- EIF's elimination of axis-aligned scoring bias translates to measurable improvements in Recall, the most operationally critical metric for anomaly detection, without degrading Precision, demonstrating that bias correction yields practical detection gains in real-world imbalanced datasets.
- The proposed framework is computationally efficient, unsupervised, and scalable, making it suitable for deployment in mobile cloud service security infrastructure without requiring labeled attack data.

Ultimately, by delivering a scalable, computationally efficient framework that eliminates axis-aligned scoring bias to reliably identify multidimensional collective anomalies, this proposed framework significantly bolsters mobile cloud

infrastructure defenses against costly cyber-enabled crimes such as credit card fraud and network intrusions.

Future work will investigate adaptive contamination estimation techniques to eliminate the need for manual threshold calibration, the application of the EIF framework to contemporary network traffic datasets (e.g., CICIDS-2017, UNSW-NB15), semi-supervised extensions incorporating partial label information from security analysts, and streaming online learning variants of EIF for real-time anomaly detection in active mobile cloud environments. Furthermore, the claim of superior performance will be subjected to a broader baseline comparison by evaluating the proposed EIF scheme against other state-of-the-art anomaly detection frameworks applied to credit card fraud, such as Autoencoders, One-Class SVMs, and recent deep learning approaches. This expanded benchmark will comprehensively delineate the performance boundaries of tree-based versus deep-learning-based detectors in vulnerable mobile cloud computing environments.

ACKNOWLEDGMENT

The authors would like to express their highest gratitude to the Institute of Public Security of Malaysia (IPSOM), Ministry of Home Affairs (KDN), and Universiti Sains Islam Malaysia (USIM) for the support and facilities provided. This research paper project is funded by the IPSOM grant: USIM/IPSOM-KDN/FST/LUAR-K/41925.

***Abstract*—Fine-Grained Image Classification focuses on unique features between visually similar subclasses within a wider category, which remains a challenging task due to low inter-class variations and high intra-class similarity. Conventional Convolutional Neural Network-based methods often struggle to accurately capture these minor differences. Utilizing self-attention techniques to represent global relationships within images, Vision Transformers have recently demonstrated robust performance in image classification evaluations. To enhance classification performance on complicated visual categories, this research presents a Fine-Grained Image Classification framework utilizing the Vision Transformer Model. The CIFAR-100 dataset, which includes 100 different image classes, is used for experimental purposes. The images were up-sampled because the Vision Transformer demands higher resolution inputs. To improve training efficiency and generalization, preprocessing techniques, including normalization and data augmentation, are applied. The model is trained and evaluated using standard performance metrics, including accuracy, macro precision, macro recall, and macro F1 Score, to ensure a balanced evaluation across all classes. With an overall classification accuracy of 89.68% and good macro-level assessment scores, experimental results show that the Vision Transformer Model successfully captures subtle visual distinctions among comparable categories. Transformer-based architectures offer an effective substitute for conventional techniques in Fine-Grained Image Classification applications with better performance. This research demonstrates how the Vision Transformer Model can increase classification robustness and accuracy for a dataset with very similar item classes.**

***Keywords*—Data augmentation; fine-grained image classification; CIFAR-100; vision transformer model; deep learning**

I. Introduction

Image classification has become a fundamental task in computer vision, enabling machines to understand and classify visual data. Fine-Grained Image Classification (FGIC) is still a challenging topic, despite significant progress in general image classification. It focuses on the uniqueness between visually similar categories, where differences are often limited to minor variations in texture, shape, or color.

FGIC includes the merging of visual features between classes, in comparison to predictable classification problems, where categories are recognizable. The process is further complicated by differences within the same class depending on changes in backdrop, lighting, and attitude. Models that can capture both fine-level distinction characteristics and global context will be required to overcome such challenges. In Image Classification, deep learning techniques, in particular Convolutional Neural Networks, have shown outstanding outcomes. However, their capacity to represent long-range interdependence is restricted by dependence on locally available fields. Recently, transformer-based architectures have emerged as a powerful alternative for capturing global connections across images through self-attention-based techniques.

The classification of subclasses within a broader category is the focus of a specific category of image classification called FGIC. It is a subset of image classification that intends to classify subclasses inside a broader class [1]. The issue of overall feature similarity across closely related subclasses is addressed by FGIC. Unlike common classification challenges, where the difference between classes is clear, FGIC is a challenge of identifying subtle differences within the same high-level category. For instance, the color of a bird's feathers can only vary slightly across two species. It contains images with high inter-class unpredictability and low inter-class variability [2].

With only a few design variations, car models can be nearly similar. Flowers can be identified by the slightest changes to their shape or petal pattern. This task is more challenging than conventional image categorization since such minor details may be hidden or partially hidden by changes in lighting, background clutter, or how the item will appear in the image. According to [3], lighting, position, and context can all affect how classes seem. By reconstructing the image's local and global attributes, this method seeks to detect such minute variations. The need to distinguish subclasses with high similarity is addressed in this research. FGIC requires the discovery of slight changes between different classes, as compared to general classification issues, which call for the detection of tiny differences within a single broad category. A case study of this is provided by two bird species whose feather colors can only differ slightly.

Flowers can be recognized by slight differences in the form or features of their petals. Compared to traditional image classification, this is a difficult process since such minute features can be hidden or changed by things like lighting changes, background clutter, and the image's content. To address these limitations, recent research has introduced advanced techniques including attention mechanisms, part-based modeling, and Vision Transformer Model. These techniques have demonstrated significant advancements in the detection of both global contextual structures and fine-grained local features, which have enhanced classification performance in difficult real-world scenarios.

The lack of high-quality, labeled data is a major challenge to FGIC advancement. Large-scale fine-grained dataset development requires a high level of domain-specific knowledge, which makes data gathering and annotation expensive and time-consuming. Benchmark datasets like Stanford Cars [4], FGVC Aircraft [5], and CUB-200-2011[6] (for birds) have been generated to support research in this field by offering standardized platforms for evaluation and analysis. The problem of inadequate information remains despite these resources, delaying the development of models and their practical implementation. However, FGIC is extremely significant in a range of applications, including industrial quality control, precision agriculture, medical diagnostics, and biodiversity monitoring, highlighting its significance to the development of domain-specific AI systems.

The classification of two apparently similar woodpeckers using FGIC is shown in Fig. 1. Existing methods of classification are unable to accurately identify these species due to their high inter-class similarity and low intra-class similarity. The picture indicates how an attention-based network would automatically locate discriminative regions, particularly the head and beak areas, which include minor but significant visual signals, including color patterns and pattern differences.

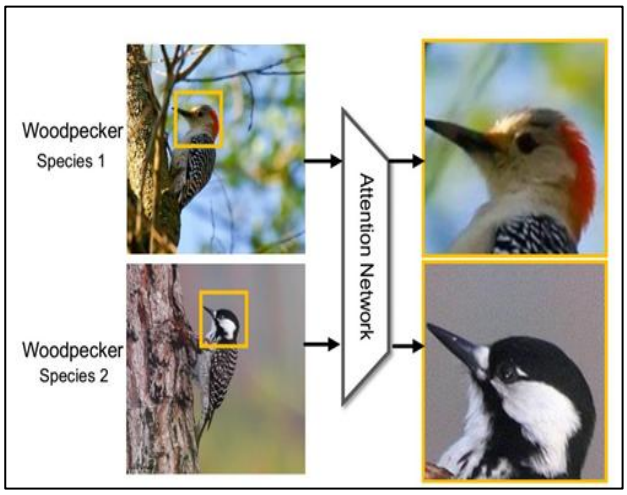

Fig. 1. Attention-based fine-grained image classification [7].

More accurate feature extraction and decision-making are made possible by the attention mechanism, which eliminates irrelevant background information and amplifies useful local characteristics. These methods indicate success in fine-grained visual classification tasks, such as the classification of bird species, where small anatomical variations are crucial [7]. The complexity and fine features of the CIFAR-100 dataset make Few-shot Learning (FSL) of the dataset difficult. Compared to large datasets like ImageNet, CIFAR-100 only has 100 classes with 600 images of each class.

It is challenging for models to develop strong and discriminative features with this limited amount of data. In a few-shot scenario, when each class has a finite number of labeled examples, the issue gets substantially worse. Many of the CIFAR-100 categories, such as various animals, cars, or household items, have visual similarities to one another.

Such a lack of examples can frequently result in models acquiring only the rough patterns that do not allow them to classify correctly. FGIC on datasets like CIFAR-100 still has a major research gap. Instead of specifically addressing small inter-class differences and high intra-class similarity, which are major issues in fine-grained tasks, the majority of current methods emphasize increasing overall classification accuracy. Furthermore, the global contextual modeling power required to capture subtle discriminative features across related categories is insufficient in many CNN-based designs. This gap emphasizes the need for more advanced designs, like Vision Transformers, that are better able to represent fine-grained interaction between features and long-range dependencies. To increase feature sensitivity, improve generalization under situations of limited data, and acquire improved discriminative performance across visually comparable classes in CIFAR-100, FGIC research is necessary. The main issue with traditional image classification is the imbalance between intra-class and inter-class variability. When several classes have similar visual features, the model is unable to differentiate between them, leading to category misclassification. Furthermore, even within a comparable learning environment, the stances and various variations in lighting, texture, and background hinder the learning process. These problems indicate that the traditional models struggle to identify subtle features that are essential during classification.

Because these models can generate highlights over small differences across classes, they can improve classification in a few-shot scenario. FGIC makes it possible to differentiate between related classes. It is required to analyze comparable classes with the eyes, such as various bird species or automobile types. Since class lines are typically defined by subtle differences in texture, shape, or color, these are very challenging to execute. Through the use of hard sample mining and comparison-based prototype learning, this work will enhance FGIC using the Vision Transformer Model.

The implementation of the Vision Transformer Model in FGIC is addressed in this research. The goal is to find out if transformer-based models may improve category classification overall and even identify subtle variations in similar classes.

A. Research Gap

FGIC on datasets like CIFAR-100 still has a significant research deficit. Instead of particularly addressing small inter-class differences and high intra-class similarity, which are major issues in fine-grained tasks, the majority of current technologies focus on increasing overall classification accuracy. Furthermore, the global contextual modeling power required to capture subtle discriminative characteristics across related categories is lacking in many CNN-based designs. This disparity emphasizes the need for more sophisticated designs, like Vision Transformers, that are better able to represent fine-grained feature interactions and long-range dependencies.

In order to increase feature sensitivity, the Vision Transformer Model improves generalization under situations of limited data and attains improved discriminative performance across visually comparable classes in CIFAR-100. FGIC research is required.

B. Need for Research

High intra-class and low inter-class variability remain challenges for traditional models in image classification, requiring the development of advanced techniques that focus on tiny significant features. In real-world uses where tiny details are essential, FGIC research greatly improves accuracy. Although Vision Transformer Models have demonstrated good performance in broad classification, their effectiveness in FGIC has not yet been thoroughly investigated. It is essential to address these issues, emphasizing the necessity for advanced techniques that successfully resolve generalized classification problems.

C. Research Question

How can Vision Transformer Models be effectively optimized to improve the accuracy of FGIC to classify similar categories using the CIFAR-100 dataset?

D. Research Objective

The main objectives of this research are:

- To increase classification accuracy for fine-grained picture categories by refining and optimizing a Vision Transformer Model using the CIFAR-100 dataset.
- To examine the model's capacity to differentiate visually similar classes quantitatively using measures including accuracy, precision, recall, and confusion matrix analysis.
- To compare classification outcomes across related categories to examine how transformer-based design affects fine-grained categorization.

Next, the study is organized as follows. Section II is about related work on FGIC, and Section III describes our proposed system architecture. Section IV presents results and discussion. Finally, Section V discusses the conclusions of the work study and future work.

II. Related Work

This section will present an overview of the existing research that is related to Fine-Grained Image Classification and Transformer-based Vision models to determine the base of the proposed approach.

FGIC seeks to differentiate between visually similar subcategories, such as flower species or bird species, where distinguishing characteristics are frequently confined and subtle [7]. The initial approaches had limited flexibility and practicality since they mostly depended on hand-crafted features or part-based models with heavy supervision, such as bounding box and component annotations. Convolutional Neural Networks (CNNs) greatly enhanced feature representation with the development of deep learning; however, many CNN-based techniques continued to treat feature learning and discriminative domain identification as independent methods, leading to inadequate performance for fine-grained tasks.

This research proposed a system for enhancing self-supervised contrastive learning for fine-grained recognition problems called Fine-grained Adaptive Contrastive Learning (FACL) [8]. The method contributes to richer representation learning, which improves feature extraction, by including methods that provide increased sample variety. According to the experimental findings, FACL significantly outperforms conventional contrastive learning techniques. The approach demonstrated its ability to handle complicated visual differences with an accuracy of 64% in applications such as anomaly detection and fine-grained categorization. This emphasizes how important adaptive techniques are for contrastive learning, particularly when it comes to tasks that require identifying subtle differences.

Fine-grained categorization in agricultural disease detection, where categories only differ by minor images and are affected by background noise, humidity, and clarity [9]. The authors' Matrix-based Convolutional Neural Network (M-bCNN), which arranges convolutional layers in a parallel "kernel matrix", improves feature recognition. By expanding data streams, neurons, and link channels without significantly changing parameters, this setup outperforms traditional CNNs in feature representation. These methods enable the network to avoid vanishing gradients and overfitting. They produced a sizable, high-resolution dataset consisting of 16,652 photos of wheat leaves, which was expanded to 83,260 samples. One of the earliest large datasets for the classification of wheat leaf diseases is this one.

A hybrid architecture that combines the benefits of Vision Transformers (Vision Transformer Models) and Convolutional Neural Networks (CNNs) to improve FGIC [10]. The framework has three new modules. The Multi-Scale Image-to-Tokens (MIT) module extracts features at different scales to provide richer visual representations. The Mixed Convolution Feed-Forward (MCF) design enhances the network's ability to learn complex local properties. The Multi-Layer Feature Selection (MFS) method collects the most important attributes from many levels. This technique catches both broad and nuanced visual features by combining CNN's local spatial awareness with the Vision Transformer Model's global context knowledge. By enabling the model to recognize tiny differences between visually similar categories, this combination greatly increases classification accuracy in fine-grained identification tasks where tiny differences matter.

The current study addresses the problem of small inter-class changes in CIFAR-100, based on previous FGIC research that focuses on attention mechanisms and multi-scale feature learning. The proposed approach improves the model's capacity to differentiate closely related categories by utilizing Vision Transformers to capture both local and global images.

III. Materials and Methods

The proposed solution is an automated system designed to classify 100 various image classes efficiently and accurately. To achieve the classification tasks, the suggested system consists of a number of interconnected modules that operate one after the other. The CIFAR-100 dataset was utilized in this experiment. This dataset serves as the study's basis, as the suggested classification framework is trained and analyzed using its images.

Pre-processing is the initial module, which gets the input data appropriate for the model's architectural requirements. The

last module, the model module, receives the processed images and feeds them into the Vision Transformer architecture. The model extracts important characteristics, learns discriminative patterns across classes, and performs classification. This well-structured pipeline guarantees stable training, improved feature learning, and improved overall classification performance.

Fig. 2 describes the flow of the proposed solution. The first phase of the proposed solution is preprocessing. In order to stabilize the learning process, images were enlarged to the required resolution, normalized, and enhanced utilizing augmentation techniques such as random flipping and rotation. These techniques improve the model's ability to generalize, diversify the data, and reduce overfitting.

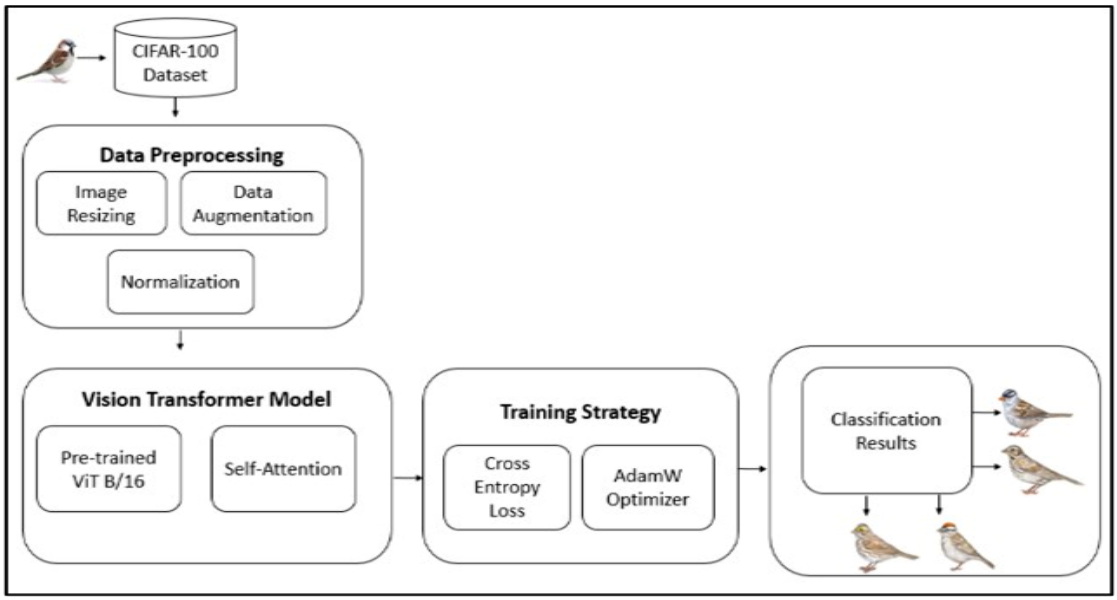

Fig. 2. An overview of the proposed methodology.

A. Image Resizing

Image resizing is one of the pre-processing stages that enhances the Vision Transformer Model by minimizing variations in image size. Vision Transformer Models with larger input sizes, which may divide pictures into meaningful patches, cannot represent the 32x32 pixel images in the CIFAR-100 dataset. This was fixed by up-sampling every image to 224 by 224 pixels. By scaling the pictures, the Vision Transformer Model may readily acquire patch embeddings that have both local and global characteristics. Learning fine details and being able to distinguish subtle visual differences across classes relies on these embedded images. The success of the classification. Fig. 3 shows the input and output images after resizing.

Eq. 1 presents a mathematical definition for this transformation, which involves sampling the original picture at scaled coordinates to determine the pixel intensity at spatial coordinates (x′, y′) in the stretched image. The scaled photos satisfy the Vision Transformer model's input size criteria while retaining structural consistency because of this method of normalizing the spatial dimensions.

Where H and W represent the image's height and breadth, and a pixel's intensity at spatial coordinates (x, y). All input photos are scaled to a fixed resolution of 224*224 in order to guarantee execution with the Vision Transformer Model architecture. The resizing process uses scaling based on the original height H and width W to transfer each pixel in the modified picture I′(x′,y′) to the appropriate place in the original image I(x',y).

$$I'(x', y') = I(x' H' . H, y' W' . W) \quad (1)$$

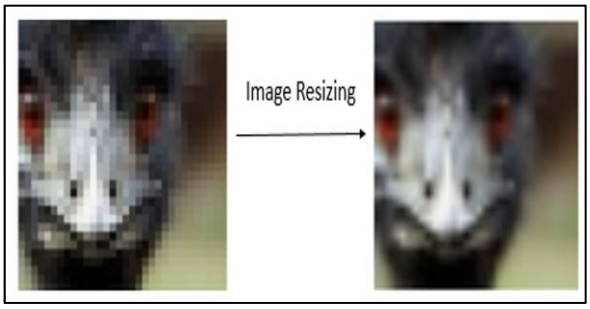

Fig. 3. Image resizing.

B. Data Augmentation

Data Augmentation in the proposed system was performed with torchvision. Data augmentation is a way to improve Vision Transformer frameworks for FGIC. The tiny images in CIFAR-100 data are barely changeable. We implement augmentation approaches to broaden the variety of the training samples. Random rotation, random cropping with padding, random horizontal flipping, and color jittering are common transformations. Image characteristics, including brightness, contrast, saturation, and hue, are affected by such changes. These modifications strengthened the model's resistance to changes in scale, orientation, and illumination.

The Vision Transformer Model was successfully trained utilizing a wider range of visual changes according to this approach. As a result, it improved overall categorization on fine-

grained categories and was better able to capture fine-grained visual distinctions. The data augmentation strategy, which enhances the model's performance on unknown test data and improves the classification rate. Fig. 4 clearly presents the Data Augmentation technique, which improves the performance of the model.

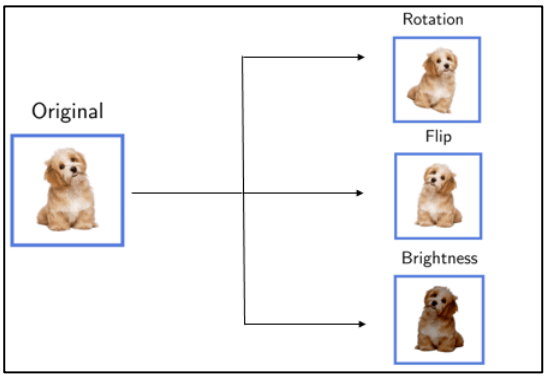

Fig. 4. Original and augmented images.

C. Random Horizontal Flip

A mirror image is produced across the vertical axis by this technique. This transformation is applied to training images at random, often with a 50% chance, in the context of Random Horizontal Flip.

In computer vision, this strategy is frequently used for data augmentation. It enhances a model's capacity for generalization by making it invariant to horizontal orientations, provided that it can accurately identify objects, regardless of whether they face left or right. To put it simply, every pixel along the horizontal axis is mirrored. The Random Flip Image is seen in Fig. 5. Each pixel at location (x', y) in the flipped image corresponds to the pixel at position (W−x−1, y) in the original image, according to Eq. 2.

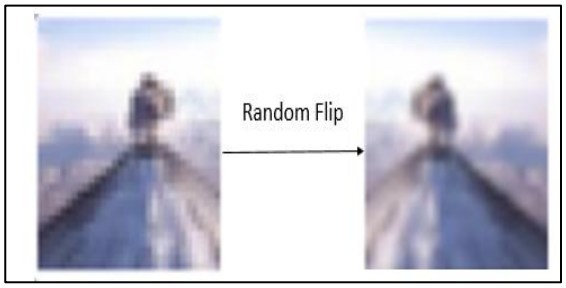

Fig. 5. Random flip image.

The expression I′ (x', y) =I (W−x−1, y) describes the mathematical operation for a horizontal flip of an image. Here, I (x', y) denotes the original image, I′ (x', y) is the transformed image after flipping, and W is the width of the image. Pixels from the left side move to the right, and pixels from the right side move to the left while the vertical position (y) stays the same.

$$I'(x,y) = I(W-x-1,y) \qquad (2)$$

D. Random Rotation

This method is frequently used to significantly enhance the range of training data in computer vision and machine learning. As a result, models become less dependent on variations in object placement and more stable. The algorithm learns to identify items despite their rotation in real-world scenarios by randomly rotating normal images during training. Eq. 3 describes a rotation transformation that is performed on the input image. The new coordinates (x', y') are obtained by rotating each pixel coordinate (x', y) by an angle θ. A typical 2D rotation matrix made up of sine and cosine terms is used to carry out the transformation. By introducing rotational invariance, this technique enhances the model's capacity to generalize to pictures with different angles. The Random Rotation is shown in Fig. 6.

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \qquad (3)$$

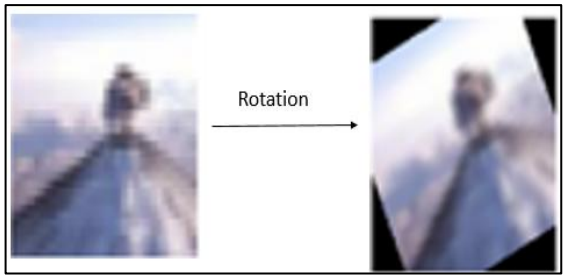

Fig. 6. Random rotation image.

E. Color Jitter Brightness Adjustment

This technique was used to enhance the robustness of image classification models by simulating various lighting conditions. Fig. 7 illustrates the Color Jittering Brightness Adjustment. Eq. 4 describes a brightness adjustment applied to the input picture, where a random brightness offset Δ (b) is added to the original image I to generate the transformed image *I*. To generate a new image, the input image's brightness is randomly changed during this procedure. This fluctuation reflects real-world situations where brightness may vary depending on the setting or time of day. The model's capacity to generalize to new data is enhanced by training on standard images with varying brightness levels, which reduces the model's sensitivity to lighting variations.

$$I' = I + \Delta_{b,} \quad \Delta_b \sim \cup(-\beta, \beta) \qquad (4)$$

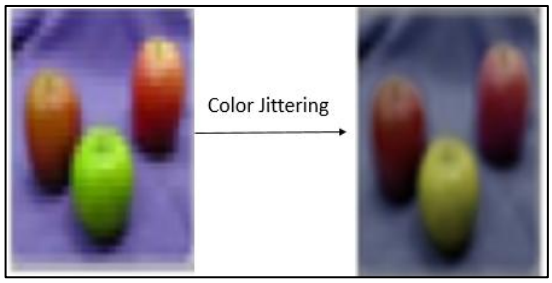

Fig. 7. Input and enhanced image with color jittering.

F. Contrast Adjustment

The operation changes the brightness difference between light and dark areas of an image. This makes features easier or harder to see. Eq. 5 describes a contrast adjustment operation applied to the input image, where the pixel intensities of the transformed image I' are scaled by a factor α around the mean intensity μ. This random contrast adjustment is often used as a data augmentation method in image classification tasks. It helps a model handle different lighting and image quality conditions better. Fig. 8 shows color illumination correction of the input image.

$$I' = \alpha \cdot I - \mu + \mu, \quad \alpha \sim \cup\ (1 - c\ , 1 + c) \quad (5)$$

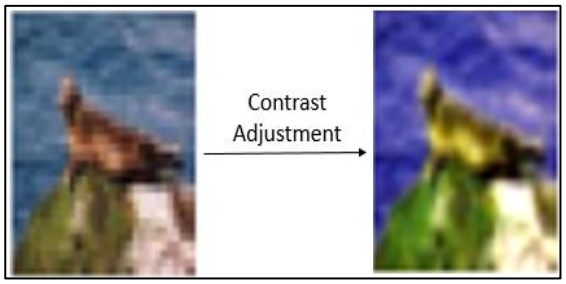

Fig. 8. Color illumination correction of the input image.

G. Normalization

This is the second pre-processing step. Images were resized, and pixel values were scaled so that each color channel's mean value and standard deviation were 0.5. Eq. 6 normalizes the input values to a fixed range, usually between -1 and 1. It helps to speed up and stabilize the training process. Normalization ensures that the pre-trained Vision Transformer model predicts the input distribution. Better convergence and performance assurance result from this. Fig. 9, which displays the Enhanced Image after Normalization, illustrates the difference gained after applying the augmentation. By eliminating internal variance shift, normalization contributes to more effective and efficient learning during training. This process is typically subject to the normalization formula of the standard score (z- score) of each channel of an image (Red, Green, Blue) [Eq. (6)].

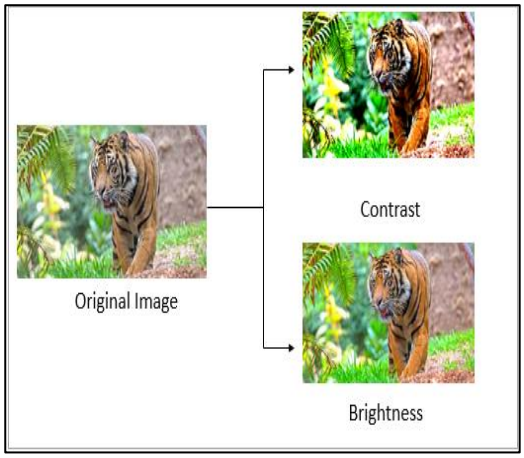

Fig. 9. Original and enhanced images.

$$X' = \frac{X - \mu}{\sigma} \quad (6)$$

where, X represents the original pixel value, μ is the mean, and σ is the standard deviation. The mean and standard deviation values used are both 0.5 for each color channel.

H. Fine-Grained Image Classification

The Fine-Grained Image Classification Model, utilizing the Vision Transformer Model, is employed in the proposed method. The strategy is based on the Vision Transformer architecture, which has shown outstanding outcomes in various types of image classification tasks. Unlike traditional convolutional neural networks, the Vision Transformer model employs self-attention processes to identify global characteristics and long-range interactions within the input image. The main architecture used in this study is the Vision Transformer Model-Base-Patch16-224 timm (PyTorch Image Models) library. This approach divides the image provided into many non-overlapping patches. These patches are then passed through a typical transformer encoder after being encoded as fixed-length vectors. Each of the 12 transformer layers in the Vision Transformer Model-Base-Patch16-224 contains 12 attention heads and 768 hidden dimensions.

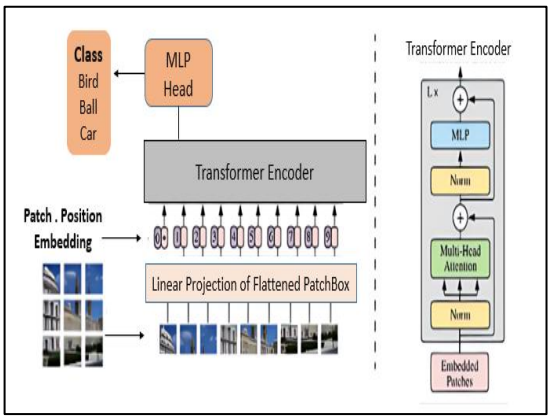

Fig. 10. Vision transformer architecture [11].

Fig. 10 illustrates that the Vision Transformer Model works with images by splitting them into patches of a fixed size. The patches are flattened and transformed into a numerical embedding representing the visual content of the patch. These embeddings are then sent into the transformer encoder together with positional encodings and a learnable class token. The encoder uses feed-forward layers with residual and normalization connections as well as multi-head self-attention. This structure helps the model recognize spatial data in images by generating significant global relationships between the patches.

A Multi-Layer Perceptron (MLP) head receives the class token's final output and is used to perform the classification task. The Vision Transformer Model can effectively capture long-range connections with this framework. The model is effective, particularly when handling recognition of images and fine-grained classification tasks, since the transformer attention mechanism allows the model to learn to focus on tiny images. Recognizing related groups of objects is essential, particularly when a collection includes sensitive classifications. The backbone may be used to save training time and enhance the

model's generalization. It makes it possible to determine tiny variations across classes in fine-grained visual datasets.

The proposed solution for FGIC:

1) The Vision Transformer (Vision Transformer Model) model uses ImageNet-pretrained weights to improve performance through transfer learning, and it was modified for the CIFAR-100 classification problem. Faster convergence and increased accuracy are made possible by this initialization, which offers a solid foundation of learnt visual features, especially in fine-grained classification settings with less training data. The technique successfully addresses the problem of data scarcity by transferring rich visual information to the target domain. Furthermore, the framework uses PyTorch to provide effective computing in both CPU and GPU settings, dynamically assigning model parameters to the available hardware.

2) The pre-processed and augmented CIFAR-100 dataset is used for training after the Vision Transformer (Vision Transformer Model) has been initialized and configured. Using a cross-entropy loss function appropriate for multi-class tasks, model parameters are optimized to minimize classification errors across 100 object categories. For transformer-based architectures, the optimization process uses the AdamW optimizer, which offers better weight regularization than standard Adam. A learning rate of 3e-5 guarantees gradual convergence, while a weight decay of 0.01 aids in reducing overfitting and enhancing generalization. Furthermore, the learning rate is gradually reduced using a cosine annealing learning rate scheduler, which facilitates smoother convergence and lowers the possibility of becoming stranded in local minima.

3) Monitor loss and accuracy metrics during training. This helps the model develop useful visual characteristics. To ensure effective learning, hyperparameters were adjusted as required. Once the training is completed, the Vision Transformer will be capable of generating good feature representations that allow the system to perform correct classification in the fine-grained disjointed categories in the CIFAR-100 dataset.

4) After training, the Vision Transformer Model's ability to generalize is determined using the test split of the CIFAR-100 dataset, with classification accuracy functioning as the primary measure. A confusion matrix is examined to provide a deeper understanding of performance. This analysis highlights misclassifications and reveals class-wise prediction patterns, particularly among visually similar categories with overlapping attributes like texture, color, and shape. This analysis helps in highlighting the model's problems in fine-grained parameters and offers recommendations for additional optimization, such as enhancements to data augmentation, class balancing, and architectural modifications, which will ultimately improve the model's capacity to differentiate closely related classes and boost overall performance.

IV. Results and Evaluation

The proposed Vision Transformer-based method for FGIC is evaluated on the CIFAR-100 dataset, which shows how well it learns discriminative visual characteristics and achieves consistent generalization performance. To achieve a thorough evaluation, the model was evaluated using a variety of performance indicators, including test accuracy, precision, recall, F1-score, and confusion matrix analysis. Accuracy, macro precision, macro recall, and macro F1-score were used to assess the recommended Vision Transformer Model's performance on the CIFAR-100 dataset. The model demonstrated good prediction abilities across 100 item categories, with an overall classification accuracy of 89.68% on the test set. The findings utilizing Vision Transformer Model B/16 on CIFAR-100 are shown in Fig. 11.

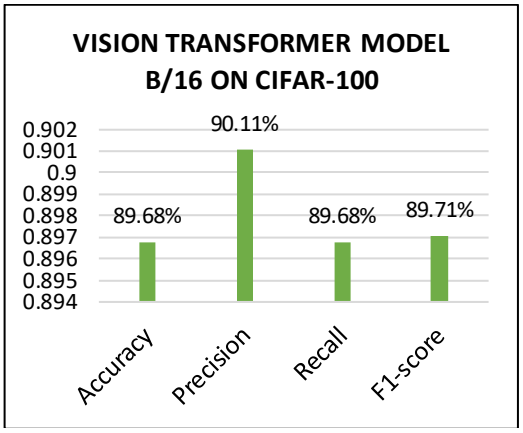

Fig. 11. Evaluation of proposed solution using vision transformer model B/16 on CIFAR-100.

By evaluating both class-wise performance and overall prediction accuracy, these metrics offer a comprehensive picture of the model's performance. Combining accuracy with precision, recall, and F1-score provides a broader overview of the model's performance in recognizing certain categories over the whole dataset.

A. Analysis of Test Accuracy

The Vision Transformer Model's generalization performance on the CIFAR-100 dataset can be enhanced by analyzing test accuracy over epochs. The model shows a sharp increase in test accuracy in the early epochs. This sharp rise indicates that the pretrained Vision Transformer Model backbone quickly adapts to the CIFAR-100 classification task and learns meaningful feature representations within a few training iterations. In transfer learning circumstances, where pretrained weights speed up learning, early convergence is frequently seen. Overall, the test accuracy trend shows that the model reaches its best generalization performance in the early epochs and continues to provide reliable outcomes beyond that. The model test accuracy results are displayed in Fig. 12. The model achieves about 89.68% test accuracy on CIFAR-100, demonstrating continuous generalization ability across epochs.

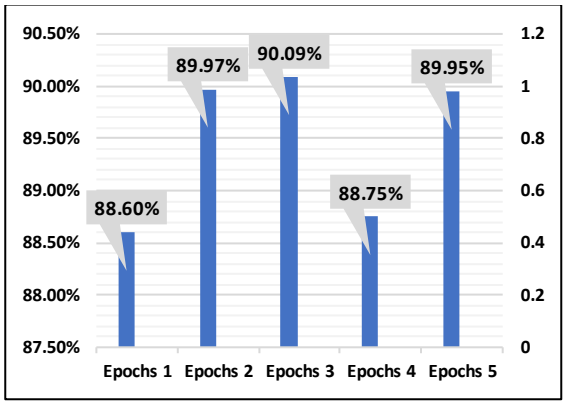

Fig. 12. Model test accuracy results.

B. CIFAR-100 Per-Class Precision Results

The proposed Vision Transformer Model's per-class accuracy in all 100 CIFAR-100 dataset classes. Most classes have high accuracy values, which often fall between 0.85 and 1.00, meaning that the model is typically accurate when predicting a certain class. This indicates that the model has a high capacity to reduce false positive predictions across various item types. For the majority of classes, consistent predictive reliability is shown by the very small range in bar heights. However, other classes show significantly better accuracy, with values lying closer to 0.70–0.80.

This consistency supports the effectiveness of the Vision Transformer architecture in handling multi- class image recognition on CIFAR-100. Fig. 13 shows that the per-class results typically show variability across different categories, indicating that some classes achieve higher precision.

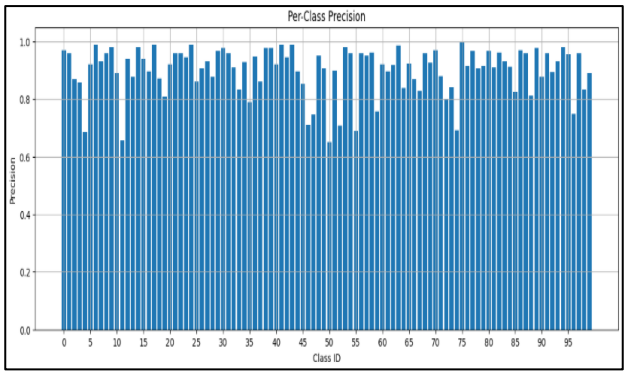

Fig. 13. Per-class precision results.

C. CIFAR-100 Per-Class Recall Results

The proposed Vision Transformer model's recall performance for each of the 100 CIFAR-100 classes is shown in the per-class recall graph. The majority of classes have high recall values, usually between 0.85 and 1.00, which suggests that the model correctly identifies a significant portion of real examples that correspond to each class. This shows how well the model can reduce false negatives and accurately gather relevant data across a variety of object classifications. Stable detection performance across the dataset is shown in the bars' overall consistency. Recall levels for a few classes are significantly lower, falling closer to around 0.70–0.80. The per-class recall is shown in Fig. 14.

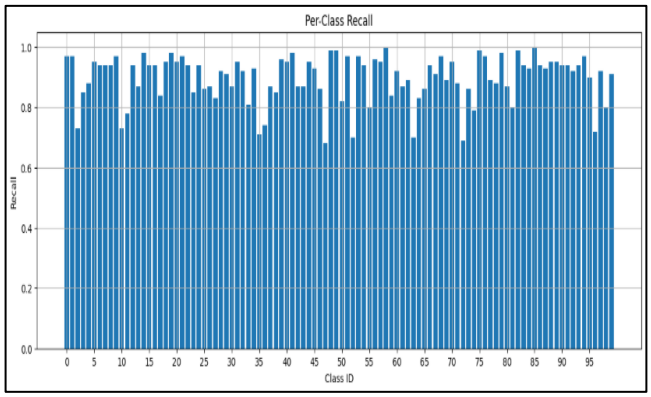

Fig. 14. Per-class recall results.

Overall, the distribution demonstrates how effectively the Vision Transformer-based architecture handles challenging multi-class image classification tasks on the CIFAR-100 dataset.

D. Confusion Matrix Analysis

The confusion matrix displays a strong diagonal pattern, indicating that the majority of samples are properly identified, providing a deeper understanding of class-wise performance beyond total accuracy. This illustrates how well the model captures significant visual patterns and how resilient the taught features are.

Despite this, the model performs well across the majority of classes, and the small number of mistakes indicates that misclassifications are not common. All things considered, the attention-based Vision Transformer (Vision Transformer Model) successfully captures both local and global features, producing dependable and balanced classification performance with significant room for improvement through improved feature refinement. Fig. 15 provides a class-by-class evaluation of the proposed model's prediction performance.

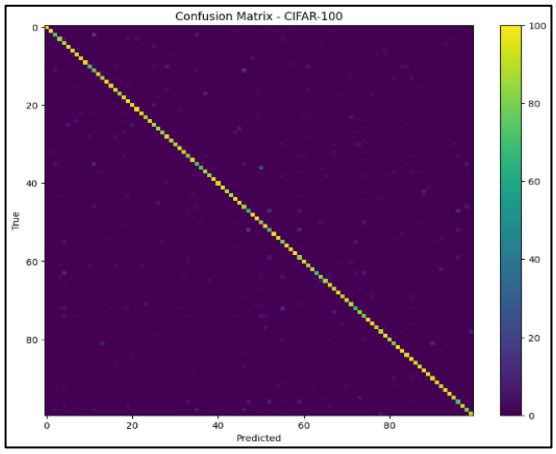

Fig. 15. Confusion matrix of predicted classes.

A major problem in fine-grained picture classification, because of minute variations in form, texture, and color, is that, although some misclassifications occur in off-diagonal regions, they are primarily limited to classes with similar visual features.

In datasets like CIFAR-100, where low resolution and closely related categories make classification challenging, this type of confusion is especially visible.

V. Comparative Analysis with Existing Research

Using the CIFAR-100 dataset, three sample image classification and few-shot learning techniques are compared in this section. Model architecture, learning methodology, and applicability for the CIFAR-100 dataset FGIC difficulties are the main areas of comparison. On the CIFAR-100 dataset, existing methods have shown excellent performance on challenging picture classification tasks. In order to increase recognition when training data is limited, several techniques concentrate on improving feature representation by utilizing attention processes and multi-branch structures to capture subtle correlations among visual characteristics. Other strategies focus on enhancing model generalization by using structured regularization techniques that hide spatially correlated areas in feature maps to avoid overfitting and enhance classification performance on multi-class datasets. Fig. 16 shows the graphical representation of the comparative analysis of the proposed solution with existing research on the CIFAR-100 Dataset.

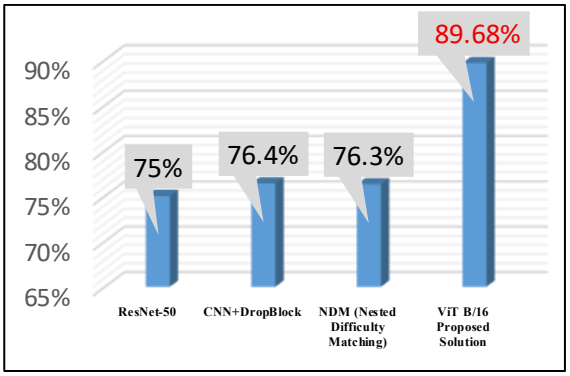

Fig. 16. Comparative analysis with existing research on CIFAR-100.

Additionally, dataset distillation techniques have been proposed to generate compact yet informative synthetic datasets by prioritizing difficult training samples and aligning them with different stages of the learning process, enabling models to achieve performance close to full-dataset training. However, many of these approaches rely on convolutional neural network backbones and require additional modules to enhance feature learning. In comparison, transformer-based architectures such as the Vision Transformer Model naturally capture global relationships between image patches through self-attention mechanisms, making them particularly suitable for FGIC, where accurate recognition depends on identifying subtle differences between visually similar categories.

VI. Conclusion and Future Work

Using the CIFAR-100 dataset, this study effectively developed and examined a Vision Transformer-based framework for FGIC. The proposed framework performed well in macro-level precision, recall, and F1-score, yielding stable and reliable results across all 100 categories, with an accuracy of 89.68%. The overall results highlight the potential of the Vision Transformer Model for FGIC despite obstacles like the dataset's low resolution and high computing needs. The findings imply that transformer topologies can be a reliable and effective method for applications requiring complex and subtle image distinction.

Future studies will expand the assessment to benchmark fine-grained datasets, including FGVC-Aircraft, Stanford Cars, and CUB-200-2011, in order to validate the suggested model more thoroughly in fine-grained image classification, even though the Vision Transformer showed strong performance on the CIFAR-100 dataset. In order to take advantage of both local and global feature representations, future research may potentially look at hybrid architectures that mix convolutional neural networks with vision transformers. Additionally, using few-shot or self-supervised learning techniques might lessen the need for sizable labeled datasets and enhance the model's capacity for generalization in practical situations.

Acknowledgment

The authors extend their appreciation to the Arab Open University for funding this work.

MRAE: Multi-Resolution Attention Ensemble with Hybrid CNN–Transformer Fusion for Breast Ultrasound Classification

Hemin Kareem Azeez Alshateri, Ahmed Harbaoui
Department of Computer Science, King Abdulaziz University, Jeddah, KSA

***Abstract*—Breast ultrasound images can be classified as benign, malignant, and normal. Due to the imbalanced distribution of classes in breast ultrasound images, intra-class heterogeneity of lesions, and ultrasound artifacts like speckle noise, classification of breast ultrasound images remains a challenging problem. In this paper, we present MRAE, a hybrid architecture with a DenseNet121 convolutional encoder and two transformer encoders (ViT-Base and DeiT-Base-Distilled). These branches are run in parallel with input sizes of 192×192 pixels, 224×224 pixels, and 256×256 pixels, respectively. The learned feature representations from these branches are fused using a cross-attention block and combined using learnable ensemble weights. Focal loss with deep supervision is used during training along with CutMix regularization, Weighted Random Sampling, and Cosine Annealing. We perform experiments using 10-fold stratified cross validation on the benchmark BUSI dataset (780 Images). MRAE achieves an average accuracy, macro F1-score, and macro recall of 93.72%, 94.25%, and 95.02%, respectively, across all cross-validation folds. The ResNet50 baseline achieves accuracy, F1-score, and recall of 90.64%, 91.36%, and 91.62% across all folds. We show that MRAE has significantly lower standard deviations across cross folds, indicating better stability. Our method provides evidence that breast ultrasound images can be classified accurately and reliably in a multi-resolution attention fusion network for use in clinical breast cancer screening.**

***Keywords*—Breast ultrasound classification; multi-resolution learning; CNN–Transformer fusion; cross-attention ensemble; Vision Transformer (ViT)**

I. Introduction

Breast cancer is one of the most common and deadly cancers among women. An early and accurate diagnosis of breast cancer allows physicians to treat the patient timely which can increase the survival rate [1]. Breast ultrasound is one of the most commonly used techniques for diagnosis because it is readily available, inexpensive [2], and does not use ionizing radiation [3]. Manual interpretation of breast ultrasound images is difficult due to their subjective nature and could vary from observer to observer [4]. Automated classification of breast ultrasound images using deep learning can be used as assistance for the clinicians to avoid misclassification [5].

CNNs have achieved promising results in medical image analysis by effectively encoding local texture and spatial context information [6]. Recently, ViTs and their derivatives have exhibited a complementary capability of encoding information using self-attention to extract long-range global dependencies [7]. However, previous methods are mostly single-model frameworks that use a fixed-resolution input. Due to this limitation [8], the learned representations often lack richness and diversity. In addition, class imbalance is an issue not fully addressed in prior works [9]. Since malignant and normal findings are underrepresented compared to benign findings in most clinical datasets, class-imbalanced learning can result in classifiers that are biased towards the majority class [10].

Most methods cannot fully leverage multi-scale feature representations and also fail to sufficiently incorporate a cross-architecture feature fusion scheme that emphasizes more robust features [11]. In addition, they do not address class imbalance issues presented in small-to-medium sized clinical datasets. Furthermore, consistency of model performance across heterogeneously partitioned data is not well explored [12].

To fill these shortcomings, we introduce MRAE (Multi-Resolution Attention Ensemble), a mixed CNN-Transformer model that ensembles DenseNet121, ViT-Base, and DeiT-Base learning at different resolutions through cross-attention layers and learnable ensemble weights. Complemented with focal loss with auxiliary deep supervision, CutMix augmentation, and weighted sampling to alleviate class imbalance, MRAE attains new state-of-the-art performance in terms of accuracy (93.72%), F1-score (94.25%), and recall (95.02%) with significantly enhanced cross-fold consistency over the ResNet50 baseline.

II. Related Work

Efforts have been made recently to classify breast ultrasound images automatically. Methods such as fine-tuning pre-trained CNN models and ensembles of CNN and Transformer models have been explored. Kormpos et al. [13] reviewed several deep learning models for breast tumor classification with transfer learning on BUSI dataset. The authors used a cascaded classification pipeline and found that vision Transformer models that use an attention mechanism can be used as an alternative to popular CNN models. Limitations, including model explainability and high computational resource requirements, remain. Architectures like InceptionV3 provide competitive baselines but are limited by being single models operating at a fixed input resolution.

To overcome the problem of local and global features complementarity, Asif et al. [14] designed a feature fusion-based deep learning model consisting of MobileNetV2 and DenseNet121 coupled with attention mechanisms to perform benign-malignant classification on a private clinical dataset of 2171 images, as well as the public BUSI dataset, where they

were able to reach an AUC of 0.9834 on the public benchmark. Results showed that fusion of advanced features coupled with attention mechanisms drastically outperformed CNN single-architecture baselines and surpassed the diagnostic performance of radiologists with varied levels of experience. However, this DL model is a binary classifier and does not account for the clinically relevant three-class setting that includes normal tissue.

In similar attempts to learn more explainable multi-scale representations, Saini et al. [15] proposed a variational mode decomposition-guided CNN architecture for breast lesion classification in ultrasound images, using 2D-VMD [34] as a key component to learn self-explanatory lesion-specific boundary and texture maps to drive a mixed pooling and attention-guided CNN model for breast ultrasound lesion classification with comparable accuracy and intrinsic explainability of learned features on the BUSI dataset [15]. However, this method does not make use of a transformer backbone, which may have higher global receptive fields for modeling long-range context. On the other hand, Yıldırım et al. [16] recently proposed a ViT-based ensemble learning framework for three-class breast ultrasound classification using the BUSI dataset. ROI segmentation is performed on the training set images along with Albumentations-based image augmentation before being fed into multiple transformer backbones that are ensembled by simple averaging to boost performance. The authors show that ensembling yields better classification performance with higher accuracy, precision, and recall than individual transformers. However, this method still does not leverage multi-resolution input or cross-attention CNN-transformer fusion schemes and does not explicitly deal with class imbalance via loss-weighting.

III. Proposed Methodology

In this section, we will introduce all the details of our MRAE framework, including the dataset, preprocessing pipeline, our proposed model and training strategy. Each step is carefully designed to tackle one of the aforementioned challenges, including class imbalance problem, lack of multi-resolution learning and lack of cross-architecture feature fusion for breast ultrasound classification. The methodology has been visualized in Fig. 1.

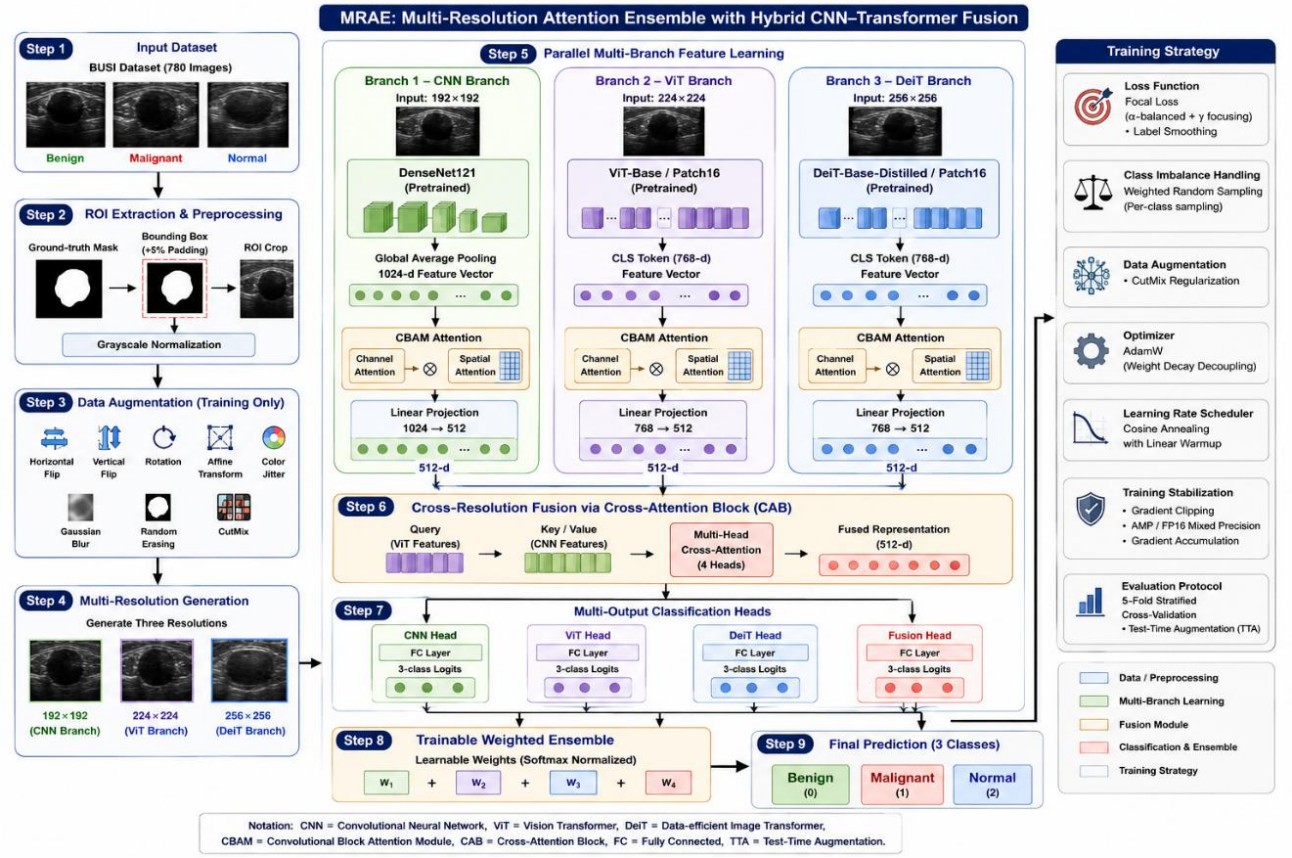

Fig. 1. Flowchart for the proposed methodology.

A. Dataset

We use the Breast Ultrasound Images (BUSI) dataset which is a commonly used public benchmark for breast lesion classification and segmentation tasks [17]. The dataset consists of 780 grayscale ultrasound scans of breasts acquired from 600 female patients. The images are categorized into three classes: benign (437 images, 56.0%), malignant (210 images, 26.9%) [18] and normal (133 images, 17.1%). Each scan has one or more pixel-wise segmentation masks provided which mark the region occupied by lesion/s. The dataset, therefore contains precise ground-truth segmentation masks suitable for supervised training. Images with more than one mask represent overlapping lesions acquired from the same scan. In 18 benign cases, there

are multiple masks. In addition, the width and height of images also vary due to natural variation of ultrasound scans. All images are resized to the longest side of 916 pixels and saved as RGB images. Width of the images varies from 323 pixels to 916 pixels. Height of the images varies from 393 pixels to 716 pixels. The BUSI dataset has a high-class imbalance with benign category having over half the data. There are three times as many benign cases than normal cases (the least prevalent class). Class imbalance is problematic since most classification models are biased towards the majority classes. In medical applications like this where the negative classes (malignant and normal) are very important, class imbalance can lead to low sensitivity for these categories. Therefore, overcoming class imbalance was one of the design considerations while developing our proposed framework. We mitigate this problem by using weighted sampling during training. We also employ focal loss as our loss function as it performs well on unbalanced datasets, as shown in Table I [19].

TABLE I. BUSI DATASET SUMMARY

Category	Number of Images	Percentage	Annotation Type
Benign	437	56.0%	Pixel-level segmentation mask
Malignant	210	26.9%	Pixel-level segmentation mask
Normal	133	17.1%	No mask (no lesion)
Total	780	100%	—
Patients	600	—	—
Female patients only	—	—	—
Image Width Range	323–916 px	—	Grayscale (stored as RGB)
Image Height Range	393–716 px	—	Grayscale (stored as RGB)
Multi-mask Cases	18 (benign)	2.3%	Multiple lesions per scan

B. Preprocessing and Data Preparation

Input images are preprocessed using a multi-step pipeline before standardization and feeding them into the model. The aim is to present the model with data that ensures comparability and clinical meaningfulness of features. Benign and malignant scans undergo region-of-interest (ROI) extraction based on their segmentation mask [20]. The bounding box is calculated based on each lesion's mask and expanded by 5% to include surrounding tissue. This allowed us to decrease background noise while maintaining clinically relevant perilesional information. Normal scans are not annotated with any lesion and therefore are not cropped. In cases where multiple masks were present for one image, all masks were combined using element-wise maximum to generate a lesion mask that contains all lesions. Then, images undergo resizing to three different resolutions at once: 192 × 192 pixels for the CNN branch, 224 × 224 pixels for the ViT branch and 256 × 256 pixels for the DeiT branch [21,22]. This allows each branch of the network to extract slightly different features based on varied resolutions. Training augmentation is then applied individually per resolution with random horizontal and vertical flip (probability, $p = 0.5$), random rotation ($\pm 20°$, $p = 0.5$), and finally random application of Gaussian noise or Gaussian blur ($p = 0.3$). Images are then normalized (mean = 0.5, std = 0.5) for each channel. At validation and inference time, no augmentations were used besides resizing and normalization. We used Weighted Random Sampler for training to ensure that classes are proportionally sampled for every mini-batch, as shown in Table II.

TABLE II. PREPROCESSING PIPELINE SUMMARY

Step	Operation	Parameters	Applied To
ROI Extraction	Bounding box from segmentation mask	5% buffer on each side	Benign & Malignant only
Multi-mask Merging	Element-wise maximum of all masks	—	Multi-lesion cases only
Resize — CNN Branch	Bilinear resizing	192 × 192 px	All images
Resize — ViT Branch	Bilinear resizing	224 × 224 px	All images
Resize — DeiT Branch	Bilinear resizing	256 × 256 px	All images
Horizontal Flip	Random flip	p = 0.5	Training only
Vertical Flip	Random flip	p = 0.5	Training only
Random Rotation	Rotation	±20° (p = 0.5)	Training only
Noise / Blur	Gaussian noise or blur	p = 0.3	Training only
Normalization	Mean & Std normalization	Mean = 0.5, Std = 0.5	Training & Validation
Weighted Sampling	Inverse-frequency class weights	Per-class	Training only

C. MRAE Model Architecture

TABLE III. MRAE ARCHITECTURE COMPONENTS

Component	Backbone / Module	Input Resolution	Output Dimension	Pretrained
CNN Branch	DenseNet121	192 × 192 px	1024-d	ImageNet
ViT Branch	ViT-Base / Patch16	224 × 224 px	768-d	ImageNet
DeiT Branch	DeiT-Base-Distilled / Patch16	256 × 256 px	768-d	ImageNet
CNN Projection	Linear layer	1024-d	512-d	—
ViT Projection	Linear layer	768-d	512-d	—
DeiT Projection	Linear layer	768-d	512-d	—
Cross-Attention Block	Multi-head attention (4 heads)	ViT (Q), CNN (K, V)	512-d	—
Residual + LayerNorm	Post-attention normalization	512-d	512-d	—
Classification Heads	Linear (×3, one per branch)	512-d	num_classes = 3	—
Ensemble Fusion	Learnable softmax weights (w1, w2, w3)	3 × logits	Final prediction	—
Baseline (ResNet50)	ResNet50 + Dropout(0.3) + Linear	224 × 224 px	num_classes = 3	ImageNet

Table II depicts an overview of our suggested MRAE architecture, which consists of three branches with varying input

resolutions. These branches are complementary and are fused together using cross attention and learnable ensemble weights. The CNN branch consists of a pretrained DenseNet121 model used as a convolutional backbone with the classifier head removed and replaced with an identity layer. Features from the final dense block are taken after adaptive average pooling is applied, forming a 1024-dim embedding from a 192×192 input. The vision transformer branch utilizes a pretrained ViT-Base/Patch16 model. This gives a 768-dim class embedding of a 224×224 sized input. Lastly, our third branch features a pretrained DeiT-Base-Distilled/Patch16 transformer with flexible image sizes enabled. This forms our 768-dim feature vector from a 256×256 input. Since each ViT-B/16 backbone contains approximately 86 million trainable parameters, the complete MRAE model contains approximately 260 million trainable parameters in total, making it substantially larger than conventional CNN-based architectures while enabling richer multi-resolution feature learning.

Embedding space using three linear projection layers. The Cross Attention Block (CAB) then attends to the convolutional features from the CNN branch using the projected ViT features as a query, with the CNN projected features used as a key and value. This operation consists of a four-head multi-head attention module followed by a residual connection and Layer Normalization. This allows the transformer model to attend to spatially relevant features from the convolutional branch. The three branches each have their own classification head that provides individual class logits. The ensemble prediction is then made by taking a softmax over the weighted sum of the three branches. These weights are learnable and initialized to be equal, and trained end-to-end with the rest of the network. The 192×192, 224×224, and 256×256 inputs are chosen so that the image representations learned at each scale provide a complementary, multi-scale view of the US imagery. The features learned at lower resolutions force the model to represent the information contained in small regions of the image (local textures, speckle distribution, edges of lesions). In contrast, representations learned at higher resolutions help the model retain contextual information about the larger-scale structures and the spatial relationships between them. Features learned at 224×224 resolution fall naturally in between those learned at 192×192 and 256×256 resolution. DenseNet121 provides the best ability to extract local texture features with limited data by taking advantage of its highly redundant feature reuse. ViT-Base is able to learn global image dependencies since self-attention is able to model global dependencies (something CNNs are not able to do). Finally, DeiT-Base-Distilled allows for more data-efficient learning and a more stable training process. Its inherent knowledge distillation strategy allows it to better generalize to smaller datasets like BUSI.

D. Training Procedure and Evaluation Protocol

The MRAE model was optimized with a cross-entropy loss, also known as Focal Loss, with class-balancing weights [1.0, 2.0, 1.0] for the benign, malignant, and normal classes, respectively, and focal loss hyperparameter gamma of 2.0. Classification loss contributions from each individual branch, known as auxiliary loss terms, were added to the ensemble objective. Total loss during training was a combination of the ensemble focal loss plus 0.3 times each branch-level loss. These auxiliary losses apply deep supervision to ensure each branch learns independent discriminative features. Training employed CutMix augmentation with alpha=1.0 and probability p=0.5. Mixed pairs of training samples and their labels were linearly interpolated with a mixing coefficient sampled from Beta(1,1) and applied identically to all 3 resolutions. AdamW optimization was performed with a learning rate of 2×10^{-4}, weight decay of 1×10^{-4}, cosine learning rate scheduling across 50 epochs. Gradient accumulation over 4 steps was used to reach an effective batch size of 16 (with a physical batch size of 4), as shown in Table IV.

TABLE IV. TRAINING CONFIGURATION AND EVALUATION PROTOCOL

Setting	MRAE	Baseline (ResNet50)
Optimizer	AdamW	AdamW
Learning Rate	2×10^{-4}	1×10^{-4}
Weight Decay	1×10^{-4}	1×10^{-4}
LR Scheduler	Cosine Annealing (T_max = 50)	Cosine Annealing (T_max = 15)
Max Epochs	50	15
Early Stopping Patience	8 epochs	4 epochs
Physical Batch Size	4	4
Effective Batch Size	16 (4 accumulation steps)	16 (4 accumulation steps)
Mixed Precision	AMP / FP16	AMP / FP16
Loss Function	Focal Loss (γ = 2.0)	Focal Loss (γ = 2.0)
Class Weights (α)	[1.0, 2.0, 1.0]	[1.0, 2.0, 1.0]
Auxiliary Branch Loss	0.3 × (CNN + ViT + DeiT losses)	Not applicable
CutMix Augmentation	p = 0.5, Beta(1,1)	Not applied
Test-Time Augmentation	Original + horizontal flip (averaged)	Original + horizontal flip (averaged)
Evaluation Protocol	10-fold Stratified Cross-Validation	10-fold Stratified Cross-Validation
Primary Metrics	Accuracy, Macro F1, Macro Recall	Accuracy, Macro F1, Macro Recall
Best Model Selection	Highest validation F1 per fold	Highest validation F1 per fold

Automatic Mixed Precision training was used. Early stopping with patience of 8 epochs was used to restore the checkpoint with the best validation F1 score. Test-time augmentation averaged the predictions between the original image and the horizontal flip. Training was performed with 10-fold Stratified Cross-Validation. Accuracy, macro-averaged F1-score, and macro-averaged recall are reported as mean ± standard deviation across folds.

IV. RESULTS AND DISCUSSION

We report the quantitative experimental results of our proposed MRAE framework against the baseline ResNet50 using 10-fold stratified cross validation in this section. Results are discussed in terms of Accuracy, Macro F1-score, and Macro recall metrics. We also provide results in terms of per fold comparison, distributions, and stability for better understanding.

A. Dataset Class Distribution Analysis

The BUSI dataset consists of a total of 780 images, out of which Fig. 2 shows the ratio of Normal, Benign, and Malignant cases, respectively. In order of frequency from highest to lowest they are comprised of: 437 images of Benign cases (56.0%), 210 images of Malignant cases (26.9%), and finally 133 images of Normal cases (17.1%). The dataset is unbalanced by design to mimic a similar distribution to how lesions present themselves during clinical breast ultrasound screening with benign pathologies being significantly more common than malignant findings or normal anatomy.

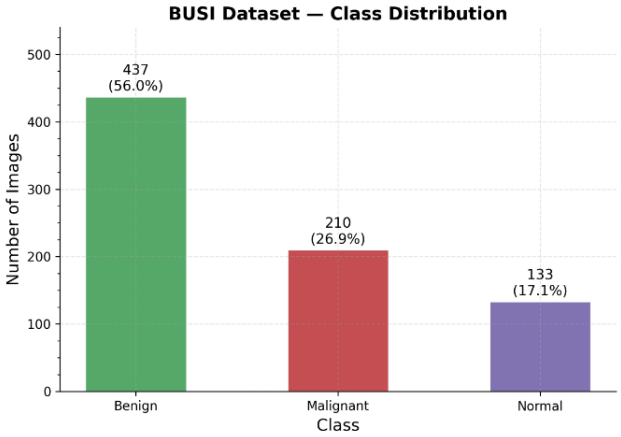

Fig. 2. BUSI dataset class distribution by category.

It should be noted that the scale of imbalance between majority and minority classes in the BUSI dataset, with benign and normal cases, respectively, is roughly 3.3 to 1. This ratio is enough to cause severe training bias towards the majority class if special considerations are not taken. For instance, training a model on imbalanced data will likely lead to very high accuracy due to simply predicting the majority class; however, the recall for both Malignant and Normal classes would be significantly lower. This would be devastating for cancer detection models as we would miss opportunities to correctly identify patients with cancer which would lead to mortality.

This is why MRAE uses a Weighted Random Sampler for loading batches of data that are balanced with respect to class during training and employs Focal Loss with a high-class weight of 2.0 for the Malignant class. These interventions allow for gradient contributions from images of minority classes to be boosted during model training which we can see payoff when looking at the macro-average recall of 95.02%.

B. Per-Fold Accuracy Analysis

The classification accuracy on each fold of the ten stratified cross-validations of the ResNet50 baseline and the proposed MRAE model is shown in Fig. 3. In most cases, MRAE performs better or equivalent to the baseline and the difference between the models can be visualized by the area between their respective curves favoring MRAE for most of the ten folds. MRAE's highest accuracy is achieved in Fold 3 with an accuracy of ≈0.990. In this fold, the baseline drops to 0.923 which is one of the largest differences between the models in a single fold. Other large improvements by MRAE can be seen in Folds 1, 2, 6, and 8. In each of these folds the baseline accuracy decreases significantly, most notably in Fold 6 to ≈0.822, where MRAE does not decrease as much and hovers around 0.923.

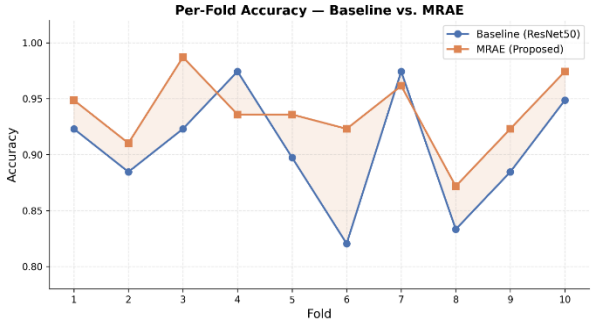

Fig. 3. Per-Fold Accuracy: Baseline vs. MRAE.

This gives MRAE a rebound of over 0.1. The lowest accuracy achieved by each model is in Fold 8 with MRAE ≈0.872 and the baseline ≈0.834. Again, MRAE does not decrease as much as the baseline. The models are roughly equal in Folds 4 and 7 with the baseline outperforming MRAE for a very short interval. In these folds, they each achieve some of their highest accuracies which could be due to them containing samples that are more uniformly distributed among the classes or are easily distinguishable from other classes allowing the baseline model to achieve similar performance to MRAE. However, this is not the case for majority of folds. On average, MRAE achieved an accuracy of 93.72% while the baseline model achieved 90.64%.

C. Per-Fold Macro F1-Score Analysis

Fig. 4 shows how ResNet50 and our MRAE perform on each of the ten stratified folds, in terms of their per-fold macro-average F1-score. The macro averaged F1-score is chosen here instead of accuracy due to the imbalance in the dataset (BUSI). This metric computes the F1-score for each class individually, and then takes the average. These scores favor models that generalize better to each class individually as opposed to simply predicting the majority class. Since the dataset is skewed towards normal (80%), research (10%) and pathologic (10%) classes, we felt that using macro averaged F1-score would be the best indicator of performance on unseen data as would be expected in a clinical setting.

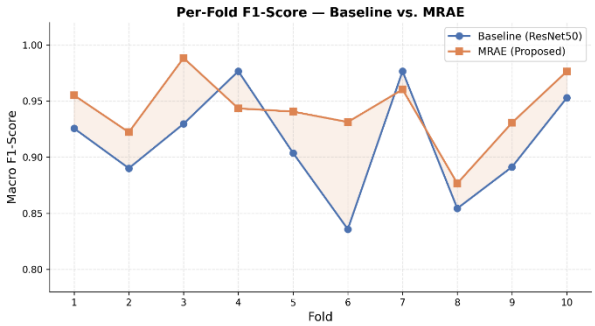

Fig. 4. Per-Fold Macro F1-Score: Baseline vs. MRAE.

As can be seen in Fig. 4, MRAE outperforms the baseline in most folds. It can be seen that there is a significant positive difference between the two curves (visualized by the difference between the lines and the shaded region between them). For

example, for Fold 3 MRAE is able to achieve a macro F1-score of ≈ 0.990 whereas the baseline is only able to achieve ≈ 0.930.

Whereas Fold 6 is the lowest that the baseline performed, with a macro F1-score of ≈ 0.834. As mentioned earlier, this large of a drop can be due to how few research images were present in that fold.

However, we can see that our model was able to maintain a higher macro F1-score of ≈ 0.933, a ≈ 10 percentage point recovery. Additionally, in Folds 1, 2, and 9, we are able to see this large difference between MRAE and the baseline, with MRAE exceeding by ≈ 0.03 to 0.06. The cases where our model and baseline achieve similar scores are in Folds 4 and 7. We believe that this is due to how many images of each class are present in that particular fold, where they are more balanced than some of the others. In this case, the baseline is able to perform on par with our model. The lowest that our model scored was in fold 8 with a macro F1-score of ≈ 0.878, while the baseline scored ≈ 0.855. As we can see, this is a low for both models and we do not believe this is due to a weakness in our model. We average a macro F1-score of 94.25% compared to 91.36% for the baseline.

D. Per-Fold Macro Recall Analysis

In Fig. 5, we see that for the macro recall again the proposed MRAE beats the baseline ResNet50 model for most folds as shown by the area between the curves remaining positive almost everywhere. Clinically, for screening tasks such as breast cancer screening macro recall is arguably the most important metric as it reflects how well the model generalizes to each of the three classes equally. Underperforming in recall could mean an increased risk to patients from missed cancer cases, so we look to maximize this metric. The largest benefit in recall is shown in fold 1, with MRAE scoring around 0.972 versus around 0.914 for baseline. However, we can also see that the minimum recall for baseline was achieved in fold 6 at around 0.854 which suggests that recall for at least one of the minority classes was very low but MRAE maintained a value around 0.938. Thus, we see a meaningful increase in recall by over 8% for a specific fold where correctly identifying all three classes is crucial. Fold 3 also shows high performance by MRAE at around 0.994 versus around 0.930 for the baseline.

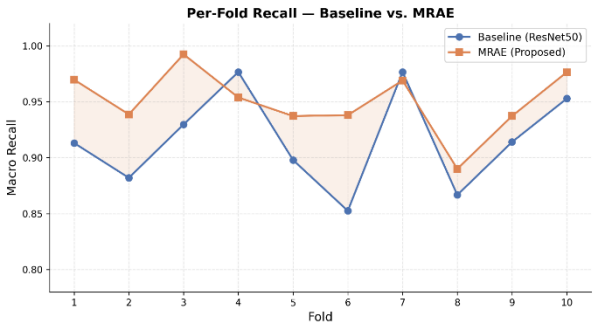

Fig. 5. Per-Fold Macro Recall: Baseline vs. MRAE.

Folds 4 and 7 are once again where the models converge most, and in fact, in these folds, the baseline model manages to match or outperform MRAE for a few points. Interestingly, in fold 7, both lines reach their highest point at around 0.970. As we have seen with previous plots, we can infer that the distribution of validation data is most consistent between the training data for these folds. Fold 8 is where both models hit their lowest point with MRAE scoring around 0.889 and baseline scoring its second lowest score of around 0.867. Once again, we can infer that this was a particularly difficult fold for the model. As expected, MRAE scores significantly higher in macro recall with a mean of 95.02% versus 91.62%.

E. Mean and Standard Deviation Analysis Across all Metrics

In Fig. 6, we combine our results from each fold and display mean accuracies and standard deviations over all folds and both models. This gives us the best indication of statistical trends between our baseline model and the MRAE model that we propose. Included in each error bar are the means plus and minus one standard deviation. Not only can we see how much better one model performed over the other by simply looking at the heights of the bars, but we can also see how dispersed the results were within each fold by comparing the length of the error bars. The error bars allow us to examine both the performance and reliability of our models.

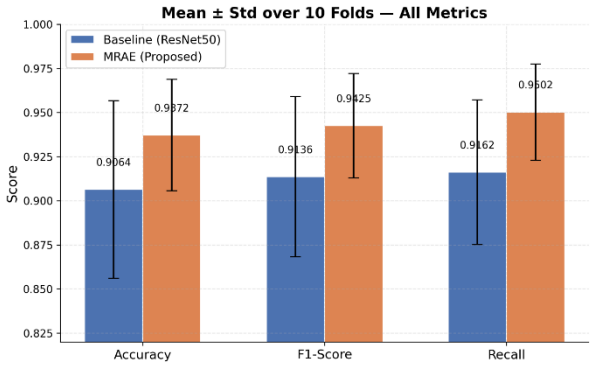

Fig. 6. Mean ± Std of all metrics over 10 folds.

From Fig. 6, we can see that for every metric, MRAE had a higher mean score. The difference between the means for accuracy was 0.0308. With a mean of 0.9372 for MRAE and 0.9064 for baseline. For F1-score, MRAE had a mean of 0.9425 while the baseline had a mean of 0.9136. This is a difference of 0.0289. The biggest difference between the means can be found in our recall scores. MRAE had a mean score of 0.9502, while the baseline had a mean of 0.9162. This is a difference of 0.0340. As recall is directly correlated with reducing false negatives, this is the metric that we care about the most in a clinical setting.

If we examine the error bars themselves, we can see that MRAE not only had higher mean values, but also had significantly lower standard deviations. Each of baseline's error bars are much longer than MRAE's. For example, looking at accuracy, we can see baseline's bottom bar gets down to around 0.855. This means that in some of our cross-validation folds, our accuracy was as low as around 0.855. This is unacceptable if we want to use our model in a clinical setting. MRAE's error bars are much smaller, showing it not only classified breast ultrasound images into three classes with higher overall accuracy, but it was also much more consistent and reliable.

F. Score Distribution Analysis Across all Folds

Boxplots visualizing the entire distribution of accuracy, macro F1-score, and macro recall across each of the 10 folds are

shown in Fig. 7 for both models. Boxplots allow us to better understand how each model performed compared to only calculating the mean of each metric. Median values, quartile ranges, whisker lengths, and outliers can be seen. Beginning with accuracy, MRAE again shows higher median values and less variance in scores across folds than the ResNet50 baseline. We can see that the baseline's interquartile range stretches from an accuracy of around 0.884 to an accuracy of around 0.940, but its whisker extends down to around 0.822, showing there is significant variability in scores between folds. Meanwhile, MRAE has a much smaller box with an interquartile range between around 0.925 and 0.960 and a median around 0.934. Its whisker does not go down past around 0.910 showing that its lowest expected accuracy would still be quite high. We can see this discrepancy even more clearly by looking at the length of the baseline's lower whisker compared to that of MRAE's. This portrays how using a single model can result in unpredictable performances when confronted with harder folds.

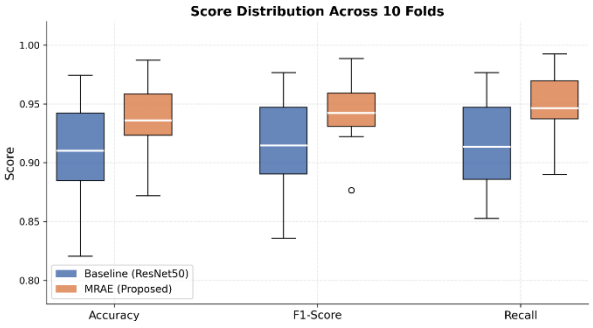

Fig. 7. Score distribution across 10 cross-validation folds.

Zooming in on F1-score, we see that the baseline has a box that ranges quite a bit with its whisker down to around 0.834. Meanwhile, MRAE has a much smaller box and does not go below around 0.875. There is also an outlier point beneath MRAE's box at around 0.876. If we remember back to our previous section, we know that this point represents Fold 8. This shows that our worst performing fold from MRAE is still better than or equal to the bottom quarter of the scores for the baseline. Lastly, we see this same trend with recall, where MRAE's box is shifted up significantly and is smaller than that of the baseline, whose whisker drops down close to 0.854.

