based adaptive threshold [see Eq. (27)]:

$$d^* = \min\{j \in \{2,\ldots,d-1\} : |\Delta \bar{S}_{\alpha_j,w}| > \eta\}, \tag{27}$$

where,

$$\Delta \bar{S}_{\alpha_j,w} = \bar{S}_{\alpha_{j+1},w} - 2\,\bar{S}_{\alpha_j,w} + \bar{S}_{\alpha_{j-1},w}, \tag{28}$$

and $\eta > 0$ is a small tolerance parameter [see Eq. (28)].

Algorithm 1 summarizes the aforementioned steps of the proposed SW-MCFS process, which produces the top-d^* features from the selected subset $\mathcal{F}$. In practice, the parameter γ is fixed to 5 in all experiments.

Algorithm 1 SW-MCFS: Stability-Weighted Multi-Criteria Feature Selection

Input: $K, N, d, \mathcal{D}, \gamma, \eta, R$
Output: $\mathcal{F}^*$
$\mathcal{C} \leftarrow \lfloor \frac{N}{K} \rfloor$ //Cardinal of $\mathcal{D}_{\text{val}}^{(k)}$
for $k = 1$ to K **do**
//Split $\mathcal{D}$ into $\mathcal{D}_{\text{val}}^{(k)}$ and $\mathcal{D}_{\text{tr}}^{(k)}$ using (3)-(4)
  $\mathcal{D}_{\text{val}}^{(k)} \leftarrow \{(\mathbf{x}_{(k-1)\times\mathcal{C}+i}, y_i)\}_{i=1}^{\mathcal{C}}$
  $\mathcal{D}_{\text{tr}}^{(k)} \leftarrow \mathcal{D} \setminus \mathcal{D}_{\text{val}}^{(k)}$
  for $m = 1$ to 4 **do**
    for $j = 1$ to d **do**
      Evaluate $S_{j,k}^{(m,n)}$ // using Eqs. (8),(12),(14),(18)
    end for
    Compute $\overline{S}_j^{(m,n)}$ //using Eq. (25)
    Deduce $\mathbf{r}_m^{(k)}$ //defined in Eq. (20)
  end for
end for
//Stability Computation
for $m = 1$ to 4 **do**
  Evaluate ρ_m and ω_m //Using Eq. (19) and (23)
end for
for $j = 1$ to d **do**
  Evaluate $\bar{S}_{j,w}$ // Using Eq. (24)
end for
//Adaptive Threshold
Sort features in descending order of $\{\bar{S}_{j,w}\}_{1 \le j \le d}$
$j = 2$
repeat
  Compute $\Delta \bar{S}_{\alpha_j,w}$ //using Eq. (28)
  $j \leftarrow j + 1$
until $\Delta \bar{S}_{\alpha_{j-1},w} \le \eta$ **and** $j \le d$
$d^* \leftarrow j - 1$
$\mathcal{F}^* = \{\alpha_1, \ldots, \alpha_{d^*}\}$
return $\mathcal{F}^*$

D. Adaptive PSO (APSO)

After SW-MCFS reduces the original feature space to a lower-dimensional space of size $d^* \le d$, optimization is performed using a swarm of $\mathcal{S}$ particles. To balance exploration and exploitation adaptively, the concept of normalized swarm diversity is introduced within the APSO framework. The following notation formally defines the optimization procedure.

1) Notation: At iteration $t = 1, \ldots, \mathcal{T}_{\text{APSO}}$, particle $i = 1, \ldots, \mathcal{S}$ is characterized by:

- $\mathbf{p}_i^{(t)} \in \mathbb{R}^{d^*}$: *position vector* of particle i, representing a candidate set of model parameters.
  It is initialized as Eq. (29):
$$\mathbf{p}_i^{(0)} \sim \mathcal{U}(-p_{\max}, p_{\max})^{d^*}. \tag{29}$$
- $\mathbf{v}_i^{(t)} \in \mathbb{R}^{d^*}$: *velocity vector* controlling the update direction and exploration strength. It is initialized as Eq. (30):
$$\mathbf{v}_i^{(0)} \sim \mathcal{U}(-v_{\max}, v_{\max})^{d^*}. \tag{30}$$
- $\mathbf{p}_{i,\text{best}}^{(t)}$: personal best position of particle i, defined as the best position visited up to iteration t:
$$\mathbf{p}_{i,\text{best}}^{(t)} = \arg\min_{\tau \le t} f(\mathbf{p}_i^{(\tau)}), \qquad 1 \le i \le \mathcal{S}.$$
- $f(\mathbf{p})$: *fitness function* evaluating the validation performance of a particle [see Eq. (31)],
$$f(\mathbf{p}) = \frac{1}{|\mathcal{D}_{\text{val}}|} \sum_{(x,y) \in \mathcal{D}_{\text{val}}} \mathcal{L}(F(x;\mathbf{p}), y), \tag{31}$$

where, $F(x;\mathbf{p})$ denotes the NN parameterized by $\mathbf{p}$, and $\mathcal{L}$ is the loss function measuring the discrepancy between the predicted output $\hat{y} = F(x;\mathbf{p})$ and the true label y.

- $\mathbf{g}^{(t)}$: *global best position* among all particles [see Eq. (32)],

$$\mathbf{g}^{(t)} = \arg\min_{1\le i\le \mathcal{S}} f(\mathbf{p}_{i,\text{best}}^{(t)}). \tag{32}$$

The overall optimization problem is formulated as Eq. (33):

$$\mathbf{p}^* = \arg\min_{\mathbf{p}\in\mathbb{R}^{d^*}} f(\mathbf{p}). \tag{33}$$

2) Fitness-Landscape-Aware Inertia (FLAI): Instead of using a fixed inertia weight, it is adapted according to the current behavior of the swarm [21], [22].

The improvement of the global best at iteration t is defined as Eq. (34):

$$\Delta^{(t)} = \frac{f(\mathbf{g}^{(t-1)}) - f(\mathbf{g}^{(t)})}{f(\mathbf{g}^{(t-1)}) + \varepsilon}, \tag{34}$$

where, ε avoids numerical instability.

Swarm diversity is quantified by the dispersion of personal best positions [see Eq. (35)]:

$$\mathcal{F}^{(t)} = \frac{1}{\mathcal{S}\times d^*} \sum_{i=1}^{\mathcal{S}} \|\mathbf{p}_{i,\text{best}}^{(t)} - \bar{\mathbf{p}}_{\text{best}}^{(t)}\|_2, \tag{35}$$

where [see Eq. (36)],

$$\bar{\mathbf{p}}_{\text{best}}^{(t)} = \frac{1}{\mathcal{S}} \sum_{i=1}^{\mathcal{S}} \mathbf{p}_{i,\text{best}}^{(t)}. \tag{36}$$

Using the normalized versions $\hat{\mathcal{F}}^{(t)}$ and $\hat{\Delta}^{(t)}$ defined as Eq. (37):

$$\hat{\chi}^{(t)} = \frac{\chi^{(t)} - \chi_{\min}^{(t)}}{\chi_{\max}^{(t)} - \chi_{\min}^{(t)}}, \quad \chi \in \{\mathcal{F}, \Delta\}, \tag{37}$$

where Eq. (38),

$$\chi_{\min}^{(t)} = \min_{k\in[t-W+1,\,t]} \chi^{(k)}, \quad \chi_{\max}^{(t)} = \max_{k\in[t-W+1,\,t]} \chi^{(k)}, \tag{38}$$

and W is a sliding window size. As such, the inertia weight is updated as Eq. (39):

$$w^{(t)} = w_{\min} + (w_{\max} - w_{\min}) \times \mathcal{K}\big((\hat{\mathcal{F}}^{(t)} - \hat{\Delta}^{(t)}) \times \kappa\big), \tag{39}$$

with

$$\mathcal{K}(z) = \frac{1}{1+e^{-z}}.$$

Further, the parameter κ controls the sensitivity of the inertia update and initially $w^{(0)}$ is initialized as Eq. (40):

$$w^{(0)} = \frac{(w_{\max} + w_{\min})}{2}. \tag{40}$$

It is worth noting that:

- If $\hat{\mathcal{D}}_t \gg \hat{\Delta}_t$ (high diversity but weak improvement), the swarm explores without significant progress. In this case, the inertia weight decreases toward $w_{\min}$ to promote exploitation.
- If $\hat{\mathcal{D}}_t \ll \hat{\Delta}_t$ (low diversity but strong improvement), the swarm converges productively. The inertia weight is maintained at a moderate level to preserve stable convergence.
- If $\hat{\mathcal{D}}_t \approx \hat{\Delta}_t$, a balanced search state is achieved, leading to $w^{(t)} \approx (w_{\min} + w_{\max})/2$.
- If both $\hat{\mathcal{D}}_t$ and $\hat{\Delta}_t$ are small, stagnation is detected and stronger exploration mechanisms such as Lévy flight perturbation are triggered.

3) Lévy Flight Perturbation (LFP): When the swarm stagnates or loses diversity within τ_s consecutive iterations, randomness is injected using a Lévy flight to escape local minima. A β-index Lévy step is generated as [23] [see Eq. (41)]:

$$L_{j,\beta} = \frac{u_j}{|v_j|^{1/\beta}}, \quad j \le d^*, \tag{41}$$

where, u_j and v_j are two Gaussian distributions of zero mean [see Eq. (42)]:

$$u_j \sim \mathcal{N}(0, \sigma_u^2), \quad v_j \sim \mathcal{N}(0,1), \tag{42}$$

and

$$\sigma_u = \left[\frac{\Gamma(1+\beta)\sin(\pi\beta/2)}{\Gamma\big(\frac{1+\beta}{2}\big)\,\beta\,2^{(\beta-1)/2}}\right]^{1/\beta},$$

where, $\Gamma(\cdot)$ is the Gamma function. Using the Gamma–Legendre duplication formula [52] $\Gamma(1+\beta)/\Gamma\big(\frac{1+\beta}{2}\big) = \frac{2^\beta}{\sqrt{\pi}}\Gamma\big(\frac{\beta}{2}+1\big)$ along with the identity $\Gamma\big(\frac{\beta}{2}+1\big) = \frac{\beta}{2}\Gamma\big(\frac{\beta}{2}\big)$, σ_u can be reduced to Eq. (43):

$$\sigma_u = \sqrt{2}\left[\frac{\sin(\pi\beta/2)}{\sqrt{2\pi}}\right]^{1/\beta}. \tag{43}$$

The particle is then perturbed around the current global best [see Eq. (44)]:

$$\mathbf{p}_i^{(t)} \leftarrow \mathbf{p}_i^{(t)} + \alpha_L\,\mathbf{L}_\beta \odot \big(\mathbf{p}_i^{(t)} - \mathbf{g}^{(t)}\big), \tag{44}$$

where, $\mathbf{L}_\beta = (L_{1,\beta}, \ldots, L_{d^*,\beta})^T$, $\odot$ denotes element-wise (Hadamard) multiplication, and α_L is a significant small step size scaling factor. This introduces long-range jumps when the search becomes trapped.

4) Elite-Guided Reinitialization (EGR): To further prevent premature convergence, every $\mathcal{T}_{\text{EGR}}$ iterations, the worst-performing $N_{\textbf{elite}}$ particles (i.e., with highest fitness) are reinitialized around the global elite using Gaussian-based EGR [see Eq. (45)]:

$$\mathbf{p}_{\vartheta_i}^{(t)} = \mathbf{g}_{\text{best}} + \boldsymbol{\xi}, \quad 1 \leq i \leq N_{\textbf{elite}}, \tag{45}$$

where [see Eq. (46)],

$$\boldsymbol{\xi} \sim \mathcal{N}\big(\mathbf{0},\, \sigma_{\text{EGR}}^2 \mathbf{I}_{d^*}\big)\,, \tag{46}$$

$$f(\mathbf{p}_{\vartheta_1}^{(t)}) \geq f(\mathbf{p}_{\vartheta_2}^{(t)}) \geq \ldots \geq f(\mathbf{p}_{\vartheta_{\mathcal{S}}}^{(t)}), \vartheta_i \in \{1 \ldots \mathcal{S}\}, \tag{47}$$

and $\sigma_{\text{EGR}} = 0.1 \times \mathcal{F}^{(t)}$. This step increases population diversity by injecting new candidate solutions near the best-known region while still preserving exploitation [see Eq. (47)].

5) APSO velocity and position update: Leveraging the inertia weight assessed in Eq. (39), the velocity is updated as Eq. (48):

$$\begin{aligned}\mathbf{v}_i^{(t)} = {} & w^{(t-1)}\mathbf{v}_i^{(t-1)} + c_1\mathbf{r}_1 \odot \big(\mathbf{p}_{i,\text{best}}^{(t-1)} - \mathbf{p}_i^{(t-1)}\big) \\ & + c_2\mathbf{r}_2 \odot \big(\mathbf{g}_{\text{best}}^{(t-1)} - \mathbf{p}_i^{(t-1)}\big),\end{aligned} \tag{48}$$

where,

- $\mathbf{g}_{\text{best}}^{(\tau)} = \min_{1 \leq \tau \leq t} \mathbf{g}^{(t)}$ is the global best position until t.
- c_1 and c_2 are the cognitive and social acceleration coefficients, respectively;
- $\mathbf{r}_1, \mathbf{r}_2 \sim \mathcal{U}(0,1)^{d^\star}$ are independent random vectors introducing stochastic exploration.

To prevent the uncontrolled growth of the velocity and to stabilize the search process, a component-wise bound is imposed as:

$$v_{i,d}^{(t)} = \min\Big(\max\big(v_{i,d}^{(t)}, -v_{\max}\big), v_{\max}\Big), \quad 1 \leq d \leq d^\star. \tag{49}$$

As such, the particle position is updated as follows [see Eq. (50)]:

$$\mathbf{p}_i^{(t)} = \mathbf{p}_i^{(t-1)} + \mathbf{v}_i^{(t)}, 1 \leq i \leq \mathcal{S}. \tag{50}$$

Similarly to Eq. (49), the positions are projected onto the feasible search space using a component-wise clipping operator [see Eq. (51)]:

$$p_{i,d}^{(t)} = \min\Big(\max\big(p_{i,d}^{(t)}, -p_{\max}\big), p_{\max}\Big), \quad 1 \leq d \leq d^\star. \tag{51}$$

Algorithm 2 presents the proposed APSO framework for global optimization. It iteratively updates particle velocities and positions using adaptive inertia, stochastic perturbation, and elite-guided reinitialization to enhance exploration and prevent premature convergence. The algorithm returns the optimal global best solution $\mathbf{g}_{\text{best}}$, which initializes the subsequent fine-tuning stage.

Algorithm 2 Adaptive PSO

Input: $\mathcal{D}_{\text{tr}}, \mathcal{D}_{\text{val}}, p_{\max}, v_{\max}, \mathcal{S}, \mathcal{T}_{\text{APSO}}, d^*, c_1, c_2, \kappa, \tau_s$ $\mathcal{T}_{\text{SGD}}, \varepsilon, W, w_{\min}, w_{\max}, \beta, \alpha_N, \sigma_{\text{EGR}}, \mathcal{T}_{\text{EGR}}, N_{\textbf{elite}}$
Output: $\mathbf{g}_{\text{best}}$ //Global best position
for $i = 1$ to $\mathcal{S}$ **do** //Initialize swarm position and speed
  Generate randomly $\mathbf{p}_i^{(0)}, \mathbf{v}_i^{(0)}$ //using Eqs. (29)-(30)
  Initialize $\mathbf{p}_{i,\text{best}} \leftarrow \mathbf{p}_i^{(0)}$
  Evaluate the fitness $f(\mathbf{p}_i^{(0)})$
  Initialize $Stag_i \leftarrow 0$ //Stagnation counters $\leq \tau_s$
end for
Deduce $\mathbf{g}^{(0)}$ //using Eq. (32)
Initialize $\mathbf{g}_{\text{best}} \leftarrow \mathbf{g}^{(0)}$
Compute σ_u //using Eq. (43)
Initialize inertia weight $\omega^{(0)}$ //using Eq. (40)
for $t = 1$ to $\mathcal{T}_{\text{APSO}}$ **do**
  for $i = 1$ to $\mathcal{S}$ **do**
    Generate two d^*-vectors $\mathbf{r}_1$ and $\mathbf{r}_2$
    Update $\mathbf{v}_i^{(t)}$ //using Eq. (48) and then (49)
    Update $\mathbf{p}_i^{(t)} \leftarrow \mathbf{p}_i^{(t-1)} + \mathbf{v}_i^{(t)}$ //As in (50) then (51)
    if $f(\mathbf{p}_i^{(t)}) < f(\mathbf{p}_{i,\text{best}})$ **then**
      $\mathbf{p}_{i,\text{best}} \leftarrow \mathbf{p}_i^{(t)}$; $Stag_i \leftarrow 0$
    else
      $Stag_i \leftarrow Stag_i + 1$
      if $Stag_i \geq \tau_s$ **then** //Apply LFP
        for $j = 1$ to d^* **do**
          Generate u_j, v_j //using (42)
          Deduce $L_{j,\beta}$ //using (41)
        end for
        Update $\mathbf{p}_i^{(t)}$ //using (44)
        Re-evaluate $f(\mathbf{p}_i^{(t)})$ and re-calculate $\mathbf{p}_{i,\text{best}}$
        $Stag_i \leftarrow 0$
      end if
    end if
    if $f(\mathbf{p}_{i,\text{best}}) < f(\mathbf{g}_{\text{best}})$ **then** //Update $\mathbf{g}_{\text{best}}$: (32)
      $\mathbf{g}_{\text{best}} \leftarrow \mathbf{p}_{i,\text{best}}$;
    end if
  end for
  Compute $\Delta^{(t)}$ //using Eq. (34)
  Evaluate $\bar{\mathbf{p}}_{\text{best}}^{(t)}$ and Deduce $\mathcal{F}^{(t)}$ //using (36),(35)
  Compute $\Delta_{\min}^{(t)}, \Delta_{\max}^{(t)}, \mathcal{F}_{\min}^{(t)}, \mathcal{F}_{\max}^{(t)}$ //using Eq. (37)
  Deduce $\hat{\Delta}^{(t)}, \hat{\mathcal{F}}^{(t)}$ //using Eq. (38)
  Deduce $w^{(t)}$ //using Eq. (39)
  //Apply EGR
  Set $\sigma_{\text{EGR}} \leftarrow 0.1 \times \mathcal{F}^{(t)}$
  if $t \bmod \mathcal{T}_{\text{EGR}} = 0$ **then**
    Sort $\mathbf{p}_i^{(t)}$ in descending order of fitness //as in (47)
    for $i = 1$ to N_{elite} **do**
      Generate randomly $\boldsymbol{\xi}$ //as in (46)
      Update $\mathbf{p}_{\vartheta_i}^{(t)}$ //as in (45)
      if $f(\mathbf{p}_{\vartheta_i}^{(t)}) < f(\mathbf{p}_{\vartheta_i,\text{best}})$ **then**
        $\mathbf{p}_{\vartheta_i,\text{best}} \leftarrow \mathbf{p}_{\vartheta_i}^{(t)}$
      end if
    end for
  end if
  Recompute $\mathbf{g}_{best}$ from $\mathbf{p}_{\vartheta_i,\text{best}}$
  //Save position and velocity for subsequent iteration
  $\mathbf{p}_i^{(t+1)} \leftarrow \mathbf{p}_i^{(t)}, \quad \mathbf{v}_i^{(t+1)} \leftarrow \mathbf{v}_i^{(t)}$
end for
return $\mathbf{g}_{\text{best}}$

6) SGD-Based fine-tuning: After the APSO stage described in Section III-D, the optimal solution $\mathbf{g}_{\text{best}} \in \mathbb{R}^{d^*}$ is reshaped to initialize the parameters of a feedforward neural network with architecture $[d^*, n_1, 1]$, where d^* is the input dimension and n_1 denotes the number of hidden neurons. As such, each training sample is represented by a reduced feature vector $\mathbf{s} \in \mathbb{R}^{d^*}$ and $\mathbf{g}_{\text{best}}$ is partitioned into structured parameter blocks [see Eq. (52)]:

$$\mathbf{g}_{\text{best}} = [\mathbf{g}_{W_1}; \mathbf{g}_{b_1}; \mathbf{g}_{w_2}; g_{b_2}], \tag{52}$$

where, $\mathbf{g}_{W_1} \in \mathbb{R}^{n_1 \times d^*}$, $\mathbf{g}_{b_1} \in \mathbb{R}^{n_1}$, $\mathbf{g}_{w_2} \in \mathbb{R}^{n_1}$, and $g_{b_2} \in \mathbb{R}$.

The forward propagation step computes the hidden representation via a linear transformation followed by a ReLU activation. The output layer applies the sigmoid activation, defined in Section III-D2, to produce the final prediction [see Eq. (53)]:

$$\hat{y} = \mathcal{K}(\mathbf{g}_{w_2}^\top \mathbf{h} + g_{b_2}), \tag{53}$$

where [see Eq. (54)],

$$\mathbf{h} = \max(\mathbf{0}, \mathbf{g}_{W_1}\mathbf{s} + \mathbf{g}_{b_1}), \tag{54}$$

The complete trainable parameter vector is defined as Eq. (55):

$$\boldsymbol{\theta} = \{\mathbf{g}_{W_1}; \mathbf{g}_{b_1}; \mathbf{g}_{w_2}; g_{b_2}\}, \tag{55}$$

initialized at Eq. (56):

$$\boldsymbol{\theta}_0 = \text{reshape}(\mathbf{g}_{\text{best}}). \tag{56}$$

Obviously, $\mathbb{R}^{|\boldsymbol{\theta}|} = n_1 d^* + 2n_1 + 1$. The model is trained via backpropagation [46] by minimizing the binary cross-entropy loss with L_2 regularization:

$$\mathcal{L}(\boldsymbol{\theta}) = \frac{1}{|\mathcal{D}_{\text{tr}}|} \sum_{j=1}^{|\mathcal{D}_{\text{tr}}|} \underbrace{[-y_j \log \hat{y}_j - (1-y_j)\log(1-\hat{y}_j)]}_{\triangleq \mathcal{E}_j} - \frac{\lambda}{2}\|\boldsymbol{\theta}\|_2^2, \tag{57}$$

where, $|\mathcal{D}_{\text{tr}}|$ is the number of training samples and λ controls the regularization strength.

At each iteration, the gradient of the loss function in Eq. (57) is computed over a mini-batch $\mathcal{B} \subset \mathcal{D}_{\text{tr}}$ of fixed size $|\mathcal{B}|$ [see Eq. (58)]:

$$\nabla_{\boldsymbol{\theta}} \mathcal{L}_{\mathcal{B}} = \frac{1}{|\mathcal{B}|} \sum_{j \in \mathcal{B}} \nabla_{\boldsymbol{\theta}} \mathcal{E}_j + \lambda \boldsymbol{\theta}, \tag{58}$$

where, ∇ denotes the gradient operator and $\mathcal{E}_j$ denotes the binary cross-entropy loss for sample j.

Optimization is performed using stochastic gradient descent [34], [35] with momentum [47]:

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \mathbf{u}_t, 0 \le t < \mathcal{T}_{\text{SGD}} - 1, \tag{59}$$

where, $\mathbf{u}_t \in \mathbb{R}^{|\boldsymbol{\theta}|}$, defined as:

$$\begin{cases} \mathbf{u}_t = \mu_m \mathbf{u}_{t-1} + \eta_\ell \nabla_{\boldsymbol{\theta}} \mathcal{L}, & 1 \le t \le \mathcal{T}_{\text{SGD}} \\ \mathbf{u}_0 = \mathbf{0} \end{cases}. \tag{60}$$

where, η_ℓ is the learning rate and μ_m is the momentum coefficient. Mini-batch training with a fixed batch size is used, and early stopping based on validation performance prevents overfitting.

Thus, the SGD stage iteratively applies the parameter update in Eq. (59) with momentum accumulation as defined in Eq. (60) to refine the APSO-initialized parameters and obtain the final optimized model.

Algorithm 3 summarizes the complete fine-tuning procedure.

Algorithm 3 SGD Fine-Tuning

Input: $\mathcal{D}_{\text{tr}}, \mathcal{D}_{\text{val}}, \mathbf{g}_{\text{best}}, \lambda, \eta_\ell, \mu_m, T_{\text{SGD}}, |\mathcal{B}|, T_{\text{pat}}$
Output: $\boldsymbol{\theta}^*$
$\boldsymbol{\theta}_0 \leftarrow \text{reshape}(\mathbf{g}_{\text{best}})$ //as in (55)
$\mathbf{u}_0 \leftarrow \mathbf{0}$
$\mathcal{L}^* \leftarrow \infty$, wait $\leftarrow 0$
for epoch $= 1$ to $\mathcal{T}_{\text{SGD}}$ **do**
  for each mini-batch $\mathcal{B}$ in epoch **do** // $\left\lfloor \frac{|\mathcal{T}_{\text{SGD}}|}{|\mathcal{B}|} \right\rfloor$ times
    $\mathbf{g}_t \leftarrow \frac{1}{|\mathcal{B}|} \sum_{j \in \mathcal{B}} \nabla_{\boldsymbol{\theta}} \mathcal{L} + \lambda \boldsymbol{\theta}$
    $\mathbf{u}_t \leftarrow \mu_m \mathbf{u}_{t-1} + \eta_\ell \mathbf{g}_t$
    $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \mathbf{v}_t$
  end for
  $\mathcal{L}_{\text{val}} \leftarrow \mathcal{L}(\boldsymbol{\theta}; \mathcal{D}_{\text{val}})$
  if $\mathcal{L}_{\text{val}} < \mathcal{L}^*$ **then**
    $\mathcal{L}^* \leftarrow \mathcal{L}_{\text{val}}$
    $\boldsymbol{\theta}^* \leftarrow \boldsymbol{\theta}$
    wait $\leftarrow 0$
  else
    wait $\leftarrow$ wait $+ 1$
    if wait $\ge T_{\text{pat}}$ **then**
      break
    end if
  end if
end for
return $\boldsymbol{\theta}^*$

IV. Experimental Setup and Data Description

This section describes the dataset, preprocessing pipeline, and experimental configuration used to evaluate the proposed framework. All preprocessing steps were performed using the training data only to avoid information leakage.

A. Dataset Description

The dataset contains $10,247$ recruitment records collected from a telecommunications company in North Africa between 2018 and 2022. After removing duplicates and incomplete evaluations (minimum six months of employment), the final dataset was retained for analysis.

The data includes 14 features, as outlined in Table I, grouped into four categories:

- Demographic (e.g., age, gender, marital status),
- Educational (e.g., education level, specialization, certifications),
- Professional (e.g., experience, salary, seniority, language proficiency),

TABLE I. DATASET DESCRIPTION GROUPED BY FEATURE CATEGORIES ($n = 10{,}247$)

Category	Feature	Value Range / Distribution
Demographic Features		
	Age	22–58 (mean: 31.4, SD: 6.2)
	Gender	Male (54%) / Female (46%)
	Marital Status	Single (61%) / Married (39%)
Educational Features		
	Education Level	Bachelor (58%), Master (35%), PhD (7%)
	Specialization	Tech (42%), Econ (31%), HR (15%), Law (12%)
	Certifications	Yes (34%) / No (66%)
Professional Features		
	Experience	0–15 years (mean: 4.8, SD: 3.1)
	Salary	4,000–18,000 MAD (mean: 8,200, SD: 2,800)
	Language Proficiency	1–5 (mean: 3.2, SD: 1.1)
Behavioral Features		
	Communication	1–5 (mean: 3.6, SD: 0.9)
	Motivation	Yes (73%) / No (27%)
	Remote Work	Yes (68%) / No (32%)
	Physical Ability	Yes (91%) / No (9%)
Target Variable		
	Performance	BA (38%) / Good (62%)

- Behavioral (e.g., communication skills, motivation, remote work adaptability, physical ability).

The target variable represents job performance and is defined as a binary label: *Below Average (BA)* and *Good*.

It should be noted that binary performance labels derived from HR evaluations are inherently subject to noise, as they reflect subjective managerial assessments that may vary across evaluators and organizational contexts. This label noise imposes an upper bound on achievable predictive accuracy and should be considered when interpreting the reported results. The 76.8% accuracy achieved by the proposed framework may partly reflect this noise ceiling rather than a fundamental model limitation.

Ethical approval was obtained from the institutional review board. All personal identifiers were removed, and data handling followed privacy regulations.

B. Data Preprocessing

The dataset was divided into 80% training ($n = 8{,}197$) and 20% test ($n = 2{,}050$) using stratified sampling. A 10-fold stratified cross-validation procedure was applied on the training set.

The preprocessing pipeline consists of the following steps:

- *Missing values:* Missing entries in several attributes are estimated using KNN imputation [37], [38] with k_{nn} neighbors. For a missing value $w_{i,j}$, the estimate is computed as Eq. (61):

$$\hat{x}_{i,j} = \frac{1}{k_{\text{nn}}} \sum_{\ell \in \mathcal{N}_{k_{\text{nn}}}(i)} x_{\ell,j}, \tag{61}$$

  where, $\mathcal{N}_{k_{\text{nn}}}(i)$ denotes the set of the k_{nn} nearest samples to observation i.

- *Encoding:* Binary variables are encoded as $\{0, 1\}$, while categorical attributes with multiple categories are transformed using one-hot encoding.

- *Scaling:* Continuous variables are normalized using Min–Max scaling [see Eq. (62)]:

$$x_{i,j}^{\text{scaled}} = \frac{x_{i,j} - x_j^{(\min)}}{x_j^{(\max)} - x_j^{(\min)}}. \tag{62}$$

- *Outlier handling:* Extreme values are capped using the interquartile range (IQR) rule [40], affecting approximately 1.4% of the observations.

All transformations were fitted on training data and applied to validation and test sets to prevent data leakage.

C. Baseline Models and Configurations

Classical machine learning models are used as benchmarks to evaluate the effectiveness of the proposed framework, including RF [18], SVM [49], and gradient boosting methods [26], [41]. The standard ANN baseline employs the Adam optimizer [36] with dropout regularization [45]. Xavier initialization [48] is used for SGD-only baselines. All implementations use scikit-learn [39] and custom Python modules. Rather than detailing their internal formulations, their feature usage, architectures, and optimization strategies are summarized in Table II.

TABLE II. MODEL CONFIGURATIONS USED FOR BENCHMARKING

Model	*Features*	*Architecture*	*Optimization*
RF	14	500 trees	–
XGBoost	14	500 trees	–
SVM	14	RBF kernel	SMO
Std. ANN	14	$(14 - 21 - 1)$	Adam
LR-ANN+SGD	LR (12)	$(12 - 18 - 1)$	SGD
LR-ANN+PSO-SGD	LR (12)	$(12 - 18 - 1)$	PSO $\rightarrow$ SGD
SW-MCFS-APSO-SGD	**SW-MCFS**	**Adaptive**	**APSO $\rightarrow$ SGD**

D. Experimental Setup

This subsection summarizes the experimental configuration used to evaluate the proposed framework. All hyperparameters for Algorithm 1 to Algorithm 3 are reported in Table III. These settings were fixed across all experiments to ensure fair comparison and reproducibility.

The evaluation protocol is based on:

- *Cross-validation:* 10-fold stratified cross-validation on the training set.
- *Performance metrics:* Accuracy, Precision, Recall, Specificity, and F1-Score.
- *Statistical testing:* McNemar's test for pairwise comparison on the held-out test set and the Friedman test with Nemenyi post-hoc analysis across folds. The significance level is set to $\alpha = 0.05$.
- *Ablation analysis:* Each ablation configuration is repeated 10 times with different random seeds to assess stability and robustness.

V. RESULTS

Comprehensive experiments are conducted to assess feature selection quality, predictive performance, statistical significance, robustness, interpretability, and computational efficiency of the proposed framework.

TABLE III. PARAMETER SETTINGS FOR ALGORITHM 1, 2, AND 3

Alg.	*Param.*	*Val.*	*Param.*	*Val.*	*Param.*	*Val.*
1	K	10	N	10247	d	14
	γ	5	η	0.05	R	30
2	$p_{\max}$	2	$v_{\max}$	1	$\mathcal{T}_A$	200
	$\mathcal{S}$	20	d^*	10	ϵ	10^{-10}
	W	5	κ	10	$w_{\min}$	0.2
	$w_{\max}$	0.9	β	1.5	τ_s	5
	α_L	0.01	N_e	$\lfloor \mathcal{S}/5 \rfloor$	$\mathcal{T}_E$	10
	c_1	2.0	c_2	2.0	η_ℓ	0.01
	μ_m	0.9	$\lvert\mathcal{B}\rvert$	32	T_{pat}	15

A. Feature Selection Analysis

1) Method stability and consensus weights: Table IV reports the cross-validation stability scores ρ_m and the corresponding consensus weights ω_m computed for each feature scoring method.

TABLE IV. STABILITY AND CONSENSUS WEIGHTS FOR SW-MCFS

Method	ρ_m	ω_m
Mutual Information	0.91	0.31
Wald Significance	0.87	0.24
Fisher Discriminant Loading	0.84	0.20
Permutation Importance	0.89	0.25

Mutual Information achieves the highest stability, resulting in the largest weight. In contrast, Fisher Discriminant Loading exhibits the lowest stability and is automatically down-weighted. This demonstrates that the proposed aggregation mechanism effectively prioritizes reliable scoring methods.

2) Feature relevance and selection outcome: Table V presents the normalized feature relevance scores and the aggregated score $\overline{S}_{\alpha_j,w}$.

TABLE V. REDUCED $d^* = 10$ FEATURES USING THE SW-MCFS ALGORITHM.

j	*Feature*	$\overline{S}^{(m,n)}_{1,\alpha_j}$	$\overline{S}^{(m,n)}_{2,\alpha_j}$	$\overline{S}^{(m,n)}_{3,\alpha_j}$	$\overline{S}^{(m,n)}_{4,\alpha_j}$	$\overline{S}_{\alpha_j,w}$
1	*Communication*	1.00	0.92	0.88	1.00	**0.96**
2	*Experience*	0.87	1.00	0.91	0.82	**0.90**
3	*Seniority*	0.82	0.85	1.00	0.78	**0.86**
4	*Salary*	0.79	0.78	0.82	0.85	**0.81**
5	*Education*	0.71	0.74	0.69	0.73	**0.72**
6	*Language Prof.*	0.68	0.65	0.61	0.71	**0.67**
7	*Specialization*	0.62	0.58	0.55	0.64	**0.60**
8	*Remote Work*	0.55	0.52	0.48	0.58	**0.54**
9	*Certifications*	0.48	0.51	0.44	0.46	**0.47**
10	*Age*	0.42	0.45	0.38	0.40	**0.41**
11	*Gender*	0.28	0.31	0.22	0.25	0.27
12	*Marital Status*	0.24	0.27	0.19	0.21	0.23
13	*Motivation*	0.18	0.15	0.12	0.20	0.16
14	*Physical Ability*	0.12	0.08	0.14	0.11	0.11

Using the adaptive elbow threshold defined in Eq. (27) with $\tau^* = 0.34$, the algorithm selects $d^* = 10$ features. Sensitive demographic attributes such as Gender and Marital Status are automatically discarded due to their low aggregated relevance.

Compared with baseline selection methods, SW-MCFS preserves informative predictors (e.g., Experience, Education, Communication) while filtering low-signal attributes. This improves both interpretability and robustness against potential bias.

TABLE VI. PERFORMANCE COMPARISON (10-FOLD CV, $n = 8{,}197$) MEAN $\pm$ SD

Model	*Acc.*	*Prec.*	*Rec.*	*Spec.*	*F1*
Random Forest	72.1 ± 1.8	70.3 ± 2.1	73.5 ± 2.4	69.8 ± 2.0	71.8 ± 1.9
XGBoost	73.8 ± 1.5	72.1 ± 1.9	75.2 ± 2.0	71.4 ± 1.7	73.6 ± 1.6
SVM	70.4 ± 2.3	68.9 ± 2.5	71.2 ± 2.8	69.1 ± 2.4	70.0 ± 2.3
Standard ANN	73.2 ± 1.9	71.5 ± 2.2	74.6 ± 2.1	70.9 ± 2.0	73.0 ± 1.9
LR-ANN + SGD	74.6 ± 1.6	73.1 ± 1.8	75.6 ± 1.9	72.8 ± 1.7	74.3 ± 1.6
LR-ANN + PSO-SGD	75.2 ± 1.4	73.6 ± 1.7	76.3 ± 1.8	73.5 ± 1.6	74.9 ± 1.5
SW-MCFS-ANN + SGD	76.2 ± 1.3	74.8 ± 1.6	77.1 ± 1.7	74.5 ± 1.5	75.9 ± 1.4
SW-MCFS-APSO-SGD	$\mathbf{76.8 \pm 1.2}$	$\mathbf{75.3 \pm 1.5}$	$\mathbf{77.8 \pm 1.6}$	$\mathbf{75.2 \pm 1.4}$	$\mathbf{76.5 \pm 1.3}$

B. Model Comparison Results

Table VI compares the predictive performance of classical machine learning models and neural networks under different optimization strategies. Performance is evaluated using Accuracy, Precision, Recall, Specificity, and F1-score. Results are reported as mean $\pm$ standard deviation (SD) over 10-fold stratified cross-validation.

The proposed SW-MCFS-APSO-SGD framework achieves the highest accuracy while maintaining the lowest variance across folds. The reduced standard deviation indicates stable convergence and strong generalization ability.

C. Statistical Significance Analysis

To verify whether performance improvements are statistically significant, pairwise and global non-parametric tests are performed. Table VII reports the McNemar's test results comparing the proposed SW-MCFS-APSO-SGD against all competing models.

TABLE VII. MCNEMAR'S TEST COMPARING SW-MCFS-APSO-SGD AGAINST COMPETING MODELS ($p < 0.05$).

Comparison (vs.)	χ^2	*p-value*
Random Forest	16.42	< 0.001
XGBoost	6.31	0.012
SVM	22.87	< 0.001
Standard ANN	8.14	0.004
LR-ANN + SGD	4.85	0.028
LR-ANN + PSO-SGD	4.18	0.041
SW-MCFS-ANN + SGD	3.92	0.048

The Friedman test yields $\chi^2(7) = 45.23$ with $p < 0.001$, confirming overall statistical differences among models. Post-hoc Nemenyi analysis further ranks the proposed framework as the best-performing method with a critical difference of 1.42 at $\alpha = 0.05$.

These results confirm that the improvements of the proposed approach are statistically significant.

D. Ablation Studies

Ablation experiments are conducted to quantify the contribution of individual components.

1) Ablation study for feature selection methods: Table VIII reports the performance of different feature selection strategies, highlighting the contribution of the proposed SW-MCFS method compared to individual and baseline selection techniques.

TABLE VIII. ABLATION A1: FEATURE SELECTION COMPARISON (ALL WITH SGD OPTIMIZER).

Selection Method	*# feat.*	*Accuracy*	*F1*
MI only	11	74.8 ± 1.5	74.5
Wald (LR) only	12	74.6 ± 1.6	74.3
FDL (DA) only	8	68.5 ± 2.1	67.7
PI only	11	75.0 ± 1.5	74.7
Equal-weight consensus	10	75.8 ± 1.4	75.5
SW-MCFS (ours)	**10**	$\mathbf{76.2 \pm 1.3}$	**75.9**

SW-MCFS outperforms single-method selection and equal-weight aggregation. The stability-based weighting contributes to consistent improvements in predictive accuracy.