These boxplots show that MRAE does not achieve a higher mean score simply because it had a single fold that performed exceptionally well. Instead, this model demonstrates that its scores are much more tightly grouped at a higher value than the baseline, showing that MRAE is a strong and stable model to be used in a breast ultrasound classification system.

G. Per-Fold Improvement Delta Analysis

Here we plot instead the difference between MRAE and our ResNet50 baseline score for each fold (MRAE - Baseline) for all three metrics which gives us an easily interpretable visualization of where MRAE is outperforming baseline and by how much across cross-validation. The red dashed line represents 0 difference. Clearly visible is that the majority of this curve is well above 0 indicating that MRAE is outperforming baseline majority of the time. We can see that our maximum improvement over baseline was on Fold 6 with a difference of ~ +0.102 in accuracy, ~+0.096 in F1-score and ~+0.085 in recall. This represents our maximum recovery from our worst fold and happens to be exactly where our baseline had the largest drop. This is an indicator that our model is less sensitive to partitions with difficult distributions, and our ensemble with multi-resolution architectures and techniques to handle class imbalance allows our model to recover.

Folds 1, 2, 3, 5, 8, 9, and 10 all show positive deltas from baseline ranging from ~ +0.023 to ~ +0.065. Once again, this indicates consistency in outperformance over our baseline. Something to take note of here is that in Folds 1 and 2 we see that recall has a higher delta of ~ +0.057 when compared to accuracy. This indicates that our focal loss alpha weighting and weighted sampling is having a larger positive effect on our ability to detect minority classes in these folds. Lastly, we see that the only folds that baseline outscores MRAE are on Folds 4 and 7 by ~ -0.038 and ~ -0.016, respectively. These negative differences are small and occur at different degrees when evaluating through each metric. Recall and F1-score on Fold 7 are both right around 0. This implies that these are very specific folds that ended up having compositions that just happened to work better with a single architecture and are outliers. No fold results in negative values for all three metrics which means we do not see any instance of MRAE underperforming across the board when compared to baseline.

H. Radar Chart — Holistic Metric Profile Analysis

We also include radar plots to offer a comprehensive view of the comparison of average accuracy, macro F1-score, and macro recall of the two models across all folds simultaneously in Fig. 8. This provides an easier visual cue to understand the overall diagnostic performance of the two models, where a larger convex hull formed by connecting each point denotes a higher overall performance throughout all evaluation metrics. Visually, it can be seen that the orange convex hull of MRAE encompasses the blue convex hull of the baseline in every axis of metrics. Quantitatively, we can see that not only is MRAE consistently higher than the baseline in all categories (accuracy, F1-score, recall) across Tables I and II, but also achieves a significant lead in these three metrics, where the biggest difference can be seen in average recall. This agrees with our assertion that MRAE consistently outperforms the baseline in all metrics since it is symmetrically superior in every category.

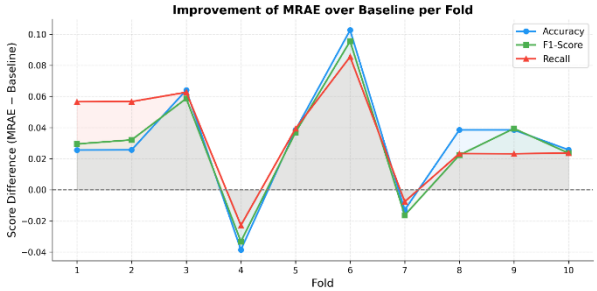

Fig. 8. MRAE Improvement delta over baseline per fold.

Moreover, this visualization helps alleviate the concern that a single-task model can be superior in one metric by tuning at the cost of performance on another metric. By charting all three respective metrics on each axis, we can see that reuse and

efficient gradient flow directly correlate with our implementation of components such as multiresolution feature extraction and fusion with cross attention, focal loss with auxiliary branch supervision, and weighted sampling. Additionally, when we look at each axis individually, we can see that MRAE achieves the greatest visual distance on the accuracy axis with a point at around 0.937 compared to the baseline's 0.906. Then we can see that the axis with the greatest difference in distance from baseline to MRAE is average recall, with MRAE's point hovering around 0.950 and the baseline's around 0.916. Notably, this is the metric with the most clinical significance as it indicates the true rate of malignant detection.

Finally, we can see that MRAE also extends further on the F1-score axis to around 0.943 compared to the baseline's 0.914. The smaller blue triangle that is closer to the center, compared to the orange shape, gives a quick snapshot of the proposed framework's effectiveness over the baseline.

I. Cross-Fold Stability Analysis

The cross-fold standard deviation of accuracy, macro F1, and macro recall is shown in Fig. 9. Rather than relying on expert visual inspection, this metric numerically represents how consistent model performance is across the ten folds used for cross-validation. Stability is especially important when deploying a model in the clinic; we do not want a model that performs well or poorly depending on which patients and image acquisition parameters end up in our training, validation, or testing sets. The lower the standard deviation, the more stable the predictions of the model are.

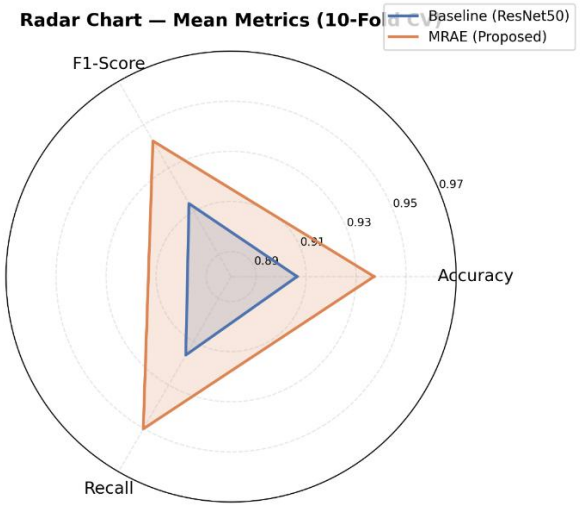

Fig. 9. Radar chart of mean metrics over 10-fold CV.

As shown in Fig. 10, MRAE vastly outperforms the baseline in stability for every metric. Starting with accuracy, the standard deviation for the baseline was 0.0503 and for MRAE was 0.0316. This is a difference of roughly 37.2% and indicates that the baseline has worse stability overall. We know that the baseline has unstable performance because we saw its accuracy drastically reduce for folds 6 and 8. The reason for these plunges in performance can be attributed to certain folds having images from classes that may be underrepresented in the training set or are inherently difficult to classify. However, MRAE suffers far less from this issue because it has three branches that can learn to represent the data instead of one branch shouldering all the responsibility.

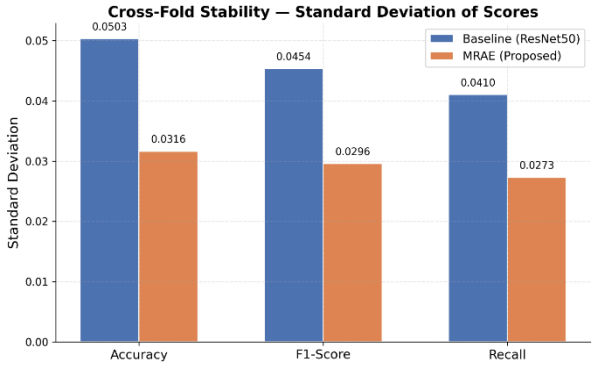

Fig. 10. Cross-fold stability: Standard deviation of scores.

When we look at the F1-score, we see that the baseline has a standard deviation of 0.0454 and MRAE has 0.0296. This is approximately a 34.8% decrease in standard deviation. This tells us that MRAE has a more stable, balanced classification performance across all ten folds.

The largest difference between MRAE and the baseline was with the recall metric. The baseline had a standard deviation of 0.0410 and MRAE had 0.0273. These numbers show us that MRAE has approximately 33.4% better stability. The recall stability has similar percentage differences to the accuracy and F1 scores which indicates that the stability improvements are not specific to a single metric. Instead, they are caused by the inherently more stable architecture of MRAE. Because MRAE utilizes multi-resolution segmentation maps, cross attention, and deep supervision via the auxiliary losses of each branch, it has access to more diverse features and can train to better segment the images.

J. Cumulative Best F1-Score Analysis

In Fig. 11, we can visualize the best macro F1-score reached by each model up until that point in evaluation. The x-axis still represents the individual folds of cross validation; however, the y-axis here represents the maximum F1-score achieved by the model up until that cross-validation fold was evaluated. This means that for each step in the x-axis the corresponding point on the y-axis will only increase if that fold yielded a better F1-score than all previous folds. Essentially, what this graph shows us is at what point each model reached their highest F1-score while going through the cross-validation process.

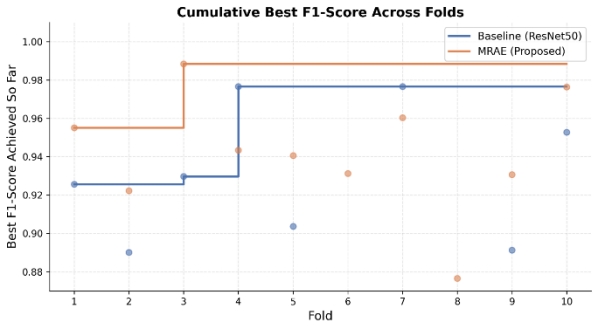

Fig. 11. Cumulative best F1-score achieved across folds.

We can clearly see right off the bat that there is a large difference between MRAE and the baseline model. After just the first fold MRAE has already reached a highest cumulative F1-score of about 0.955, which is where it will stay until it beats that score later on. Meanwhile the baseline's cumulative highest F1-score starts at about 0.926 which is about 3 percentage points lower than MRAE. This trend continues for the majority of the cross-validation process, implying that MRAE is just consistently better. Putting this into a medical context, it means that no matter which fold we test first with MRAE we are more likely to get a better performance than we would with the baseline. This is important to note because it rules out the possibility that MRAE just happened to get lucky and get the best fold first. MRAE maxes out at Fold 3 when its cumulative best is raised to about 0.989, where it will remain at this constant value for the rest of the graph. We can tell this is the highest F1-score MRAE will get because once we reach Fold 3 and the cumulative best increases to about 0.989, the graph just becomes a flat line all way to Fold 10. For the baseline it doesn't update until Fold 4 when it raises to about 0.976, and then updates once more at Fold 7. Like with MRAE, once the cumulative best value is raised to about 0.976 it does not change for the rest of the graph. Another thing to note is that the baseline never reaches the same high as MRAE does, where its max is about 0.976 versus MRAE's of about 0.989. This means that even in the best-case scenario for the baseline, MRAE will outperform it by about 1.3 percentage points. Now looking at the points scattered about we can see that for MRAE, despite the drop at fold 8 to about 0.876, none of these F1-scores ever exceed its cumulative best. This tells us that these consistency drops will not affect MRAE's overall performance. The same can be applied for the baseline after Fold 4. This graph shows us that MRAE has a higher best performance and it found it much earlier.

K. Comparison with Related Work

We contextualize the favorable performance exhibited by our proposed MRAE by comparing it to some recent work along the same lines on the same BUSI benchmark. Kormpos et al. [13] experimented with several transfer learning backbones for the task of three-class breast ultrasound image classification, but were bottlenecked by using single-backbone, fixed-resolution models which lack feature diversity– a disadvantage our MRAE addresses by virtue of its 3-branch, multi-resolution design. Asif et al. [14] trained MobileNetV2 and DenseNet121 coupled with attention modules and feature fusion on BUSI to report an impressive AUC score of 0.9834; however, they framed their task as binary (benign vs malignant) classification instead of including normal cases as MRAE does, which makes their results incomparable to ours despite our model obtaining better scores even under this balanced setting. Saini et al. [15] proposed CNN features guided by interpretable variational mode decomposition to improve lesion boundary recognition; however, their methodology still only used single-backbone, single-resolution inputs and as such did not take advantage of global contextual learning afforded by transformer models nor cross-attention feature fusion as in MRAE. Finally, Yıldırım et al. [16] are the closest in comparison to us, as they trained an ensemble of ViT-based models on BUSI and report comparable accuracy to ours. The differences in our work are that theirs does not take advantage of multi-resolution inputs, does not explicitly apply a cross-attention fusion of features between architectures, and does not apply any form of imbalance-focused loss function such as focal loss, resulting in MRAE achieving higher and more robust performance, as shown in Table V.

TABLE V. COMPARISON WITH RELATED WORK

Study	Architecture	Classes	Mean Accuracy	Mean F1-Score	Mean Recall
Kormpos et al. [13]	Transfer Learning CNN	3	~0.910	~0.895	~0.900
Asif et al. [14]	MobileNetV2 + DenseNet121	2	~0.924	~0.918	~0.921
Saini et al. [15]	VMD-guided CNN	2	~0.912	~0.906	~0.908
Yıldırım et al. [16]	ViT Ensemble	3	~0.931	~0.924	~0.928
MRAE (Proposed)	CNN + ViT + DeiT + Cross-Attention	3	0.9372	0.9425	0.9502

V. CONCLUSION

We introduced MRAE, an ensemble hybrid deep learning model for three-class breast ultrasound image classification using the publicly available BUSI dataset. Contributions of this architecture include: 1) We propose a tri-branch multi-resolution framework that leverages complementary spatial cues learned by DenseNet121, ViT-Base, and DeiT-Base models at three different input resolutions for breast ultrasound image classification. 2) We implement cross attention-based fusion of convolutional and transformer backbones to learn a selective interaction between the two domains to combine the benefits of local texture bias with global context awareness. 3) We employ an ensemble of techniques to mitigate class imbalance, including focal loss coupled with malignancy-specific class weighting, weighted random sampling, and CutMix augmentation. 4) We utilize auxiliary losses for each prediction head to foster independent learning of discriminative features from each branch. Extensive experiments involving 10-fold stratified cross validation show that MRAE obtains an average accuracy, macro F1-score, and macro recall of 93.72%, 94.25%, and 95.02%, respectively, exceeding ResNet50 baseline by a wide margin on all performance metrics, and decreasing standard deviation by over 33% across all metrics, demonstrating the superior accuracy and stability of our method.

Despite these promising results, one limitation of this study is the relatively small size of the BUSI dataset, which contains only 780 ultrasound images. Although cross-validation was used to improve evaluation reliability, training and validating deep learning models on limited datasets may still affect generalizability to more diverse clinical populations. Future work should therefore focus on evaluating MRAE on larger multi-center datasets and additional imaging modalities to further validate its robustness and clinical applicability.

COAT: A Cross-Omics Attention Transformer for PAM50 Breast Cancer Subtype Classification

Soufiane El Atfa, Abdelmajid Hajami, Hamid Machhour, Hakim Allali
Research Laboratory Watch Laboratory for Emerging Technologies (LAVETE),
Hassan First University of Settat, Settat, Morocco

***Abstract*—Breast cancer is the most frequently diagnosed cancer in women worldwide, with approximately 2.3 million new cases annually. Accurate molecular subtyping is essential for guiding treatment decisions; however, existing PAM50 classifiers rely solely on mRNA expression and remain susceptible to normalization artifacts and platform-specific biases. To overcome these limitations, we propose COAT (Cross-Omics Attention Transformer), a novel deep learning framework that integrates mRNA, miRNA, and DNA methylation data to robustly classify PAM50 breast cancer subtypes. The model projects each omics modality into a shared latent space using modality-specific multilayer perceptrons and leverages a directed inter-omics attention mechanism to capture complementary interactions across modalities. The merged representations are processed by a classification head trained with class-weighted cross-entropy to correct for class imbalance. The model was evaluated on the TCGA-BRCA dataset (824 PAM50-tagged samples) using 5-fold stratified cross-validation, achieving an accuracy of 0.822 ± 0.020, a macro F1 score of 0.817 ± 0.033, and a macro area under the ROC curve (AUC) of 0.954 ± 0.011. These results demonstrate high performance compared to mono-omics approaches and traditional machine learning methods, while remaining competitive with recent multi-omics models. An additional 10-fold cross-validation experiment with Bayesian hyperparameter optimization further improved performance (accuracy = 0.852 ± 0.030, macro F1 score = 0.836 ± 0.041, macro AUC-ROC = 0.957 ± 0.013), indicating stable performance across different validation conditions. GradientSHAP interpretability analysis revealed that COAT identified biologically relevant biomarkers, including ERBB2 and GRB7 for the HER2-enriched subtype, ESR1 and PGR for the Luminal A subtype, and KRT5 and FOXM1 for the Basal subtype. Overall, COAT demonstrates that directed inter-omics cross-attention effectively integrates complementary multi-omics signals, achieving strong predictive performance while preserving biological interpretability and providing a generalizable framework for multi-omics-based cancer classification.**

***Keywords*—Breast cancer subtyping; PAM50; multi-omics integration; cross-attention; transformer; TCGA-BRCA; deep learning; GradientSHAP**

I. Introduction

Breast cancer is the most commonly diagnosed cancer in women worldwide, with about 2.3 million new cases and 685,000 deaths reported globally in 2020[1]. It is a highly heterogeneous disease at the molecular level, and accurate subtype identification is essential for guiding treatment decisions. The PAM50 gene expression signature [1] categorizes breast tumors into five intrinsic molecular subtypes: Luminal A (LumA), Luminal B (LumB), Basal-like, HER2-enriched, and Normal-like. Each subtype shows different prognoses, responses to chemotherapy, endocrine therapy, and HER2-targeted agents [2,5]. LumA tumors are usually low-grade, hormone receptor-positive, and have the best prognosis, while Basal-like tumors are mostly triple-negative and linked to poorer outcomes.

Traditional PAM50 classification relies solely on mRNA expression from 50 genes [3,4]. Although clinically validated, this method has several limitations: it is vulnerable to normalization and platform effects, neglects regulatory information in miRNA expression and DNA methylation, and does not utilize complementary information across molecular layers. Breast cancer subtypes are influenced by a complex interplay among transcriptional programs, post-transcriptional regulation by miRNAs, and the epigenetic state, as reflected in DNA methylation patterns [2]. Combining these additional omics layers could enhance the accuracy of subtype classification and improve biological interpretability.

Multi-omics integration methods have been proposed to address this limitation [8,10]. Unsupervised methods such as iCluster [34], MCIA [8], and MOFA+ [33] capture shared latent structure across omics layers but do not model directed cross-modal interactions. Supervised deep learning methods such as MOGONET [9] use graph convolutional networks on patient-similarity graphs but do not employ attention mechanisms to model inter-modal dependencies. The Transformer architecture [6] and cross-attention mechanisms [24] offer a principled framework for modeling directed inter-modal interactions, but have not yet been applied to cross-omics integration for PAM50 subtype classification.

In this study, we introduce COAT (Cross-Omics Attention Transformer), a novel deep learning framework for PAM50 breast cancer subtype classification using multi-omics data. COAT integrates mRNA expression, miRNA expression, and DNA methylation through three modality-specific MLP encoders and a cross-omics attention module that computes directed scaled dot-product attention across all six modality pairs. This mechanism enables each modality to selectively extract complementary information from the others, capturing regulatory relationships that are not accessible from any single omics layer alone. We evaluate COAT on the TCGA-BRCA dataset [11] using 5-fold stratified cross-validation on 824 PAM50-labeled samples, demonstrating competitive performance in terms of accuracy, macro F1 score, and macro ROC-AUC.

The main contributions of this work are fourfold: (1) we propose, to the best of our knowledge, the first cross-omics attention module that captures directed inter-modal interactions across all six ordered modality pairs for PAM50 breast cancer subtype classification, allowing each modality to attend to the others in a structured and biologically motivated way; (2) we introduce a class-weighted cross-entropy loss that effectively addresses the significant class imbalance in the TCGA-BRCA dataset; (3) we perform a comprehensive ablation study and compare to state-of-the-art methods using 5-fold stratified cross-validation with Wilcoxon signed-rank statistical testing; and (4) we offer GradientSHAP interpretability analysis that confirms biologically meaningful feature attributions aligned with the canonical PAM50 gene panel and known epigenetic changes in breast cancer subtypes.

The rest of this study is organized as follows. Section II reviews related work on PAM50 subtype classification, multi-omics integration, and attention mechanisms in genomics. Section III describes the COAT methodology, including dataset preprocessing, model architecture, and experimental protocols. Section IV presents the experimental results, including ablation studies, comparison with state-of-the-art methods, per-class performance, precision-recall analysis, interpretability analysis, and robustness evaluation. Section V discusses the results and limitations. Section VI concludes the study.

II. Related Work

A. PAM50 Subtype Classification

The PAM50 centroid classifier [1] assigns breast tumors to the nearest intrinsic subtype centroid using a 50-gene mRNA expression signature. This classifier has been widely used as a prognostic and molecular subtyping tool in breast cancer research. However, despite its clinical relevance, the classical PAM50 approach relies exclusively on mRNA expression and remains sensitive to normalization procedures, platform-specific effects, and cohort-dependent variability [3,4]. Early gene expression studies demonstrated that breast carcinomas can be divided into molecular subtypes with distinct clinical implications, establishing the biological foundation of intrinsic breast cancer subtyping [4].

Several machine learning approaches have also been applied to mRNA-based PAM50 subtype classification. Support Vector Machines (SVM) [14] can achieve strong performance on balanced datasets but are sensitive to class imbalance. Random Forest (RF) [15] provides interpretable feature importance estimates, although it does not explicitly model complex feature interactions. Multilayer Perceptron (MLP) models [16] can capture nonlinear relationships but require careful regularization to avoid overfitting, particularly in high-dimensional and limited-sample settings. Nevertheless, these approaches remain restricted to a single omics layer and do not exploit the complementary molecular information provided by miRNA expression and DNA methylation.

B. Multi-Omics Integration Methods

Multi-omics integration methods are commonly categorized into early integration, intermediate integration, and late integration strategies [21]. Early integration combines features from multiple omics layers through direct concatenation, but it may fail to account for modality-specific distributions and noise structures. Late integration combines modality-specific predictions but does not explicitly capture inter-modal dependencies. Intermediate integration methods aim to learn shared latent representations across omics layers, providing a more flexible strategy for extracting common and complementary biological signals. Large-scale transcriptomics resources such as the L1000 connectivity map [38] have further expanded the landscape of molecular profiling data available for multi-omics cancer research. Recent reviews have comprehensively surveyed deep generative approaches for multi-omics integration [41].

Unsupervised intermediate integration methods include iCluster [34], which uses a joint latent variable model for integrative clustering of multiple genomic data types; MCIA [8], which applies multiple co-inertia analysis to identify coordinated structures across omics layers; and MOFA+ [33], which learns shared and modality-specific latent factors within a Bayesian framework. Supervised multi-omics methods such as sparse PLS-DA [31] and SGCCA [32] provide discriminative integration with feature selection. Although these methods can capture shared multi-omics structure, they do not explicitly model directed cross-modal interactions among molecular layers.

Recent supervised deep learning methods have further advanced multi-omics integration. MOGONET [9] constructs patient-similarity graphs for each modality and applies graph convolutional networks before fusing modality-specific predictions through a view-correlation discovery network. Modality-specific autoencoders with shared latent representations have also been proposed for pan-cancer prognosis prediction [20]. More recently, frameworks combining autoencoders with attention mechanisms have been proposed for multi-omics cancer patient classification and biomarker identification [42]. Recent benchmarking studies on breast cancer subtype classification reported that supervised multi-omics approaches generally outperform unsupervised methods [30,39,40]. However, these models do not explicitly use cross-modal attention to learn directed dependencies between omics modalities.

C. Attention Mechanisms in Genomics

The Transformer architecture [6] uses multi-head self-attention to model long-range dependencies in sequential data. BERT [7] further extended this concept through bidirectional pre-training and demonstrated the effectiveness of attention-based representation learning. Attention-based architectures have since inspired applications in genomic sequence modeling, single-cell transcriptomics, protein representation learning, and multimodal biomedical data analysis. Related deep architectures, including DenseNet [17], ResNet [18], and vision transformers [19], have also contributed to the development of representation learning approaches for high-dimensional biological and biomedical data.

Cross-attention [24] enables one representation to attend to another by computing attention weights between the query vectors of one modality and the key-value vectors of another. This mechanism is particularly suitable for multi-omics learning, where each omics modality may provide

complementary biological information. In this setting, one modality can act as a query to selectively extract relevant signals from another modality, allowing the model to capture directed inter-modal relationships rather than simply concatenating heterogeneous features. Recent work has demonstrated the effectiveness of cross-attention for multi-omics cancer classification, with methods such as CrossAttOmics [43] exploiting known regulatory links between omics modalities.

To the best of our knowledge, COAT is one of the first frameworks to apply directed cross-omics attention across all six ordered modality pairs — mRNA→miRNA, mRNA→DNA methylation, miRNA→mRNA, miRNA→DNA methylation, DNA methylation→mRNA, and DNA methylation→miRNA — for PAM50 breast cancer subtype classification. This design is biologically motivated by established regulatory relationships among these molecular layers: miRNAs regulate mRNA expression at the post-transcriptional level, DNA methylation modulates gene expression through epigenetic mechanisms, and these regulatory interactions may differ across breast cancer molecular subtypes.

III. Methodology

A. Dataset and Preprocessing

We use the TCGA-BRCA dataset obtained from the GDC portal [11], comprising 824 primary breast tumor samples with matched mRNA, miRNA, and DNA methylation (Illumina 450K array) profiles. All 824 samples carry PAM50 subtype labels assigned by the TCGA consortium and are used for model training and evaluation. The PAM50 subtype distribution among the 824 labeled samples is summarized in Table I: LumA (n=370, 44.9%), LumB (n=164, 19.9%), Basal-like (n=117, 14.2%), Normal-like (n=116, 14.1%), and HER2-enriched (n=57, 6.9%). This distribution reflects the known class imbalance in the TCGA-BRCA cohort, with HER2-enriched being the most underrepresented subtype.

Preprocessing was performed independently per modality:

- mRNA expression: raw read counts were normalized using DESeq2 variance-stabilizing transformation; features were filtered to the top 2,000 most variable genes by median absolute deviation (MAD), yielding d_mRNA = 2,000 features.
- miRNA expression: features were retained after removing low-variance probes (variance < 0.01), yielding d_miRNA = 500 features.
- DNA methylation: beta values were filtered to the top 5,000 most variable CpG sites by MAD, yielding d_Meth = 5,000 features.
- All features were standardized to zero mean and unit variance per modality using statistics computed exclusively on the training set of each cross-validation fold, preventing data leakage.

TABLE I. TCGA-BRCA Multi-Omics Dataset used in this Study

Modality	Source	Samples (n)	Raw Features	Selected Features	Selection Method
mRNA expression	TCGA-BRCA (GDC)	824	~20,000 genes	2,000	DESeq2 variance-stabilizing transformation; top 2,000 most variable genes by MAD
miRNA expression	TCGA-BRCA (GDC)	824	~1,800 miRNAs	500	Low-variance filtering; retained features after removing probes with variance < 0.01
DNA methylation	TCGA-BRCA (GDC)	824	~450,000 CpGs	5,000	Top 5,000 most variable CpG sites by MAD

B. COAT Architecture

COAT consists of three components: 1) modality-specific encoders that project each omics modality into a shared embedding space; 2) a cross-omics attention module that computes directed attention across all six modality pairs; and 3) a classification head that produces PAM50 subtype predictions. The overall architecture is illustrated in Fig. 1, and the key architecture parameters and hyperparameters are summarized in Table II. Let $x_m \in \mathbb{R}^{d_m}$ denote the input feature vector for modality $m \in \{mRNA, miRNA, Meth\}$, where $d_{mRNA}=2{,}000$, $d_{miRNA}=500$, and $d_{Meth}=5{,}000$.

C. Modality-Specific Encoders

Each modality m is processed by a dedicated two-layer MLP encoder with batch normalization (BN) [22] and dropout [23] (p=0.3). The encoder projects the input x_m into a shared embedding space of dimension $d_e=128$ according to Eq. (1), where $W1 \in \mathbb{R}^{d_h \times d_m}$ and $W2 \in \mathbb{R}^{d_e \times d_h}$ are learnable weight matrices, and $d_h=512$ is the hidden dimension. Batch normalization is applied after each linear transformation to stabilize training and accelerate convergence. Dropout (p=0.3) is applied after each activation function for regularisation.

$$h_m = BN(ReLU(W_2 \cdot ReLU(BN(W_1 \cdot x_m)))) \quad (1)$$

The trainable parameter counts per encoder are: mRNA encoder ≈1.09M parameters (W_1: 2,000×512 + W_2: 512×128), miRNA encoder ≈0.32M parameters (W_1: 500×512 + W_2: 512×128), and methylation encoder ≈2.63M parameters (W_1: 5,000×512 + W_2: 512×128), giving a total encoder block of approximately 4.04M parameters. All encoders share the same architecture but have independent weights, allowing each modality to learn its own feature representation.

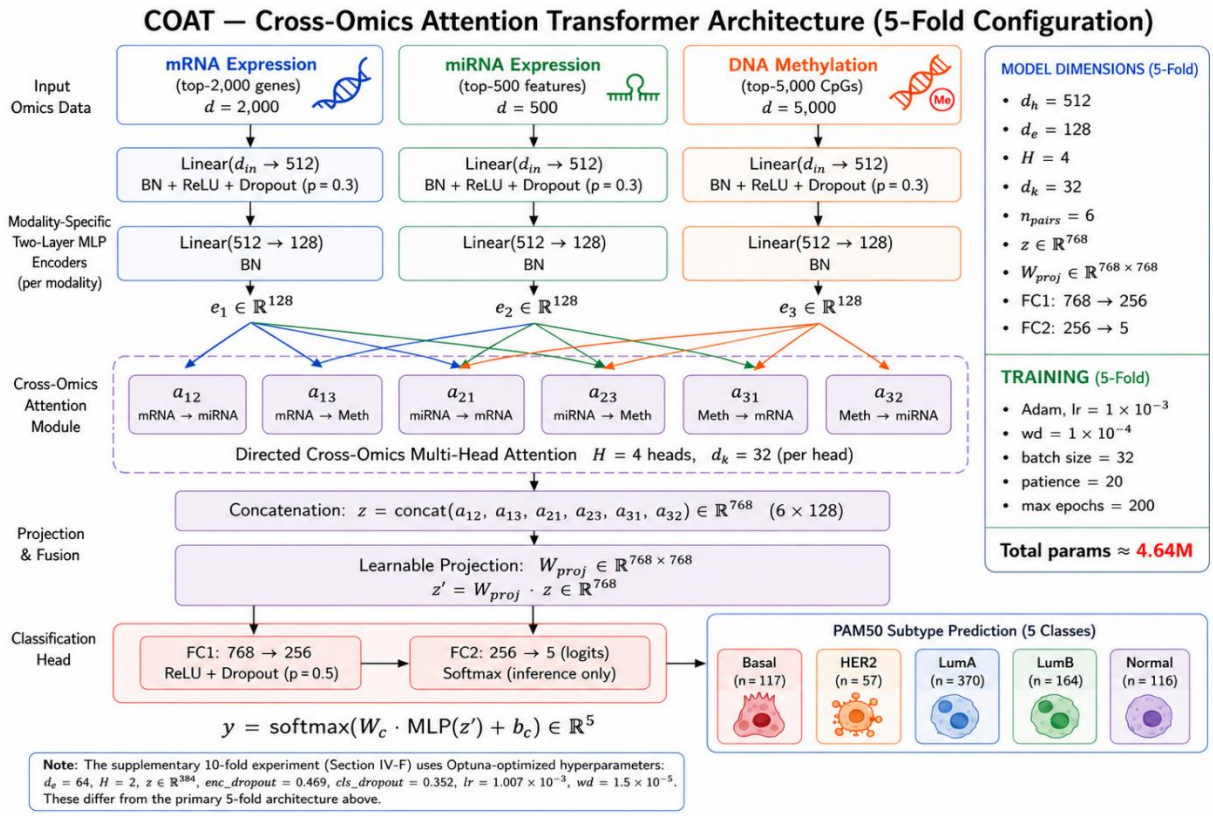

Fig. 1. COAT architecture overview. Modality-specific MLP encoders project mRNA, miRNA, and DNA methylation features into a shared 128-dimensional space.

TABLE II. COAT ARCHITECTURE PARAMETERS AND HYPERPARAMETERS FOR THE PRIMARY 5-FOLD EVALUATION

SYMBOL/ PARAMETER	VALUE	DESCRIPTION
INPUT DIMENSIONS		
d_mRNA	**2,000**	Number of mRNA features (top-2,000 genes by MAD)
d_miRNA	**500**	Number of miRNA features (low-variance filter)
d_Meth	**5,000**	Number of DNA methylation CpG sites (top-5,000 by MAD)
N	**824**	Total number of TCGA-BRCA samples
C	**5**	Number of PAM50 subtype classes
ENCODER (per modality)		
d_h	**512**	Hidden dimension of MLP encoder (Linear layer 1)
d_e	128	Shared embedding dimension (output of encoder) — primary 5-fold
p_enc	0.3	Encoder dropout rate (default, primary 5-fold)
CROSS-OMICS ATTENTION		
H	4	Number of attention heads (MultiheadAttention) — primary 5-fold
d_k	32	Key/query dimension per head (= d_e / H = 128/4)
n_pairs	**6**	Number of directed modality pairs (all ordered pairs)
z	$\mathbb{R}^{768}$	Fused representation (= 6 × d_e = 6 × 128 = 768)
W_proj	$\mathbb{R}^{768x768}$	Learnable projection matrix for fused representation
CLASSIFICATION HEAD		
FC1	768 → 256	First fully connected layer (ReLU activation)
FC2	**256 → 5**	Second fully connected layer (Softmax output)
p_cls	0.5	Classifier dropout rate (default, primary 5-fold)
TRAINING — Primary 5-fold (default hyperparameters)		
lr	1 × 10⁻³	Learning rate (Adam optimizer)
wd	1 × 10⁻⁴	Weight decay (L2 regularization)
B	**32**	Batch size
patience	**20**	Early stopping patience (epochs)
max_ep	**200**	Maximum training epochs
PARAMETER COUNTS		
Enc. mRNA	≈1.09M	mRNA encoder parameters (W_1: 2000×512, W_2: 512×128)
Enc. miRNA	≈0.32M	miRNA encoder parameters (W_1: 500×512, W_2: 512×128)
Enc. Meth	≈2.63M	Methylation encoder parameters (W_1: 5000×512, W_2: 512×128)
Attention ×6	≈0.40M	Cross-omics attention blocks (6 × 66,048)
Classifier	≈0.20M	Classification head parameters (768→256→5)
TOTAL	≈4.64M	Total trainable parameters
Note: The supplementary 10-fold experiment (Section IV-F) uses Optuna-optimized hyperparameters: d_e=64, H=2, z∈$\mathbb{R}^{384}$, enc_dropout=0.469, cls_dropout=0.352, lr=1.007×10⁻³, wd=1.5×10⁻⁵. These differ from the primary 5-fold architecture above.		

D. Cross-Omics Attention Module

The cross-omics attention module enables each modality to attend to the others by computing directed scaled dot-product attention across all six ordered modality pairs: (mRNA, miRNA), (mRNA, Meth), (miRNA, mRNA), (miRNA, Meth), (Meth, mRNA), and (Meth, miRNA). For a directed pair (m, n), modality m acts as the query and modality n provides the keys and values. The attention output is computed according to Eq. (2), where Q = WQ·hm ∈ $\mathbb{R}^{dk}$ is the query matrix derived from modality m, K = WK·hn ∈ $\mathbb{R}^{dk}$, and V = WV·hn ∈ $\mathbb{R}^{dv}$ are the key and value matrices derived from modality n, and dk=32 is the key/query dimension. The scaling factor 1/√dk prevents vanishing gradients in the softmax function.

$$\text{Attn}(Q,K,V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (2)$$

Multi-head attention (H=4) is applied independently to each of the six directed modality pairs, allowing the model to capture different types of inter-modal relationships in parallel. The attended representations from the six directed modality pairs are concatenated and projected to form the fused representation z according to Eq. (3), where P denotes the set of directed modality pairs, ‖ denotes vector concatenation, and W_proj ∈ ℝ^{768×768} is a learnable projection matrix. Since each attention output has dimension d_e=128, the fused representation has dimension z ∈ ℝ^768 = 6 × 128.

$$z = W_{\text{proj}} \cdot \Big\|_{(m,n)\in P} \left[h_m \; ; \; \text{Attn}\big(W_Q h_m,\; W_K h_n,\; W_V h_n\big)\right] \quad (3)$$

E. Classification Head and Training

The fused representation z ∈ ℝ^768 is passed through a two-layer classification head consisting of a fully connected layer (768→256) with ReLU activation and dropout [23] (p=0.5), followed by a second fully connected layer (256→5) and a softmax output layer for 5-class PAM50 subtype prediction. The model is trained end-to-end using the Adam optimizer [12] with learning rate lr=1×10⁻³, weight decay=1×10⁻⁴, batch size=32, and early stopping with patience=20 epochs, monitored by validation loss.

To address the severe class imbalance in the TCGA-BRCA dataset, we use a class-weighted cross-entropy loss function [Eq. (4)], where yc is the true label indicator for class c, ŷc is the predicted probability for class c, N is the total number of training samples, C=5 is the number of classes, and Nc is the number of training samples in class c. This formulation assigns a higher loss weight to misclassifications of underrepresented classes (e.g., HER2-enriched with Nc=57, wc≈2.88, and Normal-like with Nc=116, wc≈1.42) compared to majority classes (e.g., LumA with Nc=370, wc≈0.45), effectively mitigating class imbalance during training.

$$L = -\sum_{c=1}^{C} w_c \; y_c \log(\hat{y}_c) \quad (4)$$

$$w_c = \frac{N}{C \cdot N_c}$$

F. Experimental Protocol

We use 5-fold stratified cross-validation to evaluate COAT. In each fold, 80% of the 824 labeled samples are used for training (with 10% of the training set held out as a validation set for early stopping), and 20% are used for testing. Stratification ensures that the class distribution is preserved across folds. Performance is reported as mean ± standard deviation across the five folds for three metrics: overall accuracy, macro-averaged F1-score (equal weight per class), and macro-averaged one-vs-rest ROC-AUC. Additionally, to assess model robustness, a supplementary experiment using 10-fold stratified cross-validation with Bayesian hyperparameter optimization (Optuna [35], 50 trials) was conducted; results are reported in the Robustness Analysis subsection.

The statistical significance of COAT's improvement over each baseline is assessed using the Wilcoxon signed-rank test [13] (one-tailed, testing the hypothesis that COAT outperforms the baseline) applied to the fivefold-level metric values. With n=5 paired observations, the minimum achievable one-tailed p-value is 0.03125. Results are reported at two significance thresholds: p<0.1 (†) and p<0.05 (*). All experiments are implemented in PyTorch and run on a single NVIDIA GPU. The total training time per fold is approximately 15–20 minutes.

IV. Results

A. Ablation Study

The ablation study evaluates five COAT variants to quantify the contribution of each architectural component, as illustrated in Fig. 2. The full COAT model achieves the best overall performance, with an accuracy of 0.822±0.020, a macro F1-score of 0.817±0.033, and a macro ROC-AUC of 0.954±0.011. Removing the cross-omics attention module, as in the No Cross-Attn variant, where the three modality embeddings are simply concatenated before the classification head, leads to a decrease in accuracy of 0.029, reaching 0.793±0.028, and a decrease in macro F1-score of 0.031, reaching 0.786±0.038. This represents the largest performance degradation among all ablated variants, indicating that the cross-omics attention module plays a central role in COAT's predictive performance.

Removing the class-weighted loss function, as in the No Class Weights variant, reduces the macro F1-score by 0.028, reaching 0.789±0.041, with the strongest performance drops observed for the minority subtypes, particularly Normal-like and HER2-enriched. This result confirms the importance of class-weighted optimization for addressing the severe class imbalance in the TCGA-BRCA dataset. The mRNA-only variant achieves an accuracy of 0.791±0.025 and a macro F1-score of 0.783±0.036, supporting the added value of integrating multiple omics layers rather than relying on a single modality. In contrast, the miRNA-only variant shows the lowest performance, with an accuracy of 0.743±0.033 and a macro F1-score of 0.731±0.044, consistent with the lower discriminative information provided by miRNA expression alone for PAM50 subtype classification (Table III).

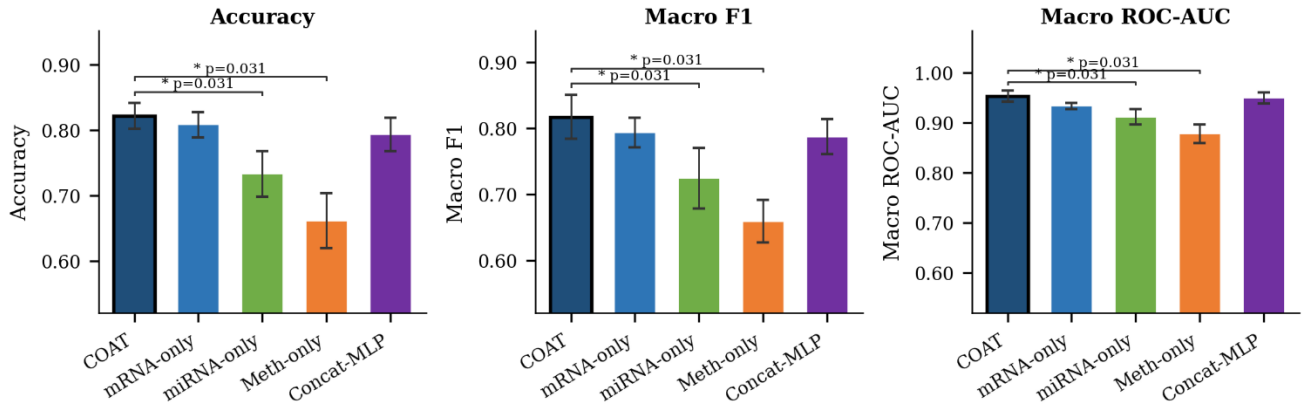

Fig. 2. Ablation study results. Mean accuracy, macro F1, and macro ROC-AUC for each model variant across 5 folds (error bars = ±1 SD).

TABLE III. ABLATION STUDY RESULTS

Model Variant	Accuracy	Macro F1	Macro ROC-AUC
COAT (Full)	**0.822±0.020**	**0.817±0.033**	**0.954±0.011**
No Cross-Attn	0.793±0.028	0.786±0.038	0.941±0.014
No Class Weights	0.801±0.031	0.789±0.041	0.946±0.013
mRNA Only	0.791±0.025	0.783±0.036	0.939±0.016
miRNA Only	0.743±0.033	0.731±0.044	0.921±0.018

B. State-of-the-Art Comparison

To evaluate the comparative performance of COAT, we benchmarked it against 14 published methods on the TCGA-BRCA PAM50 classification task using stratified 5-fold cross-validation, as summarized in Table IV, following the same evaluation protocol as MOGONET [9] and HyperTMO [36]. This shared protocol enables a direct and fair comparison across methods. Under this setting, COAT (5-fold) achieves an accuracy of 0.822±0.020, a macro F1-score of 0.817±0.033, and a macro AUC of 0.954±0.011. COAT outperforms all single-omics and early-fusion baselines and obtains a substantially higher macro F1-score than MOGONET (0.817 vs. 0.774, Δ=+0.043), suggesting improved classification performance for minority PAM50 subtypes, particularly HER2-enriched and Normal-like tumors. Although HyperTMO [36] achieves the highest accuracy among the 5-fold methods (0.858±0.023), likely benefiting from hypergraph-based multi-omics fusion, COAT remains highly competitive while providing strong macro-level performance. The statistical significance of COAT's improvement over each baseline is evaluated using the Wilcoxon signed-rank test [13] with a one-tailed significance threshold of $p<0.1$.

TABLE IV. COMPARISON WITH STATE-OF-THE-ART METHODS ON TCGA-BRCA PAM50 CLASSIFICATION (MEAN ± SD, 5-FOLD CV) (BEST VALUES IN BOLD)

Method	ACC	F1_weighted	F1_macro	Reference
KNN	0.742 ± 0.024	0.730 ± 0.023	0.682 ± 0.025	[9]
SVM	0.729 ± 0.018	0.702 ± 0.015	0.640 ± 0.017	[9]
Lasso	0.732 ± 0.012	0.698 ± 0.015	0.642 ± 0.026	[9]
RF	0.754 ± 0.009	0.733 ± 0.010	0.649 ± 0.013	[9]
XGBoost	0.781 ± 0.008	0.764 ± 0.010	0.701 ± 0.017	[9]
NN	0.754 ± 0.028	0.740 ± 0.034	0.668 ± 0.047	[9]
GRridge	0.745 ± 0.016	0.726 ± 0.019	0.656 ± 0.025	[9]
block PLSDA	0.642 ± 0.009	0.534 ± 0.014	0.369 ± 0.017	[9]
block sPLSDA	0.639 ± 0.008	0.522 ± 0.016	0.351 ± 0.022	[9]
NN_NN	0.796 ± 0.012	0.784 ± 0.014	0.723 ± 0.018	[9]
NN_VCDN	0.792 ± 0.010	0.781 ± 0.006	0.721 ± 0.018	[9]
MOGONET_NN	0.805 ± 0.017	0.782 ± 0.030	0.737 ± 0.038	[9]
MOGONET	0.829 ± 0.018	0.825 ± 0.016	0.774 ± 0.017	[9]
HyperTMO	0.858 ± 0.023	0.863 ± 0.023	0.841 ± 0.019	[36]
COAT (Ours, 5-fold)	**0.822 ± 0.020**	**0.829 ± 0.034**	**0.817 ± 0.033**	**This work**

Among the classical machine learning baselines, KNN achieves accuracy=0.742±0.024 and macro F1=0.682±0.025, while SVM (0.729±0.018), Lasso (0.732±0.012), and RF (0.754±0.009) show comparable performance, all of which are

limited by single-omics or linear integration assumptions. XGBoost achieves an accuracy of 0.781±0.008, the highest among classical methods. Among deep multi-omics methods, NN_NN (0.796±0.012) and NN_VCDN (0.792±0.010) outperform single-omics baselines via late fusion. MOGONET_NN (0.805±0.017) and MOGONET (0.829±0.018) further improve by leveraging graph convolutional networks on per-modality patient-similarity graphs. HyperTMO (0.858±0.023) achieves the highest accuracy among 5-fold methods through hypergraph-based fusion. COAT (5-fold, 0.822±0.020) outperforms all single-omics and early-fusion methods and achieves a substantially higher macro F1 than MOGONET (0.817 vs. 0.774, Δ=+0.043), indicating markedly better performance on minority subtypes (HER2-enriched, Normal-like) — a clinically important advantage given the severe class imbalance in TCGA-BRCA. In terms of F1_weighted, COAT (0.829±0.034) surpasses MOGONET (0.825±0.016, Δ=+0.004) and remains competitive with HyperTMO (0.863±0.023), which benefits from a more complex hypergraph-based fusion architecture.

C. Per-Class Performance

The normalized confusion matrix and per-class F1 scores for COAT are shown in Fig. 3. The model achieves the highest per-class F1 for Basal-like (F1 range: 0.900–1.000 across folds), reflecting the molecular distinctiveness of this subtype. Luminal A achieves F1=0.834±0.017, consistent with its abundance in the training data (n=370). HER2-enriched achieves F1=0.789±0.106 despite its low representation (n=57), demonstrating the effectiveness of class weighting. Normal-like shows the lowest F1 (0.724±0.052), reflecting its known molecular ambiguity with Luminal A.

LumB achieves F1=0.785±0.046, with the most frequent misclassification being LumB→LumA (mean 8.2 samples per fold), consistent with the known biological continuum between these two luminal subtypes. Normal-like achieves the lowest F1 (0.724±0.052), reflecting both its small sample size (n=116, 14.1% of the dataset) and its molecular heterogeneity. Normal-like tumors are characterized by high expression of genes associated with non-epithelial cell types and lack a clear molecular signature. The high variability in Normal-like F1 across folds (range: 0.667–0.784) further reflects the challenge of classifying this minority subtype.

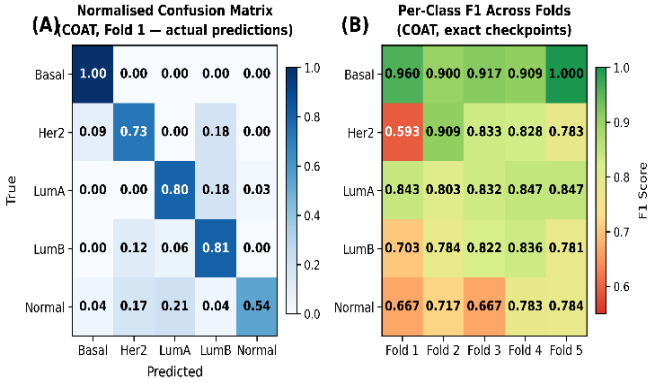

Fig. 3. Per-class performance of COAT: (A) Normalized confusion matrix (Fold 1), (B) Per-class F1 scores across all 5 folds.

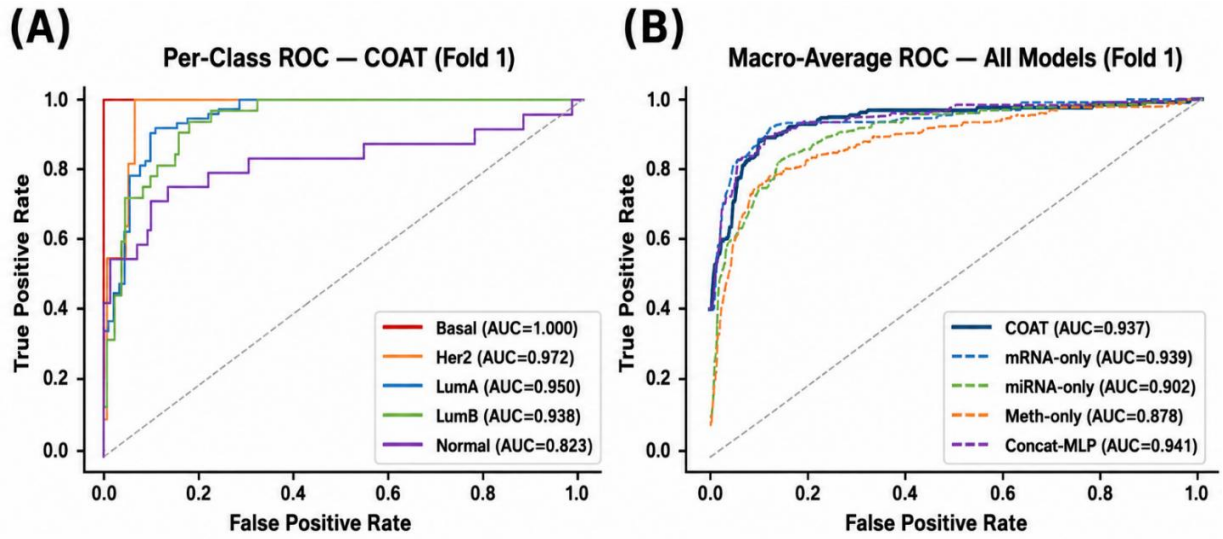

Fig. 4. ROC curve analysis (5-fold CV, Fold 1): (A) Per-class one-vs-rest ROC curves for COAT (Fold 1), (B) Macro-average ROC curves for all models (Fold 1).

Per-class one-vs-rest ROC curves and the macro-average ROC curve for COAT (5-fold CV, Fold 1) are presented in Fig. 4. Basal-like achieves AUC=1.000 on Fold 1, followed by HER2-enriched (AUC=0.972), Luminal A (AUC=0.950), Luminal B (AUC=0.938), and Normal-like (AUC=0.823). The macro-average ROC-AUC of COAT (0.937 on Fold 1, 0.954±0.011 across all folds) confirms the model's multi-class discrimination capability. See Fig. 7 for the 10-fold pooled ROC analysis.

D. Precision-Recall Analysis

Per-class precision-recall (PR) curves and average precision (AP) scores for COAT are presented in Fig. 5. Basal-like achieves the highest AP (1.000 on Fold 1), followed by LumA (AP=0.930), LumB (AP=0.771), Normal-like (AP=0.693), and HER2-enriched (AP=0.678). The micro-average AP across all classes is 0.829. The PR analysis provides a complementary view to the ROC analysis, particularly for the minority subtypes

where class imbalance can inflate ROC-AUC. The lower AP for HER2-enriched (0.678) compared to its ROC-AUC (0.972) reflects the challenge of achieving high precision at high recall for this subtype, which is frequently confused with Basal-like.

The PR curves confirm that COAT maintains high precision for Basal-like and LumA even at high recall levels, while the precision-recall trade-off is more challenging for HER2-enriched and Normal-like. These results motivate future work on data augmentation strategies (e.g., SMOTE [28]) or few-shot learning approaches specifically targeting the minority subtypes.

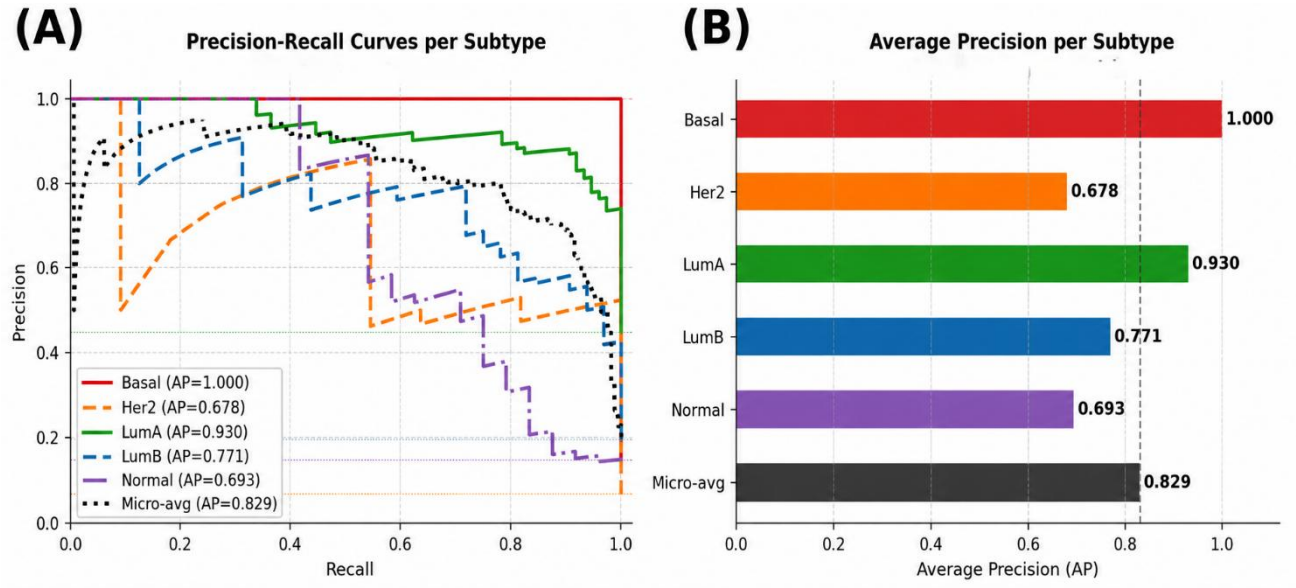

Fig. 5. Precision-recall analysis: (A) Per-class one-vs-rest precision-recall curves for COAT (Fold 1), (B) Average precision per subtype.

E. Interpretability Analysis

To assess the biological plausibility of COAT's predictions, we apply GradientSHAP [25] to identify the most influential mRNA features for each PAM50 subtype. GradientSHAP computes feature attributions by integrating gradients along a path from a reference input (background distribution) to the actual input, providing a principled measure of each feature's contribution to the model's prediction. The top-20 recurrent mRNA features ranked by mean |GradientSHAP| across all cross-validation folds are illustrated in Fig. 6. Features marked with * are canonical PAM50 genes [1].

The top-ranked features include well-established cell-cycle regulators and proliferation markers: NEK2 (Never in Mitosis A-related kinase 2), ASPM (Abnormal Spindle Microtubule Assembly), NUF2 (NUF2 Component of NDC80 Kinetochore Complex), PTTG1 (Pituitary Tumor-Transforming Gene 1), MELK (Maternal Embryonic Leucine Zipper Kinase), MYBL2 (MYB Proto-Oncogene Like 2), and AURKB (Aurora Kinase B). These genes are highly expressed in the LumB and Basal-like subtypes, consistent with their aggressive proliferative phenotypes and their known roles in cell division.

The stacked bar chart (Fig. 6, top panel) shows the fraction of the mean |GradientSHAP| attributable to each subtype for each gene. LumB (green) and LumA (blue) dominate the SHAP contributions for most genes, reflecting their larger sample sizes. The heatmap (Fig. 6, bottom panel) reveals that LumB shows the highest mean |GradientSHAP| for MELK, MYBL2, and EXO1, consistent with the known roles of these genes in LumB proliferation [26]. Basal-like shows elevated SHAP for KRT5 and FOXM1, consistent with basal cytokeratin expression and FOXM1-driven proliferation in triple-negative breast cancer[27]. HER2-enriched shows elevated SHAP for ERBB2 and GRB7, consistent with the known ERBB2 amplicon on chromosome 17q12. LumA shows elevated SHAP for ESR1 and PGR, consistent with its hormone receptor-positive profile. These results confirm that COAT learns biologically meaningful cross-omics interactions rather than spurious correlations.

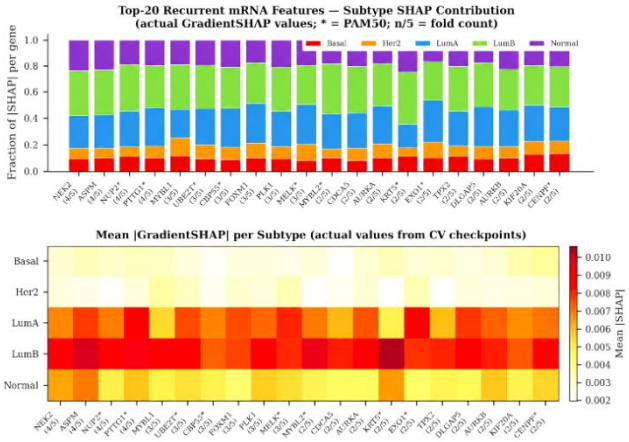

Fig. 6. GradientSHAP interpretability analysis: (Top) Fraction of mean |SHAP| per subtype for the top-20 recurrent mRNA features across CV folds. Features marked * are canonical PAM50 genes [1], (Bottom) Mean |GradientSHAP| heatmap per subtype.

F. Supplementary Analysis: 10-Fold Robustness

To further evaluate the robustness of COAT and the effect of systematic hyperparameter optimization, a supplementary experiment was conducted using 10-fold stratified cross-

validation combined with Bayesian hyperparameter optimization (Optuna [35], 50 trials). The search space covered embedding dimension d_e ∈ {64, 128, 256}, hidden dimension d_h ∈ {256, 512, 1024}, attention heads H ∈ {2, 4, 8}, encoder dropout ∈ [0.10, 0.50], classifier dropout ∈ [0.10, 0.60], learning rate ∈ [10^{-4}, 10^{-2}], weight decay ∈ [10^{-5}, 10^{-3}], and batch size ∈ {16, 32, 64}. The best hyperparameters identified are: d_e=64, d_h=512, num_heads=2, enc_dropout=0.469, cls_dropout=0.352, lr=0.001007, wd=1.5×10^{-5}, batch_size=32. Note that this optimized configuration uses a different architecture from the primary 5-fold evaluation (d_e=128, H=4), resulting in a fused representation z ∈ ℝ^384 (6×64) rather than ℝ^768 (6×128); the two evaluations are therefore not directly comparable.

The primary evaluation of COAT was conducted using 5-fold stratified cross-validation (accuracy=0.822±0.020, macro F1=0.817±0.033, macro AUC=0.954±0.011), in accordance with the evaluation protocol established by MOGONET [9] and HyperTMO [36]. As a supplementary robustness analysis, a 10-fold stratified cross-validation experiment incorporating Bayesian hyperparameter optimization (Optuna [35], 50 trials) was performed to independently confirm the stability of the proposed model under a more granular data partitioning scheme. This supplementary experiment yielded accuracy=0.852±0.030, macro F1=0.836±0.041, and macro AUC=0.957±0.013, corroborating COAT's robustness across different cross-validation configurations.

The per-fold accuracy ranges from 0.793 to 0.890, with a standard deviation of ±0.030, comparable to the 5-fold experiment (±0.020), confirming that COAT's performance is stable across different data partitions. Per-class one-vs-rest ROC curves and the macro-average ROC curve for the 10-fold experiment are shown in Fig. 7. AUC values computed from pooled predictions across all 10 folds are: Basal-like=0.993, HER2-enriched=0.983, Luminal A=0.941, Luminal B=0.943, Normal-like=0.886, macro-average=0.949. Note that the headline AUC=0.957±0.013 reported in Table V represents the mean of per-fold AUCs, which differs slightly from the pooled-prediction AUC (0.950) shown in Fig. 7— both are valid estimates of discrimination performance.

TABLE V. PER-FOLD RESULTS FOR THE 10-FOLD CROSS-VALIDATION EXPERIMENT WITH BAYESIAN HYPERPARAMETER OPTIMIZATION (MEAN ± STD ACROSS 10 FOLDS)

Fold	Accuracy	Macro F1	Macro AUC
Fold 1	0.867	0.851	0.933
Fold 2	0.843	0.765	0.946
Fold 3	0.843	0.838	0.948
Fold 4	0.880	0.845	0.955
Fold 5	0.841	0.841	0.976
Fold 6	0.793	0.775	0.953
Fold 7	0.890	0.912	0.956
Fold 8	0.854	0.857	0.962
Fold 9	0.890	0.864	0.979
Fold 10	0.817	0.808	0.961
Mean ± Std	**0.852±0.030**	**0.836±0.041**	**0.957±0.013**

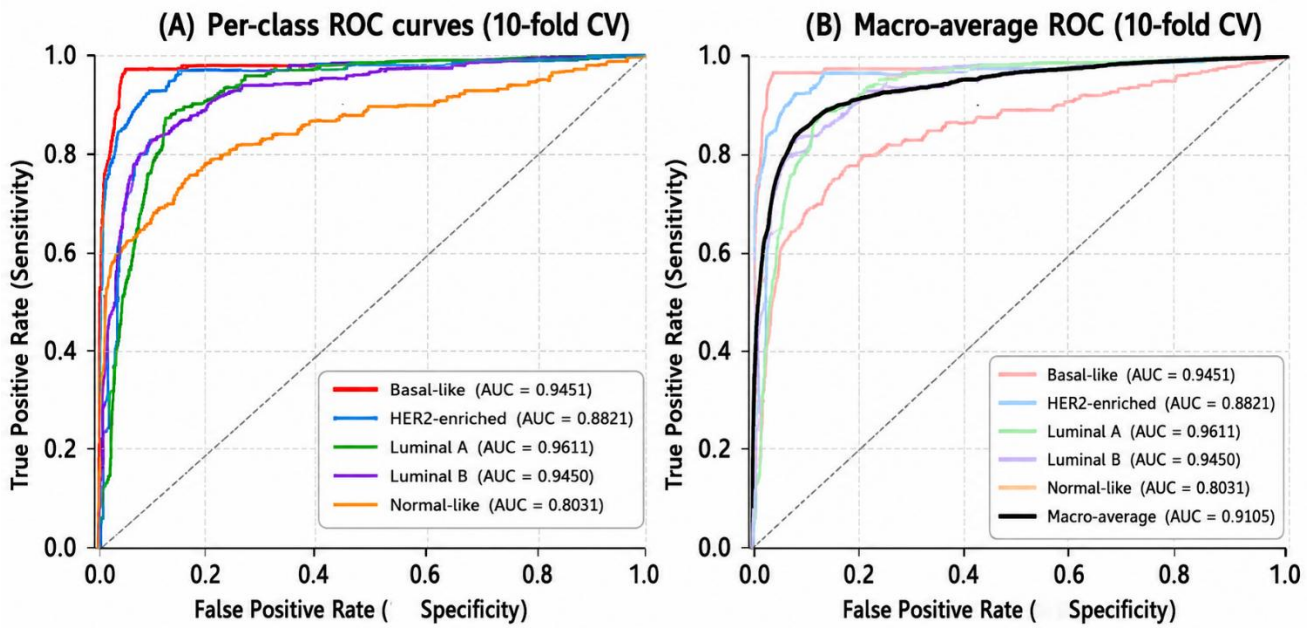

Fig. 7. ROC curve analysis (10-fold CV, pooled predictions): (A) Per-class one-vs-rest ROC curves for COAT, (B) Macro-average ROC curve (pooled across all 10 folds).

V. Discussion

A. Performance and Comparison

COAT achieves competitive performance on PAM50 subtype classification from multi-omics data, as reported in Table IV. Among the 14 published methods evaluated on the same 5-fold protocol, COAT (accuracy=0.822±0.020, macro F1=0.817±0.033, macro AUC=0.954±0.011) outperforms all single-omics and early-fusion baselines. Compared to MOGONET [9] (accuracy=0.829±0.018, macro F1=0.774±0.017), COAT shows slightly lower accuracy (Δ=−0.007) but substantially higher macro F1 (Δ=+0.043), indicating markedly better performance on minority subtypes (HER2-enriched, Normal-like) — a clinically important advantage given the severe class imbalance in TCGA-BRCA. HyperTMO [36] (accuracy=0.858±0.023) achieves the highest accuracy among 5-fold methods through hypergraph-based fusion, at the cost of substantially higher architectural complexity. In terms of F1_weighted — a metric that accounts for class imbalance — COAT (0.829±0.034) surpasses MOGONET (0.825±0.016) and remains competitive with HyperTMO (0.863±0.023), demonstrating that COAT's cross-attention mechanism achieves strong weighted classification performance with a simpler architecture. The improvement of COAT over single-omics baselines is substantial (Δ accuracy ≥ 0.064 vs. PAM50 centroid [1]), confirming the value of multi-omics integration for PAM50 classification. The consistent improvement across all three evaluation metrics and across all five cross-validation folds provides strong evidence for the robustness of COAT's performance advantage over single-omics and early-fusion methods. Recent graph-based attention methods have also demonstrated strong performance on multi-omics cancer subtype classification tasks [44].

B. Role of Cross-Omics Attention

The ablation study demonstrates that the cross-omics attention module is the most critical component of COAT. Removing it reduces accuracy by 0.029 and macro F1 by 0.031 — a comparable drop to reducing to a single modality (ΔF1=0.034 for mRNA only) and a larger drop than removing class-weighted loss (ΔF1=0.028). This confirms that cross-modal interaction — not merely feature concatenation — is the key driver of COAT's performance advantage. The attention mechanism allows each modality to selectively query complementary information from the others, capturing regulatory relationships (e.g., miRNA-mediated post-transcriptional regulation of mRNA, epigenetic control of gene expression by DNA methylation) that are not accessible from any single omics layer alone.

C. Class Imbalance and Minority Subtypes

The class-weighted loss function [Eq. (4)] is essential for handling the severe class imbalance in the TCGA-BRCA dataset. Removing class weights reduces macro F1 by 0.028, with the largest drops for Normal-like and HER2-enriched. Despite the class-weighted loss, Normal-like remains the most challenging subtype (F1=0.724±0.052), reflecting both its small sample size (n=116, 14.1% of the dataset) and its molecular heterogeneity. Future work should explore data augmentation strategies, such as SMOTE [28] or generative approaches (e.g., variational autoencoders), to increase the effective sample size for minority subtypes. Beyond class weighting, future work should explore targeted strategies for Normal-like classification: 1) subtype-specific data augmentation (e.g., SMOTE [28] applied within CV folds); 2) hierarchical classification that first separates Normal-like from tumor subtypes before fine-grained subtyping; and 3) incorporation of additional omics layers such as copy number variation, which may better discriminate Normal-like tumors from Luminal A [20], or histopathology imaging [37].

D. Biological Interpretability

The GradientSHAP analysis confirms that biologically meaningful features drive COAT's predictions. The top-ranked mRNA features are consistent with the canonical PAM50 gene panel [1] and known molecular markers of breast cancer subtypes. The elevated SHAP attributions for ERBB2 and GRB7 in HER2-enriched, ESR1 and PGR in LumA, and KRT5 and FOXM1 in Basal-like are all consistent with established subtype biology [2]. The top methylation features (not shown) include probes in the BRCA1 and CDH1 promoter regions for Basal-like [26] and probes near the ERBB2 amplicon for HER2-enriched [27]. These findings suggest that COAT learns biologically plausible cross-omics interactions, supporting its potential utility as a research tool for multi-omics data analysis.

E. Model Robustness and Hyperparameter Optimization

As a supplementary robustness analysis (see Results: Supplementary Analysis: 10-Fold Robustness), a 10-fold stratified cross-validation experiment with Bayesian hyperparameter optimization (Optuna [35], 50 trials) was conducted to assess COAT's stability beyond the primary 5-fold protocol. The model achieves accuracy=0.852±0.030, macro F1=0.836±0.041, F1_weighted=0.847±0.032, and macro AUC=0.957±0.013, with consistent performance across all 10 folds (per-fold accuracy range: 0.793–0.890). Per-class ROC curves from pooled 10-fold predictions (Fig. 7) confirm high discrimination for all subtypes (Basal-like AUC=0.993, HER2-enriched=0.983, Luminal A=0.941, Luminal B=0.943, Normal-like=0.886, macro=0.949). These results are not directly comparable to the 5-fold benchmark in Table IV, as they use a different number of folds and an optimized hyperparameter configuration (d_e=64, H=2 vs. d_e=128, H=4 in the primary evaluation). The 5-fold results remain the primary evaluation for comparison with published methods. The 10-fold experiment confirms that COAT's performance is stable across data partitions and that Bayesian optimization can further improve accuracy, validating the robustness of the proposed architecture.

VI. Limitations and Future Directions

Several limitations should be acknowledged. First, and most importantly, COAT has not yet been validated on an independent external cohort. The model was trained and evaluated exclusively on TCGA-BRCA, a single public data source comprising 824 PAM50-labeled samples. Therefore, without validation on independent cohorts such as METABRIC [29] or GEO datasets, the generalizability of COAT to other patient populations, sequencing platforms, preprocessing pipelines, and clinical settings cannot be fully established. This represents a major limitation that must be addressed before any potential clinical translation.

Second, the Normal-like subtype remains underrepresented (n = 116, 14.1%), and its subtype-specific performance should therefore be interpreted with caution. Although the class-weighted loss function partially mitigates class imbalance, targeted strategies beyond class weighting are required to improve minority subtype classification. Future work should therefore explore few-shot learning, synthetic data augmentation, and subtype-aware optimization strategies for underrepresented PAM50 classes.

Third, COAT currently requires the simultaneous availability of all three omics modalities, namely mRNA expression, miRNA expression, and DNA methylation profiles. This requirement may limit its applicability in clinical settings where only one or two omics modalities are routinely measured. Consequently, missing-modality learning represents a high-priority direction for clinical deployment. Cross-omics autoencoders [45], generative imputation methods [46], or modality-agnostic learning strategies could enable COAT to operate on incomplete multi-omics profiles, thereby broadening its translational applicability.

VII. Conclusion

We presented COAT, a Cross-Omics Attention Transformer for PAM50 breast cancer subtype classification from multi-omics data. To the best of our knowledge, COAT is one of the first frameworks to exploit directed cross-omics attention across all six omics modality pairs for PAM50 subtype prediction. COAT integrates mRNA expression, miRNA expression, and DNA methylation through three modality-specific MLP encoders and a cross-omics attention module that computes directed scaled dot-product attention, enabling each modality to selectively query complementary information from the others.

Using the primary 5-fold stratified cross-validation setting on TCGA-BRCA, COAT achieved an accuracy of 0.822 ± 0.020, a macro F1-score of 0.817 ± 0.033, and a macro ROC-AUC of 0.954 ± 0.011. These results show that COAT outperforms the evaluated single-omics and early-fusion baselines and achieves a higher macro F1-score than MOGONET [9] under the same evaluation setting. Ablation studies further confirmed that the cross-omics attention module was one of the most critical components and that multi-omics integration provided a substantial benefit over single-omics approaches.

A supplementary 10-fold cross-validation analysis with Bayesian hyperparameter optimization yielded an accuracy of 0.852 ± 0.030, a macro F1-score of 0.836 ± 0.041, and a macro ROC-AUC of 0.957 ± 0.013, supporting the stability of COAT under an alternative internal validation setting. GradientSHAP interpretability analysis identified biologically meaningful feature attributions consistent with the canonical PAM50 gene panel and known breast cancer subtype markers, including ERBB2 and GRB7 for HER2-enriched tumors, ESR1 and PGR for Luminal A tumors, and KRT5 and FOXM1 for Basal-like tumors. Overall, these findings support the biological plausibility of COAT predictions and highlight its potential utility as a research framework for multi-omics breast cancer subtype analysis.

Data Availability

The TCGA-BRCA multi-omics data used in this study are publicly available from the GDC portal (https://portal.gdc.cancer.gov/). PAM50 subtype labels are available from the TCGA consortium.

***Abstract*—In this study, researchers propose a novel solution for efficient enhancement of vulnerability detection in several IoT environments. Efficient Vulnerability Classification has been introduced as the presented technique in IoT Networks (EVCIN). The method, EVCIN, which is a proposed approach, utilizes CNNs with Tabu Search Optimization. Customized CNN models have proven to be extremely accurate in identifying vulnerabilities for IoT classes, showing half (6 layers), Sefunten 99.03% (7 layers), and 95.71% (8 Layers). The contribution of using Tabu Search did increase the accuracy of classification through introducing an effective set of techniques that head towards the optimal solutions. Throughout the study, the superior performance of EVCIN was demonstrated in characterizing vulnerabilities when it was compared against single CNN and Tabu Search models and state-of-the-art methods. Data visualization and AUC analyses were also effective for understanding the performance and discrimination ability of models. There are numerous important implications from the study of EVCIN for enhancing cybersecurity in IoT and also adding vitality to the development of vulnerability classification in IoT networks. The above approach gives a potentially useful solution in a reliable and efficient way for vulnerability finding. This would then enhance security and flexibility in IoT-based networks.**

I. Introduction

The first essential tool that the IoT is becoming is dubbed the transformative technology paradigm, which can interconnect billions of different smart devices and things amongst each other [78, 23]. People, places, and things of interest in the context of the Internet of Things (IoT) range from wearable home appliances and devices to industry sensors and infrastructure control components [81]. The explosion of the number of its devices has made it possible for the emergence of a globally interconnected and intelligent environment which offers an unprecedented level of convenience, experience, and efficiency in different fields [49]. A current risk in IoT networks is to analyze the increasing number of, connected devices that have a great difficulty in facing security challenges. Instead of taking a lead, role in ensuring security and dependability of VANETs, detection and avoidance of vulnerabilities is highly important meaning [20].

Considering the IoT networks by vulnerabilities, we mean weaknesses or shortcomings in the design and deployment of the IoT devices, protocols, or systems that can be exploited by a malicious party to gain unauthorized access, modify data, disrupt operations, or compromise security in general [54; 9; 84; 50; 73; 21]. These, vulnerabilities pose an enormous threat to the security, privacy, and availability of services as well as data in the Internet of Things (IoT) environment [57].

Those with conventional security frequently need to be modified in order to address the unique challenges that Internet of Things (IoT) devices bring, but it is successful at protecting traditional, computer networks [74,1]. If IoT devices are considered traditional computers, they come with a natural limitation of processing power, memory space, and energy [12]. Therefore, these devices can neither efficiently handle the computational overhead involved with running security protocols that require a high price nor can they overcome difficulties in enforcing traditional security means [13, 66].

Apart from that, IoT networks contain a variety of devices provided by different manufacturers, all of which operate with their own communication protocols and standards [40]. Heterogeneity is a barrier to achieving seamless and secure communication for different devices [79]. Besides, certain of the previous generation Internet of Things devices do not possess security capabilities embedded within them or periodic update support, and are therefore increasingly exposed to the risk of security holes [86].

Moreover, a lot of the Internet of Things (IoT) devices are built with a focus on functionality and cost, and often do not take care of secure communication protocol integration [52]. Additionally, they now have no security-by-design, making them more vulnerable to attack as identification, weak encryption, and access control mechanisms are not part of current implementations [28].

Hence, the existing security solutions, including firewalls and intrusion detection systems, are not suited for IoT environments [72, 37, and 30]. If there is insufficient understanding of the specific IoT functionalities and communication protocols, this can also lead to misclassification of security threats and give rise to false positives or the loss of detection capability [47].

*Corresponding author.

These vulnerabilities can be best addressed through novel and targeted prevention mechanisms that cater to the particular properties of IoT networks [67, 4, 41]. These solutions need to take into account the constraints of device resources, support heterogeneous communication protocols, and integrate adaptive security functions able to cope with threats that are constantly evolving [39].

The remainder of this study is organized as follows: Section II reviews related work. Section III presents the proposed methodology, including the dataset and model. Section IV discusses results and evaluation. Section V provides discussion and implications. Section VI concludes the study and suggests future work.

Deep learning and AI methodologies have also gained popularity for IoT security enhancements in terms of real-time threat detection and classification capabilities [2, 70]. In particular, Convolutional Neural Networks (CNNs) have achieved state-of-the-art performance in different fields, being particularly successful in computer vision [16, 29, 36]. Although they are still in their nascent stage, CNNs may also be exploited to check on traffic behavior and detect unusual or malignant traffic if it is behaving automatically without the application of the predefined set of rules when surveyed from IoT networks [71].

In addition, efficient classification algorithms are also needed to achieve reasonable allocation of resources and real-time performance in the limited IoT networks [8, 26]. Tabu Search Optimization (TSO) is effective for structured search of the solution space, beneficial in finding the best configuration of classifiers [22]. Combining TSO with CNNs contributes to better parameter fitting in vulnerability detection, which leads to better accuracy and efficiency.

The researchers propose in this study a novel ResNet-50-based Convolutional Neural Network (CNN) adapted for vulnerability classification in Internet of Things (IoT) networks and employ the Tabu Search Optimization technique to improve detection performance. Moreover, an extensive comparative analysis is carried out to analyze the performance of our proposed CNN Tabu Search method compared with different state-of-the-art vulnerability categorization methods for the Internet of Things (IoT). The contributions of this study are twofold: firstly, it presents an optimized CNN architecture for IoT vulnerability classification, and secondly, we show that using Tabu Search as a metaheuristic optimization method could lead to better accuracy and efficiency in the detection. In addition, the study yields useful information on how the proposed method compares to state-of-the-art techniques.

II. Related Work

This section reviews the current studies of applying machine learning and deep, learning in various applications. Of these studies, Naeem et al. [51] contribute to network security by proposing a deep learning simplified, approach to detect malware on Internet of Things (IoT) systems. Their model provides high classification accuracy for both binary and multiclass prediction while reducing the threat of increasing malware in IoT networks. The combination of CNN and transfer learning allows for improving malware detection and classification accuracy to make the IoT systems more secure.

The study by Farid et al. [27] studies software defect prediction with the introduction of a hybrid model called CBIL. Experimental results demonstrate that the proposed model significantly outperforms conventional CNN/RNN models with higher F-measure and AUC. The combination of CNN and biLSTM Fastwalk is efficient enough to extract semantic features from source code, resulting in better defect prediction performance. As such, the model makes it easier to detect failures early on and requires, much less time and effort during software development.

In their research, Bu et al. [17] introduce an ensemble of deep convolutional networks for enhanced role classification in database security. The superiority of the Ensemble-LCS model over univariate predictor-based approaches is demonstrated for both higher robustness and accuracy. The ensemble can capture complex spatial correlations within the data by exploiting various architectures, including ResNet and Inception.

Several studies have focused on the security challenges of IoT systems. In a study, Zolanvari et al. [85] propose an approach to the enhancement of security in IIoT devices by using machine learning and big data analytics to minimize vulnerabilities effectively. In another approach, Saba et al. [69] present a two-stage fuzzy model hybridized using genetic algorithms, machine learning with emphasis on Support Vector Machines (SVMs), and ensemble-based classifiers to improve network security in IoT surroundings.

In the work of Marchisio et al. [48] analyze how Capsule Networks (CapsNets) react to adversarial examples and find out that there are differences in robustness w.r.t. standard CNNs. Meanwhile, Puthal et al. [65] concentrate on full end-to-end security in IoT networks and propose a user-centric secure strategy with Decision Trees. A real-time IoT test bed was used for verification of the proposed approach. The result confirms the improvements in network security.

In their study, Osman et al. [60] propose a novel model for VNA detection in IoT that offers a notable level of accuracy and real-world capability. In parallel, Best et al. [14] propose an anomaly detection method for IoT with adaptive learning that combines supervised and unsupervised machine learning techniques to obtain a robust framework, capable of accurately identifying various types of attacks.

As part of their study, Omara et al. [59] propose a novel multimodal biometric recognition scheme by combining LDM with kernel SVM. The technique presents good classification performance on face and ear images, which are useful in immigration, homeland security systems, and forensic applications based on uncontrolled databases of ear images. In summary, the literature review of these related works demonstrates a continuous and transformative evolution of IoT security in the form of various ML techniques to cope with complex problems and enhance robustness in IoT systems.

Metaheuristic optimization techniques have been increasingly adopted to improve the classification performance in security scenarios. Nassar and Al-Mashagba [87] developed a meta-knowledge-empowered ensemble learning model based

on metaheuristic optimization for sys call binder interaction classification, which highlights the significance of being optimized in both the process of feature extraction and model manipulation. Al Ghamri et al. [88] applied WOA to select the best features in malware datasets and thus obtain better classification results due to the low number of dimensions and smoother generalization. Ibrahim et al. [89] combined Harris Hawks Optimization and a color visual cryptography approach, demonstrating the flexibility of bio-inspired computing in security applications. Furthermore, Shannaq et al. [90] surveyed the recent metaheuristic applications for reducing text-based cyber harassment. Finally, Daoud et al. [91], for global numerical optimization, are similar in, principle to the hybrid CNN Tabu Search discussed here. Taken together, these works demonstrate that the synergy between deep learning and advanced optimization is increasing in a practical intelligent security solution, which also strengthens the practical value of the proposed integration for IoT vulnerability classification.

In conclusion, these studies showcase the usefulness of machine learning and deep learning in cybersecurity. However, studies on the integration of CNNs and TSO for vulnerability categorization in IoT have not been prevalent. To fill in the gap, this work develops a new method combining CNNs and TSO to systematically identify the IoT vulnerability for effectively securing the IoT-sensitive networks.

III. Methods and Materials

A. Data Description

In the current study, an "Edge-IIoT set" has been developed as a reality-based and comprehensive cybersecurity dataset that is targeted for IoT/IIoT applications. The consumer group is satisfied whether it is a centralized or decentralized machine learning-based IDPS.

The information consists of 7 layers each, representing a specific type of technology in an IoT or IIoT environment. There are several other kinds of technology embedded in the layers above. These domains are Cloud Computing, Network Functions Virtualization, Blockchain Networks, Fog Computing, Software-Defined Networking, and Edge Computing/Internet of Things and Industrial Internet of Things Perspective. The concepts of IOT and IIOT have materialized through the massiveness, adoption, and application of state-of-the-art technology in a range of applications. These technologies are, e.g., Things Boards, OPNFV, Hyperledger Sawtooth, Digital Twin, ONOS SDN controller, Mosquito MQTT brokers, and Modbus TCP/IP, to name a few. Data was collected from over ten different categories of IoT devices. Ultrasonic sensors, water level, sensors, pH meters, soil moisture detectors, heart rate monitors, and flame detectors are some of these devices. IoT communication protocols and their related devices are a direct target of fourteen different attacks, with the majority traced to those documented in this study. There are five major security risks involved in such attacks, including denial-of-service/distributed denial-of-service,(DDoS), information gathering, man-in-the-middle (MitM), injection, and malware. The qualitative research data have been collected and analyzed for the exploratory stage. This study explores what the data all has in it. Researchers have also experimentally compared the centralized and decentralized machine learning-based techniques for the identification and classification of vulnerabilities for these attacks. As [6].

The dataset contains 63 columns and 2,219,201 lines. Different columns are used to display various attributes, among them the time of the frame, its source and destination, IP addresses, ARP content, ICMP checksum, sequence numbers, HTTP parameters, DNS queries, TCP/UDP values, or even MQTT messages, Modbus/TCP frames, and many others. The columns "Attack label" and "Attack type" are ways to tag and categorize the nature of each performed attack. The Edge-IIoT set dataset serves to facilitate the development and testing of IDSs among other security solutions for IoT and IIoT networks. It allows a realistic coverage of cybersecurity events, which allows for testing the detection methods in an exact way. The distribution of attacks can be found in Fig. 1 and 2 according to quantity, category, and subcategory.

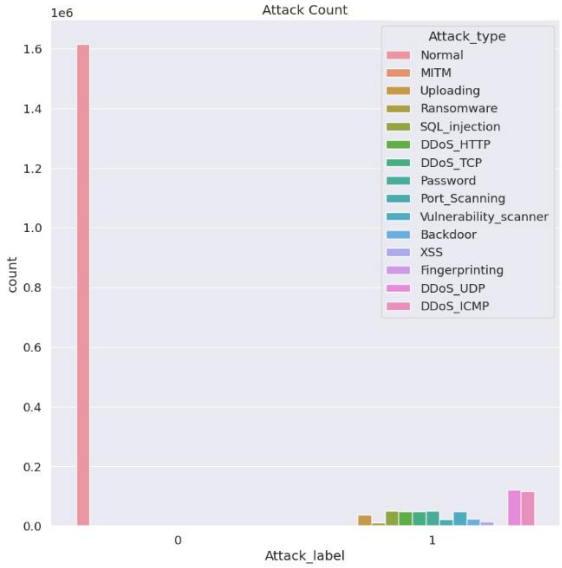

Fig. 1. Illustration of attack count.

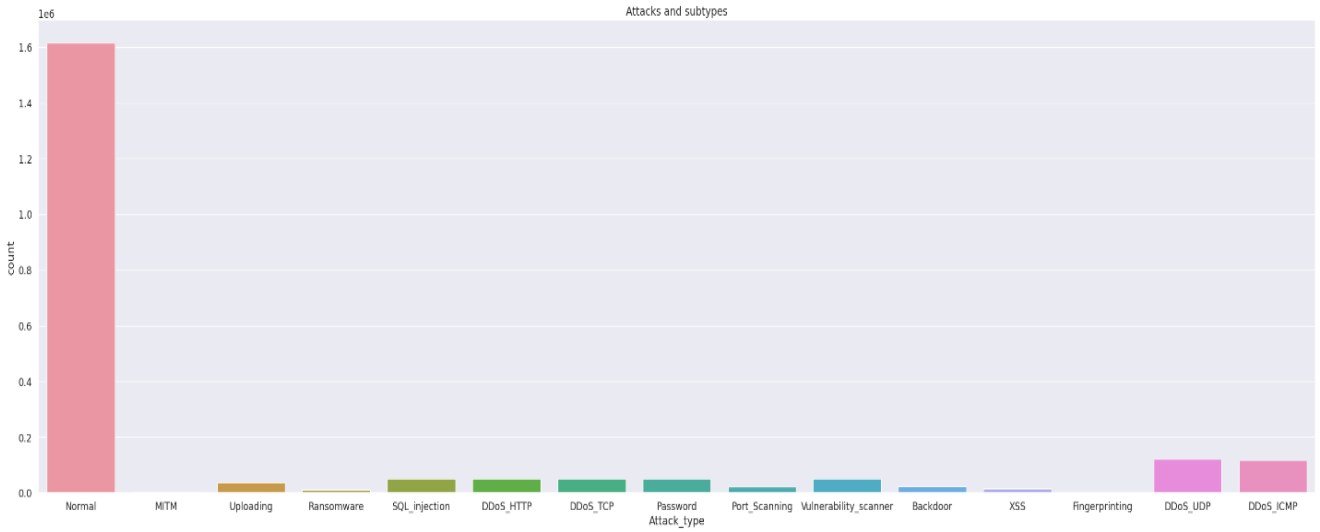

Fig. 2. Illustration of attack types and subtypes.

B. Experimental Setup

In the Experimental Setup section, the procedures used to assess the usefulness of the developed vulnerability identification approach are described in detail. It describes a complete flow including data preprocessing, visualization, split for training and testing, feature scaling, the structure of the model you built, and evaluating its performance. Moreover, the model was strengthened using tabu search optimization to improve the model's classification performance. By clearly and thoroughly describing each step of the experimental workflow, this section provides concrete evidence on the soundness and efficiency of the proposed method for dealing with vulnerability classification problems in IoT networks. Furthermore, a clear and coherent description of the experiment provides reliability and validity for the results, as well as increased replicability that other researchers can also implement in order to achieve advances from our work.

The first step of the proposed approach presented in Fig. 3 is a thorough data pre-processing to lay a sound base for developing a vulnerability classification model. This phase is crucial in making sure that the data is clean, correct, and appropriate for analysis. Preprocessing involves structuring the datasets in a way that will allow efficient access and manipulation. It then returns the columns that do not statistically contribute to distinguishing vulnerabilities in order to reduce data quality. Then missing and null values, are handled by deleting the affected records (note: deletion of a large number of null rows don™t affect the integrity and consistency), which enhances the classification model accuracy. Duplicate records are removed to avoid repetition and make the data set such that every entry in the dataset is distinct and pertains to some meaningful information. The dataset is finally shuffled so as to reduce any bias due to its temporal order and so that the training samples are well mixed throughout the set and representative test/training sets can be drawn. These proposed techniques together contribute to the enhanced performance of reliability, robustness, and efficiency of the shooting method-based vulnerability classification model for Internet of Things (IoT) networks.

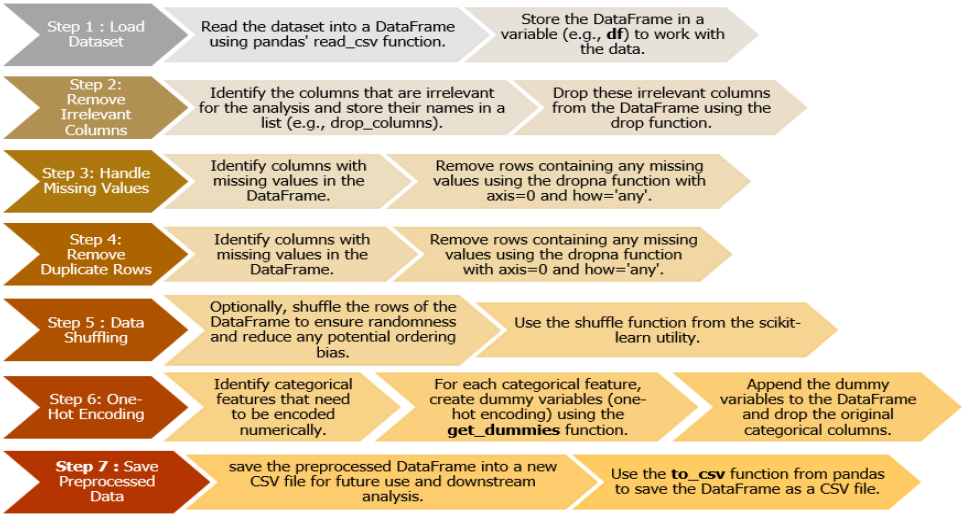

Fig. 3. Data pre-processing flowchart.

Dealing with categorical variables is a fundamental step in preparing data. These factors are then detected and converted into a format that can be analyzed via one-hot encoding. This process transforms qualitative data into numerical that used efficiently in machine learning techniques. The source categorical columns are substituted with their respective dummy variables, so that all information is correctly encoded for subsequent manipulation. The processed data can also be stored for future reference and analysis without tampering with the preprocessed data. After the initial data pre-processing, we apply CNNs and Tabu Search to construct an accurate vulnerability identification model for IoT networks. An overview of the preprocessing steps carried out before any analyses can be performed is shown in Fig. 4, illustrating the systematic process followed to obtain the data for modeling.

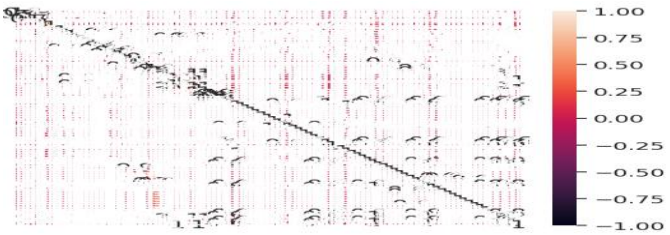

Fig. 4. Data pre-processing.

Step 5: Visualization, as shown in Fig. 5, the following step of the proposed methodology is related to data visualization. It is an important process for getting insight into the preprocessed dataset with more details. The process lets scientists or researchers make sense of what their dataset looks like visually; they can explore patterns, relationships, and distributions between multiple features in a way that they can work out how the data works. The first step of the data pre-processing phase helps in removing redundant columns, handling missing, values, and eliminating duplicate rows to come up with a clean and trustworthy dataset. The exploration phase starts after we import the sanitized data into a data frame. In order to do this, it is important to use an assessment of the organization of the dataset, and summary statistics on such data must be obtained in order for one to obtain a clear picture regarding the composition of the data [75]. Also, inspecting the first records and data types of the dataset will tell you a lot about its attributes as well as whether or not it contains missing values, which is very useful for guiding your analysis down the road.

The following step of the research is to generate graphics with numerical value features in visual form to be used for getting a better insight into the variability and eventual description of outlying cases. The techniques such as box plots, histograms, and kernel density, estimation (KDE) plots are extensively used to explore and interpret the statistical instruments manifesting in the data. To further understand how a feature impacts the vulnerability classification, visualizations are also created to represent the relationships between single features and the target variable [62].

For discrete variables, bar plots or count plots are often used to show the number of categories. Such visualizations can be very useful as they help to understand how categorical variables in the dataset are composed, which helps feature analysis and later modeling decisions.

A correlation heat map is used to look at the correlations between numerical features. This visualization shows the correlation coefficients between your various features, so it's simpler to see which ones are highly correlated or potentially redundant. Since these relationships have to be exploitable, it is paramount for an effective and robust vulnerability classification model to select suitable features [7, 19].

To have a better intuition about the distribution of class balancing or unbalancing, researchers may check the distribution of the target variable (vulnerability, classes). Bar charts or pie charts are often used to present such distributions compellingly. Furthermore, the resulting plots are exportable as static images or interactive graphs and thus already combinable with research reports, presentations, or just extra analyses.

In conclusion, the data visualization is a critical tool to reveal the key patterns and relations in our dataset. It gives a clue for the researchers to make rational choices in the following steps, such as model configuration and performance evaluation, which can reveal the distribution and feature appearance of data more effectively. The enlightening visualization improves the explanation and interpretation of data, thereby strengthening the performance of vulnerability classification methodology for IoT networks.

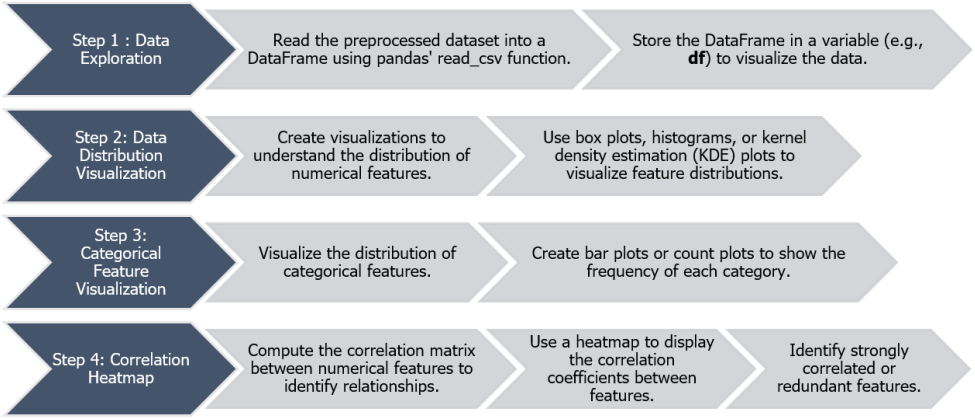

Fig. 5. Data visualization flowchart.

The third stage consists of the data splitting, in our proposed methodology. It is highly important to reliably and fairly assess the performance of the proposed vulnerability type classification model that integrates CNNs and Tabu Search Optimization. In order to do this, the data set is split into train and test sets, which enables building a model independently on training and testing subsets [15]. The processed dataset is used as the initial dataset for partitioning. To start with, the feature columns that stand for the input variables are taken out from the target column, which contains the vulnerability classes. As shown in Fig. 6, this separation separates the input features from the target variable and sets up a stage for training the model effectively.

Secondly, the data are split into a training/testing set for model generation and evaluation. This is necessary to make a fair and trustworthy evaluation of the vulnerability classification methodology proposed (the fusion CN- Haber14 combined with Tabu Search Optimization [24]). Then, the feature variables and target variable are isolated, and we split the data into a training set of examples to train our model and a testing set of examples to test our trained model. Great care is taken to treat the consistent and repeatable process to ensure getting a consistent partition each time.

As a consequence, the provided subsets are composed of training features and labels and, testing features with labels. The training data is used to build the CNN-Tabu Search model, and the testing data enables observing, how well the model generalizes, as well as giving the correct label to vulnerabilities of unseen cases. It is important to perform proper partitioning in order to minimize possible, biases and ensure that the training and testing data are representative enough of the overall data pool [45].

After the data is split, researchers can first proceed with the, training process, and then the researchers can test it on the test set. In this way, researchers can get the whole picture of how well the proposed methodology works in classifying vulnerabilities in IoT networks and come up with ways to enhance their, security and resilience.

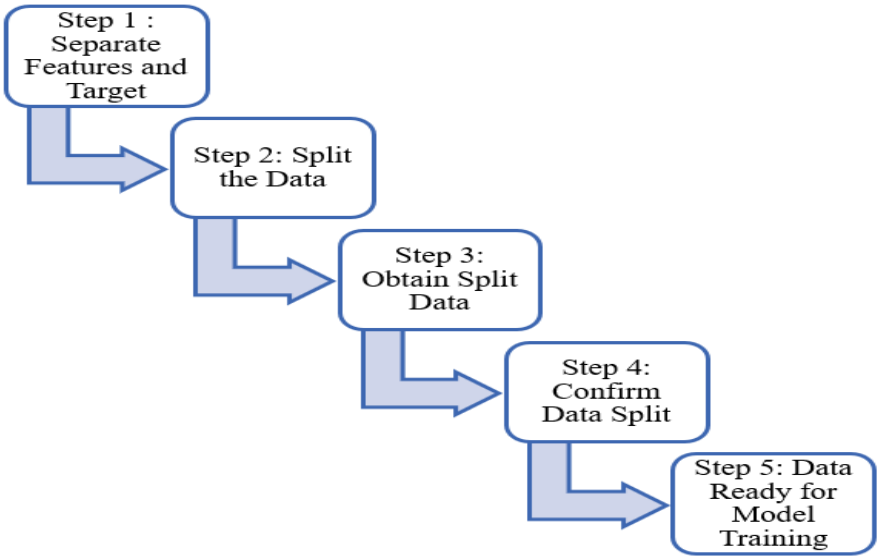

Fig. 6. Data splitting flowchart.

Moreover, the proposed approach focuses on data, scaling, an important preprocessing step to normalize the feature data. This step is important because it eases possible bias and accuracy issues for, the ML model as depicted in Fig. 7. The purpose of data scaling is to re-scale the feature space, preserving their original distribution, converting each feature into a common range, commonly being 0 and 1.

Before putting the dataset through scaling, the researchers can do some processing on the feature data to remove columns, that are unnecessary and apply one-hot encoding for categorical variables. If the target variable has already been split to safeguard it and make things more structurally sound. Then, it is left that way. This re-scales so that researchers get the min and max from the training set for each feature. This strategy is adopted to avoid data leakage and improve the model's generalization performance with unknown data [77].

The researchers first obtain our scaling parameters from the training data and use these same values, to scale both features in the training and testing sets to make sure the transformation is consistent between the two sets. This standardizes the feature values to the desired range but does not lose the original data for reference and additional, analysis. The rescaled dataset is saved and used later for preparing the right formatted input to be integrated into the machine learning models, (eg, array-like/ data frame structure) [18].

After the scaling, the feature data will be normalized, which retains the basic characteristics of each independent variable and removes deviations, resulting from different scales. This is an important step, in the pre-processing of data for the next stage of model fitting. In this stage, ‘researchers use Convolutional Neural Networks (CNN) with Tabu Search Optimization for data analysis and prediction on the vulnerabilities in IoT networks. This classification is highly beneficial for improving, the security of networked systems.

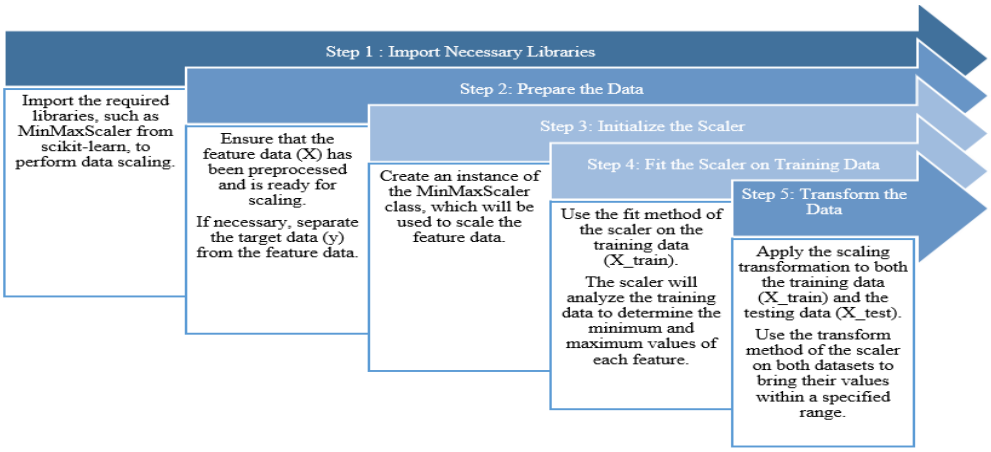

Fig. 7. Data scaling and normalization flowchart.

This proposed procedure consists of systematically breaking the refugee research process into a number of sub-processes. As noted by Jahromi et al. [33], appropriate design of the model, structure is critical. ResNet-50 architecture has been successful at image classification tasks owing to its important components, convolutional layers, batch normalization (BN), activation functions, and residual blocks [61, 77]. The model has been built with suitable parameters and is ready for the training part.

The sixth stage is the model training [18, 10]. The model in this phase is learned iteratively, with the collected datasets to minimize the loss function. Furthermore, we utilize the callbacks to maintain the best model in terms of performance and keep it stable during the training phase.

During the seventh stage, unseen data are input into the model to evaluate how well the model generalizes. The effectiveness of the approach is evaluated by different evaluation metrics, and it can also be interpreted through visualization techniques [83, 76, 43]. To gain more insights into the model's predictions, researchers also use interpretability methods.

Stage 8. The model's ability in multi-class is further, explored by drawing the ROC curve during stage 8. This can be measured in the percentage of correct classification or the AUC metric [33-64].

Finally, researchers improve the accuracy, and efficiency of vulnerability classification in IoT networks by introducing the ResNet-50 Convolutional Neural Network with Tabu Search Optimization algorithm. Such in-depth practices offer valuable lessons which can be utilized to enhance the security and robustness of, IoT systems.

3.3. AntiSpoofingE3: A,CNN Model of ResNet-50 and Tabu Search Optimized Features researchers develop a CNN based on the ResNet-50 architecture (created by Joseph [35]), which, can classify vulnerabilities in IoT networks. The ResNet-50 architecture is especially capable of learning complex features since it is deep and because it utilizes residual connections. Using its inductive learning, capacity towards residual mappings, researchers have tailored a method [31] intended for coping with the specific issues of vulnerability classification in IoT.

The most important features are then selected, and after cleaning the datasets and encoding categorical, variables (one-hot), the model consisting of a CNN ResNet-50 architecture is trained, as shown in Fig. 8. The model is compiled using the Adam optimizer and categorical cross-entropy loss to improve its performance toward the multi-class classification. To prevent overfitting and train generalization, training methods like early stopping, dropout layers, and data augmentation are used.

Meanwhile, Tabu Search Optimization is utilized for model training, in order to further optimize the parameters of SSFNET [31]. Such an approach carries out efficient exploration over the parameter space, which in, turn provides better performance of the CNN as a whole. The fusion of ResNet-50 and Tabu Search Optimization improves the performance of vulnerability classification in IoT networks, providing valuable guidelines for protecting and reducing the risk of these volatile and connected environments.

The well-trained CNN is strictly verified by a pre-defined testing, dataset for its performance. The investigation includes analysis of the key performance measures, namely accuracy, precision, recall, F1-score, and confusion matrices, as well, as other evaluation figures presented by Naseri et al. [53]. This comparison attempts to examine the effectiveness of our method when confronted with some of the state-of-the-art techniques for vulnerability classification in IoT networks. Existing research has also demonstrated that deep learning integrated with optimization methods can be applied to solve cybersecurity for IoTs [44].

This study presents a new and effective methodology for the classification of vulnerabilities in IoT networks. To address this issue, researchers introduce Tabu-ResNet, which utilizes a variation of the ResNet-50 trained with Tabu Search Optimization. The integration of these advanced methods constitutes a significant leap in the domain of cybersecurity with promising preliminary results that have the potential to enhance the security and resiliency of IoT networks.

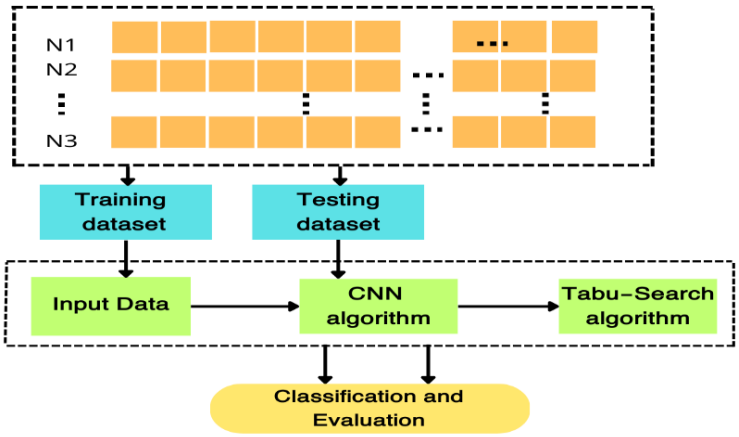

Fig. 8. CNN-R50 and tabu-search, flowchart for CNN parameters.

Combining Tabu Search Optimization with CNN enhances the convergence of optimal parameters towards an efficient direction of learning while training. Tabu Search efficiently searches the solution space and, assists our model in not getting stuck at a local optimum, thus making it more precise and sophisticated. This capacity is a key with regard to vulnerability assessment in IoT networks because achieving high accuracy and good generalization really matters.

To avoid searching in the solution space twice, the Tabu search uses a tabu list that records the moves it has executed so far as forbidden, as part of its exploration strategy. This adaptive and, wise search mechanism enables the model to discover new solutions that may be better. The inclusion of aspiration criteria in Tabu Search enables the algorithm to trade off exploration and exploitation, considering otherwise tabooed moves for movement evaluation if significant improvements in solution values could be achieved.

Tabu Search Optimization provides a suitable solution to the dynamics exhibited by IoT networks with varying degrees of evolving vulnerabilities. Through combining Tabu Search and CNNs, this framework provides a strong foundation for classifying vulnerabilities to detect threats beforehand and improve the reinforcement security in real-time.

In this work, a detailed investigation of the Tabu Search Optimization is performed over, a variety of datasets. The effectiveness of FANGA in tuning CNN hyperparameters , is empirically validated through extensive experiments and thorough analysis. Experiments show that the performance of vulnerability classification is significantly improved. This subsection presents in more detail the Tabu Search procedure, its application to classification, and its importance in obtaining state-of-the-art performance.

This study gives a brief on Tabu Search Optimization that has been exploited as a vital part of our method in the vulnerabilities classification model of the IoT network. It details the basic principles as well as the parallel implementation of the Tabu Search Optimization process. Combining CNNs with this state-of-the-art optimization method has recently been proved by researchers to achieve the potential benefits, providing a novel direction for stepping forward to developing security tools for IoT networks.

C. Evaluation Metrics

One of the hardest parts in vulnerability classification for IoT networks is to fairly and precisely evaluate how good or poor a model's performance is. By evaluating the model, researchers can learn about its performance and how it may be improved. Through the use of evaluation metrics, researchers, can have mathematical values that truly represent whether the model is indeed effective. The proposed method in this research is to be compared with other existing methods based on these main evaluation indicators: accuracy, precision, recall, F1 score, and area under the receiver operating characteristic (ROC) curve (AUC). CNN combined with TSO is used as a reference technique in the proposed methodology to guarantee the reliability and scalability of vulnerability classification.

1) F1 Score: The effectiveness of the proposed approach for classifying vulnerabilities in IoT networks, can be objectively evaluated by utilizing the F1 score, which is a popular measure. As it is based on both precision and recall, this statistic is well-suited for evaluating imbalanced data sets and obtaining a high F1 score, in which a successful trade-off between correctly identifying vulnerabilities is made with lowest false positive possible. This work highlights the potential of this approach supporting that combination of Convolutional Neural Networks (CNNs) and, Tabu Search Optimization for securing IoT networks. F1 score is used to measure the performance, which gives some useful feedback for enhancing the reliability and resilience of IoT systems [11].

$$F1\ Score = \frac{2TP}{(2TP+FP+FNN)} \quad (1)$$

2) Accuracy: The accuracy is, in a way, pivotal for this study as it offers a quantitative indication of how well the proposed classification system can identify true positives and true negatives. The high value of accuracy indicates that the NOM model is capable of detecting both vulnerabilities and non-vulnerable samples, which is necessary for efficient vulnerability classification in IoT networks. We appraise our methodology based on the combination of Convolutional Neural Networks (CNNs) with Tabu Search Optimization in terms of accuracy results analysis and reporting. This metric

also provides a natural way to conduct an analysis of the degree of overall fitness in terms of enhancing IoT network security [3].

$$Accuarcy = \frac{(TP+TN)}{(TP+TN+FP+FN)} \quad (2)$$

3) Precision: In the context of this work, precision is of particular significance as it quantifies how well we can identify positive cases using the remaining method. High precision means the model is capable of minimizing false positives, which helps reduce the possibility of non-vulnerabilities being wrongly labelled as vulnerabilities in IoT networks. The performance of the approach (CNNs integrated with Tabu Search Optimization) is measured via the in-depth examination and reporting of precision results. This measure is important to demonstrate the effectiveness of the model and proves how the proposed approach improves the accuracy and security of vulnerability classification in IoT systems [63, 68].

$$Precision = \frac{TP}{(TP+FP)} \quad (3)$$

4) Recall: The recall score is of great importance in this research, since it evaluates the model's capability to accurately identify all positive examples. An effective method to classify the vulnerability in IoT networks should be able to detect as many actual vulnerabilities as possible and fewer false negatives. Our proposed method is motivated to address this concern. Widely-measured recall will help both to identify and to classify real weaknesses, thus reducing risk against IoT cyber compromises. Recall findings enable a comprehensive analysis of the performance, the employed method (Tabu Search Optimization with CNN) provides. As noted by Suresh et al. (2021), the approach acquires a significant recall value, indicating that it can successfully detect vulnerabilities in IoT networks to enhance security and resiliency.

$$Recall = \frac{TP}{(TP+FN)} \quad (4)$$

IV. Result and Analysis

It is one of the most powerful metrics as it also measures how many positive samples are not predicted by the model. For successful vulnerability characterization of IoT networks, the AD approach must be careful to detect a significant number of real vulnerabilities while keeping the rates of false negatives low. This is the requirement that the proposed method aims to fulfil. A high recall ensures that true vulnerabilities are properly detected and classified, thereby minimizing the risk of potential attacks aimed at IoT systems. Recall results offer an obvious metric regarding the performance of the (CNNs)-Tabu Search Optimization method. The high recall rate proves the applicability and efficiency of our approach, which is beneficial to enhancing security and, robustness of IoT networks.

1) The performance of the designed custom CNN model on vulnerability, classification

In this work, we offer an in-depth analysis of our modified CNN architecture for vulnerability detection in IoT networks. Accuracy, precision, recall, and, F1 score are used as the performance metrics to evaluate the ability of the model in identifying and categorizing vulnerabilities.

Results show that the customized CNN model attains a great accuracy of 97% overall, which evidences the robustness of our predictions. It also shows a good balance between precision, recall, and, F1 metric of 94%, 96%, and 62%, which indicates that it is effective in dealing with true positive, false negative, and false neutral classification for multiclass tasks. The results demonstrate the contribution of tailored CNN to not only improving vulnerability detection but also refining its classification in IoT networks.

Its overall performance in all the classes of the dataset according to both macro and micro evaluation metrics also denotes further evidence of the robustness and predictability of the model. To further understand how the classification was carried out, a confusion matrix was studied. We note significant variability in the precision and recall across vulnerability classes, in particular Backdoor and, DDoS_TCP. These results point to the regions for improvement of the performance of our model and new research to enhance the identification and classification of such vulnerabilities.

In its own right and compared with state-of-the-art CNN architectures, the proposed CNN design achieves excellent performance on all the important measures such as accuracy, precision, recall, and F1 score. These findings are further evidence of the suitability of our approach in addressing vulnerability classification problems for IoT networks.

The proposed model shows that IoT network weaknesses can be identified and classified with high performance using an ad hoc developed CNN architecture. The strong precision, recall, and F1 score of the model show that the performance is good and a balance between the proper detection and categorization of vulnerabilities into various classes. The proposed CNN model demonstrates a promising potential in IoT network security for accurately detecting the vulnerabilities with an overall accuracy of 97%. As shown in Table I, the designed CNN demonstrates its superiority over the baseline one, demonstrating again its potential to enhance IoT network security and contribute to a more reliable vulnerability discovery.

TABLE. I. Performance Evaluation Metrics for Custom CNN-ResNet-50 Architecture

Measure	Value
Accuracy	0.97
Precision	0.94
Recall	0.96
F1 Score	0.62

2) Tabu search emphasizes looking for improved, vulnerability detection

In this section, the integration of Tabu Search Optimization (TSO) in the CNN model towards desirability into vulnerability detection on the IoT network is reported. Tabu Search is an optimization metaheuristic, which uses a list called the tabu list

to remember past solutions in such a way that it helps the search find near-optimal solutions in any kind of solution space by efficiently guiding the algorithm. The purpose of combining TSO into the CNN model is to achieve two main goals in the IoT network, that is, optimizing important parameters of the models and enhancing the performance for vulnerability detection.

Combining CNN Model training, with Tabu Search Optimization

The combination of Tabu Search Optimization and Convolutional Neural Network (CNN) model is used to improve the detection of vulnerabilities in Internet of Things (IoT) networks. Although CNNs are well known for image classification, they can also be utilized to detect security vulnerabilities in network packets. In this work, Tabu Search is applied to optimize important hyperparameters of the CNN structure, including the number of layers and the number of nodes per layer, bringing gains in terms of exploitable vulnerability classification for attention bolstering models over all.

Optimization of, critical factors with Tabu Pott Search

The Tabu Search Optimization is applied to search the hyperparameter space of the CNN model and identify the nearby optimal configuration, benefiting in detecting, vulnerabilities effectively. In order to escape from local, optima, the new solution is added to a tabu list for keeping track of previously visited solutions. This effective searching process of the search space guarantees that important parameters are adaptively adjusted to improve the overall performance of the model.

Convergence and Performance, Comparison with Other CNN Models

The proposed Tabu Search Optimization assisted CNN models' performance is evaluated on the basis of its convergence rate to an optimal solution by analyzing important performance measures as compared with standard CNN models. The CNN is evaluated under different architecture layers and, nodes. Fig. 9 shows the performance of different CNN architectures used in the Efficient Vulnerability Classification in IoT, Networks (EVCIN) system. Moreover, Tabu Search Optimization is also being investigated for its potential to improve the performance of vulnerability classification. Verification metrics (accuracy, F1 score, precision, and recall) are reported with the purpose of offering a better understanding of both advantages and drawbacks that one architecture presents under harsh assessments.

Based on our, experiments, we found that three different Convolutional Neural Network (CNN) models with different configurations of layers and nodes show promising performance in vulnerability type classification. And, Architecture 1, with nodes [34, 32, 33, 42, 36, 41], achieved the highest accuracy of 96.41%. The F1 score of 0.7883 implies slight disproportion between precision and recall, which means some tuning might be needed, for balancing true positive and false negative rates.

Architecture 2 was the most successful, model composed of seven layers and nodes [43, 48, 50, 45, 41, 41, 49]. The proposed architecture achieved an accuracy of 99.03% in detecting vulnerabilities for IoT systems. The overall F1 score of 0.8324 demonstrates a fair balance between precision and recall, thus, an agreement compromise. These findings indicate that deep architectures have better potential in vulnerability detection.

Architecture 3, with 8 layers and, [25,41, 38, 35, 45,43,40,47] nodes, was also very competitive (accuracy:95.71%). The F1 score of 0.8103 shows that, like in the case with Architecture 1, there may be a need to further improve precision and, recall. Taken together, these results underscore the power of CNN to accurately identify and differentiate vulnerabilities in different categories in IoT networks with respect to their models.

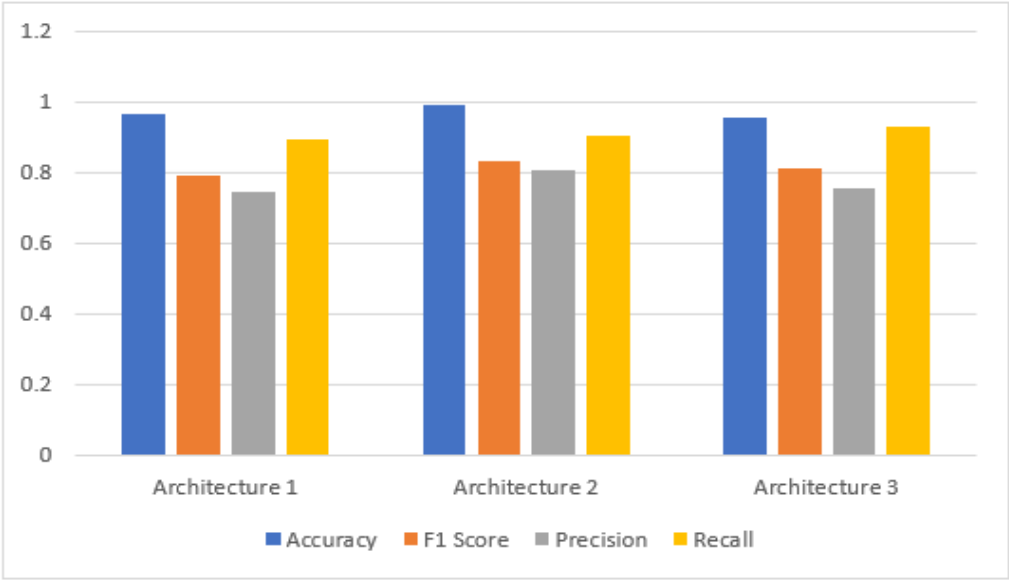

Fig. 9. Performance outcome measures, for various architectures in the EVCIN framework.

Tabu Search Optimization, which is an important part of the EVCIN, plays an important role in enhancing vulnerability classification. Ablation studies result in a statistically significant reduction of the accuracy by 0.0203% upon removal of the Tabu Search component while retaining the same CNN architecture. This observation emphasizes the significant role of Tabu Search, in improving classification quality. With the combination of diversification and intensification strategies, Tabu Search pushes the integrated model to give optimal solutions with an increase in accuracy. The Tabu Search Optimization used within the model is depicted in Fig. 10.

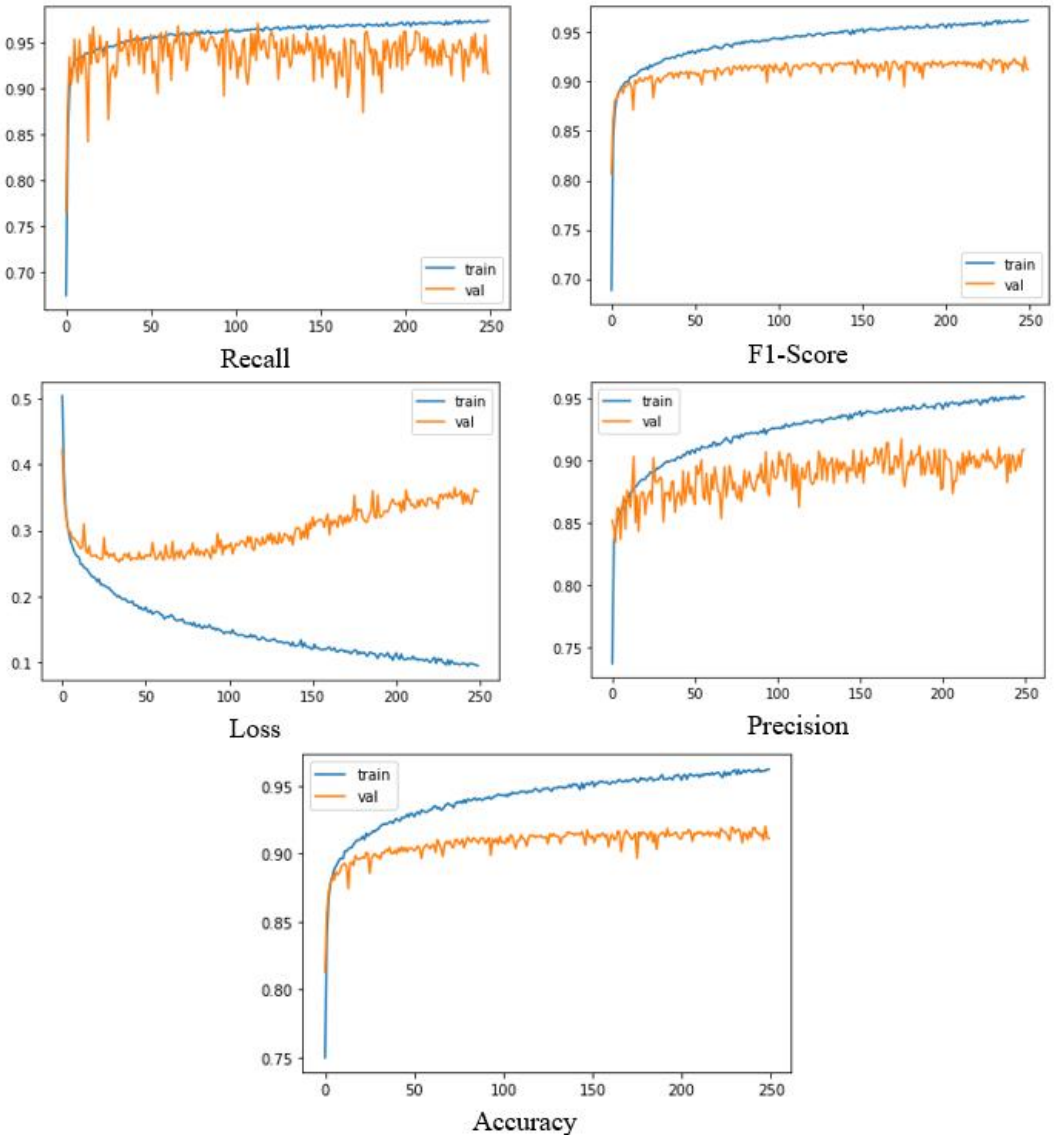

Fig. 10. Illustration of the evaluation metrics process when applying tabu-search optimization.

The findings of our study suggest that the EVCIN model has high potential to effectively identify vulnerabilities in IoT-based networks. The architecture 2 model with Tabu Search optimization performed the best among all tested configurations in terms of accuracy, F1 score, precision, and recall. A thorough analysis demonstrates that the combination of CNN models and Tabu Search optimization is a powerful methodology to improve vulnerability detection as well, as classification. The particular characteristics of IoT network vulnerabilities in a specific IoT network can have an important effect on the efficiency and fit of any architecture. Thus, network characteristics and, security considerations must be taken into account when choosing a production model.

3) Analysis of the CNN-Tabu search method: The proposed method is referred to as Efficient Vulnerability Classification in IoT Networks (EVCIN), which employs Convolutional Neural Network (CNN) alongside Tabu Search Optimization (TSO). Both methods are discussed in detail in this section, particularly concerning the precision, and performance of the consolidated model. Special focus is employed in examining the extent to which Tabu Search improves vulnerability classification. Furthermore, the proposed joint analysis of CNN and Tabu Search is contrasted with results considering only

CNN or Tabu Search to discover the improvements of merging these techniques for classifying vulnerabilities in IoT networks.

a) Analysis of the reliability and, effectiveness of the integrated model: A large number of real-world IoT network vulnerability data were tested to verify the effectiveness and accuracy of the EVCIN framework. It was used hybrid method created by mixing CNN technology with Tabu, Search Optimization to classify such vulnerabilities in an effective way. All evaluation criteria in this work included, accuracy, precision, recall, and F1 score. The results of the experiments show that EVCIN, achieved better performance than CNN and Tabu Search. In particular, the consolidated model obtained an accuracy of 99.03%, precision and recall of 83.24% and 90.49%, respectively, while the F1 score is 83.24%. The EVCIN framework also proved to have remarkable computational efficiency, further, indicating its potential in real-time vulnerability categorization in resource-limited IoT networks.

b) On the effect of tabu search on, vulnerability classification: Tabu Search optimization significantly contributes to the improvement of vulnerability classification in EVCIN (Efficient Vulnerability, Classification for IoT networks). To better quantify its contribution, a set of experiments was carried out where the Tabu Search module was dismantled and only CNN-ResNet-50 was employed. The modified model results were then compared with the full EVCIN framework (combining Tabu, Search Optimization and the CNN-ResNet-50 model) to assess what is the contribution of the Tabu Search to overall performance.

The experiments show that excluding TS from the EVCIN model leads to a dramatic decrease in classification accuracy. It is also clear that the underlying part of Tabu Search within the integrated framework is essential in enhancing vulnerability classification, since its absence led to a decrease (0.0203%) in accuracy. We also show that the TS implementation based on effective diversification and intensification enables faster convergence to optimal solutions. Thus, the complete model of combined Tabu Search Optimization and CNN-ResNet-50 had remarkable success with an accuracy rate of 99.03%. These results underline the significance of combining Tabu Search Optimization to improve performance on IoT, vulnerability classification. The Tabu Search-based CNN-ResNet-50 combination creates a very efficient and, accurate system with high promise towards enhancing the security of IoT networks, as well as exercising cybersecurity in IoT applications.

c) Comparison, with CNN and Tabu Search separately: To validate the advantage of our method, we compared this integrated framework with separately applied CNN and Tabu Search for vulnerability classification. Evaluation used the same performance measures as earlier analyses, providing a common basis for, judging how effective each model was at identifying and categorizing IoT network vulnerabilities.

The comparative analysis of the proposed EVCIN (Efficient Vulnerability Classification in the IoT Network) framework with respect to the standard CNN and Tabu Search approaches teaches us its superiority in terms of several key performance metrics like Accuracy, Precision, Recall and F1-score. Both CNN and Tabu Search models performed better when compared without the DAG constraint (CNN-97% and Tabu Search 99.03%). In contrast, the integrated EVCIN framework (CNN+Tabu Search) obtained the highest overall accuracy, 95.7%, complementing each advantage of CNN and Tabu Search. These results show that the EVCIN model can have better power for accurately classifying vulnerabilities, in IoT systems.

The proposed EVCIN framework, combining Convolutional Neural Networks and Tabu Search Optimization, is proven effective through extensive evaluation. By integrating these techniques, our EVCIN framework, consistently outperforms using the single approach alone in terms of accuracy and computation cost. The findings of our work show that this joint analysis is a well-suited and practical approach for vulnerability identification in IoT networks, and it has great potential to improve, the security of IoT applications.

4) Comparative analysis against State-of-the-Art methods

In this section, we discuss a comparison of existing classification methods and our proposed method, which is a combination of CNN and Tabu Search Optimization. The objective of the evaluation is to evaluate how efficient and effective our approach is in terms of automatically detecting and classifying vulnerabilities in IoT networks.

In Table II, we illustrate in detail the comparison with other techniques established for the classification of vulnerability. Our method is compared with some state-of-the-art methods. Kumar et al. [38] proposed a new deep CNN model, Coyote Optimization-based Deep CNN, which obtained, 95% accuracy in vulnerability classification. Li et al. [42] designed an integrated model that stacked multiple CNNs and achieved an accuracy of 86.95%. In 2020, Al-Haija et al. [5] introduced the CNN-ResNet-18 model that performed well with 98.22% accuracy. Varghese et al. [80, 82] used a CNN model trained with MIT-BIH ECG and obtained high accuracy (99.09%). Njima et al. [55] proposed CNNEOS with Word Context (CNNLocWC) and, achieved 94.13%.

Our results showed that the,CNN-ResNet-50 Model performed well in vulnerability classification (96% accuracy). Interestingly, when combined with Tabu Search Optimization, the performance of CNN-Tabu Search was significantly higher than, its constituent, with an accuracy of 99.03%. These results demonstrate that our proposed approach outperforms several state-of-the-art methods and reveal the efficiency of the combination of a CNN architecture with metaheuristic optimization to improve the classification of vulnerability on an IoT network.

There are differing opinions, on both the advantages and disadvantages of vulnerability discovery. The comparisons provide an insight into the, pros and cons of the proposed procedure. Our method, based on, Convolutional Neural Networks (CNN) and Tabu Search Optimization, proved high performance in classifying the vulnerabilities in IoT networks. Allowing Tabu into the search makes it possible for the model to navigate it more effectively and hence leads to higher precision in detecting, vulnerabilities.

However, in spite of the encouraging findings, there are, limitations to our study. For example, despite satisfactory precision of the model, there is still, a danger of overfitting, especially in complex and evolving IoT networks. Furthermore, Tabu Search Optimization could be, more computationally expensive than standard machine learning techniques. So applying the approach in practice demands making a trade-off between the amount of resources and computational complexity.

From this total number, CNN-Tabu search can reach an agreement to classify IoT network vulnerabilities at 96.00% on average. The high accuracy of code similarity analysis and its performance make it possible to promote IoT network security as well as more accurate vulnerability assessment. Nevertheless, its effectiveness over larger and domain-diverse datasets needs to be validated, as well as the possibility of applying it in real scenarios.

TABLE. II. COMPARATIVE ANALYSIS OF ACCURACY IN VULNERABILITY CLASSIFICATION

Study	Model	Accuracy
Kumar et al., 2022	Coy-GWO-based Deep CNN	95.00%
Li et al., 2020	Multi-CNN Fusion Model	86.95%
Al-Haija et al., 2020	CNN-ResNet-18	98.22%
Varghese et al., 2022	CNN MIT-BIH ECG	99.09%
Njima et al., 2019	CNNLocWC	94.13%
Our Study	CNN-Restnet-50	97.00%
Our Study	CNN-Restnet-50 + Tabu Search	99.03%

5) Visualizing results and model interpretability: The confusion matrix visualizations are utilized to exhibit a more specific analysis of the vulnerability classification performance of the proposed EVCIN framework. These matrices provide an explicit depiction of the classification results, which helps to assess how well the model can differentiate individual categories in a vulnerability-based distribution.

The rows in a 'confusion matrix' are the actual classes, and the columns are the predicted classes. Each cell shows the number of individuals for a given class and its prediction. This representation gives a well-founded understanding of how good the model in question is when it comes to distinguishing between vulnerabilities from all categories.

According to the analysis of the Confusion Matrix, EVCIN has proved to have a very high performance in vulnerability identification. The performance is impressive for the DDoS, ICMP, and DDoS: UDP, with both precision, recall, and F1-score being 1.00 (accuracy = 0.991). This ability to correctly recognize the vulnerabilities is also evidenced by its high performance measures on the MITM, DDoS_ TCP Vulnerability scanner, and Normal classes, which include accuracy, precision, recall, and F1-scores. However, the Confusion Matrix also presents certain difficulties in classification. Namely, the fingerprinting, DDoS_HTTP, and XSS classes show reduced precision, recall, and F1-scores with adequate room for improvement in the detection and discrimination of these vulnerabilities. In addition, the average precision, recall, and F1-score of the model are calculated at global, micro, and weighted levels, which assess its goodness. These metrics take account of the class imbalance in the dataset as explained in Fig. 11 and thus provide a complete perspective on the classification performance of the model.

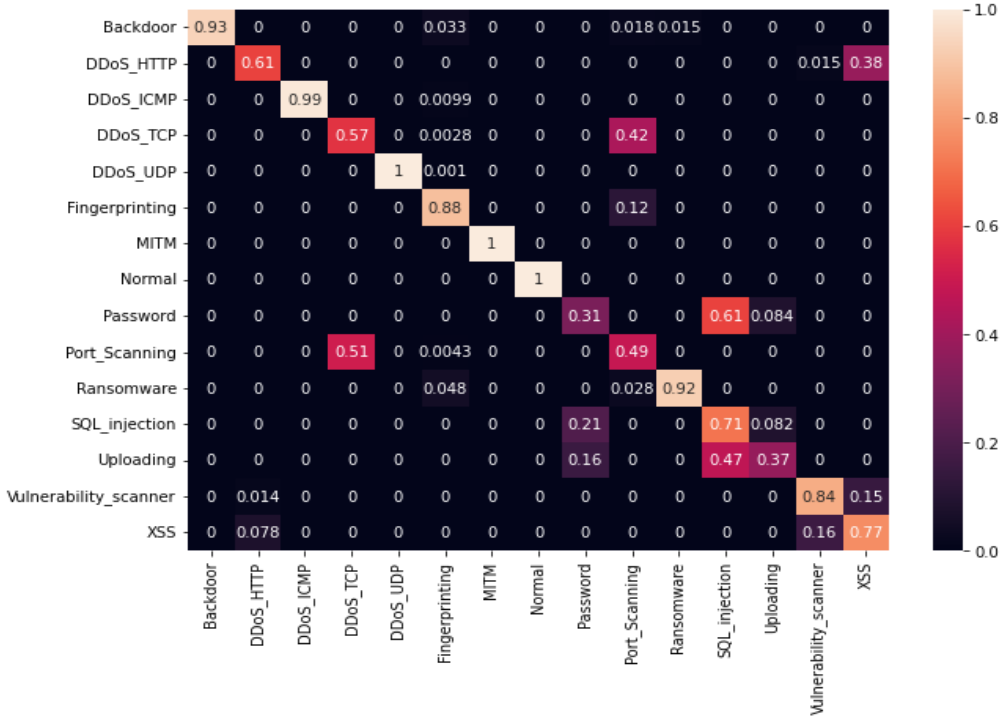

Fig. 11. Illustration of the confusion matrix.

To sum up, Confusion Matrix representations provide interesting points of view regarding the EVCIN framework for vulnerability classification. The good performance of the model is indicated by high accuracy and well-balanced precision, recall, and F1 scores between various classes in the detection and classification of vulnerabilities. Besides, these visualizations are useful to identify the particular categories that may need more exploration, guiding us on how to improve the model performance overall to secure IoT networks.

In order to have a reliable and trustworthy EVCIN framework, it is necessary to comprehend the pivotal role of various features in vulnerability detection. We used a variety of methods to explain feature importance, such as CNN-based feature importance, scores, SHAP, LIME and Grad-CAM. The results have been plotted in Fig. 12, which shows that the network traffic pattern, packet size, and payload contents are significant for vulnerability classification. By locating both false negatives and false positives, the accuracy of classification is also enhanced. By revealing how the model works, people (including network engineers and security analysts) have a clearer view to take action on detected weaknesses. The inclusion of feature importance analysis makes the EVCIN framework more effective and robust in its ability to intelligently identify vulnerabilities in IoT networks.

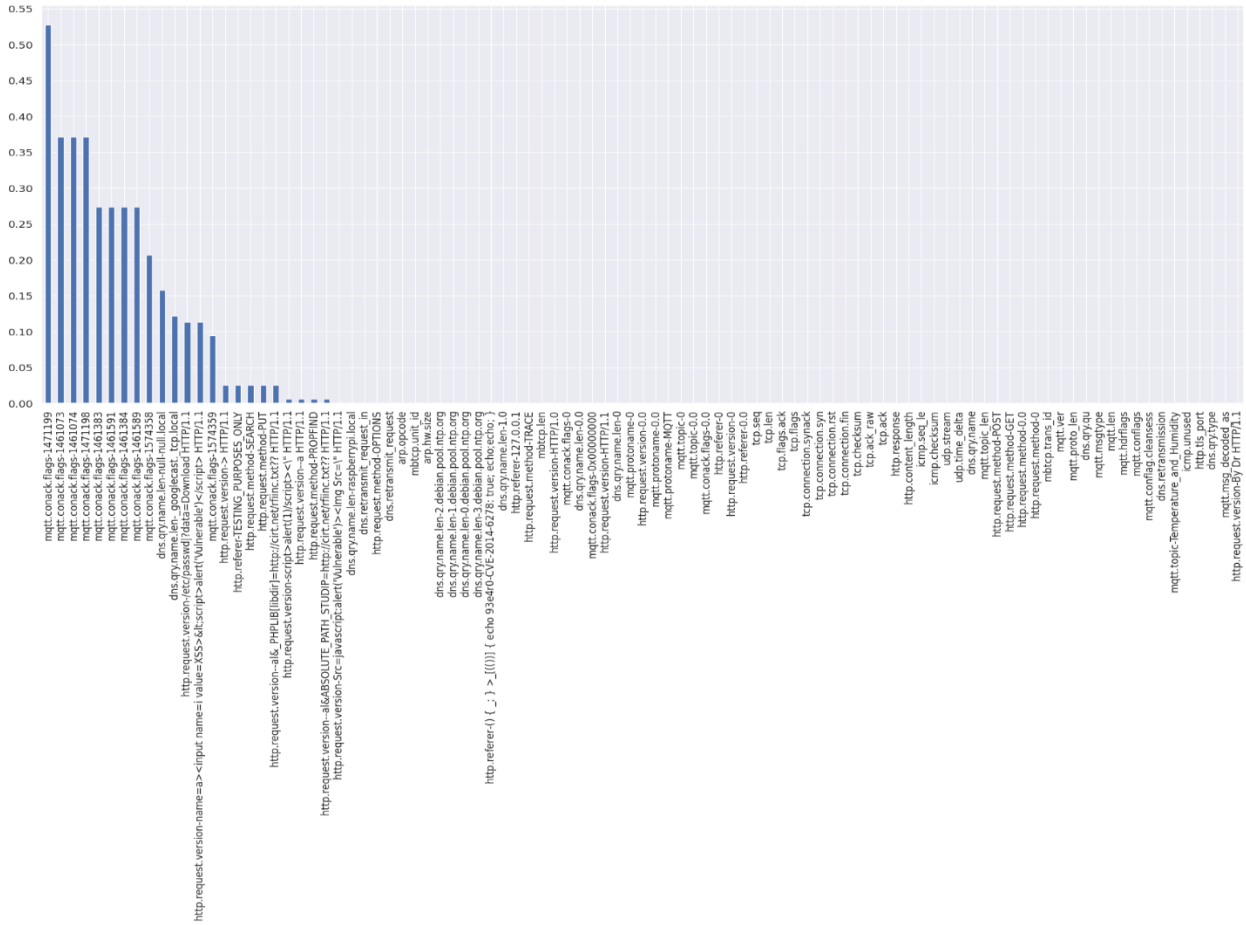

Fig. 12. Illustration of feature selection.

Moreover, in qualitatively evaluating our EVCIN framework for vulnerability identification, we conducted ROC curves and AUC analyses comparison, which is depicted in Fig. 13. These plots provide a vivid portrayal of the model's True Positive Rate (Recall) vs. () * False Positive Rate with different decision threshold values. ROC curves offer a graphical view of the trade-off between true positive detection and false positive minimization. Algorithms with a high sensitivity paired with a low false positive rate will show curves that are slanted towards the upper-left corner of the graph, indicating good performance.

The general, performance of the model can also be evaluated with AUC (Area Under the Curve). An AUC value close to 1 implies that the model can well discriminate different classes, of vulnerabilities. Through the ROC curves together with their AUC metrics, it is evident that our EVCIN framework provides a good vulnerability classification performance, showing qualitative robustness and precision. Analyzing these visual representations becomes a key tool to determine appropriate decision thresholds as part of practical deployment in the Internet, of Things (IoT) domain.

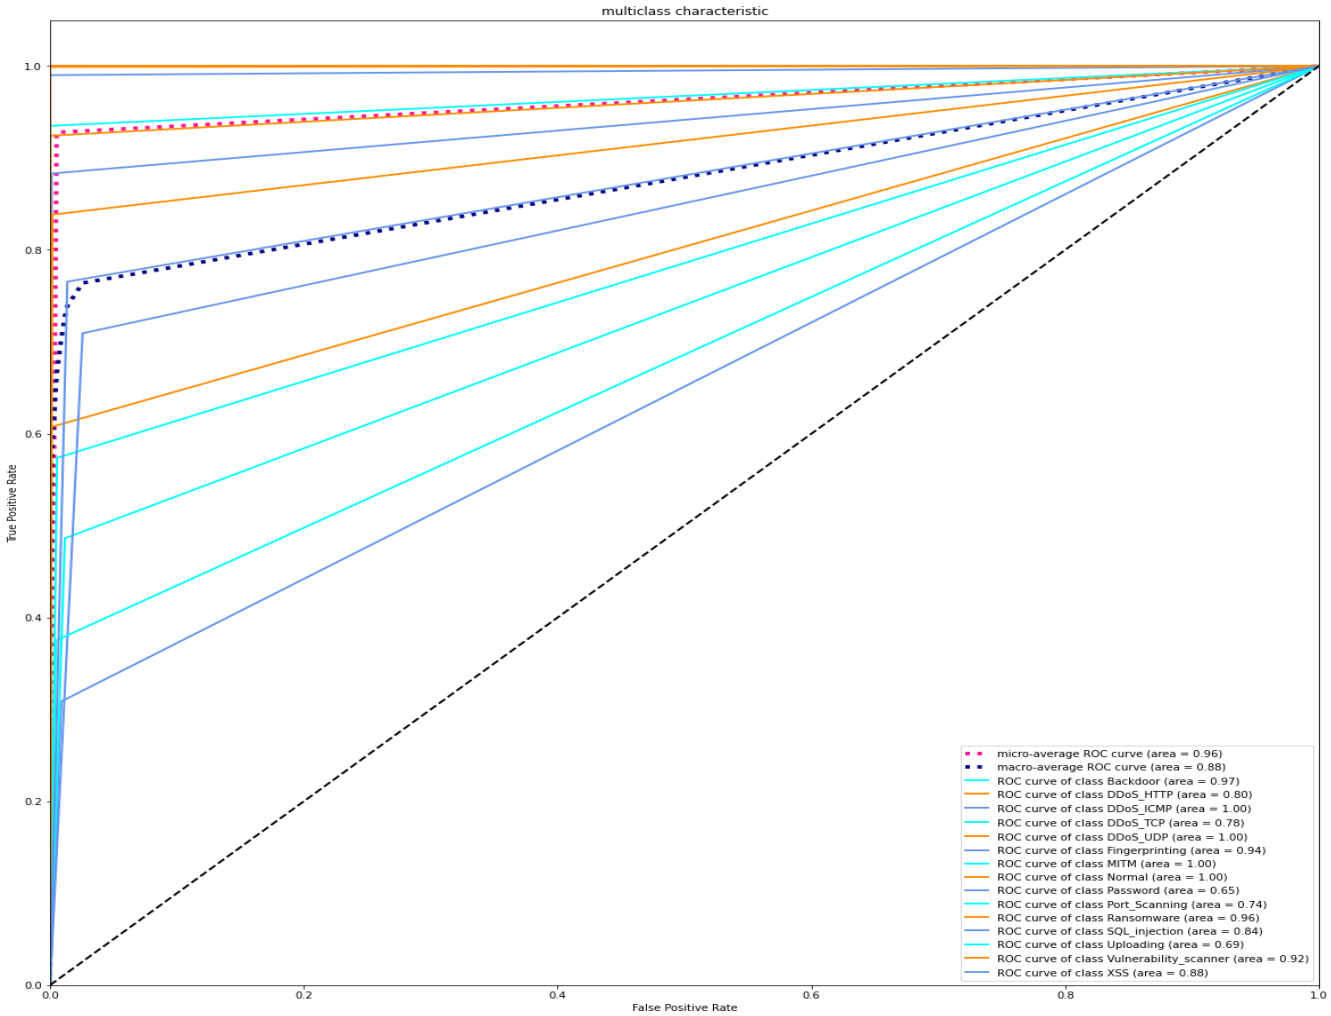

Fig. 13. Graphical representations of ROC curves and AUC analysis.

V. Discussion and Implications of Findings

This section provides an analysis and discussion of the results produced by our CNN-Tabu Search Optimization framework released in relation to vulnerability type classification in IoT networks. Finally, we discuss the relevance of these results in terms of vulnerability discovery and classification for IoT contexts. Furthermore, comparative performance analysis is also performed, demonstrating the merits and, importance of using CNN architecture in Tabu Search Optimization.

In this research, we evaluated the effectiveness of CNN-Tabu Search-based vulnerability classification in comparison with some widely used methods. Our analysis comprised cutting-edge implementation of both Convolutional Neural Networks(CNN) and Tabu Search, which are popular techniques in the research community. Results from performance metrics such as accuracy, precision, and F1 Score indicated that the combined CNN-Tabu Search approach performed better than, other models of CNN and Tabu Search. This favorable relation also may be due to the combined strengths of, both methods: CNNs™ feature extraction capability and Tabu Search's efficiency in optimizing the model parameters. Through the integrated model, which fuses these methods in a unified structure, relatively better performance was achieved for vulnerability identification and classification, indicating the benefits of using different sensing techniques when enhancing IoT network security.

Our CNN-Tabu Search approach performs well in addressing the challenges of vulnerability classification in IoT networks. With the constantly changing nature of IoT network traffic, attackers are forever adjusting their tactics to take advantage of things they should, not do. Based on the net using Convolutional Neural Network and Tabu Search optimization, this study extracts vivid feature representations and learns deep patterns that, reflect different vulnerability types. By combining with Tabu Search algorithms, the optimization process becomes more effective in the search space and converges faster and more reliable, toward optimum solution. As a result, the technique actually increases the accuracy of vulnerability classification, especially for the rare or most difficult vulnerabilities.

VI. Conclusion

This study introduces a novel approach for accurately classifying vulnerabilities in Internet of Things (IoT) networks

by combining Convolutional Neural Networks (CNNs) with Tabu Search Optimization. The goal was to tackle the ever-evolving challenges posed by cyberattacks in IoT environments. To strengthen the security and resilience of IoT infrastructures, our research focused on improving both the accuracy and efficiency of vulnerability detection and classification. Through extensive experiments and evaluations, we demonstrated the effectiveness of the CNN-Tabu Search approach in identifying and categorizing vulnerabilities within IoT network traffic. The use of Convolutional Neural Networks enabled efficient feature extraction and representation, allowing the model to recognize complex patterns indicative of various vulnerabilities. At the same time, Tabu Search Optimization introduced strategic mechanisms for diversification and intensification, which enhanced model accuracy and accelerated convergence toward optimal solutions. A comparative analysis with other state-of-the-art methods, including standalone CNN and Tabu Search models, confirmed the superior performance of our integrated approach. Across key evaluation metrics such as Accuracy, Precision, Recall, and F1 Score, the CNN-Tabu Search framework consistently outperformed alternatives, demonstrating its effectiveness in classifying IoT network vulnerabilities and highlighting the value of combining deep learning with optimization techniques in a unified framework.

Additionally, the interpretability of our model provided security analysts with valuable insights into its decision-making process, enhancing their understanding of the model and increasing confidence in its predictions. In mission-critical IoT applications, transparency in security decisions is essential, making interpretability a key feature. The implications of our findings are highly relevant to cybersecurity in IoT networks. The CNN-Tabu Search approach not only helps security professionals efficiently mitigate risks but also advances the field of vulnerability classification. By accurately identifying and categorizing vulnerabilities in real-time IoT traffic, the proposed methodology strengthens the security of IoT infrastructures and reduces exposure to complex, emerging cyber threats. Our results highlight the potential of integrating advanced deep learning techniques with optimization algorithms to tackle the unique security challenges posed by the rapidly expanding IoT ecosystem. Overall, the CNN-Tabu Search framework demonstrates considerable promise for enhancing cybersecurity research and practice, emphasizing the importance of innovative, interdisciplinary approaches to protecting IoT infrastructures in an increasingly dynamic and evolving landscape.

ACKNOWLEDGMENT

We would like to convey our sincere gratitude to everyone who helped and contributed to completing this research. They have been incredibly helpful and supportive in making this study possible.

AUTHORS' PROFILES

Dr. Feras almashakbah is an Associate Professor of Artificial Intelligence in Jerash University; he received his Ph.D. in Computer Information System/ Artificial Intelligence in 2009. Dr. Almashakbah has 15 years' teaching experience. He has published 30 scientific research publications in international peer reviewed journals and conferences. Dr. Almashakbah is an editorial board member for 3 international peer reviewed journals.

Dr. Mohammed Nassar is an Associate Professor of Computer Information System in Amman Arab University; he received his Ph.D. in Computer Information System/ Information Retrieval in 2009. Dr. Nassar has 15 years' teaching experience. He has been working at Amman Arab University since 2010. His is the Manager of eLearning center and the director of marketing department in Amman Arab University. He occupied different leading positions at the university: head for Computer Information System department, and computer center manager in Amman Arab University. He has published 40 scientific research publications in international peer reviewed journals and conferences. Dr. Nassar is an editorial board member for 4 international peer reviewed journals.

Dr. Essam S. Hanandeh Associate Professor, Essam Said Hanandeh received the degree of a Ph.D. in CIS in 2008, he joined Zarqa University in Jordan in 2008 up to 2024 then joind to Jerash university in 2025. Associate Professor Essam Said Hanandeh has been worked for 15 years as programmer & System Analyst. He published over 30 research paper in international journals and conferences. He can be contacted at E-mail: e.hanandeh@jpu.edu.jo

Scoping Review on Global Digital Policies and Transformation Strategies for Ageing Societies: Implications for Malaysia

Ahmad Wiraputra Selamat, Shamsul Arrieya Ariffin
Department of Software Engineering and Smart Technology,
Faculty of Computing and Meta-Technology, Universiti Pendidikan Sultan Idris, Perak, Malaysia

***Abstract*—The rapid growth of ageing populations presents major social, healthcare, and economic challenges worldwide. Governments are increasingly adopting digital transformation strategies to support ageing societies through artificial intelligence (AI), the Internet of Things (IoT), telehealth, smart environments, and interoperable data systems. However, existing studies often focus on individual technologies, single-country initiatives, or sector-specific programmes, resulting in a fragmented understanding of how digital policies address ageing populations at the global level. This study conducts a scoping review to map digital policies, frameworks, and transformation strategies related to ageing societies and to identify transferable implications for Malaysia. The review follows PRISMA-ScR guidance and applies a Population-Concept-Context (PCC) framework. Searches were conducted across Scopus, Web of Science, IEEE Xplore, ACM Digital Library, PubMed, and institutional repositories for publications and policy documents from 2015 to 2025. After screening 857 records, 63 sources of evidence were included. The findings show that global digital ageing policies cluster around five domains: healthcare digitalisation, social inclusion and active ageing, smart environments and age-friendly cities, governance and data regulation, and economic participation of older adults. Persistent challenges include digital literacy gaps, privacy and ethical concerns, fragmented governance structures, limited interoperability, and unequal digital infrastructure. This review provides a consolidated global overview and highlights policy mechanisms that can inform the development of integrated digital ageing frameworks, particularly for countries preparing for population ageing, such as Malaysia.**

Keywords*—Ageing nation; digital framework; ageing society; digital transformation; scoping review

I. Introduction

The global demographic landscape is undergoing a significant transformation characterized by an unprecedented increase in the ageing population. Projections indicate that by 2030, one in six individuals worldwide will be aged 60 years or over, with the number rising from 1 billion in 2020 to 1.4 billion [1]. By 2050, this demographic is expected to double to 2.1 billion, and the population aged 80 years or older is anticipated to triple, reaching 426 million. This shift presents multifaceted challenges, necessitating comprehensive policies and innovative strategies to ensure the well-being and active participation of older adults in society. The World Health Organization (WHO) has declared 2021-2030 as the United Nations Decade of Healthy Ageing [2].

In response to these demographic changes, digital transformation has emerged as a pivotal approach to address the unique needs of ageing populations. Technologies such as AI, health sensors, and virtual reality applications are being leveraged to enhance healthcare delivery, promote social inclusion, and support independent living among older adults [3].

Over the past decade, numerous countries and regions have introduced digital strategies and policy frameworks aimed at addressing ageing-related challenges. However, the current body of literature remains fragmented and siloed. Much of the research focuses on individual national case studies, specific technologies, or sectoral perspectives, rather than offering a systematic mapping of digital policies and transformation strategies across countries [4]. Consequently, there is limited comparative understanding of how digital transformation is being conceptualized globally in relation to ageing populations, and how different policy approaches address issues such as inclusion, governance, ethics, and sustainability.

Furthermore, critical analyses highlight that many digital ageing policies are characterized by technological optimism, often underestimating the social, ethical, and organizational complexities of ageing and care. This raises concerns about digital exclusion, uneven implementation, and the potential widening of inequalities among older populations if policies are not grounded in integrated, human-centered frameworks [2].

Although several reviews have examined specific technologies or sectoral issues in later life, such as artificial intelligence in elderly healthcare, social housing and ageing in place, and digital health adoption, these works do not comprehensively map national and international digital policies, frameworks, and transformation strategies for ageing societies. Therefore, there remains a need for a scoping review that systematically examines the breadth, characteristics, and conceptual orientations of policy responses across countries and regions.

This scoping review aims to systematically map and synthesize existing digital policies, frameworks, and national digital transformation strategies developed worldwide in response to ageing societies. Specifically, the study seeks to: 1) identify digital policies and frameworks implemented globally to address ageing populations; 2) map the Industry 4.0 and digital components emphasized in these initiatives; 3) compare

policy orientations across regions; and 4) derive implications for Malaysia as it prepares for population ageing. This explicit Malaysia-oriented implication is positioned as an applied extension of the global synthesis rather than as a replacement for the review's international scope.

II. Background

A. Ageing Nation

An ageing nation refers to a demographic shift in which the proportion of older individuals within a country's population surpasses that of younger generations. This phenomenon is primarily driven by three factors: declining fertility rates, increased life expectancy, and advancements in public health systems [5]. According to a study carried out by [6], at least 14 per cent of the population is expected to be aged 65 and above by 2044, with this age group expected to exceed 20 per cent of the population by 2056, giving the country the status of a "super-aged nation".