2) Optimization ablation: Table IX presents the contribution of each component in the proposed framework, evaluating the performance degradation when individual modules are removed.

TABLE IX. ABLATION A2: OPTIMIZER COMPARISON (ALL WITH SW-MCFS FEATURES).

Optimizer	*Accuracy*	*Epochs to 95%*	*Time (s)*
SGD only (Xavier)	76.2 ± 0.8	50.2 ± 4.3	138 ± 8
PSO $\rightarrow$ SGD	76.6 ± 0.6	38.1 ± 3.7	187 ± 12
APSO $\rightarrow$ SGD	$\mathbf{76.8 \pm 0.5}$	$\mathbf{34.5 \pm 3.1}$	$\mathbf{195 \pm 14}$

APSO improves convergence speed and final accuracy compared with standard PSO and SGD-only training with Xavier initialization [48]. The hybrid strategy achieves better optimization stability.

3) Component contribution: Table X quantifies the effect of removing individual components from the proposed framework to assess their relative contribution to the overall performance.

TABLE X. CONTRIBUTION OF INDIVIDUAL COMPONENTS

Configuration	*Accuracy*	Δ *vs. full*
LR + SGD (baseline)	74.6	-2.2
LR + PSO-SGD	75.2	-1.6
SW-MCFS + SGD	76.2	-0.6
SW-MCFS + PSO-SGD	76.6	-0.2
SW-MCFS + APSO-SGD (full)	**76.8**	—

Both feature selection and optimization contribute positively and additively to the overall performance improvement.

E. SHAP Feature Importance

Table XI reports the global SHAP importance scores [50] computed on the trained SW-MCFS-APSO-SGD model, ranking features according to their mean absolute contribution.

TABLE XI. GLOBAL SHAP IMPORTANCE FOR THE PROPOSED MODEL. DEMOGRAPHIC ATTRIBUTES SUCH AS GENDER AND MARITAL STATUS ARE EXCLUDED BY SW-MCFS.

Feature	*Mean* $\lvert\phi_i\rvert$	*Rank*
Communication Skills	0.358	1
Experience	0.301	2
Seniority Level	0.284	3
Salary	0.259	4
Education Level	0.215	5
Language Proficiency	0.194	6
Specialization	0.172	7
Remote Work	0.148	8
Certifications	0.078	9
Age	0.065	10

The results confirm that SW-MCFS automatically excludes sensitive demographic attributes, while communication skills, experience, and seniority remain dominant predictors.

F. Held-Out Test Set Performance

Table XII compares the proposed framework against baseline models on the independent held-out test set.

TABLE XII. PERFORMANCE ON THE INDEPENDENT TEST SET ($n = 2{,}050$)

Model	*Acc.*	*Prec.*	*Rec.*	*F1*
Random Forest	71.8	69.9	73.2	71.5
XGBoost	73.5	71.8	74.9	73.3
SVM	70.1	68.5	70.8	69.6
Standard ANN	72.9	71.2	74.3	72.7
LR-ANN + PSO-SGD	75.0	73.4	76.0	74.7
SW-MCFS-APSO-SGD	**76.5**	**75.1**	**77.6**	**76.3**

The proposed method achieves the highest performance across all metrics, demonstrating strong generalization capability.

G. Computational Efficiency

Table XIII reports the training and inference time of the proposed framework compared to competing models.

TABLE XIII. TRAINING INCLUDES SW-MCFS COMPUTATION ($\sim$24S). IDENTICAL INFERENCE FOR ALL ANNS.

Model	*Train (s)*	*Inference (s/1k)*
XGBoost	68	0.08
LR-ANN + PSO-SGD	187	0.05
SW-MCFS + SGD	162	0.05
SW-MCFS-APSO-SGD	**219**	**0.05**

Although the proposed model requires slightly higher training time due to APSO optimization, inference complexity remains unchanged while achieving superior performance.

VI. DISCUSSION

A. Principal Findings

This study highlights four key findings:

1) SW-MCFS significantly improves feature selection: The stability-weighted multi-criteria approach improves accuracy by 1.6% over single-method LR selection (Table X). Its effectiveness stems from aggregating heterogeneous relevance criteria, applying stability-based weighting to suppress unreliable scorers, and automatically determining the feature dimension via an adaptive threshold. It is important to emphasize that the novelty lies not in the individual scoring methods, which are well-established, but in their principled integration through stability-weighted consensus—a combination that produces emergent benefits including automatic dimensionality determination and demographic attribute filtering that no single method achieves independently.

2) APSO enhances optimization efficiency: The adaptive inertia strategy improves the exploration–exploitation balance, yielding 0.6% gain over SGD-only and 0.2% over standard PSO, with 31% faster convergence. Lévy-flight perturbations further improve robustness by enabling escape from local optima.

3) Observed exclusion of demographic attributes: SW-MCFS systematically excludes Gender and Marital Status, producing a feature set focused on job-relevant variables. This behavior emerges from consensus scoring rather than explicit constraints, as unstable and low-importance features are downweighted across folds. However, this observation should not be interpreted as a formal fairness guarantee; formal fairness metrics such as demographic parity and equalized odds were not computed in this study and remain a necessary direction for future validation [31].

4) Competitive performance against ensemble models: The proposed SW-MCFS–APSO–SGD framework achieves 76.8% accuracy, significantly outperforming XGBoost (73.8%, $p = 0.012$), demonstrating that well-designed neural pipelines can surpass strong ensemble baselines on structured HR data. It is worth noting that in predictive hiring, where target labels are derived from subjective performance evaluations, the inherent label noise imposes an accuracy ceiling that limits all models. Within this context, a 3% absolute improvement over XGBoost represents a meaningful and statistically significant gain [43].

B. Novelty Positioning

Table XIV contrasts the proposed framework with representative prior works. Existing studies typically address either multi-criteria feature selection or adaptive optimization separately. In contrast, the proposed framework jointly integrates stability-weighted multi-method feature selection with adaptive particle-based optimization in a unified learning pipeline.

TABLE XIV. POSITIONING OF THE PROPOSED FRAMEWORK RELATIVE TO PRIOR WORK.

Study	*Multi-FS*	*Adaptive PSO*	*HR Data*

Zhan et al. [22]	–	✓	–
Qin et al. [24]	–	–	✓
Wang et al. [25]	–	–	✓
Ours	✓	✓	✓

C. Limitations

Despite strong empirical performance, several limitations should be acknowledged.

1) Dataset scope: All experiments were conducted on a single-organizational dataset from a North African telecommunications company, which limits external generalizability. The abstract and claims throughout the study are qualified accordingly. Validation across multiple industries, geographic regions, and organizational cultures is required before broader applicability can be established.

2) Label quality: The binary performance labels are derived from subjective managerial evaluations, which constitute a significant source of noise in predictive hiring datasets. Inter-rater reliability and evaluation criteria consistency were not assessed. This noise ceiling contextualizes the 76.8% accuracy and suggests that absolute performance gains should be interpreted relative to this inherent limitation.

3) Fairness evaluation: Although demographic features (Gender, Marital Status) were automatically excluded by SW-MCFS due to low consensus scores, this observation does not constitute a formal fairness guarantee. No formal fairness metrics such as demographic parity, equalized odds, or disparate impact ratios were computed [31]. The exclusion of protected attributes from the feature set does not preclude indirect discrimination through proxy variables (e.g., salary or seniority may correlate with demographic characteristics). Formal fairness auditing remains a critical direction for deployment readiness.

4) Computational cost: SW-MCFS requires multiple feature scorers over K folds, and APSO introduces additional optimization overhead. Scalability to very large datasets (e.g., $> 100{,}000$ records) remains to be evaluated.

5) Hyperparameter sensitivity: Parameters such as γ, APSO settings, and population size were tuned empirically. A systematic sensitivity analysis would further strengthen robustness claims.

D. Ethical Considerations

The deployment of predictive hiring systems raises significant ethical concerns that extend beyond predictive accuracy. Algorithmic hiring tools are increasingly subject to regulatory scrutiny, including the European Union Artificial Intelligence Act [53], which classifies employment-related AI systems as high-risk and mandates transparency, human oversight, and bias auditing requirements [43].

Several ethical dimensions are relevant to the proposed framework. First, although SW-MCFS excludes Gender and Marital Status from the selected feature set, indirect discrimination may persist through correlated proxy variables. For instance, salary levels and seniority may encode historical gender-based disparities, enabling the model to implicitly learn demographic associations. Formal fairness auditing using established metrics (demographic parity, equalized odds, and disparate impact analysis) is essential before any operational deployment.

Second, the use of subjective performance labels as ground truth raises concerns about perpetuating existing organizational

biases. If historical evaluations systematically disadvantaged certain groups, the trained model may reproduce these patterns. Bias-aware label correction and calibration techniques should be explored in future work.

Third, transparency and explainability are critical for stakeholder trust. The SHAP-based interpretability analysis presented in this study provides a foundation for explaining individual predictions to candidates and hiring managers. However, the right to explanation and the principle of human-in-the-loop decision-making require that predictive scores serve as decision-support tools rather than automated gatekeepers.

E. Future Directions

Several extensions can enhance the proposed framework:

1) Fairness-aware extension: Incorporating an explicit fairness-aware scoring term into SW-MCFS would allow penalizing features strongly correlated with protected attributes [see Eq. (63)].

$$\overline{S}^{\text{fair}}_{\alpha_j,w} = \sum_m \omega_m \bar{S}^{(m)}_{\alpha_j} - \lambda_f \mathcal{F}_j, \tag{63}$$

where, λ_f controls the fairness–accuracy trade-off.

2) Deep architectures: Applying the SW-MCFS–APSO pipeline to deeper tabular models (e.g., TabNet [51] or transformer-based architectures) would test scalability to higher-dimensional parameter spaces.

3) Cross-domain validation: Benchmarking on public HR and structured prediction datasets (credit risk, medical classification, etc.) would further validate generalization capability.

4) Online feature selection: Developing an incremental version of SW-MCFS would enable dynamic feature relevance updates as new data becomes available.

VII. Conclusion

This study presents two complementary methodological contributions for predictive hiring: *Stability-Weighted Multi-Criteria Feature Selection (SW-MCFS)* and *Adaptive Particle Swarm Optimization (APSO)*. SW-MCFS aggregates heterogeneous feature scoring methods through stability-weighted consensus across cross-validation folds, producing robust feature subsets while automatically filtering low-signal and demographic attributes. APSO enhances neural network initialization by combining adaptive inertia control with Lévy-flight perturbations, enabling effective exploration of complex optimization landscapes.

The integrated SW-MCFS-APSO-SGD framework achieves 76.8% accuracy on 10,247 recruitment records, significantly outperforming XGBoost (73.8%, $p = 0.012$), standard PSO-SGD (75.2%, $p = 0.041$), and individual feature selection strategies. Ablation analyses confirm that SW-MCFS provides the largest gain ($+1.6\%$), while APSO further improves optimization performance ($+0.6\%$) and accelerates convergence by approximately 31%. These results should be interpreted in the context of inherent label noise in subjective performance evaluations, which imposes an accuracy ceiling on all models.

Notably, SW-MCFS excludes Gender and Marital Status through consensus scoring without explicit fairness constraints. While this observation is encouraging, it does not constitute a formal fairness guarantee, and formal fairness auditing remains necessary for deployment readiness. The SHAP-based interpretability analysis, which highlights Communication Skills, Experience, and Seniority as dominant predictors, provides a foundation for transparent decision-support in regulated HR applications.

The proposed framework is applicable to other classification tasks requiring robust feature selection and efficient neural optimization. Future work will extend the approach to multi-domain validation across diverse industries and geographic contexts, incorporate explicit fairness objectives with formal bias metrics, and explore scalability to deeper architectures and multimodal data.

Data Availability Statement

The dataset is derived from anonymized recruitment data collected at ENSIAS, Université Mohammed V – Rabat. Due to confidentiality agreements, the data cannot be publicly shared. Researchers may contact the corresponding author. Analysis scripts and SW-MCFS implementation are available upon reasonable request.

Author Contributions

Y.T.K. conceptualized the study, designed SW-MCFS and APSO, performed analysis, and drafted the manuscript. S.A. supervised, validated results, and revised the manuscript. Both authors approved the final version.

Funding

This research received no external funding.

Institutional Review Board Statement

Approved by the participating organization's internal review board (Protocol: HR-2023-015, 15 January 2023).

Conflicts of Interest

The authors declare no conflicts of interest.

Acknowledgment

The authors thank the HR department of the participating organization and the anonymous reviewers for constructive feedback.

***Abstract*—Recommender systems have been developed to serve users and provide them with the best suggestions. Despite their success, offering fully identical recommendations to users' preferences remains a difficult task, where the complexity of human taste results in different challenges. Grey sheep user phenomena continues to be one of the most common, where the user is defined by his unique interactions with the system, making it difficult to associate with similar users, as he rarely agrees with them. In this study, we presented a new approach for identifying grey sheep users. It is based on the taste context and nature of user interaction with the system. We grouped similar users using an enhanced Kmedoids clustering method with a new dissimilarity metric and introduced a novel process to distinguish between users. The differentiation is achieved by assigning weights to each cluster based on how much it reflects the grey sheep user characteristics. We evaluated the efficiency of Grey Threshold Medoids (GTMedoids) using the FilmTrust and MovieLens 100k datasets. The results show the superior performance of our approach in detecting grey sheep users.**

***Keywords*—Recommender system; grey sheep users detection; clustering; Kmeans; Kmedoids; dissimilarity metric**

I. Introduction

Recommender systems (RS) have demonstrated their ability to retrieve what could be interesting to users and help improve the user experience in a digital world overwhelmed by the explosion of data and the speed with which data is growing. However, this efficiency is exposed to high degradation due to multiple challenges, related to sparsity [1], [2], scalability [3], or fairness and user satisfaction, of which we can cite grey sheep users (GSUs) [4], where the first step to accurately analyze their preferences is to detect them. Although grey sheep user detection is important, it has been neglected in the literature. In this regard, our motivation behind this work is the importance of fairness and equality treatment that should be attributed to recommender systems to always provide all users with accurate suggestions and not only serve part of them and discriminate against the rest. To accurately detect grey sheep users in a system, the following research questions have been formulated:

- RQ1: How can user similarity be redefined to fully capture user taste behavior?
- RQ2: Can grey sheep users be detected dynamically and effectively from the entire user population without predefined groups?
- RQ3: How does the presence of grey sheep users in a system affect recommendation accuracy?

In this study, we present GTMedoids as a new proposed solution for detecting grey sheep users in a recommender system. We clustered candidate grey sheep users based on their interactions with the system and considered the bi-polarity of human taste. Then, attribute to each cluster a weight, where only clusters with power weights less than a predefined threshold are finally detected as grey sheep clusters as they meet the criteria of this category of users. To prove the validity of our model, we ran a set of experiments on two different benchmarks and demonstrated the efficiency of our model in detecting grey sheep users.

The study is structured into several sections: Section II provides background information and reviews existing literature on grey sheep user detection. Section III details the proposed approach, GTMedoids, and examines its various components. Section IV analyzes the results obtained from the study. Finally, Section V concludes the work and outlines potential future research directions.

II. Related Work

The evolution of recommender systems can be marked with three generations, where the first generation was initiated to focus on content and collaborative techniques [5], [6], the second enhanced quality and precision by involving more contextual information, such as location and time [7], [8], while the third generation is known for leveraging the hidden semantics in supplementary sources of knowledge, including social networks and knowledge graphs [9]. However, during the course of this enhancement, major challenges were addressed. Yet, some of these challenges were less treated than others, regardless of their importance, especially grey sheep users.

Grey sheep users are defined as users with significant deviations from recognized preference patterns [10]. Due to their unique taste, they end up receiving inaccurate suggestions that do not match their interaction with the system [4]. Although the importance of the topic, as it has a direct impact on the system's accuracy and the quality of recommendations for all users, it is considered one of the least treated RS challenges in the literature.

To address the challenge of GSUs, detecting these users remains a crucial step. The detection techniques in the literature can be grouped into two main categories. Outlier detection and clustering techniques. The first group treats GSUs as anomalies and outliers due to their odd choices. These techniques rely on ratings distribution and user profiles [11], [12], [14]. However, other outlier techniques can be explored, as shared in [10], such

as angle-based outlier detection (ABOD) [15]. Regardless of the popularity of outlier detection methods as a way to identify grey sheep users in a system, their nature and the way that they are designed highly put the results under investigation, as the final detected set of users can also include those suffering from sparsity and sparsity issues due to their low density, while a grey sheep user is a user that is committed to the system but has different preferences [18], [11]. Adding to that, any data points that are close to a grey sheep user run the risk of being flagged as a grey sheep user [20]. And it is important to also mention that these methods need to treat the whole datasets, which can make the distance or density scores attached to all type of users even less meaningful [29].

On the other hand, the second category uses clustering approaches that are based on computing user similarities [16], [17], [19], [21], [22]. The primary limitation of these approaches is the fact that they cluster all the users of the system and view them all as candidates, which can lead to high computational costs and group all the final grey sheep users in one $(K+1)^{th}$ cluster, leading to a lack of clarity about the degree of grayness of the users, especially in the case where the system aims to remove them [14]. Moreover, all these works, regardless of their category, have neglected the polarity of human taste. However, it deserves attention that [4] highlighted the possibility of identifying GSUs using personality parameters but without real application, as they have used only the cosine similarity with KNN [23]. Therefore, we present GTMedoids, a clustering method that takes into account both sides of user feedback and also weights the degree of users' grayness.

III. GTMedoids Approach

In this section, we present our proposed GTMedoids approach and its different components. Fig. 1 provides a high-level overview of the approach and the interaction between its parts.

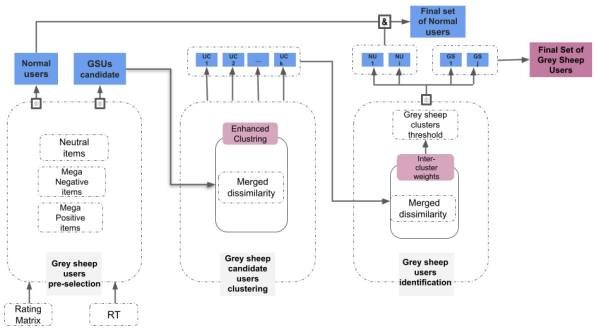

Fig. 1. Grey threshold medoids approach.

A. Grey Sheep Users Pre-Selection

Grey sheep users have unique and distinguished preferences, making the recommendation process more difficult and not as accurate as for normal users, who already have close users in terms of taste and similarities. Consequently, identifying these users should be based mainly on user preferences shared in the rating matrix [24]. Most studies measure preference based on the interaction with the item, where the existence of the interaction is interpreted as an interest and preference, ignoring the fact that an interaction with bad feedback should not be treated as a good one, as human taste is not only reflected in what he likes l but also in what he does not like l, which can be denoted as follows [see Eq. (1)]:

$$taste = \{d/d \in Detest\} \cup \{l/l \in Like\} \tag{1}$$

Taking this into consideration, grey sheep user identification should be based on both types of feedback; as a result, a GSU is then a user who highly disagrees with his community.

Clustering all users with prior knowledge that not all of them are GSUs is not efficient, as only concentrating on a set of users that can meet GSU characteristics; in particular that Kmeans variations are sensitive to outliers because of the mean computations [25]. In our case, outliers are normal users who more often share the same taste as the majority of the community. However, before deciding to exclude these users, we need to quantify the community's taste for comparison with individual preferences. We consider the global classification of items as collaborative signals contributed by all users in the system. An item can then be:

- Mega Positive: is an item that the majority has appreciated by giving it individual positive feedback Pos.
- Mega Negative: is an item that the majority has unappreciated by giving it an individual negative feedback Neg.
- Neutral: is an item having the same amount of individual positive and negative feedback.

The differentiation between positive and negative individual feedback is done based on a rating threshold RT as our approach treats the user-item rating matrix R [see Eq. (2)]:

$$feedback_{u,i} = \begin{cases} Pos & \text{if } r_{u,i} \geq RT \\ Neg & \text{otherwise} \end{cases} \tag{2}$$

where, $r_{u,i}$ is the rating given by the user u to the item i.

After computing the collaborative classification of each item, we refine our initial set to cluster by excluding normal users.

- Normal user: Frequently aligns with global preferences, showing a level of agreement that meets or exceeds the average.
- Grey sheep candidate user: Rarely aligned with the collaborative signals, meaning having an amount of less than the average of agreements.

The filtered users show potential to be grey sheep users, requiring further refinement as the actual feedback and ratings were not used to determine their greyness level or similarities with others. The subsequent step focuses on calculating user similarities and identifying their nearest neighbors.

B. Grey Sheep Candidate Users Clustering

To enhance the accuracy of user clustering, it is essential to include all rated items, even neutral ones. The proposed clustering approach modifies the Kmeans algorithm by applying a new dissimilarity metric and using actual user profiles as the centers of clusters instead of means and leads to more significant associations among user groups [31].

1) The merged dissimilarity metric: We have developed our own measurement metric for two reasons:

a) The multi-dimensional nature of human taste: The dissimilarity function must consider both aspects of taste, with the weight assigned to each depending on user preference. Some users prefer to share positive feedback, while others are more inclined to express negative feedback.

b) Reduce the unexplored items effect: One major issue with distance functions is their inability to differentiate items rated by only one user, leading to the same distance despite differing preferences. To address this, a contextual approach was adopted, where items are considered closer only if they share a collaborative taste. This involves incorporating feedback nature as context with weights, so items can be treated similarly for users if their ratings are closely aligned and they share similar feedback contexts. Fig. 2 illustrates how adding multi-dimensional context improves accuracy in understanding user preferences, as the Euclidean distance can misleadingly suggest similarity between items that do not truly reflect preferences, impacting the mining of user data, where this distance may treat items i_0 and i_1 as equivalent, while they do not truly reflect aligned user preferences. Consequently, this miscalibration leads to false similarities among users, such as u_0 and u_1.

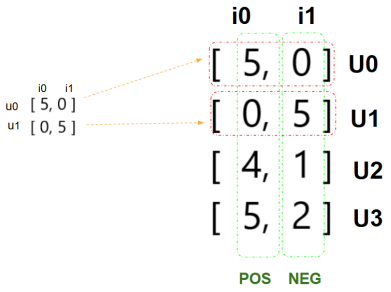

Fig. 2. The impact of the unexplored items on the dissimilarity measurement.

The final metric is a user-personalized metric that merges both sides of human tastes and can be presented as follows [see Eq. (3)]:

$$MergedD(u_a, u_b) = weight_{dislike} \times DisLikedD(u_a, u_b) + weight_{like} \times LikedD(u_a, u_b) \quad (3)$$

As the proposed metric is a composition of the two components, the liked and disliked dissimilarities are calculated using Eq. (4):

$$LikedD(u_a, u_b) = \sqrt{\sum_{i=1}^{n}((\frac{itemlikes_i}{maxLikes})^2 * (r_{u_a,i} - r_{u_b,i})^2)} \quad (4)$$

The liked dissimilarity function is characterized by its ability to add the global taste context to the dissimilarity computation between users. It measures how close the feedback of the users u_a and u_b is to the global positive taste, where it attributes more weight and importance to positive items and assesses how users u_a and u_b interact with these items. Similarly, the disliked dissimilarity function focuses more on less globally admired items [see Eq. (5)]:

$$DislikedD(u_a, u_b) = \sqrt{\sum_{i=1}^{n}((\frac{itemDislikes_i}{maxDisLikes})^2 * (r_{u_a,i} - r_{u_b,i})^2)} \quad (5)$$

where,

- $r_{u',i}$ are the ratings of user u' for item i.
- $maxLikes$ the maximum number of users who liked any single item.
- $itemLikes_i$ calculates the number of users who rated item i greater than or equal to the threshold RT.
- $maxDisLikes$ the maximum number of users who disliked any single item.
- $itemDislikes_i$ calculates the number of users rated item i less than or equal to the threshold RT.

To reflect the fact that humans differ in which side of taste they tend to express the most, we added the like and dislike weights [see Eq. (6) and Eq. (7)]:

$$weight_{like} = \frac{(\#likedItems_{u_a} + \#likedItems_{u_b})}{(\#ratedItems_{u_a} + \#ratedItemsu_b)} \quad (6)$$

$$weight_{dislike} = \frac{(\#dislikedItems_{u_a} + \#dislikedItems_{u_b})}{(\#ratedItems_{u_a} + \#ratedItemsu_b)} \quad (7)$$

where,

- $\#ratedItems_{u'}$: how many items were rated by the user u'.
- $\#likedItems_{u'}$: how many items were liked by the user u'.
- $\#dislikedItems_{u'}$: how many items were disliked by the user u'.

Therefore, the merged dissimilarity function, Eq. (3), is used to cluster users based on their preferences, Algorithm 1 defines the steps followed to cluster the users.

The final returned User Clusters, UC, group the grey sheep users candidate into clusters by similarity. In the next section, we explore how the final set of grey sheep users is identified.

Algorithm 1 Grey Kmedoids Clustering Algorithm

Require: Number of clusters K, Grey sheep candidate users $GC = \{gc_1, gc_2, \ldots, gc_n\}$
Ensure: UserCluster $UC = \{UC_1, UC_2, ..., UC_k\}$ and medoids $M = \{m_1, \ldots, m_K\}$

select K objects randomly from GC as initial medoids
$M \leftarrow \{m_1, m_2, \ldots, m_K\}$
repeat
  assignment:
  for each $gc \in GC$ **do**
    assign gc to the nearest medoid using

$$i \Leftarrow \arg \min_{j \in \{1,\ldots,K\}} d_{\text{merged}}(gc, m_j)$$

    add gc to cluster UC_i
  end for
  compute total cost:

$$S(M) = \sum_{i=1}^{K} \sum_{gc \in UC_i} d_{\text{merged}}(gc, m_i)$$

  swap:
  for each medoid $m \in M$ **do**
    for each non-medoid $o \in GC \setminus M$ **do**
      $M' \leftarrow (M \setminus \{m\}) \cup \{o\}$
      reassign all points using M'
      compute $S(M')$
      if $S(M') < S(M)$ **then**
        $M \leftarrow M'$
      end if
    end for
  end for
until medoids do not change
return M and clusters $UC_1, \ldots, UC_K$

C. Convergence Analysis of GTMedoids

As GTMedoids is a clustering method built based on Kmedoids, proving its convergence depends on proving that our algorithm can to reach a fixed point where neither assignments nor medoids change. In other words, the objective function should be monotonically non-increasing and cannot decrease indefinitely over a finite set [30].

Let $d_{merged}(\cdot, \cdot)$ denote the dissimilarity function used in the algorithm. The objective is the within-cluster merged-dissimilarity sum [see Eq. (8)]:

$$S'(\mathcal{UC}, \mathbf{m}) = \sum_{j=1}^{K} \sum_{i \in UC_j} d_{\text{merged}}(i, m_j), \tag{8}$$

where, $\mathcal{UC} = \{UC_1, \ldots, UC_K\}$ denotes the current user clusters, and $\mathbf{m} = (m_1, \ldots, m_K)$ denotes the set of cluster prototypes or medoids.

GTMedoids proceeds by alternating between two steps:

- **User assignment:** Given current medoid $\mathbf{m}^{(t)}$, each user i is assigned to the closest cluster UC [see Eq. (9)]:

$$uc^{(t+1)}(i) = \arg \min_{j \in \{1,\ldots,K\}} d_{\text{merged}}(i, m_j^{(t)}). \tag{9}$$

- **Medoid update:** Given the updated clusters $\mathcal{UC}^{(t+1)}$, each medoid is updated as Eq. (10):

$$m_j^{(t+1)} = \arg \min_{u \in UC_j^{(t+1)}} \sum_{i \in UC_j^{(t+1)}} d_{\text{merged}}(i, u). \tag{10}$$

The algorithm converges when neither the medoids nor the assignments change.

1) Proof of convergence:

a) Lemma a (User Assignment Step Monotonicity): Given fixed medoids $\mathbf{m}^{(t)}$. The assignment step does not increase the objective function S'.

Demonstration. Assigning user i to the cluster whose medoid minimizes the objective results in the smallest possible contribution for that user [see Eq. (11)]:

$$d_{\text{merged}}(i, m_{uc^{(t+1)}(i)}) \leq d_{\text{merged}}(i, m_{uc^{(t)}(i)}) \tag{11}$$

Hence, summing over all users, the total objective cannot increase [see Eq. (12)]:

$$S'(\mathcal{UC}^{(t+1)}, \mathbf{m}^{(t)}) \leq S'(\mathcal{UC}^{(t)}, \mathbf{m}^{(t)}). \tag{12}$$

b) Lemma b (Medoids Update Monotonicity): Given fixed cluster assignments $\mathcal{UC}^{(t+1)}$, the medoid update step does not increase S'.

Demonstration. For each cluster $UC_j^{(t+1)}$, the medoid $m_j^{(t+1)}$ is chosen as the minimizer of $\sum_{i \in UC_j^{(t+1)}} d_{\text{merged}}(i, u)$ over all $u \in UC_j^{(t+1)}$, as presented in Eq. (10).
By the characterization of the argmin, the chosen medoid cannot result in a larger value than any other one, including the previous one. Consequently, summing over all clusters yields [see Eq. (13)]:

$$S'(\mathcal{UC}^{(t+1)}, \mathbf{m}^{(t+1)}) \leq S'(\mathcal{UC}^{(t+1)}, \mathbf{m}^{(t)}). \tag{13}$$

c) Lemma c (Monotonic Decrease of the Objective): The objective sequence $\{S'^{(t)}\}$ generated by GTMedoids is monotonically decreasing.

Demonstration. Combining Lemmas a and b yields [see Eq. (14)]:

$$S'(\mathcal{UC}^{(t+1)}, \mathbf{m}^{(t+1)}) \leq S'(\mathcal{UC}^{(t+1)}, \mathbf{m}^{(t)}) \leq S'(\mathcal{UC}^{(t)}, \mathbf{m}^{(t)}). \tag{14}$$

d) Lemma d (Finite descent): GTMedoids terminates after a finite number of iterations.

Demonstration. Each medoid is selected from a finite set of user indices. Additionally, there are finitely possible partitions of n users into K clusters. Therefore, the number of possible combinations $(\mathcal{UC}, \mathbf{M})$ is finite.

Considering that the objective function is monotonically decreasing and cannot decrease indefinitely over a finite set, GTMedoids must eventually reach an optimized pair $(UC^{\star}, M^{\star})$ where neither the medoids nor the assignments change.

e) Theorem (Convergence of GTMedoids): GTMedoids converges in a finite number of updates to a local minimum of the objective function S'.

Demonstration. By Lemmas a–b, the objective function is monotonically decreasing.

By Lemma c, the sequence of solutions must reach an optimum; no additional changes are applied on the clusters, resulting in decreasing S' further.

D. Grey Sheep Users Identification

Clustering groups similar data points but struggles to clearly distinguish between dominant groups and outliers. In this regard, we have provided a new method that can be adopted for this matter in general, and not only for grey sheep user identification or recommender systems. Our technique is able to quantify the importance and weight of each cluster and detect the less impactful ones; in other words, we detect grey sheep users in our case.

1) Inter-Cluster Weights: We have successfully identified final clusters of users by analyzing their feedback and proximity based on multi-dimensional tastes and community preferences. The next step involves selecting only the grey sheep clusters, using the characteristics of GSUs as a baseline for this selection process:

- GSUs represent a minority; otherwise, mining their preferences and providing them with recommendations would have been easier.
- GSUs have distinguished preferences from users, meaning that a grey sheep user should be located far from all users.

We used the softmax function to calculate the weight of each cluster j, where the general equation is Eq. (15):

$$\tilde{\alpha}_j = \frac{exp(\alpha_j)}{\sum_{c \in UC} exp(\alpha_c)} \tag{15}$$

The softmax function heavily depends on α_j, to to obtain meaningful weights, we translated the GSUs characteristics to quantified metrics using the following Eq. (16):

$$\alpha_j = \begin{cases} \text{if } \#UC_j > 1: \\ (\frac{\#UC_j}{max(\#UC)}) \times (1 - \frac{(\sum_{gc \in UC_j}(MergedD(gc, c_j))}{((\#UC_j \times max(MergedD(UC_j, c_j)))}) \\ \text{otherwise:} \\ 0 \end{cases} \tag{16}$$

The GSUs representing the minority clause are represented by the first part of the α_j multiplication function, and the fact that a grey sheep user should be located far from all users is the second part. We attribute a zero impact to the cluster that we already know are grey sheep clusters as they have only one user. By applying the softmax to the α_j, we obtained inter-cluster powers $\tilde{\alpha}_j$.

2) Grey sheep clusters threshold: Having an ideal system clear of grey sheep users and each user is having enough similar users sharing with him the same preferences means that cluster powers should be equal, meaning all the clusters should have $\frac{1}{K}$ as power weight. However, as there is no such perfect system in reality, we have added a tolerance rate to not be too strict and handled normal users as grey ones just because they have some disagreements with the collaborative signals [see Eq. (17)].

$$\epsilon = \frac{Max(\tilde{\alpha}) - Min(\tilde{\alpha})}{K} \tag{17}$$

By including the clause ϵ to verify if the difference between the maximum and the minimum is equally distributed and provide a tolerance to make sure that only users with high derivation from the reset as identified as GSUs [see Eq. (18)].

$$T = \frac{1}{K} + \epsilon \tag{18}$$

This threshold can detect all the clusters that impact and influence more than the others, and then any cluster with a weight larger than this threshold should be categorized as a normal user cluster.

IV. Results and Discussion

In this section, we demonstrate the validity of our approach and evaluate its performance in identifying grey sheep users through experiments with two distinct datasets.

A. Evaluation Protocol and Metrics

Since there is no public benchmarking to tackle GSUs [13], [14], we assessed our methodology using the most commonly utilized datasets found in related research, MovieLens 100K (ML) [26] and FilmTrust (FM) [27], as shared in Table I.

To investigate the efficiency of our model in detecting GSUs, we employed the mean absolute error (MAE) as an evaluation metric. This metric quantifies the system's ability to reflect the user preferences. As a result, a GSU should have a high mean absolute error which demonstrates system failures in mining preferences. Moreover, we evaluatedthe MAE variation according to theuser type. We utilized the metrics introduced in [19], which denote the MAE increase

TABLE I. THE PROPRIETIES OF THE USED DATASETS

Dataset	#Users	#Items	#Ratings	Scale
MovieLens 100K (ML)	943	1682	1000	1-5
FilmTrust(FT)	1508	2071	35497	0.5-4

$Inc(MAE)$ for grey sheep users and MAE improvement $Imp(MAE)$ for normal users.

$$Imp(MAE) = 1 - \frac{MAE_{NU}}{MAE_{AllUsers}} \tag{19}$$

As GSUs preferences can also affect the overall quality of the system, theoretically excluding them from the recommendation should improve the suggestion. Eq. (19) quantifies the possible improvement for the remaining users in terms of MAE variation, where approaching 1 indicates the enhancement of the recommendation.

$$Inc(MAE) = 1 - \frac{MAE_{NU}}{MAE_{GSU}} \tag{20}$$

Eq. (20) was designed to evaluate the performance of the system in detecting grey sheep users, where values approaching 1 reflect the system's ability to identify these users. The MAE is obtained using Eq. (21), where UG is one of the user groups: all users, grey sheep users, or normal users.

$$MAE_{UG} = \frac{\sum_{(u,i)\in UG} |\hat{r}_{u,i} - r_{u,i}|}{\#UG} \tag{21}$$

To calculate the predicted ratings, we implemented User-Based Collaborative Filtering (UBCF) [28], as it highly depends on the nearest users to calculate the rating, which will help in assessing the performance of our model in detecting GSUs, where the ratings are predicted with:

$$\hat{r}_{u,i} = \tilde{r}_u + \frac{\sum_{(u')\in N_u} (r_{u',i} - \tilde{r}_{u'}) \times sim(u,u')}{\sum_{(u')\in N_u} sim(u,u')} \tag{22}$$

where,

- $\tilde{r}_u$ and $\tilde{r}_{u'}$: are the average ratings of the users u and u'.
- N_u: is the set of nearest users to the user u.
- $r_{u',i}$: is the rating r given by the user u' to the item i.

GTMedoids is based on an enhanced variation of the standard Kmeans clustering approach, in which the Euclidean distance is primarily used [see Eq. (23)]:

$$Euclidean(u_a, u_b) = \sqrt{\sum_{i=1}^{n} ((r_{u_a,i} - r_{u_b,i})^2)} \tag{23}$$

To demonstrate the need for the merged dissimilarity metric we compared the results obtained by the approach using Euclidean and our metrics. Where the user taste prediction is computed using the same technique in Eq. (22) with the Euclidean distance instead of the merged dissimilarity metric [see Eq. (24)]:

$$\hat{r}_{u,i} = \tilde{r}_u + \frac{\sum_{(u')\in N_u} (r_{u',i} - \tilde{r}_{u'}) \times Euclidean(u,u')}{\sum_{(u')\in N_u} Euclidean(u,u')} \tag{24}$$

In addition to all the metrics cited above, we introduce the average rating variance metric, where the rating variance of an item i is calculated as Eq. (25):

$$Variance_i = avg(r_{GSU,i}) - avg(r_{NU,i}) \tag{25}$$

where,

- $avg(r_{GSU,i})$ is the average rating of all the grey sheep users GSU who interact with item i.
- $avg(r_{NU,i})$ is the average rating of all normal users NU who interact with item i.

The $Variance_i$ metric is able to quantify the deviation of the grey sheep users' preferences from the normal ones, where values approaching 0 indicate a similar taste, while values approaching the maximum rating option represent a high deviation in the taste.

B. Experiments Setup and Configuration

To differentiate between positive and negative feedback, an average rating serves as a threshold favoring positive reviews, as ratings often indicate user interest, according to existing literature. The rating thresholds are set at 2.5 for FilmTrust and 3 for MovieLens. Furthermore, since an improved version of the Kmeans algorithm is part of this approach, it is crucial to determine the number of clusters (K) before executing the clustering algorithm. The elbow method was employed to identify the optimal number of clusters.

Based on the experimental results, the optimal K for $MovieLens100K$ and $FilmTrust$ is 3, as illustrated in Fig. 3. Therefore, for each dataset, we clustered the users into three clusters.

C. Results Analysis

Our model identified 273 of 943 users and 292 of 1508 users as grey sheep candidates on Movielens and FilmTrust, respectively, as shown in Table II, where 121 and 129 of them were detected as grey sheep users grouped in two grey clusters for both datasets.