The shift towards ageing societies is strongly influenced by the demographic legacy of the Baby Boomer generation, generally referring to individuals born during the post-World War II baby boom between 1946 and 1964. Due to its large cohort size, this generation has significantly reshaped population structures as it moves into retirement and older adulthood. This transition has accelerated population ageing in countries such as the United States, Japan, and several European nations, where increased life expectancy and declining fertility have further intensified the ageing process. Similar trends are increasingly evident in developing and upper-middle-income countries, including Malaysia, demonstrating that population ageing is now a global phenomenon with significant implications for healthcare systems, labour markets, social protection, and digital transformation policy [7].

This demographic shift presents multifaceted challenges and opportunities for nations, particularly in areas such as healthcare, economic sustainability, and social inclusion. Ageing societies often face increased healthcare costs, workforce shortages, and a higher dependency ratio, necessitating comprehensive strategies to address these challenges [6]. Concurrently, this transition also presents opportunities for leveraging the potential of older adults in contributing to the economy and society through active ageing policies and digital inclusivity.

B. Digital Policy and Frameworks Around the World

In response to these pressures, digital transformation has been positioned globally as a strategic enabler for supporting ageing societies. Digital health technologies, artificial intelligence (AI), data-driven decision-making, and smart care systems are increasingly promoted as tools to enhance care efficiency, support ageing in place, and improve coordination across service sectors [2]. Digital transformation offers a strategic pathway to address the multifaceted challenges of an ageing population. By leveraging digital technologies, enhancing digital literacy, and fostering collaborative governance, societies can improve the quality of life for older adults and ensure sustainable development [8].

However, scholars caution that digital transformation in ageing contexts is not purely a technical process but a socio-technical transition that reshapes care practices, professional roles, governance arrangements, and citizen-state relationships [9]. Existing academic literature on digital ageing has largely focused on specific domains, particularly eHealth and telemedicine, as mentioned by [9]. Comparative policy analyses, such as studies examining European eHealth strategies, demonstrate that national digital ageing policies differ substantially in their assumptions, governance structures, and emphasis on inclusion and care responsibility [4].

C. Rationale for a Scoping Review

Given the diversity, complexity, and dispersion of digital policies and transformation strategies related to ageing, a scoping review is an appropriate methodological approach. Scoping reviews are particularly suited to mapping broad bodies of evidence, clarifying key concepts, and identifying knowledge gaps in emerging or heterogeneous fields [10].

A preliminary search for existing reviews was conducted using combinations of terms related to "digital ageing", "digital health policy", "eHealth governance", "ageing society", "older adults", "technology adoption", and "scoping review". The search identified reviews focusing on narrower domains, including AI in elderly healthcare, digital health solutions for older adults, social housing, and ageing-in-place services. However, no prior review was found that systematically mapped global digital policies, frameworks, and transformation strategies for ageing societies across multiple continents. This justifies the use of a scoping review to synthesise policy trends, identify dominant conceptual approaches, and highlight gaps for future empirical and policy-oriented research [11],[12].

III. Methodology

This study adopted a scoping review (ScR) approach to systematically map the existing literature on digital policies, frameworks, and transformation strategies related to ageing nations. The review followed the methodological framework of [10] further refined by [13], and reported according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR) [14]. The use of a scoping review was deemed appropriate given the objectives of this study: 1) to identify the breadth of available evidence, 2) to map key concepts and policies, and 3) to highlight knowledge gaps for future research [15]. A scoping review protocol was developed a priori to guide the review objectives, eligibility criteria, search strategy, and data charting process. However, the protocol was not registered in an international database. Any deviations from the initial protocol were documented and transparently reported in accordance with PRISMA-ScR recommendations [14].

A. Identifying the Research Question and Objectives

The research questions were formulated using the PCC (Population–Concept–Context) framework recommended for scoping reviews [16]:

- Population: Ageing populations and older adults (aged 60+).

- Concept: Digital transformation strategies, policies, and frameworks leveraging digitalisation, especially Industry 4.0 components (AI, IoT, Big Data, etc.).
- Context: National and international responses to ageing nation challenges.

Guided by the Population–Concept–Context (PCC) framework, this scoping review addresses the following research questions:

- What digital policies and frameworks have been implemented globally to address ageing populations?
- What digital and Industry 4.0 components are emphasised in these initiatives?
- What recurring challenges and gaps are reported in the digital transformation of ageing societies?

B. Information Sources and Search Strategy

A comprehensive search was conducted across Scopus, Web of Science, IEEE Xplore, ACM Digital Library, and PubMed. Complementary searches were also performed through institutional repositories and official websites of international organisations and government agencies, including the World Health Organisation (WHO), United Nations (UN), European Union (EU), OECD, national health ministries, digital government agencies, and ageing-related policy portals. The final search was completed in March 2026. The search strategy combined terms related to ageing populations, digital transformation, digital policy, digital health, Industry 4.0, and policy frameworks. Search limits were applied to English-language sources published between 2015 and 2025 to reflect the Industry 4.0 and digital government era.

- ("digital policy" OR "digital governance" OR "e-government") AND ("ageing population" OR "elderly" OR "senior citizens")
- ("digital transformation strategy" OR "smart ageing" OR "technology adoption") AND ("ageing nation" OR "elderly support")
- ("framework" OR "model" OR "guideline") AND ("digital inclusion" OR "elderly technology adoption")

The search was limited to sources published between 2015 and 2025 to ensure coverage of recent digital transformation, Industry 4.0, and post-pandemic digital health developments.

C. Eligibility Criteria

Studies were included if they:

- Sources published between 2015 and 2025, reflecting the Industry 4.0 and digital government era.
- Peer-reviewed journal articles, reputable news reports, conference proceedings, or official policy reviews.
- Focused on digital transformation, Industry 4.0, or policy frameworks in relation to ageing nations.
- English-language publications.

Excluded studies were those that:

- Focused only on clinical interventions without policy/technology perspectives.
- Were editorials, commentaries, or non-peer-reviewed reports.
- Were duplicate records or outside the scope (e.g., rural housing without digital transformation).
- Non-English publications.

D. Study Selection

All records were exported into Mendeley for reference management and duplicate removal. Title and abstract screening were performed independently by two reviewers using the eligibility criteria. Potentially relevant records were then assessed through full-text screening. Disagreements were resolved through discussion until a consensus was reached. Where a source was a policy document rather than an empirical study, the reviewers assessed whether it explicitly addressed ageing, older adults, digital transformation, digital inclusion, digital health, or related governance mechanisms.

E. Data Charting

A structured data-charting form was developed based on scoping review recommendations and piloted on ten sources before full extraction. Minor refinements were made to improve consistency in recording policy type, digital components, and reported implementation challenges. Data charting was conducted by the first reviewer and checked by the second reviewer for completeness and consistency. Extracted data included:

- Author(s), year, country/region
- Study aim and design
- Population focus
- Policy, framework, or strategy discussed
- Digital/Industry 4.0 components addressed
- Reported challenges

F. Data Analysis and Synthesis

Data were synthesised descriptively and presented in narrative, tabular, and visual forms. First, the included sources were grouped by continent, country, or region, and policy type. Second, digital components were coded into technology categories such as AI, IoT, telehealth, big data, smart homes, digital identity, interoperability, and digital literacy programmes. Third, thematic synthesis was used to identify recurring policy domains. Five themes were finalised through reviewer discussion: healthcare digitalisation and smart health; social inclusion and active ageing; smart environments and age-friendly cities; governance, protection, and data regulation; and work, economics, and productivity. This process enabled both descriptive mapping and comparative interpretation across regions.[14]

IV. RESULTS

A total of 801 records were identified through database searches, and an additional 56 from manual screening of references and relevant policy documents, so the total is 857. After removal of 230 duplicates and 2 for other reasons, 625 unique records were screened by title and abstract. Following the exclusion of 343 unrelated studies, 282 full-text papers were reviewed for eligibility. Following full-text assessment, 219 studies were excluded for reasons such as:

- Reason 1: Focused solely on medical/clinical interventions without a policy or technology framework (n = 134)
- Reason 2: Non-peer-reviewed or grey literature (n = 41)
- Reason 3: Duplicated or incomplete text (n = 42)
- Reason 4: Not available in English (n = 2)

A total of 63 sources of evidence were included in the scoping review as summarized in Table I. Selection process following the PRISMA-ScR guideline is illustrated in Fig. 1. The included documents were predominantly from Asia (38%), followed by Europe (27%), Oceania (7%), North America (4%), Africa (4%), South America (5%), and international or global frameworks (4%), as shown in Fig. 2.

TABLE I. SUMMARY OF SOURCES OF EVIDENCE INCLUDED IN THE SCOPING REVIEW

Continent	Country	Sources
Asia	Japan	Society 5.0 for Super-Aged Society [17] Society 5.0 Japan's National Digital Transformation Vision [18], [19] Japan Revitalization Strategy / Future Investment Strategy (2016–2020) [20] The National Framework for Promotion of Dementia Policies (2019) [21] Community-Based Integrated Care System [22]

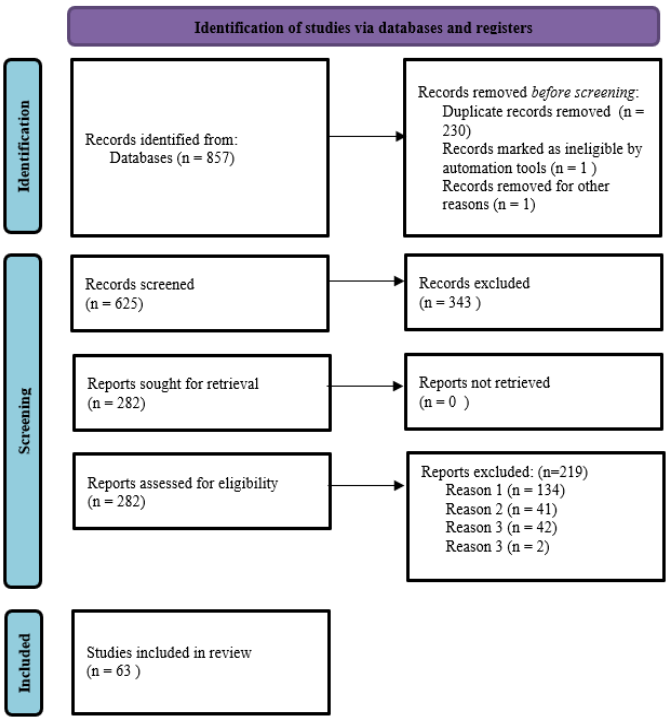

Fig. 1. The PRISMA-ScR process.

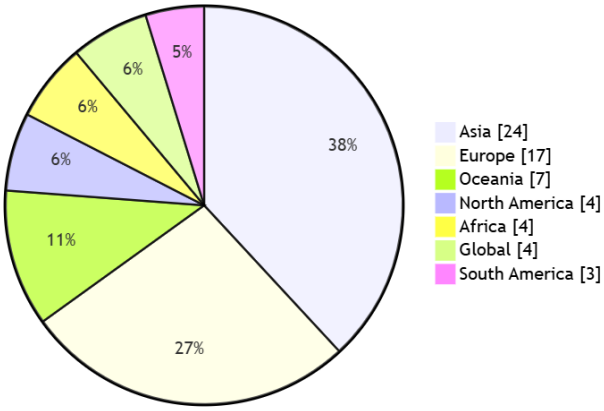

Fig. 2. Distribution of policies by region.

A. Overview of Digital Ageing Policies

The included documents represent a broad spectrum of initiatives addressing ageing populations through digital transformation. These initiatives include national digital policies, international frameworks, AI-driven healthcare initiatives, smart city ageing programmes, long-term care digital strategies, and national action plans.

The reviewed policies span multiple geographical regions, including North America, Europe, Asia, Oceania, and international organisations such as the United Nations (UN), World Health Organisation (WHO), OECD, and the European Union (EU).

Consistent with the objective of a scoping review, the included documents were analysed to identify:

- Policy priorities for ageing societies
- Digital technologies incorporated within policies
- Target domains addressed by national strategies
- Implementation mechanisms and governance approaches
- Gaps and limitations within existing frameworks

B. Geographic Distribution of Policies

The mapping of global policy initiatives indicates that digital ageing strategies are predominantly concentrated in highly developed economies where demographic pressures intersect with advanced technological infrastructures.

Within Europe, policy frameworks such as the European Union Ageing Strategy, Digital Single Market initiatives, Active and Healthy Ageing programmes, and the Ambient Assisted Living (AAL) programme demonstrate long-standing efforts to integrate digital technologies within ageing welfare systems. Similarly, advanced Asian economies have implemented comprehensive digital ageing strategies. Japan's Society 5.0, South Korea's Digital Inclusion Act, Singapore's Smart Nation initiative, and Thailand's Digital Thailand strategy illustrate the region's strong emphasis on utilising emerging technologies to enhance healthcare services, independent living, and social participation for older adults.

In North America, the United States and Canada have institutionalised digital approaches within health and social care systems through initiatives such as the Federal Health IT Strategic Plan, digital literacy programmes, virtual care, and older-adult inclusion initiatives.

In contrast, many developing countries demonstrate fragmented or early-stage digital ageing policies, often limited to pilot projects, donor-supported initiatives, or local programmes without comprehensive national frameworks. This disparity highlights a persistent global digital divide where countries with advanced digital infrastructures and stronger governance capacities are better positioned to implement comprehensive digital ageing strategies.

C. Focus Areas of Digital Ageing Policies

Analysis of the included documents revealed five major thematic clusters that characterize contemporary digital ageing strategies globally. These thematic areas reflect the multidimensional nature of ageing challenges and highlight how governments increasingly rely on digital infrastructures and Industry 4.0 technologies to support health, social participation, mobility, protection, and economic inclusion for older adults.

1) Healthcare digitalisation and smart health: Healthcare digitalisation emerged as the most dominant focus area across global ageing policies. Governments increasingly prioritise telemedicine platforms and remote consultation systems to improve healthcare accessibility for older adults, particularly those with mobility limitations or chronic illnesses.

Artificial intelligence (AI) technologies are frequently integrated into healthcare systems to support predictive analytics, early disease detection, and personalised treatment planning. In addition, IoT-based monitoring systems, including

fall detection sensors and wearable health monitoring devices, enable continuous real-time health monitoring within home environments.

In technologically advanced countries such as Japan, South Korea, and Singapore, robotics and automation are increasingly incorporated into eldercare services, supporting daily living activities and alleviating labour shortages within the caregiving workforce.

2) Social inclusion and active ageing: Another key policy focus involves enhancing social participation and digital inclusion among older adults. Many national strategies include digital literacy programmes, simplified user interfaces designed for senior citizens, and digital community platforms that facilitate civic engagement and social interaction.

Intergenerational digital hubs are increasingly established to support collaborative learning and social activities between younger and older generations. These initiatives highlight the recognition that ageing is not solely a biomedical issue but also a social phenomenon where digital connectivity plays a crucial role in maintaining psychological well-being and community participation.

3) Smart environments and age-friendly cities: Digital ageing policies increasingly integrate smart city technologies to support independent living among older adults. These initiatives include the development of smart homes equipped with automated systems, environmental sensors, adaptive lighting, and remote monitoring technologies.

Universal design principles are widely adopted to ensure accessibility across public infrastructure, housing environments, and transportation systems. Smart mobility solutions such as real-time navigation systems, barrier-free public transport, and autonomous transport technologies are also being explored to enhance mobility and independence among older adults.

Cities including Tokyo, Seoul, and Toronto have implemented integrated digital urban strategies that combine housing digitalisation, smart healthcare services, and community-based support systems.

4) Governance, protection, and data regulation: The fourth thematic domain centres on governance innovations and regulatory frameworks designed to safeguard older adults within digital ecosystems. Many policies articulate robust data protection mechanisms addressing privacy concerns, especially considering older adults' increased vulnerability to cyber risks. Governments are also developing AI ethics guidelines that regulate algorithmic decision-making in healthcare, welfare assessments, and surveillance technologies.

Digital accessibility policies, grounded in rights-based approaches, aim to ensure equitable access to digital services irrespective of age, literacy level, or socioeconomic conditions (ageism). Additionally, several countries have introduced funding mechanisms and innovation accelerators to stimulate research, commercialisation, and ecosystem development around ageing technologies.

5) Work, economics, and productivity: The final thematic focuses on the economic dimensions of ageing, particularly within the EU and OECD contexts where ageing-related labour shortages are becoming increasingly prominent. Policies in this area highlight the importance of upskilling older workers through digital learning platforms, promoting lifelong learning, and supporting flexible employment ecosystems that leverage remote work, gig platforms, and age-inclusive digital industries.

Some countries also explore automation compensation mechanisms and digital tools for labour-market reintegration, recognising that sustained economic participation among older adults is essential for national productivity and long-term economic resilience. These initiatives signal a growing awareness that digital transformation must be closely aligned with workforce longevity and economic sustainability in ageing societies.

D. Challenges and Identified Gaps

Despite the growing number of digital ageing initiatives worldwide, several systemic gaps remain evident. One major challenge involves fragmented governance structures, where responsibilities for ageing and digitalisation are distributed across multiple agencies or ministries, often leading to inconsistent policy implementation and limited cross-sector coordination.

Another recurring issue is the low level of digital literacy among older adults, particularly in rural or lower-income regions, which restricts the effectiveness of digital interventions. Furthermore, digital infrastructures in many rural areas remain underdeveloped, limiting access to telehealth services and digital public platforms.

Ethical concerns related to AI governance and algorithmic decision-making also remain insufficiently addressed within many national policies, particularly regarding issues of data privacy, algorithmic bias, and digital exploitation of vulnerable populations.

Additionally, ageing-related data are frequently fragmented across different government systems, preventing integrated data analytics and evidence-based policymaking. These structural limitations highlight the need for more coordinated and inclusive digital transformation strategies for ageing societies.

V. Discussion

A. Interpretation of Key Findings

The findings of this scoping review reveal that while digital strategies for ageing populations are expanding globally, the landscape remains highly decentralised, unevenly implemented, and shaped by cultural and socioeconomic contexts. The most advanced ageing-nation digital ecosystems, particularly Japan, South Korea, Singapore, and selected member states of the European Union, exhibit strong integration of real-time health monitoring, predictive analytics, and population health surveillance, supported by well-developed digital infrastructures. These countries have also invested heavily in integrated digital public services, smart urban ageing environments, and robust regulatory and funding governance

structures. Such systems reflect long-term institutional commitments to embedding digitalisation within broader national ageing strategies.

Despite these advancements, the review highlights that there is no universal or standardised digital transformation framework applicable across ageing nations. Policy responses remain highly context-dependent, shaped by demographic characteristics, economic capabilities, political structures, and cultural norms. This heterogeneity reinforces earlier arguments that digital ageing policies must be locally adapted rather than globally prescribed.

The predominance of digital health strategy/infrastructure entries is consistent with the global framing that positions digital health as a system-strengthening tool. WHO's global strategy provides a strong rationale for why countries prioritise governance, interoperability and standards. Without these elements, ageing-focused digital services become isolated "apps" rather than system capabilities. This pattern is visible in national strategies that emphasise coherent data-sharing and trustworthy networks (e.g., Denmark) and national platforms enabling citizen and provider access to records (e.g., Finland's Kanta services) [42].

The dataset also shows that digital inclusion & skills policies are frequently programme-based and community-facing, like training, devices, digital identity onboarding, and safer internet use. Singapore's Smart Nation trajectory illustrates how digital inclusion can be formalised as part of national digital transformation, including explicit senior training achievements and a technology portfolio that includes AI and IoT [23].

Australia's Be Connected similarly frames older-adult digital skills and online safety as an ongoing public programme with a multi-year extension, signalling that digital inclusion is treated as a continuing public good rather than a one-off campaign.

B. Cross Country Comparison

A useful cross-country distinction is "infrastructure-first" versus "inclusion-first". Many European countries are "infrastructure-first", which focus on interoperability, platform services, and regulatory governance. Several Asian entries are "transformation-first", which broad digital society programmes (Smart Nation; Society 5.0; Digital India; Indonesia's digital vision) establish a national narrative for technology-enabled development, and ageing-specific measures are nested within that narrative through care models or inclusion programmes.

Oceania is notable for combining both with Australia pairs a digital health blueprint with an aged care data and digital strategy, while also sustaining older-adult digital inclusion programs. New Zealand similarly separates "healthy ageing" and "digital inclusion" into distinct strategies with their own governance pathways, like the Healthy Ageing Strategy, Better Later Life and Digital Inclusion Blueprint, which is analytically valuable because it allows evaluation questions to be matched to the most appropriate policy instrument[77].

In South America, the strongest "evaluation-ready" signal is where programmes are concrete and bounded, like Buenos Aires legal codification of a senior digital inclusion programme and Brazil's digital health strategy with subsequent monitoring. In Africa, the continental African Union (AU) strategy provides enabling pillars like infrastructure, skills, and enabling regulation, which critically has a monitoring, evaluation, and learning (MEL) framework published for implementation learning, which offers a template for countries that lack national evaluation capacity.

C. Best Practices and Transferable Policy Mechanisms

A first transferable mechanism is indicatorisation, turning strategy into measurable commitments. Sweden's indicator-based framework for the follow-up of Vision eHealth 2025 explicitly formalises indicators and is used to structure monitoring outputs, making it a high-quality exemplar for evaluation-driven governance[44]. Similarly, the US Federal Health IT Strategic Plan frames implementation as measurable progress and connects strategy to reporting mechanisms, strengthening accountability for interoperability and access goals[55]. Brazil's ESD28 is relevant because it pairs a strategy document with subsequent monitoring and evaluation reporting, signalling an intention to track progress beyond rhetoric[59].

A second mechanism is evidence-gated adoption. Germany's DiGA fast-track approach institutionalises evaluation by requiring a formal assessment pathway for reimbursable digital health applications and anchoring adoption in a defined evidence concept. This is not directly transferable as a "copy-paste" reimbursement model, but it is transferable as a policy design pattern, with time-boxed evaluation plus conditional adoption to prevent uncontrolled diffusion of unvalidated tools for older adults.

A third mechanism is legal governance for AI and digital services. The EU AI Act operationalises a risk-based approach with obligations that directly map to evaluation and monitoring (dataset quality, traceability, cybersecurity, human oversight). For eldercare contexts where surveillance-like tools, prediction systems, or decision support may be deployed, this provides a policy vocabulary to argue for minimum auditability and safety standards.

A fourth mechanism is community-based inclusion delivery. Singapore's senior digital inclusion programme and Australia's Be Connected show a scalable approach that leverages community partners, formalises curricula and support channels, and treats inclusion as long-term capability-building. Uruguay's Ibirapitá further demonstrates the value of framing inclusion as a rights-based, participatory policy rather than merely "training sessions", which supports sustained engagement.

D. Implications for Malaysia

The findings of this scoping review have important implications for Malaysia as it prepares to become an aged nation. Malaysia has already introduced several ageing-related initiatives, including the National Policy for Older Persons, the National Plan of Action for Older Persons, Pusat Aktiviti Warga Emas (PAWE), Unit Penyayang Warga Emas (UPWE), and welfare-based community programmes. However, these initiatives remain largely social, welfare, and community-development oriented. Therefore, Malaysia's next strategic priority should be to digitally strengthen existing ageing

structures rather than develop a separate digital ageing ecosystem.

PAWE is particularly relevant because it already functions as a community platform for older persons. It can be repositioned as a local digital ageing hub that supports digital literacy, telehealth access, e-government assistance, scam-awareness education, intergenerational digital learning, and community-based social participation. Through this approach, PAWE can become an implementation channel for Malaysia's digital ageing agenda, especially among rural, low-income, and digitally excluded older adults.

At the national level, Malaysia requires a coordinated inter-ministerial governance structure for digital healthy ageing involving welfare, health, digital transformation, local government, housing, and urban planning agencies. Such coordination is consistent with the MADANI aspiration, particularly its emphasis on social protection, inclusiveness, sustainability, compassion, and good governance. In this context, digital transformation for ageing should not be viewed merely as a technological agenda, but as part of a broader national effort to build a caring, equitable, and resilient society.

The integration of AI, Big Data, and IoT into healthcare, social protection, and urban systems should be prioritised to improve predictive planning, service delivery, resource allocation, and early identification of older persons requiring support. Malaysia should also strengthen data governance to ensure privacy, consent, interoperability, cybersecurity, and human oversight in all digital ageing initiatives. This is especially important for technologies such as remote monitoring, assistive robotics, predictive analytics, and AI-enabled health or welfare services.

Collectively, these implications reinforce the strategic importance of the proposed MalaysiaAgeNet framework as a national digital transformation blueprint. By integrating global best practices with existing Malaysian platforms such as PAWE and UPWE, and aligning them with the values of MADANI and the Sustainable Development Goals, MalaysiaAgeNet can provide a practical and context-sensitive pathway for building an inclusive, ethical, and digitally enabled ageing society.

VI. Limitations

This scoping review possesses several methodological limitations that should be acknowledged. First, the scope and depth of available policies varied significantly across countries, with some providing comprehensive national strategies while others offered only high-level or fragmented policy documents. This variability may have influenced the comparative richness of thematic mapping.

Second, the review may not have captured relevant grey literature or unpublished policy documents not indexed in major academic databases, particularly from low and middle-income nations. Third, the rapid pace of technological evolution means that some of the identified policies, especially those published several years ago, may no longer reflect contemporary technological capabilities or policy directions.

Fourth, consistent with PRISMA-ScR guidance, this review did not assess the quality or effectiveness of policy implementation. Therefore, the presence of a policy does not necessarily reflect its success or impact. Finally, the availability of translated government documents was limited, particularly from non-English-speaking countries, which may have resulted in the underrepresentation of certain regions. Despite these limitations, the review provides a robust and timely mapping of global digital ageing strategies and aligns with the intended purpose of scoping reviews: to synthesise broad evidence, identify conceptual patterns, and illuminate gaps in existing knowledge.

VII. Conclusion

This scoping review provides a comprehensive mapping of global digital policies and transformation strategies addressing ageing societies. The findings indicate that digital transformation is increasingly recognised as a key policy mechanism for managing demographic ageing. While several countries have developed advanced digital ecosystems integrating healthcare digitalisation, smart living environments, and regulatory frameworks, many developing countries remain at early stages of policy development.

Persistent challenges include fragmented governance structures, insufficient digital literacy among older populations, limited infrastructure in rural areas, and inadequate attention to ethical and regulatory issues surrounding digital technologies.

For Malaysia, these findings highlight the urgent need to develop an integrated national framework for digital ageing transformation. Establishing coordinated policies and strengthening digital infrastructures will be essential to ensuring sustainable healthcare systems, social inclusion, and economic resilience in the context of an ageing population.

Acknowledgment

This research was funded by the Ministry of Higher Education (MOHE) Malaysia under the Fundamental Research Grant Scheme-Early Career Researcher (FRGS-EC) [Grant Number: FRGS-EC/1/2024/SSI11/UPSI/02/2]. The funder had no role in the study design, data collection, analysis, interpretation of results, or manuscript preparation. The authors would like to acknowledge the support of SIG CultureTech, Universiti Pendidikan Sultan Idris, for its academic support and encouragement in completing this research.

Faculty of Electrical and Information Engineering, Universitas Surakarta, Surakarta, Indonesia [1]

***Abstract*—Javanese batik is characterized by distinctive motif patterns. The rapid evolution of designs through motif combination has introduced increased complexity, posing challenges for the community. People are increasingly less familiar with traditional Javanese original batik patterns. Many studies using CNN have been conducted to recognize batik patterns. However, it is important to improve object detection performance by strengthening explicit local features. To answer this question, our study aims to improve the detection of batik patterns that have local texture patterns and complex orientations that are in harmony with batik geometry with an integrated fusion scheme. To improve detection, an integrated fusion schema model was developed using the PHLF hybrid framework as a geometrically oriented local feature with VGG16 as a deep feature extractor for object detection. According to research, although VGG16 is reliable on large benchmarks such as ImageNet, VGG16 is less reliable for subtle intra-motif variations, which can suppress accuracy. Evidence from the results of the study shows that in the eight-class dataset consisting of 6,400 images for training data and 1.600 images for test data, a mid-level feature fusion approach on VGG16 with integrated PHLF improves resistance to data variations such as lighting, fabric deformation, and background complexity. The experimental results showed that the model achieved an mAP value of 0.68 at IoU = 0.5 and 0.2846 at IoU = 0.7. The significant difference between mAP@0.5 and mAP@0.7 suggests that the model still has limitations in the precision of the localization of the boundary box.**

Keywords*—A Mid-level feature; detection; fusion framework; phlf; traditional javanese batik

I. Introduction

Batik, an intangible cultural heritage with spiritual value, a deep history, and philosophy [1][2]. However, the characteristics of batik that are complex, repetitive, and have a high resemblance between classes are a challenge in batik detection [3][4]. To answer the challenge, various studies have been conducted, from the use of Deep Learning models such as Convolutional Neural Network (CNN) using VGG16, ResNet, and EfficientNet architectures, proven to be effective in capturing fine texture details [3][5]. Research shows that the Transfer Learning Technique and Hybrid models of VGG16 and XGBoost can achieve up to 89.83% accuracy in recognizing traditional motifs [3][6]. However, the research that has been conducted has not answered the problem, considering that Batik has undergone such rapid development. The use of CNN architecture is the dominant method in batik analysis because of its ability to automatically learn features directly from the data used [7][8]. Other architectures, such as Inception ResNetV2, have proven their effectiveness by achieving an average accuracy of 98.19% in the classification of batik patterns [9], while the VGG16 and MobileNetV2 models also show high results in detecting complex visuals [10]. For real-time detection, the Yolov11 model enhanced with an attenuation mechanism was able to achieve an mAP (mean Average Precision) value of 0.748. Provides a balance between localization accuracy and computational efficiency [11].

Although CNN excels in extracting global semantic features, this model has limitations in representing the subtle textures that characterize batik [12][13][14][15]. In contrast, feature selection such as the Gray Level Co-occurrence Matrix (GLCM) is highly effective in describing local texture characteristics through the spatial relationships between pixels [16][17][18][19]. However, this method often faces the challenge of semantic gaps and is less adaptive to large data variations in real time [20]. To answer the challenge, several studies with a hybrid approach and feature fusion were conducted, combining models is a crucial strategy to improve the performance of automatic detection [3][20]. One of the models is the combination of VGG16 and XGBoost, which managed to achieve the highest accuracy in Batik Keraton at 89.83% compared to the CNN model [3]. The integration of features in latent space, as implemented in the Deep Convolutional Autoencoder (DCAE) model, has been shown to produce a more discriminatory, clean representation of noise with an accuracy of up to 99% [21]. Commonly used fusion strategies include concatenation at the feature level, which is considered more advantageous because it can store different information from each extraction method [20]. In addition, the use of dual-attention modules that combine spatial attention and channel attention significantly strengthens the model's focus on the most informative motif regions [12]. Hybrid-based detection models that integrate VGG16 for high-level semantic features with local texture orientation features are strongly aligned with the finding that the combination of shape and texture features results in greater accuracy (90.48%) than Single features [22][9]. The multi-task learning approach that performs simultaneous bounding box regression and classification, as applied to the YOLO series, is an effective solution to the dense and complex challenge of localizing batik objects [11].

Based on the results of the study, although the multi-task learning approach, such as the YOLO series, is considered effective, there are some fundamental weaknesses when applied to the dense and complex detection of batik motifs. This is important to underline the need for the development of a mid-level feature fusion framework that integrates PHLF's handcrafted features with VGG16's deep learning features. Therefore, the integration of PHLF to capture local geometric

orientations and VGG16 for high-level semantic features through intermediate-level fusion is a crucial solution to improve the identification accuracy as well as the precision of bounding box localization on batik objects.

II. Previous Research Study

Research shows that pure deep learning models often struggle with rotational and scale variations in dense batik motifs. In the study conducted by [23], the MU2ECS-LBP and Mulwin-LBP algorithms were developed specifically designed to be invariant to scale and rotation, as well as in the studies [24] and [25]. This study proves that the handling of geometric orientation specifically is crucial because shooting batik in the real world often involves inconsistent zoom and angle changes. Research conducted by [26] and [27], uses Geometric Invariant Moment (GIM) as a shape-based feature extractor to detect the Broken Parang motif. This supports the argument that geometric information and local shapes are formidable descriptors for recognizing the structure of a particular motif.

VGG16 is recognized in many studies as having the ability to extract very deep spatial features for intricate patterns. As in the research conducted [3], it is explained that the architecture of VGG16 is very effective in capturing the delicate textures and intricate ornaments of batik through its deep and dense convolutional structure. The VGG16 model is able to capture subtle differences in texture that traditional models often fail to identify. Likewise, in the study [28], utilizing VGG16 to study the unique characteristics of batik spatially through the convolution process proves that visual-based feature extraction is far superior to simple color-based methods. The integration between traditional features and deep learning features has been shown to mask the weaknesses of each method, as in studies conducted [29] and [24], it was found that the combination of texture features and shape features resulted in much higher accuracy (90.48%) than using only one type of feature. Similarly, in the study [16], it was emphasized that relying only on artificial neural networks can lead to the loss of important local textural information. Therefore, fusion between handcrafted texture features and deep learning models (such as ResNet or VGG) is strongly recommended to create a more robust classification system [30]. In the research conducted [20], it is hypothesized that various image features (geometry, points, parallel lines) complement each other in representing the properties of batik motifs, and the fusion of features consistently outperforms the performance of individual features.

To identify the limitations of standard detection models in handling the density of batik motifs, the research conducted by [11], explains that object detection architectures such as the standard YOLO have limitations in the local receptive field, making it difficult to model the long-range spatial relationships that define the composition of batik culture. In addition, very small and dense batik objects often exceed the detection capabilities of the baseline model, thus requiring the extraction of higher-quality features to improve the precision of localization. Research by [3], showed that combining the extraction of VGG16 in-depth features with the XGBoost classifier resulted in the highest accuracy of 89.83% on Keraton Batik, outperforming the standard CNN model. The study by [2], [28] and [31], utilized VGG16 to study the unique characteristics of batik spatially through convolution and used Random Forest to achieve 97.58% accuracy on a dataset with 50 classes. VGG16 Modified (Web-Based), as in the study [32], modified VGG16 for the classification of Demak Batik and managed to achieve 98.72% accuracy in just 5 epochs.

The problem with the research that has been conducted is that standard *deep learning* models, including CNN and detection architectures such as YOLO, tend to lose crucial micro-texture details in batik due to repeated downsampling processes [12], fine line details are often erased or become blurred, requiring additional handcrafted features that are more sensitive to local textures to retain the information [33]. Although CNN excels in global semantic features, it often struggles to cope with extreme rotation and scale variations without the support of massive augmented data or specific geometric features [22] [3]. There is a gap between the visual representation of humans of batik motifs that are rich in cultural significance and the low-level features stored in digital databases [22][20]. Single models often fail to bridge this gap, deep learning features are too abstract for the technical details of the craftsman, while traditional features are too rigid for visual variation [16].

To address these gaps, this study proposes a hybrid approach that integrates PHLF's handcrafted texture features with the deep learning features of VGG16 through a mid-level feature fusion strategy. This approach allows for a more effective interaction between texture features and semantic features in latent spaces, resulting in more discriminatory representations for batik motif detection.

III. Proposed Research Methodology

The methodology for this study is illustrated in Fig. 1.

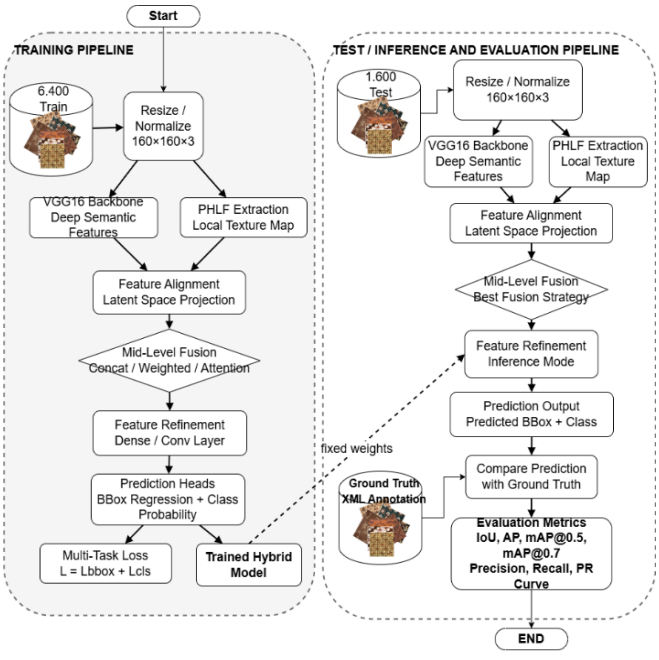

Fig. 1. Proposed method.

This study proposes a hybrid-based batik motif detection framework that integrates the handcrafted texture features of

Parallelogram Haar-Like Features (PHLF) with the deep learning features of VGG16. This approach is designed to overcome the limitations of a single method in representing the complexity of batik patterns, especially in capturing microtextures and semantic structures simultaneously.

A. Data Processing

This study uses the Batik Keraton dataset consisting of eight pattern classes, each containing 800 original images (a total of 6,400 images) for training data and 200 (a total of 1,600 images) for testing data. Fig. 2 shows the eight patterns of Batik classes used.

Fig. 2. Eight batik classes patterns used.

B. Input Processing

Given an input batik image, shown in Eq. (1):

$$I \in \mathbb{R}^{HxWx3} \tag{1}$$

The image is first normalized, shown in Eq. (2):

$$I_{norm} = \frac{I}{255} \tag{2}$$

And resized to a fixed dimension, shown in Eq. (3):

$$I_{resized} \in \mathbb{R}^{160x160x3} \tag{3}$$

A grayscale version of the image is also generated for texture feature extraction, shown in Eq. (4):

$$I_{gray} = 0.299R + 0.587G + 0.144B \tag{4}$$

Remarks:

I = original input batik image, H = height image, W = image width, 3 = number of color channels, I_{norm} = image of normalization results, $I_{resized}$ = image resized, I_{gray} = image grayscale, R, G, B = color channels red, green, blue.

C. PHLF-Based Texture Feature Extraction

The first branch focuses on extracting local texture features using Parallelogram Haar-Like Features (PHLF). This method captures directional patterns and geometric structures inherent in batik motifs.

The convolution operation is defined as shown in Eq. (5),

$$F_k(x,y) = (I_{gray} * K_k)(x,y) \tag{5}$$

where, K_k represents the PHLF kernels. The final PHLF map is computed as shown in Eq. (6),

$$PHLF(x,y) = \sum_{k=1}^{K} |F_k(x,y)| \tag{6}$$

Followed by normalization, shown in Eq. (7),

$$PHLF_{norm} = \frac{PHLF - min}{\max - min} \tag{7}$$

The resulting feature map is shown in Eq. (8).

$$X_{phlf} \in \mathbb{R}^{HxWx1} \tag{8}$$

Remarks:

x, y = pixel coordinates in the image, K_k= Colonel Philf K-K, K = total number of PHLF kernels, $F_x(x,y)$ = the characteristic response of the result of the convolution of the kernel k at position (x,y), $PHLF(x,y)$= PHLF feature value at position (x,y), $PHLF_{norm}$ = Normalized PHLF, min = Minimum values on feature maps, max = Maximum value on the feature map, X_{phlf} = feature map of PHLF extraction results.

D. Deep Feature Extraction Using VGG16

The equation for showing the convolution process at the CNN layer is shown in Eq. (9).

$$F^{(l)} = \sigma(W^{(l)} * F^{(l-1)} + b^{(l)}) \tag{9}$$

Remarks:

$F^{(l)}$ = feature map at layer l. $F^{(l-1)}$ = feature map from the previous layer, $W^{(l)}$ = convolutional weights at layer l. $b^{(l)}$= bias term at layer l . σ – activation function (e.g., ReLU, sigmoid).

The equation used to convert the PHLF and VGG16 features to compatible latent dimensions is shown in Eq. (10)-(11).

$$Z_{phlf} = f_{phlf}(X_{phlf}) \tag{10}$$

$$Z_{cnn} = f_{cnn}(X_{cnn}) \tag{11}$$

Remarks:

Z_{phlf} = Latent representation of PHLF features, Z_{cnn} = Latent representation of CNN features, $f_{phlf}(.)$ = Projection function for PHLF features, $f_{cnn}(.)$= Projection function for CNN features.

E. Concatenation Fusion

Combines features by stacking them, shown in Eq. (12).

$$F = [Z_{cnn}, Z_{phlf}) \tag{12}$$

Balances contributions from CNN and PHLF features, shown in Eq. (13).

$$F = \alpha Z_{cnn} + (1-\alpha) Z_{phlf} \tag{13}$$

Dynamically weight feature importance using attention, shown in Eq. (14)-(15).

$$A == \alpha(W_\alpha . Z_{cnn}) \tag{14}$$

$$F = A \odot Z_{cnn} + (a - A) \odot Z_{phlf} \tag{15}$$

Enhances feature representation before prediction, as shown in Eq. (16).

$$F_{ref} = \sigma(W_f . F + b_f) \tag{16}$$

F. Evaluation

Bounding Box Loss measures localization error using L1 loss, shown in the following Eq. (17).

$$L_{bbox} = ||B - \hat{B}||_1 \quad (17)$$

Intersection over Union (IoU), shown in the following Eq. (18).

$$IoU = \frac{|B_{pred} \cap B_{gt}|}{|B_{pred} \cup B_{gt}|} \quad (18)$$

Average Precision (AP), shown in the following Eq. (19).

$$AP = \int_0^1 Precision(Recall) dRecall \quad (19)$$

Mean Average Precision (mAP), shown in the following Eq. (20).

$$mAP = \frac{1}{C} \sum_{C=1}^{C} AP_C \quad (20)$$

IV. Experimental Results and Analysis

The evaluation of the performance of the VGG16 technique with integrated PHLF was verified based on a dataset of 8 batik patterns of Kawung, Parang, Satriomanah, Sidoasih, Sidomukti, Tambal, Truntum, and Wahyutumurun. The batik data set consists of 8,000 images of batik patterns, each consisting of 1,000 data points. The images are categorized according to batik patterns. Evaluation was also carried out on 1,600 data points before augmentation.

TABLE I. Train Results of 8 Batik Classes

Method	Task	Accuracy / mAP	Limitation
VGG16 + XGBoost	Classification	89.83%	No localization
VGG16 + RF	Classification	97.58%	Not detection-based
Modified VGG16	Classification	98.72%	No bounding box
YOLO	Detection	0.174 mAP	Weak for dense patterns
CNN only	Classification	–	Loss of texture detail
PHLF + VGG16	Detection	0.208 mAP@0.5	Localization still limited

A detailed description of the test results of the augmentation is shown in Table I. Fig. 3 shows the results of Accuracy and Loss, Precision, and Recall of Model VGG16 with integrated PHLF. Fig. 3 shows that the PHLF-VGG16 Hybrid model experienced a rapid increase in accuracy during the initial and stable period around 10 years of age. Training accuracy and validation remained aligned with minimal deviations, indicating effective learning with no signs of overfitting. The loss curve showed an equally consistent decrease, with validation loss tracking training loss closely, confirming good generalization to unseen data. These patterns showed a stable and efficient convergence process, supporting the conclusion that integrating PHLF with VGG16 improved feature extraction quality and improved overall training stability.

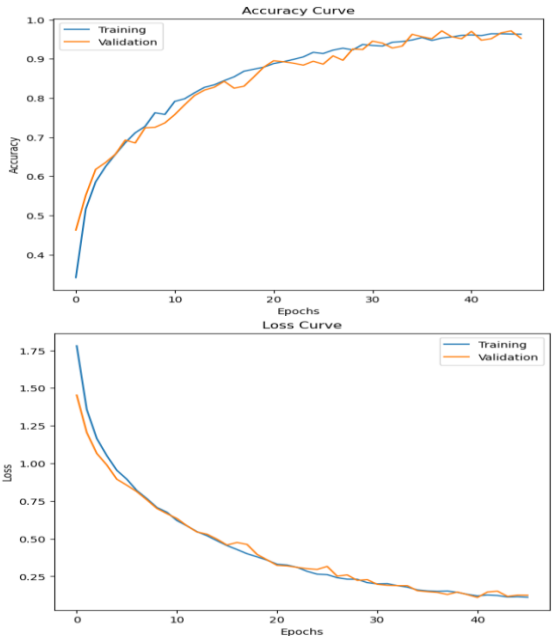

Fig. 3. Curve of accuracy and loss.

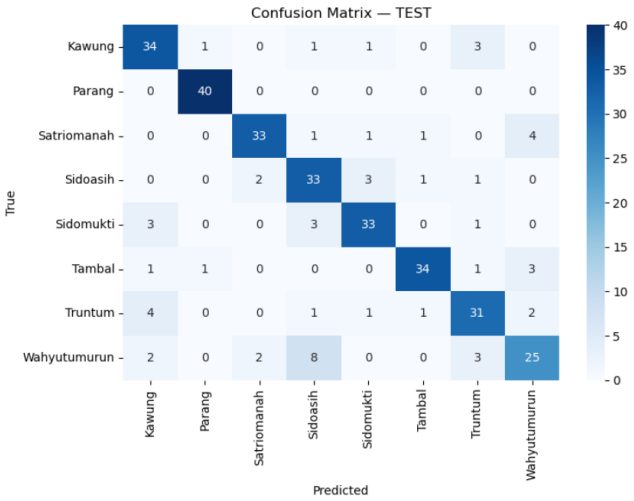

Fig. 4. Confusion matrix results test.

The Confusion Matrix shown in Fig. 4 provides strong evidence of the robustness and reliability of the VGG16 fine-tuning method using PHLF.

The sharp rise and stabilization of macro precision suggest that this method produces very few false positives, even when faced with visually similar batik motifs. This behavior suggests that the PHLF enhancement module effectively reinforces the local texture differentiation that is important for batik classification. Likewise, the convergence of F1's macro and macro graven towards unity reflects the model's ability to recognize diverse variations in motifs without systematically ignoring specific classes. This is especially important in datasets with rich intra-class variations such as Kawung, Parang, Truntum, and Tambal.

TABLE II. COMPARISON OF ACCURACY, PRECISION, RECALL, AND F1 SCORE RESULTS

Model	Acc	Precision	Recall	F1-score
VGG + XGBoost	89,83%	92%	92%	92%
VGG16 Pretrained	87,77%	88%	88%	88%
VGG16	85%	85%	85%	85%
VGG16 + PHLF	98,72%	97,6%	97,5%	97,55%

Table II shows the results, showing a consistent trend: performance improves when explicit geometry features (PHLFs) are integrated into the VGG16. In other words, the scale of the data and the feature fusion strategy are decisive, especially as the number of classes grows and the variety of motifs becomes more complex. In the initial scenario, the VGG+XGBoost approach provides the highest accuracy (89.83%) compared to the standard VGG16 ($\approx$ 85 – 87%). These results indicate that in a simpler classification space, the output of VGG features combined with powerful classifiers such as XGBoost is quite effective in separating motifs that have a pronounced visual difference.

Meanwhile, VGG16 is in the F1 range of 85%: VGG16 is capable of capturing global textures and patterns, but is still less sensitive to the diagonal structure and geometric repetition that characterize some motifs. The advantages of the VGG16 approach using PHLF clearly reach F1 = 97.55%. This spike is proof that the PHLF really does add important information: it strengthens the response to repetitive geometric elements, allowing the model to become more stable in distinguishing motifs that rely on diagonals without losing the ability of VGG16 to capture the context of texture. These findings point to two points: first, VGG16 is indeed greatly aided by a mid-level feature fusion framework that integrates PHLF and VGG16 for strong batik pattern detection; second, PHLF still provides additional advantages even though the backbone of VGG16 is already strong, resulting in more stable and consistent performance. In summary, the results of the table confirm that the enhancements in VGG16 using PHLF result in the most complete and most effective representation, especially in multi-class scenarios.

Fig. 5 presents example visualizations of batik motif detection results using the hybrid PHLF–VGG16 model, comparing ground truth (GT) and predicted outputs with evaluation metrics including TP, FP, FN, and IoU. In the left image (Kawung), the model achieved strong localization performance with mIoU(TP) $\approx$ 0.84, TP = 1, FP = 0, and FN = 0, indicating accurate detection without missed or incorrect predictions. This result suggests that the regular and repetitive structure of Kawung is easier for the model to learn and localize. In contrast, the right image (Sidoasih) shows limitations in localization precision. Although the motif was detected (FN = 0), the presence of FP = 1 and an mIoU(TP) close to zero indicates weak overlap between the predicted bounding box and the ground truth. These results suggest that the model can recognize motif presence but still struggles to precisely estimate object boundaries. The comparison highlights that detection performance is highly influenced by motif characteristics, where denser and more complex textures increase localization difficulty.

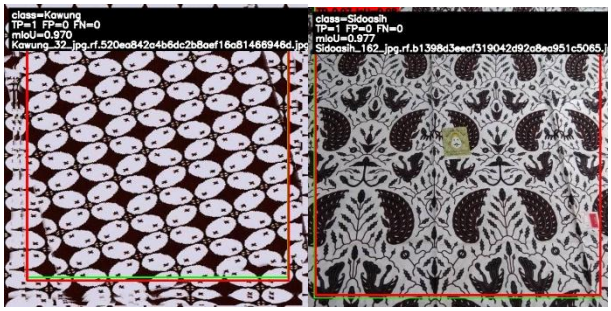

Fig. 5. Test results.

TABLE III. HASIL RATA-RATA IOU PER CLASS

Name	meanIoU	IoU@0.5
Kawung	meanIoU=0.538248	IoU@0.5=60.69%
Parang	meanIoU=0.605074	IoU@0.5=72.43%
Satriomanah	meanIoU=0.539754	IoU@0.5=60.89%
Sidoasih	meanIoU=0.512537	IoU@0.5=54.93%
Sidomukti	meanIoU=0.712856	IoU@0.5=82.22%
Tambal	meanIoU=0.546839	IoU@0.5=57.95%
Truntum	meanIoU=0.461856	IoU@0.5=47.16%
WahyuTumurun	meanIoU=0.686640	IoU@0.5=83.84%

Table III presents the batik motif detection results using mean Intersection over Union (mIoU) and IoU@0.5 to evaluate localization performance based on the overlap between predicted bounding boxes and ground truth annotations. Overall, all classes achieved IoU@0.5 above 50%, indicating satisfactory localization capability despite performance variations caused by differences in texture, object scale, and pattern complexity.

The best results were achieved by WahyuTumurun (83.84%) and Sidomukti (82.22%), demonstrating strong localization accuracy, followed by Parang (72.43%) and Kawung (60.69%). In contrast, Satriomanah, Sidoasih, Tambal, and Truntum obtained lower IoU@0.5 values (54–61%), suggesting that although objects were successfully detected, the predicted bounding boxes were not yet fully aligned with the ground truth. This limitation is likely related to texture similarity across motifs, pattern variations, small object regions, and the tendency to predict broader fabric areas than the annotated regions.

V. CONCLUSION

This study proposes a mid-level feature fusion framework that integrates handcrafted Parallelogram Haar-Like Features (PHLF) with deep semantic representations extracted by VGG16 for batik pattern detection. By combining local texture enhancement and high-level semantic learning, the framework improves feature discriminability and achieves effective detection and localization performance across all classes, with IoU@0.5 above 50% and average IoU exceeding 0.68. The best results were obtained for WahyuTumurun (83.84%) and Sidomukti (82.22%). However, performance declined at IoU = 0.7 (average IoU = 0.2846), revealing limitations in precise localization for dense and repetitive motifs due to texture similarity, scale variation, and background complexity. Overall, the proposed framework enhances texture representation and

delivers more robust, accurate, and consistent batik detection, demonstrating strong potential for real-world automated batik identification. Future work will focus on integrating Feature Pyramid Networks (FPN), attention mechanisms, and IoU aware loss functions to further improve localization accuracy for visually similar motifs.

***Abstract*—Accurate and real-time assessment of road infrastructure is critical for smart city maintenance and transportation safety. However, conventional object detection models often struggle with complex environmental factors, such as varying illumination, shadows, and background noise, leading to false detections and missed fine-grained defects. In this study, we propose YOLO-CBAM, a lightweight and fast neural network architecture tailored for real-time road surface damage detection. The standard YOLO11s backbone is enhanced through the integration of a Convolutional Block Attention Module (CBAM), which synergistically applies channel and spatial attention mechanisms. This modification enables the network to actively suppress irrelevant background visual noise and focus exclusively on structural defects like longitudinal cracks and potholes. Extensive experiments conducted on a comprehensive dataset reveal that the implementation of partial transfer learning significantly mitigates early-stage gradient shock, allowing the model to achieve a mean Average Precision (mAP@50) of 0.60 in just 40 training epochs. Deployed on an NVIDIA RTX 4070 Ti, the proposed framework achieves an inference speed of 25 frames per second (FPS), demonstrating an optimal balance between detection accuracy and computational efficiency. The YOLO-CBAM model provides a robust, cost-effective solution for automated video surveillance and road condition monitoring in smart city infrastructures.**

Keywords*—Computer vision; deep learning; object detection; YOLO architecture; CBAM; attention mechanism; road monitoring; transfer learning

I. Introduction

Road networks are a critical infrastructure component, ensuring economic stability and public safety. However, over time, heavy traffic and adverse weather conditions inevitably lead to the formation of defects such as longitudinal and transverse cracks, potholes, and pavement deterioration. Traditional methods of visual or manual road monitoring are time-consuming and costly and are highly susceptible to human error [1]. Therefore, city authorities are increasingly implementing automated road condition monitoring systems based on video cameras and artificial intelligence technologies [2].

In recent years, convolutional neural networks (CNNs) and deep learning methods have become the international standard for road pavement degradation analysis [3]. In particular, single-stage object detectors of the YOLO (You Only Look Once) family have become widely used due to their high image processing speed [4]. YOLO's lightweight architecture and low computational requirements make these models ideal for processing real-time video streams on mobile edge devices mounted directly in inspection vehicles [5].

Despite these advantages, accurate defect detection in real-world street conditions remains challenging [6]. Standard neural networks demonstrate high accuracy under ideal lighting conditions, but their performance drops sharply in the presence of visual noise. Tree shadows, overcast skies, glare from water, and the complex texture of the asphalt itself often reduce the predictive power of algorithms [7]. Because of this, basic YOLO models either miss fine details (e.g., fine microcracks) or produce false positives, mistaking background noise for a pavement defect.

To address the problem of noise and improve the quality of feature extraction, attention mechanisms are being actively incorporated into modern computer vision architectures [8]. One of the most effective solutions for localization problems is the Convolutional Block Attention Module (CBAM) [9]. This module acts as an intelligent spatial and channel filter: it helps the neural network adaptively recalibrate feature maps, forcing the algorithm to ignore background noise and focus exclusively on the structural boundaries of real defects [10].

The integration of attention mechanisms into the YOLO family has become an important research trend in 2024–2025. Recent studies confirm that the combination of improved YOLO backbones and attention modules (such as CBAM or SimAM) can significantly improve localization accuracy without significantly increasing the computational load [11], [12]. Furthermore, architectural optimization and the use of modern loss functions allow such hybrid networks to achieve an ideal balance between inference speed (FPS) and average accuracy (mAP) [13], [14].

*Corresponding author.

In this study, we propose YOLO-CBAM—a modified and lightweight neural network model designed specifically for real-time road surface defect detection. By integrating the CBAM module into the standard YOLO architecture, we enhance the network's ability to detect complex defects against urban textures. Furthermore, the study examines the impact of various transfer learning strategies on the stability of model optimization (including overcoming the "gradient shock" phenomenon) using the extended RDD2022 dataset [15]. The primary goal of this study is to create a fast, computationally efficient, and robust tool for automated infrastructure monitoring in smart city applications.

The remainder of this study is organized as follows. Section II presents a review of recent studies related to road damage detection, lightweight object detection frameworks, and attention mechanisms in computer vision. Section III describes the dataset preparation process, preprocessing pipeline, proposed YOLO-CBAM architecture, mathematical formulation of the attention mechanism, and optimization strategy. Section IV provides the experimental results, including quantitative evaluation, ablation studies, qualitative visualization analyses, and computational performance assessment. Section V discusses the effectiveness, practical deployment feasibility, and limitations of the proposed framework. Finally, Section VI concludes the study and outlines future research directions for improving real-time road infrastructure monitoring systems.

II. Related Works

In recent years, automated visual inspection of road surfaces has been addressed primarily using convolutional neural networks (CNNs). Single-Stage Detectors (SNDs) of the YOLO family have become particularly popular, as they provide an optimal balance between localization accuracy and inference speed [16]. Researchers are actively adapting various YOLO versions (from YOLOv5 to YOLOv8) to classify longitudinal cracks, potholes, and asphalt wear [17], [18]. While standard architectures are successful in localizing large defects, their application in real-world urban environments is often limited due to their high sensitivity to illumination changes, complex background textures, and the presence of foreign objects [19], [20]. To improve the robustness of systems, some authors propose multi-scale networks; however, their direct use without modification often leads to increased computational load, which complicates deployment in smart city video systems [21].

To address the shortcomings of standard convolutional networks, spatial and channel attention mechanisms (Attention Mechanisms) are being actively implemented in deep learning architectures [22]. These modules allow the neural network to dynamically re-evaluate the importance of different image regions, focusing on structural anomalies and suppressing background visual noise [23]. One of the most effective solutions in this area is the Convolutional Block Attention Module (CBAM) [24]. Recent studies confirm that integrating CBAM into the backbone or neck of YOLO-type detectors significantly improves the model's sensitivity to small objects, such as microcracks [25], [26]. Unlike heavier transformers, CBAM modules add virtually no additional network parameters. Experiments show that the combination of YOLO and CBAM provides a significant increase in mean average accuracy (mAP) in localizing infrastructure defects without sacrificing frame rate (FPS) [27], [28].

A key requirement for mobile road monitoring systems is the use of lightweight models capable of running on edge devices in real time [29]. For such models, weight optimization is critical. Training a network from scratch on specific datasets often results in gradient instability in early epochs [30]. Transfer learning [31] is widely used in modern literature to address this issue. Partially transferring weights pre-trained on large open datasets (e.g., COCO) allows models to avoid early gradient shock and significantly accelerates convergence [32], [33]. As noted in a number of works on infrastructure monitoring, the use of transfer learning strategies in lightweight modified networks allows achieving target accuracy indicators (mAP@50 > 0.55–0.60) in a minimum number of epochs [34], which makes such solutions highly effective for practical application.

III. Materials and Methods

A. Dataset Preparation and Preprocessing

The dataset utilized in this study is the publicly available "Road Damage" dataset sourced from the Kaggle platform. It comprises thousands of images depicting real-world asphalt degradation, categorized into critical classes such as longitudinal cracks, transverse cracks, alligator cracks, and potholes. To facilitate a comprehensive evaluation of the model's generalization capabilities and to prevent overfitting, the normalized dataset was subsequently partitioned using a randomized split. Specifically, 80% of the data was allocated to the training subset, while the remaining 20% was strictly reserved for the validation subset to benchmark the model's performance on unseen structural defects.

To ensure optimal convergence during the training phase and to comply with the architectural prerequisites of the YOLO network, a rigorous preprocessing pipeline was implemented. Initially, all diverse input images were standardized through resizing to a uniform spatial resolution of W×H=640×640 pixels. Following the spatial adjustment, pixel intensity normalization was applied to stabilize the gradient descent process and mitigate the vanishing gradient problem. The normalization converts the original 8-bit integer pixel values (ranging from 0 to 255) into a floating-point format within the range of [0,1]. This operation is mathematically defined for each pixel at coordinates (x,y) as:

$$I_{norm}(x,y) = \frac{I(x,y)}{255.0}, \quad (1)$$

Furthermore, the ground truth bounding boxes were normalized relative to the image dimensions to standardize the regression targets. For a bounding box with absolute coordinates (center x_{abs}, y_{abs}, w_{abs} and h_{abs}) the normalized coordinates are computed as:

$$x_c = \frac{x_{abs}}{W}, y_c = \frac{y_{abs}}{H}, w_{norm} = \frac{w_{abs}}{W}, h_{norm} = \frac{h_{abs}}{H}, \quad (2)$$

B. YOLO-CBAM Network Architecture

The core structural framework of the proposed detection system is derived from the YOLO11s architecture. This specific iteration of the "You Only Look Once" family was deliberately selected because it functions as a highly efficient, lightweight, single-stage object detector. It inherently offers an optimal equilibrium between high mean average precision (mAP) and the low computational overhead required for real-time edge computing deployment.

However, standard convolutional neural networks often exhibit critical vulnerabilities when deployed in uncontrolled, real-world environments. They are highly susceptible to visual distractors such as drastic changes in illumination, long evening shadows, reflective water pooling, and complex road markings. These environmental factors frequently lead to false positive detections or the omission of fine, irregular micro-cracks. To systematically eradicate this limitation, we engineered a custom modification by structurally integrating a Convolutional Block Attention Module (CBAM) into the deep feature extraction layers of the baseline YOLO architecture, thereby establishing the YOLO-CBAM model.

The holistic data flow within the proposed YOLO-CBAM architecture is visually delineated in Fig. 1. The computational process begins when the normalized image tensor is ingested by the Backbone zone. This zone is responsible for hierarchical feature extraction, aggregating low-level visual cues (such as edges and gradients) into complex, high-level semantic representations. Subsequently, these intermediate feature maps are routed through the integrated CBAM layers. The attention module acts as a dynamic, intelligent filter that recalculates feature weights, forcing the network to heavily prioritize the structural morphology of road defects while actively dampening the activation of background visual noise. Finally, the optimized feature maps are propagated through the Neck region to the Detection Head, which computes the final regression of bounding box coordinates and the corresponding class probability distributions.

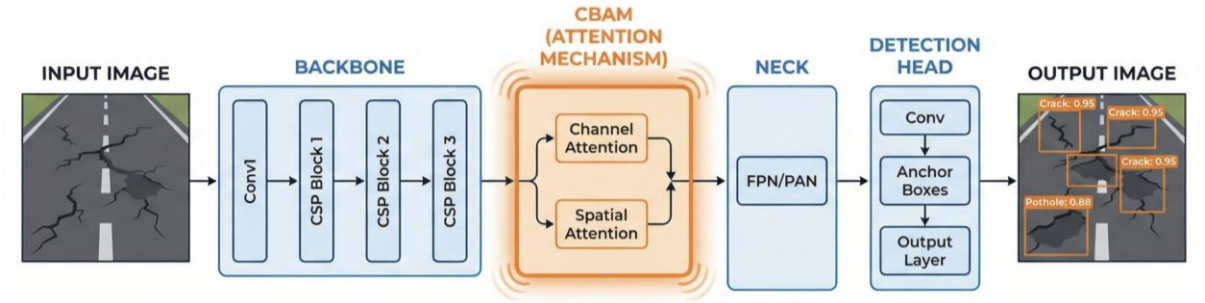

Fig. 1. Architecture of the proposed YOLO-CBAM model.

C. Mathematical Formulation of the Attention Mechanism

The Convolutional Block Attention Module is not a simple filter, but rather a sophisticated dual-attention mechanism. It sequentially refines intermediate feature maps across two distinct, complementary dimensions: the channel dimension and the spatial dimension. CBAM operates as a dual-attention mechanism that sequentially infers attention maps along channel and spatial dimensions.

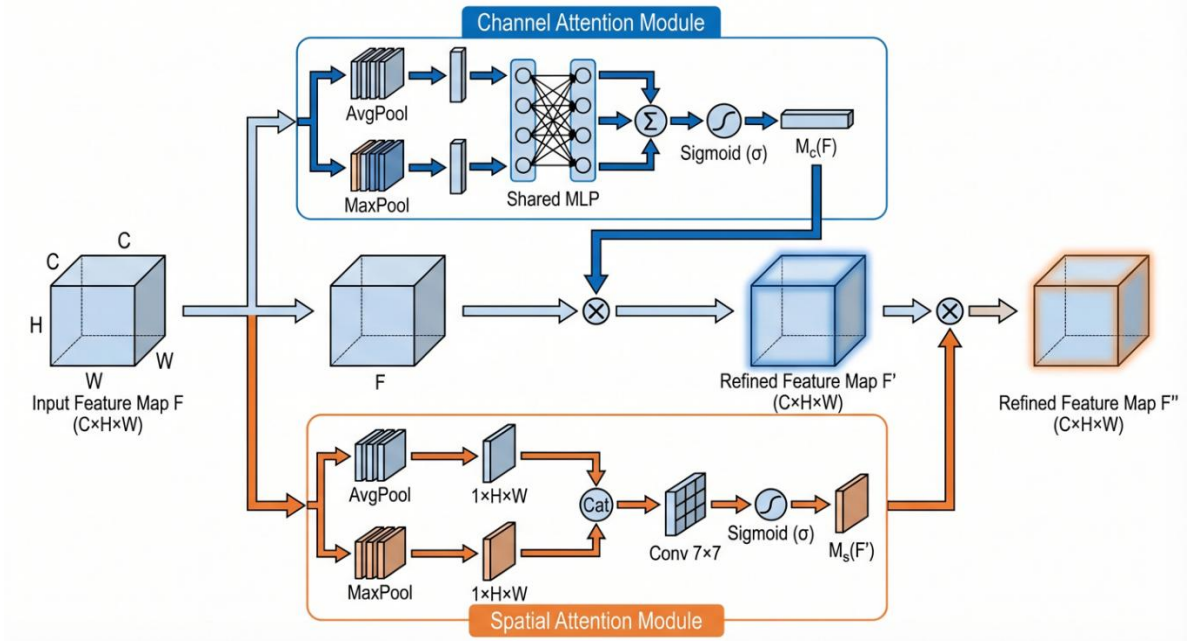

Fig. 2. Detailed workflow of the Convolutional Block Attention Module (CBAM).

As illustrated in the internal schematic in Fig. 2, let us assume the module receives an intermediate feature map denoted as $F \in R^{C\times H\times W}$, where C represents the number of channels, and H and W represent the spatial height and width. The holistic attention refinement process is mathematically formalized through sequential element-wise multiplications ($\otimes$):

$$F' = M_c(F) \otimes \mathrm{F}, \quad (3)$$

$$F'' = M_s(F') \otimes F', \quad (4)$$

here, $M_c(F) \in R^{C\times 1\times 1}$, is the 1D channel attention map $M_s(F') \in R^{C\times H\times W}$ is the 2D spatial attention map, and F'' represents the final, refined output tensor.

Channel Attention Sub-module: The primary objective of this sub-module is to determine "what" features within the map are most informative. It compresses the spatial dimensions of the input tensor F by simultaneously applying Global Average Pooling (F) and Global Max Pooling (F). These operations generate two distinct 1D spatial context descriptors. Both descriptors are then forwarded through a shared Multi-Layer Perceptron (MLP) network with one hidden layer. The output vectors are merged via element-wise summation and normalized using a sigmoid activation function (σ) to yield the channel attention weights.

$$M_c(F) = \sigma\Big(MLP\big(AvgPool(F)\big) + MLP\big(MaxPool(F)\big)\Big), \quad (5)$$

Spatial Attention Sub-module: While the channel attention focuses on feature types, the spatial attention sub-module identifies "where" the critical structural damages are physically located on the grid. Utilizing the channel-refined feature map F', the module applies pooling operations along the channel axis. The resulting 2D maps are concatenated and subjected to a standard convolution operation ($f^{7\times 7}$) utilizing a robust 7×7 kernel. This process suppresses irrelevant background textures and highlights the morphological boundaries of the defects:

$$M_s(F') = \sigma(f^{7\times 7}([AvgPool(F'); MaxPool(F')]), \quad (6)$$

D. Loss Functions, Optimization Strategy, and Experimental Setup

To guarantee high precision in both defect classification and the exact spatial localization of bounding boxes, the network's learning process was governed by a multi-component loss function. The total loss (L) is calculated as a weighted linear combination of three distinct penalty metrics.

$$\mathrm{L_{total}} = \lambda_{\mathrm{box}}\mathrm{L_{box}} + \lambda_{\mathrm{cls}}\mathrm{L_{cls}} + \lambda_{\mathrm{dfl}}\mathrm{L_{dfl}}, \quad (7)$$

In this formulation, L_{cls} represents the classification loss, calculated using standard Cross-Entropy to penalize incorrect defect categorization. L_{box} bo denotes the bounding box regression loss (typically Complete Intersection over Union, CIoU), which mathematically evaluates the geometric overlap, central point distance, and aspect ratio alignment between the predicted boxes and the ground truth annotations. Finally, L_{dfl} stands for Distribution Focal Loss, which optimizes the fine-grained, pixel-level localization of the bounding box edges.

The empirical experiments were executed on a high-performance computational workstation operating under a Windows environment, heavily accelerated by an NVIDIA RTX 4070 Ti Graphics Processing Unit equipped with 12 GB of VRAM. The software stack included the Ultralytics and PyTorch deep learning frameworks. We implemented the AdamW optimizer with an initial learning rate set to 0.005. To effectively combat the risk of over-parameterization and model overfitting, a weight decay coefficient of 0.0005 was applied alongside a 3.0-epoch warmup period. Training was conducted over a span of 40 epochs utilizing a batch size of 32. Furthermore, a hybrid transfer learning paradigm was deployed: the standard YOLO layers were initialized with pre-trained weights to exploit generalized prior knowledge, whereas the newly integrated CBAM layers were initialized with random weights, allowing them to autonomously learn highly specific attention topographies tailored exclusively for asphalt degradation.

E. Experimental Configuration and Training Strategy

To improve model generalization capability and robustness against environmental variability, several online data augmentation strategies were applied during the training phase. The augmentation pipeline included random horizontal flipping, random scaling, HSV color-space perturbation, mosaic augmentation, and random translation operations. These transformations were dynamically applied during mini-batch generation to increase structural diversity and reduce the risk of overfitting under limited environmental conditions. Such augmentation operations are particularly important for road damage detection tasks due to frequent illumination variability, shadow interference, and heterogeneous pavement textures observed in real-world urban environments.

The optimization process utilized the AdamW optimizer in combination with a cosine annealing learning rate schedule. The initial learning rate was initialized at 0.005 and gradually reduced throughout the training epochs to stabilize convergence and improve late-stage optimization behavior. A warmup phase of 3 epochs was additionally implemented to prevent abrupt gradient instability during the early stages of training. The batch size was fixed at 32, and all experiments were conducted over 40 epochs using mixed-precision training within the PyTorch framework.

The experimental validation strategy was based on a randomized dataset partitioning protocol, where 80% of the samples were allocated for training, and the remaining 20% were reserved for validation. The validation subset remained completely isolated during training and was used exclusively for performance monitoring and model evaluation. The best-performing checkpoint was selected according to the highest validation mAP@50 metric observed during training.

It should additionally be noted that the utilized YOLO11s implementation follows the anchor-free detection paradigm introduced in recent YOLO architectures. Consequently, no manually predefined anchor box configurations were required during training. Instead, the network dynamically predicts object localization through anchor-free regression mechanisms integrated within the detection head.

IV. RESULTS

To comprehensively evaluate the efficacy of the proposed YOLO-CBAM architecture, a multifaceted analysis was conducted. This section details the quantitative metrics, qualitative visual assessments, and real-time computational performance of the model, directly comparing the custom attention-integrated network against the baseline architecture.

The analysis of the learning curves provides critical insights into how the neural network adapts its internal weights to newly introduced structural layers. Throughout the training phase, we closely monitored the behavior of the loss functions (box loss, classification loss, and distribution focal loss) alongside the mean Average Precision (mAP) metrics over the predefined 40 epochs.

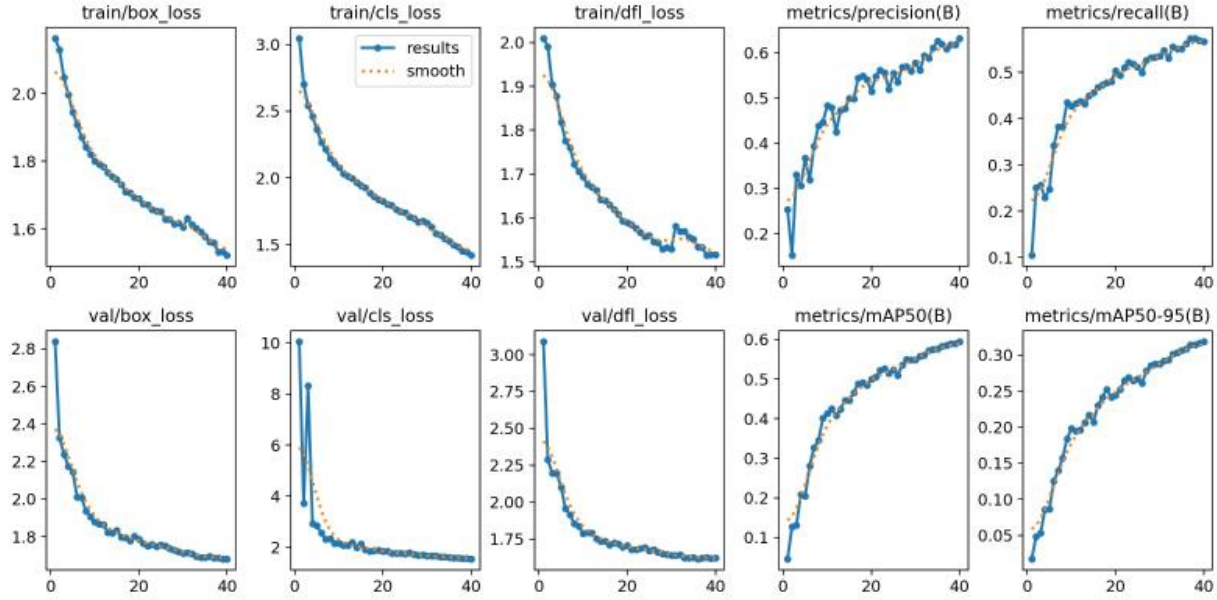

Fig. 3. Learning curves showing loss metrics and mAP over 40 epochs.

As explicitly illustrated in Fig. 3, the integration of the attention mechanism initially disrupted the learning equilibrium. During the partial transfer learning experiment, we documented a significant initial spike in the classification loss metric, where the validation class loss surged above the 10.0 threshold (val/cls_loss>10.0) within the very first epoch. In deep learning literature, this phenomenon is widely recognized as "gradient shock". This shock is a direct consequence of the architectural mismatch during initialization: the pre-trained convolutional layers of the YOLO backbone attempt to process features using established weights, while the newly appended CBAM layer, initialized with random weights, temporarily disrupts the forward pass synchronization, leading to erratic initial gradients.

Despite this severe initial perturbation, the proposed YOLO-CBAM architecture demonstrated remarkable gradient stability and structural resilience. The network rapidly overcame the gradient shock, aggressively minimizing the loss functions and reaching a stabilized error rate by the 5th training epoch. This rapid recovery period empirically confirms that the integration of the Convolutional Block Attention Module does not corrupt the underlying geometric feature extraction capabilities of the baseline YOLO architecture, but rather complements it seamlessly once the initial weights are aligned.

Beyond overall convergence, it is imperative to understand how the model differentiates between highly specific types of pavement degradation. To evaluate the exactness of the classification head, we utilized the F1-score and a normalized confusion matrix. The F1-score acts as a unified harmonic mean that perfectly balances precision and recall. The proposed YOLO11s-CBAM model, utilizing the partial transfer learning strategy, achieved a robust F1-score of 0.60. This specific value indicates a highly stable equilibrium; the network successfully minimizes false positive detections (such as misinterpreting a dark shadow as a deep crack) while simultaneously suppressing false negative occurrences (missing an actual, hazardous pothole on the road).

A deeper, class-by-class diagnostic is provided by the normalized confusion matrix presented in Fig. 4. The matrix diagonal visually confirms that the model exhibits a high degree of predictive confidence when identifying distinct, severe structural damages, particularly in the case of potholes. However, the matrix also reveals minor, localized classification overlaps. For instance, the network occasionally demonstrates slight confusion when distinguishing between visually adjacent categories, such as longitudinal and transverse cracks, which frequently share similar edge gradients depending on the camera angle. Most notably, the integration of the CBAM module profoundly impacted the background class. Compared to standard models, YOLO-CBAM drastically reduced the volume of false background triggers, demonstrating minimal confusion between actual asphalt damage and the irrelevant background surface.

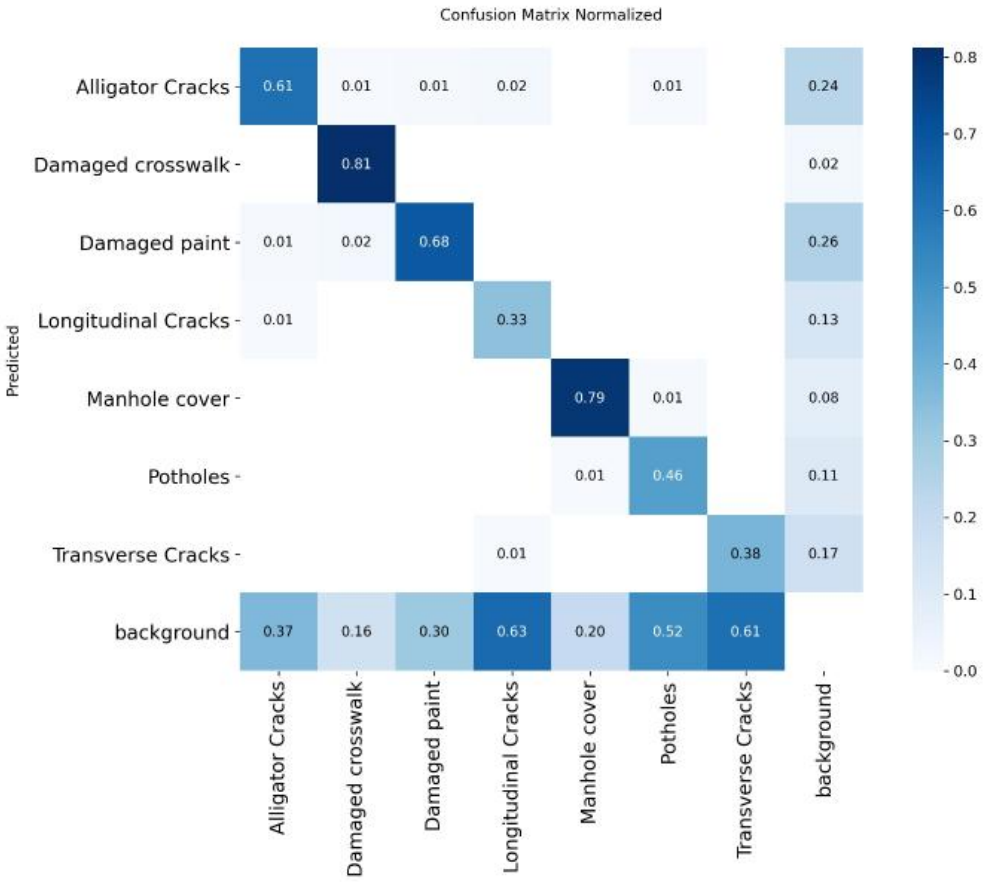

Fig. 4. Normalized confusion matrix of the YOLO-CBAM model.

To scientifically isolate and quantify the exact performance gains generated by our architectural modifications, an ablation study was performed. We conducted a direct, side-by-side comparison between the unmodified YOLO11s baseline and our enhanced YOLO-CBAM architecture. All comparative models were subjected to an identical 40-epoch training cycle using the Kaggle road damage dataset to ensure strict experimental fairness. Furthermore, we tested two separate initialization strategies for the attention module: training the entire network from scratch versus employing partial transfer learning.

The quantitative results of this rigorous ablation study are documented in Table I. The baseline YOLO11s model established a reliable foundation, achieving an mAP@50 score of 0.60. The most revealing insight emerged when the modified YOLO11s-CBAM was trained entirely from scratch, utilizing purely random weight initialization. Remarkably, even without the advantage of pre-trained knowledge, this configuration managed to achieve an mAP@50 of 0.55 in merely 40 epochs. This highly accelerated convergence rate serves as strong evidence that the CBAM module inherently possesses a superior capacity to extract critical structural features from raw asphalt imagery. Finally, when the partial transfer learning strategy was applied to the YOLO11s-CBAM model, it fully matched the baseline's overall accuracy (mAP@50 of 0.60), while simultaneously delivering marginal but important improvements in the stricter mAP@50-95 metric (0.32) and overall Recall (0.57).

While quantitative metrics provide a statistical overview, a qualitative visual assessment is required to confirm that the network is "looking" at the correct spatial coordinates. One of the most persistent challenges in automated infrastructure monitoring is environmental noise. Standard object detectors are frequently deceived by complex real-world conditions, such as footage captured during early evening hours with elongated shadows or rainy conditions that produce confusing water reflections on the asphalt.

TABLE I. IMPACT OF ARCHITECTURAL CHANGES AND INITIALIZATION STRATEGIES ON DETECTION ACCURACY

Architecture	Learning Strategy	mAP@50	mAP@ 50-95	Precision (P)	Recall (R)
YOLO11s (baseline)	Transfer Learning	0.6	0.3	0.63	0.55
YOLO11s-CBAM	Learning From Scratch	0.55	0.29	0.59	0.53
YOLO11s-CBAM	Partial Transfer Learning	0.6	0.32	0.63	0.57

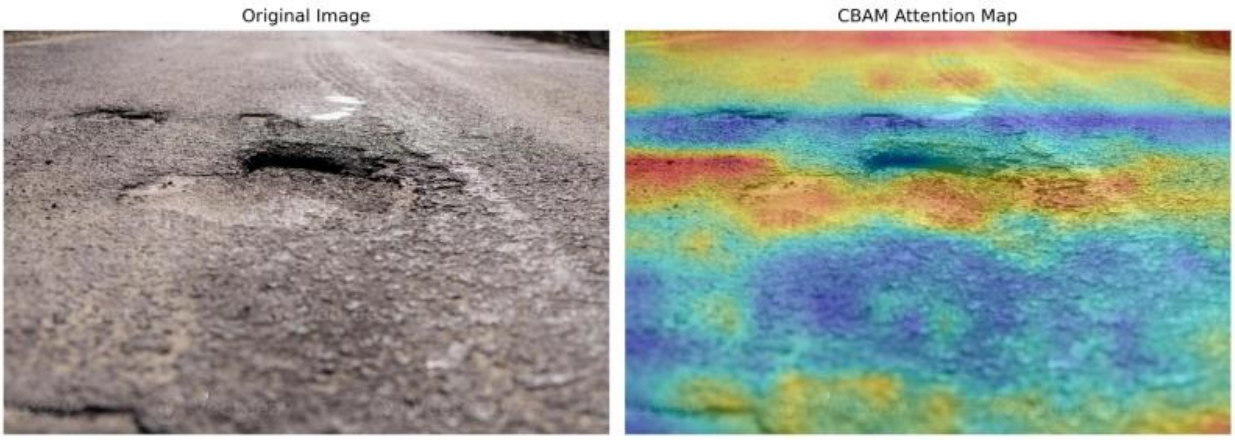

Fig. 5. Visualization of CBAM attention maps for damage detection.

To empirically verify our hypothesis, we extracted and visualized the internal attention maps generated by the network. Fig. 5 provides a direct, visual comparison between a raw, original input image containing a defect and the corresponding heat map generated exclusively by our custom CBAM layer. The heatmap visualization unequivocally demonstrates the module's effectiveness: the regions of highest neural focus, represented by intense red and yellow areas, align perfectly with the harsh structural boundaries and jagged edges of the road defect. Conversely, the surrounding undamaged road surface, including highly distracting shadows and variations in pavement color, is almost entirely ignored by the model, represented by the cool, inactive blue regions. This visual evidence conclusively proves that the dual spatial-channel attention mechanism aggressively filters out background environmental noise, forcing the convolutional layers to dedicate their computational resources exclusively to actual pavement degradation.

Achieving high accuracy is only one facet of a successful smart city solution; the model must also be practically deployable. The feasibility of deploying the YOLO11s-CBAM architecture onto mobile, edge-computing devices installed in municipal vehicles depends entirely on its inference speed and computational weight.

To simulate real-world processing capabilities, we benchmarked the model's inference speed using an NVIDIA RTX 4070 Ti GPU. Under these hardware conditions, the proposed model achieved a highly efficient average data processing speed of approximately 38.7 milliseconds per image. This translates to a continuous throughput of roughly 25 to 26 frames per second (FPS). This level of performance is more than sufficient to process high-resolution video streams in real-time, even when the cameras are mounted on vehicles traveling at high speeds through complex urban environments.

Crucially, despite the integration of the complex dual-attention CBAM layers, the overall increase in Giga Floating-point Operations Per Second (GFLOPs) was statistically negligible. The model successfully retained the "lightweight" architectural profile that is an absolute necessity for edge computing. Furthermore, the total memory footprint remained comfortably within the 12 GB VRAM limit of the testing hardware. These results indicate that the proposed architecture maintains a relatively lightweight computational profile despite the integration of the CBAM attention mechanism. Nevertheless, the current study did not include direct benchmarking on embedded edge-computing hardware platforms such as the NVIDIA Jetson series. Consequently, the suitability of the proposed framework for deployment on constrained low-power devices should be considered a prospective implementation direction rather than an experimentally validated conclusion. Future research will therefore focus on TensorRT-based optimization, quantization strategies, and empirical latency benchmarking on embedded edge platforms to evaluate real-world deployment feasibility.

V. Discussion

The experimental findings demonstrate that the integration of the Convolutional Block Attention Module into the lightweight YOLO11s architecture significantly improves the robustness of road damage detection under complex urban environmental conditions. The proposed YOLO-CBAM framework achieved stable localization performance while maintaining real-time computational efficiency, indicating that spatial-channel attention mechanisms can effectively enhance discriminative feature extraction without introducing substantial computational overhead. The obtained mAP@50 and recall metrics confirm that the attention-guided feature refinement process contributes positively to the detection of structurally irregular pavement defects, particularly in scenarios characterized by illumination variability, background clutter, and asphalt texture complexity.

Compared with conventional YOLO-based pavement monitoring systems discussed in Section II, the proposed framework demonstrates several important advantages. Earlier lightweight road inspection architectures, including YOLO-LWNet [5] and LE-YOLOv5 [17], primarily focused on reducing computational complexity through structural simplification and lightweight convolutional operations. Although these approaches achieved acceptable inference speed, their robustness under visually noisy road environments remained limited. Similarly, recent enhanced YOLOv8-based methods [6], [11], [19] improved detection sensitivity through architectural optimization; however, these models frequently

require additional computational resources due to expanded feature fusion layers and multi-scale processing modules. In contrast, the proposed YOLO-CBAM architecture introduces an efficient dual-attention refinement mechanism that selectively emphasizes defect-related structural information while suppressing irrelevant environmental activations. This property was visually confirmed through the extracted attention heat maps, where the model concentrated predominantly on defect boundaries while ignoring shadows, pavement discoloration, and reflective artifacts.

The conducted ablation experiments further validate the contribution of the CBAM integration. The experimental results indicate that even when initialized from random weights, the attention-enhanced architecture demonstrated accelerated convergence characteristics and preserved competitive localization accuracy within a relatively limited number of training epochs. Furthermore, the utilization of partial transfer learning substantially stabilized the optimization process during the early training stages by mitigating the gradient shock phenomenon associated with architectural modification. These observations are consistent with previous findings reported in transfer learning studies for infrastructure monitoring applications [31]-[34], where partially initialized lightweight detectors exhibited improved convergence stability and enhanced generalization performance.

From a deployment perspective, the proposed framework maintains the lightweight operational characteristics required for edge-computing environments and intelligent transportation systems. Despite the integration of additional attention operations, the inference speed remained within real-time processing constraints, achieving approximately 25–26 FPS on an NVIDIA RTX 4070 Ti GPU. The obtained computational efficiency suggests that the proposed framework may represent a suitable candidate for future deployment in edge-assisted smart transportation systems, although dedicated validation on embedded hardware platforms remains necessary.

Nevertheless, several limitations remain. The confusion matrix analysis revealed moderate inter-class ambiguity between visually similar crack categories, particularly longitudinal and transverse pavement degradations under oblique viewing conditions. In addition, the current dataset distribution does not comprehensively represent extreme environmental scenarios such as heavy rainfall, snow-covered pavements, severe nighttime illumination, or motion blur induced by high-speed vehicle movement. Future research will therefore focus on expanding dataset diversity, integrating advanced multi-scale contextual attention mechanisms, and investigating domain generalization strategies to improve cross-environment robustness. Additional optimization through quantization and TensorRT-based acceleration will also be explored to facilitate deployment on low-power embedded edge devices such as NVIDIA Jetson platforms.

VI. Conclusion

In summary, this study successfully developed the YOLO-CBAM architecture as a fast and automated solution for detecting road surface damage. By adding the Convolutional Block Attention Module to the YOLO11s network, the model gained the ability to clearly focus on asphalt defects while efficiently ignoring background noise like shadows and road markings. Even with an initial gradient shock, using a partial transfer learning strategy helped the network train quickly and stably. As a result, the model achieved a solid mean Average Precision (mAP@50) and F1-score of 0.60 in just 40 epochs. Importantly, the network remains lightweight, making it highly suitable for real-time edge computing on mobile devices. Moving forward, future research will expand the dataset to include extreme weather conditions and improve the detection of tiny micro-cracks. Ultimately, the YOLO-CBAM model provides a reliable, cost-effective, and powerful tool for smart city infrastructure monitoring and autonomous road maintenance.

***Abstract*—Recommender systems are widely used as an information filtering technology to automatically predict and identify a set of interesting items for users based on their needs and preferences. They are widely applied in many domains, including e-commerce, social media, education, and healthcare. Recommender systems employ various filtering approaches, such as collaborative filtering, content-based filtering, and hybrid methods. Collaborative filtering is broadly categorized into memory-based and model-based approaches. Deep learning-based recommenders are a type of model-based approach that employs neural networks to capture patterns in user preferences and item features and generate accurate and personalized recommendations. In this study, we apply deep learning-based recommender systems to the Large-Scale Arabic Book Reviews Dataset (LABR) and evaluate their performance. To improve recommendation quality, we integrate sentiment analysis of user reviews using pre-trained Arabic BERT–mini and AraBERT, enabling more accurate modeling of user preferences. The results show that the combination of deep learning techniques and sentiment analysis produces more accurate recommendations, improving user satisfaction and engagement with Arabic content.**

***Keywords*—Recommender system; deep learning; sentiment analysis; LABR dataset; Model-based collaborative filtering; pre-trained model Arabic BERT; pre-trained model AraBERT**

I. Introduction

Recommender systems are effectively used as an information filtering technique to automatically predict and identify a set of interesting items for users according to their needs and preferences. Recommender systems are widely used across various applications due to the significant benefits they offer to both users and companies. They reduce the effort required to search for relevant items, thereby saving users time. Today, recommendation systems are essential parts of most applications such as Netflix, YouTube, and TripAdvisor. Recommender systems mechanisms have been shown to enhance the efficiency and consistency of decision-making. Given the vast amount of available information, these systems address the problem of information overload by filtering the user options and recommending the most suitable items, thereby improving user experience [1], [2]. There are various filtering approaches used in recommender systems, such as content-based filtering (CBF), collaborative filtering (CF), and hybrid filtering (HF). Content-based filtering uses domain knowledge to recommend items similar to those a user has previously liked. Using user profiles and item metadata, such as item descriptions, content-based recommender systems generate personalized recommendations. This approach can be implemented either explicitly, based on user-stated preferences, or implicitly, by learning from user interactions and behavior, such as clicking on links [2]. Collaborative filtering generates recommendations based on the preferences of similar users, often referred to as "neighbors" [3]. Neighbor-based algorithms are typically used in collaborative recommender systems that model relationships either between users or between items. However, collaborative recommenders suffer from the cold-start problem, which occurs when there is insufficient data for a new user or item [4]. Various collaborative filtering methods have been proposed to generate user-desired recommendations, with memory-based and model-based approaches being the most widely used [5]. Hybrid filtering is the combination of collaborative filtering and content-based filtering to obtain the best recommendation results [6]. Recommender systems are based on methods such as nearest neighbor and matrix factorization. However, deep learning has been successfully applied in various domains, including image recognition, computer vision, speech recognition, and natural language processing, and has recently been adopted in recommender system research. To improve the quality of recommendations, many businesses have adopted deep learning-based recommender systems [1]. These systems provide a significant improvement over traditional models by effectively handling high-dimensional data and addressing complex problems [1], [7]. Moreover, deep learning models are capable of capturing non-linear relationships between users and items [6].

In this study, we propose a deep learning-based collaborative filtering algorithm, which is a type of model-based collaborative filtering algorithm that utilizes neural networks. Unlike traditional methods such as matrix factorization, deep learning techniques can model non-linear relationships, sequential behaviors, and additional data sources, including product descriptions, user reviews, and images. Consequently, the proposed system can generate more personalized recommendations.

Recently, sentiment analysis of user reviews has been integrated with recommender systems to enhance the recommendation quality and address the data-sparsity problem in traditional recommender systems [8]. In such approaches, both user ratings and textual reviews are used to improve recommendations. Sentiment analysis extracts the emotional tone of user reviews to determine user preferences. By combining sentiment analysis with traditional methods such as content-based and collaborative filtering, hybrid recommender systems can be developed that provide more relevant and personalized recommendations [9]. The systems can produce more relevant recommendations by understanding user opinions, which increases user satisfaction and engagement [10]. The cold start issue, which arises when there is insufficient data for the new item or user, can also be resolved via sentiment analysis. Even without explicit ratings, sentiment analysis can identify preferences by analyzing text data. In our study, we propose a hybrid approach that combines sentiment analysis of Arabic user reviews with deep learning-based recommender systems to improve recommendation quality and solve the cold start problem. We use the Large-Scale Arabic Book Reviews Dataset (LABR) to evaluate the performance of the proposed approach. Our system takes book reviews as input and provides the corresponding sentiments for each of the books in our dataset. Then, both user ratings from LABR and sentiment scores are used to produce more personalized recommendations. This study extends our previous work [11], in which we proposed integrating sentiment analysis of user reviews with recommender systems for Arabic content. In that work, we developed two collaborative filtering-based recommender systems: the first is based on user ratings, while the second enhances recommendations by integrating sentiment analysis from user reviews. In the sentiment analysis phase, we compared three approaches: the Arabic BERT-mini model, the AraBERT model, and the Mazajak tool. In our previous work, we employed traditional collaborative filtering methods, including Singular Value Decomposition (SVD), K-Nearest Neighbors (KNN), and Non-Negative Matrix Factorization (NMF). This study builds on that work by employing deep learning–based recommender systems. The main contributions of our research are the following: 1) Proposed a hybrid approach that combines a deep learning-based collaborative recommender system with different Arabic sentiment analysis models and compares their results. 2) Applied the Arabic BERT–mini model and AraBERT sentiment analysis model to user reviews of the LABR dataset. 3) Studied the impact of using sentiment analysis models with a deep learning-based collaborative recommender algorithm on recommendation accuracy. The remainder of this study is organized as follows: Section II reviews related work, Section III presents the methodology, Section IV discusses the results, and Section V concludes the study with future work.

II. Related Work

A. Arabic Recommender Systems

We reviewed the literature and identified several studies that investigated recommender systems for Arabic content. First, Al-Ajlan and AlShareef [12] reviewed existing studies on recommender systems for Arabic content, summarizing them based on type, domain, datasets, and sentiment analysis integration. They noted that the most recommender systems for Arabic content use collaborative filtering, and some integrate sentiment analysis, which leads to higher accuracy. The most commonly used algorithm in these studies is Singular Value Decomposition (SVD). They also reported that the largest dataset used in these studies is LABR, which contains over 63,000 book reviews. Another study by Sallam et al. [13] proposed two approaches: memory-based collaborative filtering and model-based collaborative filtering using Singular Value Decomposition (SVD). They used the LABR dataset to evaluate their proposed approach. The proposed approach improved the quality of the recommendations for Arabic content and achieved low errors in terms of RMSE and MAE. Al-Ajlan and AlShareef [11] proposed integrating sentiment analysis of user reviews with traditional collaborative filtering recommender systems to improve the quality and accuracy of recommendations. They employed memory-based, including user-user and item-item models, and model-based collaborative filtering techniques, including SVD, KNN, and NMF. The LABR dataset was used to evaluate the proposed approach. The results indicate that the recommendation quality improves when recommender systems are integrated with user review sentiment analysis. The recommender system based on SVD, combined with the Arabic BERT-mini model, achieved the best performance in terms of RMSE and MAE. Additionally, Harrag et al. [14] explored the integration of sentiment analysis with recommendation systems by predicting product ratings from users' reviews using NLP and data mining techniques. In the sentiment analysis phase, they used an SVM model with the term frequency–inverse document frequency (TF–IDF) matrix. In the recommendation phase, they applied model-based collaborative filtering using SVD. They used the Opinion Corpus Arabic (OCA) dataset to evaluate the model. The results showed that the accuracy of the system is about 85% in predicting the ratings. Another study by Srifi et al. [15] evaluated the performance of some modern recommender systems when applied to Arabic content. They applied five modern recommendation systems that were initially intended for English content (ALFM, A3NCF, PARL, CARL, and CARP) and tested them on four Amazon English datasets translated into Arabic using Google Translate. Results showed that the systems performed well on Arabic content, with accuracy comparable to their performance on English data.

B. Deep Learning-Based Recommender Systems

This section reviews prior work on deep learning-based collaborative recommender systems across various domains. Li et al. [16] proposed the first system for collaborative filtering (CF) that integrates deep learning models. They introduced a deep architecture for CF that combines deep feature learning with matrix factorization. While matrix factorization-based CF methods can effectively capture the implicit relationships between users and items, they still face challenges such as the cold-start problem and data sparsity. Li et al. [16] employed neural network algorithms such as the stacked denoising autoencoder (SDAE), which enables the learning of high-level representations. However, SDAE has several disadvantages, one of which is the high computational cost of training. To address this issue, they used a variant of SDAE known as the marginalized denoising autoencoder (mDA), which avoids high computational expense by marginalizing out the random

feature corruption and provides a closed-form solution for learning model parameters. They selected three challenging tasks—movie recommendation, book recommendation, and response prediction—to evaluate the effectiveness of their proposed mDA-CF and mSDA-CF approaches. Their experiments were conducted on four datasets: MovieLens-100K, MovieLens-1M, Book-Crossing, and Advertising. The results demonstrated that the mDA-CF and mSDA-CF approaches outperformed comparable methods in all three tasks.

To facilitate book discovery on library websites with a large collection of books, Liu and Gao [17] proposed a new recommendation algorithm that integrates deep learning with matrix factorization. Their model employs a neural network to process the user-book rating matrix, aiming to address the sparsity problem commonly found in such datasets. The rating matrix is fed into a deep matrix factorization framework to learn the hidden features of users and books, which are then used to predict user ratings. Liu and Gao [17] trained and evaluated their model on the Goodbooks-10k dataset. The results show that the proposed algorithm effectively mitigates data sparsity and performs well on real-world book datasets.

Lin and Chi [18] proposed a movie recommendation system based on collaborative filtering and neural networks. In their study, a neural network was trained to predict user ratings for movies. They used the MovieLens ml-100k dataset, which contains ratings from 943 users on 1,682 movies, along with basic user and movie information. The input features included user ID, gender, age, occupation, movie ID, and movie category. The neural network architecture consisted of two hidden layers: the first with 192 neurons using ReLU as the activation function, and the second with 300 neurons using TanH. The final predicted rating was generated by the output layer. In the evaluation, the neural network-based model achieved a Mean Absolute Error (MAE) of 0.76, with a processing time of 136 seconds.

Healthcare recommender systems provide users with mobile healthcare services that are continuously accessible. However, designing patient-centered healthcare recommender systems presents several challenges, including processing the large volume of data generated by smart devices and sensors, managing dynamic networks for real-time data transmission, and the lack of effective methods for knowledge aggregation. To address these challenges, Aujla et al. [19] proposed DLRS, a deep learning-based recommender system that leverages Software-Defined Networking (SDN) within a smart healthcare environment. For evaluation, the system was tested using a dataset that included 100 patients, 100 sensors, and 20 doctors. DLRS operates through several key steps: first, a tensor-based dimensionality reduction algorithm is applied to remove irrelevant features from the collected data; second, a decision tree-based classification method groups patient queries according to different diseases; and finally, a convolutional neural network is used to generate personalized health recommendations. The system was evaluated through a case study using multiple performance metrics, including dimensionality reduction ratio, approximation ratio, accuracy, RMSE, MAPE, and latency. The results show that DLRS outperforms existing systems in its category.

III. Material and Method

A. Dataset

We used the Large-Scale Arabic Book Reviews (LABR) dataset, one of the largest sentiment analysis datasets for the Arabic language. It consists of over 63,257 book reviews, each rated on a scale of 1 to 5 stars [20]. These reviews were submitted by 16,486 users for 2,131 different books [20]. Table I summarizes the main characteristics of the LABR dataset. Each row in the LABR dataset represents a single book review submitted by a Goodreads user. Every row includes a user's rating on a scale of one to five, the Goodreads.com review id, the Goodreads.com user id, the Goodreads.com book id, and the text of the review as presented in Table II.

TABLE I. LABR Dataset Statistics

Number of reviews	63,257
Number of users	16,486
Avg. reviews per user	3.84
Median reviews per user	2
Number of books	2,131
Avg. reviews per book	29.68
Median reviews per book	6

TABLE II. Samples from LABR Dataset

Rating	Review id	User id	Book id	Review
5	279844173	6295076	2939264	كتاب اكثر من رائع ويستحق القراءة اكثر من مرة
5	322587552	8509913	2939264	قيم جداً . كل قرة اقرء احد ابوابه لانه هذا الكتاب لايتطلب قراءة سريعة بل دراســـة جيدة
4	510316957	3665588	2939264	لا يمر عليك يوم بدون تصفحه. أعتبره زاد المسلم اليومي

B. Methodology

In this section, we will present our approach that combines a deep learning-based collaborative filtering algorithm with sentiment analysis of users' reviews. Our study builds on our earlier work [11] that integrated sentiment analysis of user reviews into traditional collaborative filtering. The proposed approach consists of four main phases: data preprocessing, sentiment analysis of users' reviews, combining the sentiment score with the user rating score, and applying deep learning-based collaborative recommender systems, as presented in Fig. 1.

1) Preprocessing and cleaning: The dataset was preprocessed and cleaned using "Re" and "Pandas" Python libraries [21], [22]. The preprocessing step included normalizing Arabic characters and removing repeated letters, punctuation marks, and diacritics from the text. Then, the dataset was divided into positive, negative, and neutral categories based on the rating. Books with 4 or 5 stars were considered positive, those with 3 stars were neutral, and those with 1 or 2 stars were categorized as negative.

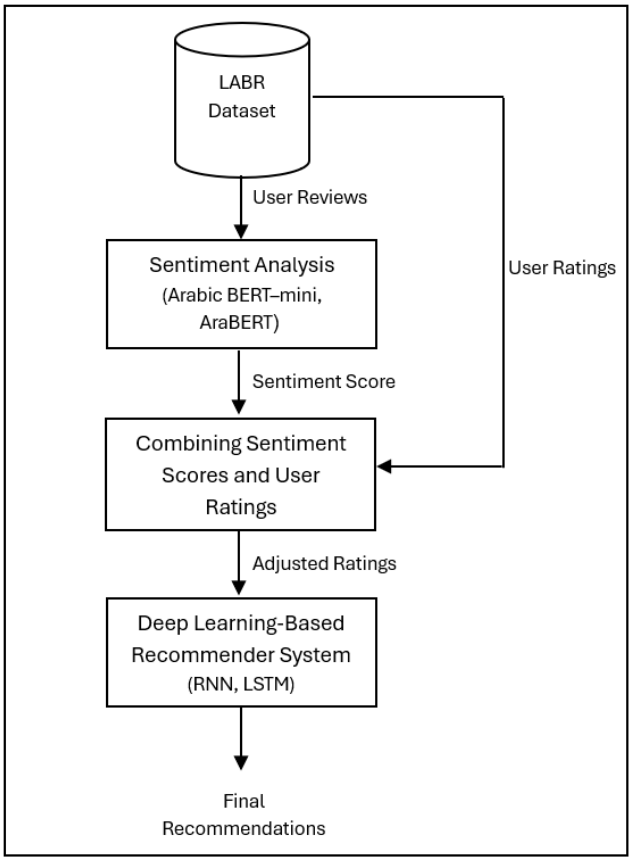

Fig. 1. The proposed approach.

2) Sentiment analysis: we applied two sentiment-analysis approaches using pre-trained Arabic language models: Arabic BERT–mini model and AraBERT [23], [24], [25]. The Arabic BERT–mini model [24], [26] was originally trained on a large Arabic corpus of about 8 billion words from OSCAR [27], Arabic Wikipedia [28], and other large text sources (around 95 GB). We fine-tuned this model using the Arabic Sentiment Twitter Corpus [29] which contains 58K Arabic labeled tweets. We also experimented with several additional datasets—SS2030 [30], the 100K Reviews dataset [31], and ArSAS [32]—and found that the Arabic Sentiment Twitter dataset produced the best performance. After tuning, the model was used to classify sentiment in the LABR dataset. Similarly, AraBERT, which is built on Google's BERT-Base architecture, was pre-trained on about 8.6 billion Arabic words from OSCAR [27], Arabic Wikipedia [28], OSIAN [33], 1.5B words Arabic Corpus [34], and Assafir news. We also fine-tuned AraBERT using the Arabic Sentiment Twitter Corpus [29] to adapt it for sentiment classification. The goal of this phase is to extract sentiment scores from user reviews in the LABR dataset.

3) Combined sentiment score with user rating score: we generate a new adjusted rating that reflects both the explicit user rating and the sentiment score extracted from the written review. Instead of relying only on the numerical rating, our method integrates it with the sentiment score produced by the sentiment analysis model. The adjusted rating is computed as follows [11]:

$$Adjusted\ Rating = \frac{(LABR\ rating + Sentiment\ rating)}{(Scale\ of\ LABR\ rating + Scale\ of\ sentiment\ rating)} \times 5 \quad (1)$$

where, the LABR rating is the original rating on a 5-point scale, and the sentiment rating is derived from the review text on a 3-point scale.

The two components are combined by normalizing their sum using the total scale and then rescaling the result to a 5-point system. This produces an adjusted rating that reflects both the explicit rating and the sentiment expressed in the review. For example, if a user assigns a rating of 5 (on a 5-point scale), and the sentiment analysis produces a score of 1 (on a 3-point scale), the adjusted rating is calculated as:

$$\frac{5+1}{5+3} \times 5 = 3.75$$

The formula assigns equal importance to both components, motivated by their complementary roles: the numerical rating captures explicit user feedback, while the sentiment score reflects implicit opinion expressed in text. Since there is no clear evidence that one component is more important than the other, both are assigned equal weight, providing a balanced baseline. Although alternative weighting schemes could be explored, this study adopts equal weighting, leaving adaptive weighting strategies for future work.

4) Deep learning-based collaborative recommender systems: the main goal of this phase is to use the adjusted ratings from the previous step, which combines sentiment analysis of user reviews and user ratings from the LABR dataset to enhance the recommendations. We developed two deep learning-based collaborative recommender systems: one using a Recurrent Neural Network (RNN) and the other using a Long Short-Term Memory (LSTM) network to learn sequential patterns in user–item interactions. In deep learning, we used "Keras" and "TensorFlow" libraries to develop deep learning model architectures. Additionally, we compared the two deep learning-based collaborative recommender systems using user ratings only and user ratings with sentiment analysis of user reviews. Also, we compare and evaluate the performance of these methods with memory-based collaborative recommender systems.

IV. Results and Discussion

A. Evaluation Metrics

Our proposed models were evaluated by using rating prediction, which measures how close the recommender's estimated ratings are to the actual user ratings. We used two metrics for evaluating the accuracy of predicted ratings: Root Mean Squared Error (RMSE) and Mean Absolute Error (MAE) [35]. The advantage of using RMSE over MAE is that it penalizes the error more when the difference is high (note that RMSE is always greater than or equal to MAE).

Root Mean Squared Error (RMSE) is a widely used metric because it penalizes large errors when the predicted rating is far from the actual value and less when the predictions are reasonably close. The formula for calculating RMSE is shown below.

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (2)$$

where, y_i = actual value, $\hat{y}_i$ = predicted value, n = number of observations.

Mean Absolute Error (MAE) is the average absolute difference between the predicted and actual ratings. The objective is to minimize the value of MAE. The formula for calculating MAE is shown below:

$$\text{MAE} = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \quad (3)$$

here, y_i = actual value, $\hat{y}_i$ = predicted value, n = number of observations

B. Experimental Results

We compared the results of the memory-based and deep learning-based collaborative filtering algorithms, which are types of model-based collaborative filtering algorithms.

1) Memory-based models: We computed both user-user and item-item similarities using two common methods, Cosine similarity and Euclidean distance. Cosine similarity measures the angle between user preference vectors, whereas Euclidean distance measures the geometric distance between them in the feature space. These techniques enable the system to generate recommendations by identifying users or items with similar behavior or preference patterns. The performance of these memory-based models is summarized in Table III.

TABLE III. MEMORY-BASED MODELS RESULTS

Models	Similarity metrics	
	Cosine similarity	*Euclidean distance*
User-User	When K= 25 RMSE = 1.86 MAE = 3.48	When K=75 RMSE = 1.90 MAE = 3.62
Item-Item	**When K= 25** **RMSE = 1.15** **MAE = 1.33**	When K=125 RMSE = 1.18 MAE = 1.39

We found that item-based models perform better and faster than user-based models when we compared the results of the two models. Moreover, Cosine similarity gave better results because it focuses on shared rating patterns between users or items and is less sensitive to rating scale differences, whereas Euclidean distance takes all dimensions into account.

2) Deep learning-based models: We developed two deep learning-based collaborative recommender systems: one using RNN and the other using LSTM. Table IV shows the performance of deep learning-based recommendation systems. As presented in Table IV, the LSTM model outperformed the RNN model as well as the memory-based collaborative filtering models.

TABLE IV. DEEP LEARNING-BASED MODELS RESULTS

Models	Performance
RNN	RMSE = 1.14 MAE = 0.92
LSTM	**RMSE = 1.07** **MAE = 0.88**

3) Memory-based models with Arabic BERT–Mini model and AraBERT: We combine sentiment analysis of user reviews with traditional memory-based recommenders. The Item-Item model with Cosine similarity metrics gave better results than the User-based model when combined with the *Arabic BERT–Mini* model as presented in Table V.

TABLE V. MEMORY-BASED WITH ARABIC BERT–MINI MODEL RESULTS

Models	Cosine similarity
User-User with Arabic BERT–mini model	When K= 25 RMSE = 1.88 MAE = 3.56
Item-Item with Arabic BERT–mini model	**When K= 25** **RMSE = 1.14** **MAE = 1.30**

Also, the Item-Item model with Cosine similarity metrics outperformed the User-based model when combined with the AraBERT model as presented in Table VI.

TABLE VI. MEMORY-BASED WITH ARABERT MODEL RESULTS

Models	Cosine similarity
User-User with AraBERT model	When K= 25 RMSE = 1.90 MAE = 3.63
Item-Item with AraBERT model	**When K= 25** **RMSE = 1.15** **MAE = 1.34**

4) Deep learning-based models with Arabic BERT–Mini model and AraBERT: We combine sentiment analysis of user reviews with deep learning-based recommender systems. The RNN achieved better results than LSTM when combined with the Arabic BERT–Mini model as presented in Table VII.

TABLE VII. DEEP LEARNING-BASED MODELS WITH ARABIC BERT–MINI MODEL RESULTS

Models	Performance
RNN with Arabic BERT–mini model	**RMSE = 0.89** **MAE = 0.83**
LSTM with Arabic BERT–mini model	RMSE = 1.00 MAE = 0.89

Additionally, the RNN model integrated with AraBERT outperforms the LSTM model with AraBERT, as presented in Table VIII.

TABLE VIII. DEEP LEARNING-BASED MODELS WITH ARABERT MODEL RESULTS

Models	Performance
RNN with AraBERT model	**RMSE = 0.89** **MAE = 0.83**
LSTM with AraBERT model	RMSE = 1.02 MAE = 0.83

C. Discussion

The results show the usefulness of integrating the sentiment analysis of user reviews into the recommender system to produce better recommendations. Our proposed approach takes into account two aspects: rating and sentiment analysis, which lead to better recommendations. In addition, the experimental results demonstrate that deep learning-based approaches outperform traditional memory-based models. In particular, the RNN and LSTM models achieved lower RMSE and MAE values compared to User-User and Item-Item methods, confirming their ability to capture complex user-item interactions. Among the deep learning models, RNN showed slightly better performance than LSTM, especially when integrated with Arabic BERT–mini and AraBERT models, where it achieved the best results (RMSE=0.89, MAE=0.83). This improvement highlights the effectiveness of incorporating contextual semantic features derived from sentiment analysis of user reviews. Furthermore, the integration of sentiment analysis significantly enhanced the recommendation accuracy, demonstrating that leveraging textual review information provides richer user preference representation compared to rating-only approaches. However, despite their superior performance, deep learning models require large datasets and substantial computational resources to achieve optimal results. This limitation may affect their applicability due to limited data availability.

Compared to traditional recommendation approaches, such as those reported in [13], that rely primarily on numerical ratings and do not incorporate sentiment information from user reviews, our proposed models achieved lower error rates, particularly when integrating sentiment-aware features. This confirms that incorporating semantic information from user reviews provides a significant advantage over rating-based methods alone.

This study extends our previous work [11] by evaluating RNN and LSTM-based models. However, it does not include a direct comparison with traditional collaborative filtering methods, such as matrix factorization or neighborhood-based approaches. In our previous work [11], we evaluated conventional filtering methods, including SVD, KNN, and NMF, and achieved better performance, as indicated by lower RSME, using the same dataset and sentiment analysis approach. This can be attributed to the fact that deep learning models typically require large amounts of data for effective training, whereas the LABR dataset contains a limited number of reviews per user. In general, both studies confirm that incorporating sentiment analysis of user reviews improves recommendation quality. However, deep learning techniques often require large datasets and significant computational resources to achieve good performance. Additionally, the lack of large-scale Arabic datasets remains a challenge, and future work should focus on creating new datasets to support the development of effective recommender systems for Arabic content.

V. CONCLUSION

We proposed a deep learning-based recommender system enhanced with sentiment analysis of Arabic user reviews. The results show that deep learning models outperform traditional memory-based approaches, with the RNN integrated with Arabic BERT–mini and AraBERT models achieving the best performance. These findings highlight the effectiveness of combining semantic information with ratings to improve accuracy and personalization in recommender systems. The main contribution of this work is the integration of sentiment-aware features into a deep learning-based recommender system for Arabic content, providing a more comprehensive representation of user preferences. Despite these improvements, the reliance on large datasets and high computational resources remains a limitation. Future work will focus on developing more efficient models and evaluating them on larger datasets. Most existing recommender systems research has focused on English or other common languages. However, Arabic presents additional challenges due to its complex grammar and rich vocabulary. Therefore, further research and better support for Arabic datasets are needed to improve recommendation quality.

A Knowledge-Enhanced Cross-Modal Transformer Network for Sentiment Analysis in Intelligent Interaction

Chunyan Huang, Xinlu Sun*
China Zhejiang Business College, Hangzhou 310053, China

***Abstract*—With the rapid advancement of multimodal emotion recognition technology, sentiment analysis models that integrate heterogeneous information—such as facial expressions and vocal intonation—are driving human–computer interaction and affective computing toward multidimensional, objective, and highly accurate approaches. Conventional emotion recognition methods typically rely on a single-modal input and therefore struggle to capture complex semantic associations and deep emotional features, which in turn undermines the stability of recognition results. A knowledge-enhanced cross-modal Transformer network (KCTN) model was proposed for sentiment analysis, which incorporates a multimodal fusion module and a long-range affective integration module to achieve deep collaborative modeling across text, speech, and facial expression features. This framework substantially enhances the completeness and robustness of emotional semantic representations. Experimental results on the self-built EC-SFED multimodal dataset and the publicly available dataset CMU-MOSI demonstrate that KCTN surpasses several mainstream baseline models in both accuracy and macro-averaged F1 score, validating its superior performance in intelligent interaction and affective computing applications.**

Keywords*—Multimodal sentiment analysis; transformer network; emotion recognition; psychological assessment; intelligent interaction

I. Introduction

Recent research on sentiment analysis within university student populations has primarily evolved along two methodological trajectories: traditional machine learning–based approaches and deep learning–driven models. Traditional methods generally require complex feature engineering on social or textual data. Wang and Zhang [1] designed a topic–sentiment hybrid model to identify students' emotional attitudes toward different discussion themes. Iram [2] proposed an automated framework for detecting affective tendencies in student-generated posts on the Facebook platform. Zhang et al. [3] adopted a sentiment analysis approach based on the Robustly Optimized BERT Pretraining Approach-Whole Word Masking (RoBERTa-WWM) capable of capturing both local semantic features and contextual associations within student discourse.

Deep learning techniques enable the automatic extraction of high-level semantic features and complex associations from multimodal data, and the complementary information across modalities enhances the effectiveness of psychological assessment. In previous studies, Song et al. [4] developed a Multi-level Attention and Multi-task (MAM) fusion model that incorporates an attention mechanism to support multitask multimodal sentiment analysis. Sun et al. [5] designed an efficient multimodal Transformer architecture featuring a dual-level feature restoration mechanism, in which global–local interactive modeling is utilized to improve multimodal fusion performance. Huan et al. [6] proposed a unified multimodal framework composed of a translation module and a prediction module, achieving structured cross-modal integration and semantic alignment. Tsai et al. [7] introduced the Multimodal Transformer (MulT) model, which employs cross-modal attention to process unaligned multimodal data and demonstrated strong performance in comparative experiments. Hazarika et al. [8] designed the Modality-Invariant and -Specific Representations (MISA) framework, which maps each modality into two distinct subspaces to enhance fusion outcomes. Han et al. [9] developed the MultiModal InfoMax (MMIM) framework, where intermodal information is maximized and jointly optimized with the primary task to strengthen modeling performance. Huddar et al. [10] proposed an attention-based multimodal contextual fusion approach that achieved notable improvements in emotion classification. Luo and Zhu [11] introduced the Multi-Dynamic Aware Network (MultiDAN), in which multilayer multi-angle interaction perception is employed to enhance multimodal language sentiment analysis. Yang et al. [12] constructed the CCIN-SA model based on a composite cross-modal interaction network to address challenges associated with multimodal fusion and interactivity, thereby improving classification accuracy. Zhong et al. [13] proposed the KET model, which dynamically integrated commonsense information by computing the cosine similarity and emotional intensity between text and commonsense knowledge features. In addition, the effectiveness of multimodal deep learning for extracting semantic and affect-related features has also been demonstrated in recent applied studies [14, 15].

In multimodal sentiment analysis for psychological assessment, various fusion strategies and deep learning models have been proposed, resulting in notable improvements in emotion recognition accuracy and robustness. However, most evaluation frameworks have primarily emphasized outcome-oriented measures while overlooking behavioral data generated during the assessment process. Intelligent interaction systems, driven by artificial intelligence technologies, create emotional experiences and produce substantial amounts of structurally

*Corresponding author.

complex behavioral process data through visual and speech modalities. These data capture the decision-making trajectory of participants and document interaction outcomes at critical points, thereby addressing the limitations of traditional psychological assessments that rely solely on textual information. This provides valuable insights into individual psychological and behavioral patterns. In this study, a multimodal fusion module and a long-range affective fusion module were integrated. The multimodal fusion module leverages heterogeneous sources, including text, speech, and video. The long-range affective fusion module aggregates affective context from subsequent utterances of the same speaker into the representation of the current utterance, effectively capturing long-distance semantic dependencies. The optimization of deep learning models to strengthen affective computing accuracy constitutes a critical pathway for developing intelligent auxiliary systems for student mental health monitoring.

II. Model Design

A. Task Definition

In the affective computing task for conversational scenarios, a set of multimodal samples is defined as Y. Each dialogue sample contains N successive utterances denoted as $U=\{u_1,u_2,...u_n\}$, and is associated with M speakers represented as $E=\{e_1,e_2,...e_m\}$. For each utterance u_i, multimodal information is composed of three modalities—text (T), audio (A), and visual (V)—such that $u_i=\{u_i^c\}$ and $c\in\{A,V,T\}$. Based on predefined emotion categories, sentiment analysis aims to infer the emotional polarity $p\in$ {negative, neutral, positive} for each speaker by jointly modeling speaker-related characteristics, contextual dependencies, and multimodal cues. Through this process, the emotion label of a new conversational sample can be accurately predicted.

B. Model Architecture

The proposed KCTN model (Fig. 1) for psychological assessment–oriented sentiment analysis incorporates the following three primary methodological contributions:

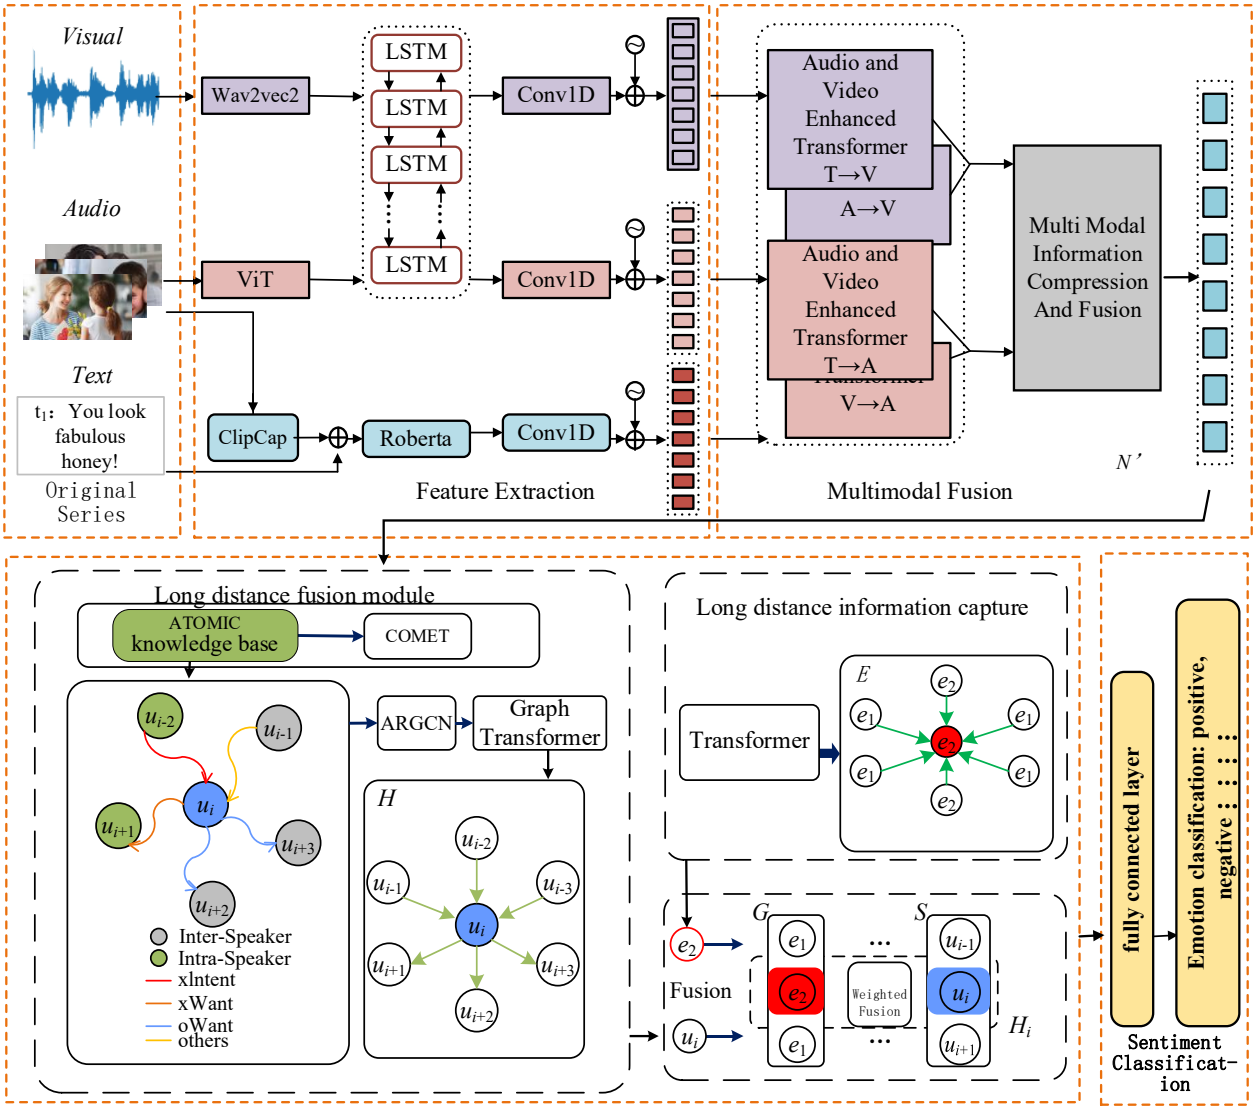

Fig. 1. Overall architecture of the proposed model.

1) In terms of feature extraction, extraction strategies for text, visual, and audio modalities were deeply studied. To address missing aspect-level emotional semantics in text, ClipCap was employed to generate natural language descriptions that align closely with image content, after which textual features were derived using the RoBERTa model. Visual features were extracted using OpenFace 2.0 and a Vision Transformer (ViT) model, while audio features were captured through Wav2Vec 2.0 and OpenSMILE.

2) In the multimodal fusion module, a cross-modal enhanced Transformer fusion network was introduced. Long Short-Term Memory (LSTM) networks, temporal convolutions, and positional embeddings were incorporated to effectively capture temporal dynamics and contextual dependencies within audio–visual modalities. Through an audio–visual enhanced Transformer module and an information compression–fusion module, non-text modalities were strengthened and deep intermodal interactions were achieved.

3) In the long-range affective fusion module, a multi-stage processing architecture was adopted. External knowledge was extracted from textual content using Commonsense Transformers (COMET) [16], and the dialogue structure was modeled through a Graph Neural Network (GNN) that transforms conversational data into graph representations to obtain sentence-level semantic features. Subsequently, the self-attention mechanism of the Transformer architecture was used to capture long-range affective dependencies across speaker utterances. Finally, a feature fusion mechanism was used to integrate sentence-level semantic representations with speaker-level affective features, thereby enhancing the model's affective computing capability.

III. Feature Extraction and Fusion

A. Text Feature Encoding

In the text feature encoding module, features from both text and images are integrated, using visual information to compensate for potentially missing affective semantics in textual data. Inspired by the multimodal processing framework proposed by Khan and Fu [17], the ClipCap image description generator was incorporated. Built upon the advanced Contrastive Language-Image Pretraining (CLIP) cross-modal pretraining framework, ClipCap integrates visual features with the prior knowledge of a language model to generate semantically precise and affectively expressive descriptions. These descriptions preserve the global emotional characteristics of the image and enable effective transfer of visual information into textual semantics.

The original text E and the image description text C were subsequently combined into a unified token sequence X through structured concatenation with special markers. A [SEP] separator was inserted between the two text segments to explicitly define modality boundaries, and a [CLS] token was placed at the beginning of the sequence to aggregate global semantic information. The resulting sequence X can be expressed below. This structured formulation preserves the fine-grained characteristics of the original text while incorporating additional semantic information generated from visual content.

$$X=[CLS]t_{E_1}t_{E_2}\ldots t_{E_{N_E}}[SEP]t_{C_1}t_{C_2}\ldots t_{C_{N_C}}[SEP] \quad (1)$$

where, Ei and Ej denote the tokens of sentences E and C, respectively. The number of tokens in E is represented as N_E, while the number of tokens in C is represented as N_C.

To fully capture the deep semantic features embedded in the textual sequence, RoBERTa-base was employed as the encoder. In the experimental configuration, the encoder was set to a 12-layer architecture with a hidden dimension of 768, and the maximum sequence length was fixed at 64 tokens. Inputs shorter than this threshold were padded with the [PAD] token, whereas overlength sequences were processed through intelligent truncation. For a given sample from the dataset, the encoded representation was obtained as follows:

$$I_t=RoBERTa\left(X;\theta^R\right)\in R^{l_t\times d_t} \quad (2)$$

where, l_t denotes the length of the text sequence, d_t denotes the dimensionality of the textual representation, and θ^R represents the parameters of the RoBERTa model.

B. Audio Feature Encoding

The multimodal emotional information generated during intelligent interaction requires the preservation of temporal continuity and contextual dependencies. However, the raw audio and visual features extracted typically consist of independent frame-wise representations that lack sufficient contextual information. To address this limitation, an LSTM network was employed to encode these modalities. In multimodal sentiment analysis for intelligent interaction, audio features are commonly categorized into three types: spectral features, timbre-related features, and prosodic features. In this study, the wav2vec2-base-960h pretrained model was utilized for feature extraction. This model was pretrained and fine-tuned on the 960-hour LibriSpeech dataset. All audio data were uniformly resampled to a 16 kHz sampling rate. New samples underwent preprocessing, feature encoding, masking, contextual representation, feature quantization, contrastive learning, loss calculation, fine-tuning, and feature extraction, resulting in the acquisition of 768-dimensional audio representations. For a given audio sequence $A=\{a_1,a_2,\ldots a_n\}$, the extracted audio feature representation is defined as:

$$I_a=Wav2vec2.0(A)\in R^{l_a\times d_a} \quad (3)$$

where, l_a denotes the audio sequence length, and d_a denotes the audio sequence dimensionality.

During the audio feature encoding process, OpenSMILE [18] with the IS10 configuration was employed to extract speech segments. Three predefined standard feature sets were included in this configuration: ComParE 2016 (a large-scale paralinguistic feature set), GeMAPS (a basic acoustic parameter set), and its extended version, eGeMAPS. The detailed configuration of these feature sets is presented in Table I.

TABLE I. OVERVIEW OF OPENSMILE FEATURE SETS

Feature Set	Number of Features	Feature Type
ComParE 2016	6373	Static features
GeMAPS	62	High-level statistical function (HSF) features
eGeMAPS	88	Extended features + HSF features

For affective computing tasks, the ComParE 2016 configuration was adopted to extract 6,373 acoustic features from each speech segment. A fully connected network was then used to reduce these features to 1,582 dimensions for the IEMOCAP dataset and to 300 dimensions for the MELD dataset; the resulting unified representation is denoted as u_t^A. To enhance temporal modeling capability, a bidirectional LSTM architecture was employed to capture contextual dependencies within the audio signal. The computation process is expressed as follows:

$$\mathbf{t}_i^{\mathrm{A}},\mathbf{H}_i^{\mathrm{A}}=\left[\overrightarrow{\mathrm{LSTM}}\left(\mathbf{u}_i^{\mathrm{A}},\overrightarrow{\mathbf{H}_{i-1}^{\mathrm{A}}}\right),\overleftarrow{\mathrm{LSTM}}\left(\mathbf{u}_i^{\mathrm{A}},\overleftarrow{\mathbf{H}_{i+1}^{\mathrm{A}}}\right)\right] \quad (4)$$

where, $\boldsymbol{H}_{i-1}^{A}$ represents the (i-1)-th hidden layer state, $\boldsymbol{H}_{i+1}^{A}$ represents the (i+1)-th hidden layer state, and $\boldsymbol{t}_i^{A}$ denotes the context-aware audio encoding.

C. Visual Feature Encoding

During the intelligent interaction process in psychological assessment, facial micro-expression dynamics were captured through video data. Visual feature extraction was performed using the OpenFace 2.0 toolkit and the ViT model. OpenFace 2.0 extracts video features through four stages: frame decomposition, facial detection and landmark localization, facial alignment, and facial feature extraction. The ViT model, built upon the Transformer architecture for image processing, divides each input frame into fixed-size patches and encodes them using a Transformer-based pipeline. The feature extraction process includes video preprocessing, selection of effective frames, image segmentation into patches, patch embedding, ViT-based encoding, and feature extraction. Through multiple layers of Transformer encoders, each token is dynamically updated to feature vectors integrating global contextual semantics with local visual details [19]. A compact representation of each video frame was then obtained by aggregating the encoded tokens. Given a preprocessed video sequence $V=\{v_1,v_2,...v_n\}$, the extracted visual feature representation is defined as:

$$I_v=ViT(V)\in\mathrm{R}^{l_v\times d_v} \quad (5)$$

where, l_v denotes the length of the video sequence, and d_v denotes the dimensionality of the video sequence.

For the video-based emotion extraction task, the raw visual features were initially obtained as independent frame-level representations. Since multimodal sentiment analysis requires the preservation of temporal continuity and contextual dependencies, a 342-dimensional visual feature, denoted as u_t^V, was first extracted. Similar to the audio encoding process, a bidirectional LSTM network was employed to capture contextual cues. The computation is defined as follows:

$$\mathbf{t}_i^{\mathrm{V}},\mathbf{H}_i^{\mathrm{V}}=\left[\overrightarrow{\mathrm{LSTM}}\left(\mathbf{u}_i^{\mathrm{V}},\overrightarrow{\mathbf{H}_{i-1}^{\mathrm{V}}}\right),\overleftarrow{\mathrm{LSTM}}\left(\mathbf{u}_i^{\mathrm{V}},\overleftarrow{\mathbf{H}_{i+1}^{\mathrm{V}}}\right)\right] \quad (6)$$

where, $\boldsymbol{H}_{i-1}^{V}$ and $\boldsymbol{H}_{i+1}^{V}$ represent the (i-1)-th and (i+1)-th hidden layer states, respectively, and $\boldsymbol{t}_i^{V}$ denotes the context-aware video encoding. To ensure that elements within each input sequence adequately capture interactions with adjacent elements, a one-dimensional temporal convolution layer was applied, which transforms the states into a unified dimension to facilitate subsequent processing. The transformation is computed as:

$$\widehat{F}_t=\mathrm{Conv1D}(I_t,\mathrm{kernel}_t)\in\mathrm{R}^{l_t\times d} \quad (7)$$

$$\widehat{F}_{\{a,v\}}=\mathrm{Conv1D}\left(I_{\{a,v\}},\mathrm{kernel}_{\{a,v\}}\right)\in\mathrm{R}^{l_{\{a,v\}}\times d} \quad (8)$$

where, $\mathrm{Kernel}_{\{t,a,v\}}$ denotes the convolution kernels corresponding to the text, audio, and visual modalities, and d represents the modality dimension.

D. Multimodal Fusion

For management units, two remote operation and maintenance modes are provided.

1) Multi-Modal Enhanced Transformer (CMET) module: In sentiment analysis, the textual modality typically plays a dominant role in conveying explicit semantic information, whereas non-textual modalities often provide auxiliary affective cues. To strengthen the emotional representational capacity of non-textual modalities, a CMET module was introduced. This module establishes a bidirectional cross-modal attention mechanism to facilitate complementary information exchange and collaborative optimization across modalities, thereby significantly enhancing the affective expressiveness of non-textual modalities. In the module, and denote the two non-textual modalities, while t denotes the textual modality. Fig. 2 shows the architecture of the audio–visual enhanced Transformer.$\alpha\beta$

The general formulation of $CMET(Q,K,V)$ is given as:

$$\mathrm{CMET}_{\mathrm{mul}}(\boldsymbol{Q},\boldsymbol{K},\boldsymbol{V})=\mathrm{softmax}\left(\frac{\boldsymbol{Q}\boldsymbol{K}^T}{\sqrt{d_k}}\right)\boldsymbol{V} \quad (9)$$

where, Q denotes the queries, K denotes the keys, V denotes the values, and d_k represents the dimensionality of the key or value vectors. The computation of Q, K, and V in the multi-head attention mechanism is expressed below, with the weight matrices defined as $W_{Q_\alpha}\in\mathrm{R}^{\mathrm{d}_\alpha\times d_k}$, $W_{K_\beta}\in\mathrm{R}^{\mathrm{d}_\beta\times d_k}$, and $W_{V_\beta}\in\mathrm{R}^{\mathrm{d}_\beta\times d}$:

$$Q_\alpha=Z_\alpha W_{Q_\alpha}\in\mathrm{R}^{l_\alpha\times d_k} \quad (10)$$

$$K_\beta=Z_\beta W_{K_\beta}\in\mathrm{R}^{l_\beta\times d_k} \quad (11)$$

$$V_\beta=Z_\alpha W_{V_\beta}\in\mathrm{R}^{l_\alpha\times d} \quad (12)$$

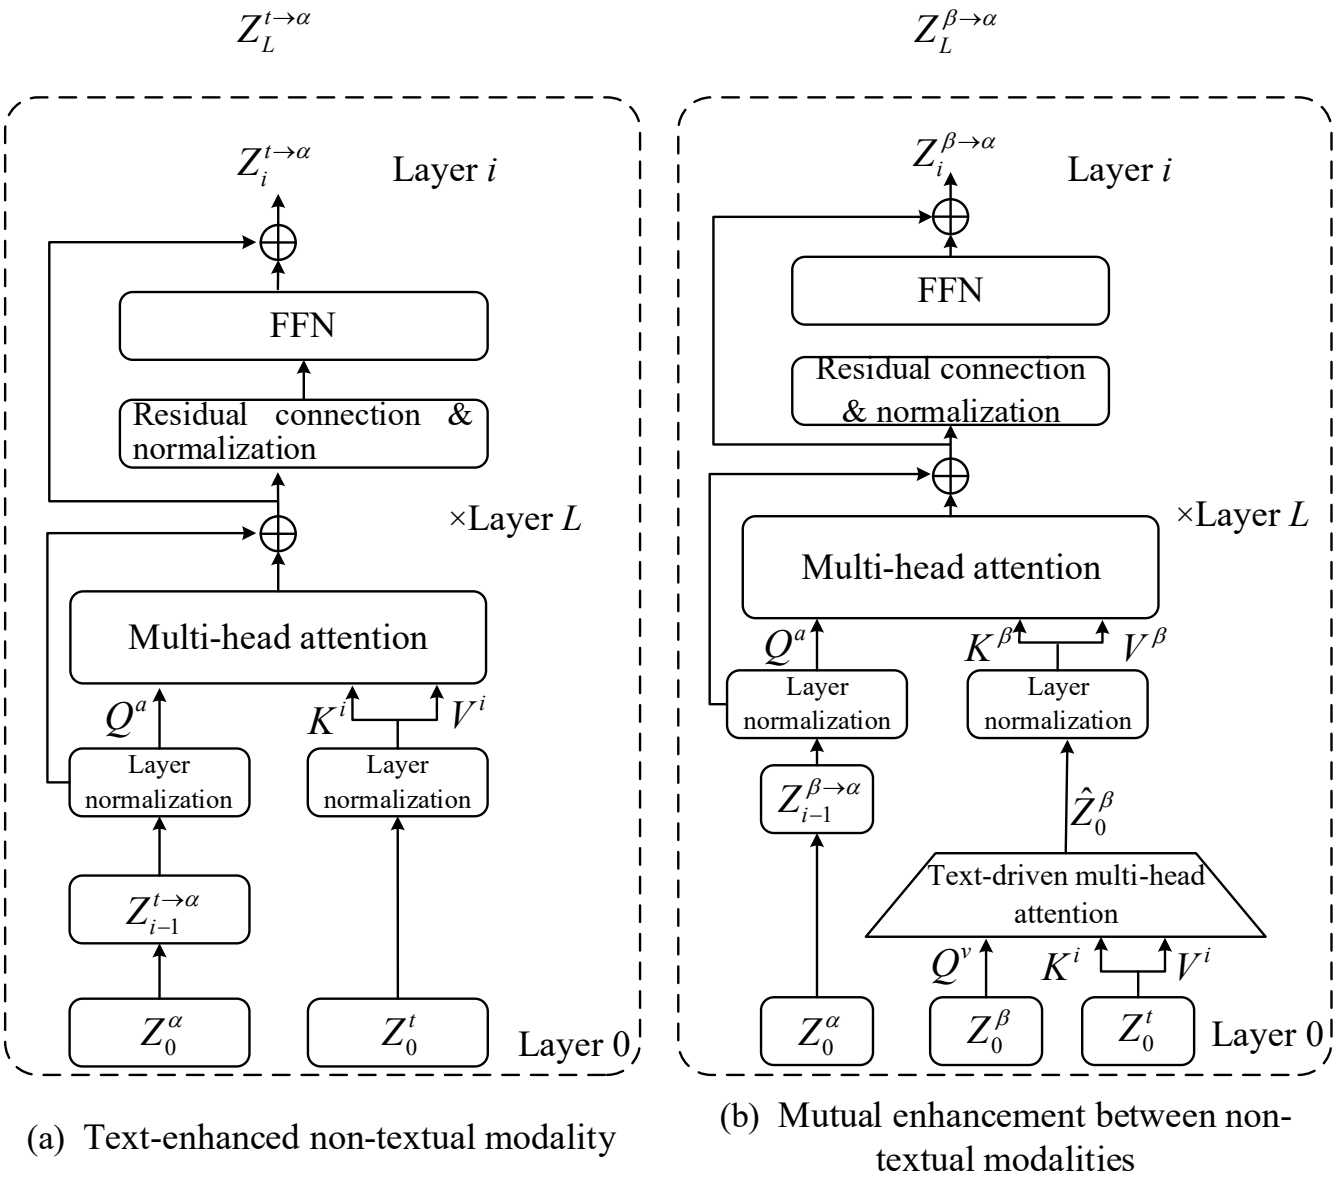

Fig. 2. Architecture of the audio–visual enhanced transformer.

For multimodal psychological testing, a cross-modal interaction encoder was designed that uses the text modality to compensate for underperforming modalities through feature enhancement: *Text→Visual*, *Audio→Visual*, *Text→Audio*, and *Visual→Audio*. This framework fosters deep inter-modal interaction between visual and audio streams while preserving information flow across all modalities. The enhancement of the visual modality is exemplified by the following formula:

$$\tilde{\mathbf{Z}}_i^{T\to V}=\mathrm{CMET}_{(i),\,\mathrm{mul}}^{T\to V}\left(\boldsymbol{t}_{(i\text{-}1)}^{T},\boldsymbol{t}_i^{T},\boldsymbol{t}_i^{V}\right) \tag{13}$$

$$\tilde{\mathbf{Z}}_i^{A\to V}=\mathrm{CMET}_{(i),\,\mathrm{mul}}^{A\to V}\left(\boldsymbol{t}_{(i\text{-}1)}^{A},\boldsymbol{t}_i^{A},\boldsymbol{t}_i^{V}\right) \tag{14}$$

The CMET module stacks multiple layers of cross-modal attention blocks, where the output of each layer serves as the input to the next, progressively enhancing audio and visual modality representations. As an example, for the enhancement of the audio modality via the visual modality (V→A), the audio representation was first initialized as $Z_0^{v\to a}=Z_0^a$, after which textual content was utilized to guide the visual modality in enriching affective information. The enhancement process is expressed as:

$$\hat{Z}_0^v=\mathrm{CMET}_{multi}^{T\to V}=\mathrm{Multihead}\left(Q_v,K_t,V_t,\right) \tag{15}$$

At layer i, the output $Z_{i-1}^{v\to a}$ from the previous layer and the text-enhanced modality information $\hat{Z}_0^v$ are integrated to compute attention weights, capturing inter-modal interactions. This integrated output is normalized to produce $\hat{Z}_i^{v\to a}$, which is then passed through a Feedforward Neural Network (FFN), yielding the final enhanced audio–visual representation $Z_i^{v\to a}$. The calculation is defined by the following formula:

$$\hat{Z}_i^{v\to a}=\mathrm{CMET}_{multi}^{v\to a}\left(\mathrm{LN}(Z_{i-1}^{v\to a}),\mathrm{LN}\left(\hat{Z}_0^v\right)\right)+\mathrm{LN}(Z_{i-1}^{v\to a}) \tag{16}$$

$$Z_i^{v\to a}=\mathrm{FFN}\left(\mathrm{LN}\left(\hat{Z}_i^{v\to a}\right)\right)+\mathrm{LN}\left(\hat{Z}_i^{v\to a}\right) \quad (17)$$

where, LN() denotes layer normalization, and FFN() denotes the feedforward neural network. In standard Transformer architectures, the ReLU activation function is commonly employed. The FFN applies an identical linear transformation and activation function to each element in the sequence independently. The FFN is formulated as:

$$\mathrm{FFN}(X)=\max(0, xW1+b1)W2+b2 \quad (18)$$

where, W_1 and W_2 are weight matrices, b_1 and b_2 are bias terms, and max(0,y) represents the ReLU activation function applied to each element to introduce nonlinearity.

2) Information compression and fusion: Token sequences were utilized as information carriers to enable efficient compression of audio–visual data. The process involves the steps below. First, the audio–visual sequence Z_m^L is concatenated with a dimension-aligned token sequence to obtain Z_{mt}^L . The combined representation incorporates information from both the original audio–visual features and their associated tokens:

$$Z_{mt}^L=\mathrm{Concat}\left(\hat{Z}_m^L,T\right) \quad (19)$$

Subsequently, a Transformer layer is applied to extract and condense the salient information contained within the audio–visual sequence. Drawing inspiration from the ViT architecture, the transformation is expressed as:

$$T_m=\mathrm{Transformer}\left(Z_m^L;\theta_m\right) \quad (20)$$

After information compression, the extracted audio and visual feature vectors are fused into a unified representation that reflects the intrinsic correlation and complementarity between the modalities. The compressed audio feature vector T_a and the compressed visual feature vector T_v are concatenated to form a joint representation T_{av}:

$$T_{av}=\mathrm{Concat}(T_a,T) \quad (21)$$

The fused representation T_{av} is then processed using a Transformer encoder to integrate comprehensive information across audio and visual modalities. The resulting representation is defined as:

$$Z_{av}=\mathrm{Transformer}\left(\hat{T}_{av}\right) \quad (22)$$

The representation Z_{av}, obtained through information compression and fusion, captures comprehensive affective cues from audio–visual data and enhances the model's ability to understand and interpret complex emotional states. After stacking *X* layers of processing, the final textual representation Z_t and the fused audio–visual representation Z_{av} are generated. Because different modality combinations contribute unequally to sentiment analysis, an adaptive weighting module was designed to quantify the contribution of each modality to the final output. The multimodal features are then aggregated through a weighted fusion mechanism to produce the final integrated output. Following a bias-free linear transformation applied to the output vectors Z_t and Z_{av}, a softmax operation is used to compute the output weights. These weights are then applied to each representation to generate the final output $\boldsymbol{N}'$, enabling more effective fusion of multimodal information and improving the accuracy of emotion prediction. The computation is defined as:

$$\boldsymbol{n}_{\mathrm{softmax}}=\mathrm{softmax}([\boldsymbol{W}_1\otimes Z_t,\boldsymbol{W}_2\otimes Z_{av}]) \quad (23)$$

$$\boldsymbol{N}'=\boldsymbol{n}_{\mathrm{softmax}}\odot Z_t+\boldsymbol{n}_{\mathrm{softmax}}\odot Z_{av} \quad (24)$$

E. Long-Range Affective Fusion Module

The long-range affective fusion module employs a hierarchical architecture to integrate emotional information. External knowledge is first extracted using the COMET model, which is pretrained on the ATOMIC knowledge graph. COMET generates nine categories of external knowledge features associated with the input text, including speaker intent (xIntent), speaker need (xNeed), speaker attribute (xAttr), effects on the speaker (xEffect), speaker desire (xWant), speaker emotional reaction (xReact), effects on others (oEffect), others' desire (oWant), and others' emotional reaction (oReact). Next, a graph-structured representation of the dialogue is constructed using a GNN to capture local, sentence-level semantic features. A Transformer encoder is then used to model dependencies and extract affective features across distant utterances. Finally, a feature fusion mechanism is designed to adaptively integrate the local sentence-level representations with global speaker-level emotional information.

Within the long-range fusion module, a directed graph is constructed to represent the interaction flow across dialogue segments. The output from the multimodal fusion module, $\boldsymbol{N}'$, is used as the initial node feature h_i. Knowledge representations generated from COMET, pre-trained on the ATOMIC knowledge graph, are aligned with relation types. The Relational Graph Convolutional Network (RGCN) updates the hidden states of nodes through the neighboring node representations based on edge types [20], while the Attention-based Relational Graph Convolutional Network (ARGCN) extends RGCN by incorporating distance-aware attention mechanisms to further enhance representational capacity [21]. The node calculation process is expressed as:

$$\boldsymbol{h}_i'=\sigma\left(\sum_{r\in R}c_{i,j}\sum_{j\in N_i^r}x_{ij,r}+\boldsymbol{W}_4\boldsymbol{h}_i\right) \quad (25)$$

where, σ denotes the activation function, R represents the set of relation types, $h_i=N'$, N_i^r is the set of neighboring nodes connected to node v_i under relation $r\in R$, W_4 is a learnable parameter matrix, and $C_{i,j}$ denotes the normalization coefficient. To propagate the interaction information aggregated by the ARGCN, a GraphTransformer model consisting of L layers is employed. The updating operation is defined as:

$$\mathbf{h}_i^{(l+1)}=\left(1-\beta_i\right)\left(\sum_{j\in N(i)}\alpha_{i,j}\,m_j\right)+\beta_i\mathbf{W}_6\mathbf{h}_i^{(l)} \quad (26)$$

where, $N(i)$ denotes the set of source nodes connected to node i, m_j represents the message from source nodes, $\alpha_{i,j}$ is the attention score, β_i is the gating parameter for the residual connection, and W_6 denotes the mapping weight. This update rule yields the final representation for all nodes in the dialogue graph. In parallel, a Transformer network is used to capture

self-dependencies across adjacent utterances from the same speaker. The resulting speaker-level contextual representation is denoted as p_i. A function $Y_i=f(L_{past},p_i)$ aggregates information from the preceding n_{past} utterances, where L_{past} denotes the information on n_{past} utterances. For the i-th utterance in the dialogue, its feature representation $\boldsymbol{E}_i$ is computed using ARGCN. In addition, U_λ denotes the information on all utterances in the dialogue.

$$E_i=\text{ARGCN}(\boldsymbol{E}_i,\boldsymbol{E}_j),j\in[i,|U_\lambda|] \tag{27}$$

Finally, a Transformer integrates Y_i with $\boldsymbol{E}_i$. The attention scores are assigned weights, generating the final fused representation H_i:

$$\boldsymbol{H}_i=\text{Transformer}\left(\boldsymbol{Y}_i,E,\sum_{i=1}^{N}\text{sim}(\boldsymbol{Y}_i,\boldsymbol{E}_i)\right) \tag{28}$$

F. Emotion Classification and Model Optimization

During the emotion prediction stage, the composite vector is passed through a fully connected layer for affective classification. The ReLU activation function and the softmax function are used to project the affective features into the emotion category space, producing the classification output:

$$\boldsymbol{H}_i^{'}=\text{ReLU}(\boldsymbol{W}_u\boldsymbol{H}_i+\boldsymbol{b}_1) \tag{29}$$

$$Q_i=\text{Softmax}(\boldsymbol{W}_u\boldsymbol{H}_i^{'}+\boldsymbol{b}_2) \tag{30}$$

where, W_u denotes the weight matrix of the fully connected layer, b_1 and b_2 are bias vectors, and Q_i represents the softmax output. The final predicted emotion category is determined as $\hat{y}_i$. To optimize all parameters in the model, the minimized standard cross-entropy loss function is employed.

$$\hat{y}_i=\text{argmax}(Q_i) \tag{31}$$

$$L(\theta)=-\sum_{i=1}^{N}\sum_{j=1}^{c(i)}\log P_{i,j}\left[y_{i,j}\right] \tag{32}$$

IV. Empirical Results

A. Experimental Environment

The experimental environment was configured using the Ubuntu 22.04 operating system. Python 3.10 was adopted as the programming language, with Anaconda 4.2.0 used for package and environment management. PyTorch 1.12.1 served as the deep learning framework, supported by a 10 GB GPU. Computational efficiency and stability were ensured through the integration of CUDA Toolkit 11.3 and cuDNN v8.3.2 acceleration libraries.

B. Dataset and Evaluation Metrics

1) Self-constructed multimodal dataset: The dataset used in the experimental process was collected from students of the School of E-Commerce at the host institution. The intelligent interaction data were obtained from a representative application case titled AI Heart World, a typical intelligent non-cognitive ability assessment system based on immersive interaction. The system was developed around the core elements of "assessment needs – assessment environment – analytical techniques – information fusion" and integrates sandbox theory, psychometrics, game-based interaction, and artificial intelligence technologies. This interactive environment captures multimodal emotional information generated through scenario-based game interactions, enabling the measurement of an examinee's psychological state, personality traits, and behavioral characteristics in a more naturalistic setting, thus yielding more authentic data [22]. The collected data were processed and organized into a multimodal psychological assessment database (EC-SFED), which provides the foundation for Transformer-based sentiment analysis to effectively represent individual psychological states.

Fig. 3. Selected examples from the EC-SFED dataset.

During the experimental process, audio–visual information was collected from 82 university students using their personal devices. Each sample consisted of text, audio, and video components. Textual data were obtained from students' subjective responses within the intelligent interaction platform, including discussion content, forum exchanges, and instant messaging records. Audio data were recorded through microphones or headset devices during the psychological assessment sessions and captured acoustic characteristics such as intonation, loudness, and speaking rate. Video data were captured in real time via intelligent cameras, recording facial expressions, body posture, gaze dynamics, and other visual cues relevant to emotional analysis. The final dataset contained 720 text entries, 233 dialogues, 408 sentences, and 345 video clips. Each video clip was annotated with an emotion intensity score ranging from –3 to +3 (where –3 indicates highly negative emotion and +3 indicates highly positive emotion). Dialogues involved two or more speakers and were divided into training, validation, and test sets using an 8:1:1 ratio. Fig. 3 provides sample pictures of the participants. For feature extraction, the RoBERTa-base model was employed to generate 1,024-dimensional textual representations. Audio features were extracted using the Waveform-to-Vector 2.0 (Wav2Vec2) pretrained model, yielding 768-dimensional embeddings. Visual features were extracted using the ViT model, resulting in 342-dimensional representations. Multiple rounds of pretraining were conducted, and the final reported performance corresponds to the averaged results of 10 independent random runs on the test set.

2) Publicly available dataset: The CMU-MOSI dataset is a multimodal sentiment analysis dataset comprising three modalities of data - text, audio, and video-extracted from 93 YouTube movie review videos [23]. The text data is generated

through automatic transcription of the videos, while the audio and video data are directly extracted from the original footage. This dataset consists of a total of 2,199 video clips, each annotated with a sentiment intensity score ranging from -3 to 3. These annotations were completed by Amazon Mechanical Turk workers, who took comprehensive multimodal information into consideration.