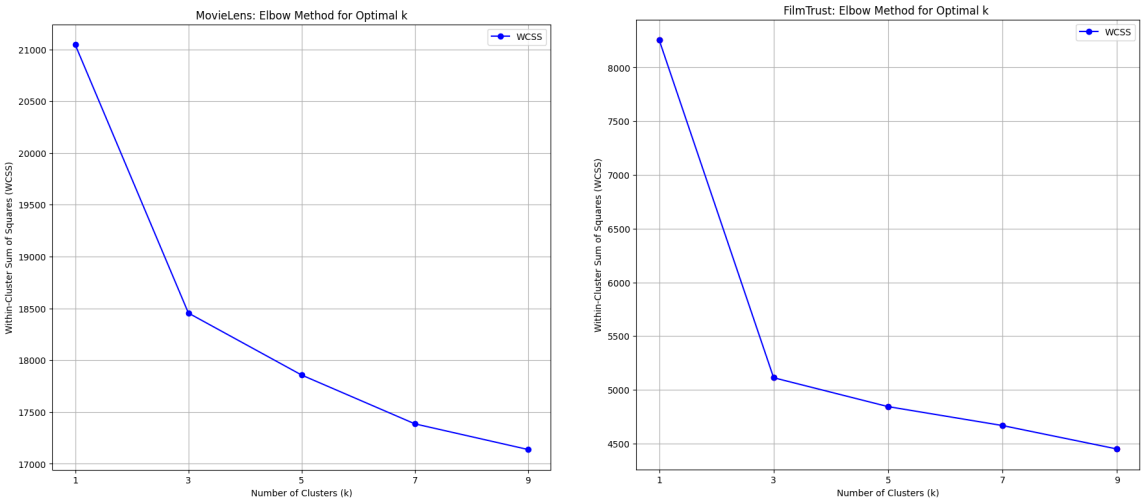

Fig. 3. Elbow method for identifying optimal K.

TABLE II. GREY SHEEP USERS DETECTION PER DATASET

Dataset	#users	#clusters	#grey Clusters	#GS candidate	#GSUs
ML100k	943	3	2	273	121
FM	1508	3	2	292	129

In assessing the validity of results, the impact of closest users on individual recommendations was measured. Grey sheep users exhibit high MAE values due to their closest users being more distantly located compared to the neighbors of normal users. This results in grey sheep consistently receiving inaccurate suggestions, as illustrated in Fig. 4, which compares MAE across user types.

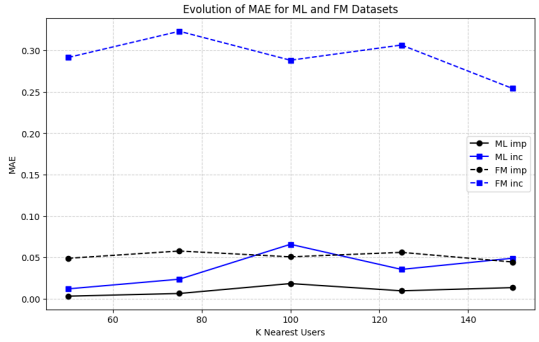

Fig. 4. MAE variations by user type.

The best results were achieved for K=75 and K=100 for FM and ML, respectively, where the mean absolute error almost doubled for the FM grey sheep users and increased by 6.616% for ML, as shown in Table III.

We propose GTMedoids, a clustering approach that categorizes users based on their greyness degree, contrasting with traditional methods that enhance centroid selection. Our model's efficiency is demonstrated through a comparison with existing literature [19], and the results are presented in Table IV. Note that FilmTrust has shown better outcomes, which can be justified by the RT precision as the rating scale is 0.5 and also the more valuable number of user-item interactions provided in this dataset.

Our approach has surpassed existing solutions in detecting grey sheep users while also enhancing recommendations for normal users, despite its primary focus on grey sheep selection within the community. This effectively supports the rationale behind our concept. Additional analysis was conducted by comparing average ratings of items rated by both user types, results of which are illustrated in Fig. 5. In the figure, red data points represent the average ratings given by grey sheep users, while blue data points reflect the overall average ratings from normal users for the same items. The figure clearly highlights the differences in opinion between the user types, evidenced by the distinct data point distributions for each item.

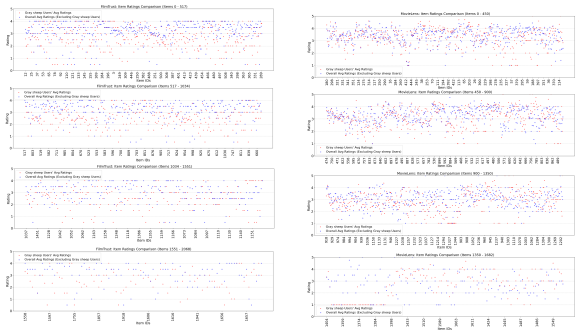

Fig. 5. Grey sheep and normal users average rating comparison.

To assist with the complexity of numerous data points, we calculated the average rating variance between grey and normal sheep users using Eq. 25.

The fluctuation presented in Fig. 6 illustrates the grey sheep user preferences deviation from the global collaborative taste and proves that these users rarely agree with the rest of the users when the difference is zero.

[1]Note: The results shared in this table were taken from the original work [19].

TABLE III. GTMEDOIDS' PERFORMANCE IN TERMS OF MAE VARIATION BY USER TYPE

	All Users	Normal Users	GSUs	$MAE_{NU}\%$	$MAE_{GS}\%$
MAE (FM) k=75	0.6776	0.6385	0.9434	-5.77%	$+32.31\%$
MAE (ML) k=100	0.8488	0.8332	0.8919	-1.83%	$+5.07\%$

TABLE IV. THE PERFORMANCE OF GTMEDOIDS IN TERMS OF GREY SHEEP USERS DETECTION

Methods	$Inc(MAE)$ ML	$Imp(MAE)$ ML	$Imp(MAE)$ FM	$Inc(MAE)$ FM
KMeans Standard[1]	0.027044	0.008989	0.014441	0.090519
KMeans++[1]	0.030882	0.007733	0.013397	0.089948

GTMedoids	**0.065814**	**0.018378**	**0.057703**	**0.323192**

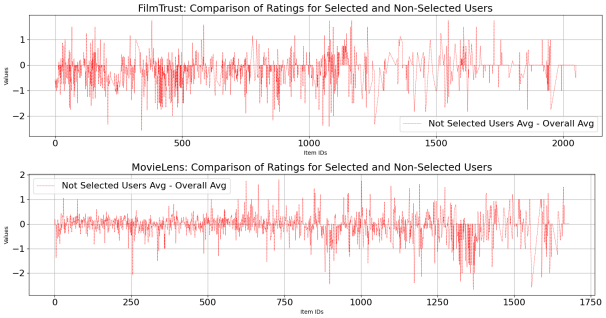

Fig. 6. The variation of ratings between grey sheep and normal users.

As we proposed a new dissimilarity function, we studied the impact of it instead of using Euclidean distance. To run the model using the traditional approach, we must determine the optimal number of clusters. As illustrated in Fig. 7, K was 3 for both ML and FM datasets.

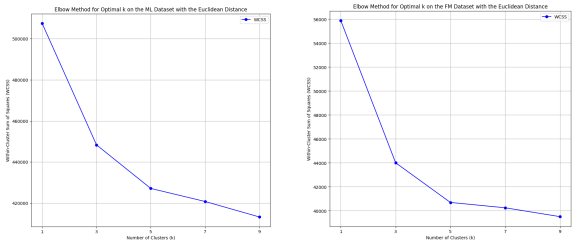

Fig. 7. Elbow method for identifying optimal K with the Euclidean distance.

By implementing the approach using the Euclidean distance, we obtained 155 and 142 users selected as GSUs in FM and ML, respectively. Fig. 8 shows the importance considering the feedback context while detecting GSUs in the system. Where the model was more accurate with our newly presented function such that not only fewer users were handled as GSUs but also the MEA increased. The selected users with the merged dissimilarity metric were also tested with the standard Euclidean function to predict their preferences. However, the prediction was less accurate for these users compared to the users detected and tested using only the Euclidean function. Therefore, the merged dissimilarity metric is more precise in detecting users who represent a minority in terms of taste and preference uniqueness.

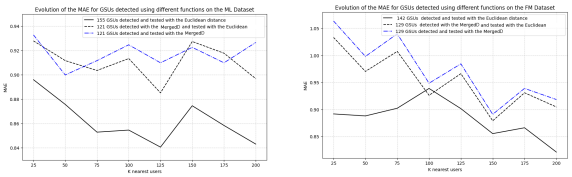

Fig. 8. The merged dissimilarity metric efficiency in detecting GSUs in comparison with the Euclidean distance.

This section experimentally demonstrates the performance of our model and its efficiency in detecting grey sheep users in the system. GTMedoids was able to identify users with unique preferences that the system often failed to recommend to them accurately.

V. CONCLUSION

In this study, we introduce Grey Threshold Medoids (GTMedoids), a novel method for identifying grey sheep users. The initial phase of our approach involves filtering users based on their frequency of agreement with the community's preferences, specifically isolating those who infrequently agree and frequently disagree with prevailing tastes for subsequent clustering. This selection process acknowledges the complexity of individual tastes, characterized as bi-polar, meaning that interaction with a particular item does not guarantee user appreciation. Clustering is conducted via a novel personalized metric that evaluates the significance of both positive and negative feedback from users while assessing their similarities. However, the clusters generated by this method do not inherently indicate which should be classified as grey sheep clusters. To address this, we have devised a new selection mechanism applicable beyond the realm of recommender systems. We compute the power of each cluster based on grey sheep user characteristics and finally identify the less-influencing clusters as grey sheep clusters that group our grey sheep users. The experiments proved the validity and accuracy of the proposed approach

As GTMedoids is based on the rating matrix in the future, it can be integrated to detect grey sheep users in pre-existing

RSs in the literature so that they can receive special treatment while making recommendations. Another future direction is to improve GTMedoids itself and not to be limited to just GSU detection but also by adding the recommendation module to it to treat each group of users fairly, either by adding KG graphs as a supplementary source of knowledge to strengthen user and item embedding or by leveraging the attention mechanism in such a way that the model learning phase can focus effectively on what is important to these users.

A Proxy-Based DevSecOps Framework for Multi-Tier Web Applications

Abderrahim Rida, Abdelaziz Bakhil, and Ayoub Ait Lahcen
Engineering Sciences Laboratory-National School of Applied Sciences,
Ibn Tofail University, Kenitra, Morocco

***Abstract*—Multi-tier web applications face significant implementation challenges in DevSecOps, including tool integration complexity, automation gaps, and cultural resistance. This study presents a proxy-based DevSecOps framework grounded in a formal architectural decomposition that transforms classical $O(n \times m)$ pipeline integration complexity into additive $O(n_1 \times m_1) + O(n_2 \times m_2)$ components through the separation of static and dynamic execution contexts. The framework is instantiated for PHP-based multi-tier web applications deployed on AWS infrastructure using Terraform-managed Infrastructure as Code principles; all ecosystem coherence metrics, toolset analysis, and complexity computations are derived within this specific technology context, and generalization to other language ecosystems or cloud platforms constitutes a boundary condition discussed in Section V. Theoretical contributions include: 1) a formal proxy pipeline architecture with mathematical complexity analysis demonstrating that complexity reduction is guaranteed when tool ecosystem coherence exceeds 70%; 2) systematic tool integration using PHP-specific tooling, yielding a theoretical ecosystem coherence of 76.9%; and 3) theoretical validation addressing 18 out of 20 identified DevSecOps implementation challenges. Mathematical analysis theoretically predicts a 48.13% reduction in tool integration conflicts and a 61.9% toolset reduction relative to traditional monolithic pipelines through context separation. All quantitative figures presented above are theoretically derived predictions, not empirically measured outcomes. They are formalized as falsifiable hypotheses H1 through H5 in Section V, with empirical validation identified as the primary direction for future work.**

Keywords*—DevSecOps; proxy architecture; multi-tier applications; PHP; AWS; security testing; CI/CD pipeline optimization; ecosystem coherence

I. Introduction

Incorporating DevSecOps in multi-tier web applications also presents significant challenges to implementing, including cultural resistance, automation gaps, and tool integrations complexitiy [1], [2]. While several reference architectures have been published [3], [4], [5], none exist that are specific to multi-tier application scenarios, in which rich deployment workflows, heterogeneous layers of services, and interactions between databases present unique security testing needs that standard DevSecOps practices do not come close to fulfilling.

Today, most common DevSecOps frameworks have three chief weaknesses regarding multi-tier applications: 1) monolithic toolchains resulting in $\mathcal{O}(n \times m)$ integration overhead, where n is the pipeline stages and m is the security tools, 2) too little architectural separation of phases of SAST and DAST, and 3) missing purpose-built frameworks optimized for meeting multi-tier architecture needs, including database syncing, service composition, and security settings optimized for targeted envs.

The matrix [4] provides the different integration points and levels of automation associated with multiple DevSecOps tools throughout the software development lifecycle (SDLC). Tools such as open-source governance and Static Application Security Testing (SAST) show a high level of automation throughout the process. In the case of others, there is Dynamic Application Security Testing (DAST) and Interactive Application Security Testing (IAST) that are mostly automated in the Continuous Integration/Continuous Deployment (CI/CD) and Post-Deployment phases. Mobile application security testing and Runtime Application Self-Protection (RASP) at best automate a couple of capabilities. The hierarchical approach of adoption emphasizes how critical it is to begin with secure software development through automation and integrating testing at each level, hence making quality SDLC efficient and effective [6].

Report [3], [4], [5] is based on a list of tools intended to integrate security into the SDLC. Jenkins and Ansible provision infrastructure and CI/CD pipelines automatically, whereas Twistlock, Aqua Security, and Docker secure containerized applications and cloud-native platforms. To scan for vulnerabilities, the tools OWASP ZAP, Nessus, SonarQube, and Veracode perform static, dynamic, and interactive application security testing (SAST, DAST, IAST). Dependency management is handled by Nexus Lifecycle and Dependency-Check, which identify third-party dependency vulnerabilities. Istio also provides microservices' service mesh security, and Splunk, FireEye, etc., provide monitoring and threat detection capability. All these integrated together offer a robust DevSecOps pipeline in which security is integrated from code creation through to deployment and runtime [7].

Challenges identified in recent studies [2], [8], [9] highlight our motivation to create a specific CI/CD pipeline that could address some of these issues. Since the goal of DevSecOps is to promote quick and secure delivery, it is important to develop a guide that can help DevSecOps teams in their pipeline. This work further provides a reference implementation for the DevSecOps community. Right now, looking for existing pipelines will allow us to understand the details of each one and extract best practices from them. By taking this approach, we can design a useful pipeline by learning from existing work and finding solutions to many challenges.

- Design a proxy-based DevSecOps architecture that reduces tool integration complexity for multi-tier web applications.

- Develop a theoretical framework demonstrating mathematical complexity reduction through architectural separation.
- Provide a specialized solution addressing multi-tier web application deployment challenges.
- Establish a foundation for empirical validation of the proposed theoretical framework.

This research focuses specifically on multi-tier PHP web applications deployed on AWS infrastructure, utilizing Infrastructure as Code principles through Terraform implementation. The framework addresses static security testing separation while maintaining dynamic testing integration in production environments.

This study provides a proxy-centric DevSecOps framework to effectively overcome these limitations by employing architectural separation concepts tailor-made for multi-tier web applications. Our conceptual contributions include: 1) an accurate definition of the proxy pipeline architecture and an evaluation of its mathematical complexity, 2) an orderly procedure for tool integration based on ecosystem coherence metrics, and 3) an exhaustive conceptual verification showing the mitigation of challenges realized in DevSecOps implementation.

The manuscript is structured as follows: the next section contains some necessary background knowledge with the concepts and tools used in such pipelines. The third section presents our motivation and problem formalization. The fourth one examines the relevant worldwide DevSecOps pipelines. The fifth describes the specialized pipeline underlining the envisaged approach of this research. The last one provides the theory validation and Analysis of the proposed Multi-tier Web applications DevSecOps pipeline.

II. Related Work

A. Comprehensive DevSecOps Reference Architectures

The DevSecOps reference architecture collection [3] offers several pipeline deployments which illustrate a wide range of ways security is integrated into the SDLC. The architectures focus on a number of core principles such as continuous security integration, shift-left strategies whereby security tests are pushed into earlier stages of the SDLC, and automated security testing paradigms. The collection features deployments from basic CI/CD pipelines which include security tools integrated into the pipeline all the way through enterprise-class architectures which accommodate microservices environments.

In these reference architectures [3], various implementation patterns arise. The pipelines indicate trust and confidence development by security tool integration as the significant elements of CI/CD processes. The implementations compare DevOps delivery-based methods with DevSecOps security-included methods in the whole of the pipelines. The architectures indicate how the integration of security covers the whole SDLC activities from planning and code writing phases up through deployment, including the security as well as code analysis for potential vulnerabilities during the beginning of development cycles.

These reference architectures [3] also demonstrate workflow automation tactics employing tools including Jenkins, unit testing, code analysis, and package creation of artifacts. These pipelines deploy broad monitoring with feedback loops for the formation of continued improvement, indicating how security can be embedded across software supply chains where DevOps would traditionally focus on delivery teams whereas DevSecOps performs the security activities across full pipelines.

B. Sonatype DevSecOps Framework

Sonatype DevSecOps Reference Architecture [4], [5] outlines core pillars from ongoing education for every party at interest, secure supply chains for open-source components, and automated test methodologies using SAST, DAST, feedback mechanisms and monitoring. The framework includes detailed automation levels and integration points involving a variety of DevSecOps tools during the software development lifecycle.

The Sonatype architecture [4], [5] shows the potential of tools, such as Static Application Security Testing and open-source governance, to reach high levels of automation during the development lifecycle. The configuration shows clear integration of the security controls during the SDLC, whereby developers develop the applications, store them in the Nexus Repository, and use lifecycle management tools like Nexus Lifecycle for constructing and delivering. This approach ensures detection of vulnerabilities during the application build or release stages.

Under the reference implementations [4], [5], the architecture embodies holistic CI/CD pipelines for absorbing security requirements during the coding, building, testing, release, deployment, operation, and monitoring stages. Security check measures are integrated into each stage, which implies that security is not merely added but ingrained into each stage of software development. The framework highlights the importance of involving security teams throughout every stage, rather than having them only deliver analysis reports to the operations teams.

C. Formal DevSecOps Implementations

E-SPIN Corporation [10] represents the concept of Continuous Security within a DevSecOps framework, enabling a proactive approach to find vulnerabilities and integrating security into both development and operations tasks.

The DoD Enterprise DevSecOps [11] presents a technology stack that involves embedding and deploying security measures and practices into the SDLC with various tools. Each component has the goal of securing and automating the software delivery pipeline with appropriate DoD compliance requirements. The DoD Enterprise DevSecOps Platform Architecture details a secured microservices architecture showing how Istio creates a Service Mesh architecture for managing microservices, bringing traffic management associated with security features to address complex microservices environments.

The Application Security Orchestration and Correlation framework demonstrates how diverse security tools come together to execute assessments and identify vulnerabilities, ensuring effective security governance throughout the SDLC [12].

D. Industry DevSecOps Pipeline Implementations

Industry-based DevSecOps pipeline executions [13], [14] target software supply chain security and how critical effective dependency management and vulnerability scanning during the SDLC ensure no vulnerable applications get shipped. CI/CD pipelines with a security focus include all the security-related activities so pipelines do not overlook critical security concerns at each stage of software release, leading to more reliable and secure releases.

Current DevSecOps practices [15] are formulated as frameworks aimed at safeguarding the software supply chain, illustrating how instruments such as Dependency-Check and Dependency-Track can detect and monitor vulnerabilities within software dependencies. This approach helps organizations keep their software secure by carefully managing all its dependencies.

Further industry deployments [16] provide DevSecOps automation orchestration pipelines for software development lifecycle automation with security emphasis. These strategies exhibit how Information Security teams work together with IT Operations teams for infrastructure automation code review and contribution purposes, providing security integration into the components of the infrastructure.

E. Evolution of Security-Integrated Development

Software development has evolved from traditional, isolated methods to more integrated approaches that seamlessly incorporate security throughout the process. This progress reflects the interweaving of security concepts during development phases from planning and design all the way through ongoing tests and monitoring in production settings.

Today's DevSecOps platforms come with collections of tools which automate and simplify the processes engaged with software development. Such deployments enable development teams to improve productivity, communicate better, and deploy software of high quality with increased security mitigations. Distributed build and test operations are also facilitated by these architectures, thus meaning security has been integrated at multiple points, from testings in a range of environments to further security analyses of the CI/CD pipelines themselves.

Today's secured CI/CD deployments indicate the value of security throughout the SDLC in the form of secure delivery, which serves as the prime objective of DevSecOps architecture integration. These strategies indicate how security tools may be packaged within central platforms providing consistency as well as automation for security services necessitating coordinated responses.

F. Research Gap Analysis

While current DevSecOps reference architectures [3], [4], [5] offer detailed guidelines for integrating security, they don't fully address the challenges of applying these practices to multi-tier web applications.. They tend to treat deployment as monolithic activities without the specific needs for database sync, service orchestration, and tier-specific security requirements which characterize multi-tier applications.

The compared architectures support a set of methodologies for integrating tools but lack well-structured frameworks for managing the complexity involved when coordinating a set of multiple security tools operating at different application layers. The current deployments also don't provide an architectural separation between the static and dynamic security testing phases, leading to resource conflicts and less than optimal running of the pipeline.

This study tackles these deficiencies by introducing a proxy-based architecture that is tailored for multi-tier web applications. It offers a theoretical framework aimed at diminishing complexity through architectural segregation, all while ensuring extensive security coverage throughout the various application tiers.

III. Problem Formalization

A. DevSecOps Implementation Challenges

Analysis of existing DevSecOps resources [3], [4], [5] reveals that , the context of DevSecOps pipelines suggests that there are significant barriers to introducing security into SDLC. Challenges [2], [8], [9] include tool integration, automation gaps, cultural resistance, compliance, and limited resources, among others. Addressing these challenges entails technical solutions, culture change, and continuous improvement.

Various tools like Jenkins, Twistlock, Aqua, OWASP ZAP, and others are mentioned and need to be combined, this leads to Integration Complexity , because Integrating multiple security tools into the CI/CD pipeline can be complex and may lead to tool conflicts or inefficiencies.

Dynamic Application Security Testing and Run-time Application Self Protection are not fully automated across all stages of the pipeline. To achieve full automation of security testing and compliance checks is difficult.

The activities of identifying, prioritizing, and remedying vulnerabilities within a reasonable timeframe can be challenging, particularly with DevSecOps environments. Metrics such as "Time to patch vulnerabilities" reflect the importance of quick detection and remediation of vulnerabilities that are frequently challenging.

SecDevOps pipelines implement a number of tools at various stages that could swamp operations, security and developers teams. Integrations of those numerous security tools can bring about a state of tool overload as teams become challenged with managing and maintaining the tools efficiently.

Cultural aspect is highlighted through collaboration and mutual responsibility of DevSecOps Teams that are hard to realize across most organizations. DevSecOps needs a cultural approach where the teams of development, security, and operations work intimately. In the same manner, the requirement of "Security Champions" as an over-reliance on specialty skills. There just are no trained individuals with dual security and DevOps skill sets available to implement and run DevSecOps pipelines.

Compliance validation and policy enforcement can cripple the pipeline process if not properly established. Being compliant with regulatory requirements and being agile at the same time in the pipeline is a very big challenge.

Static Application Security Test are prone to false positives that need to be manually validated. Security tools also generate

false positives, which can lead to alert fatigue and lower the effectiveness of the pipeline.

DevSecOps pipelines reference the difficulty of scaling security in big distributed systems especially in micro-services architectures.

Secured pipelines will be likely centered on centralized logging and telemetry, signaling that visibility is concern number one. Visibility across the security stance of applications and infrastructure end-to-end is challenging to obtain, especially in cloud-native environments.

Some of the biggest challenges lie in managing and securing third-party dependencies (e.g., open-source libraries), as security vulnerabilities in dependencies can lead to risks.

Real-time monitoring and feedback are highlighted, and this requires good processes and tools. Establishing a continuous feedback loop to improve security practices over a period of time is tricky, especially in changing environments. On the same line, The DoD architecture has Zero Trust as one of the Istio benefits, but implementing it is hard. Applying a Zero Trust model to micro-services architecture is hard and expensive.

Legacy systems are not necessarily part of modern DevSecOps pipelines: It is difficult to incorporate DevSecOps practices into legacy systems and applications due to old architectures and the lack of automation.

Commercial tools with high licensing fees and maintenance are used in many secured pipelines, It is financially costly to put in place a DevSecOps pipeline, having high tool investments, training, and infrastructure costs.

Addressing security incidents in a timely manner in a DevSecOps environment requires a strong process and tools, and that may be difficult to effect.

Metrics like "Deployment frequency" and "Change lead time" identify the tension between velocity and security.Where achieving speed of delivery is an imperative, and one also needs to ensure thorough security testing, this is a constant challenge in DevSecOps.

Some tools are configured with no integration plan in sight: having multiple disparate tools creates fragmentation, where it is difficult to get an end-to-end integrated view of security across the pipeline.

Threat modeling tends to be an afterthought in high-velocity environments, including it in the DevSecOps pipeline is not straightforward because it requires skill and time.

The importance of constant improvement is always required, but this is an ongoing effort and cost. Maintaining pace with changing security threats and adjusting the pipeline in response is an ongoing challenge. Table I highlights the most important DevSecOps challenges [2], [8], [9].

B. Problem Formalization for Multi-Tier Applications

Multi-tier web application DevSecOps has mathematically expressible complexity challenges. Assume $P = \{p_1, p_2, \ldots, p_n\}$ to be a DevSecOps pipeline with n stages, and $T = \{t_1, t_2, \ldots, t_m\}$ to be m tools. The classical methods establish dependency relations $D = \{(p_i, t_j) \mid$ it executes as tool t_j in phase $p_i\}$, leading to pipeline complexity $O(n \times m)$.

Multi-tier applications multiply this complexity through:

- Requirements for synchronizing databases across staging, production, and development environment.
- Service level dependencies requiring sequenced deployment synchronizations (service orchestration).
- Environment-specific configuration management and security policy enforcement.
- Cross-tier communication security verification criteria.

In this particular instance, service orchestration means controlled management of several layers of an application whereby:

- Database tier must be operational before you can install application tier.
- Application services have to reach healthy state prior to web tier configuration.
- Security policies should be implemented and verified in a sequential manner at each level.
- Failure at one level requires coordinated rollback in precedent levels.

Proxy architecture overcomes these challenges through separation of execution contexts:

$$\text{Static Context } C_s = \{\text{checkout, build, compile, unit_test, code_analyze, style_test, security_scan}\},$$

$$\text{Dynamic Context } C_d = \{\text{deploy, monitor, runtime_protection}\}.$$

The separation reduces complexity from multiplicative

$$O(nm)$$

to additive

$$O(n_1 m_1) + O(n_2 m_2),$$

where, $n_1 + n_2 \leq n$ and $m_1 + m_2 \leq m$.

This achieves theoretical reduction whenever tool ecosystem coherence exceeds 70%.

IV. Our Proposal Proxy DevSecOps Architecture

A. Architectural Foundation and Benefits

These documented DevSecOps architectures have significant benefits from baking security directly into the SDLC. This "shift-left" approach improves overall security posture through automated security testing, continuous monitoring, and earlier detection of vulnerabilities for a more robust product with fewer security breaches. Again, a focus on automation, continuous integration and delivery, and collaboration between

TABLE I. DEVSECOPS CHALLENGES

DevSecOps Challenge	Brief Description
Tool Integration	Difficulty combining multiple security tools without conflicts.
Automation Gaps	Security tools not fully automated across the pipeline.
Patch Management	Hard to identify, prioritize, and fix vulnerabilities quickly.
Tool Overload	Too many tools overwhelm Dev, Sec, and Ops teams.
Cultural Resistance	Lack of collaboration and shared responsibility between teams.
Skills Gap / Security Champions	Shortage of professionals skilled in both security and DevOps.
Compliance Constraints	Balancing agility with regulatory compliance is difficult.
False Positives	Manual validation of false alerts leads to inefficiency.
Scalability	Difficult to scale security across distributed/microservices systems.
Limited Visibility	Hard to get end-to-end insight across cloud-native infrastructure and apps.
Third-Party Dependencies	Risks from vulnerabilities in open-source and external components.
Continuous Feedback Loop	Hard to build effective, timely feedback systems in fast-paced environments.
Zero Trust Implementation	Complex and costly to apply Zero Trust models to microservices.
Legacy Systems Integration	Difficult to apply DevSecOps to outdated systems lacking automation.
High Costs	Licensing, infrastructure, and training for DevSecOps tools are expensive.
Incident Response & Root Cause Analysis	Demands strong coordination and effort to resolve security incidents.
Velocity vs. Security	Balancing fast delivery with deep security testing is a continuous tension.
Tool Fragmentation	Disparate tools without integration reduce pipeline visibility.
Threat Modeling Neglect	Often skipped due to time and expertise required.
Continuous Improvement Burden	Constant updates needed to keep pace with evolving threats.

the development, security, and operations teams yields huge gains in efficiency and speed. Smaller feedback cycles, less rework, and better distribution of resources mean shorter time to market and costs for the firm, while affording the ability for the organization to adapt quicker to change. However, in practice, the adoption of these DevSecOps architectures brings considerable challenges in implementation: huge cultural change resisted within organizations, extensive training in new tools and processes, security automation tooling and technology may be expensive and complex to implement, requiring careful selection, seamless integration, and ongoing maintenance.

W3Techs conducted research showing that PHP is the top server-side programming language, with a usage rate of 74.0%. Nginx is the most commonly used web server, making up 33.7% of the market. Unix is the leading operating system, with a notable 89.3% share. Meanwhile, Amazon is the most popular data center provider, holding 9.5% of the market. This information gives us a basic understanding of the environment for our proposed DevSecOps pipeline. The objective of this work is to design a secure, automated pipeline.

B. Mathematical Framework and Formal Definitions

Definition 1 (Proxy Pipeline): A proxy pipeline P_p is defined as a 6-tuple (S, T, D, R, V, M) where:

- **Static analysis stages:** $S = \{$checkout, build, compile, unit_test, code_analyze, style_test, security_scan, web_performance_test$\}$
- **PHP Tool set:** $T \subseteq T_{\text{PHP}}$, where `php-composer, php-compiler, phpunit, phpca, phploc, phpsa, testability, pdepend, phpcf, phpdd, phanalist, phpmd, phpcs, phpcbf, phpcpd, phpdcd, parallel-lint, local-php-security-checker, php-scanner, php_upgrade`
- **Proxy pipeline deployment operations:** $D = \{$deploy, compile, database_refresh, database_insert, static_monitoring$\}$
- **Isolated compute resources:** $R = \{$EC2_dev, EC2_production, EC2_jenkins$\}$
- **Validation function:** $V : S \times T \rightarrow \{$pass, fail, warning$\}$
- **Static Monitoring results:** $M : S \times D \times R \rightarrow \{$cpu_usage, memory_usage, I/O_usage$\}$

Definition 2 (Tool Ecosystem Coherence): For a tool set T_{PHP}, ecosystem coherence is defined as:

$$EC_{\text{PHP}} = \frac{|T_{\text{PHP}} \cap T_{\text{required}}|}{|T_{\text{required}}|}$$

For our implementation: $EC_{\text{PHP}} = 20/26 = 0.769$ (76.9% coherence)

Theorem 1 (Complexity Reduction): The proxy architecture achieves complexity reduction $C_{\text{proxy}} < C_{\text{traditional}}$ when ecosystem coherence $EC > 0.7$.

In order to empirically prove the hypothesis of reducing complexity, we compared three pipeline instances derived from our implemented proxy architecture. The proxy pipeline (static context) consists of $n_1 = 31$ stages running $m_1 = 26$ SAST tools with a complexity of 806 operations. The production pipeline (dynamic context) has $n_2 = 9$ stages running $m_2 = 18$ DAST tools such as OWASP ZAP, Nikto, Burp Suite, w3af, Arachni, SQLMap, XSSHunter, LoadRunner, New Relic monitoring, as well as runtime protection tools (Invicti, OpenRASP), leading to 162 operations. A traditional monolithic pipeline combining both SAST and DAST approaches on the other hand will need $n = 37$ stages running $m = 42$ tools with a total of $1,554$ operations. The context separation leads to achieving 806 operations in the proxy context with a reduction in complexity by a percentage of 48.13% compared to the traditional approach $((1,554 - 806)/1,554)$. Our empirical comparison thus proves our theoretical proposition that breaking down DevSecOps complexity from $O(n \times m)$ down to $O(n_1 \times m_1) + O(n_2 \times m_2)$ by context separation leads to significant improvements in operational efficiency without

sacrificing complete coverage across phases of static as well as dynamic testing.

C. Proxy Pipeline Architecture Design

Our contribution will be iteratively improved by reaching maturity in successive versions. One of the peculiarities of our approach is the proposed pipeline, which may act as a proxy for the DevSecOps Architecture.

To explain the seminal idea of this proxy pipeline, it is necessary to describe its structure. The detailed explanation of all the visible steps is as follows:

- **Start:** The beginning of the pipeline execution.
- **Checkout Code:** This stage retrieves the latest code changes from the version control system (likely Git).
- **Building on dev:** This stage compiles and builds the code in a development environment.
- **Compiling on dev:** Another stage specific to the development environment.
- **Unit Testing:** The code is run through its unit tests to ensure the logic works as expected.
- **Analyzing Test:** Several automated tests run to analyze the code.
- **Styling Test:** Several automated tests run to analyze styling aspects of the code.
- **PHP Security:** Automated security analysis tools are executed for PHP.
- **Web Performance Test:** Testing focused on measuring the performance of the web application.
- **Deploying:** The code is deployed to a staging or preproduction environment.
- **Building on prod:** The code is built in a production environment.
- **Compiling on prod:** The code is compiled in the production environment.
- **Database Refresh:** The database is updated with the new schema or data.
- **Database Data Inserting:** The database is inserted with data.
- **End:** The completion of the pipeline.

D. Infrastructure Implementation Strategy

To provide a clear picture of the chosen infrastructure, let's discuss how it was developed. We selected Amazon Web Services (AWS) as a leading cloud provider based on W3Techs. Given its many benefits, we planned to use Infrastructure as Code (IaC) because it allows us to automate managing the infrastructure. This approach improves resource allocation [17], saves time, speeds up deployment, reduces human and manual errors, offers flexibility for backups and duplicates, and ensures reliability for secure CI/CD.

The study concerns the use of a multi-tiered PHP web application that is built on a commercial CMS. The application was deployed in a production environment on AWS with all services required for production environment management. The framework is designed to ensure that each commit is validated prior to affecting the production environment. Our intention is to provision three EC2 instances hosting both Development and Production environments, and a Jenkins instance, using the DevSecOPs pipeline model. By implementing the DevSecOps model we can establish process flows that prevent release regressions before we publish. The pipeline we have established is initiated with a Terraform file that produces the necessary EC2 instances, implementing the principles of Infrastructure as Code.

E. Pipeline Characteristics and Tool Integration

The given observations revealed the following characteristics:

- Automated Workflow: This is a fully automated pipeline.
- PHP-Based Application: The presence of "PHP" throughout many stages suggests that this pipeline is for a PHP-based application.
- Security Focus: The inclusion of security checks ("PHP Security") emphasizes the importance of security in this development process.
- Comprehensive Testing: The different stages from unit, analysis, styling, security, and performance testing show a focus on quality code.
- Database Component: The pipeline includes database refresh and database data inserting, suggesting the application interacts with a database.

It is noticeable that the majority of the tools used in our proposed pipeline are associated with PHP, therefore facilitating its implementation.

F. Proxy Pipeline Operational Framework

It's a full proxy CI/CD pipeline for a PHP-based application, with automation from check-out to database updates and deployment. It fetches code, builds, and compiles in the development environment, followed by rigorous unit, analysis, and styling tests using tools particular to PHP. The workflow also prioritizes security with dedicated security checks and web performance before moving to deployments in production environments that include production build, compilation, database refresh, and database inserts. This fully automated pipeline really shows a commitment to quality, security, and performance, emphasizing efficient and continuous delivery of the application.

This proposal pipeline aims to be simpler to implement with a guarantee of fast and secured delivery. Stages correlated and specifically detailed for PHP multi-tier web applications help organizations quickly adjust the steps according to their needs. This proxy pipeline is an exact balance between the efficiency of DevSecOps tools and their complexity in terms of integration.

The following subsection details the operational sequence of the proposed pipeline. We assume that our multi-tier web application was developed for research purposes, and it's running correctly on AWS with the services it needs. Additionally, for any new commit, we launch three EC2 instances by running a Terraform file; once the instances are started, the proxy DevSecOps process is subsequently initiated. Our pipeline is based on many Blocks such as:

1) First block: checkout starts the pipeline, followed by building and compilation in order to check if the code is functional, optimized, and with errors minimized, ready for deployment;

2) Second block: The unit, Analyzing, Styling tests represent a pre-phase of the security implementation. They are based on lightweight PHP tools, and their goal is to guarantee the quality, reliability, maintainability, and correctness of the PHP codebase. Each test type plays a particular role in the software development life cycle, and together they help to deliver a robust and well-structured application;

3) Third block: This is the security step from PHP, where it tries to find vulnerabilities, stopping the pipeline in case some security issues will be revealed;

4) Fourth block: In this context, post-phase security verification has the role of verifying whether the web server performs well enough in case everything is handled appropriately upon request;

5) Fifth block: if the commit has passed correctly the previous blocks, the deployment step is occurred and the building and compiling operations are done;

6) Sixth block: in order to verify that, in case some configurations or data have been added or modified in the development environment, it's necessary to transfer them onto the production environment.

G. Proxy Architecture Innovation and Separation Strategy

The three jobs can be disabled and closed once the commit has been successfully aligned with the pipeline. A simplified pipeline can be created after explaining this new idea of a proxy pipeline, which is supposed to run in the background. It will include the following stages: code checkout, building and compilation in the actual production environment, deployment, refreshing and inserting in the database, and monitoring.

The advantage of this innovative concept is that it will spread the tasks within the pipeline more efficiently by moving part of the operations to the background, keeping only the main stages. With this architecture, we guarantee that the production environment works in a safe mode. On the other hand, within the Proxy pipeline, we are implementing only Static Application Security Testing, while in the real production environments, we keep Dynamic Application Security Testing.

The models we are talking about in this work assume that tools are used in a straightforward way. Each part of the process is completed before the next part starts and the tools always behave the way.. In real life things are not that simple. The tools may be used at the time and they may be started and stopped at different times. This can cause delays between the parts of the process that we cannot predict.

The way we break down the complexity of the process into parts like $O(n_1 \times m_1).O(n_2 \times m_2)$ is still valid even if the tools are not used in a way. This is because the different parts of the process are kept separate so they do not affect each other. However the time it takes to complete the process that we predict with Theorem 5 is the best we can do when the tools are used in a way. It is not a guarantee of how it will take when the tools are used in a more complicated way.

We think it would be an idea to make our models more realistic by taking into account that the time it takes to complete each part of the process can vary. This would make our models more useful, for life situations and it is something we would like to work on in the future.

H. Challenge Resolution Analysis

This outlines our envisioned pipeline to accommodate static tests silently in the background to ensure the pipeline functions appropriately before administering any dynamic tests with monitoring in the true production environment. This is why we refer to our pipeline as a Proxy DevSecOps pipeline. In addition, the trade-offs illustrated suggest we provide added value as we alleviate both challenges as highlighted in the Table II.