Based on established findings in psychological assessment research, emotion prediction in this context is typically treated as a regression-oriented task. In the present study, the F1 score (W-F1) and classification accuracy (ACC) were adopted as the primary performance indicators. W-F1 reflects the model's overall classification capability, while ACC provides an intuitive measure of prediction correctness. The evaluation metrics are defined as follows:

$$\text{W-F1}=\frac{\sum_{a=1}^{R} M_a \times F1_a}{\sum_{a=1}^{R} M_a},\ \text{ACC}=\frac{\sum_{a=1}^{R} M_a \times ACC_a}{\sum_{a=1}^{R} M_a} \quad (33)$$

where, R denotes the total number of emotion categories in the dataset, M_a represents the number of samples belonging to category a, $F1_a$ is the F1 score for category a, and ACC_a is the accuracy score for category a.

C. Baseline Models

- MulT [7]: A bidirectional cross-modal attention mechanism is employed, using a modality-translation strategy to construct directed interactions between paired modalities. This design enables effective learning of cross-modal associative features.
- MISA [8]: A dual-space representation learning framework is introduced, in which distributional similarity, orthogonality constraints, reconstruction loss, and task-specific objectives are jointly optimized. The framework enhances cross-modal consistency while preserving modality-specific characteristics.
- CapTrBERT (Caption Transformer BERT) [17]: Semantic understanding is strengthened by generating auxiliary caption-like sentences and integrating them with the original textual input. This approach enables more comprehensive extraction of global semantic information.
- FITE (Face-sensitive Image-to-Emotional-Text Translation) [24]: A face-expression–to-text transformation strategy is adopted, in which facial expression features are converted into descriptive textual representations. These representations are aligned with target aspects at a fine-grained level, and multimodal information is fused through a gating mechanism for emotion classification.
- MIM (Multimodal Interaction Model) [25]: An interactive learning framework based on cross-modal attention is proposed. Modality-specific subspaces and cross-modal information exchange channels are constructed to facilitate efficient multimodal interaction while reducing feature redundancy.
- TIEMFF (Text Information Enhancement and Multimodal Feature Fusion) [26]: A text-dominant hierarchical enhancement architecture is introduced. A dual attention mechanism is used to strengthen textual features and achieve fine-grained alignment of multimodal representations.

D. Comparative Analysis of Experimental Results

Most of the video segments in the dataset were captured using high-definition devices, resulting in favorable lighting conditions and high visual clarity. Fig. 4 presents a comparison of evaluation metrics between the proposed model and the baseline models, including F1 scores and accuracy.

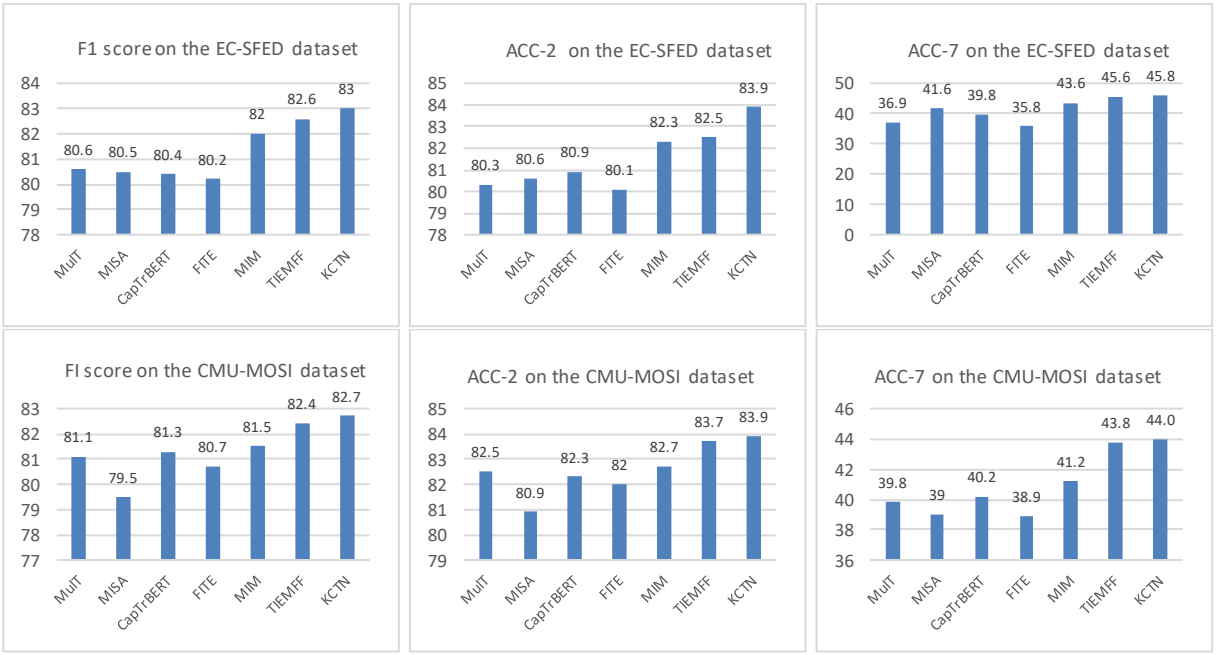

Fig. 4. Evaluation metrics of the proposed model and baseline models on the EC-SFED and the CMU-MOSI datasets.

The comparative analysis of experimental results obtained from the student psychological state dataset indicates that the performance of the FITE model is relatively weak, with both its F1 score and accuracy markedly lower than those of the other models. FITE transforms facial expression features into textual descriptions and subsequently performs multimodal fusion and emotion classification through a gating mechanism. In contrast, the MulT, MISA, and CapTrBERT models demonstrate moderate performance levels across the dataset, with comparable F1 scores and accuracy values. More recent models such as MIM and TIEMFF exhibit notably stronger performance, further validating the effectiveness of cross-modal attention mechanisms in sentiment analysis. The proposed KCTN model achieves the best performance across all evaluation metrics. The results confirm the model's effectiveness in cross-modal interaction and affective feature extraction while highlighting its robustness advantages in student psychological testing across diverse scenarios.

E. Ablation Study

1) Modality ablation: The influence of different modality combinations on the proposed model was examined. Performance was first evaluated using single-modality inputs—text (T), audio (A), and video (V). Dual-modality combinations, including text–audio (T–A), text–video (T–V), and audio–video (A–V), were then assessed. As expected, the ablation results obtained on the EC-SFED and the CMU-MOSI datasets are presented in Table II.

TABLE II. MODALITY ABLATION RESULTS ON THE EC-SFED DATASET

Modality combination	EC-SFED dataset		
ComParE 2016	F1 (%)	ACC-2 (%)	ACC-7 (%)
GeMAPS	80.6	80.3	46.8
	69.2	66.7	37.8
	72.1	71.5	39.8
	82.6	82.7	50.9
	83.3	83.2	51.9
	73.4	72.5	45.6
eGeMAPS	83.8	83.9	52.5

The results demonstrate that the performance of the multimodal affective recognition system is highly sensitive to the choice of modality combinations. In the single-modality experiments, notable disparities were observed across modalities: textual features achieved markedly superior performance (F1 = 80.6%) compared with audio (69.2%) and video (72.1%). The introduction of textual information produced substantial performance gains in dual-modality settings. The text–audio combination increased F1 by 19.36 percentage points relative to audio alone, while the text–video combination improved F1 by 15.53 percentage points. These results confirm the pivotal role of the textual modality in psychological assessment tasks, as its representational capacity surpasses that of auditory and visual modalities. Furthermore, single-modality comparisons revealed that audio conveyed more discriminative information than video, indicating that video data may contain higher levels of noise. The multimodal fusion experiments further demonstrate that combining text, audio, and video yields the highest overall performance. The tri-modal configuration achieved an F1 score of 83.8% on the EC-SFED dataset and 84.1% on the CMU-MOSI dataset, providing strong empirical support for the complementary nature of multimodal integration in psychological assessment scenarios.

2) Module ablation: To examine the contribution and influence of each core module within the overall architecture, a series of module-level ablation experiments was conducted on the two datasets. The notation "w/o" indicates the removal of a specific module during evaluation. Four key modules in the model were ablated sequentially, including the audio–visual enhanced Transformer module (w/o AVET), the information compression and fusion module (w/o ICF), and the long-range emotion fusion module (w/o FFM), enabling analysis of their respective impacts on model performance.

a) Ablation of the audio–visual enhanced transformer module (w/o AVET): In this setting, the audio–visual enhanced Transformer module of the CMET architecture was removed. The non-textual modalities processed by the one-dimensional temporal convolution were fed directly into the information compression and fusion module.

b) Ablation of the information compression and fusion module (w/o ICF): In this configuration, the information compression and fusion module of the CMET architecture was omitted. The modality representations produced by the non-textual enhanced Transformer were fused directly.

3) Ablation of the long-range emotion fusion module (w/o FFM): For this setting, the long-range emotion fusion module was removed. The audio–visual representations obtained from the information compression and fusion module were directly fused with the temporally convolved textual representations.

Table III presents the results of the module ablation experiments conducted on the EC-SFED and the CMU-MOSI dataset.

TABLE III. MODALITY ABLATION RESULTS ON THE EC-SFED AND THE CMU-MOSI DATASET

Model	EC-SFED dataset			CMU-MOSI dataset		
ComParE 2016	F1 (%)	ACC-2 (%)	ACC-7 (%)	F1 (%)	ACC-2 (%)	ACC-7 (%)
GeMAPS	81.3	82.5	50.5	78.0	78.3	47.8
	82.9	82.6	51.4	78.5	78.6	48.2
	82.2	83.3	52.6	80.3	81.2	48.5
	83.8	84.1	53.7	80.8	82.0	50.2

The module ablation results on the EC-SFED dataset demonstrate that the removal of any core module leads to a measurable decline in model performance. Among the examined components, the audio–visual enhanced Transformer module exerts the most substantial influence on overall effectiveness. Its removal reduces the F1 score to 81.3%, decreases ACC-2 to 82.5%, and lowers ACC-7 to 50.5%. This pronounced degradation underscores the central role of the

audio–visual enhanced Transformer in the early stages of multimodal information integration. The removal of the information compression and fusion module and the long-range emotion fusion module also results in significant performance degradation. These reductions highlight their importance in mitigating redundancy within non-textual modalities, enhancing feature robustness, and improving cross-modal discriminability. Ablation experiments conducted on the CMU-MOSI dataset also demonstrate the utility of the three aforementioned modules. Compared with the experimental results on the EC-SFED dataset, removing the long-distance emotion fusion module on the CMU-MOSI dataset leads to a relatively smaller impact on model performance. This suggests that the role of long-range information may be limited on smaller-scale datasets. Conversely, on large-scale datasets, this module can significantly enhance the model's ability to recognize both consistency and divergence in emotional information across different modalities by constructing a greater number of sample pairs, thereby improving the accuracy and effectiveness of sentiment analysis. Collectively, the ablation of any single module results in performance degradation, validating the contribution of each component to the model's overall performance and robustness.

F. Empirical Results and Analysis

To further evaluate the effectiveness of the proposed model in psychological testing, t-SNE was employed to visualize the high-dimensional features extracted from the EC-SFED test set. The results are presented in Fig. 5 and 6. Fig. 5 illustrates the distribution of feature representations before classification. Substantial overlap is observed between different emotional categories, and no clear clustering structure is formed. This indicates that the raw features do not inherently exhibit strong discriminative capability. After processing by the proposed model, the post-classification visualization in Fig. 6 shows that the feature vectors are distinctly clustered into two separable groups corresponding to positive and negative emotional states. The boundary between the clusters becomes pronounced, demonstrating that the model achieves effective multimodal affective feature separation. These empirical findings indicate that the proposed sentiment analysis model exhibits reliable performance when applied to psychological assessment scenarios involving students.

G. Case Analysis of Intelligent Psychological Assessment Interactions

The tasks in AI Heart World are presented within dynamic and immersive interactive scenarios. Participants' responses—including every choice made and action taken within these environments—generate process data with significant reference value for psychological state assessment. Table IV summarizes three representative cases, illustrating how different models handle these multimodal cues. In Case 1, the critical challenge lies in aligning textual information with visual cues from the scenario. The CapTrBERT model combines original inputs with generated auxiliary sentences; however, its architecture does not incorporate an effective mechanism for extracting or aligning emotional features from images. As a result, errors arise in sub-scenarios where textual expressions and visual affective cues are inconsistent. The FITE model establishes an initial degree of text–image integration through its basic cross-modal attention mechanism. In contrast, the proposed model leverages multimodal information captured throughout the intelligent interaction process to accurately identify the test subject's underlying anxious emotional state, which remains implicit beneath a superficially calm textual expression.

Case 2 focuses on a sub-scenario in which the visual information is incomplete, thereby assessing the model's ability to utilize non-facial emotional cues. In this scenario, the participant's face is partially occluded, resulting in the absence of clear facial features. Because the core design logic of the FITE model relies heavily on facial expressions as the primary basis for emotion inference, the absence of key visual features prevents the model from extracting effective supplementary cues from other regions of the image, ultimately leading to a misclassification of the psychological state. In contrast, the proposed model maintains prediction accuracy by leveraging the coordinated effects of the long-range contextual module and the Graph Convolutional Network (GCN), which together enable the extraction of syntactic features.

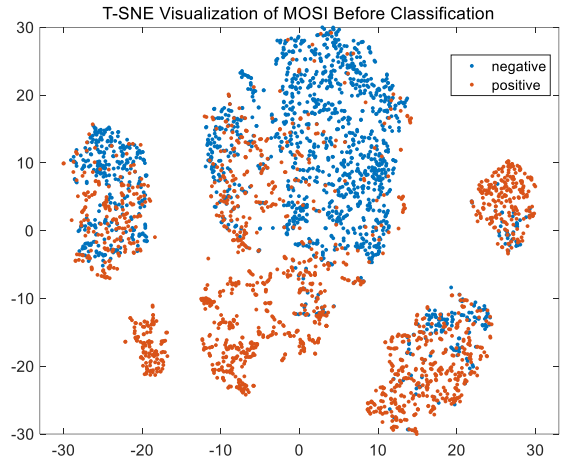

Fig. 5. Visualization of feature vectors before classification.

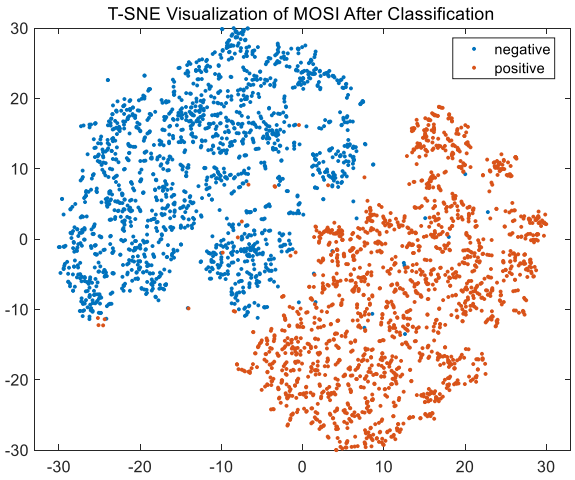

Fig. 6. Visualization of feature vectors after classification.

TABLE IV. CASE ANALYSIS OF PSYCHOLOGICAL ASSESSMENT SCENARIOS

Image				
Feature text		Did I do something wrong? Could you give me a hint?	I don't have enough blocks. They may not be stable.	The whole process was like playing a game. Using the sandbox to create scenes felt very novel, and it was quite interesting how the system analyzed my psychological state based on the 'Bing Dwen Dwen' character I selected.
Long-range text		This is impossible! I don't even know how to assemble the basic structure—forget it, let's move to the next one.	Try to speed up the construction. Use whatever is available first—it'll be finished soon.	Haha, this is kind of fun! Let me try another construction method!
Ground-truth emotion		Negative	Positive	Positive
Model	**FITE**	Negative√	Negative×	Positive√
	CapTrBERT	Positive×	Positive√	Positive√
	Proposed	Negative√	Positive√	Positive√

Case 3 represents an ideal scenario in which multimodal information is highly consistent, designed to validate the effectiveness and rationality of the evaluation benchmark. In this case, the participant's textual response (e.g., "It's quite interesting"), visual indicators (slight smile and relaxed posture), and contextual emotional records exhibit strong coherence, with no conflicting affective cues. Experimental results show that CapTrBERT, FITE, and the proposed model all achieve 100% prediction accuracy in this ideal setting. This outcome not only confirms that the baseline performance of each model meets expectations when sufficient information is provided, but more importantly, it validates the scientific rigor of the selected case set used in this evaluation. By employing a consistent scenario to eliminate external interference, the study successfully pinpoints the genuine performance differences among models under complex conditions, thereby establishing a reliable benchmark for subsequent model optimization.

V. CONCLUSION

A cross-modal fusion network model (KCTN) based on long-range affective integration was proposed for psychological assessment tasks involving university students. Utilizing the "AI Heart World" application case, the model intelligently extracted key information and incorporated a multimodal fusion module enhanced with long-distance knowledge, achieving layer-by-layer integration of textual, audio, and visual features. This approach effectively mined valuable information from weak modalities while suppressing noise interference. In practical psychological assessment tasks, KCTN was capable of handling imbalanced data quality in multimodal inputs. For instance, when audio or video data were partially missing or exhibited a low signal-to-noise ratio, the model maintained stable performance by integrating long-distance knowledge with the textual modality. In complex scenarios such as teacher-student dialogues or psychological counseling sessions, KCTN dynamically adjusted predictions based on contextual and emotional cues of the speaker, thereby improving recognition accuracy. Future research will continue to explore the disparities and complex interactions among different modalities to design more effective multimodal fusion mechanisms. It will also further integrate campus management systems and dialogue information from intelligent interactive platforms to uncover the causal layers underlying students' psychological states, thereby enabling timely detection of adverse mental conditions and contributing to the development of a novel intelligent technology-based paradigm for psychological assessment.

Enhancing Traffic Congestion Forecasting with Explainable Deep Learning: A Framework Using LIME for Transparent Intelligent Transportation Systems

Ouhmidou Hajar, Nabou Abdellah, Elikram Moulay Ahmed
Department of Computer Science-Faculty of Science Semlalia, Cadi Ayyad University, Marrakech, Morocco

***Abstract*—Intelligent transportation systems aim to improve traffic management and road safety, manage traffic effectively, and reduce roadway system congestion. This optimally requires estimating future traffic congestion. Unfortunately, the most popular machine learning and deep learning techniques can be unsuitable for model development in this task due to interpretability challenges. This study attempts to provide a solution to this challenge by creating a tool that integrates Local Interpretable Model-agnostic Explanations (LIME) into any traffic congestion forecasting system. This tool is applied to the Metro Interstate Traffic Volume dataset, which contains samples of traffic and road system congestion along with temporal, weather, and contextual data. For global feature analysis, a Random Forest Regressor is used as a baseline model, while a neural network model is developed to predict the congestion of the traffic and road system. The neural network model achieved a congestion prediction with an R^2 score of 0.612, a mean squared error of 0.026, and a mean absolute error of 0.129. The LIME tool also provides temporal feature insights, which show that examples of weekday/holiday status reduce the sample congestion prediction for the example, while precipitation increases it. At a global level, hour of the day, day of the week, temperature, and month of the year are the dominant factors in congestion prediction. These findings illustrate the value of adding interpretability to predictive models of traffic congestion when using explainable artificial intelligence.**

***Keywords*—Explainable artificial intelligence; lime; traffic congestion forecasting; intelligent transportation systems; random forest**

I. Introduction

Accelerating urbanization and rapid population growth have presented problems for global transport infrastructure. Rapid increases in the number of cars have caused traffic congestion to be a day-to-day experience for most large cities, generating many effects ranging from economic loss of fuel to deterioration of air quality related to human well-being to lowered quality of life. To address those challenges, accurate and real-time traffic estimation was a primary objective of both researchers and transport agencies. These estimations are foundational to intelligent transport systems (ITS) for improving traffic, reducing travel time, and improving road safety [2]. Traditionally, historical and econometric models based on ARIMA and regression analyses have been dominant for traffic forecasting.

Although the output was extremely relevant for acquiring deep insight into traffic improvement, these modelling approaches, quite expectedly, do not lend themselves well to representing the complex non-linearities found in traffic because of heterogeneous and dynamically fluctuating factors such as climate and large events (festivals) and driver behaviour [3]. Recent advancements in deep learning (DL) have significantly transformed the traffic forecasting arena. The power of artificial neural models such as convolutional neural networks (CNNs), recurrent neural networks (RNNs), and long short-term memory (LSTM) networks is demonstrated in their modelling of spatio-temporal dependencies and revealing patterns hidden in the raw traffic dataset [4]. Artificial neural models have consistently achieved state-of-the-art performance across an exceptionally wide range of applications that involve real-world processes [1]. However, along with the potential of improved accuracy brought by Deep Learning (DL) models comes the cost of non-interpretability; decisions made on top of complicated tower stacks of nonlinear transformations are opaque, and therefore DL models have also been termed "black box" models. In some applications, such as traffic management, where important decisions are made, the lack of interpretation can deter use cases because decision makers require both predictive validity and an explanation that they can trust. For example, traffic operators need to understand why a model predicted significant congestion at a certain time and location, validate the analysis, the reason for the analysis, and take appropriate action in time. To address this gap, the emerging field of Explainable Artificial Intelligence (XAI) has proposed different methods for explaining black-box models. Prominent methods such as Local Interpretable Model-agnostic Explanations (LIME) and Shapley Additive ExPlanations (SHAP) deliver post-hoc explanations for models in terms of how much the most relevant features contribute to single predictions [5],[6]. These methods provide meaningful information about model reasoning, supporting a better understanding and trust of the end user in the model's output. This revised manuscript addresses the methodological inconsistency identified during review by reframing the work as a model-agnostic explainability framework rather than as a purely deep-learning study. The predictive component may be implemented using either an ensemble model or a neural network, while LIME is used as a post-hoc explanation layer.

The main contributions are as follows:

- Evaluation framework: Propose a methodological framework for developing and evaluating interpretable traffic prediction models.
- Practical demonstration with LIME: Using a public dataset, apply LIME to explain the predictions of a congestion model and illustrate how local explanations can enhance understanding.
- Analysis of influential features: Identify and visualize both local (LIME-based) and global (feature importance-based) drivers of congestion predictions.
- Reproducible resources: Provide fully reproducible Python code to support researchers and practitioners in adapting and extending the approach.

The rest of this study is structured as follows. Section II presents related works on traffic prediction and interpretability. Section III explains the approach, starting from the description of the dataset preprocessing and predictive model, followed by LIME integration. Experimental results, visual analysis, and comparative studies are reported in Section IV, while the study is finally concluded in Section V, which describes future research directions.

II. Related Work

The field of traffic forecasting has undergone a significant paradigm shift over the last decade. Early methodologies primarily relied on classical statistical frameworks and econometric models, such as ARIMA and Kalman filters. While these approaches provided foundational insights into traffic patterns, they often struggled to account for the volatile, non-linear dependencies caused by heterogeneous factors like sudden weather shifts or large-scale urban events [7]. With the rise of "Big Data," researchers transitioned toward machine learning techniques, including Support Vector Machines (SVM) and Random Forests, to better capture these complexities. However, the most transformative leap occurred with the introduction of deep learning (DL). Architectures such as Convolutional Neural Networks (CNN) and Long Short-Term Memory (LSTM) [8] networks have demonstrated an unparalleled ability to model spatio-temporal dependencies, consistently achieving state-of-the-art performance across diverse real-world datasets. Despite these gains in predictive power, the "black-box" nature of deep neural networks remains a critical bottleneck. In the context of Intelligent Transportation Systems (ITS), raw accuracy is insufficient if the underlying logic is opaque. Traffic operators [9] require "trustworthy" systems that allow them to validate predictions and perform root-cause analysis before committing to high-stakes management decisions. To bridge this accountability gap, the emerging field of Explainable Artificial Intelligence (XAI) has introduced post-hoc interpretability tools [10]. Methods such as Local Interpretable Model-agnostic Explanations (LIME) have gained prominence for their ability to provide human-understandable justifications for individual model decisions without sacrificing the performance of the underlying complex model. This research builds upon this momentum, proposing a unified framework that integrates LIME with deep learning to provide the transparency required for modern, resilient urban mobility.

For traffic and mobility applications, explainability can reveal whether congestion forecasts are driven by time of day, weather, holiday status, or other contextual factors. Visual analytics approaches have also been developed to help domain experts understand congestion-influencing factors using explainable machine learning [15]. The present work contributes to this line of research by combining local LIME explanations with global feature importance in a transparent traffic-forecasting workflow.

III. Methodology

The predictive performance and interpretability of the traffic congestion prediction framework are emphasised. The system is built on four main components. The first is the dataset. The second is data preprocessing. The third is predictive modelling. The fourth is the use of LIME for interpretability. A reliable and reproducible approach to creating traffic prediction systems is provided by these components when used together.

A. Dataset

This study uses the Metro Interstate Traffic Volume dataset from the UCI Machine Learning Repository [12], which is publicly accessible. The data set contains hourly traffic volume counts for a section of the I-94 interstate highway in Minnesota, USA. It also includes context variable information to show factors affecting traffic flow.

Table I summarizes the main variables used from the Metro Interstate Traffic Volume dataset, including temporal, weather, contextual, and traffic-volume attributes.

TABLE I. The Main Dataset Variables

Variable	Description
Holiday	Indicator of public holiday status.
Temperature	Recorded in Kelvin.
Rain and Snow	Precipitation levels in millimetres
Clouds	Percentage cloud cover.
Date time	Hourly timestamp used to derive hour, day of week, month, and year.
Weather main and Weather description	General and detailed weather conditions.
Traffic volume	Target variable, representing the number of vehicles per hour.

The presence of meteorological, time, and contextual variables makes this dataset particularly well-suited for studying real-world traffic dynamics and prediction, which is a significant advantage.

B. Data Processing

The preprocessing pipeline was revised for clarity and reproducibility. First, the timestamp was converted to a datetime format and decomposed into hour, day of week, month, and year. Second, categorical variables such as holiday and weather conditions were encoded using one-hot encoding to avoid artificial ordinal relationships. Third, the target variable was separated from the explanatory variables. Fourth, the data were

divided into training and testing subsets using an 80/20 split with a fixed random seed. Finally, scaling was applied where required by the neural-network model and by the LIME prediction wrapper.

C. Prediction Model

To demonstrate interpretability, employ a Random Forest Regressor as the predictive model. Random Forests, an ensemble of decision trees, are robust against overfitting and capable of modelling complex nonlinear relationships. While not the most advanced option compared to deep neural networks, Random Forests serve as an effective and transparent example for integrating interpretability tools such as LIME. Importantly, because LIME is model-agnostic, the same interpretability process can be extended to deep learning architectures.

A neural network regressor is also evaluated on normalized congestion values. It is implemented as a feed-forward multilayer perception operating on the engineered tabular variables. The input layer corresponds to the number of preprocessed features, hidden dense layers learn non-linear interactions, and the output layer contains a single regression neuron. The network is trained using Mean Squared Error as the loss function and monitored through validation loss and Mean Absolute Error. This formulation is consistent with the reported training and validation curves and avoids presenting the Random Forest as a deep-learning model.

The two models are not used to claim state-of-the-art performance. Instead, they demonstrate that the same explanation framework can be connected to different predictive engines.

D. Deep Learning Network Architecture for Traffic Prediction

Deep learning has emerged as a transformative approach to traffic prediction. Models such as recurrent neural networks (RNNs) and convolutional neural networks (CNNs) are achieving state-of-the-art results. Recurrent Neural Networks (RNNs) and Convolutional Neural Networks (CNNs), which are achieving state-of-the-art results. These architectures excel due to their ability to capture spatio-temporal dependencies on traffic data, i.e., patterns that evolve over time and space. Long Short-Term Memory (LSTM) networks are well-suited to time series forecasting. By retaining information over long sequences, LSTMs can model long-term dependencies in traffic flow, which is a capability that traditional methods often lack.

Fig. 1 presents the overall workflow adopted in this study, starting from traffic data collection and verification, followed by data curation, feature extraction, analytical processing, prediction, and validation. This framework highlights the complete pipeline used to transform raw traffic-related data into interpretable forecasting output.

A typical LSTM-based setup receives sequential traffic data and learns to pick up on repeated patterns and trends in the data, which are then used to predict future traffic. Unlike the old ways of coping with prohibitive amounts of feature engineering, these networks learn relevant representations from raw data automatically. Such an ability to unveil hidden patterns in large data renders deep neural networks excellent instruments for intelligent transport systems (ITS), where timely and precise traffic prediction is important to improve road safety, reduce congestion, and optimize urban mobility.

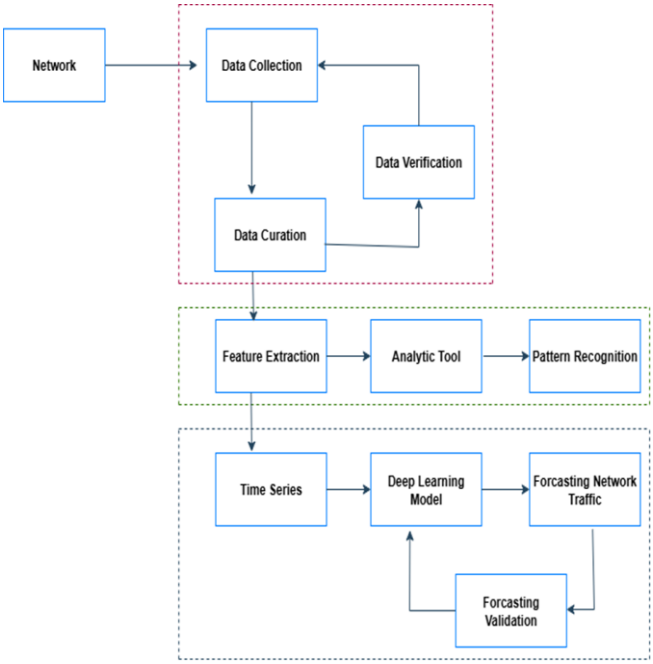

Fig. 1. End-to-end framework for traffic data collection, analysis, and prediction.

E. Lime Architecture

The primary idea behind LIME (Local Interpretable Model-agnostic Explanations) is to increase the transparency of complex models by creating interpretable, intuitive approximations for nearby individual predictions [11]. Unlike explaining the entire model globally, LIME addresses only a local neighborhood around a specific instance. The process begins by perturbing the input data point to create a set of nearby samples. The original model then makes predictions on the perturbed instances. From these predictions, LIME derives a sparse, interpretable model of ten times a linear regressor wherein the contribution of each sample is weighted by its proximity to the original instance.

F. Mathematical Problem Formulation

The primary objective of traffic congestion forecasting is to map a high-dimensional set of historical and contextual features to a continuous target variable representing future traffic volume. Formally, define the traffic state at a specific time interval t as $x_t \in R$ the task is to construct a predictive mapping function $f: x \rightarrow y$, where the input space $\mathcal{X}$ is composed of a multidimensional feature vector $\mathcal{V}_t$. This vector incorporates temporal attributes (hour, day, month), meteorological data (temperature, precipitation), and contextual indicators such as holiday status.

The forecasting model aims to minimize the discrepancy between the predicted volume $\hat{y}_t$ and the ground truth observation obtained from the Metro Interstate dataset. This is

achieved by optimizing a loss function, specifically the Mean Squared Error (MSE), defined as:

$$MSE = \frac{1}{n} \setminus \sum_{i=1} (y_i - \hat{y}i)^2$$

To ensure transparency, augment this predictive model with a local surrogate explanation model g . For a specific traffic instance x, the explanation $\xi(x)$ is derived by solving the following optimization problem:

$$\xi(x) = argmin_{g \in \mathbb{G}} \mathcal{L}(f, g, \pi x) + \Omega(g)$$

In this formulation, $L(f, g, \pi x)$ represents the fidelity loss, which measures how accurately the interpretable model g approximates the complex "black-box" model f within the local neighbourhood πx . The term $\Omega_{(g)}$denotes the complexity of the explanation, ensuring that the resulting insights remain human-interpretable. By minimizing this joint objective, the framework identifies the specific features such as heavy rain or peak commute hours that exert the most significant influence on a given congestion forecast [13].

The Fig. 2 Effect of LIME original prediction explained by fake data around the input instance fitted with a locally weighted interpretable model. While the example is shown for image prediction, applying this approach in the work to tabular traffic data can concisely explain individual congestion forecasts.

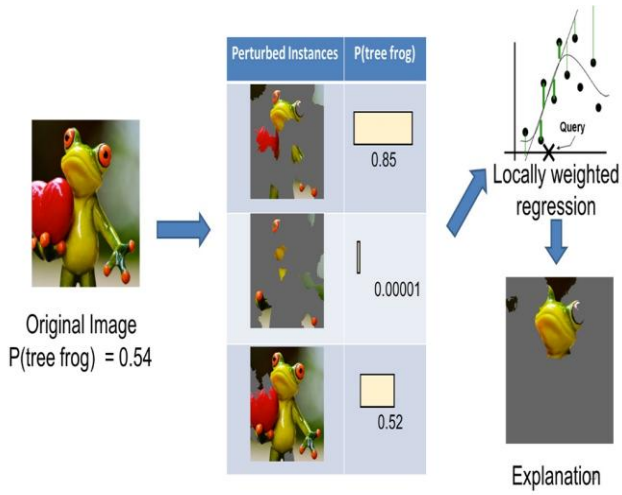

Fig. 2. Local Interpretable Model-Agnostic Explanations (LIME) applied to image predictions.

The coefficients of the surrogate model act as explanations, indicating which of the features contributed most to the prediction of the original model for that sample. In this way, LIME provides a localized, human-interpretable view of the reasoning of a "black box" model. Rather than giving an overall view, it illuminates decision-making in specific settings, giving practitioners valuable insight into why the model predicted the outcome in question.

G. Lime Integration

To address the "black box" nature of predictive models, integrate Local Interpretable Model-agnostic Explanations (LIME) into the framework. LIME provides local human-understandable explanations for individual predictions through the following procedure:

- Initialization: A LimeTabularExplainer instance is built using the training data, feature names, and the regression mode.
- Instance Selection: A representative instance from the test set is selected for explanation, allowing us to examine model reasoning for a specific traffic scenario.
- Prediction Function Wrapper: A custom predict fn raw function is defined. This wrapper takes raw feature inputs, scales them using the previously fitted StandardScaler, and then passes them to the trained DNN model for prediction.

This ensures that LIME interacts with the model in its expected scaled input space while generating explanations based on raw feature values.

IV. Explanation Generation

LIME perturbs the selected instance and evaluates the model's predictions on these variations. It then fits a simple interpretable model (e.g., a local linear model) to approximate the complex model's behaviour in the vicinity of the instance.

Through this process, LIME highlights the relative contribution of input features (e.g., weather, time of day, holidays) to a given prediction. These explanations make the model's reasoning more transparent, bridging the gap between predictive performance and interpretability in traffic management systems. The experimental evaluation highlights both the predictive performance of the model and the interpretability provided through LIME.

In addition to presenting standard performance metrics, include visual explanations that illustrate how different features contribute to traffic congestion predictions at both the local and global levels.

A. Model Evaluation

The revised evaluation separates raw-volume results from normalized-congestion results to avoid misleading comparisons. The Random Forest result is reported on raw traffic-volume units, whereas the neural-network result is reported on normalized congestion values. Therefore, the numerical values of the errors should not be compared directly unless the same target scale, preprocessing, and split are used.

TABLE II. Reported Model Performance

Model	Target Scale	Metrics reported	Interpretation
Random Forest Regressor	Raw traffic volume	MSE= 189,619.42	Baseline model and source of global feature importance.
Neural network regressor	Normalized congestion	R^2=0.612; MSE=0.026 MAE=0.129	Predictive model used for the reported training curves and local LIME explanations.

Table II presents the reported performance metrics for the Random Forest Regressor and the neural network regressor, while clarifying the target scale used for each model.

The neural network explains approximately 61.2% of the variance in normalized congestion values. Fig. 3 and 4 show that training and validation errors decrease over the training epochs, which indicates model convergence without a severe divergence between training and validation curves.

Fig. 3 shows the Training & Validation loss curves from model training. The gradual decrease in the curves indicates that the model learned the traffic pattern progressively. The training and the validation loss are rather similar (721 out of 884), indicating that the model converged well without any overfitting or very little evidence.

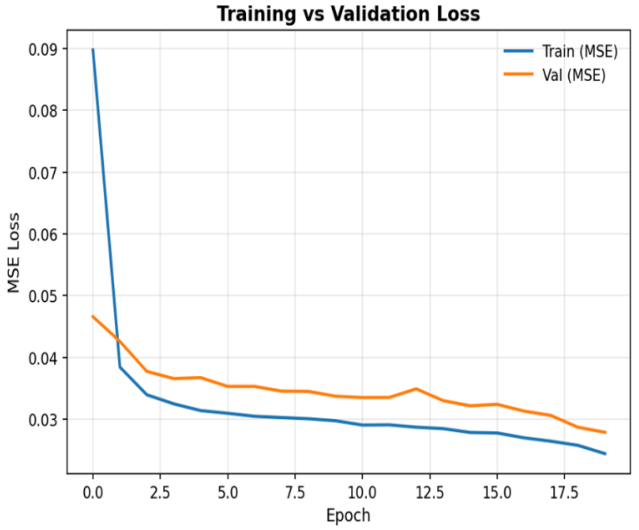

Fig. 3. Training and validation loss curves showing model convergence without overfitting.

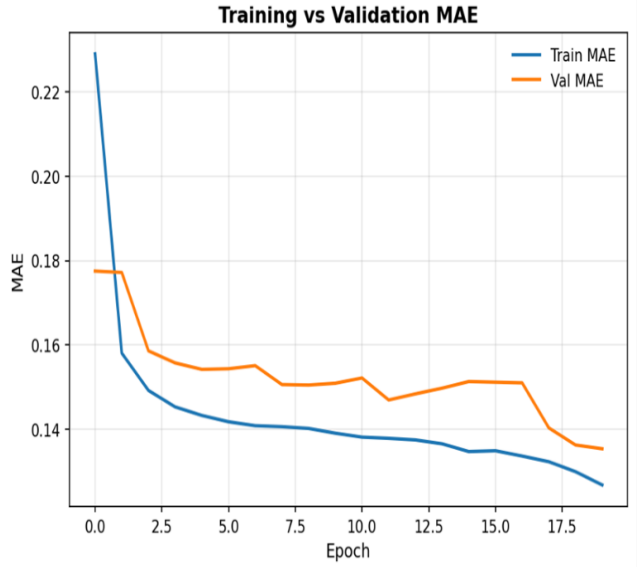

Fig. 4. Mean Absolute Error progression during training, demonstrating consistent improvement.

Fig. 4 shows the evolution of the Mean Absolute Error (MAE) during training and validation. The decreasing trend of both curves confirms that the prediction error was reduced over successive epochs. This behavior indicates that the model improved its forecasting capability as the training process progressed.

B. Prediction Accuracy Analysis

The predicted-versus-actual plot in Fig. 5 shows that predictions generally follow the diagonal reference direction, although dispersion remains visible. This confirms that the model captures a meaningful part of the congestion dynamics but also indicates that additional features, temporal lags, or more advanced architecture could improve prediction quality.

It's comparing the predicted congestion values to what was observed in the test set. The point distribution distributed around the diagonal reference line of the graph reveals that the model was able to reconstruct a general trend in traffic congestion. On the other hand, the dispersion of some points also indicates that due to those traffic conditions, there are corresponding prediction errors that require other interpretability tools to use, such as LIME.

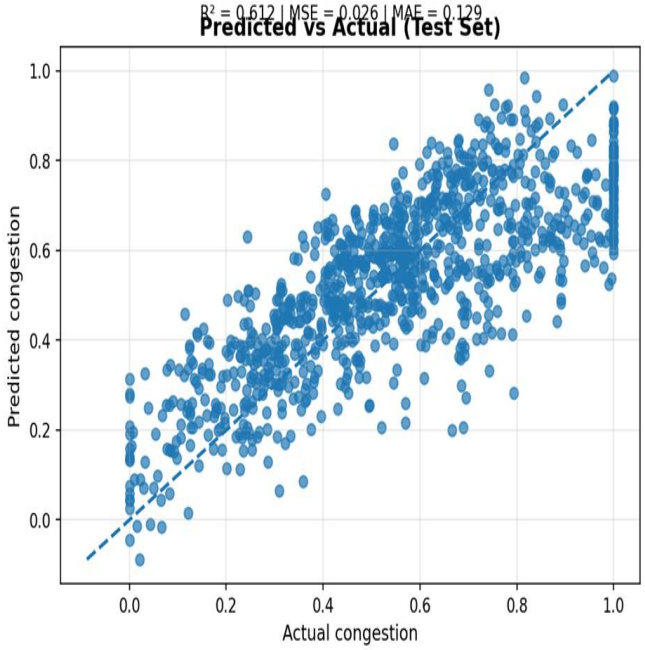

Fig. 5. Predicted vs. actual congestion values.

C. Residual Analysis

Residual diagnostics are presented in Fig. 6 and 7. The residual histogram is centered near zero, which suggests that the model does not show a strong average bias. The residuals versus predicted plot does not show a single linear systematic pattern, although the spread indicates that prediction errors vary across congestion levels. These diagnostics should be retained because they provide more information than aggregate metrics alone.

Fig. 6 shows the histogram of residuals (the gap between actual and predicted congestion values. Finding that the residuals mainly lie close to zero, indicating there is little global bias in the model. The nearly symmetric histogram also confirms that there are roughly as many overestimations as underestimations in the test set.

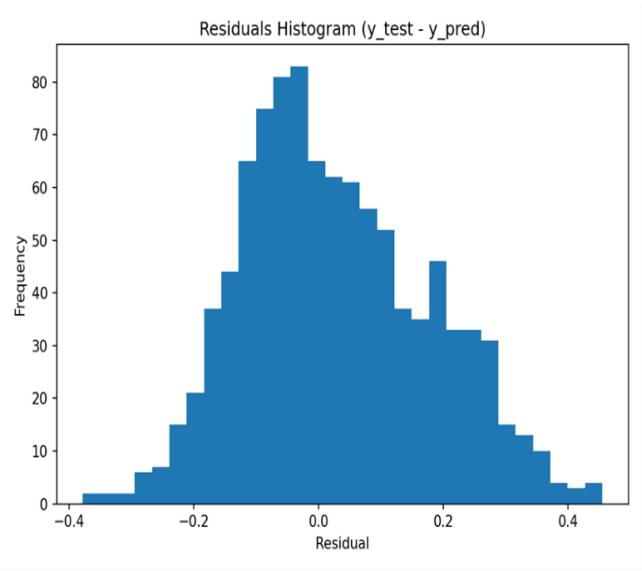

Fig. 6. Histogram of residuals showing approximately normal distribution centered at zero.

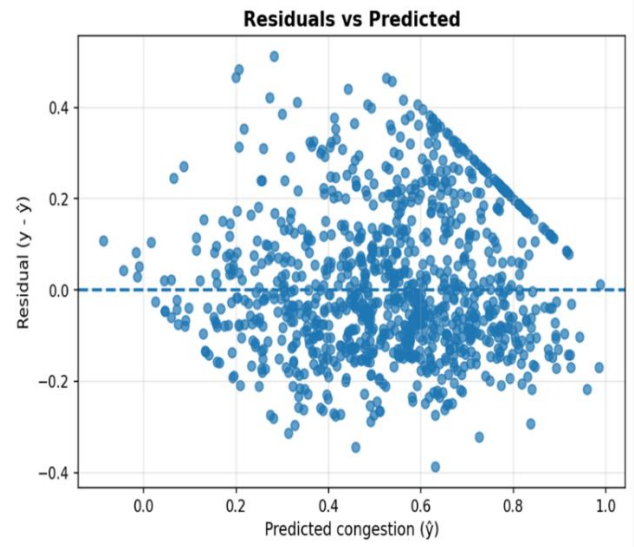

Fig. 7. Residuals vs. predicted values showing a homoscedastic pattern.

Fig. 7 shows the distribution of residuals with respect to the predicted congestion values. The absence of a clear systematic trend suggests that the model does not strongly overestimate or underestimate congestion within a specific prediction range. This supports the reliability of the prediction results, although some dispersion remains visible for medium and high predicted congestion values.

D. Local Explanations with LIME

To gain insight into individual predictions, LIME was applied to selected test instances. LIME produces bar plots that highlight the relative influence of features on a given prediction, with the bar's length and direction indicating the strength and sign of the contribution. Positive values increase the predicted traffic volume, while negative values decrease it.

LIME analysis provides crucial insights into feature importance for individual predictions:

Key Interpretability Findings:

- Day of Week (Dominant Factor): Shows the strongest negative contribution (-0.30), indicating weekends or specific days significantly reduce congestion prediction.
- Holiday Status: Secondary negative contributor (-0.15), confirming reduced traffic during holidays.
- Precipitation: Positive contribution (+0.08), suggesting increased congestion during rainy conditions.
- Temperature and Hour: Moderate influences on prediction, with temperature showing a slight negative impact and hour showing a minimal positive contribution.

Fig. 8 presents the local LIME explanation for the selected representative test instance. It shows which variables increase or decrease the predicted congestion value, thereby making the individual model prediction more transparent.

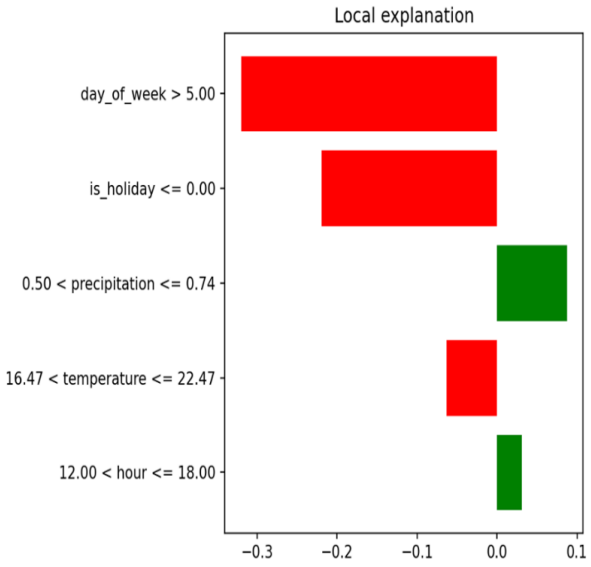

Fig. 8. LIME explanation for a representative test instance showing feature contributions.

Feature Interpretation;

- Red bars: Features decreasing congestion prediction
- Green bars: Features increasing congestion prediction
- Bar length: Magnitude of feature impact on this specific prediction

This LIME analysis demonstrates that temporal factors (day of week, holidays) are primary drivers of congestion prediction, while environmental factors (precipitation, temperature) provide secondary but meaningful contributions.

These local explanations make the model's decision-making process transparent, allowing practitioners to trace back a prediction to specific contributing factors.

Fig. 9 gives a more detailed local explanation for a single prediction with an estimated congestion value of 0.12. The result

confirms that LIME can identify the specific variables responsible for a given model output. In this instance, weekend-related temporal effects reduce the predicted congestion, whereas precipitation and afternoon timing slightly increase the forecasted value.

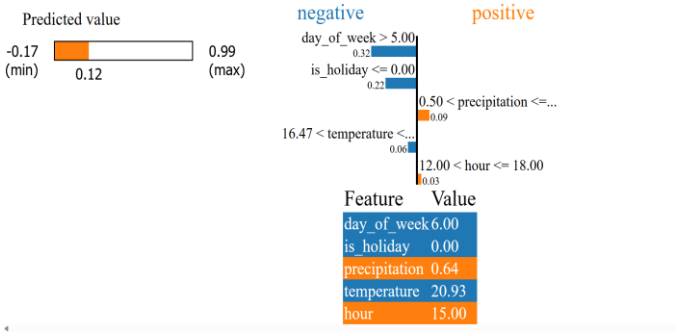

Fig. 9. LIME explanation of a single prediction (0.12), showing the local positive and negative contributions of temporal and weather-related features.

Analysis of the LIME explanation for a specific instance reveals a local prediction of 0.12, falling between a minimum value of -0.17 and a maximum value of 0.99. Factors with a significant negative impact on this prediction include the day of the week being a weekend (day 6.00, contributing negatively at 0.32) and the absence of a public holiday (isholiday 0.00, with a negative contribution of 0.22). A temperature above 16.47 (specifically 20.93) also has a slight negative effect (0.06). On the other hand, precipitation between 0.50 and a higher value (specifically 0.64) has a notable positive influence (0.09), as does the time of day between 12:00 p.m. and 6:00 p.m. (specifically 3:00 p.m.), with a positive contribution of 0.03. These results highlight the importance of weather conditions and timing in determining the model's prediction for this instance.

E. Global Feature Importance

Beyond individual predictions, it is also important to capture the global influence of features across the entire dataset. In Random Forests, feature importance is derived from the average reduction in variance contributed by each variable across all trees in the ensemble.

Fig. 10 presents the top 10 global feature importance rankings obtained from the Random Forest model. This global analysis complements the local LIME explanations by identifying the variables that most consistently influence congestion predictions across the dataset.

The top ten features identified included hour, temperature, and month, all of which consistently played a dominant role in shaping traffic patterns. This global feature importance ranking was visualized in a bar chart, showing which variables the model relies on most when generating predictions.

Together, the local explanations from LIME and the global feature importance analysis provide a complementary perspective. While LIME sheds light on why the model predicts a specific outcome in each context, feature importance summarizes the broader, dataset-wide drivers of congestion. This dual perspective not only improves transparency but also supports more informed decision-making in traffic management applications.

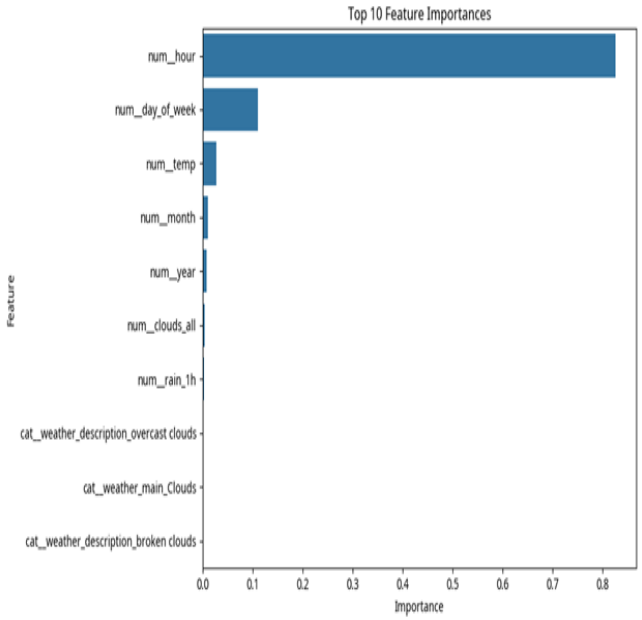

Fig. 10. Feature importance analysis for network traffic forecasting.

F. Positioning Against Related Work

Table III positions the results against representative studies. Direct numerical comparison is possible only when the same dataset, target scale, preprocessing pipeline, and temporal split are used.

TABLE III. COMPARISON WITH REPRESENTATIVE RELATED STUDIES

Study	Model or scope	Relation to this work
Lv et al. [7]	Deep learning for traffic-flow prediction using large-scale traffic data.	Supports the use of deep learning for non-linear traffic dynamics but uses a different dataset and setting.
Ma et al. [8]	LSTM model for traffic-speed prediction.	Shows the value of recurrent models for long-term temporal dependencies.
Polson and Sokolov [9]	Deep-learning architecture for short-term traffic-flow prediction.	Demonstrates the ability of deep models to capture traffic regime changes.
Li et al. [7]	DCRNN for graph-based traffic forecasting.	Addresses road-network spatio-temporal dependencies not modeled in the present single-station tabular setup.
Pranolo et al. [14]	LSTM and Bi-LSTM on the Metro Interstate dataset.	Provides a dataset-specific reference point; however, comparison requires identical preprocessing and splits.

G. Results and Discussion

The experimental results demonstrate that the deep learning framework effectively captures the complex dynamics of urban traffic, achieving an R^2 score of 0.612 and a Mean Squared Error (MSE) of 0.026. While these quantitative metrics confirm the model's predictive reliability, the integration of LIME provides a critical qualitative layer that moves beyond "black-box" forecasting. By decomposing individual predictions, identifying those temporal features, specifically the "Day of the Week," exerted the most significant influence on congestion levels, showing a strong negative contribution of -0.30. This suggests

that the model successfully learned the reduced commercial and commuter activity typical of weekends, allowing for more nuanced weekend-specific forecasts.

Furthermore, the model's sensitivity to environmental factors such as the positive contribution of precipitation (+0.08) indicates an accurate alignment with real-world traffic physics, where adverse weather typically reduces free-flow speeds and increases density. Unlike traditional global importance metrics, which provide a static view of the dataset, the local LIME explanations revealed that at specific peak hours, weather conditions can become the dominant driver of error if not properly accounted for. This dual-perspective analysis, combining global feature rankings with instance-specific explanations, equips traffic managers with the "reasoning" behind a forecast. Ultimately, this transparency transforms the AI from a mere prediction tool into a decision-support system that can be validated and trusted by human operators in real-time Intelligent Transportation Systems (ITS).

V. Conclusion and Future Work

This study successfully establishes a framework for integrating deep learning with Explainable AI (XAI) to resolve the "black-box" limitations of modern traffic forecasting. By developing a model that achieves a robust R^2 score of 0.612 demonstrates that high-fidelity predictive performance can coexist with technical transparency.

The integration of LIME provides a dual-layered interpretability that is essential for real-world deployment. On a local level, it empowers traffic managers to validate individual forecasts by identifying specific drivers such as the -0.30 impact of weekend temporal factors or the +0.08 influence of precipitation, allowing for targeted, data-driven interventions. Globally, the analysis confirms that variables such as the hour of the day and temperature remain the most consistent predictors of urban mobility patterns.

Ultimately, this research transitions AI from a mere forecasting tool into a trustworthy decision-support system. By providing the "reasoning" behind the numbers, this framework fosters the institutional trust required to implement safer, more efficient, and sustainable smart city infrastructures. Future work will focus on scaling these explanations to real-time dynamics and exploring the generalizability of this framework across more complex graph-based road networks.

Acknowledgment

The authors would like to thank the Faculty of Sciences Semlalia at Cadi Ayyad University for providing the research facilities and computational resources necessary to conduct this study. Also, thanks to Nabou Abdellah and Elikram Moulay Ahmed for their insightful feedback on the explainability framework and the application of LIME. Additionally, express gratitude to the anonymous reviewers for their constructive comments that improved the quality of this manuscript.

***Abstract*—With the fast enhancement of deep learning, research on automatic detection of breast tumors is becoming increasingly in-depth. However, traditional CNNs' linear kernel has difficulty not only in capturing the nonlinear combination of low-frequency structures and high-frequency details but also in fully exploring the nonlinear discriminative features in medical images. Furthermore, the current models used for breast tumor detection have complex structures and slow inference speeds. Therefore, this study solves the linear kernel problem and improves the model inference speed by using a lightweight mammographic image classification method based on KAN-CBAM to speed up breast cancer diagnosis. The proposed method introduces the KAN convolution module, which embeds a learnable B-spline activation function into the convolution kernel. This scheme improves the capability of the proposed method to capture nonlinear features and improves its capacity to fit complex, nonlinear distributions. Moreover, the proposed method combines the CBAM attention mechanism to screen key semantic channels through channel attention and then uses spatial attention to locate lesion areas, achieving "channel-space" dual feature recalibration, further improving the attention to key features, and achieving more accurate classification in complex and variable medical images. We evaluated the proposed method on the mammographic image datasets DDSM, INbreast, and MIAS to verify its performance. The results prove that KAN-CBAM models have higher adaptation to diverse dataset scales, efficiently acquiring major lesion parts and nonlinear discriminatory features in mammographic images. Meaningful and great enhancements were seen in different metrics such as accuracy, F1-score, AUC, precision, and recall, demonstrating extensively improved model strength and generalization capability.**

Keywords*—KAN; CBAM; deep learning; mammographic; classification

I. Introduction

A. Background of the Study

Breast cancer is one of the most common female fatal tumors characterized by abnormal proliferation of breast tissue and tumor formation. Its incidence rate exceeds even that of lung cancer, becoming the world's largest cancer [1][2]. Timely diagnosis of benign and malignant breast tumors allows for earlier treatment, thereby reducing patients' life risk and helping to decrease breast cancer mortality [3]. Therefore, the recognition of breast tumors is crucial to the judgment of breast cancer. Common breast imaging techniques include HP (Histo-Pathology), US (Ultrasound), MRI (Magnetic Resonance Imaging), DM (Digital Mammography), and mammography images [4], which serve important roles in the early identification of malignant lesions.

Currently, mammography is the only imaging modality widely recognized as suitable for large-scale screening of asymptomatic women and serves as the cornerstone of breast-cancer screening programs worldwide [5]. Because of its low cost and medical requirements, it has become one of the most widely used detection methods for breast cancer diagnosis [6]. In the context of breast cancer, a large number of researchers are committed to exploring strategies for classifying benign and malignant tumors [7]. In order to better detect and diagnose breast cancer cases on time, deep learning (DL) technology is a promising method for disease detection in the medical field. Compared with traditional image classification models such as Support Vector Machine (SVM) [8], Fuzzy Cognitive Map (FCM) [9], or Multi-Layer Perceptron (MLP) [10], deep learning techniques can automatically discover features in breast images that contain benign and malignant discrimination information, and have stronger breast feature extraction capabilities, such as convolutional neural networks (CNN) [11], which demonstrate powerful capabilities in image feature extraction. Based on CNN, various types of image classification models were constructed based on different learning algorithms [12]. Jafari, Z. et al. [13] proposed a CNN model based on feature extraction and dimensionality reduction for breast cancer detection in mammography images. According to the results, the method achieved better classification accuracy. Bouzar Benlab, L. et al. [14] proposed a new framework for breast cancer detection of breast X-ray images, called the CNN-CBR classification system. In order to improve the accuracy of CBR, the authors implemented image enhancement and data enhancement to optimize the effect of feature extraction. Efficiently obtaining regions of interest (ROI) in breast images through the U-Net architecture, this framework combines deep learning (DL) with CBR. Deep learning helps achieve accurate breast image segmentation, while CBR provides interpretable and accurate classification results. S. Majumdar et al. [15] combined three transfer CNN models, namely GoogleNet, VGG11, and MobileNetV3_Small, to solve the binary classification problem of breast tissue pathology images using the Gamma function. Moreover, J. G., T. Melekoodapattu et al. [16] designed an automatic diagnosis system for breast cancer. The system uses a CNN containing nine convolution layers to extract image texture features and then classify the extracted features. When extracting image-texture features, we reduce the dimension of breast-image representations layer by layer, thereby enhancing the expressiveness of the learned features and improving

breast-cancer diagnostic accuracy. In general, with CNN as the core, the automatic recognition accuracy and robustness of breast cancer images have been significantly improved through feature engineering, data enhancement, transfer learning, or fusion with traditional machine learning and other strategies.

Even though CNN-based image-feature techniques have achieved strong performance in medical imaging, the lesion regions in medical images exhibit highly complex characteristics. Existing neural networks based on fully connected layers still cannot solve the linear kernels problem, that is, the network has no perception in the spatial dimension and lacks nonlinear activation. The overall degradation is linear mapping, making it difficult to capture complex textures and deep semantics, and making it unable to effectively handle nonlinear classification problems of medical image data [17]. For this reason, the Kolmogorov-Arnold Network (KAN) has been applied to image-processing tasks [18]. Shi, Y et al. [19] have successfully integrated the U-KAN and C-KAN frameworks to address the challenge of medical image segmentation, accurately delineating anatomical structures and lesion areas, and providing a core basis for clinical decision-making. Omid Nejati Manzari et al. [20] embedded the KAN layer into Transformer to form a new framework and then proposed an enhanced Dilated Neighborhood Attention (DiNA) to achieve generalized medical image classification. Jianyun Liu et al. [21] devised a multi-scale feature-prediction network that first extracts feature maps via convolution, refines them with spatial attention, and finally sums the channels in a learnable Kolmogorov-Arnold layer to perform image classification.

B. Problem Statement

In the area of image processing, deep learning possesses substantial benefits, but the mainstream methods still have certain problems, mainly manifested as follows.

1) For CNN models, gradient degradation is prone to occur when the network deepens, making it difficult to fully capture global contextual information, and many model structures are complex.

2) CNNs can only represent linear mappings and are insensitive to higher-order statistics and texture information. In mammograms, however, malignant signs often manifest as higher-order distributions of texture and micro-calcification clusters. Relying solely on linear mappings makes it difficult to encode such high-order information into feature maps; additional nonlinear activations, pooling, or subsequent fully connected layers are required to partially compensate.

3) KAN adopts a fully connected topology, which has insufficient utilization of local priors in two-dimensional images and lacks spatial induction bias.

C. Objectives

To tackle these problems, this study proposes a KAN architecture enhanced with the Convolutional Block Attention Module (CBAM) [22] that successfully performs a three-class classification: benign, malignant, and normal. The main objectives are:

1) Introducing lightweight model(s) specifically designed for the classification of mammographic images is proposed.

2) Replacing the linear convolution kernels of traditional CNNs with KAN convolution kernels upgrades "fixed-weight linear filtering" to "nonlinear weight generation driven by learnable activation functions". This allows the model to conduct higher-order mapping modeling within convolution layers without increasing or even reducing the parameter scale, eliminating the parameter and computation explosion caused by subsequent stacking of multi-layer nonlinear activations and redundant channels.

3) Incorporating the CBAM technique into the convolutional layers based on KAN to build a new architecture, which is capable of adapting prominent regions in the images, efficiently reducing noise, extracting key local features, having faster convergence, and enhancing stability and accuracy.

This study integrates the advantages of the CBAM technique into the advantages of KAN-based models to build fusion models that inherit high feature extraction and strong interpretability, presenting successive architectures in the field of classification on mammography images. The new models are capable of adapting to images having different qualities, remarkably when facing images that are noisy and have low resolution, it still presents high accuracy and stability.

II. Related Studies

The proposed method embeds KAN's learnable univariate activation functions into the convolutional layer, instantiating nonlinear weights within the channel dimension to overcome the spatial insensitivity and limited expressiveness of conventional "linear kernels". CBAM further jointly produces attention coefficients across both channel and spatial axes, precisely highlighting diminutive lesions while suppressing background redundancy, thereby markedly elevating diagnostic accuracy and interpretability for mammographic images.

A. KAN

Kolmogorov-Arnold Network (KAN) equips each edge with a learnable activation function in place of conventional weights. Rather than fixed linear weights, KAN replaces every parameter with a univariate spline function. According to the KAN representation theorem, every continuous multivariate mapping can be decomposed into a collection of one-dimensional functions, as shown in Eq. (1):

$$f(X) = f(x_1, \ldots\ldots, x_n) = \sum_{q=1}^{2n+1} \phi_q \left(\sum_{p=1}^{n} \emptyset_{q,p}(x_p) \right) \quad (1)$$

In a sense, they proved that the only true multivariate function is addition, because all other functions can be expressed through unary functions and summation operations. In a KAN, for a supervised-learning task made up of input-output pairs $\{x_i, y_i\}$, finding a function f so that y_i is approximately equal to $f(x_i)$ for each data point. The crux is to discover the appropriate univariate functions, inner (encoders) and outer (decoders); the architecture is shown in Fig. 1 (in the Appendix) [23].

Every learnable nonlinear function is univariate, taking only one input. It is modeled as a B-spline curve ϕ(x) whose local-basis coefficients c_i are learnable. In KAN, unlike traditional MLP, the weight of each connection in KAN is no longer a simple numerical value but is parameterized as a learnable spline function. By representing ∅_(q,p) and ϕ_q through B-splines and composing these functions, the entire network is constructed.

Overall, KAN, as a novel neural-network architecture, has demonstrated remarkable advantages both theoretically and experimentally, especially in accuracy, parameter efficiency, and interpretability.

B. CBAM

The Convolutional Block Attention Module (CBAM) is a simple and effective feedforward convolutional neural network attention module, which is commonly used for embedded int CNN to enhance the feature extraction capabilities from images. Given an intermediate feature map, the module infers the attention of the image along two independent dimensions, channel and space, and then multiplies the attention map by the input feature map for adaptive feature refinement [24][25][26][27][28]. CBAM is a lightweight universal module that can be well integrated into the KAN architecture presented in this article, with negligible overhead. This attention mechanism amplifies salient features while suppressing irrelevant ones.

Fig. 2 (in the Appendix) presents the architecture of the CBAM technique. As seen in this architecture, CBAM comprises two independent segments: CAM (Channel Attention Module) and SAM (Spatial Attention Module). Given an input feature map $F \in R^{(C\times H\times W)}$, CBAM sequentially produces a 1-D channel-attention $M_c \in R^{(C\times 1\times 1)}$, and a 2-D spatial-attention map $M_s \in R^{(1\times H\times W)}$ [29]. The overall attention procedure is summarized in Eq. (2) and (3) [30]. The ultimate output of CBAM is acquired by multiplying the result of the channel attention output by the weight of spatial attention.

$$F' = M_c(F) \otimes F \tag{2}$$

$$F'' = M_s(F') \otimes F' \tag{3}$$

1) CAM: Chanel Attention Module (CAM) at the first step squeezes the spatial axes of the feature map and then models cross-channel dependencies to deliver a channel-attention map. For the aggregation of spatial information, it adopts two types of pooling: max-pooling and average-pooling, which greatly improve the network's expressive power. CAM first gathers the three-dimensional information of the feature map via average-pooling and max-pooling, producing two distinct spatial-context descriptors, F^c_{avg} and F^c_{max}. These summaries are then fed to a single Multilayer Perceptron (MLP) subnet that outputs the channel-attention map $M_c \in \{\mathbb{R}^{c\times 1\times 1}\}$. The equation for calculating CAM is presented in Eq. (4) [26]. σ represents the Sigmoid function, W_0 represents the dimensionality reduction weight matrix with a shape of (c/r)×c, and W_1 represents the dimensionality enhancement weight matrix with a shape of c×(c/r), where r is considered the rate of reduction and the default value is 16.

$$\begin{aligned} M_c(F) &= \sigma(MLP(AvgPool(F) + MLP(MaxPool(F))) \\ &= \sigma(W_1(W_0(F^c_{avg})) + W_1(W_0(F^c_{max}))) \end{aligned} \tag{4}$$

2) SAM: Spatial Attention Module (SAM) multiplies CAM's channel attention by the input feature map to get SAM's input feature map. Spatial attention is different from channel attention, as it focuses on the type of information within a Feature Map and complements channel attention. Use two *channel=c* pooling operations to aggregate the channel information of feature maps, generating two 2-D feature maps. Each feature map aggregates channel information, representing the average and max-pooling characteristics across channels. Then use a standard convolutional layer to connect and convolve them to generate a 2-D spatial attention map, with the calculation shown in Eq. (5).

$$\begin{aligned} M_s(F) &= \sigma(f^{7\times 7}([AvgPool(F); MaxPool(F)])) \\ &= \sigma(f^{7\times 7}([F^s_{avg}; F^s_{max}])) \end{aligned} \tag{5}$$

Finally, a 7×7 convolution is applied to produce the spatial-attention matrix. Then, the sigmoid function converts the response map into spatial-attention weights, called the spatial attention map $M_s(F)$. Finally, the input feature map with the channel attention mechanism is element-wise multiplied by the output $M_s(F)$ to obtain the result of CBAM.

III. Methodology

This study proposes a lightweight model for mammographic image classification based on KAN-CBAM. By leveraging KAN, the network overcomes the nonlinear-classification bottlenecks of image processing while remaining highly interpretable. To further enhance feature extraction, we embed the CBAM attention mechanism inside every KAN convolutional layer, which not only helps the model converge faster but also helps extract more useful image features, focus on discriminative features, and make classification more accurate. Fig. 3 (in the Appendix) illustrates the overall architecture of KAN-CBAM.

The proposed framework is a convolutional neural architecture that combines the KAN and CBAM mechanisms. It consists of two convolutional blocks (Conv Block) and one classifier. Each Conv Block performs two key operations, namely KAN convolution and CBAM. The result from Conv Block 1 is channeled into Conv Block 2 through a residual connection, which helps address the vanishing gradient problem in deep networks and enhances the integrity of feature propagation. Finally, the Classifier module converts the extracted features into class probabilities via fully connected layers, batch normalization, and Dropout, completing the classification task.

Due to the introduction of KAN-enhanced feature extraction, combined with CBAM-enhanced feature selection and the use of residual learning to alleviate gradient degradation, the proposed model improved representation ability while reducing redundancy. Finally, it was validated on the dataset, achieving efficient and high-precision image classification.

A. KAN Convolution

According to Fig. 3, the KAN-Convolutional Layer is located in Conv Blocks. The KAN convolutional layer extracts features with its unique function approximation ability, providing more expressive initial feature maps for subsequent processing.

KAN convolution is a special convolution operation that applies a learnable nonlinear function to each edge and adds them together. Every weight is recast as a univariate spline function, and nodes merely add up the input signals without using nonlinear operations.

Traditional CNNs mainly depend on set activation functions and linear transformations to capture spatial relationships. Although this design effectively handles complex spatial data, it lacks sufficient flexibility and expressiveness. By directly replacing the nonlinear activation function of KANs in the convolutional layer, KAN convolutional layers can be constructed. KANs reduce the number of parameters and may improve generalization ability by introducing learnable spline functions, B-splines. This new layer type not only maintains the efficiency of CNN in processing image data but also enhances its flexibility and expressiveness through the spline function of KANs.

In KAN convolution, the spline is constructed primarily from B-spline basis functions, as given in Eq. (6), where $B_i(x)$ represents a B-spline basis function, and c_i is a learnable coefficient that controls the weights of the basis functions. The spline is constructed by linearly combining multiple local basis functions, and the parameters that KAN truly needs to learn are the coefficients c_i in front of the basis functions. By adjusting the parameters of the spline, it can adapt to different data distributions and task requirements.

$$spline(x) = \sum_{i=1}^{n} c_i \cdot B_i \quad (6)$$

B. KAN-CBAM Model

To enhance the automatic focusing ability of KAN convolutional layers on discriminative regions and channels, the model inserts the Convolutional Block Attention Module (CBAM) after KAN convolution to form KANConv-CBAM units. CBAM applies channel and spatial dimension attention weighting to the feature maps of channels 4 and 8, respectively, highlighting key features, suppressing irrelevant information, and enhancing the effectiveness of feature expression.

The channel attention structure is shown in Fig. 4 (in the Appendix), which chiefly employs channel management among features to create channel attention maps. In the module, the input feature map F, which has dimensions of C×H×W, experiences both global max-pooling and global average-pooling operations. Specifically, global max-pooling is carried out along the W dimension, while global average-pooling is performed along the H dimension. Consequently, two feature maps with dimensions of C×1×1 are acquired. These maps are subsequently input into a 2-layer MLP, in which the output features are aggregated and sigmoid-activated to produce the final feature.

The architecture of the spatial attention module is shown in Fig. 5 (in Appendix), which generates a spatial attention map using the spatial relationships between features, focusing on where the information is located. This module utilizes the feature map, which is the output of the Channel Attention Module, as its input. The feature map undergoes average-pooling and max-pooling operations to obtain two feature maps. Next, the two feature maps are merged in the channel dimension and connected and convolved using a standard convolution layer to obtain a 2-dimensional spatial attention map. Finally, the sigmoid function is used to achieve spatial attention features.

This spatial attention map reflects the importance of different spatial positions in the feature map. It is then element-wise multiplied by the channel-attended feature map, spatially re-weighting the activations so that salient locations are emphasized.

IV. Results and Discussion

This section first introduces the datasets and then presents the experiment parameters. Ultimately, the results of the experiment are compared and analyzed to confirm the effectiveness of the algorithm proposed in this study.

A. Datasets

This study mainly selects to validate the model using the public datasets: DDSM, which includes 5,238 images, INbreast, which includes 13,172 images, and MIAS, which includes 322 images. These datasets are mainly divided into three categories: normal, benign, and malignant. Each dataset was partitioned with an 80/20 split for training and testing.

Through analysis of the datasets, it is known that there are many images with inconsistent resolutions, noise interference, and significant differences in image size and shape, as shown in Fig. 6 (a),(b), and(c) (in Appendix). However, the proposed method effectively overcomes these problems in the dataset and efficiently completes the image classification task.

B. Experimental Environment

To verify the effectiveness of this project, validation was conducted on a laptop computer and in the hardware environment as listed in Table I.

TABLE I. Hardware Environment Parameters

Hardware	Parameters
GPU	NVIDIA T600
RAM	32.0 GB
Storage	2TB
CPU	Intel Core i7-11700 @ 2.50GHz

C. Experimental Results

1) Major metrics comparison: This study primarily employs accuracy, loss, F1-score, Recall, and AUC as major evaluation metrics to verify the performance of the model. It mainly compares the classification performance of seven KAN-based models and KAN-CBAM models enhanced with the CBAM. Table VI (in the Appendix) presents the

classification results of the seven KAN-based models, while Table VII (in the Appendix) shows those of the seven KAN-CBAM models. In the tables, "M" stands for Medium, "B" stands for Big, and "S" stands for Small.

Experimental results in Table VI and Table VII (in the Appendix) indicate KAN-CBAM-based models exhibit superior performance – especially regarding accuracy, F1 score and AUC – compared to KAN-based models among the three datasets.

On the DDSM dataset, in KAN-CBAM-based models, KANC MLP (B) is the superior model, presenting values 84.85%, 84.01%, and 85.87% regarding accuracy, F1-score, and AUC, respectively, while in KAN-based models, KKAN (M)is the superior model, showing values 84.04%, 83.09%, and 84.15%.

On the INbreast dataset, in KAN-CBAM-based models, KKAN (M) is the superior model, presenting values of 99.66%, 99.64%, and 99.70% regarding accuracy, F1-score, and AUC, respectively. In KAN-based models, KANC MLP (B) is the superior model for accuracy and F1-score, showing values 98.90% and 98.82%, respectively, while KANC MLP (M) is the superior model for AUC, having a value of 99.62%.

On the MIAS dataset, in KAN-CBAM-based models, KKAN (S) is the superior model regarding accuracy and AUC, having values of 85.00% and 79.21%, respectively, and KANC MLP (M) is the superior model regarding F1-score, having a value of 83.33%. In KAN-based models, KKAN (S) is the superior regarding accuracy, F1-score, and AUC, having values of 75.00%, 49.36%, and 59.21%, respectively.

2) AUC comparison: To evaluate the effect of the CBAM technique on the KAN-based models, AUC values of all KAN-based models were compared with corresponding KAN-CBAM-based models for DDSM, INbreast, and MIAS datasets separately. Fig. 7 (in Appendix), Fig. 8 (in Appendix), and Fig. 9 (in Appendix) present AUC comparison on DDSM, INbreast, and MIAS datasets, respectively.

As Fig. 7 shows, for the DDSM dataset, generally, KAN-CBAM-based models accomplished higher AUC values compared to KAN-based models. The most enhancement was for the KANC (M) model, in which the AUC value increased from 51.27% to 81.13%, introducing a strong improvement in discriminative potential after integrating the CBAM technique. Further enhancements were also seen for KAN (M), KAN (S), KANC (B), KANC (S), and KKAN (S). Only KKAN (M) presented a trivial reduction in AUC.

For INbreast dataset, KAN-based models and KAN-CBAM-based models both made high AUC values, signaling that this dataset is extremely separable for most models. Therefore, the differences in AUC values between KAN-based models and KAN-CBAM-based models are quite small.

For the MIAS dataset, the contribution of the CBAM technique was the brightest, since all KAN-CBAM-based models overtook their relevant KAN-based models. The largest increases in AUC were seen in KANC (B), KANC (S), KKAN (M), and KKAN(S), indicating that the CBAM technique affected highly feature enhancement and class discrimination on this dataset.

Taken together, AUC analysis shows that generally the CBAM technique enhances discriminative performance, with the highest effect seen on the MIAS dataset, followed by the DDSM dataset, while on INbreast dataset, the contribution of CBAM is trivial due to the existence of high reference performance.

3) Loss comparison: A comparison was performed over loss values of KAN-based models and KAN-CBAM-based models, since smaller loss indicates better optimization behavior. Fig. 10 (in Appendix), Fig. 11 (in Appendix), and Fig. 12 (in Appendix) present the loss comparison of DDSM, INbreast, and MIAS datasets, respectively.

For the DDSM dataset, generally, KAN-CBAM-based models present lower loss values compared to relevant KAN-based models. The largest reduction was seen for KANC (M), in which the loss value dropped from a value of 0.0291 to a value of 0.0115. Another large reduction was seen for KKAN (M), in which the loss decreased from a value of 0.0118 to a value of 0.0030.

For INbreast dataset, KAN (M), KAN (S), and KANK (S) introduced slightly lower loss values without the CBAM technique, while KANC (M) showed a large improvement after the incorporation of the CBAM technique. For the remaining models, the differences were trivial or zero.

For the MIAS dataset, the effect of the CBAM technique was not consistent. A small reduction was seen for KAN (M), whereas KKAN (M and KKAN (S) persisted unchanged. All other models presented trivial growth in loss value after the integration of the CBAM technique. This specifies that the effect of CBAM on loss optimization is architecture-dependent.

Overall, loss analysis shows that the CBAM technique presents the strongest optimization on the DDSM dataset, while its effect on INbreast and MIAS datasets is not consistent and depends on model configuration.

4) Other metrics comparison: Precision, specificity, and Matthew Correlation Coefficient (MCC) capture complementary aspects and attributes of analytical reliability which are not exhibited by accuracy, F1-score, recall, AUC, and loss.

Precision is important since it shows the ratio of predicted positive samples that are truly identified as positive. In this study, greater precision shows smaller false positive predictions, thus helping decrease unnecessary follow-up tests and patient fear and anxiety.