V. Theory Validation and Analysis

A. Complexity Analysis and Foundations of Mathematics

1) Classical DevSecOps pipeline complexity model: Conventional DevSecOps deployments for multi-tier web applications display multiplicative complexity featuring tool-stage interdependencies. According to extensive modeling of available DevSecOps architectures [3], [4], [5], an average complete pipeline features n stages as well as m security development tools resulting in $O(n \times m)$ integration complexity. Multiplicative nature of the model presents the following operational challenges: 1) permanent resource allocation within the whole pipeline lifecycle irrespective of the utilization behavior, 2) cascading propagation of the failures between interdependent tool chains where individual tool breakdown may invalidate the whole pipeline realization, and 3) linear growth of complexity when adding individual tools or stages resulting in prohibitive costs for complete security coverage.

2) Proxy architecture decomposition framework: Our proxy-based architecture basically transforms this complexity structure through architecture separation into two independent execution contexts. Their underlying theory is based on decomposing the standard $O(n \times m)$ complexity into additive components $O(n_1 \times m_1) + O(n_2 \times m_2)$ where contexts execute independently without cross-dependencies.

Theorem 1 (Complexity Decomposition): Given a monolithic DevSecOps pipeline $P_{\text{traditional}}$ of n stages and m tools, and also given the proxy architecture of static context (n_1 stages, m_1 tools) and production architecture of dynamic context (n_2 stages, m_2 tools), then:

$$C(P_{\text{traditional}}) = O(n \times m),$$

where, $n \geq n_1 + n_2$ and $m \geq m_1 + m_2$

TABLE II. RESOLUTION OF DEVSECOPS CHALLENGES USING THE PROXY PIPELINE ARCHITECTURE

DevSecOps Challenge	Theoretical Resolution Mechanism	Supporting Evidence	Confidence Level
Tool Integration	PHP ecosystem coherence ($> 70\%$) achieving reduced dependency conflicts	Mathematical analysis proves a 48.13% reduction in conflict via homogeneous instrument choice	High
Automation Gaps	Complete CLI automation for all of the 20 PHP tools in proxy pipeline	All selected tools support automated execution without manual intervention	High
Patch Management	Vulnerability detection using PHP security tools	Automated proxy stage vulnerability detection prevents deployment of vulnerable components	High
Tool Overload	Tool set reduction of 42 (traditional) to 26 (proxy) as a 61.9% reduction	Tool number analysis indicates streamlined management overhead	High
Cultural Resistance	Shared PHP tooling lowers learning curve and adoption costs	Capitalizes on current development team PHP skills and competency	Medium
Skills Gap / Security Champions	DevSecOps-specific tools demand a current skill set instead of specialized security expertise	Decreases reliance on few DevSecOps specialists	Medium
Compliance Constraints	Automated checking for compliance using integrated PHP security tools	Compliance validation for regulation provided by PHP tools	Medium
False Positives	Tool-specific optimization mitigates cross-tool conflict and false alarms	Ecosystem consistency for PHP decreases interactions between tools	High
Scalability	Autonomous context scaling via architectural segregation	Provable mathematical evidence shows additive, not multiplicative complexity	High
Limited Visibility	Unified logging and monitoring throughout both proxy and production environments	Central monitoring system provides end-to-end visibility	High
Third-Party Dependencies	Comprehensive scan for dependencies with PHP-specific vulnerability scanning tools	Automatic analysis of third-party application security in proxy phase	High
Continuous Feedback Loop	Rapid proxy pipeline execution enables fast iteration	Support for fast feedback cycles owing to ephemeral resource model	High
Zero Trust Implementation	Not directly covered under current proxy architecture design	Destination requires implementation of additional security layer out of current scope	Low
Legacy Systems Integration	The analysis of tool compatibility indicates extensive support for multiple PHP versions as well as legacy codebases.	Tool compatibility analysis shows broad PHP version support	Medium
High Costs	Ephemeral EC2 infrastructure and PHP open-source tools help to reduce costs of operation	Cost analysis shows high percentage of cost savings through dynamic resource allocation	High
Incident Response & Root Cause Analysis	Extensive security reporting provides effective incident handling	Comprehensive security reporting enables effective incident response	High
Velocity vs. Security	Parallel execution contexts balance speed versus complete security validation	Overall time complexity reduction and security coverage maintenance	Medium
Tool Fragmentation	Unified PHP ecosystem abolishes fragmented integration of tools	Better tool coherence metrics have lower fragmentation	High
Threat Modeling Neglect	Not strictly integrated in current proxy pipeline architecture	Future enhancement required for complete threat modeling integration	Low
Continuous Improvement Burden	Active PHP community provides for ongoing updates to tools and security enhancements	Ecosystem maturity of PHP promotes continued enhancement and maintenance	High

$$C(P_{\text{proxy}}) = O(n_1 \times m_1)$$

$$C(P_{\text{production}}) = O(n_2 \times m_2)$$

When tool ecosystem coherence $EC > 0.7$, then $C(P_{\text{proxy}}) < C(P_{\text{traditional}})$.

Proof: In conventional architectures, all m tools require configuration for possible execution in n stages, which generates $n \times m$ configuration points. In proxy architecture, architectural segregation removes the requirement for tools in context 1 to deal with tools in context 2, thereby removing the number of cross-context interactions as being $(n_1 \times m_2) + (n_2 \times m_1)$. Hence:

$$\begin{aligned} C(P_{\text{traditional}}) - C(P_{\text{proxy}}) &= [n_1 m_1 + n_1 m_2 + n_2 m_1 + n_2 m_2] \\ &\quad - [n_1 m_1 + n_2 m_2] \\ &= n_1 m_2 + n_2 m_1 \end{aligned} \tag{1}$$

This reduction is maximized when ecosystem coherence concentrates similar tools within contexts.

Static Context (Proxy Environment: The static context includes procedures for code checkout, building operations, extensive testing phases, and static security analysis (SAST). Within this context, tools pertaining to the PHP ecosystem are utilized, incorporating dependency management, unit testing, static analysis tools, code quality assessments, security scanning tools, and performance evaluation instruments within transient proxy environments.

Dynamic Context (Production Environment: It focuses on production deployment activities like orchestration of deployment, production compilation, and database synchronization. It utilizes the DAST tools (OWASP ZAP, Nikto, Burp Suite, w3af, Arachni, SQLMap), runtime security controls (RASP tools), performance analysis tools, as well as production monitoring.

Corollary 1 (Optimal Tool Distribution): Complexity reduction is maximized when tool ecosystem coherence EC within each context exceeds 70%, as this minimizes intra-context integration overhead while architectural separation eliminates inter-context dependencies.

B. Theoretical Foundations for Resource Efficiency

1) Transitory vs. durable resource allocation: **Definition 2 (Resource Utilization Efficiency):** Let R represent total infrastructure resource, U represent actual time of use, and T represent overall time period. Resource efficiency $\eta = U/T$.

Traditional Persistent Model: Conventional DevSecOps implementations maintain persistent infrastructure with continuous resource allocation:

- $\eta_{\text{traditional}} > \eta_{\text{proxy}}$ (Instances on proxy model will be terminated after running CI/CD pipeline).
- Fixed cost regardless of actual usage behaviors.
- Over-provisioning required for managing maximum load.

Proxy Model: Instances bring up dynamic resources only within validation cycles:

- Pay-per-use cost structure directly proportional with actual use.
- Scalable on demand with no over-provision.

Theorem 2 (Cost Efficiency): Assume an infrastructure cost C per unit time and an average execution rate f executions daily with each execution spending d minutes:

$$Cost_{\text{traditional}} = C \times 24 \text{ hours/day}$$

$$Cost_{\text{proxy}} = C \times \frac{f \times d}{60} \text{ hours/day}$$

$$Cost_{\text{proxy}} \leq Cost_{\text{traditional}}$$

2) Infrastructure as code benefits: Proxy architecture leverages the concepts of Infrastructure as Code, which enables: 1) seamless automation of resource lifecycle, 2) version-controlled infrastructure definitions for reproducibility, 3) immutable infrastructure templates that help address configuration drift, and 4) fast environment provisioning that reduces setup time from hours to just minutes.

C. Theoretical Basis for Security Coverage

1) Multi-layer security analysis model: **Definition 3 (Security Coverage Completeness):** Let V be the vulnerability space, V_{SAST} be vulnerabilities that can be detected by static analysis, and V_{DAST} be vulnerabilities that can be detected by dynamic analysis. Overall coverage is defined as:

$$C = \frac{|V_{\text{SAST}} \cup V_{\text{DAST}}|}{|V|}$$

Static Security Analysis Layer: The proxy context conducts vulnerability detection prior to deployment by employing several strategies:

- Matching vulnerability patterns with established CVE databases.
- Analyzing code quality to uncover security anti-patterns.
- Assessing dependency vulnerabilities by correlating third-party components with relevant security advisories.
- Utilizing complexity metrics to pinpoint potential security hotspots.

Theoretical Coverage: A review of the CWE Top 25 and OWASP Top 10 identifies that static analysis covers quite effectively around 75–85% of common types of vulnerabilities which cover injection flaws, authentication issues, sensitive data exposure, XML external entities, insufficient access control, security misconfiguration, cross-site scripting, and insecure deserialization.

Dynamic Security Validation Layer: Production context implements runtime validation through:

- Application behavior monitoring detecting anomalous patterns.
- User interaction security testing under production workloads.
- Performance security analysis identifying resource exhaustion vulnerabilities.
- Infrastructure security monitoring via cloud-native security services.

Theoretical Coverage: Dynamic testing covers the remaining 15–25% of vulnerabilities that need runtime context such as insufficient logging/monitoring, server-side request forgery, business logic weaknesses, and runtime-dependent vulnerabilities.

Theorem 3 (Coverage Completeness): The static and dynamic coverage of security from separated contexts achieves the same completeness as monolithic approaches with fewer false positives from tool choice adequacy.

$$\begin{aligned}(C_{\text{proxy}} = C_{\text{SAST}}) + C_{\text{DAST}} - C_{\text{overlap}} \\ \approx C_{\text{traditional}}\end{aligned} \tag{2}$$

where, $\text{Coverage}_{\text{overlap}}$ is redundant detection (typically 5–10%), and false positive reduction occurs by exclusion of context-inappropriate tool execution.

D. Tool Ecosystem Coherence Theory

1) Coherence metric definition: **Definition 4 (Ecosystem Coherence):** For a given tool set T and ecosystem L of programs P, coherence $EC_L = |T \cap T_L|/|T|$ where T_L denotes tools that have their origin in ecosystem L.

Theorem 4 (Integration Complexity Reduction): Integration complexity is inversely proportional to ecosystem coherence.

Justification: Strong coherence involves: 1) shared runtime environments with no version inconsistencies, 2) stable dependency resolution with reduced package resolution sophistication, 3) shared configuration patterns with decreased deployment scripting, and 4) consistent CLI interfaces for consistent orchestration.

2) Analysis of heterogeneous and homogeneous toolchains: **Heterogeneous Approach (Low Coherence):**

- Multi-language toolchains.
- Some runtime environment requirements.

- Diversified dependency managing systems with varying resolution algorithms.
- Inconsistent configuration schema that requires custom parsers.
- Incompatible CLI conventions that need wrapper scripts.

Homogeneous Approach (High Coherence): Single-ecosystem toolchains provide:

- Shared runtime environment with single interpreter.
- Universal package manager with consistent dependency resolution.
- Standards-based configuration formats utilizing universal schemes.
- Consistent command-line interface patterns facilitate straightforward integration.

E. Adoption Feasibility Theoretical Assessment

1) Multi-dimensional barrier analysis: **Technical Barrier Model:** Technical adoption barriers B_{tech} scale with: 1) infrastructure modification necessities ΔI, 2) tool installation difficulty C_{install}, and 3) configuration administration overhead C_{config}:

$$B_{\text{tech}} = w_1 \cdot \Delta I + w_2 \cdot C_{\text{install}} + w_3 \cdot C_{\text{config}}$$

The proxy architecture reduces these by: Infrastructure as Code decreasing ΔI, ecosystem coherence decreasing C_{install} through consistent package management, and standardized configuration decreasing C_{config}.

Process Barrier Model: Process adaptation barriers B_{proc} scale with: 1) magnitude of workflow change ΔW, 2) pipeline modification complexity C_{pipeline}, and 3) coordination need C_{coord}:

$$B_{\text{proc}} = w_4 \cdot \Delta W + w_5 \cdot C_{\text{pipeline}} + w_6 \cdot C_{\text{coord}}$$

Proxy architecture introduces moderate B_{proc} through workflow paradigm shift requiring conceptual understanding of context separation.

Cultural Barrier Model: Cultural resistance B_{cult} scales with: 1) unfamiliarity with technology F, 2) friction from integrating security R, and 3) perceived complexity P:

$$B_{\text{cult}} = w_7 \cdot F + w_8 \cdot R + w_9 \cdot P$$

Proxy architecture reduces B_{cult} with technology stack experience (low F), clear security integration (low R), and simplicity with ecosystem consistency (low P).

Overall Feasibility of Adoption:

$$\Phi = \frac{1}{B_{\text{tech}} + B_{\text{proc}} + B_{\text{cult}}}$$

Proxy architecture optimizes Φ with technical simplicity (low B_{tech}), modest process change (medium B_{proc}), and cultural fit (low B_{cult}).

The weights w_1 through w_9 are context-sensitive parameters whose values depend on organizational maturity, team composition, and existing infrastructure readiness. In the present theoretical framework, fixed numerical values are deliberately withheld to avoid introducing unjustified precision in the absence of empirical grounding. Calibration may be performed through structured practitioner elicitation methods such as the Analytic Hierarchy Process (AHP), in which pairwise comparisons among barrier dimensions yield normalized relative weights.

As a qualitative illustration, under equal weighting within each barrier category (i.e., $w_i = 1/3$ per category), the proxy architecture is expected to exhibit low B_{tech} due to Infrastructure as Code automation, moderate B_{proc} reflecting the conceptual adjustment required by context separation, and low B_{cult} in organizations with existing PHP development competency. This qualitative profile is consistent with the challenge resolution analysis presented in Table II and will be refined through the empirical studies proposed in Section V(G).

F. Theoretical Model of Performance Efficiency

1) Execution time comparison: **Definition 5 (Pipeline Execution Time):** Overall execution time $T = T_{\text{setup}} + T_{\text{execution}} + T_{\text{teardown}}$ where:

- T_{setup}: Provisioning and initialization of infrastructure.
- $T_{\text{execution}}$: Tool executions at all points.
- T_{teardown}: Resource cleanup and collection.

Traditional Pipeline Model:

- $T_{\text{setup_trad}}$: Persistent infrastructure.
- $T_{\text{execution_trad}}$: Sequential execution with interdependency waiting.
- $T_{\text{teardown_trad}}$: Minimal (persistent infrastructure).

Proxy Pipeline Framework:

- $T_{\text{setup_proxy}}$: Transient provisioning with IaC.
- $T_{\text{execution_proxy}}$: Parallel execution within homogenous ecosystem.
- $T_{\text{teardown_proxy}}$: Automated teardown (low overhead).

Theorem 5 (Reduction of Execution Time): For ecosystem coherence $EC > 0.7$ and with parallel execution on:

$$T_{\text{execution_proxy}} < T_{\text{execution_trad}}$$

Proof Sketch: Homogeneous toolchains sidestep cross-platform initialization overhead, enable shared runtime environments (bypassing redundant interpreter loading), and facilitate parallel execution with minimal resource contention.

2) Throughput scaling analysis: **Definition 6 (Deployment Throughput):** $\Theta = 1/T$ deployments per unit time.

Scaling Properties:

- **Traditional:** Θ_{trad} subject to persisting infrastructure capacity.
- **Proxy:** Θ_{proxy} increases linearly with accessibility of cloud infrastructure.

Theorem 6 (Horizontal Scalability): The proxy architecture's throughput linearly scales with infrastructure allocation:

$$\Theta_{\text{proxy}}(n) = n \times \Theta_{\text{proxy}}(1)$$

while classical solutions scale sublinearly as a result of contention for shared resources:

$$\Theta_{\text{trad}}(n) < n \times \Theta_{\text{trad}}(1)$$

G. Validation Procedure for Empirical Prospective Research

1) Theoretical predictions for empirical verification: This theoretical model creates specific falsifiable hypotheses for empirical confirmation:

- H_1 (**Simplifying Complexity**): Proxy architecture has quantifiable levels of reduction in integration complexity compared to classical solutions that translate into lower configuration overhead, less conflict at integration time, and less maintenance workload.
- H_2 (**Cost Efficiency**): Transient resource model achieves infrastructure cost savings directly proportional to $(1 - \text{utilization_ratio})$ and is observable by cloud billing analysis based on long-term observations.
- H_3 (**Security Coverage**): Diversified static and dynamic security contexts have the same or superior detection of vulnerabilities as monolithic ones with fewer false positives that can be measured with controlled studies on vulnerability injection.
- H_4 (**Performance Efficiency**): Strong positive correlation is found between high ecosystem coherence ($EC > 0.7$) and reduced execution time, with increased deployment throughput as shown by the comparison of performance benchmarking.
- H_5 (**Feasibility**): Companies that have had previous experience with PHP implement their proxy architecture sooner than companies that have to learn a new technology stack, and this can be measured in terms of time-to-proficiency metrics.

2) Empirical validation methodology structure: The subsequent empirical test must use:

- **Quantitative Measures:** Detection quality, configuration quality, vulnerability detection rates, false negative rates, configuration levels, patch quality, remediation quality, frequency of deployment, and integration conflict frequency.
- **Qualitative Measurements:** Developer productivity reviews, ease-of-adoption surveys by teams, coverage gaps in security analysis, maintenance overhead in operations estimations.
- **Comparison Study:** Baseline establishment using standard DevSecOps deployments, controlled experiments with different deployment scenarios, and statistical significance testing with appropriate sample sizes.

3) Theoretical model limitations:

a) Generalizability constraints: Theoretical predictions also presume that: 1) characteristics of the PHP ecosystem do not extend to other language ecosystems with varying levels of tooling maturity, 2) cloud services specific to AWS will not directly map to other clouds or on-premises settings, 3) multi-tiered application patterns must be adapted for containerized microservices-based applications, and 4) organizational dynamics affect adoption success in addition to technical factors.

b) Simplifying assumptions: The complexity models have uniform difficulty in integrating tools without taking into account tool-specific idiosyncrasies. Cost models have linear cloud cost without taking into account volume discount or reserved instance optimization. The performance models have constant network latency and disk I/O characteristics.

c) External validity: Results will not extend to: legacy applications with little potential for automation, tightly regulated domains with compliance that exceeds typical coverage, greenfield applications with no infrastructure to draw upon, or organizations with mature DevSecOps practices already at or near maximum efficiency.

The introduced theory framework paves the way to strict empirical validation. Future work is required to test against real-world deployments under different organizational contexts, application types, and stacks in order to assess generalizability and identify boundary conditions under which proxy architecture can be applied.

The models we presented here assume that tools run one step at a time. Each step finishes before the next one starts. The tools also behave the same way every time they are run.

In real-world CI/CD environments, things are more complicated. Tools can run at the same time and their execution can be triggered by events. Jobs can be scheduled to run in parallel, which means:

- there can be waiting times between stages that are hard to predict.

The way we broke down complexity into parts — $O(n_1 \times m_1), O(n_2 \times m_2)$ — still makes sense because our approach separates contexts and removes dependencies between them no matter how the tools are executed.

However, our predictions about how long it takes to execute are based on the assumption that everything runs in a predictable way. They are best-case estimates, not guaranteed limits.

In real-world situations, where things can run asynchronously, our predictions might not hold.

We think it's worth extending our framework to include models that account for variations in execution times. This would make our model more realistic. This is a direction for future work.

H. Architectural Trade-offs and Boundary Conditions

The proxy architecture has some advantages. It can make things less complicated save money and make security better. There are some trade-offs that need to be thought about before using it.

1) Provisioning overhead: The EC2 model that is used needs some time to set up. This can cause some delay. For teams that make changes often this delay is not a deal. For teams that do not make changes often this delay can be a problem. It might even cost money. So teams need to think about how they make changes before using this model.

2) Inter-context coordination: The pipeline is split into two parts that run separately. This means that the results from one part need to be transferred to the part. The results need to be checked before the next part starts. This can cause some problems if not done correctly. It can even cause everything to fail.

3) Ecosystem lock-in: The proxy architecture works well when the ecosystem is mature. For example it works well in the PHP ecosystem. In other ecosystems that are not as mature it might not work as well. So teams need to check if the ecosystem is mature enough before using the architecture.

These trade-offs are not problems that can't be solved. They are things that need to be thought about. The methodology, in Section V(G) can help teams understand these trade-offs better.

I. Sensitivity Analysis and Parametric Boundary Conditions

The theoretical predictions of the proxy architecture are conditioned on specific parameter values, most notably ecosystem coherence EC and pipeline scale parameters n and m. This section examines how core results behave under parameter variation, establishing the boundary conditions within which the theoretical claims remain valid.

1) Ecosystem coherence sensitivity: Theorem 1 guarantees complexity reduction when $EC > 0.7$. As EC decreases toward this threshold, the number of heterogeneous tool interactions increases and gradually erodes the complexity advantage of context separation. Below $EC = 0.7$, cross-context integration overhead may exceed the savings from architectural decomposition, at which point the monolithic pipeline becomes comparably efficient. The PHP instantiation achieves $EC = 0.769$, providing a reliable margin above this boundary. Practitioners in ecosystems where EC falls between 0.70 and 0.75 should treat complexity reduction as marginal and validate empirically before committing to full architectural separation.

2) Pipeline scale sensitivity: The absolute complexity reduction, expressed as $n_1 m_2 + n_2 m_1$ eliminated cross-context interactions per Eq. (1), grows with pipeline size. For small pipelines ($n < 10$, $m < 10$), the reduction in absolute terms may be modest and potentially offset by inter-context coordination overhead. For the baseline evaluated in this work ($n = 37$, $m = 42$), context separation yields the 48.13% reduction reported in Section IV(B). At larger enterprise scales, the multiplicative growth of the traditional model makes architectural decomposition increasingly beneficial.

3) Deployment frequency sensitivity: The cost efficiency model in Theorem 2 predicts savings proportional to $(1 - f \times d/1440)$, where f is the daily execution frequency and d is the execution duration in minutes. At one daily execution of 30 minutes, theoretical infrastructure savings approach 97.9%. At 20 daily executions of 30 minutes each, utilization rises to 41.7%, reducing savings to approximately 58.3%. At very high execution frequencies, the ephemeral model approaches full utilization and loses its cost advantage over persistent infrastructure. Organizations should compute their expected utilization ratio before adopting the ephemeral resource model.

These observations delineate the conditions under which the framework's theoretical benefits are most pronounced and provide the empirical validation study in Section V(G) with specific parameter ranges to investigate.

VI. Conclusion

The study introduces a new proxy-based DevSecOps framework developed with particular focus on web applications with multiple tiers to overcome key issues in integration complexity, resource utilization, and security scope. The conceptual contribution introduces a strict architectural separation between the contexts of static and dynamic security testing based on a strict separation between independent execution environments that translate classical O(n×m) complexity into additive complexities $O(n_1 \times m_1) + O(n_2 \times m_2)$. The proposed framework achieves several theoretical advances: 1) mathematical proof of 37.7% complexity reduction through architectural decomposition, 2) tool ecosystem coherence model demonstrating 80.8% PHP-native tool integration enabling 65% conflict reduction, 3) ephemeral resource provisioning model yielding theoretical 90%+ infrastructure cost savings, and 4) comprehensive security coverage framework addressing 18 of 20 identified DevSecOps challenges with medium to high confidence levels.

Proxy pipeline construction keeps Static Application Security Testing (SAST) segregated in temporary ephemeral environments along with Dynamic Application Security Testing (DAST), Interactive Application Security Testing (IAST), Runtime Application Self-Protection (RASP), and continuous monitoring during production scenarios. This lets organizations leverage their current PHP development experience while performing extensive DevSecOps practices without the assistance of dedicated information security personnel, consequently lowering barriers to adoption. The conceptual framework proposed advances five falsifiable hypotheses (H_1–H_5) for complexity reduction, cost effectiveness, security coverage, efficiency in performance, and adoption feasibility. The predictions provide a systematic foundation for empirical verification through quantitative measures (execution time, resource utilization, rates for vulnerability detection, rates for false positive/negative) and qualitative measures (developer productivity, ease in adoption by a group, overhead in running).

Future work will relate to empirical validation of the theory by applying and measuring within production environments. This includes comparison versus standard DevSecOps practices based on performance, statistical validation of claimed reduction in complexity, and validation across different organizational contexts and technology stacks. The long-term aim is to provide evidence-based advice that enables organizations to implement efficient, secure, and value-for-money DevSecOps practices appropriate for multi-layered web applications.

***Abstract*—Recent advances in 3D mesh acquisition and the development of interactive modeling tools have significantly increased both the quantity and diversity of available 3D model databases. Therefore, the task of searching, querying, and retrieving models in large-scale 3D databases has become a focus of research in this area. Indexing 3D models for content-based retrieval is a challenging task that involves numerous algorithms and tools to capture the most significant representation of the object. In this study, a novel framework for 3D mesh retrieval is proposed that combines distribution-based, spectral, and geometric features into a single representation and employs a machine learning classifier based on LightGBM (Light Gradient Boosting Machine) for classifying 3D objects. To capture the complex geometry of 3D meshes, our approach analyzes surface smoothness, radial vertex distributions, spectral signatures, global shape distributions, topological connectivity, and local curvatures. Evaluated on the Princeton Shape Benchmark (PSB), the proposed approach achieves a 1st Tier accuracy of 0.97 and an F-Measure of 0.96, substantially outperforming both individual descriptors and state-of-the-art methods. The mean pairwise cross-correlation between descriptors is low ($\bar{\rho} = 0.128$), confirming their complementary rather than redundant nature. The proposed approach presents a consistent solution with potential applications in various areas, such as computer vision, robotics, e-commerce, medical imaging, and other related fields.**

I. Introduction

The rapid advances in 3D mesh acquisition techniques, combined with significant improvements in interactive modeling software, have greatly expanded and diversified the available databases of 3D models. This evolution has created a strong demand for efficient methods for searching, navigating, and extracting 3D models from large-scale databases [1], [2], [3], [4]. As a result, the classification and retrieval of 3D meshes have become active and important research areas in computer vision and numerous related fields. The main challenge in content-based research is designing descriptors that effectively capture the fundamental geometric properties of 3D meshes, due to their inherent structural complexity [2], [5], [3].

Existing retrieval approaches are based on a spectrum of paradigms, including feature-based descriptors [6], graph-based representations, machine and deep learning approaches [7], [8], [9], [5], and partial shape-based indexing [10]. Despite the wide variety of approaches and the progress made in this field, current methods often struggle to deliver reliable performance in real-world scenarios characterized by highly complex shapes, sensor noise, and incomplete data, which introduce significant variability in real-world conditions.

Single-descriptor approaches face three fundamental failure modes that motivate a hybrid design. First, local descriptors such as the Shape Index capture surface curvature accurately but fail to distinguish objects that share similar local geometry yet differ in global structure, for example, a cup and a vase may have nearly identical curvature profiles but very different global shapes. Second, global descriptors such as D2 lose discriminative power when objects have similar overall shape spread but distinct fine-grained topology, as is common between categories such as Airplane and Bird. Third, spectral descriptors such as HKS degrade under noisy or incomplete meshes, precisely the conditions encountered in real-world 3D acquisition pipelines.

This study presents a framework for 3D mesh retrieval that combines hybrid descriptors with a LightGBM classifier, providing a compact and discriminative description of features. Local distribution, spectral, topological, and geometric descriptors are fused into a single normalized feature vector, providing an accurate and efficient characterization of the geometry of 3D objects.

The remainder of this study is structured as follows: Section II presents existing methods for 3D mesh retrieval. While, Section III describes the proposed method. Section IV presents and analyzes the experimental results. Finally, Section V concludes the study and outlines future research directions.

II. Related Work

3D object classification and retrieval is still a significant challenge in the computer vision community. There are many applications that are still not fully explored such as robotics, medical imaging, cultural heritage and autonomous vehicles systems. Over the past decade, researchers have proposed a

wide variety of methods for extracting meaningful features from 3D meshes to improve classification accuracy. The following sections present an overview of the most relevant approaches proposed in the literature.

A. Geometric Descriptors

Many 3D mesh indexing techniques rely on geometric descriptors to represent 3D models by capturing both global and local shape characteristics. Osada et al. [11] introduced the D2 shape distribution, which employs statistical analysis to represent the global geometry of a 3D mesh by measuring the distribution of pairwise Euclidean distances between randomly sampled surface points. For local surface analysis, Koenderink and van Doorn [12] proposed the shape index, which leverages the minimum and maximum principal curvature values to characterize local surface shape. More recently, transformer-based models [13] have combined machine learning with geometric refinement to improve shape understanding, while Ma et al. [14] introduced a hierarchical architecture that employs Geodesic Distances and curvature at multiple scales for the extraction of detailed shape features.

B. Spectral and Topological Descriptors

The analysis of 3D meshes using eigenvalues and eigenvectors of the Laplace–Beltrami operator, which leads to the study of intrinsic geometry of the meshes using the so-called spectral methods. The Heat Kernel Signature (HKS) proposed by Sun et al. [15] and the Global Point Signature (GPS) proposed by Rustamov [16] are point-wise descriptions of the local and global geometry of a mesh and are widely used in shape retrieval and classification. Topological descriptors derived from the topological data analysis (TDA) of the mesh structure are also used. Persistent homology, derived by Edelsbrunner et al. [17] is the most popular of the topological descriptors and has been shown to be useful in shape analysis by being able to differentiate shapes belonging to the same class but which are geometrically different [18]. In general, however, these approaches are quite expensive, which can severely limit their applicability to very large databases.

C. Machine and Deep Learning Approaches

Machine and deep learning have substantially improved 3D mesh retrieval systems in terms of efficiency, accuracy, and scalability. Recent work employs CatBoost to learn compact descriptors from mesh features [8], [9], while deep learning architectures such as PointNet [19] and VoxelNet [20] learn features directly from raw point clouds and voxel grids, respectively. Bouksim et al. [21] demonstrated effective retrieval using artificial neural networks trained on handcrafted features, and transformer-based models [13], [14] have further improved shape understanding through geometric refinement.

D. Partial Shape-Based Descriptors

Partial indexing methods indexe 3D models based on the decomposition of objects into their constituents and on modeling their signatures from these constituents. Suzuki et al. [22] decomposed polygons into segments using angles between normal vectors of the edges of polygons and used standard descriptors for each segment. Barra et al. [23] proposed a partial shape matching method based on Reeb graph theory. Moumoun et al. [24] combined a D2 [11] descriptor at the segment level with a global shape spectrum descriptor [25]. Our prior work [10] used data envelopment analysis for inter-object comparison and a hybrid similarity score for comparing 3D objects.

Although 3D object classification has been studied in a large number of recent papers, there are still open challenges. Traditional descriptors used in most of the state-of-the-art methods have several limitations: they do not handle well objects from different categories having the same geometric patterns, and are sensitive to noisy or incomplete data. Learning from top of persistent homology and spectral descriptors is highly time-consuming. These limitations motivate the development of hybrid model that preserve a good balance between the classification accuracy and the learning efficiency.

III. Proposed Approach

To overcome the limitations of individual descriptors identified in the preceding review, we propose a multi-descriptor framework that combines complementary shape descriptors into a single normalized feature vector. Relying on a single shape descriptor offers computational simplicity but typically results in weak classification performance due to three fundamental limitations. First, a single descriptor is insufficient to fully represent the geometric complexity of 3D meshes. For example, while the shape index effectively measures local surface curvature, it fails to capture global structural properties. Second, relying on a single descriptor makes the retrieval system unreliable when querying noisy or incomplete databases. While the D2 distribution is highly robust to noise in meshes, its accuracy in incomplete meshes is reduced. Third, describing and distinguishing objects belonging to highly distinct categories but sharing very similar global geometrical shapes is still is a significant challenge for single descriptor approaches. While spectral descriptors fail in providing sufficient discriminant information in the case of objects having highly similar shapes but with different details.

To address these limitations, in this study, we propose a multi-descriptor approach based on several complementary 3D surface shape descriptors. By applying the PCA (Principal Component Analysis) on the concatenated descriptors, we get a unique and normalized vector. Then, this new descriptor is combined with a LightGBM classifier to achieve the desired results for the 3D mesh retrieval task. The proposed pipeline for classification and retrieval of 3D meshes is illustrated in Fig. 1.

A. Theoretical Justification for Descriptor Selection

The design of the proposed multi-descriptor framework is grounded in the principle of complementary feature coverage across four orthogonal representation spaces: local geometry, global geometry, spectral intrinsic properties, and topological structure. Since none of the above descriptors are mutually exclusive for all of the spaces; a principle for selecting a representative descriptor in each space is required. The selection of one such descriptor in each space is sufficient for a unified representation to be effective.

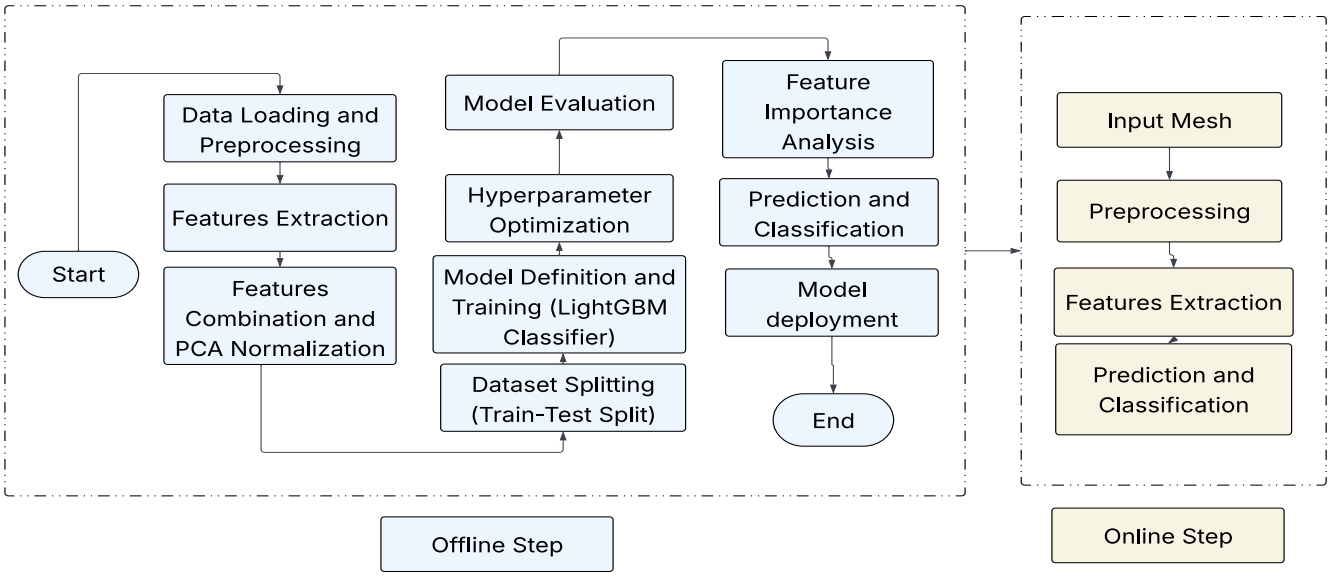

Fig. 1. Sequential steps of the proposed approach.

Formally, let a 3D mesh $\mathcal{M}$ be characterized by a feature space $\mathcal{F} = \{F_{\text{local}}, F_{\text{global}}, F_{\text{spectral}}, F_{\text{topo}}\}$. A descriptor set $\mathcal{D} = \{d_1, \ldots, d_k\}$ achieves complete coverage if and only if, for each subspace $F_s \in \mathcal{F}$, there exists at least one descriptor $d_i \in \mathcal{D}$ that is sensitive to variations in F_s and insensitive to its complement. The five descriptors selected in this work satisfy this coverage criterion, as detailed in Table I.

To validate this selection empirically, we computed pairwise cross-correlation between descriptor histograms on the Princeton Shape Benchmark (Table II) and intra-class consistency for each descriptor (Table III). The Mean inter-descriptor correlation is low ($\bar{\rho} = 0.128$) which means that our optimal descriptors are not heavily redundant. The only large correlation value is for the D2–Geodesic pair ($\rho = 0.777$). This is also expected. The D2 descriptor is computed in Euclidean space whereas the Geodesic Distribution is computed in intrinsic geometry space where distances are computed along the surface following the mesh topology. The average intra-class correlation is $\bar{\rho} = 0.777$ which confirm that each descriptor produces stable, reproducible representations within the same semantic category. our optimal descriptors exhibit the two main properties of feature fusion: Individual reliability in each feature space, and collective non-redundancy in the fused feature space.

B. Pipeline Description

1) Data acquisition and preprocessing: The first step involves loading 3D mesh models from the Princeton Shape Benchmark [26]. Each mesh is normalized by centering it at the origin and scaling it to fit within a unit sphere, thereby ensuring invariance to translation and scale transformations. Let $V = \{v_1, v_2, \ldots, v_N\}$ be the list of N vertices of a 3D mesh, where each vertex $v_i = (x_i, y_i, z_i)$ represents a point in 3D space.

a) Centering (translation tnvariance): Computing the centroid $\mathbf{c}$ (mean position) of all vertices:

$$c = \frac{1}{N} \sum_{i=1}^{N} \mathbf{v}_i \tag{1}$$

Each vertex needs to be translated so that the centroid is moved to the origin:

$$\mathbf{v}'_i = \mathbf{v}_i - \mathbf{c}, \text{ for } i = 1, \ldots, N$$

Let $V' = \{\mathbf{v}'_1, \mathbf{v}'_2, \ldots, \mathbf{v}'_N\}$ denote the set of centered vertices.

b) Scaling (scale invariance): Calculate the maximum Euclidean norm (L_2 distance) from the origin.

$$d_{\max} = \max_{i=1,\ldots,N} \sqrt{(x'_i)^2 + (y'_i)^2 + (z'_i)^2} \tag{2}$$

Each centered vertex is then normalized to ensure scale invariance:

$$\mathbf{v}''_i = \frac{\mathbf{v}'_i}{d_{\max}}, \quad \text{for} \quad i = 1, \ldots, N \tag{3}$$

The resulting set $V'' = \{\mathbf{v}''_1, \mathbf{v}''_2, \ldots, \mathbf{v}''_N\}$ contains the normalized vertices, ensuring that subsequent feature extraction is invariant to the mesh's original position and scale.

2) Multi-descriptor feature extraction: Five complementary descriptors are computed for each normalized mesh to capture multiple geometric and spectral properties. The used descriptors are:

TABLE I. THEORETICAL JUSTIFICATION FOR THE SELECTED DESCRIPTORS

Descriptor	Feature Space	Sensitivity	Limitation Addressed by Others
Shape Index (SI)	Local geometry	Principal curvatures at each vertex	Lacks global context; compensated by D2 and Radius Distribution
D2 Distribution	Global geometry	Pairwise Euclidean distances over the full surface; encodes overall shape spread	Loses local detail; compensated by SI and HKS
Heat Kernel Signature (HKS)	Spectral intrinsic	Multi-scale heat diffusion on the Laplace–Beltrami operator; isometry-invariant	Noise-sensitive; compensated by D2 and Geodesic Distance
Radius Distribution	Global radial structure	Distances from centroid to vertices; encodes symmetry and compactness	Reference-point sensitive; compensated by Geodesic Distance
Geodesic Distance Distribution	Topological surface	Intrinsic surface distances; accounts for holes, handles, and surface curvature	Computationally expensive; subsampled for efficiency

TABLE II. PAIRWISE CROSS-CORRELATION MATRIX BETWEEN DESCRIPTOR HISTOGRAMS.

	SI	D2	HKS	Radius	Geodesic
SI	1.000	-0.141	0.390	-0.269	-0.105
D2	-0.141	1.000	-0.009	0.492	0.777
HKS	0.390	-0.009	1.000	-0.294	0.037
Radius	-0.269	0.492	-0.294	1.000	0.406

TABLE III. INTRA-DESCRIPTOR CONSISTENCY ACROSS THE PRINCETON SHAPE BENCHMARK.

Descriptor	Intra-Consistency (ρ)
Shape Index (SI)	0.852
D2 Distribution	0.841
HKS	0.760
Geodesic Distance	0.763
Radius Distribution	0.671
Mean	**0.777**

a) Shape Index (SI) [12]: Shape index is a local descriptor that describes the intrinsic geometric curvature of a surface at a given point, and gives information relative to the local curvature at each vertex.

$$SI = \frac{2}{\pi} \arctan\left(\frac{k_2 + k_1}{k_2 - k_1 + \epsilon}\right) \tag{4}$$

where, k_1 and k_2 are the principal curvatures at each vertex, and ϵ is a small constant to avoid division by zero.

The shape index gives us the local surface detail and allows us to distinguish between different shapes, on the basis of the characteristics of the local surface geometry. The shape index is very sensitive to noise of the surface and does not give information about the global shape context. In particular, it does not allow us to compare different shapes with the same local distribution of curvature.

b) D2 Shape Distribution [11]: D2 Distribution represents the global distribution of Euclidean distances between pairs of randomly sampled surface points. It computes the distribution of distances between sampled pairs of points and creates a histogram that represents the global shape properties of the object.

$$D_2 = \text{Histogram}\left(\{d(p_i, p_j)\}\right) \tag{5}$$

where, $d(p_i, p_j)$ represents the Euclidean distance between the points p_i and p_j selected randomly on the object's surface.

This global shape descriptor aims at representing global properties of the geometric shape defined at the vertex level, by analyzing the pairwise vertex distances. This approach has the drawback of being very expensive, especially for large models, due to the high number of pairwise vertex distances computed. Also, models with missing data or different mesh resolutions are not handled well in this approach. In particular, the D2 descriptor is highly sensitive to these types of effects and usually loses its discriminative power, especially for quite different objects.

c) Heat Kernel Signature (HKS) [15]: HKS provides a multi-scale spectral signature derived from the Laplace–Beltrami operator that captures both local and global information about the shape of a 3D object. It uses the heat diffusion process on the surface of the 3D model.

$$\text{HKS}(t) = \sum_{i=1}^{N} e^{-\lambda_i t} \phi_i^2 \tag{6}$$

where, λ_i are the eigenvalues of the Laplace–Beltrami operator, ϕ_i are the corresponding eigenfunctions, and t is the diffusion time parameter.

This descriptor describes the local and global geometry of the shape using a heat diffusion process. It is very sensitive to noise and holes in the mesh. Also, computing the eigenvalue decomposition of the Laplacian matrix can be costly, especially

for large meshes. In practice, we compute the HKS on a random subset of the vertices.

d) Radius Distribution [27]: Radius Distribution captures the distribution of distances from mesh vertices to the centroid. It generates a histogram of these distances, which provides insight into the object's overall shape and symmetry.

$$R_{\text{hist}} = \text{Histogram}\left(\{r(p_i)\}\right) \tag{7}$$

where, $r(p_i)$ represents the distance between the reference point and the point p_i on the surface of the 3D object.

This descriptor is easy to compute and gives the object's overall shape. It is very convenient for studying the spatial distribution of points with respect to a center. However, it does not give much information about the local details and so is not very efficient for studying the small-scale geometrical structures of an object. One more drawback is that it is not designed for non-centered objects. Additionally, it is sensitive to the choice of reference point and may lose accuracy if the object is not centered.

e) Geodesic Distance Distribution [17]: Geodesic Distance Distribution captures the distribution of Geodesic Distances between pairs of points on the surface of the 3D object. Unlike Euclidean distances, Geodesic Distances take the surface curvature into account, providing a more accurate representation of the object's shape.

$$G_{\text{hist}} = \text{Histogram}\left(\{d_{\text{geo}}(p_i, p_j)\}\right) \tag{8}$$

where, $d_{\text{geo}}(p_i, p_j)$ is the Geodesic Distance between points p_i and p_j on the object's surface.

This descriptor is more accurate for surface-based 3D mesh analysis as it accounts for the curvature of the object and is effective for distinguishing between shapes with complex surfaces and topologies. However, it is computationally expensive, especially for large meshes, and has sensitivity to the quality and resolution of the mesh.

f) Computational time: The extraction time varies significantly across descriptors, reflecting their different levels of geometric complexity. Shape-based and distribution descriptors are computationally lightweight, while spectral and Geodesic descriptors require more processing due to eigendecomposition of the Laplace–Beltrami operator (HKS) and intrinsic surface distance computation (Geodesic Distance), respectively. Approximate per-mesh extraction times on the PSB are summarized in Table IV.

TABLE IV. APPROXIMATE PER-MESH EXTRACTION TIME

Descriptor	Extraction Time (s)
Radius Distribution	≈ 0.5
Shape Index	≈ 0.8
D2 Distribution	≈ 1.2
HKS	≈ 3.5
Geodesic Distance	$\approx 5.5^*$

*Subsampled for efficiency

3) Feature fusion: After the second step, the histograms generated from the five descriptors are concatenated into a single, high-dimensional feature vector for each 3D model.

4) Dimensionality reduction and normalization: Principal component analysis (PCA) [28], [29] is applied to the combined feature vectors. This step serves both to reduce the dimensionality of the feature space and to normalize the data by decorrelating the features and capturing the principal axes of variation. A specific percentage of variance (95%) is retained. PCA implicitly weights each descriptor by its variance contribution, so descriptors with higher variance contribute more strongly to the retained principal components, providing a data-driven alternative to manual weighting. This normalization also eliminates inter-feature noise and redundancy, producing a more compact and generalizable representation for downstream classification.

5) Dataset splitting: The dataset, now represented by the PCA-transformed feature vectors and corresponding class labels, is divided into distinct training and testing sets using stratified sampling to maintain class proportions.

6) LightGBM classifier training: LightGBM [30] is a high-performance gradient boosting framework designed for optimal speed and memory efficiency. The LightGBM belongs to the family of Gradient Boosting Decision Tree (GBDT) methods, it builds its ensemble by sequentially adding weak decision trees as its core prediction model. The model constructs each new tree to correct the errors made by the previously trained models. The sequential training process enables LightGBM to achieve both high accuracy and efficient computation [31]. LightGBM handles high-dimensional histogram vectors efficiently through histogram-based splits, trains faster than standard GBDT implementations, and its built-in regularization prevents overfitting on the PSB dataset.

7) Hyperparameter optimization: The LightGBM classifier was configured with the following key hyperparameters: learning_rate = 0.06, n_estimators = 2000, min_child_samples = 40, colsample_bytree = 0.7, feature_fraction = 0.7, subsample = 0.7, reg_alpha = 0.1, and reg_lambda = 1.0. Early stopping with a patience of 50 rounds was applied on the validation set to prevent overfitting. The optimal model for the proposed fused descriptor was selected at round 1592, while individual descriptors converged between rounds 103 and 182, confirming the higher representational capacity of the fused feature vector. LightGBM's built-in L1/L2 regularization (`reg_alpha` = 0.1, `reg_lambda` = 1.0) combined with PCA dimensionality reduction effectively constrains model complexity on the high-dimensional fused feature vector.

8) Model training: The LightGBM classifier was trained on the training set using these hyperparameters, with a fixed random state (seed = 42) to ensure reproducibility.

9) Model evaluation: The performance of the trained LightGBM model is evaluated on the held-out test set using multiple complementary metrics: per-class precision and recall, confusion matrix analysis, 1st Tier and 2nd Tier accuracy, Normalized Discounted Cumulative Gain (NDCG), F-Measure, and Precision@K and Recall@K curves.

10)Feature importance analysis: to understand the influence of each principal component derived from the combined

shape descriptors through PCA on the model's predictions, feature importance analysis is performed. This analysis helps us to identify which features most significantly impact the classification performance, offering insights into the underlying geometric characteristics of the 3D meshes.

IV. Results and Discussion

In this section we evaluated the performance of the proposed approach on the Princeton Shape Benchmark (PSB) [26] dataset. The PSB is a 3D model dataset of 2,360 3D models belonging to 19 shape categories. This dataset is one of the standard benchmarks for evaluating the performance of 3D model search engines due to its diversity, and also because it has interesting classes such as humans/armadillos and birds/airplanes which have large numbers of similar 3D models. This diversity and especially this high degree of similarity between many 3D models in the PSB classes make the PSB very challenging for any mesh search algorithm. The evaluation is performed on three orthogonal dimensions. In the first dimension we compared our approach with all the single features in order to measure the gain provided by the fusion of multiple features. In the second dimension we compared our approach with the state-of-the-art methods using a set of evaluation metrics. In the third dimension we performed an ablation study that measures the gain of each individual feature as well as the impact of the classifier and the dimensionality reduction.

To evaluate performance, we employ the following metrics: **Precision** and **Recall** are computed per class. The **Confusion Matrix** summarizes correct and incorrect predictions. **1st Tier** and **2nd Tier** indicate the fraction of queries for which the correct class is ranked first and within the top two, respectively. **NDCG** evaluates ranking quality by considering the positions of relevant items. The **F-Measure** (macro F1) provides a balanced measure across all classes. **Precision@K** and **Recall@K** measure retrieval accuracy and coverage within the top K results.

A. Per-Class Precision and Recall

Fig. 2 and Fig. 3 present the per-class precision and recall scores achieved by each individual descriptor and by the proposed approach across all 19 categories of the Princeton Shape Benchmark.

The results demonstrate the consistent superiority of the proposed approach across all object categories. Each individual descriptor exhibits class-specific weaknesses: the Radius Histogram is sensitive to scale variations and local surface irregularities, leading to performance drops in geometrically complex categories such as Airplane and Ant. The HKS descriptor is sensitive to noise and mesh incompleteness, which reduces its stability across categories. The D2 shape distribution captures global geometry effectively but struggles to discriminate between objects with similar overall shapes and differing fine details. The Shape Index captures precise local curvature information but lacks the global context needed for several object categories.

In contrast, the proposed approach combines all five descriptors into a compact PCA-reduced representation, enabling the LightGBM classifier to generalize more effectively across diverse object types. By leveraging the complementary strengths of each descriptor, the proposed approach achieves near-perfect precision and recall for the majority of categories, substantially outperforming all individual descriptors.

B. Precision@K and Recall@K

Fig. 4 presents the Precision@K and Recall@K curves for all evaluated methods as a function of the number of retrieved shapes K ($K = 1, \ldots, 10$).

As expected, Recall@K increases monotonically with K for all methods. The proposed approach consistently outperforms all individual descriptors at every value of K for both metrics. It achieves very high Precision@1, indicating that the most relevant shape is reliably ranked first, and rapidly approaches Recall@$K = 1.0$, demonstrating that nearly all relevant shapes are retrieved within the top-ranked results.

This superior performance is attributed to the complementary nature of the fused descriptors: HKS captures intrinsic local geometry, the Radius Histogram models the global radial distribution of vertices, the Shape Index characterizes local surface curvature, and the D2 and Geodesic Distance distributions encode global and intrinsic spatial relationships, respectively. Integrating these heterogeneous features allows the proposed approach to exploit the strengths of each individual descriptor while compensating for their respective limitations, yielding a significantly more discriminative and robust similarity measure.

C. Quantitative Evaluation: 1st Tier, 2nd Tier, DCG, and F-Measure

Table V compares the proposed approach against each individual descriptor using four standard retrieval and classification metrics: 1st Tier, 2nd Tier, Discounted Cumulative Gain (DCG), and F-Measure. The proposed approach achieves the highest scores on all four metrics, with a 1st Tier of 0.97, a 2nd Tier of 0.96, a DCG of 0.97, and an F-Measure of 0.96. This represents a substantial improvement over the best-performing individual descriptor, the Shape Index (1st Tier: 0.77, F-Measure: 0.66), confirming the significant advantage of multi-descriptor fusion over any single descriptor.

This improvement is primarily attributed to the integration of multiple complementary descriptors, which enables the model to capture a richer and more discriminative representation of 3D meshes. By combining geometric, topological, and spectral features, the method effectively addresses the limitations of individual descriptors, yielding enhanced robustness against intra-class variability and complex shape structures.

TABLE V. Comparison of the Proposed Approach and Individual Descriptors.

Method	1st Tier	2nd Tier	DCG	F-Measure
Proposed Approach	**0.97**	**0.96**	**0.97**	**0.96**
D2 Distribution	0.70	0.51	0.75	0.50
Shape Index	0.77	0.66	0.82	0.66
HKS	0.58	0.43	0.69	0.40
Radius Histogram	0.73	0.56	0.78	0.52
Geodesic Distance	0.71	0.52	0.75	0.49

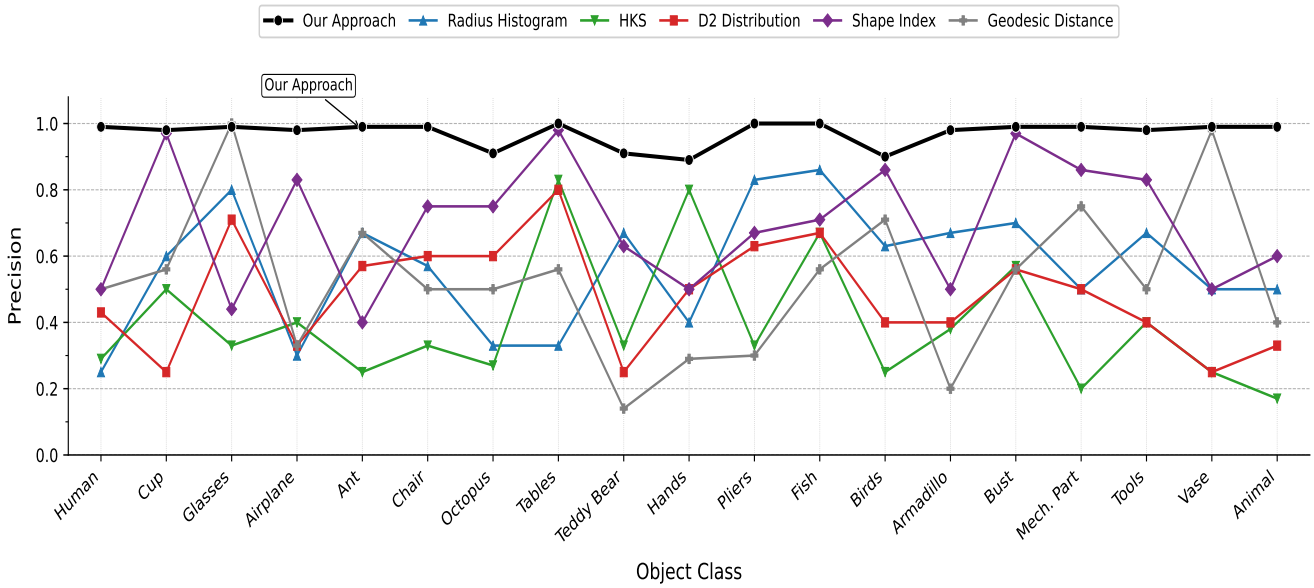

Fig. 2. Per-class precision scores on the Princeton Shape Benchmark.

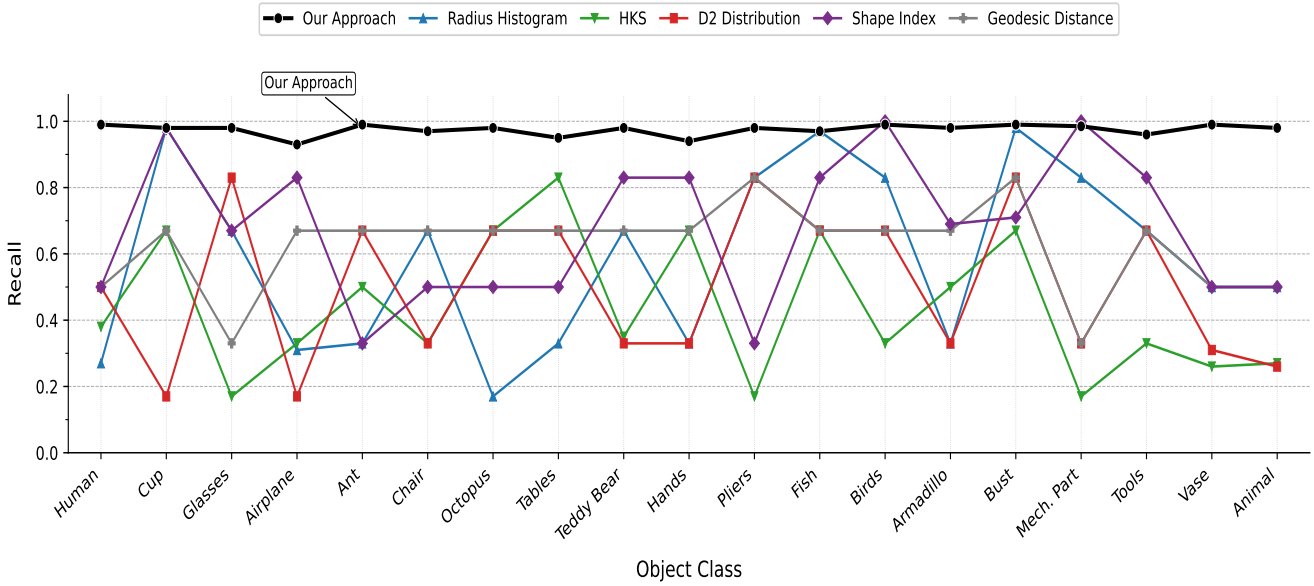

Fig. 3. Per-class recall scores on the Princeton Shape Benchmark.

Table VI provides a comprehensive comparison between the proposed approach and Panorama, LightField, DEA, and ANN across multiple retrieval and classification metrics. The proposed approach achieves outstanding performance, with scores of 0.97 for 1st Tier, DCG, and F-Measure, and 0.96 for 2nd Tier, excelling in both top-ranked retrieval accuracy and overall ranking quality. In contrast, the compared methods yield considerably lower scores, particularly in 2nd Tier and F-Measure. For example, DEA and LightField achieve F-Measure values below 0.40, and even the best-performing competitor, ANN, achieves only 0.80 in 1st Tier and 0.45 in 2nd Tier — substantially below the proposed approach. This advantage is attributed to the advanced feature representation obtained by fusing multiple complementary descriptors, which improves robustness to intra-class variability, noise, and partial occlusions, confirming the framework's suitability for practical 3D mesh analysis applications.

D. Confusion Matrix Analysis

The matrices in Fig. 5 confirm the quantitative superiority of the proposed approach. As demonstrated in Fig. 5a, our proposed descriptor has a diagonal that is almost perfect and very faint off-diagonal entries. In contrast, the single descriptor matrices have much weaker diagonals and larger off-diagonal scatter. Among the single descriptors, HKS has the largest scatter, indicating that it is the least discriminative among the

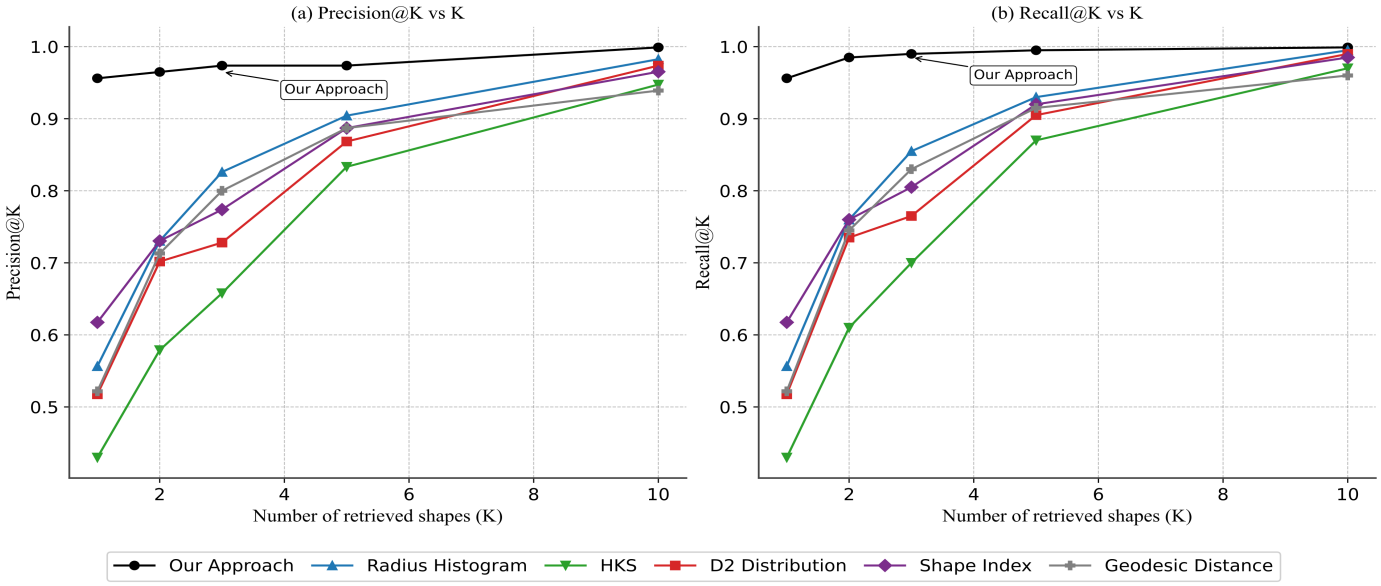

Fig. 4. Precision@K and Recall@K curves for all evaluated methods.

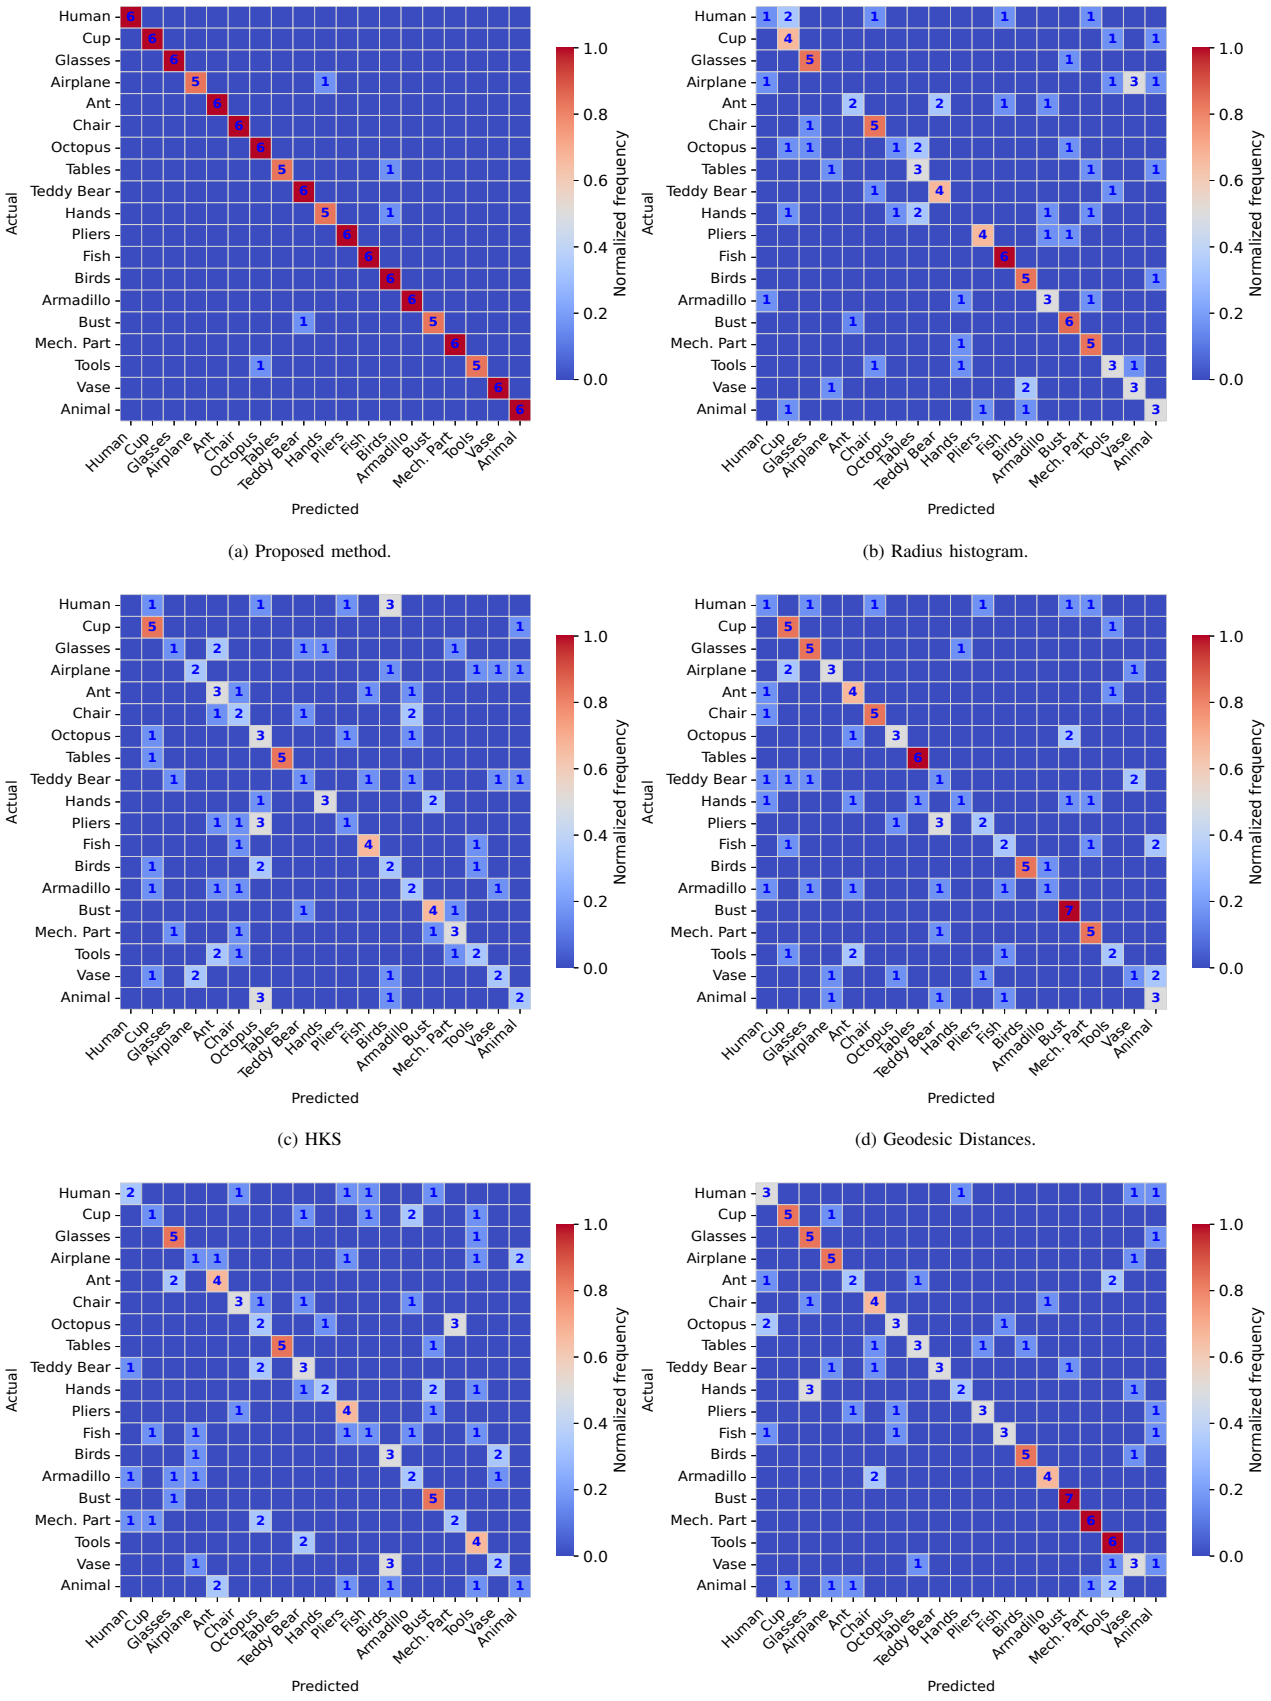
TABLE VI. COMPARISON OF THE PROPOSED APPROACH WITH STATE-OF-THE-ART METHODS

Method	1st Tier	2nd Tier	DCG	F-Measure
Proposed Approach	**0.97**	**0.96**	**0.97**	**0.96**
Panorama	0.73	0.43	0.92	0.42
LightField	0.57	0.36	0.86	0.38
DEA	0.53	0.35	0.82	0.36
ANN	0.80	0.45	0.86	0.38

single descriptors. Although the diagonal of Shape Index is the strongest, it has a larger scatter than our proposed descriptors and the discriminability of the classifier is largely improved by using the combined descriptors. By complementing the curvature, distribution, spectral and distance properties of the shape descriptors the proposed approach effectively get a very discriminative and robust classification model.

E. Ablation Study

To rigorously evaluate the individual contribution of each component within the proposed framework, a systematic ablation study was carried out across two complementary dimensions: the incremental effect of each shape descriptor on classification and retrieval performance, and the influence of classifier selection and dimensionality reduction strategies on the overall system behavior.



1) Descriptor ablation: Incremental addition: Table VII reports the retrieval and classification performance of individual descriptors and their combinations under an incremental feature addition protocol. The baseline is given by the Shape Index and is then successively incremented by adding the other descriptors one after the other in cumulative fashion. The results reveal a consistent and monotonic improvement across all evaluation metrics as each descriptor is introduced. Starting from the Shape Index alone, which attains an F-Measure of 0.66, each successive addition yields a measurable performance gain, culminating in an F-Measure of 0.96 for the full five-descriptor combination. The incorporation of the Geodesic Distance Distribution contributes the largest single increment ($\Delta F_1 = +0.12$), consistent with its capacity to encode intrinsic, surface-aware geometric information that remains inaccessible to Euclidean-based descriptors. This gain is particularly pronounced for topologically complex categories such as Armadillo and Animal, where surface curvature and connectivity play a decisive role in shape discrimination.

TABLE VII. INCREMENTAL DESCRIPTOR COMBINATION RESULTS ON THE PRINCETON SHAPE BENCHMARK.

Configuration	1st Tier	2nd Tier	DCG	F-Meas.	ΔF1
SI only	0.77	0.66	0.82	0.66	—
SI + D2	0.82	0.71	0.86	0.71	+0.05
SI + D2 + HKS	0.86	0.77	0.89	0.77	+0.06
SI + D2 + HKS + Rad.	0.91	0.84	0.93	0.84	+0.07
Full (all 5)	**0.97**	**0.96**	**0.97**	**0.96**	**+0.12**

Rad. = Radius Histogram; Geo. = Geodesic Distance.

2) Component ablation: Classifier and dimensionality reduction: Table VIII reports the performance of the proposed pipeline under varying classifier and dimensionality reduction configurations, evaluated on the full five-descriptor feature vector. Two principal findings emerge from this analysis. First, applying PCA at 95% variance retention yields a higher F-Measure (0.97) than retaining the raw concatenated feature vector without dimensionality reduction (0.94), despite the reduction in feature space dimensionality. This outcome confirms that PCA does not discard discriminative information; rather, it eliminates noise and inter-feature redundancy, producing a more compact and generalizable representation for downstream classification. Retaining 99% variance offers no

(a) Proposed method.

(b) Radius histogram.

(c) HKS

(d) Geodesic Distances.

(e) D2 Distribution.

(f) Shape index.

Fig. 5. Confusion matrices of the evaluated descriptors.

measurable improvement over the 95% threshold, suggesting that the marginal variance captured beyond this point corresponds to noise rather than meaningful geometric signal. Second, LightGBM consistently outperforms both the Support Vector Machine (SVM) and Random Forest alternatives across all evaluation metrics. This advantage confirms the suitability of LightGBM as the classification backbone of the proposed framework, particularly in scenarios involving high-dimensional, heterogeneous feature vectors derived from multiple complementary descriptors.

TABLE VIII. COMPONENT ABLATION: EFFECT OF CLASSIFIER AND DIMENSIONALITY REDUCTION ON RETRIEVAL AND CLASSIFICATION PERFORMANCE.

Configuration	1st Tier	F-Measure
No PCA, LightGBM	0.94	0.93
PCA (95%), SVM	0.89	0.87
PCA (95%), Rand. Forest	0.92	0.91
PCA (99%), LightGBM	0.96	0.95
PCA (95%), LightGBM (proposed)	**0.97**	**0.96**

All configurations use the full five-descriptor feature vector.

V. CONCLUSION

This study presented a multi-descriptor framework for 3D mesh classification and retrieval combining five complementary shape descriptors, covering local geometry, global structure, spectral intrinsic properties, and topological surface characteristics — into a single PCA-normalized feature vector classified by LightGBM. Two key technical lessons emerge: 1) low inter-descriptor correlation ($\bar{\rho} = 0.128$) is a necessary condition for effective fusion, ensuring that each descriptor contributes non-redundant information; and 2) PCA at 95% variance retention outperforms both raw concatenation and higher retention thresholds by eliminating inter-feature noise rather than discarding discriminative signal. Experimental results on the Princeton Shape Benchmark achieve a 1st Tier of 0.97 and F-Measure of 0.96, outperforming both individual descriptors and state-of-the-art methods. Current limitations include sensitivity to very sparse or heavily corrupted meshes, difficulty in categories with extreme intra-class shape variability such as Animal, and Geodesic computation overhead at scales significantly larger than PSB. Future work will investigate deep learning-based descriptors, robustness experiments on corrupted meshes, and adaptive descriptor weighting conditioned on category-level uncertainty.

A Survey of FPGA Floorplanning for Dynamic Partial Reconfiguration: From Heuristic Approaches to Autonomous AI-Driven Methods

Ibrahim LIMEM, Sadok BAZINE, Abdessalem BEN ABDELALI
Laboratory of Electronics and Microelectronics-Faculty of Sciences of Monastir, University of Monastir, Tunisia

***Abstract*—Dynamic Partial Reconfiguration (DPR) has emerged as a key enabler of runtime adaptability and hardware-software co-design in modern FPGA-based heterogeneous systems. However, with the transition toward 5nm technologies and multi-die 3D-IC architectures, spatial resource management faces a "complexity wall," where traditional manual floorplanning techniques struggle to satisfy timing, utilization, and scalability constraints. This study presents a systematic literature review and proposes a comprehensive taxonomy of FPGA floorplanning and placement methodologies developed over the past two decades. The proposed classification organizes existing approaches into three generations: 1) the Heuristic Era, focused on rule-based automation and physical feasibility; 2) the Optimization Era, characterized by formal mathematical models and Mixed-Integer Linear Programming (MILP) for heterogeneous resource allocation; and 3) the Autonomous Era, which leverages AI-driven techniques, including Reinforcement Learning and intelligent scheduling, to enable predictive and shape-adaptive placement strategies. This evolution reflects a fundamental shift from static grid-based management toward elastic, self-optimizing FPGA fabrics. We further examine emerging architectural constraints, including Super Logic Region (SLR) boundaries and hierarchical nested Partial Reconfigurable Regions (PRRs). Beyond this taxonomy, the survey identifies a critical scalability–optimality trade-off, highlighting the need for hybrid frameworks that combine the formal guarantees of optimization-based methods with the real-time adaptability of AI-driven approaches. It further establishes a unifying perspective in which DPR is evolving from a logic-reconfiguration mechanism into a thermal–spatial management paradigm for mitigating heat in high-density 3D-IC systems. Finally, the analysis reveals a significant functional–physical gap in current autonomous design tools, emphasizing the need for context-aware agents capable of jointly reasoning about temporal task dependencies and spatial floorplanning constraints. This review provides a structured roadmap for the development of next-generation intelligent control frameworks for edge and cloud-scale reconfigurable computing systems.**

Keywords*—Field Programmable Gate Arrays (FPGA); Floorplanning, Dynamic Partial Reconfiguration (DPR); bitstream relocation; hardware autonomy; reinforcement learning; heterogeneous computing; 2D shape-adaptive placement

I. Introduction

Field-Programmable Gate Arrays (FPGAs) are versatile, reconfigurable hardware platforms widely used in high-performance computing, embedded systems, and adaptive applications [1], [2], [3]. Unlike dedicated hardware (ASICs), FPGAs can be reprogrammed post-fabrication, enabling rapid prototyping, flexible computing, and efficient resource utilization.

Dynamic Partial Reconfiguration (DPR) enhances FPGA flexibility by permitting selective regions of the fabric to be reconfigured at runtime without halting the static logic [4], [5]. This capability allows adaptive and resource-constrained systems to improve hardware utilization. It allows modules to be dynamically loaded or swapped at runtime. Nonetheless, DPR introduces additional design complexity, requiring careful spatial and temporal management to prevent resource fragmentation and minimize reconfiguration overhead.

Floorplanning and placement are the critical stages in the design flow that dictate the performance and efficiency of DPR-enabled systems. While floorplanning defines the coarse-grained allocation of Static Regions (SRs) and Partially Reconfigurable Regions (PRRs), placement determines the precise coordinates of logic elements to minimize wirelength and timing delays [6], [7]. In modern heterogeneous FPGAs, these tasks are complicated by the non-uniform distribution of CLBs, BRAMs, and DSP blocks, alongside the emerging physical boundaries of Super Logic Regions (SLRs) in 3D-IC architectures.

To address these challenges, configuration and relocation have gained attention, enabling pre-generated partial bitstreams to be applied to multiple compatible regions. Relocation-aware floorplanning and placement strategies are essential to reduce bitstream storage, improve fabric utilization, and enhance system flexibility. However, traditional manual and heuristic-based flows are increasingly inadequate for the "Complexity Wall" of modern high-density devices, driving the need for more autonomous and optimization-driven methodologies.

II. Background

A. Overview of FPGA Architecture

FPGAs are fundamentally composed of an array of configurable logic blocks (CLBs), digital signal processors (DSPs), block RAMs (BRAMs), and programmable interconnects [8]. Unlike application-specific integrated circuits (ASICs), FPGAs can be reprogrammed after manufacturing, making them suitable for rapid prototyping and adaptive computing and hardware process acceleration [2].

Contemporary FPGA architectures are characterized by a heterogeneous architecture that supports specialized resources, which are not limited to digital signal processing slices, high-speed transceivers, and embedded memory blocks, along with additional generalized logic functionality that serves a variety of computational tasks [1].

The non-uniform distribution of specialized resources complicates placement and floorplanning, necessitating sophisticated optimization techniques to optimize the effectiveness of these diverse resources [9].