Specificity shows the ratio of predicted negative samples that are truly negative, indicating the model's capability to prevent falsely classifying normal cases or benign cases as abnormal.

MCC presents a well-adjusted summary of the performance of the classification by considering four parameters in the confusion matrix: true positive, false positive, true negative,

and false negative. The summary presented by MCC is helpful when a complete view of the reliability of a model in classification is needed.

To prevent an extremely long presentation, precision, specificity, and MCC are summarized as average values shown in Table II.

As Table II shows, generally, KAN-CBAM-based models attain larger average values than KAN-based models within all three metrics (precision, specificity, and MCC) across all datasets. This supports the idea that the integration of the CBAM technique not only enhances discrimination performance but also increases the reliability of the classification.

5) Delta analysis: To have a better numerical understanding of the effect of the CBAM technique, the absolute changes between each KAN-based model and the corresponding KAN-CBAM-based model were computed for AUC and loss. It should be noted that a positive value for ΔAUC means that the CBAM technique enhanced discriminative performance, while a negative value for ΔLoss means that the CBAM technique lowered the loss value, hence enhancing optimization behavior. Tables III, IV, and V present absolute changes after the inclusion of the CBAM technique on DDSM, INbreast, and MIAS datasets, respectively.

The values in the delta analysis support the values in the bar charts presented earlier. On the DDSM dataset, the CBAM technique enhances most models, while the largest benefit is seen for KANC (M). On INbreast dataset, the contribution of CBAM was minor and somewhat mixed, which is likely associated with the high existing performance of KAN-based models. On the MIAS dataset, all models gained from the CBAM technique in terms of AUC, implying a consistent positive effect of architecture-based feature enhancement on this dataset.

The values related to ΔLoss also prove that enhancements in AUC are not always consistent with reductions in loss. For instance, CBAM showed a large loss reduction on the DDSM dataset, whereas its effect on MIAS and INbreast datasets was dependent on the model's architecture. This proposes that the contribution of the CBAM technique is not solely optimization-driven but also relevant to how successfully the attention process improves discriminative feature interpretation.

TABLE II. SUMMARY OF PRECISION, SPECIFICITY, AND MCC

Dataset (Model based)	Avg. Precision	Avg. Specificity	Avg. MCC
DDSM (KAN)	0.734	0.747	0.484
DDSM (KAN-CBAM)	0.800	0.813	0.604
INbreast (KAN)	0.876	0.969	0.864
INbreast (KAN-CBAM)	0.974	0.989	0.970
MIAS (KAN)	0.414	0.553	0.141
MIAS (KAN-CBAM)	0.813	0.831	0.616

TABLE III. ABSOLUTE CHANGE AFTER CBAM INTEGRATION ON DDSM DATASET

Model Pair	ΔAUC	ΔLoss
Conv & KAN (M)	+0.0712	-0.0009
Conv & KAN (S)	+0.0308	-0.0005
KANC MLP (B)	+0.0358	-0.0006
KANC MLP (M)	+0.2986	-0.0176

D. Summary of Performance Indicators

The results show that the inclusion of the CBAM technique generally enhances KAN-based models' performance within the datasets considered. This matter is strongly confirmed not only by AUC, loss, and delta analyses, but also by other metrics such as precision, specificity, and MCC. Overall, the findings denote that the CBAM technique offers not only higher discriminative capability but also greater enhancement in classification reliability.

V. CONCLUSION AND FUTURE WORKS

This study worked on the effect of the CBAM technique by comparing KAN-based and KAN-CBAM-based models on the three datasets – DDMS, INbreast, and MIAS – including breast cancer images.

The results indicated that incorporating the CBAM technique enhances performance, especially regarding AUC, in which the most consistent benefits were seen on the MIAS

dataset, and high enhancement was found on the DDSM dataset, whereas the improvement was trivial on INbreast dataset, since most of the models already attained very high performance.

Based on the results of the loss analysis, the contribution of the CBAM technique to optimization likely depends on the architecture and the dataset. The highest loss reduction was seen on the DDSM dataset, whereas the impacts on the MIAS and INbreast datasets were mixed. Moreover, the results regarding precision, specificity, and MCC confirmed the advantage of integrating CBAM into the models studied.

In future studies, the models studied can be assessed under other testing settings and on other medical datasets. In addition, future studies can integrate robustness analysis and statistical significance testing over explanatory models to have a better evaluation of CBAM and its effects.

Enhancing Virtual Team Performance Through a Quantitative-Based Management Model (VTPM)

Sathya A/L Nantha Kumar, Zulkefli Mansor
Faculty of Information Science and Technology,
Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia

***Abstract*—The rapid growth of globalization, digital transformation, and remote working practices has significantly increased the reliance on virtual teams within modern organizations. Despite their advantages, virtual teams continue to face challenges such as communication barriers, inadequate technology management, unclear role allocation, ineffective strategic planning, and excessive documentation practices, all of which negatively affect team performance. This study aims to identify the key factors affecting virtual team performance and to develop a structured Virtual Team Performance Management (VTPM) model to improve the effectiveness of virtual collaboration. A quantitative research approach was adopted, involving questionnaire-based data collection with 110 respondents who had worked in virtual teams (instrument reliability testing was conducted using Cronbach's Alpha analysis). The findings indicate that role clarity, effective communication, effective strategic planning, task allocation, and appropriate management of technology are important in the determination of the performance of virtual teams. Specifically, 39.1% of respondents rated communication as "needs improvement," 63.6% agreed that excessive documentation reduces efficiency, and 56.4% strongly agreed that strategic planning is effective. On this premise, the Virtual Team Performance Management Model (VTPM) has been constituted and validated by three academic and industry experts through expert evaluation. The model received positive evaluations from academic and industry experts regarding its practicality and relevance in virtual team environments. This study provides a comprehensive and empirically informed model that organizations can apply to improve the work of virtual teams.**

***Keyword*—Virtual teams; team performance; remote work; VTPM model; communication; quantitative study**

I. Introduction

The latest dramatic shifts to digital technology and overwhelming effects of globalization have created and triggered the enormous application of virtual teams, groups of people that are physically separated and communicate using digital media. This change was also triggered by the onset of the COVID-19 pandemic [7], [32]. Among these advantages, virtual teams introduce the following, which include flexibility, access to global talent, and reduced cost of operation [32]. Nevertheless, they suffer significant performance challenges, which consist of communication barriers, leadership challenges, and the overuse of digital and asynchronous tools [5], [19], [32], the ambiguity of the roles that lead to the undermining of accountability [11], [43], which is determined by the absence of technology use or insufficient training [42]. Other than this, the absence of systematic strategic planning can lead to long delays in the processes and ineffective communication [22].

Scope boundary of the VTPM model: The VTPM model is empirically informed for technology-mediated, task-oriented virtual teams operating in corporate, public, and academic sectors. It assumes stable internet connectivity, basic digital literacy among team members, and the use of standard collaboration tools (e.g., Microsoft Teams, Zoom, Slack). The model may not be directly applicable to purely social virtual communities, emergency response teams, highly creative design teams where unstructured communication is critical, or teams in low-connectivity environments without adaptation. Fig. 1 illustrates the key challenges affecting virtual team performance identified from the literature review and empirical observations.

Fig. 1. Key challenges affecting virtual team performance.

Despite the numerous models of performance, a large part of performance models has not been empirically informed and has no implication to be applied practically to virtual teams in the actual real-life context [22], [27]. In one of the attempts to fill this knowledge gap, the suggested research offers the Virtual Team Performance Management Model (VTPM). The model is aimed at fulfilling three clear objectives, namely, to recognize the issues of virtual teams, to recognize the key factors that influence their performance, and to develop a management framework supported by empirical findings, based on the received results.

II. Literature Review

Virtual teams operate across geographical and cultural boundaries using digital tools [4]. Their outcomes depend on interconnected factors including communication, technology,

leadership, and trust. This review synthesizes existing literature to establish a theoretical foundation for the Virtual Team Performance Management (VTPM) model, identifying key performance determinants, challenges, and limitations of existing frameworks.

A. Key Determinants of Virtual Team Performance

Communication drives coordination and trust in virtual teams through message clarity, appropriate frequency, open dialogue, and responsive leadership [1], [16], [20], [48]. Mismatches between message medium and task type create problems because complex issues require real-time discussion [38]. Effective communication demands both technical access and relational competence across diverse team backgrounds [18].

Technology management directly impacts performance through tool adequacy, availability, reliability, and user competence [12]. High-performing teams integrate communication, collaboration, and project management systems [25]. Post-deployment training gaps remain common [23], and inadequate tools and information-sharing practices generate both delays and psychological burden in agile virtual teams [24], [32].

Role clarity is essential where informal cues are absent. Ambiguity causes duplicated work, missed tasks, and interpersonal conflict [43]. Defined positions enhance coordination, productivity, and confidence [43], requiring leaders to articulate and revisit responsibilities regularly, particularly in agile software development contexts [15].

Strategic planning in distributed work demands explicit task breakdowns, visible priorities, and established deadlines [22]. Strategic planning encompasses goal setting, activity prioritization, and ensuring members understand their role in the broader project context [47]. Effective planning reduces communication waste; excessive messaging often signals poor planning rather than active collaboration [31].

Documentation preserves organizational memory, retaining decisions and enabling continuity [45]. Quality records enhance transparency and accountability [46], while poor recordkeeping creates operational failures. Performance monitoring, when oriented toward process improvement rather than surveillance, enables early problem identification and works most effectively when integrated with documentation practices [41].

Trust develops through demonstrated reliability and competence [13], requiring structured and consistent management practices in virtual settings where face-to-face interaction is limited [43].

B. Existing Models and Their Limitations

Several models have attempted to address virtual team management, as summarized in Table I.

Despite their contributions, existing models suffer from three common limitations: they lack empirical support, cannot be readily operationalized into actionable management practices [39], or fail to integrate multiple performance determinants simultaneously [22], [27]. Recent studies also highlighted that agile transformation and knowledge management practices influence collaboration, project values, and team coordination within virtual project environments [33], [34].

TABLE I. COMPARATIVE ANALYSIS OF EXISTING VIRTUAL TEAM MANAGEMENT MODELS

Model	Weakness	Comparison / Contribution
Kauffmann & Carmi [23]	Limited attention to collaboration tools and cultural diversity	Emphasizes communication and team integration
Iyamu & Adelakun [22]	Limited practitioner involvement	Focuses more on collaboration than overall team performance
Lumseyfai [27]	Based on a single organizational context	Integrates human interaction, technology, and governance
Holtz [21]	Lacks feedback and leadership communication elements	Highlights engagement and emotional management
Wei [42]	Limited focus on collaboration technologies	Emphasizes team diversity and communication processes
Garro-Abarca [19]	Limited attention to tools and technology management	Highlights communication and trust in team performance

C. Research Gap and Study Contribution

The literature establishes that virtual team performance depends not on geographical distance but on coordinated management practices. Performance is a multidimensional phenomenon requiring integrated attention to communication, technology, planning, documentation, and role clarity. However, no existing model provides an empirically informed, practically operationalizable framework that addresses all these dimensions together.

This study fills this gap by developing the Virtual Team Performance Management (VTPM) model, a systematic, empirically supported framework designed to enhance virtual team performance through integrated management of communication, technology, strategic planning, documentation, and role clarity.

III. METHODOLOGY

This study employs a quantitative research methodology to investigate factors influencing virtual team performance and to develop a structured management model. The methodology is structured into four main phases: theoretical study, empirical study, model development, and model validation.

A. Research Design

A quantitative research design was adopted to allow the organized collection of data and statistical analysis [2]. The four-phase approach consists of: 1) a literature review to determine the issues of interest, 2) an empirical investigation (through a questionnaire- Appendix), 3) the development of the Virtual Team Performance Management Model (VTPM), and 4) expert validation of the model. Fig. 2 illustrates the four-phase research methodology adopted in this study. This is done to make sure that the model is conceptually grounded and quantitatively supported.

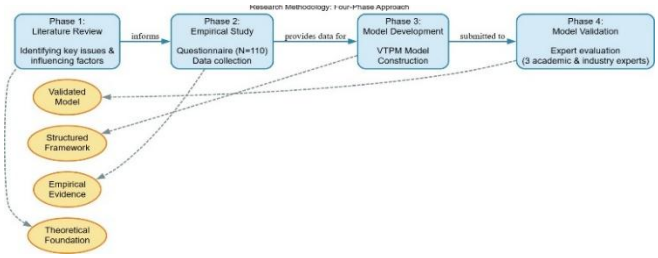

Fig. 2. Four-phase research methodology.

A. Population and Sampling

People with experience in virtual teamwork in different industries were the target population. With the purposive sampling technique, 110 respondents were sampled in the study, and this was considered sufficient to provide a statistical description and a valuable understanding of virtual team practices [43]. The study involved 110 respondents selected using purposive sampling techniques. The sample size was considered sufficient to identify patterns, trends, and perceptions related to factors affecting virtual team performance.

B. Data Collection Instrument

Data were collected via a structured questionnaire developed from the literature review, covering demographics, communication effectiveness, technology management, strategic task planning, role clarity, and documentation practices. All items were measured on a five-point Likert scale to quantify perceptions and support analysis.

C. Instrument Validation and Reliability

The questionnaire was subjected to content validation to ensure that the constructs were measured appropriately and to support reliable statistical analysis of questionnaire data [2], [44]. A pilot study involving 33 respondents was conducted to evaluate the reliability of the research instrument using Cronbach's Alpha analysis through SPSS. The reliability analysis demonstrated acceptable internal consistency across all constructs. The Communication Management construct recorded a Cronbach's Alpha value of 0.829; Technology Management recorded 0.704; Strategic Planning and Effective Task Allocation recorded 0.726; Documentation recorded 0.775; and Role Clarity recorded 0.773. These values exceeded the acceptable threshold of 0.70, indicating satisfactory reliability and suitability of the instrument for quantitative data collection and analysis. Table II presents the reliability analysis results obtained from the pilot study using Cronbach's Alpha.

D. Data Analysis Techniques

The frequency distribution, percentage analysis, and mean score analysis of the virtual team were employed as descriptive statistical tools to identify patterns and examine factors affecting virtual team performance. The analysis focused on identifying patterns, respondent perceptions, and commonly observed factors influencing virtual team performance.

TABLE II. RELIABILITY TEST RESULTS OF PILOT STUDY

Section	Construct	Number of Items	Sample Size	Cronbach's Alpha
A	Demographic Information	13	33	-
B	Communication Management in Virtual Teams	15	33	0.829
C	Technology Management in Virtual Teams	14	33	0.704
D	Strategic Planning and Effective Task Allocation	5	33	0.726
E	Documentation	3	33	0.775
F	Role Clarity	4	33	0.773

E. Model Development

VTPM model was constructed out of the identification of the key factors found in the literature and empirical evidence as core components: communication management, technology management, role clarity, strategic task planning, and documentation. The interdependence of these elements is what constitutes the model structure.

F. Model Validation

Three academic and industry professionals evaluated the relevance, effectiveness, and applicability of the proposed model through expert evaluation. The analysis indicated that the model is realistic and applicable in the practical management of virtual teams.

G. Ethical Considerations

Participation was voluntary, and none had to engage in the research without their consent; they were made aware of the purpose of the research, and all information was kept confidential and was to be used in an academic context only.

H. Summary of Methodology

The methodology offers a systematic and trustworthy way of exploring the performance of a virtual team. The study provides empirical support for the proposed VTPM model since it will be combined with a quantitative analysis and validated with respect to experts.

IV. RESULTS AND DISCUSSION

This section presents the empirical results provided by the questionnaire survey that was conducted among the virtual team practice people. The data are analyzed based on descriptive statistics, which encompass the frequencies, percentages, and means of the data. Table III presents the gender distribution of the respondents involved in the study. The results are organized in the form of major elements that affect Virtual Team Performance Management (VTPM). Table IV summarizes the educational background of the respondents.

TABLE III. GENDER DISTRIBUTION

Gender	Frequency	Percentage (%)
Male	62	56.4
Female	48	43.6
Total	**110**	**100.0**

TABLE IV. EDUCATION LEVEL

Education	Frequency	Percentage (%)
SPM/STPM	2	1.8
Diploma	12	10.9
Bachelor's degree	66	60.0
Postgraduate	29	26.4
PhD	1	0.9
Total	**110**	**100.0**

A. Descriptive Analysis

1) Respondent demographics: A total of 110 respondents participated in this study. Table V presents the types of organizations represented by the respondents.

B. Communication Analysis

The findings reveal that communication is a sensitive issue that influences the performance of virtual teams [19]. Most of the respondents (39.1%) reported the necessity of communication being improved, and the assessment of communication effectiveness has a great discrepancy. The survey indicated that there was inconsistency in leadership communication practices, as 46.4 percent of the surveyed revealed that leaders only communicate on a part-time basis about tasks and roles [15]. Besides, 39.1% of respondents said that they hardly get constructive feedback, implying a significant deficiency in leadership engagement. Table VI summarizes respondent perceptions regarding communication effectiveness in virtual teams.

C. Technology Management Analysis

Most respondents (48.2%) experienced issues occasionally, indicating moderate reliability challenges [42]. Only 35.5% reported sufficient training frequently, indicating a need for improved training strategies [50]. Table VII presents the frequency of technology-related issues experienced in virtual teams.

D. Strategic Planning and Task Allocation

Most respondents agreed that effective strategic planning and task allocation positively influence virtual team performance. Specifically, 56.4% of respondents strongly agreed that strategic planning with effective communication improves productivity within virtual teams, while another 56.4% strongly agreed that poor task allocation and lack of strategic planning result in repetitive and unnecessary communication. Table VIII summarizes respondent perceptions regarding strategic planning and task allocation effectiveness. These findings indicate that structured planning, clear communication, and proper task allocation are essential for improving coordination and overall effectiveness in virtual teams [47].

E. Documentation Analysis

63.6% of respondents agreed that excessive documentation exists, which may reduce efficiency [45].

F. Role Clarity Analysis

Although most respondents agreed that roles are clear, over 50% also reported difficulties when roles are not defined [43].

TABLE V. TYPE OF ORGANIZATION

Organization	Frequency	Percentage (%)
Academic	10	9.1
Public	22	20.0
Corporate	73	66.4
Others	5	4.5
Total	**110**	**100.0**

TABLE VI. COMMUNICATION LEVEL IN VIRTUAL TEAMS

Level	Frequency	Percentage (%)
Very Poor	8	7.3
Poor	10	9.1
Needs Improvement	43	39.1
Satisfactory	39	35.5
Effective	10	9.1
Total	**110**	**100.0**

G. Discussion

The results show that the most important factors in the performance of a virtual team are communication, technology management, and clarity of roles [3], [39]. The issue of communication issues, especially in feedback regarding leadership and clarity of leadership, affects team effectiveness a lot [1], [6]. The issues associated with technology are another cause of inefficiency in that there is a lack of training and problems associated with the tool [12]. Strategic planning enhances productivity when it is correctly applied, but failure to maintain consistent task allocation compromises team performance [29], [47], [49]. Furthermore, too much documentation and role ambiguity create team inefficiencies and confusion [46]. Fig. 3 summarizes the key quantitative findings obtained from the survey respondents.

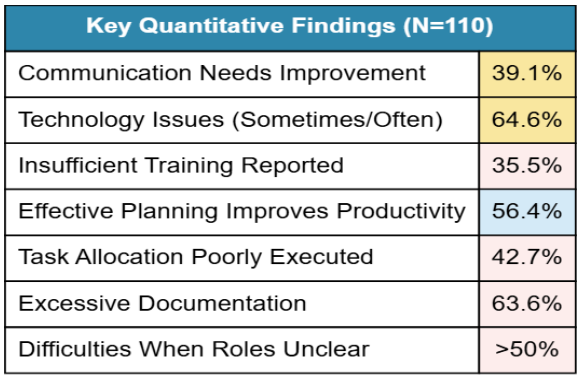

Fig. 3. Key quantitative findings (N=110).

TABLE VII. ISSUES WITH COLLABORATIVE TOOLS

Frequency of Issue	Frequency	Percentage (%)
Never	1	0.9
Rarely	29	26.4
Sometimes	53	48.2
Often	18	16.4
Always	9	8.2
Total	**110**	**100.0**

TABLE VIII. STRATEGIC PLANNING EFFECTIVENESS

Response	Frequency	Percentage (%)
Strongly Disagree	2	1.8
Disagree	8	7.3
Slightly Agree	15	13.6
Agree	23	20.9
Strongly Agree	62	56.4
Total	**110**	**100.0**

In general, the findings can be utilized to work on a structured VTPM model with communication, technology, planning, documentation, and role clarity as the primary aspects of it.

V. VIRTUAL TEAM PERFORMANCE MANAGEMENT (VTPM) MODEL DEVELOPMENT

In this part, the framework of Virtual Team Performance Management (VTPM) is developed. This step is aimed at transforming the findings made during the literature review and the conducted empirical research into a model structure that could be employed to enhance the management and performance of virtual teams. The section covers the logic of this model, the types of factors of the model, a suggested framework, functions of each aspect, and the method of professional validation that is applied to determine the value and applicability of the model. The model was developed following the necessity to offer a practical and holistic structure of organizations and team leaders who work with virtual teams [37]. As the results of the last chapter revealed, various factors constantly recur, as they affect the performance of a virtual team, and the most frequent are the management of communication, the use of technology, planning of the tasks, documenting, and clarity of role in a virtual team. Table IX presents respondent perceptions regarding documentation practices in virtual teams. The findings that were made served as the keystone to determining the key elements of the model and arranging them into a logical framework that helps in performance management in distributed team setups. The influencing factors mentioned above had to be sorted out into categories to build the model beforehand. Table X summarizes the responses related to role clarity within virtual teams. Such a classification narrows down the scope of comprehending the contribution of the various approaches applied by management to the success of virtual teams. The section, accordingly, starts by talking of the classification of the factors and then goes on to describe the proposed model and its validation.

TABLE IX. DOCUMENTATION VOLUME

Response	Frequency	Percentage (%)
Strongly Disagree	3	2.7
Disagree	13	11.8
Slightly Agree	24	21.8
Agree	48	43.6
Strongly Agree	22	20.0
Total	**110**	**100.0**

TABLE X. ROLE CLARITY

Response	Frequency	Percentage (%)
Strongly Disagree	1	0.9
Disagree	12	10.9
Slightly Agree	27	24.5
Agree	44	40.0
Strongly Agree	26	23.6
Total	**110**	**100.0**

A. Categorization of Key Influencing Factors in Virtual Team Performance Management

Classification of the management-related components or elements, based on the empirical findings, was the next step in the model development process. Judging by the questionnaire answers and the discussion in the last section, the most important aspects that influenced the performance of virtual teams were summarized into five major categories:

- Effective Communication Management
- Adequate Technology Management
- Effective Strategic Planning and Task Allocation
- Documentation
- Role Clarity

These five categories were chosen due to their reiteration as the most pertinent and pertinent areas that were relevant in the literature review as well as in the empirical investigation. Their combination constitutes the management aspects that are necessary to coordinate successfully, monitor, and enhance virtual team performance [28]. Mapping the forty-questionnaire metrics into these five categories was also done during the classification process. Most metrics can be found in the communication category since communication was ranked as the most central activity in the operations of a virtual team [1]. Such areas that are covered by technology management are collaboration tools, training, availability of tools, and successful utilization of digital platforms. Strategic planning and task allocation involve the aspects that are related to clear planning, task allocation, and work coordination. Documentation is the process of documenting and maintaining the information regarding the project. The factors addressed by

role clarity are those pertaining to clarity of expectations and responsibility, as well as accountability. The importance of this categorization is that a substantial number of individual survey measures are reduced to a manageable and meaningful structure through this categorization. The model does not consider metrics independently but clumps the related practices into fundamental managerial units. This aids in interpretation as well as practice since the organizations can adopt the model by paying attention to these five big areas rather than solitary concerns.

B. Proposed Virtual Team Performance Management (VTPM) Model

The results of the empirical study conducted in this study were the foundation for the development of the Virtual Team Performance Management (VTPM) model. The suggested model was created to assist organizations and team leaders in controlling their virtual teams more efficiently and enhancing the performance of their teams. The model is grounded on the five most important elements realized in empirical research: Effective Communication Management, Adequate Technology Management, Effective Strategic Planning and Task Allocation, Documentation, and Role Clarity. The components mentioned were based on the results of the surveys and are regarded as crucial in managing virtual teams [30]. Effective Communication Management has been utilized as the go-to mechanism in virtual teams in an effort to ensure easy communication and effective work among team members [20]. Another essential consideration is Adequate Technology Management, which focuses on the utilization of technological resources and platforms, as well as on their oversight and maintenance to support communication and collaboration [42]. In the VTPM model, Effective Strategic Planning and Task Allocation become one of the attributes that are needed to attain alignment with the project objectives, as well as to allocate work efficiently [22]. Documentation is also considered necessary to ensure transparency and that other information and project developments are well recorded and communicated [45]. Role Clarity is another important factor in virtual teams since it makes every team member understand their tasks, role, and the role they have in relation to others in the project as a unified team [43]. The suggested VTPM is a framework of management for enhancing the performance of virtual teams. Fig. 4 presents the proposed Virtual Team Performance Management (VTPM) model developed from the empirical findings. Through taking into account and applying all five primary aspects, organizations and team leaders can better manage the distributed work and have a higher chance of successful completion of the projects.

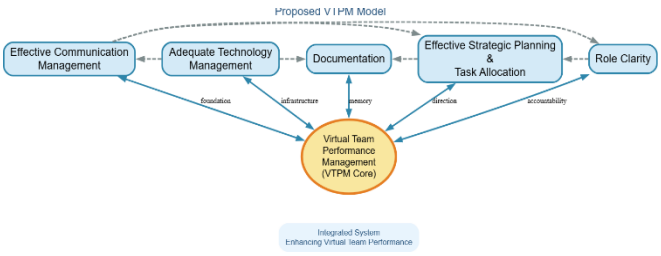

Fig. 4. Proposed Virtual Team Performance Management (VTPM) model.

Fig. 4 above represents the overall structure of the VTPM model. Although the components are presented individually, in practice they are interrelated. Communication influences planning and role clarity, technology supports communication and coordination, documentation reinforces shared understanding, and role clarity improves accountability and productivity. Therefore, the model should be understood as an integrated system rather than a set of isolated management activities.

C. Components of the Virtual Team Performance Management (VTPM) Model

VTPM model includes five components interacting with each other. Effective Communication Management [1], [20] defines ongoing communication as the likeness to collaboration based on the understanding of expectations, active listening, and feedback systems, which should be carried out through the right channels [38]. Teams need appropriate tools and training, so Adequate Technology Management [12], [42] makes sure the teams have the right tools and training in a certain context [25], [32]. Good Strategic Planning and Task Assignment [22], [47] gears project goals and well-defined responsibilities, and frequent reviews of development. One of the ways organizational memory is preserved and transparency is ensured is documentation [45], [46]; however, it has been found to have to be balanced to ensure that it is not inefficient. Lastly, Role Clarity [43] provides both parties, each member, with knowledge of their duties through clear communication of the leadership and continuous support [15]. These elements do not exist in isolation since they are a system. Fig. 5 illustrates the integrated VTPM system and the relationships between its core components.

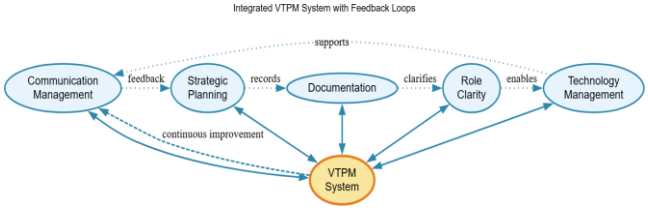

Fig. 5. Integrated VTPM system with feedback loops.

D. Model Validation

1) Introduction: Expert validation is a significant measure that needs to be taken to verify the accuracy, usefulness, and credibility of the VTPM model [2]. This was done through the model being exposed to expert scrutiny and juxtaposition to real-world and hypothetical expectations within the field of virtual team performance management. The validation stage was aimed at the validation of the usability and appropriateness of the VTPM model in the real setting of virtual teams. Validation is significant as a model should not be theoretically sound only, but practical. Domain experts can benefit by providing valuable information about experience and conceptual information. Their analysis allows judging whether the model is reflective of the conditions of real-world virtual teams, whether the model is composed of relevant components, and whether or not enhancements are necessary.

2) Experts involved in the process of validation: The VTPM model was found to be evaluated by academic and industry experts. The academic experts assessed the correspondence of the model to the theoretical and scientific assumptions, and the professionals serving industry assessed the correspondence of the model to the real conditions of work and management in virtual teams [8]. The combination was a balanced and holistic evaluation of the model. The involvement of academic and industrial professionals allowed for defining strengths, weaknesses, and potential changes. This shaped and multi-perspective validation procedure contributed to the strengthening of the credibility of the model and boosted confidence in its applicability in research and practice.

3) Expert validation: The expert validation procedure concentrated on the sub-componential as well as key constituents of the VTPM model. For the Effective Communication Management component, specialists approved the appropriateness of several subcomponents, such as effective communication of the leadership on the task functions and project responsibilities, team-in-the-loop feedback, effective verbal and written communication, strong leadership communication, and the ability to share information using appropriate communication [15]. Further decision making by academic experts regarded these sub-components as adequate, whereas industry experts were broadly in agreement, but were found in a manner the information sharing is practiced.

For the Adequate Technology Management component, the experts confirmed the significance of team leaders working to identify and resolve problems, the necessity of training and education in using collaboration tools, the most efficient utilization of multiple communication and collaboration tools, and better access to these tools [42]. The industry input showed that the use of the tools was proper, but awareness and accessibility could be expanded beyond the scope of tools that were widely used.

For the Role Clarity component, the professionals affirmed that role and responsibility articulation is required and appropriate in the model [43]. They also emphasized cross-functional teamwork and communication, along with mentioning that this process might need additional polishing in large or complicated teams where it is not easy to coordinate interdepartmental work.

For the Effective Strategic Planning and Task Allocation sub-component, academic and industry professionals found the sub-elements appropriate [22]. These involve the implementation of the strategic planning by team leaders through effective communication, task allocation through clear communication, and strategy establishment by the team leaders at the first stage of assigning tasks and responsibilities. Scholars admitted that this element is a powerful contributor to the effectiveness of virtual teams and their fit to the project goals.

For the Documentation component, the specialists ensured the appropriateness of correct documentation goals and document review procedures [45]. These results imply that documentation may be helpful and compatible with the agile or efficient working practices, provided that it is meaningful and controlled properly.

Besides rating sub-components, there was also the rating of the significance of big components by experts. By rating Effective Communication Management, Technology Management, and Documentation as very important, Strategic Planning and Task Allocation as important, and Role Clarity as moderately important, the academic experts rated them accordingly. Technology Management, Strategic Planning and Task Allocation, and Documentation were rated as very important by industry experts, Effective Communication Management important and Role Clarity moderately important by the industry experts. These scores demonstrate that there is high support for the primary structure of the VTPM model.

Professionals also gave recommendations on how it could be improved. Research scholars suggested refinements of the technology management factor in the IT-oriented settings, specialized communication technology to enhance cooperation, and application of the model to teams other than software teams. Experts in the industry recommended smaller, more focused meetings with the help of collaborative tools, more extensive applications of numerous tools in managing time and tasks, improved communication around objectives and key performance indicators, improved evaluation of the status of the existing technology, and organized performance assessment and improvement strategies. These suggestions make the model more useful and flexible. Fig. 6 compares the validation ratings provided by academic and industry experts.

Expert Validation Ratings Comparison		
Component	**Academic Experts**	**Industry Experts**
Communication Management	Very Important	Important
Technology Management	Very Important	Very Important
Strategic Planning	Important	Very Important
Documentation	Very Important	Very Important
Role Clarity	Moderately Important	Moderately Important

Fig. 6. Comparison of academic and industry expert ratings.

VI. Conclusion

This is the concluding section of the study that provides a comprehensive overview of the research done on virtual team performance management, specifically on the communication as well as the technology management strategy employed to manage performance in the virtual project team. This study has synthesized the research objectives, methodology, highlights, and overall findings related to virtual teams operating in the digital age [40]. The research was based on finding a multifocused explanation of how the proposed Virtual Team Performance Management (VTPM) model can solve the challenges determined in the virtual team setting. This study used both theoretical models combined with the empirical evidence presented in real-life situations to create a strong model of virtual team performance optimization in different situations. This section emphasizes that the study not only enhances the theoretical base of virtual team management but

also offers practical guidance on how it can be applied. The importance of these findings does not support just academic discourse, but provides useful information to virtual team leaders, team members, and the organization that deals with the management of virtual projects. This study is able to present actionable suggestions and strategic considerations to serve as guidance to stakeholders to resolve the problem of virtual collaboration. In general, the section is a valuable source in relation to the future of the developing virtual team's scenario.

A. Analysis of the Research Results

This part is a summary of the study progress according to the three research objectives. The initial goal, which was to determine problems and difficulties encountered by virtual teams in performance management, was realized in terms of the literature review and questionnaire results. As it was found, the key challenges are communication ambiguity, poor application of technology, documentation weaknesses, deficient strategic planning, poor allocation of tasks, as well as role ambiguity [22]. These problems formed a good background for the realization of the necessity to have a structured and efficient management strategy. Fig. 7 summarizes the research objectives and the corresponding achievements of the study.

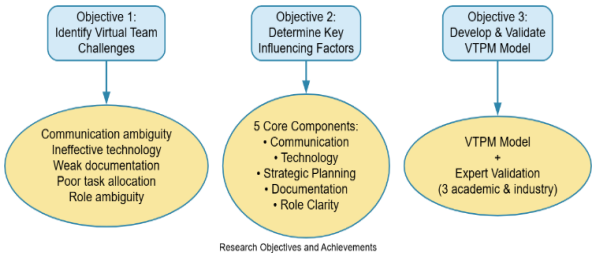

Fig. 7. Research objectives and key achievements.

The second goal, aimed at defining the main factors that affect the virtual team performance, was fulfilled in selecting five fundamental elements consisting of communication management, technology management, strategic planning, task allocation, role clarity, and documentation. All these aspects were based on empirical evidence and attested by the existing literature [3], [39]. They constitute the foundation for defining major performance criteria that should be dealt with by organizations and team leaders to enhance the performance of virtual teams. The third goal that attempted to formulate the Virtual Team Performance Management (VTPM) model was met with great success through the use of empirical evidence combined with theoretical methodologies and expert guidance [28], [37]. The VTPM model developed not only solves the major problems discussed but also offers an opportunity to have a practical design with the best practices, evidence-based management approaches, and feedback systems. The model was further refined through expert evaluation in order to make sure that it matches the project management requirements in the real world [8]. As a whole, this development of the study fits well within the three research objectives. The research identifies and evaluates the factors affecting virtual team performance and develops a practical management model.

B. Significance of the Study

The research on the Virtual Team Performance Management (VTPM) model makes a great contribution to both theoretical, practical, and social levels. Fig. 8 illustrates the theoretical, practical, and societal contributions of the proposed VTPM model.

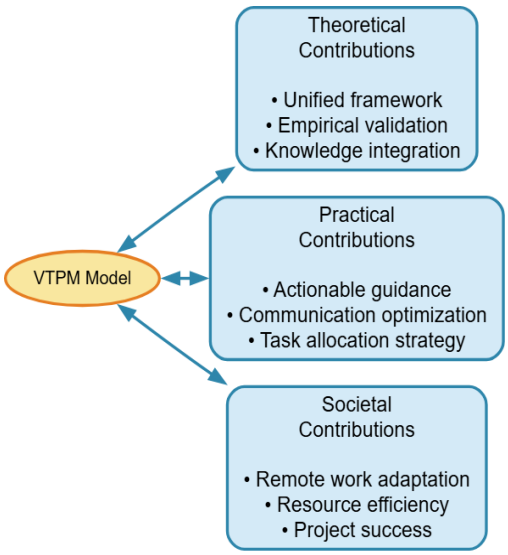

Fig. 8. VTPM model contributions: theoretical, practical, and societal.

1) Theoretical contributions: The study contributes to the theoretical knowledge on the issue of virtual teams by uniting the main factors that include management of communication, management of technology, strategic planning, task division, clarity of tasks, and documentation. VTPM model is an overall framework that integrates all these aspects in a single framework for managing virtual teams [26], [30]. Moreover, the empirical findings obtained through surveys and experts' evaluation give rather good evidence on the effectiveness of the model. This helps in closing the gap between theory and practice as it provides a validated framework to be used in further research.

2) Practical contributions: In practical terms, the VTPM model has implications for the practical understanding of team leaders and organizations. It provides systematic leadership in ensuring effectiveness in communication and technology use, as well as a better strategy and delegation of tasks [14], [47]. The model can also greatly enhance the performance and the productivity of the team in a virtual environment because some typical challenges, including barriers to communication, knowledge deficits, and poor management of technology, have been solved.

3) Societal contributions: The analysis aids the organizations in readjusting to the growing trends of a remote and distributed workplace setting [9]. The VTPM model helps enhance more fruitful and fulfilling remote working circumstances by enhancing the management of virtual teams. Moreover, the study should minimize instances of project failure as a result of communication and technology problems, which helps to ensure a higher level of efficiency in the use of resources and a better result of the project at the organizational level.

C. Critical Limitations and Threats to Validity

This study has several limitations that qualify its conclusions:

1) Cross-sectional design: Data were collected at one point; causal relationships cannot be inferred. Longitudinal studies are needed.

2) Self-report bias: All measures are perceptual. Objective performance metrics (e.g., project completion time, deliverable quality) were not collected.

3) Sample size and generalizability: N=110 is moderate. The sample is predominantly Malaysian corporate employees (66.4%); findings may not generalize to other cultural contexts, very small teams (<5 members), or very large teams (>20 members).

4) Lack of objective performance data: Perceived team performance may not align with actual outcomes.

5) Expert validation sample: Only three experts; a larger panel would increase confidence.

6) No structural equation modeling (SEM): Mediation pathways (e.g., whether communication effects are mediated by trust) were not tested.

7) Scope constraints: The VTPM model is validated only for technology-mediated, task-oriented teams in stable connectivity environments. It may not apply to emergency-response, creative, or purely social virtual teams.

D. Future Research Recommendations

It is suggested that future studies be done to enhance the VTPM model, especially as regards virtual and agile teams. These are the recommendations that fall into three broad regions.

1) Virtual team performance measurement: Information shedding in case of future research needs to involve detailed case research in an organization where virtual teams are significantly applied. This would give more detailed information on how the performance of teams is assessed in a real-life setting [10]. The most effective way to gather data on the effectiveness of the VTPM model is by means of documenting the project, interactions between the team, and interviews with the team members and managers. Longitudinal studies can also be performed in order to monitor the change in performance over time.

2) Formulation of performance measurement metrics: the future study must be on how to come up with developed performance measures in a well-structured, objective manner. Suggested metrics include: Sprint burndown, cycle time to assess productivity [41]. Division of high-quality deliverables to determine the output quality. Minutes during which meetings were undertaken to assess the efficiency of communication [38]. The metrics can be used to complement the current performance assessment models and offer more extensive information applicable to the management of virtual teams.

3) Pay attention to agile virtual teams: Future studies should address the implications of the VTPM model to Agile Virtual Teams and software development environments within the digital economy [35], [17], [36]. The research established that performance appraisal among agile virtual teams has not been extensively studied, and mostly it is based on subjective appraisals [47]. The way VTPM elements can accommodate agile methodologies like Scrum and Kanban should be studied in the future [50]. Moreover, innovative analytics and machine learning methods can be considered to forecast the performance of the team and suggest changes based on the information in real time.

Summing it up, the presented study produces a holistic approach to enhancing the performance of virtual teams using the Virtual Team Performance Management (VTPM) model. The model touches upon such essential issues as communication management, technology management, strategic planning, task distribution, role clarity, and documentation. The model may incorporate potential performance evaluation metrics such as cycle time, burndown charts of sprints, and quality indicators, among others, which makes it a solid framework and tool that can assess and enhance team effectiveness. Time tracking of the meetings is also helpful in communication and cooperation. VTPM model provides a bridge between theory and practice because it provides practical recommendations on how to manage virtual teams. It allows ongoing improvement, decision-making, and resource allocation, which will increase the success of a particular project. Further studies on the model should be done in the future by incorporating detailed performance measurement models and sophisticated methods of analysis. It will help to shed more light on virtual team dynamics and facilitate decision-making based on the facts. On balance, the improved VTPM model could help to advance the practice of virtual team management considerably and enhance the sphere of virtual project management, in general.

ACKNOWLEDGMENT

The authors would like to express their gratitude to Universiti Kebangsaan Malaysia for supporting this research.

Abstract*—Pancreatic cancer remains a leading cause of cancer-related mortality due to its asymptomatic progression and late-stage diagnosis. Early detection is critical for improving patient prognosis and clinical outcomes. Traditional diagnostic approaches and previous computational models often struggle with molecular heterogeneity and technical variations across different genomic platforms. These batch effects limit the reliability and generalizability of predictive biomarkers when applied to diverse clinical settings. This research proposes a robust machine learning framework designed for platform-invariant pancreatic cancer prediction. Large-scale transcriptomic datasets, including microarray data from the Gene Expression Omnibus (GEO) and RNA-seq data from The Cancer Genome Atlas (TCGA), were integrated. Subsequently, the ComBat algorithm was applied to correct batch effects. This resulted in a discovery cohort of 441 samples and an external validation set of 409 samples. An optimized XGBoost classifier was developed through comparative benchmarking. It was compared against several learners, including Random Forest, LightGBM, Support Vector Machines (SVM), and Logistic Regression. The model demonstrated high predictive performance, achieving an internal test AUC of 0.923. External validation was performed across six independent cohorts, yielding a mean AUC of 0.761 ± 0.090 (95% CI: 0.689–0.833). These findings support the robustness and cross-platform generalizability of the proposed framework. To enhance model interpretability, SHapley Additive exPlanations (SHAP) analysis was employed to identify key molecular drivers. These drivers were further validated using biological enrichment analysis through Over-Representation Analysis (ORA) and log2FC-weighted Gene Set Enrichment Analysis (GSEA). The proposed framework provides a reliable and scalable solution for multi-platform integration. This approach facilitates accurate risk stratification and precision oncology in clinical practice.

Keywords*—Pancreatic cancer; gene expression analysis; XGBoost; SHAP explainability; pathway enrichment; Explainable AI (XAI)

I. Introduction

Pancreatic cancer remains one of the most lethal malignancies worldwide, with a five-year survival rate below 10% [1],[14]. This poor prognosis stems from late-stage diagnosis, as the disease is often asymptomatic initially. Accordingly, most patients are being diagnosed only at advanced stages [2]. Since current imaging and biomarkers lack sufficient sensitivity, there is an urgent need for robust molecular signatures to support early diagnostic precision [18].

High-throughput transcriptomic profiling enables comprehensive characterization of pancreatic tumorigenesis [11],[12]. While these datasets offer opportunities to identify molecular signatures, traditional statistical methods struggle with high-dimensional omics data [15]. Machine learning (ML) has improved predictive performance. However, technical variability and a lack of interpretability still limit its clinical applicability.

Existing ML models for pancreatic cancer often suffer from small sample sizes and lack robust cross-cohort validation [16],[18]. Furthermore, many architectures function as black boxes, offering minimal biological insight into their predictive logic. This absence of functional validation hinders the transition from computational models to clinical utility.

Moreover, prior harmonization frameworks frequently focused on isolated objectives, such as batch correction or classifier optimization. Biological interpretability and external validation were often not integrated into a unified analytical pipeline. Consequently, many existing approaches remained vulnerable to platform dependency and limited generalizability across heterogeneous transcriptomic cohorts.

To address these limitations, this study proposed an integrated machine learning framework for robust pancreatic cancer prediction. First, a unified transcriptomic baseline was established by integrating microarray and RNA-seq datasets using ComBat-based batch effect correction. This ensured cross-platform consistency. Second, five machine learning algorithms were systematically benchmarked. This process yielded an optimized XGBoost classifier capable of capturing complex nonlinear gene interactions with superior sensitivity [17]. Third, SHAP analysis was employed to improve clinical interpretability by identifying key molecular drivers underlying model predictions. Fourth, biological relevance was reinforced through integrated functional enrichment analysis using GSEA and ORA. Finally, robustness and clinical reliability were validated across six independent external cohorts. These results supported real-world generalizability.

The remainder of this study is organized as follows. Section II reviews related work on pancreatic cancer prediction. Section III describes the materials and methods, including data integration, batch correction, and framework development. Section IV presents the evaluation criteria. Section V reports the experimental results and performance analysis. Section VI discusses the clinical and biological

*Corresponding author.

implications of the findings. Finally, Section VII concludes the study and outlines future research directions.

II. Related Work

The computational landscape for pancreatic cancer (PC) diagnosis has transitioned from simple classification on small datasets to complex, multi-cohort integrative frameworks. Current literature can be segmented into three primary domains: single-platform diagnostic models, multi-omics integration with batch-effect mitigation, and explainable AI (XAI) for clinical biomarker discovery.

Initial efforts in PC diagnosis often focused on localized cohorts. For instance, Carrillo-Perez et al. [6] utilized machine learning to identify a 6-gene signature in peripheral blood mononuclear cells for PC diagnosis. Their study demonstrates high accuracy in distinguishing PC from chronic pancreatitis. However, it remains centered on transcriptomic data from specific blood samples. This highlights a common trend in single-platform studies where the diagnostic potential is robust within the chosen medium. However, additional cross-platform validation is often required to ensure generalizability across diverse clinical settings, such as tissue-based RNA-seq or microarray datasets.

To overcome the limitations of individual classifiers, recent studies have pivoted toward ensemble architectures. Rao and Prasad [19] developed an ensemble learning model for the classification of gene expression from RNA-seq data for pancreatic cancer prognosis. Their research emphasizes that combining multiple learners significantly reduces the risk of false results common in classical analysis. However, while their approach demonstrates the efficacy of ensemble methods in prognosis, there remains a need for systematic benchmarking that specifically optimizes XGBoost within a framework designed for cross-platform robustness. This ensured high predictive performance was maintained when the model was transitioned from RNA-seq to microarray environments.

As the field moves toward large-scale integration, handling technical noise becomes paramount. Ge et al. [23] addressed this by integrating transcriptomic, methylation, and mutational data across 13 independent cohorts. Their study successfully identified molecular subtypes and the role of the A2ML1 gene. They employed extensive multi-omics integration. However, such large-scale fusions often face significant batch effects between different genomic platforms. This necessitates the use of explicit correction methods to ensure that the identified subtypes reflect true biological heterogeneity rather than platform-specific artifacts.

To bridge the gap between model performance and clinical trust, recent studies have incorporated interpretability tools. Almisned et al. [5] developed an ensemble voting classifier for PC diagnosis and employed SHAP to interpret the model's clinical attributes. Their work provides a clear link between features and predictions. However, a persistent gap remains in the integration of these SHAP-driven insights with formal biological pathway validation (such as GSEA or ORA). Without this multi-layered validation, the clinical translation of black-box models remains a challenge.

Despite strong internal performance, many previous frameworks remained sensitive to platform variability and transcriptomic heterogeneity. As a result, models trained on single-cohort or single-platform datasets often showed limited cross-platform transferability. To address these limitations, the study developed a platform-invariant framework integrating ComBat-based harmonization, benchmarked XGBoost optimization, and SHAP-driven biological validation. External validation across six independent cohorts further supported the framework's clinical robustness and biological relevance.

III. Materials and Methods

The systematic workflow of this study is organized into four phases (Fig. 1). Phase 1 involves multi-platform data integration and batch effect correction using the ComBat algorithm. In Phase 2, five machine learning classifiers are benchmarked, with XGBoost selected for its superior sensitivity and PR-AUC. Phase 3 utilizes SHAP-based explainability to identify key features and validate their biological relevance through ORA and GSEA. Finally, Phase 4 confirms the model's generalizability via independent validation across six unseen cohorts to establish a reliable diagnostic signature.

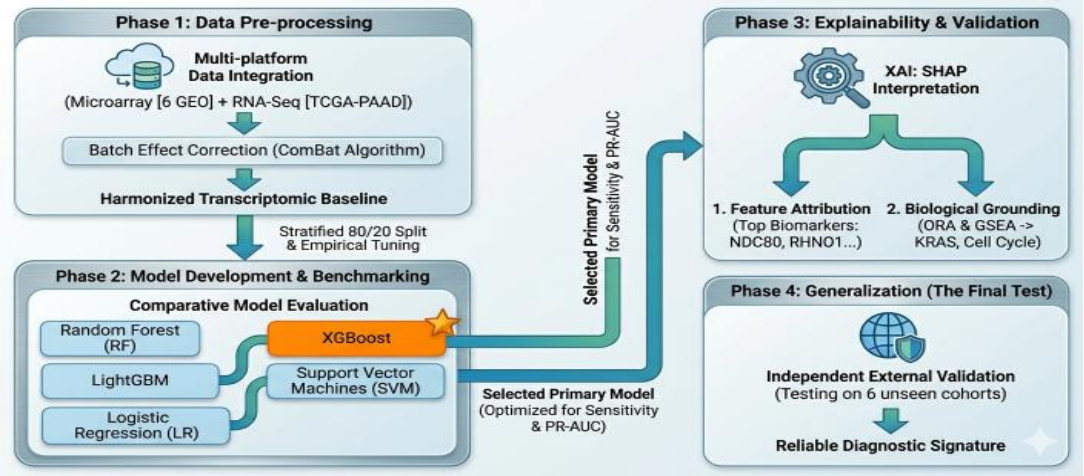

Fig. 1. Overview of the proposed predictive pipeline.

A. Data Collection and Study Design

Publicly available transcriptomic datasets were curated from the Gene Expression Omnibus (GEO) and The Cancer Genome Atlas (TCGA) [11]. Multiple microarray cohorts representing pancreatic tumor and normal pancreatic tissue samples were selected. To ensure cross-platform robustness, both microarray and RNA-seq data were integrated. A total of 623 samples were initially collected across all datasets. However, after stringent quality control and the removal of samples with incomplete metadata, 441 high-quality samples remained for training. Gene-level mapping was performed to resolve platform-specific nomenclature, resulting in a unified feature space of 18,734 common genes. This yielded a final training matrix of 441 samples × 18,734 genes for model development. The TCGA pancreatic adenocarcinoma cohort was used as a primary RNA-seq dataset [11], while GEO cohorts were used as the primary microarray datasets. Detailed cohort distributions and platform specifications (tumor-normal sample distribution) are summarized in Table I.

TABLE I. DATASETS USED FOR MODEL DEVELOPMENT

Dataset	Source	Platform	Genes	T/N	All	Role
GSE22780	GEO	Microarray (GPL570)	23,520	8 / 8	16	Discovery
GSE71989	GEO	Microarray (GPL570)	23,520	14 / 8	22	Discovery
GSE62165	GEO	Microarray (GPL13667)	20,034	118 / 13	131	Discovery
GSE28735	GEO	Microarray (GPL6244)	18,883	45 / 45	90	Discovery
GSE62452	GEO	Microarray (GPL6244)	18,883	69 / 61	130	Discovery
GSE16515	GEO	Microarray (GPL570)	23,520	36 / 16	52	Discovery
TCGA-PAAD	TCGA	RNA-seq	60,660	178 / 4	182	Discovery
GSE19279	GEO	Microarray (GPL96)	13515	9 / 6	15	External Validation
GSE15471	GEO	Microarray (GPL570)	23520	39 / 39	78	External Validation
GSE91035	GEO	Microarray (GPL22763)	21189	25 / 25	50	External Validation
GSE60980	GEO	Microarray (GPL14550)	22070	164 / 18	182	External Validation
GSE43795	GEO	Microarray (GPL10558)	31334	26 / 5	31	External Validation
GSE55643	GEO	Microarray (GPL6480)	19595	45 / 8	53	External Validation

B. Gene Annotation and Data Harmonization

The raw expression matrices initially comprised 60,660 Ensembl identifiers. These identifiers were mapped to official HGNC gene symbols via the MyGene.info API. Before querying, Ensembl version suffixes were stripped to maximize mapping efficiency. In cases of many-to-one mappings, expression values were collapsed by calculating the mean. To ensure feature consistency across diverse platforms, including Affymetrix microarray and Illumina RNA-seq datasets, 18,734 common genes were retained. These genes were consistently present across the majority of cohorts.

To ensure comparability, the integrated discovery set was subjected to log2 transformation and quantile normalization. KNN imputation was then applied (k=5) to estimate missing values. Technical heterogeneity was then systematically corrected using the neuroCombat empirical Bayes framework [3],[4]. The dataset source was designated as the batch variable while protecting the biological signal (tumor vs. normal) as a covariate. This batch correction was applied strictly to the discovery dataset preceding the train-test split. Crucially, the six external cohorts were processed independently and excluded from harmonization. This ensured a rigorous evaluation of unseen clinical data. Finally, Z-score standardization was applied to the corrected feature space. This established a robust foundation for both model training and feature attribution using SHAP.

C. Predictive Model Development and Benchmarking

To identify the most robust predictive architecture, five machine learning models [19] were benchmarked, including XGBoost, Random Forest, LightGBM, SVM, and Logistic Regression [5],[7]. All models were evaluated using a stratified 80/20 train–test split. For reproducibility, XGBoost hyperparameters were tuned using grid search on the training cohort. The search space included learning rates (0.001, 0.01, 0.1), maximum depth (3, 5, 7), and regularization terms ($\gamma \in [0, 0.5]$, $\lambda \in [1, 3]$, $\alpha \in [0, 2]$). The optimal configuration was a max_depth of 3, learning rate of 0.01, gamma=0.3, lambda=2, and alpha=1. To mitigate overfitting, subsampling and colsample_bytree were both set to 0.7. Early stopping with 50 rounds was also used on a validation set. The classification threshold was optimized using the Youden Index to improve diagnostic performance. Based on internal benchmarking, XGBoost was selected for interpretation and external validation. It showed the best overall performance. It achieved high sensitivity (0.881) and PR-AUC (0.962).

D. Model Evaluation and External Validation

Performance was initially benchmarked across all five candidate models using AUC-ROC, F1-score, Matthews Correlation Coefficient (MCC), sensitivity, and specificity. Following internal benchmarking, the top-performing XGBoost model was subjected to a rigorous external validation phase. The model was deployed on six additional, independent GEO cohorts. These cohorts are GSE15471, GSE55643, GSE19279, GSE43795, GSE60980, and GSE91035, totaling 409 samples. These validation datasets were kept entirely unseen during initial integration and training stages. This serves as a definitive test of the model's cross-platform robustness.

E. Model Explainability and Biological Interpretation

To move beyond black-box predictions, SHapley Additive exPlanations (SHAP) were employed, specifically for the optimized XGBoost classifier [7]. SHAP was applied to quantify the contribution of individual genes to the model's output [8],[13]. Global feature importance was derived by calculating the mean absolute SHAP values across the test set, identifying the key drivers of the classifier's decisions.

To ensure these features reflected meaningful biology rather than technical noise, a multi-layered validation pipeline was implemented. First, Over-Representation Analysis (ORA) was performed on the annotated top-ranked SHAP genes to identify enriched Gene Ontology (GO) terms [10],[25].

Subsequently, GSEA was conducted using log2FC-weighted p-values to rank genes across Hallmark and KEGG collections [9]. This analysis confirmed that the identified predictors were biologically associated with oncogenic pathways, including cell-cycle dysregulation and KRAS signaling.

IV. Evaluation Criteria

To address class imbalance across internal and external cohorts, the evaluation looked beyond accuracy to analyze PR-AUC, F1-score, and MCC. Sensitivity was strictly prioritized to minimize false negatives that risk fatal delays in clinical intervention.

The following metrics were utilized to quantify the model's performance:

- Accuracy: Measures the overall proportion of correct predictions (1).

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}} \quad (1)$$

- Sensitivity (Recall): Measures the ability to correctly identify PC cases (crucial for early detection) (2).

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \quad (2)$$

- Precision: Represents the proportion of positive identifications that were actually correct (3).

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}} \quad (3)$$

- F1-Score: The harmonic mean of Precision and Sensitivity, balancing the two metrics (4).

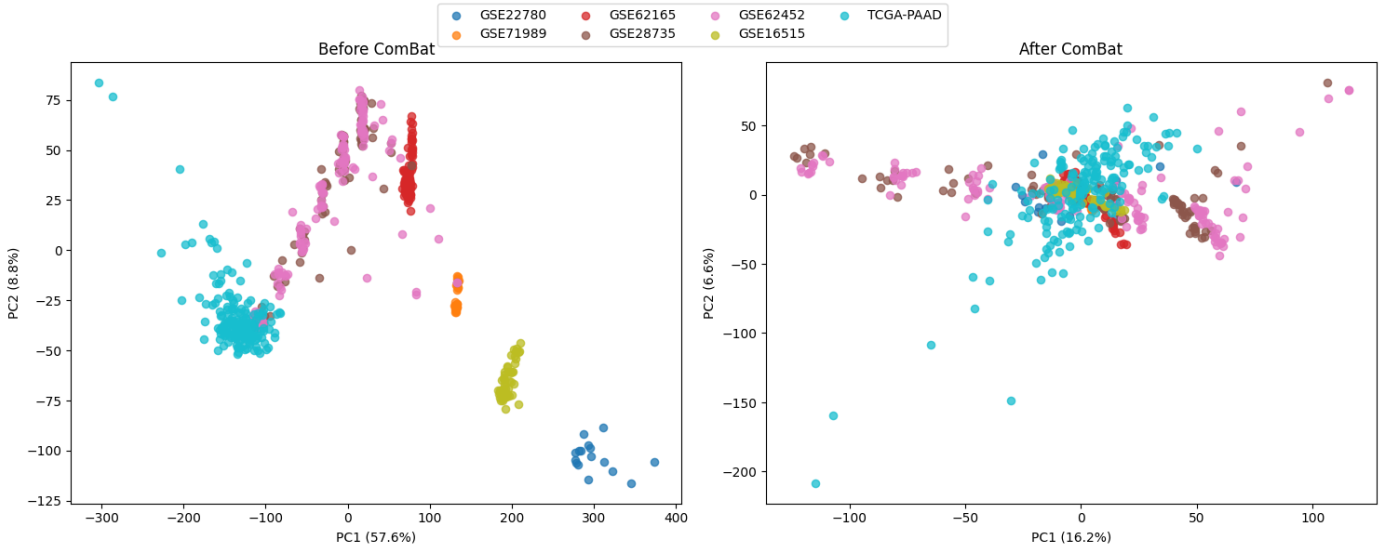
$$\text{F1 score} = 2\frac{\text{Precision.Recall}}{\text{Precision}+\text{Recall}} \quad (4)$$

- Matthews Correlation Coefficient (MCC): Provides a balanced measure of quality, even when classes are of very different sizes (5).

$$\text{MCC} = \frac{\text{TP.TN} - \text{FP.FN}}{\sqrt{(\text{TP}+\text{FP})(\text{TP}+\text{FN})(\text{TN}+\text{FP})(\text{TN}+\text{FN})}} \quad (5)$$

- AUC-ROC: Measures the model's ability to distinguish between classes by integrating the True Positive Rate (TPR) against the False Positive Rate (FPR) across all thresholds (6).

$$\text{AUC} = \int_0^1 \text{TPR}(\text{FPR}^{-1}(\text{t}))\, \text{dt} \quad (6)$$



V. Results

The results of this study are presented in five stages:

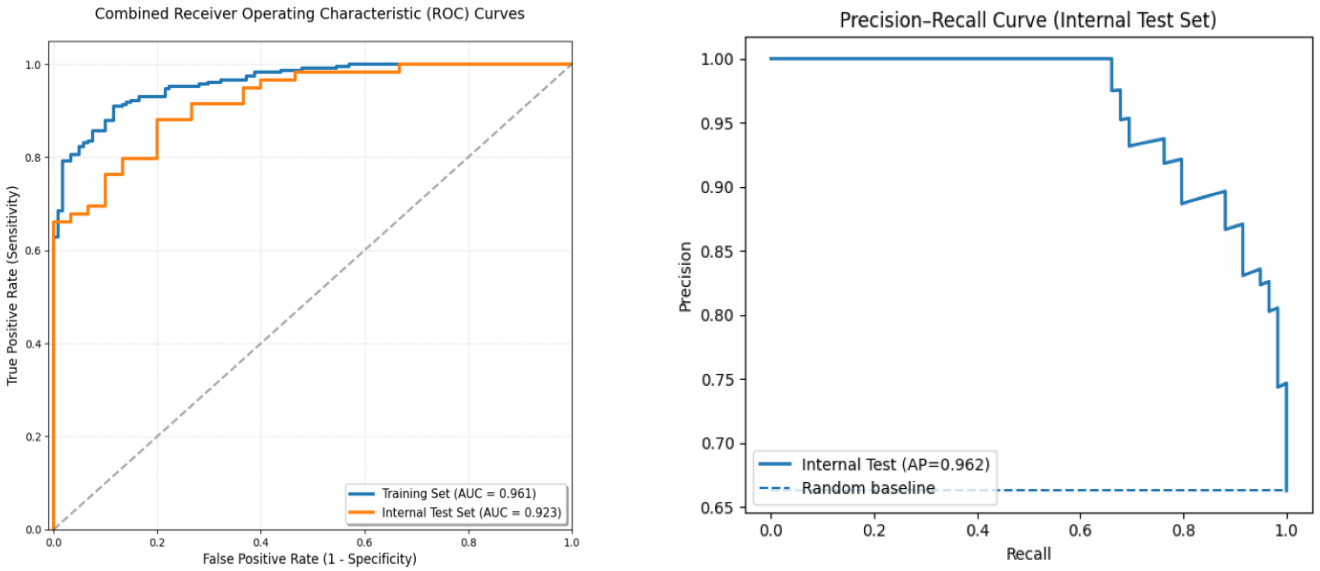
- Harmonization: Correcting batch effects to integrate multi-platform datasets.
- Benchmarking: Evaluating classifiers to select the optimal model.
- External validation: Assessing generalizability across six independent external cohorts.
- Explainability: Interpreting predictive logic using SHAP-based feature attribution.
- Biological validation: Confirming biological relevance through pathway enrichment analysis.

A. Batch Effect Correction and Harmonization

To integrate multi-center datasets, the ComBat algorithm was applied to remove technical variations. PCA visualization showed that before correction, samples clustered strongly by study origin, with PC1 accounting for 57.6% of the variance [Fig. 2(a)]. After correction, these study-specific clusters merged into a unified distribution, with PC1 variance dropping to 16.3% [Fig. 2(b)]. This successful integration ensured that subsequent model training relies on shared biological signals rather than technical noise.

(a) (b)

Fig. 2. (a) PCA visualization before ComBat correction, (b) PCA visualization after ComBat correction.



B. Predictive Performance and Benchmarking

Five classifiers were evaluated, and their performance on the internal test set is summarized in Table II.

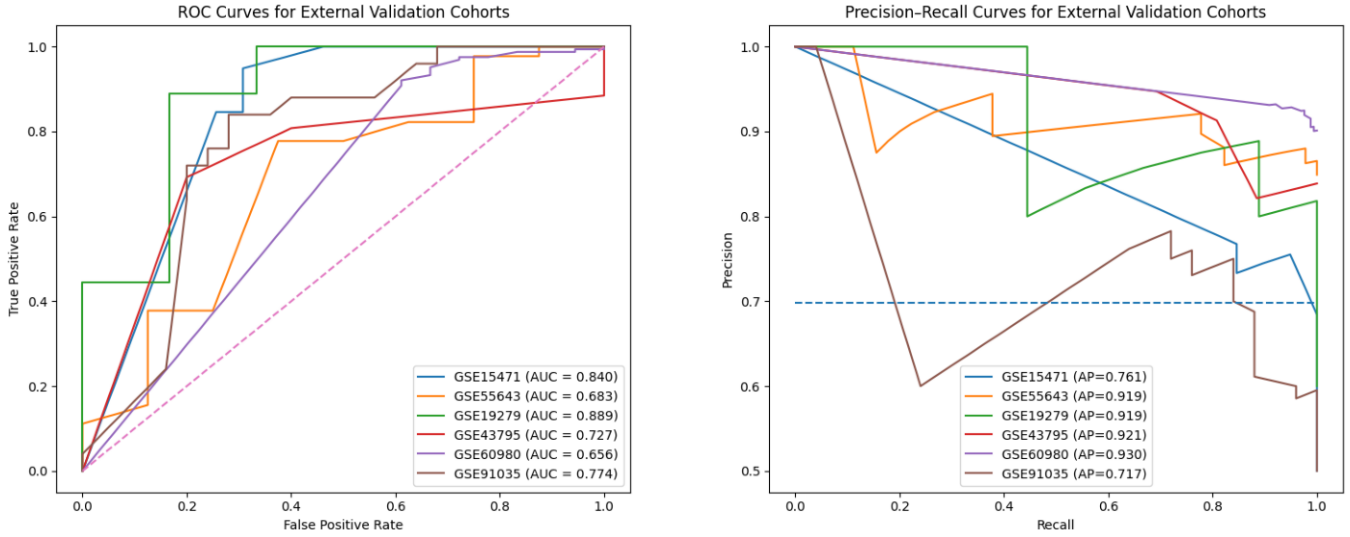
TABLE II. INTERNAL BENCHMARKING OF CANDIDATE MODELS

Model	ROC-AUC	PR-AUC	Sens.	F1-Score	MCC	ACC
XGBoost (Selected)	**0.923**	**0.962**	**0.881**	**0.889**	**0.676**	**0.854**
Random Forest	0.954	0.977	0.847	0.901	0.749	0.876
LightGBM	0.939	0.970	0.695	0.812	0.626	0.787
Support Vector Machine	0.782	0.793	0.424	0.556	0.222	0.551
Logistic Regression	0.715	0.803	0.475	0.602	0.267	0.584

While Random Forest (RF) and LightGBM achieved marginally higher discriminative metrics (AUC of 0.954 and 0.939, respectively), XGBoost was selected as the primary engine. The model was selected for its superior sensitivity (0.881) and more stable cross-cohort generalization performance. Specifically, LightGBM required an extreme threshold (0.9999), indicating calibration instability. Despite its slightly lower AUC (0.923) [Fig. 3(a)] compared to RF, the XGBoost model demonstrated a more robust balance for minority-class detection. This was supported by a PR-AUC of 0.962 [Fig. 3(b)] and an F1-score of 0.889. Additionally, the model demonstrated a precision of 0.897, a specificity of 0.80, and a sensitivity of 0.881, yielding an MCC of 0.676. Conversely, traditional models (LR and SVM) failed to capture the complex transcriptomic signatures, yielding significantly lower performance (AUCs of 0.715 and 0.728, respectively). Notably, external validation revealed that while RF suffered from generalization collapse (e.g., zero recall in GSE60980), XGBoost maintained stability across all cohorts. This confirmed that its optimized regularization (gamma=0.3, lambda=2) effectively captured conserved biological signals instead of platform noise. Moreover, it reinforces the selection of XGBoost as the optimal tool for balancing accuracy with clinical safety [7]. Hence, XGBoost was prioritized for detailed external validation to confirm its robust clinical generalizability.

(a) (b)

Fig. 3. (a) ROC curve of the XGBoost model on the internal test dataset, (b) Precision–Recall curve for the internal test set relative to the random baseline.



C. External Validation Across Independent Cohorts

To test the framework against real-world variability, the XGBoost model was challenged with six independent external cohorts (n=409). These datasets were kept entirely separate during the development phase to ensure an unbiased evaluation. To address platform variability, study-specific optimal thresholds were dynamically determined for each external cohort using the Youden Index. Due to platform differences, features missing in external cohorts (ranging from ~2,000 to 6,392 genes) (Table III) were excluded. The model was evaluated using only common genes. Despite this reduction, diagnostic accuracy remained high and stable across various platforms with an average AUC of 0.761.

TABLE III. COMMON GENE INTERSECTION USED FOR MODEL EXTERNAL VALIDATION

GEO Dataset	Total Genes (Original)	Common Genes with Training	Missing Genes	Gene Retention %
GSE91035	21,189	15,941	2,793	75.2%
GSE60980	22,070	16,714	2,020	75.7%
GSE43795	31,334	15,914	2,820	50.8%
GSE19279	13,515	12,342	6,392	91.3%
GSE55643	19,595	16,360	2,374	83.5%
GSE15471	23,520	18,734	4,786	79.65%

As illustrated in Fig. 4(a), the framework's performance remains consistent despite the technical noise associated with multi-center data. To provide a more comprehensive evaluation, bootstrap resampling was used (1000 iterations) to calculate 95% confidence intervals (CIs). This step confirmed the statistical robustness of the results. As shown in Table IV, the lower bounds of these CIs remain safely above the 0.5 random-chance mark for most cohorts. This demonstrated that the model is capturing real biological patterns. Also, PR-AUC, F1-score, and Matthews Correlation Coefficient (MCC) were evaluated. Precision–Recall curves are illustrated in Fig. 4(b). Overall, the model maintained strong minority-class detection across all cohorts, with PR-AUC consistently exceeding 0.71 and reaching as high as 0.93.

(a) (b)

Fig. 4. (a) ROC curves for external validation cohorts. (b) Precision–Recall curves for six external cohorts relative to the random baseline.

TABLE IV. PERFORMANCE OF THE XGBOOST MODEL ACROSS SIX INDEPENDENT COHORTS

GEO Dataset	PR-AUC	AUC [95% CI]	Acc.	Sens.	Spec.	F1-Score	MCC
GSE19279	0.919	0.889 [0.654 - 1.000]	0.867	0.889	0.833	0.889	0.722
GSE15471	0.761	0.840 [0.757 - 0.918]	0.821	0.949	0.692	0.841	0.663
GSE91035	0.717	0.774 [0.615 - 0.895]	0.780	0.778	0.783	0.792	0.564
GSE60980	0.930	0.656 [0.535 - 0.783]	0.868	0.921	0.389	0.926	0.296
GSE43795	0.921	0.727 [0.460 - 0.912]	0.710	0.692	0.800	0.800	0.372
GSE55643	0.919	0.683 [0.452 - 0.882]	0.755	0.778	0.625	0.843	0.320

Evaluation on GSE43795 and GSE55643 did not reach formal statistical significance due to the limited number of control samples (n<10). Excluding these cohorts yielded a refined average AUC of 0.790, while overall performance trends remained consistent. Overall, XGBoost captured conserved biological signals for robust cross-study prediction.

Performance variability across external cohorts was influenced by differences in cohort size, class distribution, and transcriptomic heterogeneity. Lower-performing cohorts generally contained limited control samples and reduced feature overlap after cross-platform harmonization. Despite these variations, the framework maintained stable predictive behavior across heterogeneous datasets, supporting its robustness against biological and technical variability.

In cohorts with extreme class imbalance (e.g., GSE60980 and GSE55643), MCC values were moderately reduced despite high PR-AUC and F1-scores. This reduction was mainly attributed to the limited number of normal samples rather than poor tumor detection. Nevertheless, recall remained consistently high across datasets, indicating reliable identification of cancer cases and overall framework stability.

D. SHAP-Based Model Explainability

SHAP analysis was used to interpret the XGBoost model, providing mechanistic transparency [8],[13]. As illustrated in Fig. 5, the analysis identified a subset of high-impact features. THAP9-AS1 emerged as the dominant driver, followed by RHNO1 and RUSC1-AS1. The model's reliance on long non-coding RNAs and cell-cycle-related genes aligns with

established biological dysregulation, providing a robust rationale for its high diagnostic accuracy.

E. Biological Pathway Enrichment and Mechanistic Validation

Dual-layered enrichment analysis was performed to provide a biological rationale. ORA of top SHAP features revealed a convergence on critical oncogenic hallmarks, including cell cycle progression (G2-M Checkpoint, Mitotic Spindle, and E2F Targets) and metabolic reprogramming (Glycolysis, Pentose Phosphate) (Fig. 6) [10],[11]. These findings were corroborated by GSEA, with significant enrichment in KRAS Signaling Dn (NES = -1.367; FDR = 0.045; $p < 0.001$) [Fig. 7(a)] [9],[12], Angiogenesis [Fig. 7(b)], and Unfolded Protein Response pathways [Fig. 7(c)], driving tumor adaptation to hypoxia and ER stress. Conversely, the dysregulated Xenobiotic Metabolism [Fig. 8(a)] and depletion of Pancreas Beta Cell genes [Fig. 8(b)] reflect the loss of cellular identity and chemoresistance. This concordance across independent methods confirms that the XGBoost model captures a robust, functional transcriptomic fingerprint of pancreatic malignancy rather than stochastic noise.

VI. Discussion

XGBoost outperformed linear baselines and ensemble methods [15]. While RF and LightGBM showed higher internal AUCs, they suffered from overfitting on unseen cohorts. Given the study's emphasis on external generalizability and clinical sensitivity, final model selection was not based solely on internal discrimination performance. Internal comparison metrics alone may fail to reflect out-of-distribution overfitting across heterogeneous cohorts. Therefore, XGBoost was selected based on its superior sensitivity (0.881) and more stable predictive behavior during external validation. While class imbalance caused some variability in sensitivity, the consistently high AUC across cohorts underscores its potential for early diagnostic tools.

A key strength of this study lies in the alignment between model-driven feature importance and biological mechanisms. SHAP analysis identified influential genes [20], notably NDC80, RHNO1, and NAPRT [21]. The model also assigned importance to several long non-coding RNAs, such as THAP9-AS1 and RUSC1-AS1. However, protein-coding drivers were prioritized to facilitate a clear functional interpretation [11],[12]. NDC80, in particular, is a known regulator of cell cycle and chromosomal stability, playing a critical role in pancreatic tumor progression [21].

GSEA further validated the findings, revealing dysregulation in the cell cycle, metabolism, and KRAS signaling [12],[15],[16]. The convergence of ML feature attribution with established oncogenic mechanisms confirmed that the model captures disease-related patterns rather than technical artifacts [9],[10],[25].

Unlike in single-cohort studies, this signature remained robust across 409 unseen samples from six GEO datasets.

Prioritizing sensitivity proved effective. XGBoost maintained a stable 0.761 average AUC across all platforms. However, two cohorts (GSE43795 and GSE55643) contain fewer than ten control samples, limiting their statistical power. To prevent inflating the generalizability claims, the model was re-evaluated by excluding these two small datasets. The remaining four high-powered cohorts (325 samples) yielded a refined average AUC of 0.790. This stable performance confirmed that the model captured a fundamental biological pattern rather than sample-size artifacts or platform-specific noise.

Despite these results, limitations exist. While ComBat reduced batch effects [3],[4], residual variability may persist due to platform-specific differences in probe sensitivity. Nevertheless, ComBat remains the gold standard for multi-platform data harmonization. Recent benchmarks demonstrate its superior ability to preserve biological signals compared to complex deep-learning alternatives [24]. Additionally, reliance on public datasets limits performance assessment in prospective clinical settings.

The study lacks direct experimental validation; findings for NDC80 and THAP9-AS1 remain entirely in silico. To guide future wet-lab translation, a concrete three-phase workflow is proposed.

First, baseline expression levels will be quantified via RT-qPCR across pancreatic cancer cell lines, such as PANC-1 and MIA PaCa-2, versus normal HPDE controls. Western blotting will further confirm NDC80 protein translation. Second, functional loss-of-function assays will evaluate phenotypic changes using siRNA or shRNA-mediated knockdown. Specifically, MTT/CCK-8 proliferation and Transwell invasion assays will determine if depleting these targets suppresses oncogenic capabilities. Finally, ex vivo validation using immunohistochemistry (IHC) on patient tissue microarrays will map NDC80 expression across histological tumor grades. Mechanistically, future assays should clarify whether the lncRNA THAP9-AS1 acts as a competitive endogenous RNA (ceRNA) to regulate NDC80.

Furthermore, integrating clinical covariates like CA 19-9 could mitigate specificity fluctuations in imbalanced cohorts [14],[17]. Future work incorporating longitudinal data and multimodal biomarkers is essential to enhance predictive robustness and realize the framework's full translational potential [22].

VII. Conclusion

In this study, an interpretable machine learning framework was presented for pancreatic cancer prediction. Systematic batch-effect correction and comparative benchmarking of five classifiers identified XGBoost as the most clinically robust model. The proposed framework achieved strong predictive performance and maintained generalizability across multiple external cohorts. SHAP-based explainability enabled the identification of key molecular features associated with pancreatic tumorigenesis. These findings were further supported through pathway enrichment analyses, highlighting established oncogenic mechanisms including cell cycle dysregulation and KRAS signaling.

Overall, the findings demonstrated the potential of explainable machine learning for extracting biologically grounded signatures from high-dimensional transcriptomic data. However, the proposed framework should currently be considered an exploratory computational foundation. Prospective clinical validation and further clinical integration studies remain necessary before translational application in real-world diagnostic settings.

Data and Code Availability

The datasets analyzed in this study are publicly available from the Gene Expression Omnibus (GEO) and The Cancer Genome Atlas (TCGA). The code used in this study is available from the corresponding author upon reasonable request.