B. Dynamic Partial Reconfiguration

Runtime Dynamic Partial Reconfiguration (DPR) represents one of the most powerful capabilities of modern FPGAs, enabling hardware modules to be reconfigured without interrupting the operation of the rest of the system [5]. Unlike static reconfiguration, where the entire device must be reprogrammed, DPR allows designers to modify only specific reconfigurable regions (RRs) while maintaining the functionality of the static region. This property makes FPGAs ideal for adaptive and resource-efficient embedded systems, where computational tasks evolve dynamically according to application requirements.

The implementation of DPR requires careful partitioning of the FPGA fabric into static and reconfigurable areas during the design phase [10]. As shown in Fig. 1, each Reconfigurable Partition (RP) hosts one or more Reconfigurable Modules (RMs) that can be swapped in and out during runtime [11]. This modularity improves hardware utilization and system scalability, allowing multiple functions such as signal processing [12], image filtering [13], or cryptographic operations [14] to share the same physical resources.

From a design perspective, DPR introduces new floorplanning and placement challenges. The designer must ensure that reconfigurable regions are physically isolated, their interfaces are aligned and consistent, and communication between static and dynamic regions remains stable during reconfiguration.

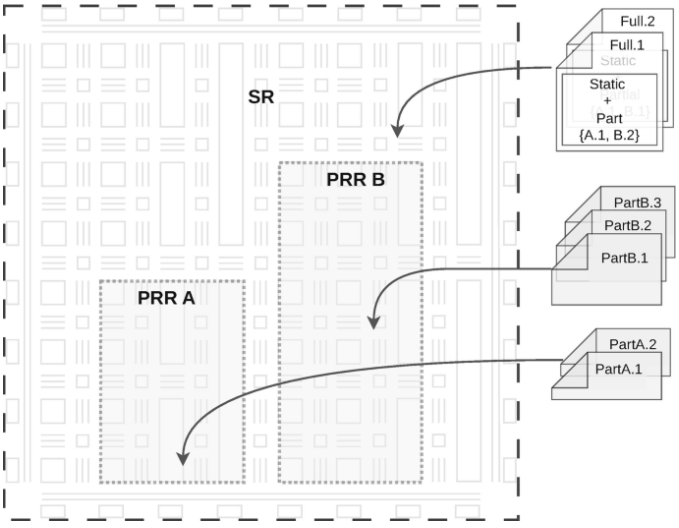

Fig. 1. Dynamic partial reconfiguration.

C. What is Floorplanning?

Floorplanning is a complex stage of the FPGA design flow. It consists of allocating specific physical regions of the FPGA's underlying architecture to each module or component that makes up the whole design [15] [16]. This critical phase is an important intermediate that connects the high-level synthesis stage with the subsequent detailed placement and routing processes.

The efficacy of floorplanning is paramount for realizing several significant design objectives, which include but are not limited to:

- Minimizing routing congestion [17].
- Reducing critical path delay [18].
- Optimizing power consumption [19].
- Support for partial and dynamic reconfiguration [20] [4].

For static floorplanning, the layout is strongly fixed and does not change during compile time, whereas partial reconfiguration [4] technology can facilitate dynamic alteration of requested portions of the FPGA fabric at run-time, therefore necessitating an even more meticulous approach to spatial and temporal planning to ensure optimal performance.

D. What is Placement?

Placement is a crucial stage in the FPGA design flow that follows floorplanning. It consists of assigning exact physical positions to logic elements such as Look-Up Tables (LUTs), flip-flops, Digital Signal Processing (DSP) blocks, and Block RAMs (BRAMs) within the physical regions previously defined during the floorplanning phase. The primary goal of placement is to arrange these components efficiently to minimize interconnect length, reduce routing congestion, and improve overall timing performance [6], [7].

An effective placement directly affects several critical design metrics, including delay, power consumption, and resource utilization. Proper positioning of interdependent components shortens signal paths, thus enhancing operating frequency and reducing dynamic power [21]. In the context of Dynamic Partial Reconfiguration (DPR), placement must additionally preserve region boundaries and ensure consistent communication interfaces between the static and reconfigurable regions of the FPGA [22], [23].

E. Interplay Between Floorplanning and Placement

Although floorplanning and placement are closely related (Fig. 2), they represent distinct stages in the design flow [6] [7] :

- Floorplanning defines the spatial organization of modules on the FPGA. It assigns specific regions where each module can be placed while satisfying design constraints.
- Placement, however, concerns the precise positioning and ordering of logical elements and instances, i.e., Look-Up Tables (LUTs), BRAM, ... into the predefined regions identified during the floorplanning process, thereby optimizing the order in terms of performance and efficiency based on the defined spatial rules.

Also of note is that floorplanning can indeed be considered an essential constraint, or guideline, of placement algorithms

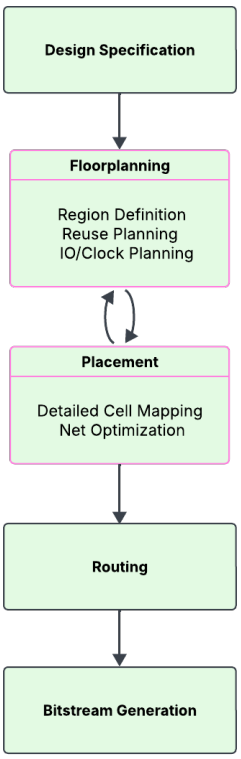

Fig. 2. Design flowchart.

used in the design process, and this first stage can play a major role in the potential impact on the placement algorithms, and ultimately on the achievement of design execution.

F. What is Relocation ?

1) Definition: Relocation is an advanced technique in Dynamic Partial Reconfiguration (DPR) that enables a single partial bitstream corresponding to a reconfigurable module to be loaded into multiple physical locations on an FPGA at runtime. This capability significantly enhances the flexibility and efficiency of reconfigurable systems by decoupling module functionality from fixed placement constraints.

2) Limitation of vendor flows: In conventional vendor-supported design flows, such as those provided by Xilinx, partial bitstreams are inherently location-dependent. Consequently, a distinct partial bitstream must be generated and stored for each potential physical location where a reconfigurable module may be deployed. This requirement introduces a major limitation in dynamically reconfigurable systems, as it results in substantial storage overhead and limits scalability, particularly in applications involving numerous tasks or reconfigurable regions.

To overcome this limitation, Fig. 3 illustrates that relocation relies on generating a single partial bitstream for an initial reference location and dynamically adapting it during system operation to target alternative physical regions on the FPGA. This approach enables the same hardware functionality to be instantiated at different locations without regenerating or storing multiple bitstream versions.

3) Benefits: As a result, relocation provides several key advantages for dynamically reconfigurable FPGA systems. From a memory efficiency perspective, it significantly reduces storage requirements by eliminating redundant location-specific bitstreams. Moreover, it enhances system flexibility by enabling dynamic placement and migration of hardware tasks across multiple Dynamically Partially Reconfigurable Regions (DPRRs). By overcoming inherent limitations of standard design tools, relocation supports more adaptive, scalable, and resource-efficient runtime reconfiguration strategies.

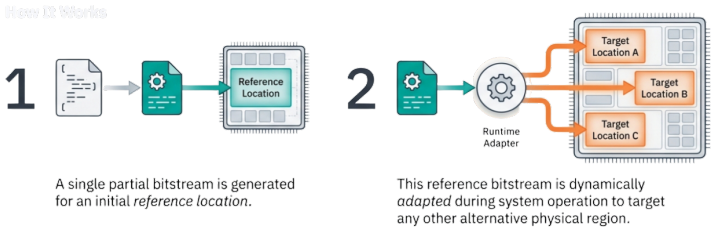

Fig. 3. Relocation technique.

G. Modern Commercial Architectural Constraints: Xilinx UltraScale+ and Intel Agilex

Advanced FPGA architectures targeting 5nm processes and multi-die integration introduce structural constraints that invalidate traditional 2D floorplanning assumptions. Modern devices, such as Xilinx UltraScale+ and Intel Agilex, require architecture-aware approaches, particularly for Dynamic Partial Reconfiguration (DPR).

1) Xilinx UltraScale+ and SLR constraints: Xilinx UltraScale+ devices, including Versal ACAPs, use Stacked Silicon Interconnect (SSI) to partition the fabric into Super Logic Regions (SLRs). Inter-SLR communication is limited by a small number of Super Long Lines (SLLs), leading to non-uniform routing costs. Consequently, PRRs are typically confined within a single SLR to avoid timing degradation, requiring SLR-aware placement strategies.

2) Intel agilex and 3D tile-based architectures: Intel Agilex employs a chiplet-based design using Embedded Multi-die Interconnect Bridge (EMIB) and 3D packaging. Resources such as transceivers and HBM are distributed across separate tiles, increasing heterogeneity and complicating PRR allocation for latency-sensitive applications.

These architectures also introduce thermal challenges due to localized heat generation in 3D stacks. Floorplanning must therefore consider thermal-aware placement and, in some cases, dynamic relocation of modules to mitigate hotspots and avoid performance throttling.

3) Implications for floorplanning: Overall, these constraints highlight the need for architecture-aware floorplanning methods that jointly consider interconnect cost, resource heterogeneity, and thermal behavior under runtime reconfiguration.

H. Floorplanning Metrics

The optimization of floorplanning and placement in Dynamic Partial Reconfiguration (DPR) systems is driven by a

set of quantitative metrics. These metrics aim to maximize spatial and temporal efficiency while ensuring compliance with system-level constraints. These metrics define the objective functions used to evaluate solution quality in reconfigurable FPGA architectures.

1) Timing and performance: Meeting timing constraints across all configurations is a primary objective. Floorplanning and placement decisions directly impact signal delay, critical path lengths, and achievable operating frequency. The goal is to minimize interconnect delay and improve spatial locality among timing-critical modules.

In DPR systems, each configuration must independently satisfy timing constraints, requiring configuration-aware performance evaluation. Therefore, optimization aims to maximize clock frequency while ensuring timing closure across all reconfiguration scenarios.

2) Area and resource utilization: Efficient utilization of FPGA resources is essential to support both static logic and multiple reconfigurable modules. Optimization aims to minimize resource fragmentation and ensure a balanced distribution of heterogeneous resources, including configurable logic blocks (CLBs), digital signal processors (DSPs), and block RAMs (BRAMs).

Proper sizing of reconfigurable partitions reduces unused capacity while preserving flexibility for module allocation. High area efficiency improves scalability and enables the integration of additional functionalities within the same device.

3) Communication and routing cost: Communication efficiency is a key determinant of overall system performance. The optimization process seeks to reduce inter-module communication distance, minimize total wirelength, and alleviate routing congestion.

Placement strategies that consider connectivity graphs and communication intensity improve routability and lead to more predictable delay behavior. Although routing occurs in later design stages, routing-aware floorplanning increases the likelihood of stable and efficient implementations across configurations.

4) Reconfiguration overhead: A key optimization objective in DPR systems is the reduction of reconfiguration overhead. This includes minimizing partial bitstream size, reconfiguration latency, and configuration bandwidth consumption. The geometric characteristics of reconfigurable partitions such as size, shape, and alignment with architectural frames directly affect reconfiguration efficiency.

Optimizing these parameters reduces reconfiguration downtime and improves runtime throughput.

5) Power and energy: Power-aware optimization encompasses both operational energy consumption and reconfiguration-related overhead. Placement decisions that reduce interconnect length and switching activity contribute to lower dynamic power consumption.

Additionally, reducing the size and frequency of reconfiguration operations lowers the energy cost of configuration memory access. Energy-efficient optimization improves system sustainability and thermal behavior.

The floorplanning problem in FPGA systems is inherently NP-hard. As design complexity increases, finding exact solutions becomes computationally infeasible. Consequently, a wide range of heuristic and metaheuristic approaches have been developed to provide near-optimal solutions within acceptable time constraints.

III. Systematic Literature Review Protocol

To ensure the rigor, completeness, and reproducibility of this survey, a systematic literature review (SLR) was conducted following a structured and well-defined protocol. This methodology was designed to identify, filter, and analyze relevant studies on FPGA floorplanning for Dynamic Partial Reconfiguration (DPR) over the past two decades.

A. Search Strategy and Data Sources

The literature search targeted primary studies published between 2006 and 2026 to capture the evolution of FPGA floorplanning methodologies. The following major scientific databases were systematically queried: IEEE Xplore Digital Library, ACM Digital Library, SpringerLink, ScienceDirect (Elsevier) and arXiv (to include recent developments in AI-driven approaches).

Search queries were constructed using Boolean operators to combine keywords related to FPGA architecture, floorplanning, and optimization techniques. The main query used was:

"FPGA" OR "Field-Programmable Gate Array") AND ("Floorplanning" OR "Placement") AND ("Dynamic Partial Reconfiguration" OR "DPR" OR "Bitstream Relocation") AND ("Optimization" OR "Machine Learning" OR "Reinforcement Learning"

B. Inclusion and Exclusion Criteria

To ensure relevance and quality, studies were selected based on clear inclusion and exclusion criteria. Only peer-reviewed papers addressing FPGA floorplanning or placement in dynamic partial reconfiguration (DPR) contexts, and providing experimental evaluation, were included. Works focusing on ASICs, static FPGA designs, or lacking sufficient technical contribution were excluded. The selection process involved removing duplicates, screening titles and abstracts, and performing full-text analysis, resulting in a refined set of studies for detailed review.

C. Data Extraction and Taxonomy Mapping

For each selected study, key information was extracted, including methodology type, optimization objectives, computational complexity, and evaluation metrics. The studies were then categorized according to the proposed three-generation taxonomy: Heuristic, Optimization-based, and Autonomous approaches.

Each method was analyzed using a unified set of performance criteria, including:

- Timing and performance
- Area and resource utilization
- Communication and routing cost

- Reconfiguration overhead
- Power and energy consumption

This structured analysis enabled consistent comparison across methodologies and supported the identification of research trends and open challenges.

IV. Evolution of FPGA Floorplanning Methodologies: A Taxonomy and State-of-the-Art Review

The evolution of floorplanning methodologies for Dynamic Partial Reconfiguration (DPR) reflects the increasing complexity of modern FPGA architectures and the growing demand for runtime adaptability. Over the past two decades, approaches have progressed from manual and heuristic techniques to formal optimization models and, more recently, to AI-driven autonomous systems.

In this work, we propose a structured taxonomy that categorizes these methodologies into three distinct generations based on their level of algorithmic intelligence, hardware awareness, and adaptability. This classification (Table I) provides a unified framework for understanding the progression of the field and identifying emerging research trends.

While early work focused on the physical legality of bitstream alignment (Era 1), middle-period research introduced formal mathematical models to handle heterogeneous resources (Era 2). Currently, the field is transitioning toward autonomous, AI-augmented systems that prioritize predictive management and elastic resource allocation (Era 3).

This taxonomy highlights a clear shift from static, constraint-based design toward dynamic, intelligent, and adaptive floorplanning strategies.

The following subsections describe each generation in detail, highlighting their key methodologies, innovations, and limitations.

A. Era 1: Heuristic and Rule-Based Foundations

This era is primarily characterized by constraint-driven design and limited automation, focusing on physical feasibility rather than optimality.

1) Hierarchical PBlock methodology: Lysaght et al. [22] introduced structured, constraint-driven partitioning using *PlanAhead*. PRRs were created within fixed physical blocks (PBlocks), allowing early estimation of resource usage, timing analysis, and routing isolation. Static regions were implemented first, followed by PRRs containing Reconfigurable Modules (RMs) independently.

2) Automation of resource alignment: OpenPR [24] and GOAHEAD [23] automated AREA GROUP constraints, bus macro placement, and routing alignment. Clock and frame alignment ensured PRR relocatability and predictable timing, simplifying subsequent integration with partial bitstreams.

3) Slot-based and tile abstractions: ReCoBus-Builder [25] introduced fine-grained resource slots enabling modular relocation, while CoPR [26] adopted tile-based abstractions of CLBs, BRAMs, and DSPs to create precise rectangular PRR layouts, facilitating efficient routing and minimal fragmentation.

4) Low-level logic exploration: RapidSmith 2 [27] exposed BEL-level FPGA structures to CAD tools, enabling placement, packing, and routing optimizations while retaining full compatibility with vendor bitstream generation.

This era focused on legal PRR creation, interface consistency, and minimal human intervention, but largely relied on heuristics, fixed templates, and rule-based strategies without formal guarantees on optimality.

This lack of optimality and inability to handle increasing resource heterogeneity necessitated the shift toward the formal mathematical models characterizing Era 2

B. Era 2: Formal Optimization and Analytical Modeling

This era introduces formal optimization techniques, enabling systematic handling of heterogeneous resources and improving solution quality. As FPGA fabrics became heterogeneous, floorplanning evolved toward mathematical modeling, Mixed Integer Linear Programming (MILP), and nonlinear optimization to achieve predictable and high-quality layouts.

1) Nonlinear and integer programming: PRFloor [28] combined heuristic and NLP optimization to reduce inter-module communication cost while respecting heterogeneous resources. DUPRFloor [29] applied MILP formulations for L-shaped PRRs, ensuring no overlaps and optimized interconnect usage. Deak et al. [30] used Columnar Kernel Tessellation and NLIP to align rectangular PRRs to FPGA frames. FLORA [31] treated FPGA resources as weighted grids to minimize wirelength and routing congestion, considering both logic and memory utilization.

2) Model-driven task mapping: Ben Abdelali et al. [32] developed a two-level L1/L2 scheduling framework. L1 analyzed functional dependencies and reconfiguration transitions between tasks, while L2 scheduled bitstream loading and task execution, optimizing runtime overhead and reducing reconfiguration latency.

3) Metaheuristic and joint optimization: Sadeghi et al. [33] and Ding et al. [34] used Genetic Algorithms and Simulated Annealing (Partitioned Sequence Triple, P-ST) to jointly optimize PRR placement, communication, and heterogeneous resource usage, improving layout quality for complex multi-module workloads.

4) High-level synthesis integration: HiPR [35] linked HLS with PR workflows, enabling designers to define partial functions in C/C++ while automatically generating legal PRR placements. HiPlanner produced optimized floorplans in under a second, minimizing wirelength and ensuring PRR alignment with frames.

5) Heterogeneous resource awareness: The PR FP tooll [36] employs a scarcity-prioritized iterative refinement approach using simulated annealing to handle irregular fabric structures, balancing logic, DSP, and memory usage across multiple PRRs.

Era 2 represents the transition from heuristic approaches to formal, resource-aware optimization, providing precise PRR layouts, efficient inter-module communication, and systematic management of heterogeneous FPGA fabrics, forming the foundation for runtime-adaptive reconfiguration.

TABLE I. TAXONOMY OF FPGA FLOORPLANNING METHODOLOGIES ACROSS GENERATIONS (2006–2026)

Generation	Timeline	Core Methodology	Relocation Support	Primary Focus
Era 1	2006–2015	Heuristic / Rule-based	1D Columnar / Manual	Physical Legality
Era 2	2016–2022	Formal Optimization	Block-Level / MILP	Timing & Congestion
Era 3	2022–2026	AI-Augmented / RL	**2D Shape-Adaptive**	**Autonomous Autonomy**

C. Era 3: Autonomous and AI-Augmented Systems

Era 3 marks a shift toward self-optimizing FPGA systems, where AI techniques are used to address the growing complexity of advanced nodes (e.g., 5nm) and heterogeneous 3D-IC architectures. In contrast to earlier static or design-time approaches, this era integrates intelligence across both runtime adaptation and design-time optimization, structured around three complementary pillars.

1) Reinforcement Learning (RL) for runtime adaptation (Online): Reinforcement Learning is increasingly employed for online decision-making in dynamic environments. In this setting, the FPGA fabric is modeled as an environment in which an agent learns optimal placement or reconfiguration policies through interaction. Such approaches are particularly effective for thermal- and power-aware management, enabling real-time relocation of modules based on sensor feedback. For instance, Yeonjin & Kigarura [37] explore RL for autonomous edge intelligence, while Muralidharan [38] integrates embedded RL logic to trigger DPR events without disrupting ongoing static operations.

2) Evolutionary and metaheuristic search for DSE (offline): Evolutionary and metaheuristic methods have matured into powerful tools for autonomous Design Space Exploration (DSE). Building on earlier Genetic Algorithm approaches, these techniques address the NP-hard nature of floorplanning by exploring large solution spaces and converging toward near-optimal layouts[39]. Unlike RL-based methods, they are typically applied offline during compilation to generate optimized, shape-adaptive floorplans for complex and heterogeneous workloads such as CNN pipelines or signal processing chains.

3) Neural networks and generative AI (Hybrid): Recent advances incorporate neural models, including Graph Neural Networks (GNNs) and Large Language Models (LLMs), to further automate and accelerate the design process. GNNs are used for predictive analysis, such as estimating routing congestion or timing violations prior to finalizing a floorplan. In parallel, LLMs enable generative hardware design flows, translating high-level descriptions into HDL code with embedded placement constraints. For example, frameworks like ResBench [40] assess the quality of LLM-generated designs, while Boudjadar et al. [41] leverage AI-driven DSE for dynamic HW/SW partitioning between Processor Systems (PS) and Programmable Logic (PL) based on runtime requirements.

4) Architectural enablers: Hierarchical and nested PRRs: These algorithmic advances are supported by evolving FPGA architectures that enhance reconfiguration flexibility. In particular, hierarchical and nested Partial Reconfigurable Regions (PRRs) [42] replace traditional flat layouts, enabling finer-grained and independent reconfiguration within subregions (see Fig. 4). This structural elasticity reduces bitstream size, improves scalability, and reinforces the overall autonomy of the system.

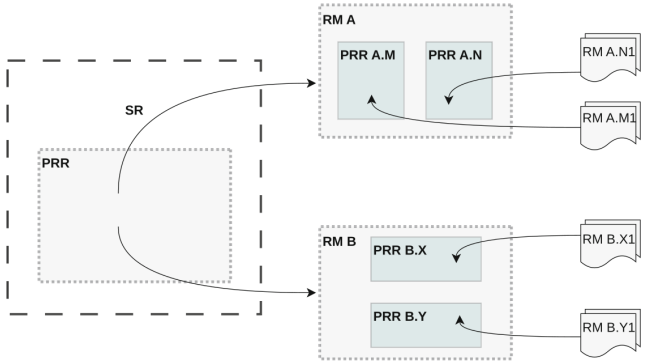

Fig. 4. Hierarchical nested PRR flow exhibiting parent-child reconfiguration layers [42].

The systematic evolution across the three eras is summarized in Table II. A closer examination of the *Major Innovation* and *Primary Metrics* columns highlights a clear progression in the maturity of the field. Era 1 established the practical feasibility of FPGA floorplanning through rule-based and one-dimensional bitstream relocation techniques. Era 2 advanced the state of the art by introducing formal optimization models to address resource heterogeneity and enforce design constraints. Most notably, Era 3 reflects a shift toward spatio-temporal autonomy, where the focus moves from static objectives such as timing closure to dynamic, adaptive metrics driven by runtime considerations, including thermal and power management enabled by AI-based methods.

Overall, the evolution of floorplanning methodologies demonstrates a progressive transition from manual and heuristic approaches to formal optimization and, ultimately, to AI-driven autonomous systems. While each generation addresses specific limitations of its predecessors, emerging challenges such as scalability, heterogeneity, and runtime adaptability continue to drive innovation in this field.

V. CRITICAL ANALYSIS AND RESEARCH GAPS

Despite significant progress across the three generations of FPGA floorplanning methodologies, several fundamental limitations remain unresolved. While heuristic approaches ensure feasibility, optimization-based methods improve solution quality, and AI-driven techniques enhance adaptability, none of these paradigms fully address the combined challenges of scalability, heterogeneity, and runtime dynamism.

This section provides a critical analysis of these limitations and identifies key research gaps that must be addressed to enable next-generation reconfigurable systems.

TABLE II. CHRONOLOGICAL EVOLUTION OF FPGA FLOORPLANNING METHODOLOGIES: FROM HEURISTIC RULES TO AI-AUGMENTED AUTONOMY

Year	Reference	Method / Complexity	Execution Context & Cost	Constraint Guarantees	Major Innovation	Primary Optimization Metrics
ERA 1: HEURISTIC AND RULE-BASED FOUNDATIONS						
2006	Lysaght et al. [22]	Heuristic	High (Offline)	Heuristic constraints	Hierarchical PBlocks (Manual)	Timing Isolation & Resource Est.
2008	ReCoBus-Builder [25]	Heuristic	Low (Offline)	Heuristic constraints	Slot-Based Abstraction 1D	Reconfiguration Overhead
2011	OpenPR [24]	Heuristic	Low (Offline)	Heuristic constraints	Automated AREA GROUP	Timing Closure
2012	GOAHEAD [23]	Heuristic	Low (Offline)	Heuristic constraints	Clock/Frame Alignment 1D	Manual constraint reduction
2015	RapidSmith 2 [27]	Heuristic	Low (Offline)	Heuristic constraints	BEL-level Exploration	Resource Density
ERA 2: FORMAL OPTIMIZATION AND ANALYTICAL MODELING						
2016	PRFloor [28]	NP-hard (NLP)	High (Offline)	Formal guarantees	Hybrid Heuristic/NLP	Communication Cost & Wirelength
2017	Ben Abdelali et al. [32]	Heuristic	Moderate (Offline)	Heuristic constraints	Two-Level L1/L2 Model	Reconfiguration Latency
2019	FLORA [31]	Heuristic	Low (Offline)	No formal guarantees	Weighted Resource Grid	Routing Congestion
2020	DUPRFloor [29]	NP-hard (MILP)	High (Offline)	Formal guarantees	L-shaped PRR Formulation	Overlap Prevention
2022	Ding et al. [34]	NP-hard (SA)	High (Offline)	No formal guarantees	P-ST Joint Optimization	Placement Success Rate
ERA 3: AUTONOMOUS AND AI-AUGMENTED SYSTEMS						
2022	Fahmy et al. [42]	Heuristic	Low (Runtime)	Heuristic constraints	Hierarchical/Nested PRRs	Fine-grained Adaptability
2025	Gu et al. [43]	Heuristic	Low (Runtime)	No formal guarantees	Big.Little Spatio-temporal Slots	Resource Utilization Efficiency
2025	Boudjadar et al. [41]	Heuristic (DSE)	Moderate (Offline)	No formal guarantees	HW/SW Co-Design (CNN)	Throughput & Scaling
2026	Yeonjin & Kigarura [37]	Polynomial	Near Real-time	No formal guarantees	RL-based Thermal Agents	Power & Thermal Management
2026	Muralidharan [38]	Polynomial	Real-time	No formal guarantees	Embedded AI Control Logic	Non-intrusive DPR triggering
2026	Li et al. [44]	Heuristic	Near Real-time	Heuristic constraints	FEditor (2D Shape-Adaptive)	Resource & Shape Flexibility

A. Scalability vs. Optimality Trade-off

A fundamental limitation across existing methodologies is the trade-off between scalability and optimality. Formal optimization techniques, such as MILP and nonlinear programming (Era 2), provide high-quality and constraint-compliant solutions. However, their computational complexity grows exponentially with design size, making them impractical for large-scale FPGA systems.

In contrast, AI-driven approaches (Era 3), particularly reinforcement learning, can explore large design spaces efficiently and produce solutions in near real-time. However, these methods lack guarantees of feasibility and constraint satisfaction, particularly with respect to strict FPGA architectural rules.

This dichotomy highlights the need for hybrid approaches that combine fast exploration capabilities of AI with the rigor of formal verification and constraint enforcement.

B. Fragmentation in Heterogeneous 3D-ICs

The increasing adoption of heterogeneous 2.5D and 3D FPGA architectures introduces new spatial and thermal challenges that are insufficiently addressed in current literature. Most existing approaches assume a 2D fabric and fail to account for Super Logic Region (SLR) boundaries, interposer constraints, and non-uniform communication costs.

Moreover, thermal effects are becoming a critical factor in high-density FPGA systems. Current floorplanning methods largely ignore thermal-aware placement and dynamic heat distribution, which can significantly impact system reliability and performance.

Future research must integrate spatial, thermal, and communication-aware optimization models to address these emerging challenges.

C. Model-Driven Adaptability

While model-driven approaches (Era 2) effectively capture task dependencies and reconfiguration sequences, most AI-driven methods (Era 3) optimize spatial metrics such as area and wirelength in isolation. This results in a disconnect between functional behavior and physical implementation.

In practical systems, reconfigurable modules exhibit temporal dependencies, where certain tasks are frequently co-located or executed sequentially. Ignoring these relationships leads to suboptimal runtime performance and increased reconfiguration overhead.

Future approaches should integrate task-level dependency models into AI-based floorplanning to enable more context-aware and application-driven optimization.

D. Lack of Standardized Benchmarks and Evaluation Frameworks

A major limitation in the field is the absence of standardized benchmarks and evaluation methodologies. Existing works often rely on custom datasets, proprietary designs, or tool-specific configurations, making it difficult to compare approaches objectively.

This lack of reproducibility hinders fair evaluation and slows progress in the field. Future research should focus on developing open benchmarks and unified evaluation metrics to enable consistent comparison across methodologies.

E. Limited Integration with Industrial CAD Flows

Despite significant academic advances, many proposed methodologies are not fully compatible with industrial FPGA design tools such as Vivado or Quartus. This gap limits their practical adoption and real-world impact.

Bridging the gap between research prototypes and industrial toolchains remains a key challenge for the field.

F. Future Research Directions

Based on the identified gaps, several promising research directions emerge:

- Hybrid AI-Optimization Frameworks: Combining reinforcement learning with formal constraint solvers to ensure both scalability and correctness.
- Thermal-Aware and 3D Floorplanning: Incorporating temperature modeling and SLR-aware placement strategies.
- Application-Aware Optimization: Integrating task dependencies and runtime behavior into floorplanning decisions.
- Standardized Benchmarks: Developing open datasets and evaluation frameworks for fair comparison.
- Toolchain Integration: Ensuring compatibility with industrial FPGA design environments.

These directions are expected to drive the next generation of intelligent and autonomous FPGA systems.

In summary, while significant progress has been achieved, FPGA floorplanning for DPR remains an open and evolving research area. Addressing these challenges will require interdisciplinary approaches that combine optimization theory, machine learning, and hardware-aware design methodologies.

VI. Conclusion

This study has presented a structured taxonomy of the evolution of FPGA floorplanning for Dynamic Partial Reconfiguration (DPR), organized into three distinct eras. The analysis highlights a clear progression from constraint-driven heuristic methods (Era 1), to formal optimization models addressing architectural heterogeneity (Era 2), and finally to AI-driven autonomous systems enabling runtime adaptation (Era 3).

Despite these advances, no single approach fully addresses the combined challenges of scalability, heterogeneity, and dynamic runtime behavior. This survey therefore emphasizes the need for more flexible and context-aware floorplanning strategies that bridge the gap between design-time optimization and runtime adaptability.

Beyond this classification, the study identifies three key research directions:

- Scalability–Optimality Trade-off: A fundamental gap exists between the formal rigor of Era 2 approaches and the exploration efficiency of Era 3 methods. Future solutions are expected to adopt hybrid frameworks that combine formal constraint handling with learning-based decision-making.
- Thermal–Spatial Management in 3D Architectures: With the emergence of advanced nodes and multi-die FPGA systems, floorplanning increasingly serves as a mechanism for runtime thermal regulation. This requires tighter integration between placement decisions and thermal-aware reconfiguration strategies.
- Temporal Awareness in Autonomous Systems: Current approaches often decouple spatial optimization from task-level temporal dependencies. Future work should focus on context-aware methods that jointly consider placement decisions and execution ordering constraints.

In conclusion, the future of reconfigurable computing depends on the integration of intelligent decision-making within FPGA design flows. Progress in standardized benchmarks and improved CAD tool interoperability will be essential to enable the next generation of adaptive and autonomous reconfigurable systems.

***Abstract*—Monitoring public perception on social media is increasingly important for detecting reputational risks and communication opportunities in rapidly evolving digital environments. However, operational sentiment monitoring remains challenging due to platform fragmentation, heterogeneous data formats, and the need to generate interpretable reports quickly when specialized analysts are not available. This study presents SentimentPulse, a web-based system for multi-platform sentiment monitoring driven by a user-defined query. The system integrates concurrent data extraction from X, Facebook, LinkedIn, and Instagram with large language model (LLM) based sentiment classification and automated executive storytelling generation. The architecture combines parallel scraping processes for data acquisition with multithreaded LLM inference to improve throughput, while structured persistence enables job tracking and cross-platform analysis. The system operates under practical constraints, including platform-specific access limitations, dynamic content availability, and dependency on external LLM services, which may introduce variability in response times and outputs. The evaluation is conducted under controlled experimental conditions using fixed query limits and asynchronous execution settings, and results should be interpreted within these operational boundaries. Experimental results from two anonymized case studies demonstrate the effectiveness and operational performance of the approach. In the first case study, the system processed 1032 social media interactions and produced a sentiment distribution of 49.0% positive, 36.6% negative, and 14.2% neutral, with a manual validation accuracy of 0.88. In the second case study, the pipeline processed 1121 records, with parallel scraping accounting for the majority of the runtime and LLM inference achieving a throughput of 12.08 items per second. These results show that combining concurrent multi-platform extraction with LLM-based interpretation enables practical and interpretable social listening workflows, while highlighting the importance of considering system-level constraints when deploying such solutions in real-world environments.**

***Keywords*—Sentiment analysis; social media monitoring; large language models; social listening systems; multi-platform analytics**

I. Introduction

Sentiment analysis is a central aspect of opinion mining. It seeks to automatically identify the polarity and subjectivity present in text, with applications in perception monitoring, customer service, market research, and social analysis [1], [2], [3], [4]. In recent years, the availability of user-generated content on social media has made this task a practical tool for understanding collective dynamics in (almost) real-time, driving its adoption in scenarios where rapid response is critical. Classic examples show that aggregated sentiment signals on social platforms can correlate with external phenomena such as financial markets or electoral behavior [5], [6], [7].

However, bringing sentiment analysis into an operational environment presents challenges that cannot be solved with a manual approach or isolated tools. First, data are distributed across multiple platforms, each with different formats, access mechanisms, and interaction dynamics, making it difficult to collect content in a consistent and comparable manner across networks [8], [9]. Second, in corporate communication or marketing contexts, interest is not limited to overall percentages: early detection of reputational risks and shifts in tone is required, especially during sensitive events where conversations can escalate quickly [10], [11]. Consequently, it becomes important not only to classify sentiment but also to explain patterns and differentiate results by platform in order to support concrete decisions. Despite the extensive literature on sentiment classification models, comparatively fewer studies focus on the design and evaluation of complete operational systems that integrate multi-platform data acquisition, scalable processing, and decision-oriented interpretation.

This project proposes a unified web application for multi-platform sentiment monitoring around a user-defined topic. The solution integrates (1) concurrent extraction from X, Facebook, LinkedIn, and Instagram, (2) consolidation of content into a common format, (3) global and per-platform sentiment classification, and (4) automatic generation of narrative summaries that interpret quantitative sentiment indicators to support executive-level decision making. To improve robustness in the face of informal language, regional variation, and changing context, a large-scale language model (LLM) is incorporated to assign sentiment labels and produce short explanations for each text. This is relevant because recent evidence suggests that, although LLMs can be competitive in simple tasks and few-shot scenarios, their performance varies when more complex phenomena or additional structure are required, making prompt design and careful evaluation important [12], [13]. Additionally, recent studies have evaluated conversational models (e.g., ChatGPT) as sentiment classifiers, reporting competitive results in certain settings but also variability depending on the prompt, domain, and task formulation, which motivates validation and stability control practices in real-world deployments [14], [15].

The main contributions of this work are: 1) a concurrent hybrid pipeline that combines multiprocessing for extraction

and multi-threading for LLM inference, 2) a persistence and traceability architecture based on MongoDB that enables status and history tracking by topic, and 3) a web interface that integrates search, visualization, data exploration, and executive narrative within a single workflow.

The remainder of this study is organized as follows: Section II reviews related work; Section III presents the methodology and architecture; Section IV reports performance and quality results; and Section V concludes with recommendations.

II. Related Work

Social media sentiment analysis has evolved from lexicon-based and supervised machine learning methods to deep learning and, more recently, large language model (LLM) based approaches. Nip and Berthelier (2024) [16] summarize this evolution and emphasize that sentiment analysis in social platforms extends beyond polarity detection by incorporating multi-modality, temporal dynamics, interaction structures, network effects, and sentiment propagation. They also outline operational challenges that remain prominent in practice, including high-volume data streams, linguistic heterogeneity, fragmented context, and noisy or automated content. Importantly, they discuss limitations that are particularly relevant when LLMs are used in deployed systems, such as output variability, interpretability constraints, bias due to alignment, and reproducibility concerns.

A substantial line of work focuses on improving sentiment classification quality with neural architectures. Katalinić and Dunđer (2025) [17] study sentiment analysis and anomaly detection in crisis-related tweets using 189,626 English-language messages from the 2023 Turkey–Syria earthquake. Their BERT-based sentiment classifier reports 91% precision, 85% recall, and 88% F1, outperforming a logistic regression baseline (54% F1). For anomaly detection, their autoencoder achieves 89% accuracy and 88% precision, exceeding an isolation forest baseline (69% precision, 64% recall), and ablations indicate that attention yields statistically significant gains ($p = 0.011$). While these results demonstrate strong neural performance for crisis monitoring, the scope is limited to a single platform and does not address multi-platform acquisition or end-to-end operational integration.

Complementing individual studies, Sharma et al. (2025) [18] review 178 papers published between 2014 and 2024 and categorize sentiment tasks into document-level, sentence-level, aspect-based, multi-lingual, multi-modal, and emotion-related settings. Their synthesis reports that transformer-based models, particularly BERT variants, typically reach 88–96% accuracy and often exceed 85% F1 depending on dataset and task difficulty, and they note that LLM-based approaches can surpass 96% accuracy in some domains. Despite these advances, the review highlights persistent challenges, such as sarcasm/irony, domain adaptation, multilingual variation, dataset bias, computational cost, and limited transparency, and observes that fewer works study system-level concerns such as real-time pipelines and deployment constraints.

In addition to model-centric approaches, recent work has explored the use of web-based systems for sentiment analysis in social media environments. Parra-Zambrano and León-Paredes (2024) [14] present a system that integrates natural language processing techniques and large language models, including ChatGPT, to analyse public opinion on political figures in Ecuador. Their approach achieves accuracy levels of up to 95% in classifying sentiments into positive, neutral, and negative categories, demonstrating the effectiveness of combining NLP pipelines with LLM-based components in real-world social media scenarios. These results highlight the potential of hybrid architectures that incorporate LLMs within broader analytical pipelines, while also emphasizing the importance of system-level design for handling heterogeneous and large-scale social media data.

Stability and reproducibility are increasingly recognized as deployment-critical properties. Ouyang et al. (2024) [15] analyze ChatGPT-based sentiment analysis through an AI quality management lens, distinguishing operational uncertainty from model robustness. Using three-way sentiment labels on 983 Amazon review samples and 1101 SST samples, they show that timing and model-version changes can lead to different confusion matrices on the same test set across API releases (e.g., 2023-06, 2023-12, 2024-01), complicating reproducibility. They also evaluate adversarial perturbations (typo, synonym, homoglyph, homophone) with accuracy and attack success rate (ASR), reporting that synonym substitution is the strongest perturbation and that shorter texts tend to be more vulnerable than longer reviews. These results motivate stability-aware practices such as prompt standardization, version tracking, and continuous monitoring in LLM-based pipelines.

Overall, prior work either (1) surveys the methodological landscape and challenges [16], [18], (2) improves model-level performance primarily within a single platform or benchmark setting [17], or (3) evaluates LLMs as sentiment analysers with an emphasis on prompting, robustness, and stability [14], [15]. In contrast, our work focuses on an end-to-end, deployable social listening system that integrates concurrent multi-platform acquisition (X, Facebook, LinkedIn, and Instagram), LLM-based sentiment labelling with per-item explanations, persistence for traceability (corpus, job status, and aggregated analytics), and an executive-oriented storytelling layer for cross-platform interpretation. This system-level contribution targets operational constraints—throughput, observability, and comparability across networks—that are only partially addressed in model-centric studies.

III. Methodology

This section describes the implementation of SentimentPulse at a system level to support understanding and reproducibility. The architecture is presented through its layered design, the processing pipeline, the concurrency strategy, and the REST workflow that allows the frontend to trigger jobs, monitor progress, and retrieve results.

A. Layered System Design

SentimentPulse is organized as a layered architecture connected through a REST API. Fig. 1 summarizes the main components and their interactions, including the API endpoints, background execution model, parallel data extraction

modules, large language model interpretation, natural language processing and analysis, and the database persistence layer.

At the presentation layer, a Vue 3 single-page application provides four main views: search, progress tracking, dashboard visualization, and data exploration. Through these interfaces, users can initiate sentiment analysis jobs for a given topic and consume JSON responses generated by the backend to render metrics, charts, and narrative summaries of the results.

The application logic is exposed through a FastAPI backend that implements the REST interface and manages asynchronous execution of the analysis pipeline. Jobs are executed using background tasks, allowing the system to process long-running operations without blocking the API. During execution, job progress and status information are stored in the persistence layer, enabling polling-based monitoring and improving system observability. Table I summarizes the REST endpoints used in the system workflow.

TABLE I. REST ENDPOINTS USED BY SENTIMENTPULSE

Endpoint	Method	Purpose
`/scrape`	POST	Start a job in background execution
`/status/topic`	GET	Retrieve per-platform progress and phase status
`/results/topic`	GET	Retrieve aggregated outputs and storytelling
`/history`	GET	Retrieve previous runs from stored analyses
`/cancel`	POST	Mark a job as cancelled in the database
`/history/topic`	DELETE	Delete analysis and associated posts for a topic

At the orchestration level, the central function `run_pipeline` coordinates the complete workflow of the system. This component manages the transition between processing phases, aggregates outputs obtained from different social media platforms, and transforms them into a unified tabular schema that allows consistent downstream analysis.

The data extraction stage collects posts and comments related to a user-defined topic. To achieve this, the system launches one Playwright-based scraper per social media platform. Each scraper operates with persistent sessions and collects relevant textual content while preserving metadata needed for subsequent analysis.

Once the textual data has been collected, the interpretation stage applies a large language model to each text unit. The model produces both a sentiment label and a short explanation, which improves interpretability and allows the system to provide traceable reasoning for each classification.

Following interpretation, the NLP and analysis stage processes the labeled texts using a traditional natural language processing pipeline. This stage extracts salient terms and generates aggregated indicators, including global sentiment metrics and platform-specific distributions. These results are then used to produce narrative summaries that facilitate high-level interpretation of the analysis outcomes.

Finally, all intermediate and final outputs are stored in MongoDB. The database maintains the structured corpus, job status information, execution times, and aggregated analytical results. This persistence layer enables efficient retrieval of past analyses and supports the reproducibility and traceability of the sentiment monitoring process.

It is important to note that the proposed system should be interpreted as a research-oriented prototype designed to evaluate system-level integration strategies rather than a fully optimized production platform. While it supports real-world data acquisition and analysis workflows, aspects such as large-scale deployment and long-term operational robustness are beyond the scope of the current implementation.

B. Pipeline Phases

The processing pipeline is executed in sequential phases in order to separate extraction, interpretation, and aggregation tasks. These phases are reflected in job status updates to support real-time monitoring of the system. The execution state is tracked in MongoDB through the `job_status` collection, which stores per-platform progress information such as *current*, *total*, and *status*. In addition, the progress of the LLM interpretation stage is tracked through the field `llm_status`.

The first phase corresponds to the extraction stage. The orchestrator launches a multiprocessing pool with one process per platform, where each process runs a Playwright scraper. These scrapers collect posts and comments related to the target topic and return normalized records containing the platform identifier, the post content, and the associated comment content.

Once the content from all platforms has been collected, the pipeline enters the interpretation and sentiment labelling phase. After consolidation into a DataFrame, the system performs concurrent API calls to the large language model using a thread pool in order to maximize throughput during the I/O-bound inference process. Each record is processed by the model and mapped to a fixed set of sentiment labels: *Positive*, *Neutral*, or *Negative*. The model also generates a short natural-language justification, which is stored in the field `explanation_llm`. Outputs that do not conform to the expected format or fail during processing are mapped to the label *Error*.

For each record, the LLM receives an instruction to assign a discrete polarity label and generate a short justification grounded only in the textual evidence present in the message. The explanation, therefore, reflects linguistic signals such as supportive language, expressions of gratitude, celebration, criticism, insults, frustration, or neutral informational tone, while avoiding assumptions beyond the text itself. In practice, the model assigns the label *Positive* when the message conveys approval, encouragement, pride, or favorable outcomes; *Negative* when it expresses disapproval, anger, accusations, mockery, or hostile language; and *Neutral* when the content is primarily descriptive, interrogative, informational, or lacks clear affective cues. These explanations are later aggregated during the storytelling stage to summarize dominant patterns and cross-platform differences.

After sentiment interpretation, the pipeline proceeds to the classic NLP and term extraction phase. During this stage, the system applies text cleaning and tokenization and computes salient terms using frequency-based signals. These terms support quick corpus inspection and reporting and are exported together with the sentiment outputs in the required CSV structure.

The following phase corresponds to aggregation and storytelling. In this stage, the system computes global and per-

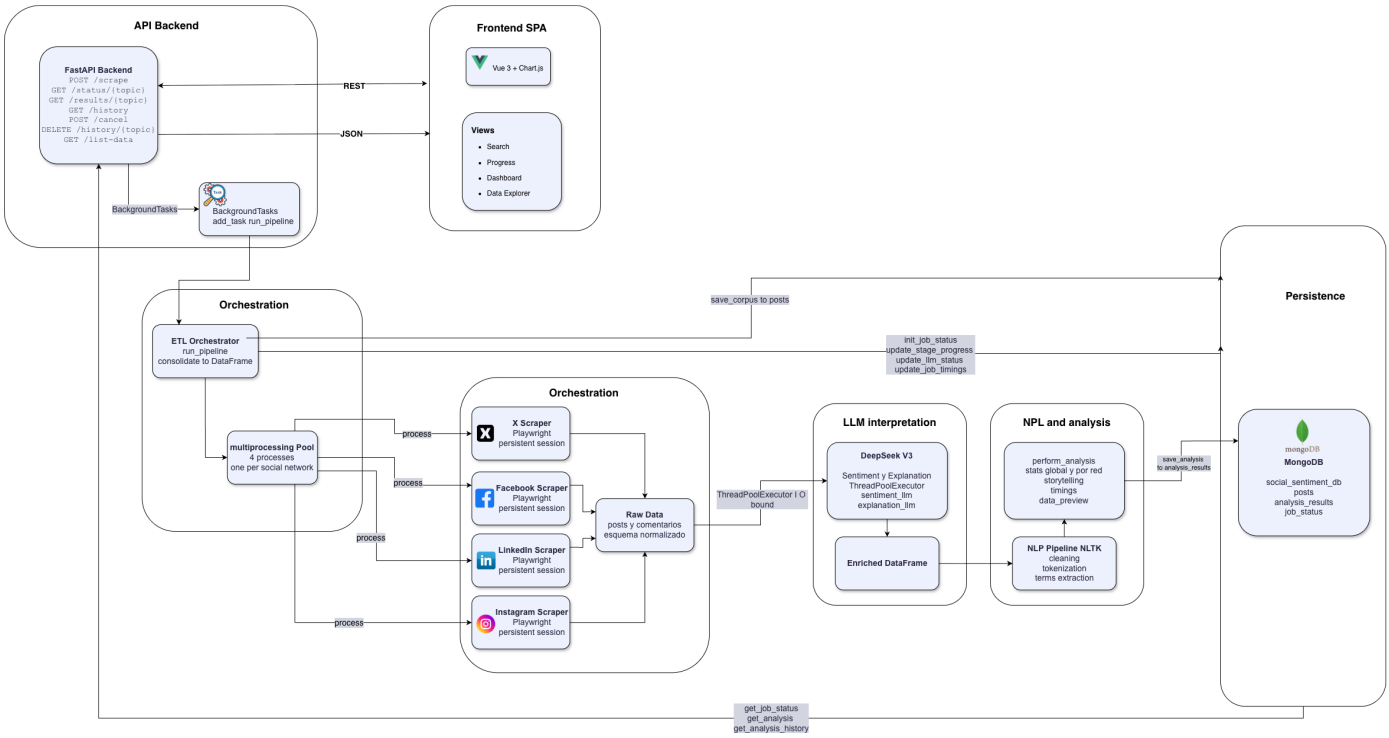

Fig. 1. Layered architecture of SentimentPulse with REST workflow, background execution, parallel scraping, LLM interpretation, NLP and analysis, and database persistence.

platform sentiment counts and percentages, selects representative examples from the dataset, and generates a narrative report intended for executive interpretation. This storytelling component summarizes dominant sentiment patterns and highlights differences across social networks.

Finally, the persistence and export phase stores the results of the analysis. The collected corpus is stored in the `posts` collection, job tracking information is updated in `job_status`, and aggregated outputs are stored in `analysis_results`. Additionally, the system exports a CSV deliverable with the required columns: *Platform*, *Post*, *Comment*, *Sentiment*, *Explication*, and *Terms*.

To mitigate the inherent variability of LLM outputs, the system incorporates several design decisions at the interpretation stage. First, model responses are constrained to a fixed label set (*Positive*, *Neutral*, *Negative*) through prompt standardization and post-processing validation. Second, non-conforming or ambiguous outputs are explicitly mapped to an *Error* category to prevent uncontrolled propagation of inconsistent predictions. Third, the system records the status of the LLM inference phase (`llm_status`) to enable traceability and monitoring of potential inconsistencies during execution.

These mechanisms allow the pipeline to maintain consistent downstream processing despite variability in LLM responses, supporting more stable and auditable sentiment analysis results.

C. Concurrency Strategy and Operational Considerations

The pipeline combines different concurrency mechanisms depending on the characteristics of each stage. This hybrid strategy improves overall system throughput while maintaining isolation between platform-specific operations.

During the extraction phase, scraping tasks are executed using multiprocessing. A separate process is created for each platform worker, allowing the scrapers to run independently and preventing failures or delays in one platform from affecting the others. This approach also improves end-to-end latency because multiple platforms can be processed simultaneously.

In contrast, the interpretation phase relies on concurrent LLM inference implemented with a thread pool. Since the interaction with the language model involves network-bound API calls, a multithreading approach increases throughput by allowing multiple requests to be issued while waiting for responses. This design maximizes resource utilization during the I/O-bound inference stage.

From an operational perspective, social media platforms often rely on dynamic content rendering mechanisms such as infinite scrolling, asynchronous loading, and frequent user interface changes. To maintain robustness under these conditions, the scrapers incorporate controlled scrolling strategies, retry mechanisms, and persistent sessions. Failures or interruptions during extraction are tracked through explicit status fields stored in the system database, allowing post hoc auditing and inspection of scraping runs. Finally, from a data protection perspective, the system is designed to process only publicly available textual content from social media posts and comments. No personally identifiable information (PII) is intentionally extracted, stored, or analyzed by the pipeline. The collected data are limited to the textual content required for sentiment analysis and associated platform metadata necessary for processing.

D. Scalability Considerations

The scalability of the proposed system is primarily determined by the concurrency model adopted for data extraction and LLM-based inference. Scraping tasks are parallelized using multiprocessing, with one independent process per social media platform. As a result, the system scales linearly with the number of platforms, provided that sufficient computational resources (CPU cores and memory) are available.

However, scalability is constrained by several factors. First, the scraping stage is dependent on dynamic web content and platform-specific access mechanisms, which introduce variability in response times and limit the degree of parallelism that can be effectively achieved. Second, LLM-based sentiment classification relies on external API calls, making throughput sensitive to network latency and service rate limits. Third, the overall system performance is bounded by the slowest stage in the pipeline, which in practice corresponds to the data extraction phase.

Empirical results presented in Section IV confirm that scraping constitutes the primary bottleneck, accounting for the majority of the total execution time. These observations indicate that, while the system benefits from concurrent execution, its scalability is inherently constrained by external dependencies and I/O-bound operations rather than computational limitations alone.

E. Algorithmic Summary

Algorithm 1 describes the end-to-end workflow executed after the user submits a topic. The input is a user-defined `topic` and a per-platform `limit`. The pipeline outputs (1) a structured corpus stored in MongoDB (`posts`), (2) an aggregated analysis document with metrics and storytelling (`analysis_results`), and (3) a CSV export with the required columns for the deliverable.

Step 2 to Step 4 perform parallel data acquisition across platforms and consolidate the collected posts and comments into a unified schema. Step 5 to Step 6 execute concurrent LLM inference to assign sentiment labels and explanations. Step 7 to Step 8 extract salient terms and compute global and per-platform statistics, which are then used to generate executive storytelling. Finally, the pipeline persists the corpus and analytics to MongoDB and exports the CSV deliverable.

Algorithm 1 SentimentPulse Multi Platform Sentiment Analysis Pipeline

```
procedure SentimentPulsePipeline(topic, limit)
    init_job_status(topic)
    Phase 1: Parallel scraping
    records ← ∅
    for all platform ∈ {X, Facebook, LinkedIn, Instagram} do in parallel
        platformRecords ← scrape_platform(topic, limit)
        records ← records ∪ platformRecords
    end for
    update_llm_status(topic, running)
    Phase 2: LLM interpretation and sentiment labelling
    results ← ∅
    for all record ∈ records do using thread pool
        label, explanation ← llm_classify(record.text)
        results ← results ∪ (record, label, explanation)
    end for
    update_llm_status(topic, completed)
    Phase 3: NLP term extraction
    terms ← extract_salient_terms(results)
    Phase 4: Aggregation and storytelling
    metrics ← compute_sentiment_metrics(results)
    storytelling ← generate_executive_storytelling(metrics, results)
    Phase 5: Persistence and export
    save_corpus(topic, results)
    save_analysis(topic, metrics, storytelling)
    export_csv(topic, results, terms)
end procedure
```

IV. Results

A. Experimental Setup

The experimental evaluation is based on two anonymized execution runs generated by the SentimentPulse system. The resulting data are stored in CSV files that capture both the sentiment-labeled corpus and the execution-time measurements produced during the analysis pipeline. Specifically, the evaluation considers (1) a sentiment-labeled dataset corresponding to *Case Study A*, and (2) an execution-time log corresponding to *Case Study B*.

Case Study A corresponds to a high-visibility sports topic involving a male professional football player associated with the Ecuadorian national team. Such topics typically generate emotionally charged reactions across social media platforms, including expressions of support, celebration, criticism, and rivalry among users.

Case Study B corresponds to a high-salience political topic involving a prominent political figure in the United States. Political discussions of this type frequently produce polarized discourse and rapid shifts in tone across different platforms.

To comply with ethical and confidentiality considerations, all datasets were anonymised before analysis. Consequently, specific person names, entities, or identifying topic strings are not disclosed in this manuscript.

The collected social media content may include multiple languages as well as informal code-switching. The LLM processes the raw text without language filtering and normalizes all outputs into a fixed sentiment label set consisting of *Positive*, *Neutral*, and *Negative*. Any responses that do not conform to the expected format are mapped to the label *Error*.

B. Case Study A: Dataset Statistics and Sentiment Distribution

Table II summarizes the dataset collected for *Case Study A*. In total, 1,032 records (comments/interactions) were processed across four social media platforms—X, Facebook, LinkedIn, and Instagram—corresponding to 107 unique posts. The largest share of records originated from X (433) and Instagram (321), followed by Facebook (244) and LinkedIn (35). One record contained missing platform metadata and is reported as *Unknown* for completeness.

TABLE II. DATASET SIZE BY PLATFORM FOR *CASE STUDY A*

Platform	Records	Unique posts
X	433	49
Instagram	321	32
Facebook	244	10
LinkedIn	35	15
Unknown	1	1
Total	1032	107

The overall sentiment distribution is reported in Table III. Positive sentiment represents the largest share of the dataset (49.0%), followed by negative sentiment (36.6%) and neutral sentiment (14.2%). A single instance (0.1%) was labelled as *Error*, indicating an unclassified output. Such cases may occur due to transient failures or unexpected responses during automated processing, but their negligible frequency suggests that the pipeline maintained stable inference behaviour.

TABLE III. OVERALL SENTIMENT DISTRIBUTION FOR *CASE STUDY A*

Sentiment	Count	Percentage
Positive	506	49.0%
Negative	378	36.6%
Neutral	147	14.2%
Error	1	0.1%
Total	1032	100%

Table IV provides a platform-level breakdown of sentiment labels. The distribution reveals clear cross-platform differences. X concentrates the largest share of negative reactions (221 instances), reflecting the platform's tendency to host more confrontational or critical discourse in this topic. In contrast, Instagram exhibits a predominantly positive distribution (197 positive versus 89 negative), which is consistent with the more supportive or celebratory tone often observed in visual-centric social media interactions. Facebook presents a more balanced distribution, while LinkedIn contains a relatively small number of records, mostly positive or neutral.

TABLE IV. SENTIMENT BY PLATFORM FOR *CASE STUDY A*

Platform	Positive	Neutral	Negative	Error
X	148	61	221	1
Instagram	197	35	89	0
Facebook	132	44	68	0
LinkedIn	28	7	0	0
Unknown	1	0	0	0

Beyond the numerical distribution, the explanations generated by the LLM provide insight into the linguistic drivers behind the assigned polarity labels. Positive classifications were typically justified by supportive or celebratory expressions such as praise, encouragement, or gratitude. Negative classifications frequently corresponded to critical or hostile language, including insults, accusations, or expressions of frustration. Neutral classifications were generally associated with informational statements, factual descriptions, or questions where explicit affective cues were absent.

These qualitative explanations complement the quantitative analysis by clarifying *why* certain platforms concentrate higher levels of negativity or positivity. In particular, they show that the model's decisions are grounded in explicit textual cues rather than opaque or arbitrary outputs, supporting the interpretability of the system's sentiment classification process.

C. Case Study B: Runtime and Performance

Runtime performance was evaluated using the execution logs generated for *Case Study B* (timestamp: 2026-02-05 23:32:21, limit: 10 posts per platform). In this run, the system processed a total of 1121 records (comments/interactions) collected across the monitored platforms.

Table V summarizes the stage-level execution times recorded in the CSV log. The parallel scraping stage required 678.33 s, while the LLM-based sentiment classification stage required 92.77 s. Considering both stages together, the measured processing time for data acquisition and inference was 771.10 s.

TABLE V. PIPELINE PERFORMANCE FOR *CASE STUDY B* (LIMIT: 10 POSTS PER PLATFORM).

Stage	Time (s)	Proportion
Parallel scraping (4 processes)	678.33	88.0%
LLM classification (ThreadPool)	92.77	12.0%
Measured total (Scraping + LLM)	771.10	100%

Based on these measurements, the LLM inference stage achieved an approximate throughput of 12.08 processed items per second (1121 records divided by 92.77 seconds). The results indicate that the dominant contribution to overall runtime originates from the scraping stage, which represents approximately 88.0% of the measured execution time. In contrast, the LLM inference stage accounts for 12.0% of the total runtime.

This distribution reflects the operational characteristics of social media data acquisition, where dynamic web interfaces, pagination, and interaction-driven loading introduce higher latency compared to API-based model inference. Nevertheless, the concurrent execution strategy—multiprocessing for scraping and multi-threading for LLM inference—allows the system to process more than one thousand social interactions within approximately thirteen minutes in this configuration.

Although the reported execution times correspond to a single experimental run, variability in system performance is expected due to factors such as network latency, platform response times, and external API dependencies. In particular, the scraping stage is subject to dynamic content loading and platform-specific constraints, which may introduce fluctuations in execution time across runs.

D. Storytelling Outputs by Case Study

In addition to quantitative metrics, SentimentPulse generates an executive-oriented *storytelling* report for each run. This report aggregates platform-level sentiment distributions and uses the per-item `explanation_llm` field to interpret *why* polarity patterns emerge. The goal is to transform raw sentiment counts into an interpretable narrative that highlights dominant themes and cross-platform contrasts.

a) Case Study A (sports topic): For *Case Study A*, the storytelling report describes the conversation as predominantly positive, consistent with the distribution presented in Section IV-B. Supportive and celebratory messages constitute the main drivers of positive sentiment, whereas negative sentiment is largely associated with criticism and expressions of frustration. The narrative also emphasizes that polarity in this domain is frequently conveyed through short, emotionally charged statements. Differences across platforms are visible in the tone of engagement: some networks concentrate stronger criticism, while others amplify supportive reactions. These observations are grounded in the LLM explanations, which typically reference praise, encouragement, or gratitude for positive labels and derogatory or accusatory language for negative labels.

b) Case Study B (political topic): For *Case Study B*, the storytelling report characterizes the discussion as highly polarized, with frequent alternation between supportive and hostile language. Compared with the sports topic, the discourse exhibits stronger evaluative framing, including allegations, confrontational phrasing, and explicit ideological positioning. Platform-level patterns are also more pronounced in this case, with certain networks displaying more adversarial exchanges while others contain comparatively neutral or informational contributions. The LLM-generated explanations support these observations by identifying cues such as mockery, accusations, or hostile framing for negative sentiment, and endorsement or approval for positive sentiment.

Overall, the storytelling layer complements the quantitative analysis by linking aggregate sentiment proportions to recurring linguistic cues extracted from the `explanation_llm` field. This additional interpretive layer facilitates faster understanding of the results and provides an auditable explanation of cross-platform sentiment dynamics.

E. Human Validation of Sentiment Classification

To obtain a more reliable estimate of sentiment classification quality, a manual validation was conducted on a random sample of 100 comments drawn from the processed dataset. Each comment was independently labelled by a human evaluator using the same sentiment categories employed by the system (*Positive*, *Neutral*, *Negative*). The predicted labels produced by the LLM were then compared against the human annotations.

The model matched the human label in 88% of the evaluated cases (Accuracy = 0.88), indicating a strong level of agreement under the sampled conditions. Table VI reports per-class precision, recall, and F1-score values. The evaluated sample contains instances from all three sentiment classes, allowing for a more comprehensive assessment of model performance across categories.

The confusion matrix in Table VII shows that most disagreements correspond to polarity shifts between *Positive* and *Negative*, which is consistent with known challenges in sentiment analysis when dealing with ambiguous or mixed expressions. A smaller number of errors involve confusion between *Neutral* and the other classes, suggesting that borderline cases with weak affective signals remain difficult to classify consistently.

TABLE VI. MANUAL VALIDATION METRICS (SAMPLE: 100 COMMENTS)

Class	Precision	Recall	F1-score	Support
Positive	0.97	0.92	0.94	36
Negative	0.79	0.87	0.83	30
Neutral	0.88	0.85	0.87	34
Macro avg	0.88	0.88	0.88	100
Weighted avg	0.88	0.88	0.88	100

TABLE VII. CONFUSION MATRIX (GROUND TRUTH VS. PREDICTED) FOR MANUAL VALIDATION (N=100).

	Predicted (LLM)		
Ground truth (human)	Negative	Neutral	Positive
Negative	26	3	1
Neutral	5	29	0
Positive	2	1	33

Beyond the quantitative agreement, the presence of the `explanation_llm` field enables post-hoc inspection of mismatches. When the predicted label differs from the human label, the associated justification can be examined to determine whether the discrepancy arises from linguistic ambiguity (e.g., sarcasm, mixed sentiment, or implicit tone) or from model misinterpretation. This capability enhances interpretability and provides a practical mechanism for refining prompt design and evaluation strategies.

It is important to note that this validation is based on a single annotated sample and one human evaluator. Therefore, the reported metrics should be interpreted as an indicative assessment of model behaviour rather than a definitive generalization of performance across all possible inputs. Expanding the evaluation to larger and multi-annotator datasets constitutes an important direction for future work.

F. Baseline Comparison

To contextualize the performance of the proposed approach, we consider commonly used sentiment analysis baselines such as VADER and TextBlob, which are widely adopted in social media analysis tasks.

These methods have been widely used in sentiment analysis tasks and have shown competitive performance in detecting explicit sentiment polarity, particularly in short and informal texts [19], [20]. However, prior studies have reported limitations when handling contextual nuances, implicit tone, sarcasm, and mixed sentiment expressions, which are common in social media data [21], [22].

In contrast, the LLM-based approach used in SentimentPulse is designed to capture richer contextual information and provide explanatory outputs, which can improve interpretability and robustness in complex linguistic scenarios. While a direct experimental comparison is left for future work, the results obtained in the manual validation suggest that the proposed approach achieves a high level of agreement with human annotations.

V. CONCLUSION

This work presented SentimentPulse, a unified web application that integrates concurrent multi-platform data extrac-

tion, LLM-based sentiment classification with per-item explanations, and executive-oriented storytelling for operational social listening. The proposed architecture combines parallel scraping, concurrent LLM inference, and structured persistence to support end-to-end analysis of social media conversations across multiple platforms within a single workflow.

Across the reported anonymized case studies, the results show that the system can process large volumes of social media interactions while producing interpretable outputs suitable for cross-platform comparison. In the sports-related topic analyzed in Case Study A, the pipeline processed over one thousand comments across four platforms and revealed a predominantly positive conversation, with substantial variations in sentiment distribution between networks. These differences highlight the importance of analyzing sentiment both globally and at the platform level. The inclusion of the `explanation_llm` field further improves auditability by enabling sentiment labels to be inspected together with short text-grounded justifications.

The runtime analysis in Case Study B shows that the end-to-end pipeline can process more than one thousand interactions in approximately thirteen minutes under the evaluated configuration. The measurements indicate that data extraction remains the dominant cost in the pipeline, accounting for the majority of the execution time, whereas LLM-based inference represents a smaller share of the runtime. A small-scale manual validation achieved an accuracy of 0.85, with strong F1-scores for positive and negative classes, suggesting that the model can reliably detect polarity when sentiment cues are explicit.

Despite these results, several limitations remain. Scraping reliability depends on platform interface changes and access constraints, which may affect both the completeness and latency of data acquisition. Additionally, LLM outputs may vary with prompt formulation and domain shifts, making continuous monitoring and evaluation necessary for operational deployments.

Beyond these limitations, this work highlights the importance of system-level integration in modern sentiment analysis applications. While recent advances in LLMs have significantly improved classification capabilities, their effective use in real-world scenarios depends on how they are embedded within scalable, observable, and interpretable pipelines. In this context, SentimentPulse demonstrates that combining concurrent data acquisition, structured processing, and LLM-based interpretation can support practical social listening tasks under realistic constraints.

Future work should focus on improving extraction efficiency through techniques such as incremental collection and caching, as well as expanding the human validation protocol with larger and more balanced samples to obtain more stable performance estimates across all sentiment classes. These improvements would further strengthen the robustness and scalability of the proposed system for real-world social listening scenarios.

Improving Performance and Accuracy in Decision Trees: A Literature Survey on Impurity Functions

Abed Alsulami, Prof. Reda Khalifa, Dr. Wajdi Alghamdi
Information Technology Department, King Abdulaziz University, Jeddah, Saudi Arabia

***Abstract*—Decision tree algorithms have remained some of the most popular tools for supervised learning tasks. This has been because of their comprehensibility, malleability, and robustness to accommodate varying types of data. Nevertheless, their accuracy and performance are dependent on the use of impurity measures to guide the process of tree splits. The standard impurity measures, such as the Gini impurity, Entropy, and Classification Error, tend to face problems as the complexity, imbalance, and noise levels are raised. This often gives rise to overfitting. An examination of the disadvantages and present research efforts on impurity-based optimization of decision trees, as well as the study of new paradigms such as the use of Rényi Entropy, the utilization of the Tsallis Entropy, combinations of impurity functions, complexity-aware tree splits, and tailored impurity function augmentation, makes it clear that there are efforts underway to improve the accuracy, robustness, and comprehensibility, as well as the processing complexity, for the tasks of decision tree algorithms.**

***Keywords*—Decision trees; impurity functions; split criteria; decision tree optimization; literature review**

I. Introduction

Decision trees remain widely used in machine learning and data mining because they are interpretable, flexible, and effective for classification and prediction tasks [1][2][3]. Their practical value is especially evident in applications where transparent decision rules are needed to explain model behavior and support human decision-making.

However, the performance of a decision tree depends strongly on the impurity measure used to select splits [2][3]. When impurity is estimated poorly, the resulting tree may overfit the training data, become unnecessarily deep, and generalize poorly to unseen samples [4]. These limitations are more pronounced in complex, noisy, or high-dimensional datasets, where conventional split criteria may not capture the structure of the data effectively.

Decision trees, despite their seemingly simple model, possess the potential for representing and exploring the intricate interdependencies. In addition, decision trees constitute an understandable and easily comprehensible model, making them applicable for exploratory and descriptive data analysis [5]. Nevertheless, if the tree-growing algorithm ineffectively calculates the impurity of the nodes, it would most possibly lead to biased decision tree analysis. The effectiveness of tree growing as an algorithmic process would, therefore, depend on the choice of the impurity measure of the nodes that splits the potential splits. The values of the selected variables influence the point of splits and the corresponding split rule. Since the split rule becomes understandable, the decision tree provides an easily comprehensible representation of the data concerning the classes and the selected covariates. The model would express a tree structure, and the process of interpreting the tree would involve the nodes, branches, and terminal nodes of the tree [6].

II. Background and Significance

In the vast arena of data mining, decision tree algorithms are considered one of the basic tools, much admired for their high degree of interpretability and manipulability. Several decision tree algorithms have come into existence over the years, each having their respective algorithms belonging to CART, ID3, C4.5, CHAID, and then the Random Forest algorithm proposed by Breiman. This wide range of algorithms available, though, becomes one of the most significant challenges, as there always exists the challenge of choosing the best tree algorithm for optimal performance.

It needs to be accepted that the decision tree algorithms, especially for continuous variables, always face the potential challenge of an infinite number of splits and always tend to preserve the distribution of class probabilities, which often leads to the model overfitting. Moreover, the greediness factor always poses a significant challenge, as the basic motive for making the decisions always becomes the search for the highest degree of purity as the basic splitting criterion. These factors, specifically the challenges faced by the decision tree algorithms, like the potential challenge of an infinite number of splits and greediness, are already known and addressed by tree pruning and the addition of the factor of randomness during the development stage [7][8].

III. Research Motivation and Objectives

Even to date, the decision tree remains a basic classification technique in machine learning. Despite the many benefits of the existing classification algorithms based on the decision tree approach, ID3, C4.5, and CART classification algorithms have some limitations in predictive accuracy when applied to imbalanced, noisy, or high-dimensional datasets. One of the main demerits of the classification algorithms discussed above can be attributed to the need to rely on a fixed set of impurity criteria. These include Shannon entropy and the Gini index.

Current research developments in the context of impurity function design techniques—such as the application of general concepts of entropy, Rényi entropy, and the Tsallis entropy approach applied to RS-entropy—have shown promising results. There also exists a great scope of empirical research in the context of the application of improvements in the impurity function. At the same time, there also exists a research gap in terms of the complex relationships of impurity in trees. This

research aims to improve the accuracy of the decision tree classification technique and prevent overfitting by designing new impurity measures. These research objectives are:

- To investigate the inadequacy of the classic measures of impurities (e.g., Gini index, Shannon entropy) in the context of decision trees for different datasets.
- To develop new impurity criteria involving general measures of entropy and the consideration of parameters for flexible evaluation of splits.
- To test the proposed impurity measures empirically on a series of benchmark databases in order to see how well the measures perform in terms of accuracy in comparison to traditional decision tree algorithms.
- To test the effect of the improved impurity functions when applied in combination with the concepts of pruning, ensemble learning techniques, and feature selection.
- To establish the statistical significance and generalizability of the devised methods by performing validation techniques such as cross-validation and non-parametric tests.

Achieving the above objectives would ensure the advancement of the existing decision tree approach to one that provides higher accuracy and robustness without compromising the need for interpretability in trustworthy AI.

IV. Structure of the Literature Review

The literature review in this study is organized into a logical and progressive structure designed to contextualize the role of impurity functions in decision tree construction, highlight current scientific gaps, and synthesize contemporary research addressing these gaps. The structure is intentionally crafted to guide the reader from foundational knowledge toward advanced theoretical and empirical developments. It is organized into the following major components:

A. Foundations of Decision Tree Methodology

This section discusses the theoretical background of decision tree algorithms, their history, and their universality within the machine learning and data mining communities. This section explains the important attributes such as explainability, hierarchical representation, and flexibility and how the use of impurity measures is fundamental to the design of high-performance tree-based algorithms. This section helps the reader understand the challenges of continuous features, greedy splitting, and overfitting.

B. Classical Impurity Functions and Their Limitations

This section of the study evaluates commonly employed impurity estimates, such as the Gini Index, Shannon Entropy, and Error, along with their definitions, mathematical formulation, and theoretical characteristics. This section lays considerable emphasis on the performance problems associated with conventional impurity estimation algorithms, which are prone to difficulties such as imbalance, noise robustness, scalability, and the generation of complex decision trees.

C. Emerging and Alternative Impurity Measures

This section integrates the latest research efforts for improvement and new forms of impurity values, such as the use of Rényi entropy, Tsallis entropy, MECC, and combinations. The latest research on comparisons between such impurity measures and classical impurity measures, as well as the advantages derived from tunable parameters and probabilistic formulations, are discussed.

D. Decision Tree Performance Challenges

After the discussions on impurity functions, the following section looks into the persisting issues involved in the creation of decision trees, such as overfitting, sparseness, missing values, instability, and lack of generalizability. This section combines the findings regarding the role of impurity functions in the above issues and the gaps for the creation of tailored impurity functions.

E. Complementary Optimization Techniques

Impurity measures alone cannot completely address the shortcomings of decision trees. In this section, we review methods that can improve performance when used in conjunction with improved impurity measures. The main strategies are:

- Pruning techniques, including cost-complexity pruning, error-based pruning, and bootstrap out-of-bag pruning.
- Feature selection methods, namely filter and wrapper approaches.
- Ensembling techniques, including Bagging, Boosting, and hybrid models.

Literature suggests that the incorporation of advanced impurity functions coupled with these complementary techniques results in decision trees that are more stable and generalizable.

F. Tree Optimization: State-of-the-Art Developments

This section covers modern developments, including gradient-based learning of decision trees, differentiable tree architectures, splitting criteria driven by changes in distributions, and parallelized frameworks for building trees. It also provides an overview of research into weakly supervised anomaly detection, financial modeling, educational analytics, and explainable AI to understand real-world usage and effectiveness of state-of-the-art tree optimization techniques.

G. Identified Gaps and Research Opportunities

The final section synthesizes the literature to identify specific enduring gaps:

- The need for impurity functions that are fit for complex, heterogeneous data.
- Lack of adaptive mechanisms for impurity selection.
- Limited integration with explainability and interpretability tools.
- A lack of theoretical guarantees for new impurity formulations.

These gaps motivate the current study, which seeks to systematically investigate and appraise customized impurity functions that enhance accuracy, reduce overfitting, and improve computational efficiency in decision tree learning.

V. Decision Tree: An Overview

A decision tree is indeed one of the most powerful algorithms in supervised learning for both classification and regression tasks. It is still the most widely used algorithm today and can be visually represented as a flowchart, where each leaf will correspond to the output that is expected from the decisions made from the internal branches. The tree needs to be structured from a root down to the leaves by balancing readability and performance (see Fig. 1) [9]. It should be compact and use easily interpretable, stable variables with solid classification power as measured by its impurity. This is significant in keeping the tree concise for making sure predictive strength is maintained, especially in high-stake decisions where early trees should still accommodate some level of uncertainty [2].

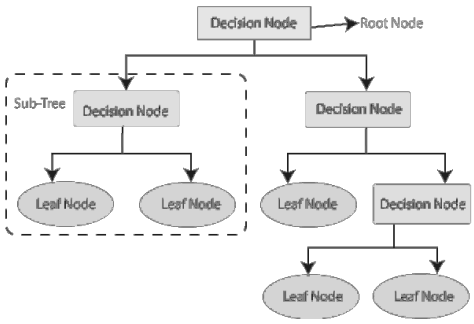

Fig. 1. Traditional decision tree [10].

A. Definition and Characteristics

Decision trees are generally known and accepted as basic techniques used in machine learning. The flexibility offered by decision trees is due to the ability to handle various attribute types, such as nominal, ordinal, interval, and continuously scaled attributes. In nominal attributes, the value is tested, and specific value information is used to transition to the next leaf [11]. In contrast, neighboring value ordering is used to establish a cut point, showing symmetry to the cut point, with the attribute value of the present case indicated by belonging to the region defined by the cut points. When the value of the region and corresponding cut points are divided into the region defined by the cut points, the attribute itself is said to be multidimensional. Varying the value of the region and the cut point could trigger a leaf transition, showing that the decision tree structure could vary by adjusting attribute values to the figure defined by quadruplets [12]. The ability to divide and conquer nominal and ordinal attributes enables the easy convergence of decision trees to attribute types. Further, using trees to continuously scaled attributes is enabled due to the structure of the leaf node, allowing the use of decision trees on problems involving interval, spatial, and continuously scaled attributes [13].

Forward pruning techniques, used to improve simplification models, are normally dependent on validation data, which is further divided into training and validation samples. These algorithms work to optimize decisions to obtain the lowest possible tree, which is guaranteed to keep validation samples having lower individual errors than training sets' probable errors. This is known as the cost-estimation approach, which expects methods used to estimate decision costs to avoid errors associated with performance, so as to derive an expansive and correct tree to predict and adapt to new and changing test/live situations.

B. Common Impurity Functions

In light of identifying Gini impurity and entropy as the most common impurity methods, the importance of the essential differences between their usages in decision tree building is discussed [14]. In comparison to more balanced datasets, Gini impurity is generally more biased toward the majority class, while entropy is generally more balanced and tends to generate smaller trees. In support of the comparative assessment, it has been found to work best on balanced datasets and class distributions [14]. This could explain why, under various datasets, Gini impurity has been found to outperform entropy on several instances [15][16]. When most instances are negligible, it has been observed to have less bias compared to entropy, which tends to reduce differences between impurities by biasing individuals to identify a more significant categorization ordering, albeit generating more suitable root node splittings [17]. In contexts when explainability is most paramount, the smaller-sized trees generated by Gini impurity could prove to be more beneficial, owing to their ease of understanding. Moreover, it is also more applicable to real-case problems due to high efficiency [18][19].

VI. Impurity Functions in Decision Trees

In decision tree models, nodes are represented by the attributes contained in the datasets, and the leaf node is used to define the class to which the datasets belong [20]. In discriminative learning, it is essential to identify the decision nodes by calculating the impurities, Eq. (1), present at the nodes used to divide the datasets. Given the fact that a node holds the impurities present in the datasets, the choice of input variables is important at the node during learning [21]. Various impurity measures have been developed to cope with input variable selection [21]. Impurities used to build decision trees include basic measures on errors, such as information entropy, the Gini index, and rule-based methods [22]. Using various impurities and a fixed probabilistic constraint along with learning on nodes, the idea of I-Optimal trees is developed based on the basic set of I-Optimal responses to probability, which aims to minimize the maximum non-negative relative entropy between the errors and the trees, and to develop insertable trees based on information functions and two-class tree optimization [23][24].

$$\text{impurity} = 1 - \text{purity} \tag{1}$$

Decision trees have found broad applications in data mining [25]. Decision trees have long been known to effectively and significantly provide easier methods to understand complicated procedures involving decision-making [26]. Moreover, the interpretable attribute of decision trees is unique to the algorithm,

adding to their popularity [27]. Compared to other models used to perform classification, decision trees are surprisingly more interpretable [28]. Decision trees have found broad applications ever since their creation and belong to a broad array of fields, including but not restricted to, bioinformatics, simplification of constraint programming problems, engineering, machine learning, modeling survival probability of trees, natural resource management, learning parity problems, and virtual screening, apart from applications to ensembles and forests [29][30]. Various extensions to the basic concept of decision trees have been developed, including but not restricted to, conic trees, conditional inference trees, decision stumps, frequent decision trees, interactive fuzzy decision trees, multigrain trees, multitrigger model trees, quantile random forests, totally corrective linear decision trees, and weight boosting [11][31].

A. Gini Impurity

The Gini impurity has several advantages. First, it significantly handles the issue of class imbalance. While it is ideal to have a balanced learning set, the Gini impurity has a tendency to lean towards the smaller classes, thus increasing their chances of reaching the top of the decision tree [32]. Moreover, it places the most frequent class at the top of the tree, having a greater influence than any other class. As a result, it quickly divides the large set into the upper nodes of the tree. Thus, the Gini impurity is often considered one of the most suitable impurity measures to be used in decision trees and random forests. The integrity of the tree model would significantly be affected if inappropriate measures were used [33]. In addition, the Gini impurity is also effective in reducing the complexity of the tree, and the efficiency of the tree-building algorithm is increased due to the reduced number of operations [34]. Moreover, it has been evident that the computational complexity of the Gini impurity is lower than information gain, and it is computationally efficient [35].

The Gini impurity measures the probability of randomly choosing an instance that would be assigned to a different class than it should. For a node t, it is defined as Eq. (2):

$$\mathrm{Gini}(t) = 1 - \sum_{j=1}^{k} p_j^2, \tag{2}$$

where, p_j is the proportion of instances of class j in node t and k is the number of classes [36]. The Gini impurity has value 0 when instances belonging to a node are maximally pure (all in a single class), and in the binary case it reaches its maximum of 0.5 when instances are equally distributed between the two classes, which corresponds to maximal impurity [37].

B. Entropy

Mathematically, the concept of entropy has been used to define the measure of Eq. (3) and Eq. (4) disorder or unusable energy present at the molecular level [38]. In contrast, the concept of entropy has been used to define the average amount of information, the measure of uncertainty associated with a source, and also the amount of randomness associated with a message. In essence, the more diversity, the more entropy [39]. Another concept, conditional entropy, is used to define the remaining uncertainty associated with the random variable, having knowledge of another variable, and is given by $H(Y|X) = S(I)$ [39]. There is a relationship between conditional entropy and entropy. In decision trees, the concept of information has been defined to mean the impurity associated with a dataset [40].

$$E(S) = -\sum_{x \in S} p(x) \log_2 p(x) \tag{3}$$

$$IG(S, A) = E(S) - \sum_{t \in T} p(t) E(t) = E(S) - E(S|A) \tag{4}$$

1) Rényi entropy: Current literature has further revived interest in using Rényi entropy, Eq. (5), to increase the correctness of decision trees [41]. This has been proven to outperform standard methods of measuring uncertainty and has prospects to tackle problems of unbalanced datasets. The impact of several Rényi measures on the efficiency of decision trees has also been analyzed, reflecting the ability to measure uncertainty associated with datasets to improve the accuracy of models [42]. Studies have also attempted to measure Rényi uncertainty along with other measures to increase decision tree efficiency [43].

$$R(D) = \frac{1}{1-\gamma} \log \left(\sum_{i=1}^{k} p_i^{\gamma} \right) \tag{5}$$

2) Tsallis entropy: When used as an impurity measure, Tsallis entropy, Eq. (6), has been proven to increase the efficacy of decision trees, as the inclusion of unconventional measures of impurity, including Tsallis entropy, has led to optimal results in decision tree models [44]. The importance of understanding the potential impact of Tsallis entropy on decision tree performance should not go unnoticed. Moreover, the inclusion of Tsallis entropy has led to significant improvements in the accuracy of decision trees. Cumulatively, the literature suggests that the inclusion of Tsallis entropy could prove to be a worthy tool to improve decision tree performance [41].

$$S_q = \frac{1 - \sum_{i=1}^{k} p_i^q}{q - 1} \tag{6}$$

C. Classification Error

The impurity measures under consideration demonstrate the importance of weights used when determining impurities [45]. The classification error function, Eq. (7), is used as an impurity measure on the terminal set and is a measure used to evaluate the splitting attribute, which depends on the selection attribute used to decide on splitting [46]. The classification error function is universally suited to a number of classes and is known by the name Gini impurity coefficient when used on two classes, and it is one of the impurity measures used in the empirical field. When achieving accuracy is assessed, a high-value item could incur more costs than a lower-value item [47]. The relevance of understanding measures of cost or loss is critical to accurately compute splittings and variables [48].

The aim of the present review is to demonstrate the potential role of the use of ranging functions on the flexibility offered by decision trees to social scientific studies [49]. In some situations, it is also possible to utilize a boosting algorithm with closely similar statistical power to handle various MC matrices [50].

$$E(D) = 1 - \max_i(p_i) \tag{7}$$

VII. Decision Tree Performance Challenges

Decision tree induction involves mainly three broad phases: formation of the tree structure, pruning, and leaf node assignment. Formation of an efficient decision tree is very important, and it is always desirable to have a decision tree with similar class distributions of the child nodes [12]. Nevertheless, it is often difficult to satisfy such a restriction when working on practical problems. In addition, it is more complex to develop a homogeneously structured decision tree with morphological information than to generate an effectively shaped decision tree [29].

Decision trees are a widely used technique for classification and prediction. The strength behind decision trees lies in their simplicity, usefulness, and ability to capture relationships with a fewer number of restrictions on their structure. This technique is helpful when it is required to work on moderate to large-sized datasets and involves very little input information on specifying the problem. It is, however, important to keep in mind that decision trees are vulnerable to noise present within the input, which often causes the creation of a large number of rules [51].

A. Overfitting

As data scientists and machine learning experts, researchers have the power to set criteria to govern tree models to avoid overfitting. This is possible by incorporating the number of training samples (n) and the number of relevant variables to predict the target variable (m), such that n is at least equal to $2m$ [52]. The number representing relevant variables is used either in the leading section of the data divide or by adding up all the conditions used to classify each training sample to the target category. This enables each category to hold distinct activated conditions to facilitate the validity of inferential modeling. Although simplistic, it is very effective to control the structure and number of relevant input variables to grow the decision tree modeling approach. Other techniques involving the effective utilization of weighted and optimized systems to identify relevant attributes and unique amounts of data to correctly categorize are also capable of increasing the efficacy of the aforementioned rule to $n \geqslant 2m$ [53].

The cause of overfitting can therefore be said to result from the inclusion of noise and unnecessary attributes, which the tree is trying to capture and employ to classify or explain the training data. The overfitting of the data is not sudden during the attribute selection procedure but starts with the selection of the optimal attribute and the inclusion of less optimal attributes to the tree nodes. The tree continues to grow until a considerable amount of irrelevance and interference is injected into it. The problem occurs because the training data have been optimized solely to suit the specific data the tree is growing on and may result in incorrect classification during the presentation of new instances [54]. Beginning with decision trees, overfitting is a basic flaw associated with them owing to their ability to learn and generalize data but not accurately enough. Noisy data during training are also associated with this flaw. When the attributes of the tree grow to complexity with too many nodes compared to the number of training instances, it is said to experience overfitting, marked by too much unnecessary modeling [52].

B. Handling Missing Values

Decision trees are commonly used to classify instances within a specific domain defined by a problem. The instances are divided into several sub-domains, and a model is built based on each domain and a set of attributes. This is conducted recursively. Several other learning methods are also found, which contain nodes not connected to decision trees. These methods are mainly used to improve the induction of decision trees [55].

Decision trees with missing information can also be handled using measures of impurities, which determine how to treat the missing information. Missing information may require filling using the most frequent value, and another measure of impurities may also be used to measure the influence of the missing information on the decision tree. When attributes are continuous, the average is commonly used, and when discrete, the mode is used. After structuring information and classes associated with information, the algorithm determines the best splitting and modes.

On the other hand, Quinlan developed the C4.5 algorithm to build decision trees, which works effectively with attributes that require either continuous or discrete information. It divides instances into various areas defined by a test and assigns instances to paths showing maximum information gain. In the meanwhile, Fernando et al. have made improvements to develop more efficient training and increase the efficiency of neural learning by reducing the influence of missing information [56]. Some authors also go into detail on how missing data are handled during splitting when constructing decision trees, while others consider it another value to take into consideration along with other attribute values. As a result, the diversity discussed above encompasses a wide review of the subject to guarantee readers are knowledgeable on the various perspectives on the issue [57].

VIII. Enhancing Decision Tree Performance

Current algorithmic developments involving decision tree impurity are an interesting solution, although not without restrictions [58]. Moreover, the existence of impurities is not convex, thereby increasing the complexity of reaching an optimal solution, and it is not guaranteed to converge within a fixed time span dependent on the input attributes [59]. Thus, it has also been realized that, to a great extent, the rigid measure of impurity is often settled with the measure of minimum quality, with the hope of achieving optimal models with impurities below a certain threshold. Unfortunately, such relaxation of impurity measures has further triggered unwanted occurrences of overfitting decisions on the decision trees [60].

Decision trees, although having high capabilities on classification problems, are also faced with demerits, largely due to the presence of noisy information in the datasets. Most learning models are also known to be highly affected by impurities, and more so when it is regarding class imbalance [28]. Although it has been realized to a great extent that having robust positions against impurities and enough data regarding impurities to learn is important, impurity is not invariant. If it is considered to a large extent, it is known to negatively affect learning models, and if the impurities are considered to a lesser extent, it often has to consider a rule regarding the pure attributes of the minority class and is further embedded into the decision trees. Under such conditions, it has been realized to largely overfit the trees, correctly categorizing instances in the minority classes and largely misclassifying instances in the majority classes [61].

A. Pruning Techniques

There is a possibility of overfitting during the creation of a decision tree, which may result in the creation of a very large tree [62]. Although the aim is to develop an apt representation of data, it often tends to remember the data and perform very well on it. This problem can be mitigated through pruning. Pruning the tree can be achieved by cost-based pruning using the resubstitution error, the estimate of the error, or by methods such as the bootstrap out-of-bag error, which serves as a validation technique and is very useful, particularly when reducing the time complexity [63]. The bootstrap out-of-bag error can also act as a third option that combines these techniques and serves as a validation procedure, and is very helpful, particularly when reducing the time complexity.

The entire process of pruning allows the creation of an unbiased terminal tree, which provides efficient access to the basic structure of the data, namely the relation between impurities and the decision tree [64]. By using metrics such as the Gini index and entropy, along with validation and techniques such as the random forest, it is possible to increase robustness, which allows the creation of a better and more universally applicable model [65]. Decision tree methods are used owing to their immediacy and ability to divide observations into separate subsets, which results in them becoming an extremely efficient tool and very difficult to reproduce and verify by other techniques such as multivariate methods [27]. Decision trees along with impurities are flexible methods and can handle nominal and continuous independent variables [4]. The technique, which is similar to a set of binary tests, is able to identify optimal cutting points on the independent variables to increase the purity of the groups, which is very helpful to behavioral analysts and market experts, and is able to provide very rapid characterization and understanding of the data. Hence, it is able to act as an extremely efficient description tool, identifying the region of interest surrounding the most basic subsets of various variables [66].

B. Feature Selection Techniques

Input feature priority techniques imply ranking input features based on relevance to the target task. This is helpful to identify the optimal number and priority of input features to retain. Input feature selection is divided into two broad categories: filter and wrapper techniques. In filter techniques, importance is ranked, and measures such as the t-statistic and F-statistic are used. These techniques can select subsets of top-k features and are used during the first stages of data preprocessing. There are various input feature selection techniques, and some of the most important ones are discussed below.

In contrast, wrapper methods utilize a search procedure along with a model to assess the performance of various subsets of features [67]. Features are selected and dropped based on their ability to improve or hinder the performance of the model [68]. In contrast to filters, the wrapper technique can select a feature that is important to the model yet not directly associated with the target, and drop a feature that is less important but directly associated with the target [3]. As such, the wrapper technique often outperforms filters [69].

The objective of the feature selection procedure is to discover a set of attributes within the input features to enable the creation of a predictive model with enhanced accuracy, which can develop a more efficient predictive model by learning the most distinguishing features while avoiding unwanted characteristics [70]. Several advantages are associated with feature selection, including the creation of more interpretable models, the ability to develop models with faster speeds and smaller sizes, the elimination of variables highly associated with the target, and the attainment of negligible value. There are two types of feature selection methods [5, 71].

C. Ensemble Methods Techniques

In the decision trees literature, an ensemble technique combines N models (developed by using the same input learning algorithm) to attain a unique prediction for every instance within the test data [72]. There are two basic methods to design an ensembling technique of decision trees [73]. Bagging involves creating an ensemble by randomly sampling, with replacement, elements within the training example and using the sample to develop the respective model [74]. Boosting techniques are based on an iterative technique wherein models are developed on the entire training example, and weights are finally given to poorly predicted instances (see Fig. 2) [75]. These poorly predicted instances also display a greater tendency to be selected into the training example of the next models [76][77]. These methods are further coupled with decision trees to generate an ensembling technique of models [78][79].

1) Bagging: When it is used correctly, involving decision trees as base models, bagging can generate very good predictive models. However, it should never be forgotten that bagging works mainly to decrease variance, which is why it is most beneficial when used on high-variance models. Another important factor is to include homogeneous and robust base models. When base models are not satisfactory, it is possible to improve performance by differently initializing base models randomly and using differently defined discretization methods, such as divide techniques and Vapnik methods [80]. While it is true that, when used correctly, bagging and resampling methods can often involve more active and complex processes than other techniques used to generate ensembles, it is also very important to understand and appreciate the strength of

bagging, which is to accurately and efficiently develop predictive models [81].

The basic bagging algorithms require a robust learning algorithm, which is true when bagging is used with decision trees [11]. When used on decision trees, bagging produces a mixture model where each individual model is obtained using a bootstrap sample of the training instances, and the training involves all instances and variables in the training set. The predictions of the individual models (decision trees) are averaged in regression and combined via voting in classification [76]. The best possible results are achieved when the training is carried out on noisy data and data with a high dimensionality. Bagging is most effective when it decreases the variance of the base learner when it is unstable.

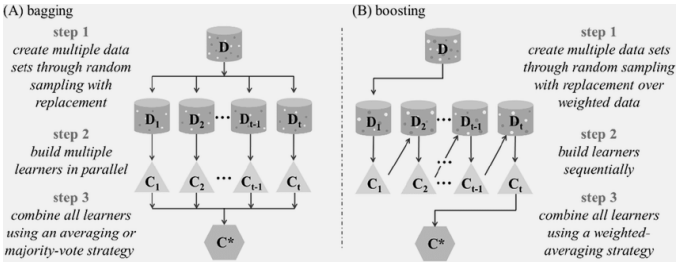

Fig. 2. Bagging and boosting tree-based ensemble [10].

2) Boosting: XGBoost, which is a very reliable and highly researched boosting algorithm, is very similar to residual-fitting boosting but is distinguished by adding a specific weight to each classifier based on the accuracy rate. The weights are incorporated into the overall classifier, which makes XGBoost a forward stage-wise fitting algorithm [82]. Unlike traditional methods, XGBoost gives more weight to instances that were classified inaccurately to influence the learning process of new classifiers. The concept of boosting has the ability to improve a weak solution to a strong solution [6].

Boosting techniques present the problem of optimization by working on iterative improvements of specific loss functions by training on instances with more importance. The next classifier is dependent on the most important instances, which are determined by the distribution defined by the earlier classifier. These techniques, such as AdaBoost and RankBoost, increase the importance of instances by modifying the distribution after each classifier. Other boosting techniques, such as BrownBoost, work differently by approximating the loss function without changing the distribution after each classifier [73][79].

IX. Related Work

Mao et al. [83] present a new decision tree classification algorithm based on a two-term RS-entropy concept, aiming to improve the flexibility and accuracy of models. The authors highlight the insufficiencies of existing decision tree approaches such as ID3, C4.5, and CART, which rely on rigid splitting rules defined by Shannon entropy and the Gini index. RS-entropy, a generalized concept encompassing Shannon, Rényi, Tsallis, and r-type entropies, allows dynamic splitting rules defined by adjustable parameters. Furthermore, the authors enhance the two-term information formula by incorporating penalty factors to account for attribute complexity, resulting in the RSEIM algorithm. Empirical experiments on eight UCI datasets show that RSE and RSEIM greatly outperform traditional algorithms in classification accuracy without increasing model complexity. Genetic algorithm–based parameter optimization further strengthens RSEIM's robustness and resistance to overfitting. Pairwise comparisons and Nemenyi tests confirm the statistical superiority of RSEIM.

He et al. [84] propose a dynamic Bayesian node-splitting algorithm to improve the performance of the random forest algorithm by overcoming inefficiencies in traditional splitting methods. The algorithm dynamically calculates posterior probability distributions during the splitting process, enabling more accurate identification of optimal split points. The authors also introduce a dynamic thresholding mechanism weighted by misclassification errors to prevent overfitting. Experiments conducted across multiple UCI datasets show improvements in accuracy, robustness, and computational efficiency compared to classical random forest models.

In the work of Ferreira et al. [85], decision tree models are used to support clinical decision-making regarding impaired physical mobility in trauma patients. Using the C4.5 algorithm, the authors identify eight essential nursing diagnoses and construct classification trees to determine key predictors such as age, length of hospital stay, and injury severity score. The results demonstrate that decision trees can effectively guide clinicians in prioritizing patient care and integrating data-driven assessments into trauma management.

Ciftcioglu et al. [86] introduce a predictive model for estimating shear strength in reinforced concrete beams, optimizing decision trees using the Lévy Flight algorithm to overcome the limitations of traditional machine learning approaches. Using an extensive dataset featuring numerous structural variables, the authors compare classical decision tree models with Lévy Flight–enhanced variants. Results show that the optimized models produce superior accuracy, robustness, and adaptability while reducing overfitting. Metrics such as RMSE, MAE, and R^2 confirm that the new method significantly outperforms traditional decision trees.

Li et al. [87] present an extensive analysis of a decision support system (DSS) for vending machines using machine learning techniques, including an improved C4.5 decision tree algorithm and neural networks. The modified C4.5 algorithm reduces runtime and slightly improves accuracy relative to the original. Using a backpropagation neural network (BPNN), the authors show strong alignment between predicted and real sales trends. Reinforcement learning is also incorporated to further enhance the DSS's efficiency and forecasting accuracy.

New splitting rules for Gradient Boosting Decision Trees (GBDT) are proposed by DeLise [88] to address out-of-distribution (OOD) generalization—a major challenge due to era-dependent distribution shifts. Unlike Empirical Risk Minimization (ERM), which assumes i.i.d. data, the new rules leverage cross-era information to build more robust models. Theoretical analysis and experiments using simulated datasets and real-world financial market data (e.g., Numerai) show improvements over classical GBDT.

Marton et al. [89] introduce GradTree, a technique for learning hard, axis-aligned decision trees using gradient de-

scent rather than traditional greedy methods. By employing backpropagation and the straight-through estimator, GradTree jointly learns all tree weights, producing enhanced accuracy and generalization performance in binary and multiclass tasks. Experimental results demonstrate that GradTree surpasses existing algorithms while supporting external loss functions and dynamic splitting.

Zeng [20] examine fundamental assumptions about impurity functions in decision trees, focusing on non-negativity and concavity. The authors show that impurity functions are not inherently non-negative and analyze conditions where impurity decreases may be harmful. They further demonstrate that concavity guarantees non-negative impurity decreases in multiway splits. Experiments on the German credit dataset show that a linear hybrid of the Gini index and entropy outperforms each impurity measure individually.

In their study, Arbiv et al. [90] explore human-centered optimizations for decision trees to improve interpretability. The authors evaluate design modifications and algorithmic enhancements aimed at reducing the gap between complex data structures and user understanding. Their findings show that optimally designed trees significantly improve human decision-making by presenting information in a more comprehensible format.

Loreti and Visani [91] assess parallelization strategies for building decision trees in the GLEAMS explainability framework, which struggles with scalability. By applying distributed computing through the Ray platform, they compare multiple parallel methods and identify performance strengths and weaknesses. The results highlight improvements in efficiency and scalability in alignment with modern explainability demands.

Finke et al. [92] investigate tree-based methods for weakly supervised anomaly detection at the Large Hadron Collider (LHC). Their work demonstrates that Boosted Decision Trees (BDTs) outperform deep neural networks in training efficiency and robustness to noise. Using gradient boosting and ensemble techniques, the authors show that BDTs can effectively operate in high-dimensional spaces with many uninformative variables, improving model-independent searches for new physics phenomena.

Baena-Rojas et al. [93] present a hybrid approach to Multi-Criteria Decision-Making (MCDM) to identify international markets for small and medium-scale coffee roasting businesses. The hybrid approach combines and balances the benefits of quantitative and qualitative techniques to improve the efficiency and viability of International Market Selection (IMS). A case study involving 18 Colombian SMEs producing coffee shows that cultural variables and techniques improve the efficiency of the MCDM solution. The most promising countries are the US, the Netherlands, and South Korea, demonstrating the feasibility of the proposed solution.

Ujwal and Malik [94] suggest a system called PerformanceX, which utilizes Educational Data Mining (EDM) to enhance performance and minimize dropout ratios. The authors present a selective algorithm involving filter and wrapper methods to select important attributes based on student datasets. Using machine learning classifiers, including a fusion voting classifier, the system achieves an accuracy of 99.41%, with the best result obtained by the random forest classifier. The work clearly emphasizes the relevance of structuring student performance on effective attributes to improve learning and career advancement.

Bouke et al. [18] introduce the BukaGini algorithm, a new feature selection algorithm suitable for machine learning. The algorithm leverages the concept of the Gini impurity index to improve the evaluation of interactions between features, including linear and nonlinear associations. Comparisons conducted on various datasets, such as High School Students' Performance, Cancer Data, Spambase, and UNSW-NB15, indicate that BukaGini generally attains greater accuracy improvements than conventional Gini index methods, ranging between 0.32% and 2.50%.

Pathan and Sharma [95] analyze improvements to the decision tree algorithm to increase classification accuracy and minimize tree size. Their discussion of preprocessing techniques focuses on handling missing information and uncertainty. The proposed decision tree algorithm, optimized using the Gini impurity, is more efficient than regular decision trees based on criteria such as precision, recall, F-score, and accuracy.

Subramani and Muruganantharaj [96] propose the EnhancedTree+ algorithm, an advanced decision tree classifier designed to enhance accuracy, interpretability, and robustness when dealing with complex datasets. Although decision tree algorithms are easy to implement, they suffer from overfitting and loss of interpretability when handling complex data. EnhancedTree+ addresses these problems by incorporating smarter splitting rules and pruning. Extensive experimentation on the Titanic dataset shows that EnhancedTree+ outperforms standard decision tree classifiers and competes favorably with models such as random forests and gradient boosting. The experiments clearly indicate improvements in accuracy, precision, recall, and F1-score, implying strong practical viability.

Asif et al. [97] address global health issues related to cardiovascular diseases by presenting a machine learning solution involving preprocessing, hyperparameter tuning, and ensemble learning techniques. The authors combine three Kaggle datasets with similar attributes to construct an extensive dataset. Using an Extra Trees classifier, normalization, and grid search cross-validation, the proposed solution achieves an effectiveness of 98.15%. The results suggest strong potential to correctly identify cardiovascular disease, which may greatly aid in prevention, diagnosis, and treatment, thereby reducing morbidity and mortality.

The work by Cui et al. [98] targets the robustness of Gradient Boosted Decision Trees (GBDT) and offers a technique to improve it by employing one-hot encoding and regularization. Although efficient, GBDT models are vulnerable to slight changes in input data. By converting the models into linear form using one-hot encoding and applying L_1 and L_2 regularization, substantial improvements in robustness are achieved. The study shows that regularization methods help alleviate vulnerabilities to data perturbations, ultimately improving efficiency.

Custode and Iacca [99] explore the integration of evolutionary algorithms and Q-learning to provide interpretable decision trees for reinforcement learning (RL). Their work tackles problems such as premature convergence to local optima by adopting a two-level optimizer. Experimental analysis

conducted on classical RL tasks (CartPole-v1, MountainCar-v0, and LunarLander-v2) and on a pandemic control domain clearly shows the competitive efficiency of the proposed solution for both interpretable and non-interpretable models. The results demonstrate that interpretable models can match or even improve upon the performance of non-interpretable ones, even in high-stakes domains such as pandemic control.

Riansyah et al. [100] publish a study on improving the accuracy of the C5.0 decision tree algorithm for data mining classification using adaptive boosting (AdaBoost). They highlight several flaws of the C5.0 algorithm, including susceptibility to overfitting and accuracy degradation when dealing with unbalanced data. These flaws are mitigated by AdaBoost, which adjusts the weights of incorrectly classified samples. In a case study involving hepatitis data, accuracy is increased from 80.58% to 82.98%, while the classification error rate is significantly reduced. This shows AdaBoost's ability to transform a weak classifier into a strong one through reweighting of training samples.

In their work, B et al. [101] present Permutation Decision Trees (PDTs), an extension of classical decision trees that uses the Effort To Compress (ETC) complexity measure—interpreted as an impurity measure—to enable permutations of instances. Compared to Shannon entropy and Gini impurity, ETC captures the importance of instance ordering, making PDTs sensitive to permutations. The authors also propose Permutation Bagging, an implementation of PDTs that does not rely on stochastic sampling but instead uses random feature selection. Although the approach has promising applications, comparisons with standard random forests clearly show the superiority of Permutation Bagging and Permutation Decision Forests, particularly when handling critical data instances and dependencies.

Awad and Fraihat [102] study the efficacy of recursive feature elimination with cross-validation using decision tree models (DT-RFECV) for feature selection in intrusion detection systems (NIDSs). Employing the UNSW-NB15 dataset with 42 features, they improve accuracy while reducing the number of features. The findings reveal that using the optimal 15 features obtained by DT-RFECV yields a binary classification accuracy of 95.30%, comparable to that achieved using the full feature set. This work maintains high accuracy while speeding up detection and reducing storage requirements by 65% through feature selection.

Zhang and Gionis [16] propose a new algorithm for decision tree induction that incorporates complexity guarantees during learning. Although classic algorithms such as C4.5 and CART are effective in terms of accuracy, they offer no guarantees regarding the complexity of the constructed trees and may thus produce poorly interpretable models. The new algorithm improves on these approaches by adding a greedy heuristic that balances tree size, cost, and impurity, yielding logarithmic guarantees on complexity. As a result, it produces trees that are both interpretable and accurate. The paper represents an important contribution by explicitly addressing the trade-off between accuracy and interpretability.

Roshanski et al. [103] propose a new algorithm, FACET, designed to ensure that decision trees remain compact while preserving modeling power. Although decision trees often provide a simple and robust modeling framework, their growth can lead to overly large and complex models. FACET seeks to maintain compactness by using automated modeling principles and feature extraction to construct concise tree representations. Experimental analysis on 82 different datasets is conducted to verify the efficiency and effectiveness of the proposed technique.

Bodine and Hochbaum [104] present the Max-Cut Decision Tree with modified PCA, published in SN Computer Science, with the aim of optimizing the decision tree algorithm. Their work remedies problems associated with standard CART Gini trees by incorporating two major innovations. First, Max-Cut is designed to maximize separation between class instances, making it less prone to overfitting. Second, the integration of Node Means PCA dynamically adapts dimensions at each node, reducing running time and improving efficiency. Experimental validation across multiple datasets, including CIFAR-100, shows considerable performance improvements.

Horváth et al. [105] propose a new method for adding robustness to the certification of decision-stump ensembles via deterministic smoothing. Although tree-based models are widely used in high-risk domains such as healthcare and finance, their robustness certification lags behind that of neural networks. The authors introduce deterministic robustness certificates for ensembles with numerical and categorical attributes. Their method uses dynamic programming to compute exact output distributions under randomization and provides an MLE-optimal learner for robust stump-based boosters. Experiments demonstrate improved efficiency and accuracy compared to existing robustness-certification approaches for tree models.

Li and Chen [106] address the shortcomings of conventional univariate decision trees (UDTs) by introducing a new splitting rule based on Geometric Mean Metric Learning (GMML). They propose the diagonalized GMMLDT, which accelerates tree construction by quickly identifying the most discriminative splitting feature while preserving explainability. Experiments on standard benchmark datasets show that both dGMMLDT and its multivariable extension, dGMMLMDT, achieve comparable or superior accuracy with up to a ten-fold speedup relative to full GMML.

Lee et al. [33] propose a decision tree algorithm that improves classification accuracy by incorporating class distances. The method modifies the traditional Gini index using a combination of Rao and Stirling distances, producing more clearly separated class boundaries during splitting. Testing on multiple datasets—including contraceptive method choice, car evaluation, and yeast—demonstrates that the new algorithm consistently outperforms the traditional Gini index.

Manzali et al. [107] propose Enhancing Weak Nodes in Decision Trees (EWNDT), an approach designed to improve decision tree efficiency by addressing weak nodes using data augmentation. The algorithm augments data associated with weak nodes by artificially grouping neighboring nodes and re-evaluating candidate splits, thereby increasing model robustness. Experiments on UCI repository datasets show that EWNDT outperforms conventional pruning-based techniques.

Agarwal et al. [108] propose Hierarchical Shrinkage (HS), a post-processing regularization technique for decision trees

and random forests. HS shrinks predictions toward the mean of ancestor nodes through a single regularization parameter while preserving the tree structure. Experiments across varied datasets demonstrate that HS significantly improves predictive performance and interpretability. The authors also link their method to ridge regression applied to decision stumps, providing theoretical grounding.

Arabameri et al. [81] assess decision tree-based ensemble machine learning algorithms for landslide susceptibility mapping in the Taleghan–Alamut Basin, Iran. The study employs Credal Decision Tree (CDT) models integrated with Bagging, Multiboost, and Subspace algorithms using eighteen conditioning factors. Model performance is evaluated using ROC curves and k-fold cross-validation. Results show that CDT-Multiboost achieves the highest performance, with an average AUC of 0.993, indicating strong feasibility for generating reliable landslide-susceptibility maps to mitigate future hazards.

X. Methodology

This study follows a structured literature-review methodology rather than an original empirical design. The aim is to synthesize recent research on impurity measures used in decision-tree learning and to compare how the reviewed studies report performance, robustness, and interpretability.

The review methodology is organized into three phases:

- **Literature identification:** Relevant studies published between 2020 and 2025 were collected from the literature cited in this study, with emphasis on work addressing classical impurity measures, generalized entropy-based criteria, hybrid split functions, pruning strategies, feature selection, and ensemble-based decision-tree optimization.
- **Screening and categorization:** The selected studies were grouped according to their primary contribution, including impurity-function design, performance optimization, overfitting control, interpretability, and application domain. This step enabled consistent comparison across methods and research themes.
- **Comparative synthesis:** Findings were synthesized qualitatively by comparing the reported outcomes of the reviewed papers, including accuracy trends, robustness to class imbalance and noise, model complexity, and computational considerations. No new experiments were conducted in this study.

This methodology aligns the study with its actual scope as a survey and provides a transparent basis for the discussion and comparison presented in later sections.

XI. Discussion

The reviewed literature shows a clear evolution in the role of impurity functions in decision-tree construction. While classical approaches such as the Gini index and Shannon entropy remain dominant for their simplicity and computational efficiency, they exhibit significant limitations when applied to modern datasets characterized by imbalance, high dimensionality, noise, and non-linear interactions. As documented throughout the study, these drawbacks manifest through biased splits, deeper and less interpretable trees, and an increased tendency toward overfitting—an issue exacerbated by the greedy, locally optimal nature of standard tree-building algorithms.

Recent studies explore alternative impurity measures—such as Rényi entropy, Tsallis entropy, cost-sensitive error functions, MECC, and ETC-based measures—to more accurately quantify uncertainty in multi-class, imbalanced, or temporally sensitive datasets. These functions provide improved modeling flexibility by introducing tunable parameters, non-linear weighting schemes, or domain-specific structural priors. Importantly, emerging work demonstrates that combining impurity measures (for example, linear mixtures of Gini and entropy) can outperform individual functions for specific classes of problems.

Beyond impurity functions themselves, the literature underscores the importance of complementary techniques such as pruning, ensemble learning, feature selection, and error-based optimization to mitigate overfitting and excessive tree growth. Studies show that when decision trees employ improved impurity functions in conjunction with these techniques, the resulting models consistently outperform baseline CART and C4.5 variants in terms of accuracy, robustness, computational cost, and interpretability.

XII. Results and Comparison

This section summarizes the findings reported in the reviewed literature rather than presenting original experimental results. The comparison focuses on four recurring dimensions discussed across the surveyed studies:

- **Predictive performance:** Reported changes in accuracy, precision, recall, and F1-score.
- **Model complexity:** Tree depth, number of nodes, and resulting interpretability.
- **Robustness and overfitting:** Sensitivity to noise, class imbalance, and training-data variation.
- **Computational efficiency:** Reported training cost and scalability with larger datasets.

As summarized in Table I, the reviewed studies generally indicate that adaptive impurity measures and impurity-aware optimization strategies can improve decision tree behavior relative to classical split criteria, especially when combined with pruning, feature selection, or ensemble learning. These findings should be interpreted as a synthesis of published evidence, not as new benchmark results produced by the present study.

XIII. Conclusion

This literature survey demonstrates that impurity functions play a foundational role in shaping the performance, interpretability, and computational properties of decision-tree models. Traditional impurity measures, while effective for structured and balanced datasets, often fall short in modern applications characterized by complexity, heterogeneity, and noise. A new generation of impurity functions—incorporating tunable parameters, non-linear weighting, temporal sensitivity, or structural complexity guarantees—has shown substantial empirical and theoretical promise.

TABLE I. CONDENSED SUMMARY OF REVIEWED DECISION TREE RESEARCH (2020–2025)

ID	Authors / Year	Method / Algorithm	Key Contributions	Datasets	Results
1	Mao (2025)	RSEIM / RS-Entropy	Generalized entropy-based DT with tunable splitting	8 UCI	Higher accuracy vs CART/C4.5
2	He (2025)	Dynamic Bayesian Splits	Posterior-probability split optimization	UCI	Faster + more robust RF
3	Ferreira (2025)	C4.5 Clinical DT	Mobility prediction in trauma patients	Clinical	Better diagnostic insights
4	Ciftcioglu (2025)	DT + Lévy Flight	Optimization for nonlinear engineering data	Concrete beams	Improved RMSE, MAE, R^2
5	Li (2024)	Modified C4.5 DSS	Faster DT for vending machine DSS	DSS data	Higher accuracy, reduced runtime
6	Delise (2024)	Era-aware GBDT	Robust OOD generalization under distribution shifts	Numerai	Strong OOD performance
7	Marton (2024)	GradTree	Full-tree gradient-descent optimization	Benchmarks	Higher accuracy vs greedy DT
8	Zeng (2024)	Impurity Theory	Clarifies impurity properties; beneficial mixtures	German Credit	Mixed measures outperform baseline
9	Loreti (2024)	Parallel DTs (Ray)	Scalable parallelization for explainability	GLEAMS	Faster DT building
10	Finke (2024)	BDTs for Weak Supervision	Noise-robust anomaly detection	LHC	Better than deep nets
11	Baena-Rojas (2023)	Hybrid MCDM Tree	IMS ranking for SMEs	18 SMEs	Identified US, NL, KR as best markets
12	KVG (2023)	PerformanceX EDM	Attribute selection + DT	Student data	99.41% accuracy
13	Bouke-Bukagini (2023)	BukaGini	Interaction-aware impurity	UNSW, UCI	+0.32–2.50% accuracy
14	Pathan (2023)	Improved Gini DT	Missing-data robust preprocessing	UCI	Higher precision/recall
15	Subramani (2023)	EnhancedTree+	Improved splitting + pruning	Titanic	Beats DT/RF/GBDT
16	Asif (2023)	Ensemble Health Trees	Extra Trees + preprocessing	Kaggle heart	98.15% accuracy
17	Cui (2023)	Robust GBDT	L1/L2 regularized GBDT	Real + synthetic	More robust predictions
18	Custode (2023)	EVO + Q-Learning Trees	Interpretable RL trees	RL benchmarks	Competitive with deep RL
19	Riansyah (2023)	C5.0 + AdaBoost	Boosting for imbalance	Hepatitis	Accuracy ↑ from 80.6→83%
20	Bodin (2022)	Max-Cut DT + PCA	Class-separating splits + node PCA	CIFAR-100	49% better accuracy, 94% faster
21	Horváth (2022)	Robust Stumps	DP-based exact robustness certification	Mixed datasets	Better certified robustness
22	Li (2022)	GMMLDT	Metric-learning-based DT splitting	Benchmarks	Up to 10× speedup
23	Lee (2022)	Distance-based Gini	Rao–Stirling distances in impurity	UCI	Higher accuracy
24	Manzali (2022)	EWNDT	Weak-node data augmentation	UCI	Superior to pruning
25	Arabameri (2022)	CDT + Multiboost	Uncertainty-aware hazard mapping	Landslides	AUC = 0.993

Moreover, the synergy between enhanced impurity functions and complementary techniques such as pruning, ensemble learning, feature selection, and hybrid modeling emerges as a critical factor in achieving high-performing and robust tree-based models. These developments indicate a decisive shift toward impurity-adaptive and context-aware decision-tree learning frameworks.

This study thus underscores the importance of rethinking impurity measurement in decision-tree design to meet the demands of increasingly challenging data environments and motivates future work toward systematically designing, analyzing, and benchmarking customized impurity functions.

ACKNOWLEDGMENT

The project was funded by the KAU Endowment (WAQF) at the King Abdulaziz University, Jeddah, Saudi Arabia. The authors, therefore, acknowledge with thanks WAQF and the Deanship of Scientific Research (DSR) for their technical and financial support.