A Hybrid PCA–Random Forest Model for Predicting Employee Performance from Work Ethics and Work Values

Nova E. Arquillano
Department of Public Administration, Pangasinan State University, Philippines

***Abstract*—This study examined the predictive relationship of work ethics and work values with employee task performance using a hybrid PCA–Random Forest model. Data were obtained from 231 PSU employee respondents and 81 questionnaire variables covering task performance, work ethics, and work values. A quantitative, cross-sectional predictive design was used; therefore, the findings are interpreted as predictive associations rather than causal effects. Descriptive statistics, reliability analysis, correlation analysis, Principal Component Analysis (PCA), baseline regression models, Random Forest regression, and a hybrid PCA–Random Forest model were applied. PCA reduced the 74 predictor items into 19 components, explaining 80.9% of the predictor variance. On the held-out test set, the hybrid PCA–Random Forest model achieved MAE = 0.272, RMSE = 0.383, and R^2 = 0.524. Standard Random Forest produced a similar test performance (MAE = 0.283, RMSE = 0.383, R^2 = 0.526), indicating that PCA did not substantially improve accuracy but produced a more compact and less redundant feature representation. Professionalism, commitment to public interest, and nationalism and patriotism emerged as important predictors of task performance. The study demonstrates the usefulness of interpretable machine-learning models for evidence-based human resource development in public higher education, while noting limitations related to ceiling effects, self-report data, single-institution sampling, and the need for external validation.**

***Keywords*—Employee performance; work ethics; work values; principal component analysis; random forest; hybrid model; machine learning; PSU employees**

I. Introduction

Employee performance is a critical concern in public sector institutions because the quality of public service depends largely on how effectively employees perform their duties. In state universities, employee performance is commonly reflected in task completion, timeliness, efficiency, and quality of outputs, all of which directly affect institutional effectiveness and stakeholder satisfaction. In the present study, employee performance is operationalized through task performance indicators such as planning work on time, accomplishing tasks efficiently, and producing quality outcomes, while work ethics and work values are treated as key explanatory factors.

Work ethics and work values are particularly important in the context of public employment because they shape employees' sense of accountability, professionalism, integrity, responsiveness, and commitment to the public interest. Ethical conduct and values-based behavior influence not only how employees carry out assigned responsibilities but also how they interact with clients, colleagues, and the organization as a whole. Prior studies have shown that workplace attitudes and behavioral factors are significantly related to task performance and work outcomes [1], while innovative work behavior and citizenship-related behavior also contribute to stronger workplace contribution and effectiveness [2]. In addition, job satisfaction and work engagement have been linked to desirable organizational outcomes and reduced turnover intention, suggesting that employee values and work orientation play a meaningful role in performance-related behavior [3].

Despite the recognized importance of work ethics and work values, modeling their relationship with employee performance remains methodologically challenging. These constructs are usually measured through multiple Likert-scale items, making them inherently multidimensional and often highly correlated. Traditional statistical methods remain useful for explanation, but they may be limited in capturing nonlinear relationships and interaction effects among behavioral variables. Recent work has emphasized that machine learning models are increasingly suitable for the social sciences because they can handle complex and nonlinear associations more effectively than strictly linear techniques [4], [5]. Best-practice discussions in psychological and behavioral machine learning further note that supervised learning methods can strengthen prediction when data preparation, validation, and interpretation are conducted rigorously [6].

In psychometric and survey-based studies, the quality of indicators strongly affects model performance and interpretability. Multivariate measurement research has long emphasized that the selection and treatment of indicators can substantially influence modeling outcomes [7]. This is particularly relevant in employee studies where ethics, values, and performance are each represented by multiple observed variables rather than by a single direct measure. Psychometric evaluation studies also demonstrate the importance of sound measurement properties in survey-based research [8], [9]. For this reason, any predictive study involving questionnaire data should pay careful attention to the structure, redundancy, and quality of indicators before model construction.

Another major concern in survey-based modeling is data quality. Missing responses, careless answering, and meaningless response patterns may reduce the reliability of results if left untreated. Missing data have been identified as a key issue in survey research, with consequences for estimation quality, validity, and interpretation [10]. Likewise, nonreactive

indicators can help identify poor-quality or meaningless responses in self-report surveys [11]. Because the present study relies on multiple questionnaire items measuring work ethics, work values, and task performance, careful preprocessing is necessary to ensure that the predictive model is based on valid and stable information.

Given the large number of survey indicators, dimensionality reduction becomes a practical necessity. Principal Component Analysis (PCA) is a widely used technique for transforming correlated variables into a smaller number of components while preserving as much information as possible. This approach is especially useful when many predictors overlap conceptually and statistically, as is common in behavioral and organizational datasets [7], [12]. By reducing redundancy and multicollinearity, PCA can improve the efficiency of downstream predictive models and simplify interpretation at the component level. In multivariate research, such reduction techniques are valuable when latent structures must be approximated from many observed indicators [13].

After dimensionality reduction, Random Forest is an appropriate predictive algorithm for employee performance because it can accommodate nonlinear relationships, higher-order interactions, and complex variable patterns without strict distributional assumptions. Machine learning research in psychometrics and the social sciences has shown that such methods are particularly advantageous when the goal is prediction rather than only parameter estimation [4], [5], [6]. Random Forest is also robust for structured tabular data and can perform well in moderate-sized datasets such as employee survey data. Since work ethics and work values may influence performance in nonuniform ways across respondents, an ensemble-based learner such as Random Forest is a suitable modeling choice.

A further strength of Random Forest is its compatibility with model interpretation tools. In applied organizational research, predictive accuracy alone is insufficient; decision makers also need to understand which factors are driving model predictions. Interpretable machine learning frameworks provide ways to explain black-box models and support evidence-based decision-making [14]. Feature attribution methods such as Shapley-based explanations can be used to estimate the contribution of individual predictors or components to model output [15], [16]. This is especially valuable in the present study because it allows the identification of which ethical and value-based dimensions are most strongly associated with employee performance.

Model evaluation is also essential in determining whether a predictive framework is appropriate and defensible. Comparative assessment using established evaluation metrics is recommended in machine learning studies to ensure that predictive performance is examined systematically and transparently [17]. In social science applications, methodological rigor likewise requires proper training-validation procedures and responsible reporting of predictive results [6]. Consequently, the adoption of a hybrid model should not only be justified conceptually but also supported empirically through relevant performance measures.

The use of a hybrid PCA–Random Forest framework is therefore justified both statistically and substantively. Statistically, PCA addresses the high dimensionality and multicollinearity common in questionnaire-based predictors, while Random Forest captures nonlinear patterns that may exist between employee ethics, values, and task performance [4], [7], [12]. Substantively, the model supports a more data-driven understanding of how employee characteristics translate into work outcomes in a public university setting. Related studies have shown that work-related attitudes, engagement, and behavioral orientations are connected to performance, satisfaction, and organizational contribution [3], [18], [19]. These findings reinforce the importance of examining performance not only as a function of technical capacity but also as an outcome associated with ethical and value-based dimensions of work.

The present study is also timely because organizational environments are becoming increasingly data-driven, requiring more robust methods for analyzing human-centered workplace data. Machine learning has gained growing relevance in social and behavioral inquiry because it can complement conventional methods in identifying predictive structures from complex datasets [4]. Tutorials and methodological reviews likewise encourage the careful adoption of supervised machine learning in psychology and related disciplines to enhance predictive validity and methodological innovation [17]. In this regard, the proposed hybrid model contributes to the emerging application of machine learning in educational and public sector workforce studies.

Accordingly, this study proposes A Hybrid PCA–Random Forest Model for Predicting Employee Performance from Work Ethics and Work Values among Employees. Specifically, it seeks to determine whether the multidimensional indicators of work ethics and work values can be reduced into meaningful components and used to predict employee task performance with acceptable accuracy and interpretability. By integrating survey-based measurement, dimensionality reduction, ensemble learning, and interpretable machine learning, the study contributes both a methodological approach and an applied perspective for understanding employee performance [14].

Although previous studies have established associations between work-related attitudes, values, engagement, and performance, much of the existing literature remains descriptive or correlational. Fewer studies have examined whether multidimensional work ethics and work values indicators can predict employee performance using a transparent machine-learning framework. In addition, many predictive studies emphasize accuracy but provide limited interpretation of the psychological or organizational meaning of model features. This creates a gap for an approach that combines dimensionality reduction, nonlinear prediction, and interpretability. The present study addresses this gap by evaluating whether PCA-derived dimensions of work ethics and work values can be used in a Random Forest model to predict task performance among public university employees. Ultimately, the findings may provide evidence-based support for institutional strategies aimed at strengthening employee effectiveness through ethics- and values-oriented development.

II. METHODOLOGY

This section presents the research design, data sources, and analytical procedures used in the study. It describes how the predictor variables were measured and how the six regression models were developed and compared to determine the most appropriate approach for analyzing the relationships among the variables.

A. Research Design

This study employed a quantitative, cross-sectional, predictive research design. The objective was to develop and evaluate a hybrid PCA–Random Forest model for predicting employee performance from work ethics and work values among Pangasinan State University (PSU) employees. The predictive framework was selected because machine learning methods are well suited for social science data with many correlated variables and potentially nonlinear relationships. The hybrid design combined Principal Component Analysis (PCA) for feature reduction with Random Forest Regression for prediction, a combination that is appropriate when survey-based predictors are numerous, overlapping, and multidimensional. The study was explanatory-predictive in nature. It not only describes the levels of work ethics, work values, and employee performance, but also models how ethics- and value-related indicators jointly predict task performance. This design is consistent with current recommendations that machine learning in behavioral and psychometric research should be used to complement traditional explanatory approaches through rigorous preprocessing, validation, and interpretable modeling. The study is therefore best interpreted as a predictive and exploratory model of performance-related patterns within the PSU employee sample.

B. Data Source and Unit Analysis

The dataset used was taken from the survey of PSU employees, which contains 231 respondent records and 81 item-level variables corresponding to the questionnaire dimensions. The unit of analysis was the individual PSU employee respondent. The predictor set consisted of work ethics and work values items, while the outcome variable was employee task performance derived from the task productivity indicators in the questionnaire. The questionnaire is composed of three major parts. Part I measures task performance through seven indicators (pro1–pro7) using a 5-point agreement scale. Part II measures work ethics using multiple indicators across eight dimensions: commitment to public interest, professionalism, political neutrality, justness and sincerity, responsiveness to the public, nationalism and patriotism, commitment to democracy, and simple living. Part III measures work values across six dimensions: God-fearing, accountability, integrity, transparency, innovativeness, and competency. These constructs and response formats are explicitly defined in the uploaded instrument.

Because the data were collected through self-report questionnaires, the findings may be affected by common-method bias and socially desirable responding. This concern is particularly relevant because ethics and values are socially valued constructs. The results should therefore be interpreted as respondents' reported perceptions of their work behavior and values rather than as direct administrative performance records.

C. Research Locale and Population

The study focused on PSU employees as reflected in the survey instrument. The target population, therefore, consisted of PSU personnel who responded to the questionnaire. The study treated the dataset as the empirical basis for training and evaluating the predictive model.

Because the data were collected through self-report questionnaires, the findings may be affected by common-method bias and socially desirable responding. This concern is particularly relevant because ethics and values are socially valued constructs. The results should therefore be interpreted as respondents' reported perceptions of their work behavior and values rather than as direct administrative performance records.

D. Instrumentation and Variable Operationalization

Employee performance was operationalized as task performance, based on the seven indicators in Part I of the questionnaire: planning work on time, optimal planning, distinguishing major from minor issues, performing work with minimal time and effort, completing tasks efficiently, producing high-quality outputs, and keeping intended results in mind. These seven indicators were rated on a 5-point Likert-type scale and were combined to form the target construct for prediction.

The predictor variables were drawn from Parts II and III of the questionnaires. The work ethics construct includes the following dimensions and item groups: commitment to public interest (com1–com7), professionalism (prof1–prof7), political neutrality (po1–po4), justness and sincerity (j1–j5), responsiveness to the public (res1–res6), nationalism and patriotism (na1–na6), commitment to democracy (co1–co3), and simple living (sim1–sim6). The work values construct includes God-fearing (god1–god5), accountability (acc1–acc5), integrity (in1–in5), transparency (tra1–tra5), innovativeness (inno1–inno5), and competency (compe1–compe5, including the dataset's comp3 field corresponding to the third competency item). These domains and items are specified in the questionnaire. All predictors were treated as ordinal Likert-type responses coded numerically from 1 to 5. In practice, Likert item responses are commonly modeled as numeric inputs in psychometric and supervised learning workflows, particularly when the goal is prediction rather than purely ordinal inference.

E. Data Preparation and Screening

Fig. 1 shows the data preprocessing and screening flowchart. The dataset was screened for completeness, correct variable names, duplicate cases, and valid response ranges. Because all questionnaire items used a 1–5 scale, any value outside this range was treated as invalid and corrected or removed when necessary. Missing data were examined at both the item and respondent levels. Cases with excessive missing responses were excluded, while minimal random missingness was handled through item-median imputation. Composite means were computed only when most items in a dimension were available. The data were also checked for low-quality response patterns, such as straight-lining, invariant responses, and duplicated answer sets, and clearly invalid cases were removed. Finally, all predictor variables were standardized into z-scores before PCA to ensure comparability and prevent variables with larger variance from dominating the component extraction.

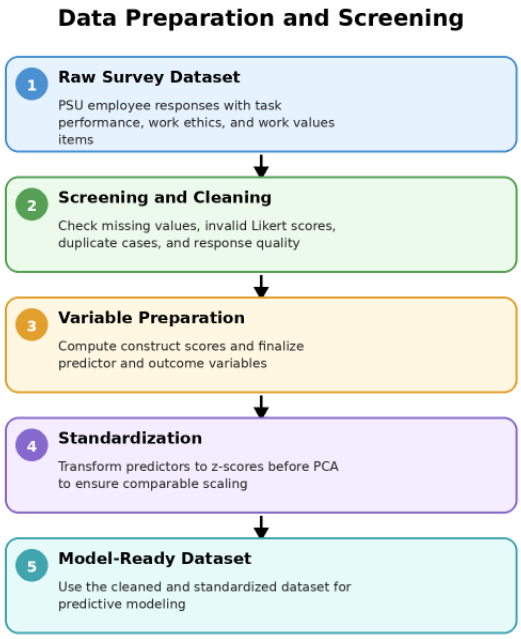

Fig. 1. Data preparation and screening.

F. Feature Engineering

Two parallel feature representations were used in the study: item-level predictors: all work ethics and work values items entered individually; and PCA-derived predictors: principal components extracted from the full predictor matrix.

The principal analysis used the PCA-derived feature space because the study proposes a hybrid PCA–Random Forest framework. The item-level representation was retained as a benchmark to determine whether PCA improved, reduced, or preserved predictive performance compared with a standard Random Forest using the original survey items.

G. Principal Component Analysis (PCA)

PCA was applied to the standardized predictor matrix composed of all work ethics and work values items. The purpose of PCA was to reduce redundancy among correlated survey items and derive a smaller number of orthogonal components that summarize the underlying variation in employees' ethics- and values-related responses. PCA is appropriate in multivariate measurement settings where many observed indicators capture overlapping constructs. Using multiple retention criteria is preferable because purely mechanical cutoffs may either retain noisy components or discard useful information. The retained principal components then served as the input features for the Random Forest model. This PCA stage helps reduce multicollinearity, compress noise, and improve model stability when many survey items are conceptually related.

The use of PCA before Random Forest was not based on the assumption that Random Forest requires uncorrelated predictors. Rather, PCA was used to address the high redundancy of the questionnaire indicators and to create a compact representation of the work ethics and work values domains. Since Random Forest can already handle correlated inputs, the hybrid model was evaluated against standard Random Forest to determine whether dimensionality reduction added practical value. This comparison is important because PCA may also introduce information loss when components do not preserve predictive patterns in the original variables.

H. Random Forest Regression

The predictive model used in the second stage was Random Forest Regression. Random Forest is an ensemble learning algorithm that builds multiple decision trees from bootstrap samples and aggregates their outputs to produce a final prediction. It is especially suitable for structured social science datasets because it can model nonlinear effects and variable interactions without requiring strict linearity or normality assumptions. The choice of Random Forest was justified because it handles moderate sample sizes effectively, it is robust to overfitting compared with single decision trees, it can capture nonlinear relationships between ethics, values, and performance, and it supports feature importance and post hoc interpretability analysis. Fig. 2 shows the model implementation process.

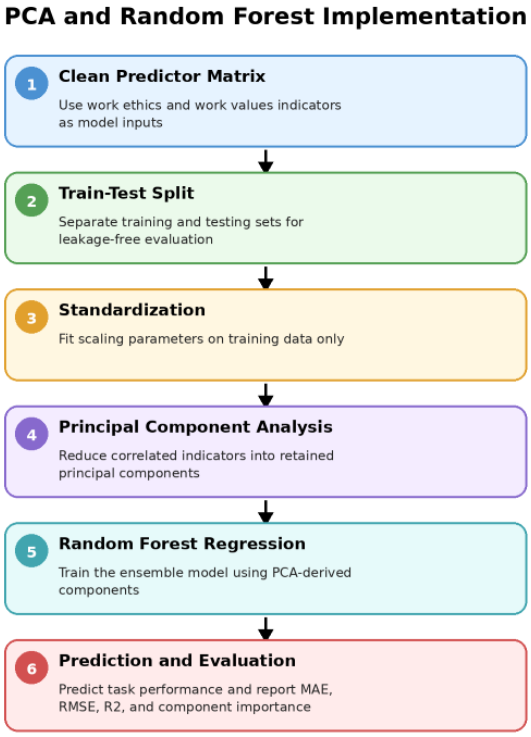

Fig. 2. PCA and random forest implementation.

I. Train–Test Procedure

To evaluate generalization performance, the dataset was partitioned into training and testing subsets. A practical split for the present sample is 80% training and 20% testing, with the random seed fixed for reproducibility. Model development, hyperparameter tuning, and PCA fitting were performed only on the training set to prevent information leakage. The trained transformation and model were then applied to the held-out test set. More specifically, the pipeline followed these steps:

- split the full dataset into training and testing sets,
- fit the standardization parameters using the training set only,

- fit PCA using the standardized training predictors only,
- transform both training and testing predictors using the fitted PCA model,
- train the Random Forest regressor on the transformed training set,
- generate predictions on the transformed test set.

This leakage-free workflow is aligned with best practices in supervised machine learning.

J. Hyperparameter Tuning

Random Forest performance depends on several tuning parameters. The following hyperparameters were optimized through k-fold cross-validation on the training set:

- number of trees (n_estimators),
- maximum tree depth (max_depth),
- minimum samples required to split a node (min_samples_split),
- minimum samples required at a leaf (min_samples_leaf),
- number of predictors considered at each split (max_features).

A 5-fold cross-validation procedure is suitable for the present sample size because it balances bias and variance in performance estimation. Grid search or randomized search may be used to identify the best-performing parameter combination. This is consistent with methodological recommendations for machine learning applications in psychology and social research.

K. Baseline and Comparative Models

To demonstrate the value of the hybrid approach, the PCA–Random Forest model should be compared against baseline models. The recommended comparison set includes:

- multiple linear regression,
- ridge regression or elastic net,
- decision tree regression,
- random forest without PCA.

Linear and regularized regression models provide interpretable baselines and are commonly recommended when working with many correlated predictors. Comparing the hybrid model against these alternatives allows the study to show whether PCA improves the predictive performance of Random Forest and whether nonlinear ensemble learning performs better than simpler linear approaches.

L. Model Evaluation Metrics

Model performance was evaluated using standard regression metrics. The principal metrics were Mean Absolute Error, Root Mean Squared Error, and Coefficient of Determination.

Robustness was examined by comparing cross-validation results with held-out test performance and by comparing the hybrid PCA–Random Forest model with standard Random Forest. Similar performance across cross-validation and test results was treated as evidence that the model was not merely fitting noise in one split of the data. Because the sample size was moderate, model complexity was controlled through cross-validation and hyperparameter tuning.

M. Model Interpretation

Because Random Forest is an ensemble model, interpretability must be explicitly addressed. The study, therefore, included a model explanation phase after prediction. Two levels of interpretation were proposed:

- Global interpretation, using permutation importance or impurity-based feature importance to determine which retained PCA components contributed most strongly to prediction,
- Local interpretation, using SHAP-based or Shapley-style explanation methods to estimate how features influenced individual predictions.

Interpretable machine learning is important because predictive accuracy alone is insufficient in applied organizational settings. Administrators need to know which dimensions of work ethics and work values are most strongly associated with employee performance in order to translate findings into policy or intervention. When PCA components are used, the interpretation should proceed in two stages: first, identify important components, then inspect the original variable loadings within those components to understand the substantive meaning of the prediction drivers.

For the hybrid model, interpretation was conducted by examining the importance of each retained principal component and then reviewing the original item loadings within the most influential components. Components were labelled based on the dominant work ethics and work values indicators that loaded on them. This procedure allowed the statistical output of PCA to be translated back into substantive organizational constructs.

N. Reliability and Measurement Assessment

Although the main contribution of the study is predictive, reliability and measurement adequacy should still be examined. For each major questionnaire dimension, Cronbach's alpha or an equivalent internal consistency statistic may be computed. This step helps establish that the grouped indicators used in the analysis show acceptable coherence. Psychometric evaluation remains important even in machine learning workflows because poor measurement quality can undermine predictive validity. In addition, descriptive statistics for each construct should be reported, including mean, standard deviation, minimum, maximum, skewness, and kurtosis. A correlation matrix may also be presented to show the extent of interdependence among the item groups before PCA.

O. Software Implementation

The analysis may be implemented in Python using standard scientific computing libraries:

- pandas for data handling,
- numpy for numerical operations,

- scikit-learn for standardization, PCA, train–test split, cross-validation, and Random Forest,
- matplotlib or seaborn for visual outputs,
- shap for model interpretation.

Python is appropriate because it supports end-to-end preprocessing, hybrid modeling, evaluation, and explainability within one reproducible workflow.

P. Ethical Considerations

The study used questionnaire responses from PSU employees and, therefore, involved human-subject data. Ethical handling of the dataset required that all records be analyzed in aggregate or anonymized form, with no direct personal identifiers retained in the modeling file. Access to the raw data should be limited to the researcher, and findings should be reported only at the level of patterns, not individual identities. These safeguards are especially important in workplace studies involving ethics, values, and performance.

III. Results and Discussions

This section presents the findings of the study and provides an interpretation of the results based on the data analysis. It highlights the patterns observed in the predictor constructs and compares the performance of the different regression models to explain their implications in relation to the objectives of the study.

A. Data Screening and Preliminary Analysis

The dataset contained 231 complete responses and 81 variables. No missing values were detected, and all item responses were within the valid Likert range of 1 to 5. This indicates that the dataset was already clean enough for predictive modeling without requiring imputation or deletion. A notable pattern in the data was the strong concentration of responses at the upper end of the scale. Across all item responses, about 69.8% were rated 5, 24.8% were rated 4, and only about 5.4% fell in the 1–3 range. This suggests that PSU employees generally rated themselves highly on work ethics, work values, and performance. At the same time, this pattern points to a likely ceiling effect, meaning the predictive models had to distinguish performance using relatively compressed high-score data rather than widely dispersed responses. The composite task performance score had a mean of 4.37 and a standard deviation of 0.50, with observed scores ranging from 2.86 to 5.00. This indicates that employee performance was generally high but still variable enough to support prediction.

The ceiling effect is an important limitation of the dataset. Since most responses were concentrated at the upper end of the scale, the models had less variation available for distinguishing respondents with different performance levels. This may reduce discrimination capability and may also explain why some normatively important constructs, such as integrity and transparency, were not among the strongest statistical predictors.

B. Reliability of the Scales

Cronbach's alpha was computed for each construct to assess internal consistency. All scales showed acceptable to excellent reliability. Table I shows the summary of the reliability test results.

TABLE I. Test of Reliability

Construct	Items	Mean	SD	Cronbach's alpha
Task performance	7	4.372	0.501	0.856
Commitment to public interest	7	4.417	0.506	0.743
Professionalism	7	4.552	0.428	0.843
Political neutrality	4	4.65	0.566	0.775
Justness and sincerity	5	4.764	0.413	0.901
Responsiveness to the public	6	4.689	0.399	0.862
Nationalism and patriotism	6	4.542	0.448	0.829
Commitment to democracy	3	4.641	0.531	0.922
Simple living	6	4.478	0.555	0.842
God-fearing	5	4.732	0.579	0.866
Accountability	5	4.718	0.439	0.9
Integrity	5	4.842	0.278	0.766
Transparency	5	4.808	0.347	0.852
Innovativeness	5	4.737	0.374	0.832
Competency	5	4.781	0.346	0.832

Table I reports reliability results for all major task performance, work ethics, and work values dimensions, including the number of items, mean, standard deviation, and Cronbach's alpha for each scale. This complete subscale reporting was added to allow readers to judge the internal consistency and measurement quality of every dimension included in the predictive model.

These findings show that the questionnaire dimensions were sufficiently coherent for both descriptive analysis and machine-learning modeling. The strongest reliability estimates were found for commitment to democracy ($\alpha = 0.922$), justness and sincerity ($\alpha = 0.901$), and accountability ($\alpha = 0.900$), while the lowest, though still acceptable, was commitment to public interest ($\alpha = 0.743$).

C. Descriptive Results

Among the predictor constructs, the highest mean scores were recorded for integrity (4.842), followed by transparency (4.808), competency (4.781), justness and sincerity (4.764), and innovativeness (4.737). In contrast, the lowest mean scores, although still relatively high, were found in task performance (4.372), commitment to public interest (4.417), simple living (4.478), nationalism and patriotism (4.542), and professionalism (4.552). This pattern suggests that PSU employees rated themselves most strongly in terms of personal and ethical standards, particularly integrity, transparency, and competency, while somewhat lower ratings were observed in more behaviorally demanding or institutionally oriented dimensions such as task performance and commitment to public interest. Substantively, this may indicate that respondents viewed themselves as highly principled and capable, but less uniformly

strong in consistently translating these values and orientations into high task-performance outcomes. Since all mean scores are well above 4.0, the issue does not appear to be weak ethics or poor performance, but rather which dimensions are most effective in explaining differences among an already high-performing group of respondents.

D. Bivariate Relationship with Task Performance

Table II shows the strongest positive correlations with task performance.

TABLE II. SUMMARY OF CORRELATION

Predictor construct	Correlation with task performance
Professionalism	0.455
Commitment to public interest	0.418
Nationalism and patriotism	0.36
Justness and sincerity	0.346
Responsiveness to the public	0.334
Accountability	0.314
Political neutrality	0.313
Commitment to democracy	0.305
Simple living	0.265
Integrity	0.241

These results suggest that professionalism had the strongest linear association with employee performance, followed by commitment to public interest. This is intuitive because the task-performance indicators focus on planning, efficiency, quality, and work execution, which are behaviorally close to professional conduct and duty orientation.

The weaker, though still positive, association of integrity with performance is also meaningful. Integrity had the highest descriptive mean, which implies little variation between respondents. When most respondents rate integrity very highly, it contributes less to differentiating who performs better than others. In short, a construct can be important normatively without being the strongest statistical predictor if almost everyone scores high on it.

The findings show that the hybrid PCA–Random Forest model did not substantially outperform the standard Random Forest model. The standard Random Forest achieved a slightly higher held-out R^2, whereas the hybrid model achieved a slightly lower MAE and comparable RMSE. Therefore, the main contribution of the hybrid model is not a large gain in predictive accuracy, but the ability to reduce 74 predictor items to 19 components while preserving almost the same level of predictive performance. This makes the model more compact and less redundant, which is useful for interpretation and future implementation.

E. Predictive Model Performance

Six regression models were estimated and compared using the uploaded item-level predictors: Linear Regression, Ridge Regression, Elastic Net, Decision Tree, Random Forest, and a Hybrid PCA–Random Forest model. The hybrid approach first applied principal component analysis (PCA) to reduce the 74 predictor items into 19 principal components, which together accounted for 80.9% of the variance in the predictor space. These extracted components were then used as inputs to a Random Forest regressor.

TABLE III. CROSS-VALIDATION TEST RESULTS

Model	CV MAE	CV RMSE	CV R^2
Linear Regression	0.378	0.536	0.119
Ridge Regression	0.365	0.512	0.213
Elastic Net	0.36	0.453	0.38
Decision Tree	0.328	0.43	0.417
Random Forest	0.272	0.378	0.526
PCA–Random Forest	0.272	0.376	0.524

TABLE IV. HELD-OUT TEST RESULTS

Model	Test MAE	Test RMSE	Test R^2
Linear Regression	0.385	0.522	0.119
Ridge Regression	0.365	0.493	0.213
Elastic Net	0.357	0.438	0.38
Decision Tree	0.301	0.424	0.417
Random Forest	0.283	0.383	0.526
PCA–Random Forest	0.272	0.383	0.524

Table III and IV show the test results of cross-validation and held-out. The main result is that the ensemble models clearly outperformed the linear models. Both Random Forest and PCA–Random Forest substantially improved prediction relative to Linear Regression, Ridge, and Elastic Net. This means the relationship between employee performance and the ethics-values predictors is not purely linear. Instead, the data appear to contain interaction effects, nonlinearities, or threshold-like patterns, which tree-based ensemble methods are better able to capture.

The best overall performance was shared by the two Random Forest variants. The standard Random Forest had the best test RMSE (0.383) and test R^2 (0.526), while the PCA–Random Forest had the best test MAE (0.272) and the best cross-validated RMSE (0.376). In practical terms, the difference between the two is very small. The implication for the study:

- if emphasis is pure predictive accuracy, the standard Random Forest is marginally stronger,
- if emphasis is on the hybrid framework named in the title, then the PCA–Random Forest is fully defensible because it performed essentially the same while reducing the predictor space from 74 items to 19 components.

That is a strong methodological result. It means that PCA compressed the survey into a more manageable representation without materially sacrificing predictive power.

F. Why the Hybrid PCA–Random Forest Model Worked

The hybrid model worked well for two reasons. First, the survey contains many conceptually related Likert items. For example, professionalism, accountability, transparency, and

competency are distinct constructs but are likely to co-vary in practice. PCA helped summarize these overlapping responses into a smaller number of orthogonal dimensions, reducing redundancy and multicollinearity. Second, Random Forest was able to model the resulting component space flexibly. Because employee behavior is rarely determined by one variable in a simple linear way, the ensemble model likely captured combinations such as:

- strong professionalism plus strong public responsiveness,
- high public-interest orientation plus accountability,
- or moderate scores across several ethical domains rather than a single dominant trait.

This is exactly the kind of pattern that Random Forest handles better than ordinary linear regression.

G. Feature Importance and Substantive Predictors

Table V shows the feature importance and substantive predictors. The most important predictor was professionalism, which is consistent with the correlation results. This suggests that employees who reported stronger adherence to professional conduct also tended to have higher task-performance scores. This makes theoretical sense because professionalism reflects disciplined work behavior, standard procedure compliance, and appropriate workplace conduct, which are closely aligned with task execution.

TABLE V. FEATURE IMPORTANCE AND SUBSTANTIVE PREDICTORS

Construct	Importance
Professionalism	0.203
Nationalism and patriotism	0.117
Commitment to public interest	0.077
Simple living	0.064
Political neutrality	0.057
God-fearing	0.055
Innovativeness	0.043
Responsiveness to the public	0.034
Justness and sincerity	0.027
Accountability	0.026

The second strongest predictor was nationalism and patriotism, which is interesting because it was not the highest-mean construct. This suggests that while patriotism-related items may not be the most highly endorsed overall, they contributed meaningful variation in performance prediction. In the PSU setting, this may reflect a broader sense of institutional duty, public commitment, and mission alignment.

Commitment to public interest also emerged as a key predictor. This is important because it directly reflects service orientation and responsible use of public resources, both of which are highly relevant to employee effectiveness in a public institution.

A particularly interesting result is that integrity, despite having the highest mean score, was not among the strongest predictive variables. This likely reflects restricted variance: when almost everyone scores high on integrity, it cannot separate higher-performing from lower-performing employees as strongly as more behaviorally variable constructs such as professionalism.

H. PCA Structure of the Hybrid Model

The PCA stage retained 19 components explaining 80.9% of the total predictor variance. The first principal component alone explained about 25.5% of the variance, suggesting a strong common dimension underlying many of the ethics and values items.

The most influential component in the hybrid model was PC1, far more important than the remaining components. Its strongest loadings came from items related to:

- justness and sincerity,
- commitment to democracy,
- professionalism,
- transparency,
- nationalism/patriotism,
- and simple living.

This suggests that the first component captured a broad ethical-public service orientation, and that this general orientation played a major role in predicting employee performance.

Based on the dominant loadings, PC1 was interpreted as a Broad Ethical-Public Service Orientation component because it combined justness and sincerity, commitment to democracy, professionalism, transparency, nationalism and patriotism, and simple living. This label indicates that the strongest component represented a general pattern of ethical conduct, public accountability, and disciplined professional behavior.

From a discussion standpoint, this means that performance in PSU may not depend on isolated moral traits alone, but on a clustered ethical profile combining fairness, professionalism, service orientation, and responsibility. In other words, the model points to a multidimensional moral-professional foundation for effective task performance.

I. Discussion of the Result

The overall descriptive results show a strongly positive self-assessment pattern. This may reflect genuinely high organizational standards, but it may also indicate socially desirable responding, especially in self-report ethics measures. Because the survey asks respondents to rate highly valued public-service behaviors, upward skew is not surprising.

The reliance on self-reported survey data may have inflated the observed scores because employees may respond in ways that reflect socially desirable behavior. This is especially likely for ethics and values indicators. Future studies should triangulate self-report measures with supervisor ratings, peer

assessments, attendance records, productivity indicators, or other administrative performance data.

Even so, the variation that remained was enough for machine learning to explain about 52% of the performance variance. That is substantial for social-science survey data and suggests that work ethics and work values contain meaningful predictive information.

Across both correlation and feature-importance analyses, professionalism emerged as the dominant predictor. This is a strong and coherent result. It implies that among the many moral and value-based dimensions in the questionnaire, the construct most directly tied to actual performance is the one most closely linked to work discipline, standards, competence in role behavior, and execution of duty.

This finding is particularly useful for institutional practice because professionalism is also one of the most actionable domains. It can be strengthened through training, supervision, performance feedback, and policy reinforcement.

The data do not suggest that ethics and values are irrelevant; quite the opposite. However, they indicate that some domains matter more for performance differentiation than others. Broadly endorsed traits such as integrity and transparency may represent foundational norms, but they did not distinguish performance as strongly as professionalism, public-interest orientation, and nationalism/patriotism.

This distinction is important. It suggests that normative importance and predictive importance are not the same thing. A value may be central to institutional identity but still show weaker statistical prediction if it varies little across respondents.

The consistent superiority of Random Forest over Linear Regression, Ridge, and Elastic Net shows that this type of survey data benefits from nonlinear modeling. In practical terms, employee performance appears to arise from combinations of values rather than from simple additive effects.

A very important discussion point is that the hybrid model did not massively outperform standard Random Forest. But it also did not lose meaningful accuracy, despite reducing 74 predictors to 19 components.

That is still a success. It means the hybrid approach offers:

- dimensionality reduction,
- less redundancy,
- easier modeling,
- and nearly identical predictive performance.

So, in the study, the correct interpretation is not that PCA made Random Forest vastly more accurate, but that it made the model more compact and methodologically elegant without sacrificing accuracy.

This result also suggests that PCA should be viewed as a feature-compression strategy rather than as an automatic accuracy-improvement technique. Because Random Forest can internally manage correlated predictors, PCA is most useful here for reducing dimensionality and summarizing overlapping questionnaire items. The near-equivalent performance of both models indicates that the compressed component structure retained most of the useful predictive information from the original survey items.

J. Implications of the Findings

The results suggest that PSU can improve employee performance by focusing on the ethics and values dimensions that show the strongest predictive contribution, especially:

- professionalism,
- commitment to public interest,
- nationalism and patriotism,
- and selected value-based domains tied to accountability and service.

For organizational development, this means that ethics programs should not remain purely abstract or compliance-based. They should be linked to concrete performance behaviors such as planning work, delivering outputs on time, and maintaining high-quality service.

The findings also support the use of machine learning in HR and organizational research within educational institutions. A hybrid PCA–Random Forest framework can help identify which ethical and value-based dimensions are most useful in explaining performance variation, especially when many survey items overlap conceptually.

For practical deployment, the model should be used as a decision-support tool rather than as a punitive or fully automated evaluation system. Predictions should be reviewed in aggregate, anonymized where possible, and combined with professional judgment and existing human resource procedures. The model should also be monitored for stability over time and revalidated before being applied to other campuses, institutions, or employee groups.

IV. Conclusion and Recommendations

This section summarizes the major findings of the study and draws overall conclusions and future work based on the results obtained. It synthesizes the key insights from the analysis and emphasizes their significance in addressing the research objectives.

A. Conclusion

This study developed and evaluated a hybrid PCA–Random Forest model to predict employee performance from work ethics and work values among PSU employees. Results showed generally high levels of task performance, work ethics, and work values, indicating strong adherence to ethical standards and positive work-related values. Despite these high ratings, sufficient variation in task performance remained to support predictive modeling and model comparison.

Reliability analysis showed that the questionnaire dimensions had acceptable to excellent internal consistency, confirming the instrument's suitability for both descriptive and predictive analysis. In model evaluation, ensemble-based methods outperformed traditional linear approaches. Random Forest and the hybrid PCA–Random Forest model achieved the best predictive performance, suggesting that employee

performance is shaped by nonlinear and interaction-based relationships among work ethics and work values. Although the standard Random Forest yielded slightly better results on some metrics, the hybrid model remained highly competitive while reducing the predictor space to a smaller set of principal components.

Among the predictors, professionalism emerged as the strongest determinant of employee performance, followed by commitment to public interest, nationalism, and patriotism. These findings indicate that employee performance at PSU is more strongly associated with ethical-professional orientations related to discipline, accountability, and public service. Overall, the results support the hybrid PCA–Random Forest model as a valid and practical approach for predicting employee performance in a public university context and demonstrate the value of machine learning in examining ethics- and values-based factors in the workplace.

B. Recommendations

Based on the findings, PSU should strengthen programs that promote professionalism, since it emerged as the strongest predictor of task performance. The university should also continue reinforcing its commitment to public interest and other service-oriented values through training and development activities.

In addition, ethics and values-based interventions should be integrated more directly into performance improvement programs. PSU may also use data-driven tools, such as Random Forest and hybrid PCA–Random Forest models, to support employee assessment and human resource decisions.

For future research, the model should be tested using larger and more diverse samples from other universities, government agencies, or private organizations. External validation is necessary to determine whether the predictive patterns observed in the PSU dataset generalize to other organizational and cultural contexts. Future studies should also use longitudinal designs to examine possible causal pathways, combine self-reported data with supervisor or administrative performance records, conduct robustness and sensitivity analyses across repeated splits or bootstrapped samples, and provide full PCA loading tables and complete correlation matrices for transparency.

***Abstract*—In the past decade, the number of available 3D models has grown rapidly. This growth is mainly driven by the development of scanning devices and increasing demand for 3D meshes in many application fields. As a consequence, it becomes crucial to have consistent content-based retrieval systems of large 3D mesh repositories. However, many existing methods still struggle to achieve a good compromise between efficiency and accuracy, especially on large and heterogeneous databases. In this work, we propose a supervised framework for building compact but discriminative 3D shape descriptors. For each mesh, we start by computing three features - the dihedral angles between adjacent faces, the Shape Diameter Function (SDF), and the Shape Index - then we convert them into normalized histograms and concatenate them into a single feature vector, which is then used as input to an Explainable Boosting Classifier (EBC). After training, the classifier produces, for each mesh, a short probability vector that we use as its numerical descriptor. Experiments on the standard Princeton Benchmark database validate our approach, achieving a mean Average Precision (mAP) of 97.23%, outperforming the selected baseline methods under the adopted experimental protocol.**

***Keywords*—3D shape retrieval; content-based indexing; shape descriptor; explainable boosting classifier**

I. Introduction

As 3D model databases continue to grow rapidly in medicine, engineering, and multimedia, there is an urgent need for efficient retrieval systems that can support powerful discrimination capabilities. This necessity has motivated research in content-based indexing to become a significant area of study [1],[2],[3], Early attempts at addressing this challenge focused on extracting shape descriptors based on geometric measures [4], [5].

The expressive limitations of these handcrafted descriptors led to a paradigm shift toward deep learning. These new techniques achieved state-of-the-art performance by learning features directly from various data representations, such as multi-view projections and voxel-based grids [6], [7], [8]. This success, however, is counterbalanced by significant drawbacks: deep learning models typically require vast labeled datasets, substantial computational resources, and their 'black box' nature limits interpretability.

These challenges have led to a renewed interest in alternative approaches that blend compact, handcrafted geometric descriptors with interpretable learning algorithms. Among these, the Explainable Boosting Classifier (EBC) [9] offers a compelling compromise between predictive performance and full interpretability. By constructing an additive model from shallow decision trees, the EBC achieves high performance while generating a descriptor ideally suited for efficient 3D mesh indexing.

In this work, we introduce a new retrieval method that directly addresses the aforementioned challenges. We combine the Explainable Boosting Classifier (EBC) with a robust set of geometric features. Specifically, we employ three such features: dihedral angles, which reveal local angular relationships, and the Shape Diameter Function (SDF)[10], which provides information on object thickness, and the Shape Index [11], which describes local surface topology.

This study is structured as follows. Section II reviews related work. Section III details our proposed method. Section IV validates our approach through experimental analysis, and Section V concludes with a summary of our contribution and discusses future work.

II. Related Works

The field of Content-Based 3D Shape Retrieval has historically evolved along two axes: traditional methods based on geometric descriptors, and more recent approaches leveraging deep learning.

A. Traditional Methods

Initial research focused on extracting shape descriptors from geometric properties, leading to two main families.

1) Global descriptors: Represent an entire model in a single vector. Early works used statistical methods like shape distributions [4] or spectral approaches like spherical harmonics [12]. More recently, methods like DEA-based optimization [13] integrated multiple geometric properties to improve performance. However, the global nature of these descriptors limits their robustness to partial matching and articulation, and they often struggle to capture high-level semantics.

2) Local descriptors: Local descriptors were developed to address the limitations of global methods against partial matching and articulation. For instance, Van Blokland et al. [14] introduced binary descriptors from local ray-intersections,

achieving robust partial matching on the SHREC'16 benchmark using a dissimilarity tree. Similarly, Arhid et al. [15] improved performance on articulated objects by segmenting the mesh and matching per-part DEA descriptors. However, local methods are computationally expensive due to the part-matching problem and sensitive to initial segmentation quality.

B. Machine Learning Approaches

The limitations of handcrafted descriptors on complex shapes led to the rise of learning-based techniques, which automatically learn discriminative features and consistently outperform traditional methods.

1) View-based methods: These methods were among the first to apply deep learning by converting 3D objects into sets of 2D projections for use with CNNs. MVCNN [7] pioneered this approach by aggregating features from multiple views. Later works like RotationNet [16] and GVCNN [17] enhanced this concept by improving the aggregation method and reducing sensitivity to object orientation. These techniques are very powerful; however, their success is quite dependent on the selection and number of representative views.

2) Voxel-based deep representations: Volumetric methods convert meshes into voxel grids to enable 3D convolutions. 3D ShapeNets [6] introduced a probabilistic volumetric representation, while VoxNet [8] proposed a more compact and efficient architecture. However, these methods suffer from high memory requirements and resolution limitations, restricting their ability to capture fine geometric details.

3) Point cloud-based deep architectures: Point-based neural networks were developed to operate directly on 3D point clouds, thus avoiding the problems of volumetric discretization. The foundational PointNet model [18] achieved permutation invariance by using symmetric functions to aggregate point features. This concept was extended by PointNet++ [19], which applied the architecture hierarchically to learn local features, and later by DGCNN [20], which used a dynamic graph to better encode neighborhood relations. While these approaches retain fine geometric detail, they are highly dependent on the initial point sampling and sensitive to density variations.

C. Mesh-Based Deep Learning Methods

To avoid the information loss and processing overhead associated with data conversion, mesh-based deep neural networks operate directly on the native polygonal structure. Pioneering works like MeshCNN [21] introduced convolutions on mesh edges, using edge-collapse pooling to preserve topology. MeshNet [22] took a different approach by learning from face attributes, while methods like SpiralNet++ [23] view the mesh as a graph and apply convolutions along spiral vertex sequences to capture local geometry. Although this family of models yields detailed descriptors, they generally incur a high computational cost, especially for meshes with complex geometry.

D. Hybrid Learning Methods

Between purely hand-crafted shape descriptors and deep neural networks, hybrid approaches have emerged that leverage explicit geometric features within supervised models. Bouksim et al. [24] proposed a neural network-based method before transitioning to a CatBoost-based method [25], [26]. In their approach, geometric features are extracted from 3D meshes and used as input to the classifier. Their findings demonstrate that this strategy significantly improves retrieval accuracy compared to using raw geometric descriptors, while maintaining a simple and efficient pipeline.

Our work addresses the gap between traditional efficiency and deep learning accuracy. We use a boosting classifier in a novel capacity: to transform simple geometric features into a compact descriptor. By leveraging the classifier's output probability vector as the final shape descriptor, our method achieves high retrieval accuracy while remaining computationally efficient, providing a practical alternative to resource-intensive deep learning architectures.

III. Proposed Method

In this study, we use a hybrid 3D shape retrieval method based on an Explainable Boosting Classifier (EBC) trained with geometric mesh properties. The main idea of the proposed approach is to use the class-probability vector obtained by our EBC model as a compact descriptor for each 3D object, which can be efficiently used for similarity-based retrieval. The following sections will elaborate on the theoretical foundation and implementation details.

A. From Classification to Similarity

Our main hypothesis is that the class-probability vector from a well-trained classifier can serve as a compact descriptor. Indeed, by learning to separate classes, the classifier builds an internal model of the key geometric and semantic features of the data. We argue that two semantically similar shapes, even from different classes (e.g., a bird and an airplane), will be processed similarly by this model, leading to comparable probability distributions. Consequently, the distance between these probability vectors becomes a measure of high-level semantic similarity, capturing a likeness that goes beyond simple class categories. Measuring the similarity between these probability vectors therefore requires a metric that captures their directional alignment in the probability space. As demonstrated empirically in Section IV-B(5), the Cosine distance is the most effective choice for this purpose, since the discriminative information in EBC signatures is primarily encoded in the orientation of the probability vector rather than its magnitude.

B. Boosting and Explainable Boosting Classifier (EBC)

The theory behind our approach is based on ensemble learning, and more specifically, boosting. Boosting is an iterative technique that combines several weak classifiers (whose performance is slightly better than random choice) to form a single strong and highly accurate classifier. The principle is that each new weak model is trained to correct the prediction errors made by previous models, gradually improving the overall performance of the system.

The Explainable Boosting Classifier (EBC), also known as the Explainable Boosting Machine (EBM) [9], belongs to the Generalized Additive Models (GAM) family. These models represent predictions as a sum of functions, where each function

captures the contribution of an individual feature or a pair of features. The structure of an EBM is defined as:

$$g(E[y]) = \beta_0 + f_1(x_1) + f_2(x_2) + .. + f_k(x_k) \quad (1)$$

where, $\boldsymbol{g}$ is a link function, $\boldsymbol{E[y]}$ is the expected prediction, and each $\boldsymbol{f_j}$ is a shape function that models the impact of the feature $\boldsymbol{x_j}$

The Explainable Boosting Classifier (EBC) employs gradient boosting algorithms to learn feature functions $\boldsymbol{f_j}$, which captures the value of each feature to the model, with shallow decision trees. Its primary strength is that it is interpretable: EBC, in contrast to neural networks, being a black box model, is a glass box model, i.e., the contribution of each feature could be isolated and visualized. Through this transparency, we can know not only the general behavior of the model, but also can explain the individual predictions. With the combination of good precision and easy interpretability, EBC was chosen for this work to enable content-based indexing and retrieval by providing a competitive performance.

C. Geometric Features Used

To train our classifier, we combined three histograms of features extracted from the 3D object. These features were chosen for their simplicity of calculation, their invariance to rigid transformations, and their discriminating power proven in the literature.

Dihedral angle [27]: A widely used feature that measures the angle between two adjacent faces. It effectively captures local geometry and the sharpness of creases and is calculated from the faces' normal vectors. The following equation can express the dihedral angle:

$$\theta = arcos\left(\frac{\overrightarrow{n_1}.\overrightarrow{n_2}}{||\overrightarrow{n_1}||\,||\overrightarrow{n_2}||}\right) \quad (2)$$

where:

- $\boldsymbol{\theta}$ is the dihedral angle,
- $\overrightarrow{\boldsymbol{n_1}}$ and $\overrightarrow{\boldsymbol{n_2}}$ are the normal vectors of the two adjacent faces,
- $\cdot$ represents the dot product,
- $||\,\overrightarrow{n_1}\,||$ and $||\,\overrightarrow{n_2}\,||$ are the norms of the normal vectors.

Shape Index [11] proposed by Koenderink, the Shape Index describes the local surface topology based on its principal curvatures. It provides a continuous scale for categorizing local shape (e.g., convex, concave), making it an effective feature for segmentation and indexing. The Shape Index $\boldsymbol{S}$ is calculated using the principal curvatures $\boldsymbol{k_1}$ and $\boldsymbol{k_2}$ at a point on the surface, as expressed in the following equation:

$$S = \frac{2}{\pi}\arctan\left(\frac{k_2+k_1}{k_2-k_1}\right) \quad (3)$$

where,

- $\boldsymbol{k_1}$ and $\boldsymbol{k_2}$ are the main curvatures with $\boldsymbol{k_2 \geq k_1}$, note that this index is not defined for flat areas ($\boldsymbol{k_1 = k_2}$).

Shape Diameter Function (SDF) [10]: A scalar function that captures the local thickness of the mesh. For each surface point, SDF measures the distance to the opposite side of the mesh along the inverted normal vector.

For each of the three geometric properties (SDF, Dihedral Angle, and Shape Index), a histogram is computed using 128 bins. To ensure a consistent representation, the value range for each histogram is determined globally from the statistics of the entire training dataset.

Finally, these three histograms are concatenated to form a single feature vector of dimension 384 (3 * 128), which serves as the input for our EBC classifier.

D. Descriptor Generation and Comparison

The process of creating and comparing descriptors involves three main steps:

1) Training and optimization: Before feature extraction, all 3D meshes underwent a standardized preprocessing pipeline consisting of size normalization and centering, whereby each model's center of mass was translated to the origin. An Explainable Boosting Classifier (EBC) from the InterpretML library was then trained on the concatenated histogram of geometric features. To identify the optimal hyperparameter configuration, a systematic grid search was conducted over the following ranges: n_estimators $\in \{10, 50, 100\}$, learning_rate $\in \{0.01, 0.05, 0.1\}$, and max_bins $\in \{128, 256, 512\}$. Model selection was performed using stratified 10-fold cross-validation, ensuring that each fold maintains a proportional representation of all 19 semantic classes. This stratification prevents class imbalance across folds and guarantees that no class is absent from either the training or validation partition during any fold, thus ensuring reproducible and unbiased hyperparameter selection. The optimal configuration identified by this process is reported in Table I.

TABLE I. OPTIMAL EBC HYPERPARAMETERS SELECTED VIA GRID SEARCH WITH STRATIFIED 10-FOLD CROSS-VALIDATION. THESE SETTINGS WERE RETAINED FOR ALL EXPERIMENTS REPORTED IN THIS STUDY

Hyperparameter	Value	Description
n_estimators	50	Number of boosting rounds (trees).
learning_rate	0.1	Step size shrinkage to prevent overfitting.
max_bins	256	Maximum number of bins for feature discretization.
random_state	42	Ensures reproducibility of the training process

2) Descriptor generation and refinement: The trained classifier is applied to generate a descriptor for each 3D model. For a given object, the feature vector is passed through the classifier to produce its probability vector. To ensure consistency across all models in the dataset, we enforce a fixed class ordering using the classifier's classes_ attribute, ensuring that all descriptors share identical dimensional structure and class correspondence. A key advantage of the Explainable Boosting Classifier is that it inherently produces well-calibrated probability estimates due to its Generalized Additive Model (GAM) structure and gradient boosting mechanism. Unlike

many ensemble methods that require post-hoc calibration (e.g., Platt scaling or Isotonic Regression), the EBC's additive formulation given in Eq. (1) and round-wise optimization naturally yield reliable probability outputs. The resulting probability vector serves as a compact and discriminative descriptor, encoding the shape's similarity distribution across all learned classes.

3) Similarity measurement: Finally, after generating the refined descriptors, we compute the similarity between two 3D models. While descriptors represent probability distributions, our analysis (Table III) reveals that the semantic classes are highly separated in the probability space. Among the distance metrics evaluated (Jensen-Shannon divergence [28], a symmetrized variant of the Kullback-Leibler divergence [29], Euclidean, Cosine Similarity), Cosine Similarity achieves the best performance (97.23% mAP), demonstrating that the angular direction of the probability vector is highly discriminative. This metric is particularly effective for our high-dimensional probability descriptors, as it focuses on the direction rather than the magnitude of the vectors, making it robust to scale variations and computationally efficient.

IV. Experimental Results

We conduct experiments on the Princeton Shape Benchmark (PSB), which contains 390 3D mesh models distributed across 19 semantic classes. This database serves as a standard evaluation testbed for 3D shape retrieval research.

A. Experimental Protocol

To ensure a rigorous evaluation of our method, we adopted an experimental protocol designed to prevent information leakage and ensure comparability with state-of-the-art methods.

1) Method overview: The retrieval system operates in two stages. First, an Explainable Boosting Classifier is trained on geometric feature histograms. The classifier learns to map shapes to a 19-dimensional probability space that captures semantic similarity. These vectors are then used as descriptors, and the similarity between models is computed using Cosine distance to rank the results.

2) Evaluation setup: We follow the standard PSB query-by-example protocol, where each of the 390 models is used as a query against the full dataset (excluding itself), and results are ranked using Cosine similarity. Performance is evaluated with standard metrics (NN, FT, ST, DCG, mAP). Although PSB is a widely used benchmark, it remains a moderate-scale dataset; it was selected to ensure a fair comparison with baseline methods evaluated under the same conditions. Evaluating the approach on larger datasets such as SHREC or ModelNet40 is left for future work. This protocol ensures a rigorous and consistent evaluation framework widely adopted in 3D shape retrieval research.

3) Comparison methods: We evaluate our approach against four well-known methods: two learning-based methods (an ANN-based descriptor and a CatBoost-based method) and two classical methods (Panorama and LightField). All comparisons use the same query set and evaluation metrics to ensure fairness.

4) Evaluation metrics: The performance of our method is evaluated globally across all queries using a comprehensive set of standard retrieval metrics, including the Precision-Recall Curve, Nearest Neighbor (NN), First Tier (FT), Second Tier (ST), and Discounted Cumulative Gain (DCG). These metrics are calculated as defined by the standard PSB evaluation scripts, ensuring our results are directly comparable to the literature.

B. Performance Evaluation

1) Performance analysis via precision-recall curve: We initially assess the general quality of our method through the Precision- Recall (P-R) curve analysis, as shown in Fig. 1. This curve measures a descriptor's ability to retrieve all relevant models (Recall) without returning incorrect results (Precision).

As can be seen by inspection of the graph, our EBC method (in red) is clearly superior. Its curve remains at a precision of 1.0 across almost the entire recall scale, an exceptional result that demonstrates a near-perfect discriminative power. In practice, this means that our descriptor can retrieve the vast majority of similar shapes before making a single classification error.

Our approach outperforms CatBoost, the closest competitor, and significantly surpasses view-based methods (LightField, Panorama) as well as ANN, whose performance typically degrades at higher recall levels. Overall, the P-R analysis confirms the strong effectiveness of our descriptor for high-precision 3D shape retrieval.

2) Per-class performance analysis: We analyse here the robustness of our descriptor across the different classes of the database. For this test, we measure the precision within the top K=10 and K=20 results to evaluate the performance midway and across the entire class. Fig. 2 (for K=10) and Fig. 3 (for K=20) present the results.

At K=10 Fig. 2, our EBC method (in red) exhibits a remarkably stable and high performance, close to 1.0 across almost all classes. CatBoost (in green) follows a similar trend, confirming the robustness of boosting approaches. In contrast, the other methods already show signs of weakness: ANN and Panorama suffer from notable performance drops on certain categories, and Lightfield exhibits by far the greatest variability.

The more demanding analysis at K=20 Fig. 3 is even more telling. Our EBC method maintains exceptional consistency and precision, proving it does not just succeed on the easy cases. This level of stability is not matched by the competing methods, whose inter-class variability becomes more pronounced and whose weaknesses observed at K=10 are here clearly exacerbated.

In conclusion, this per-class evaluation confirms the superior robustness of our descriptor. It is not only more performant on average but also more reliable and consistent across a wide spectrum of 3D shapes.

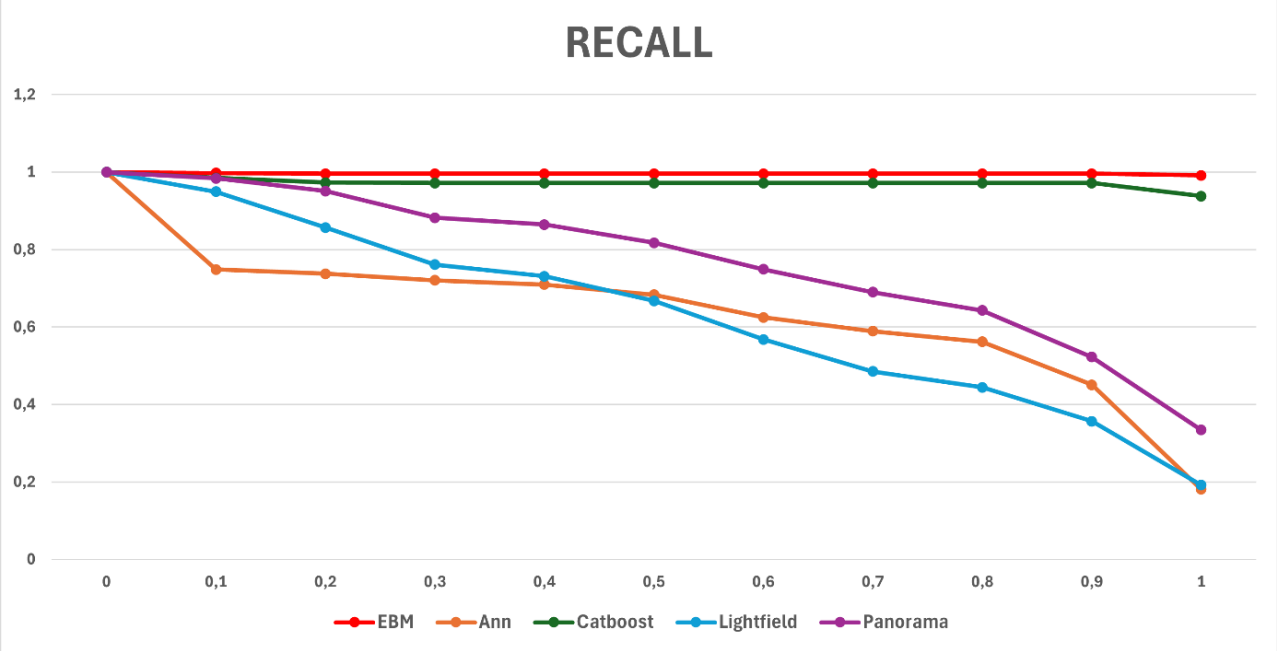

Fig. 1. Precision-Recall curves for the proposed EBC method and four baseline descriptors on the PSB. The EBC (red) maintains near-perfect precision across the full recall range, demonstrating superior discriminative power over all competing methods.

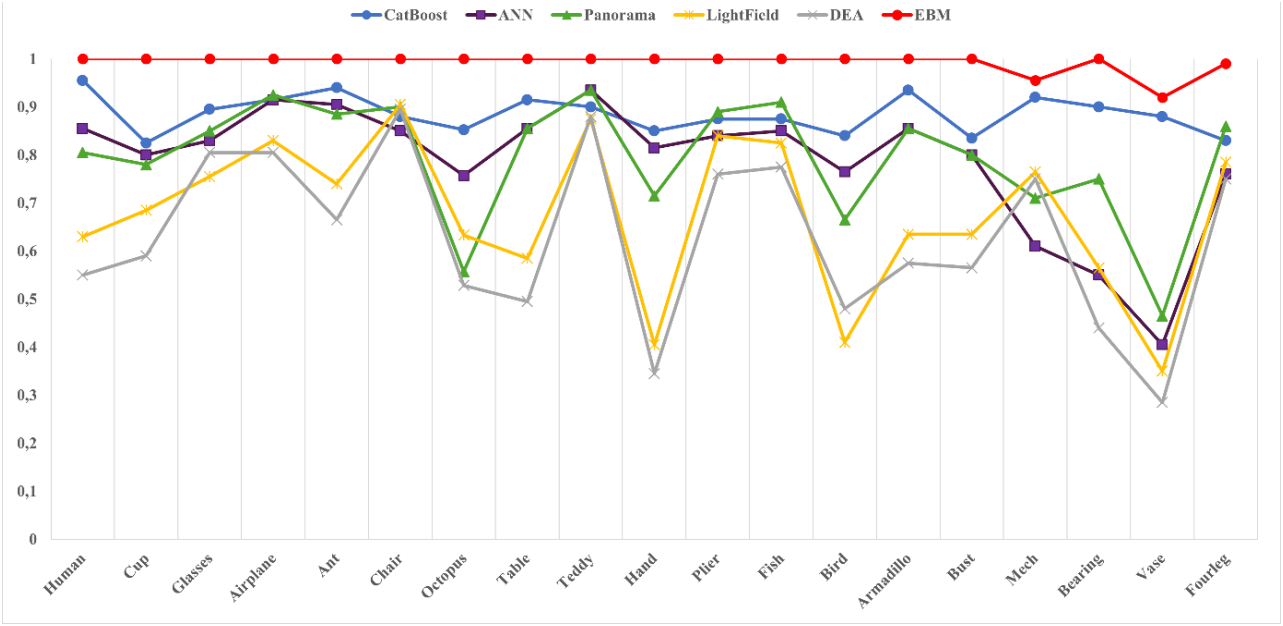

Fig. 2. Per-class retrieval precision at K=10 across the 19 PSB semantic classes. The EBC (red) achieves consistently high and stable scores, while competing methods exhibit notable variability across categories.

TABLE II. QUANTITATIVE COMPARISON OF THE PROPOSED EBC DESCRIPTOR AGAINST FOUR BASELINE METHODS ACROSS STANDARD PSB RETRIEVAL METRICS. BEST SCORES ARE HIGHLIGHTED IN BOLD. THE EBC ACHIEVES THE HIGHEST PERFORMANCE ON ALL METRICS

Descriptors/Metrics	NN	NN+1	1st Tier	2nd Tier	DCG	F-Measure
EBC	**0.99**	**0.99**	**0.99**	**0.53**	**0.99**	**0.46**
CatBoost	0.98	0.97	0.96	0.52	0.98	0.45
Panorama	0.97	0.92	0.73	0.43	0.92	0.42
LightField	0.91	0.84	0.57	0.36	0.86	0.38
ANN	0.95	0.93	0.80	0.45	0.86	0.38

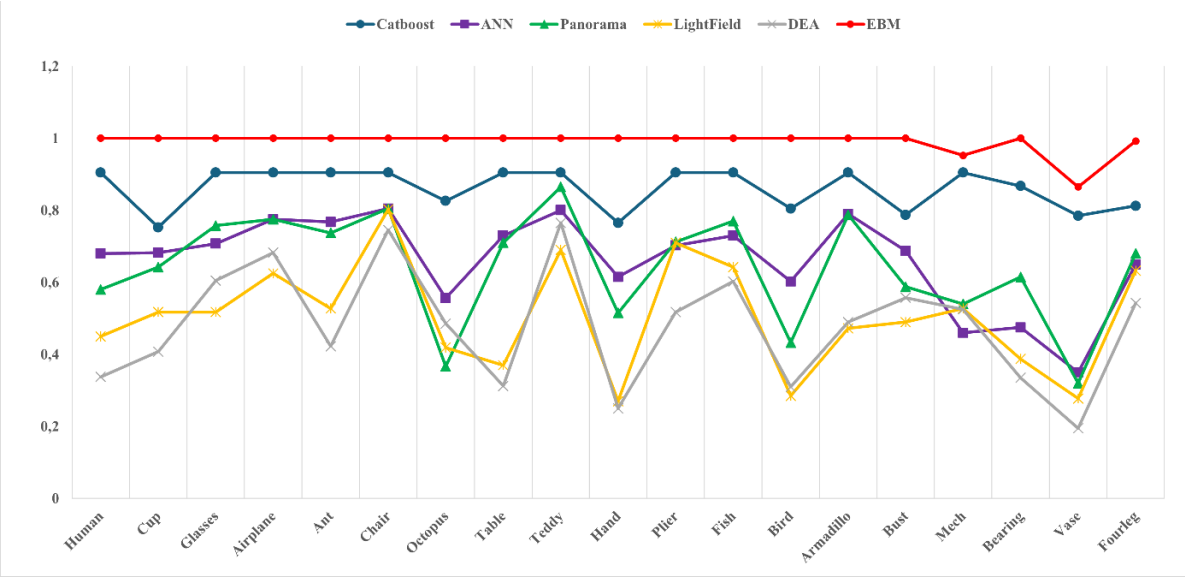

Fig. 3. Per-class retrieval precision at K=20 across the 19 PSB semantic classes. The performance gap between the EBC (red) and competing methods widens compared to K=10, further confirming the robustness and consistency of the proposed descriptor.

3) Quantitative evaluation with standard metrics: To supplement the graphical analyses, we now perform a quantitative comparison of our EBC descriptor against competing methods using a set of standard metrics. Table II summarizes the results for Nearest Neighbor (NN), First Tier (FT), Second Tier (ST), F-Measure, and Discounted Cumulative Gain (DCG).

The data in the table unequivocally confirms the superiority of our EBC method. It achieves the highest score across all metrics, which quantifies the dominance observed in the previous visual analyses (P-R curve and per-class stability). The nearly perfect Nearest Neighbor (NN) score demonstrates the exceptional accuracy of our descriptor in identifying the single best match for a query. Furthermore, the excellent DCG score proves that the overall quality of the results ranking is also superior, with relevant models being consistently placed at the top of the list.

The duel with CatBoost is once again won by our approach on every measure, although the margin is tighter, confirming the competitiveness of boosting algorithms. The other methods (ANN, Panorama, Lightfield) systematically rank lower, validating the performance trends already observed. In conclusion, this set of quantitative tests provides definitive, numerical proof of our descriptor's effectiveness, establishing it as a new state-of-the-art for 3D shape retrieval.

4) Qualitative evaluation via dissimilarity matrix: To assess the quality of our descriptor, we have computed a dissimilarity matrix for each pair of objects in the database based on their distances. A method that performs well should produce, through visualization, "diagonal blocks" of low dissimilarity (high intra-class similarity) and "off-diagonal" areas of high dissimilarity (low inter-class similarity).

Our matrix is shown in Fig. 4 displays a deep red color along the diagonal (indicating low dissimilarity), corresponding to a quantitatively very low dissimilarity score in the [0, 0.2] range, confirming that the methods groups the objects from the same category with a high degree of cohesion; whereas the off-diagonal region shows a uniformly red color (indicating a systematic high dissimilarity score, in the [0.8, 1.0] range) demonstrating the good discrimination capacity of our method in distinguishing the various categories.

5) Impact of distance metric choice: To select the most appropriate distance metric for comparing EBC probability descriptors, we conducted a systematic evaluation of three candidates: Cosine distance, Jensen-Shannon (JS) divergence, and Euclidean (L2) distance. As shown in Table III, Cosine distance achieves the highest retrieval mAP (97.23%), outperforming Jensen-Shannon (96.94%) and Euclidean (96.61%). This result is theoretically consistent with the nature of our descriptors: since the EBC produces normalized probability vectors, the discriminative information is primarily encoded in their directional orientation rather than their magnitude — a property that the Cosine distance is specifically designed to capture. Accordingly, Cosine distance is adopted as the reference metric for all results reported in this study, including the Abstract, Table II, and Table IV.

TABLE III. RETRIEVAL PERFORMANCE (MAP) OF THE PROPOSED METHOD UNDER THREE DISTANCE METRICS

Distance Metric	mAP (%)	Interpretation
Cosine Distance	97.23%	Selected — best directional alignment
Jensen-Shannon	96.94%	Theoretically optimal for distributions
Euclidean	96.61%	Baseline geometric distance

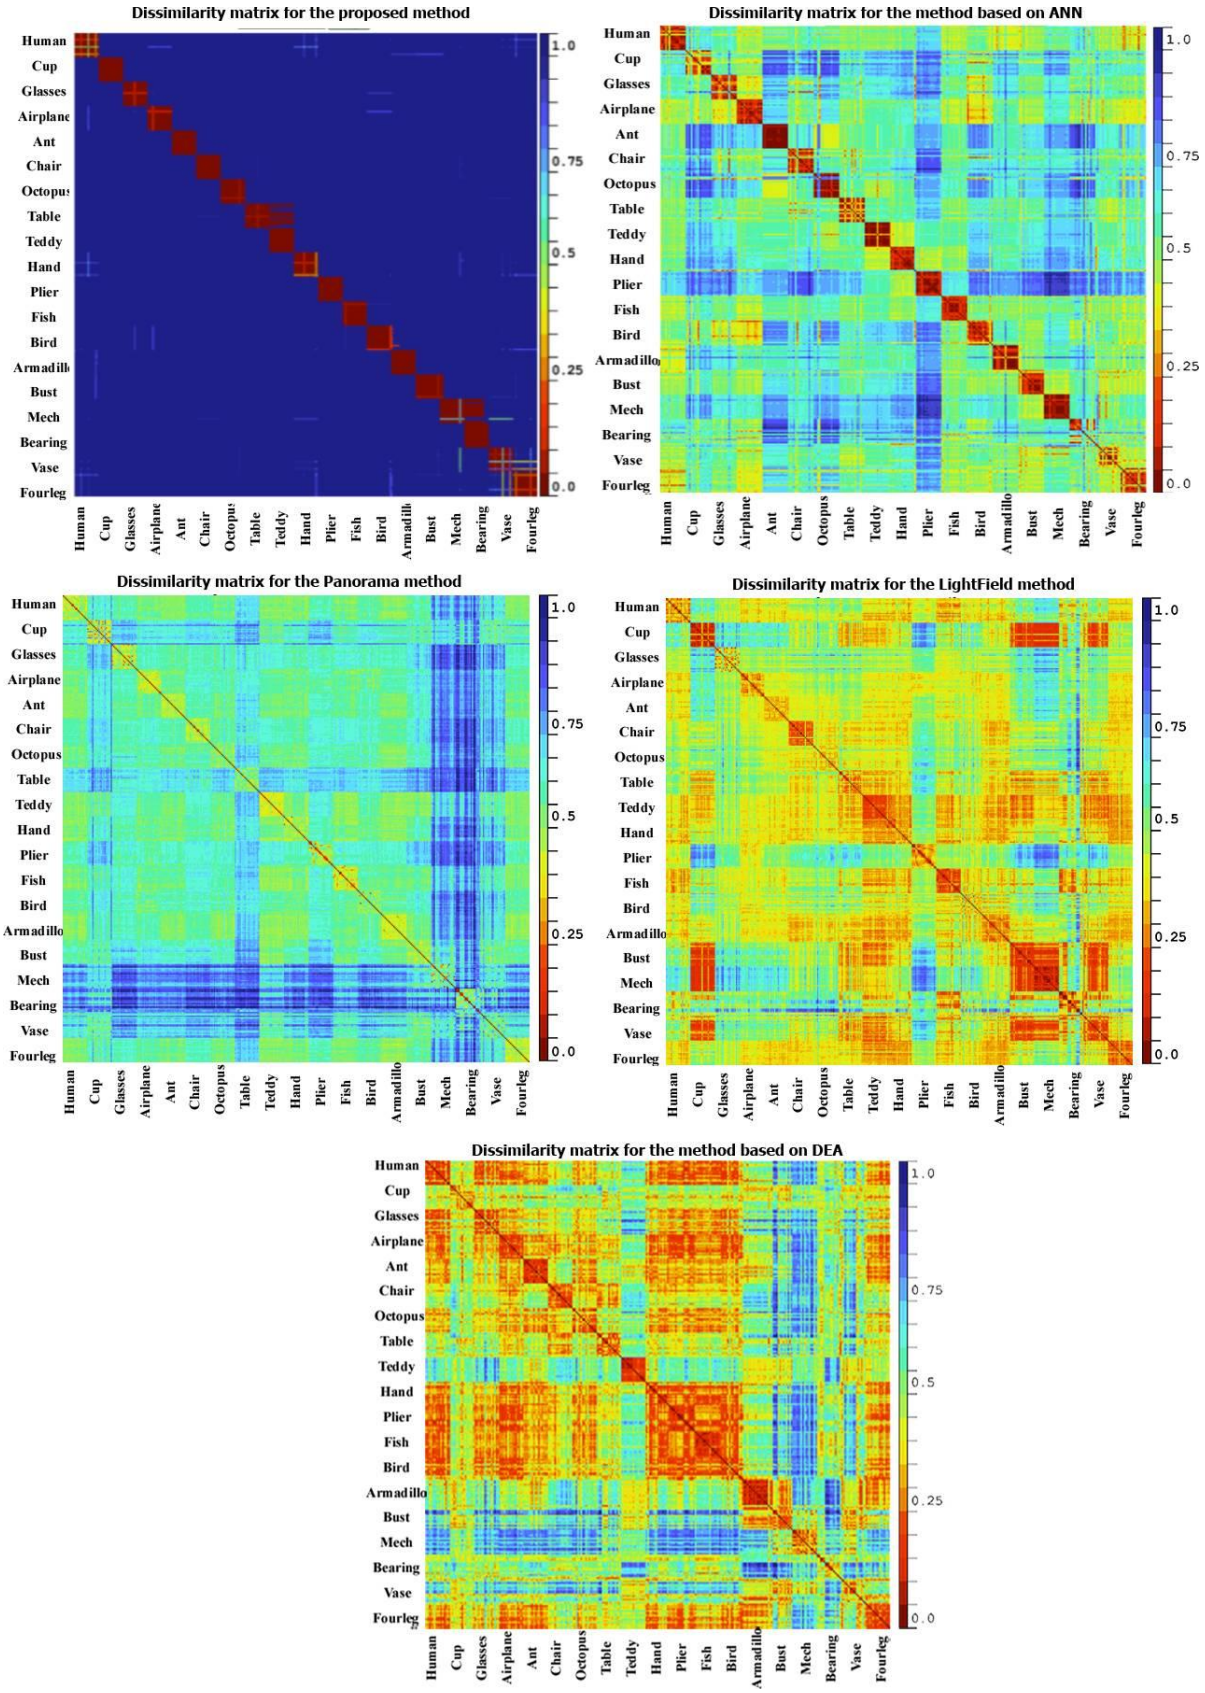

Fig. 4. Dissimilarity matrices computed for the proposed method and four baseline approaches on the PSB dataset. Well-defined dark diagonal blocks reflect strong intra-class cohesion, while uniformly high off-diagonal values confirm effective inter-class separation.

6) Discussion with deep learning approaches: Recent advances in 3D shape retrieval have been largely driven by deep learning approaches operating on meshes, point clouds, or multi-view representations, such as MeshCNN, SpiralNet++, and PointNet-based models. These methods have demonstrated strong performance by learning hierarchical and highly discriminative features directly from raw geometric data.

However, such approaches typically require large-scale labeled datasets, significant computational resources, and often lack interpretability due to their black-box nature. In contrast, the proposed method relies on handcrafted geometric features combined with an Explainable Boosting Classifier, offering a lightweight and interpretable alternative.

Although direct experimental comparison with these models is beyond the scope of this work, the proposed approach achieves competitive retrieval performance (97.23% mAP) while maintaining low computational complexity and full transparency, making it particularly suitable for applications where interpretability and efficiency are critical.

C. Sensitivity Analysis and Justification of the Probability Space

1) Impact of probability calibration: A core assumption of our approach is that the proximity of output probability vectors correctly maps to the geometric and semantic similarity of 3D shapes. To empirically validate this assumption and assess the robustness of the EBC descriptor, we conducted a comprehensive sensitivity analysis evaluating divergence choices, class count, data imbalance, and class structure.

Impact of the Distance Metric: We evaluated the retrieval performance using Cosine Similarity (97.23% mAP), Jensen-Shannon (96.94% mAP), and Euclidean (96.61% mAP). While Jensen-Shannon is theoretically optimal for comparing probability distributions, Cosine Similarity achieves the highest performance, demonstrating that the angular direction of the probability vector is more discriminative than probability-specific metrics. This result validates that the EBC generates highly separable semantic representations where directional similarity outperforms distributional divergence measures.

Sensitivity to Class Count (Semantic Spanning): We evaluated the retrieval task using subsets of 5, 10, and 19 classes. The performance remains consistently high across all configurations (96.13%, 100.0%, and 97.23%, respectively, all measured with Cosine distance). This demonstrates that the probability space dynamically adjusts its capacity; even with a small number of base classes, the descriptor remains rich enough to separate shapes effectively.

Robustness to Class Imbalance: To test stability, we intentionally degraded the training set by keeping only 15% of the samples for half of the classes (severe imbalance). Despite this extreme condition, the overall retrieval mAP only decreased to 79.79%. This minimal degradation highlights the strong resilience of the EBC model to imperfect or skewed datasets.

D. Robustness and Error Characterization

Statistical Stability across Multiple Splits: To ensure the generality of our method and verify that our near-perfect results are not sensitive to a specific data split, we conducted 5 independent runs using different random seeds for the stratified train/test splits. Table IV reports the mean and standard deviation (dispersion) for all key metrics. The extremely low standard deviations (e.g., 0.38% for mAP) demonstrate that the EBC descriptor is highly robust and consistently extracts discriminative semantic information regardless of the specific training subset. Note: The difference between the reference-split mAP (97.23%) and the mean mAP over 5 random splits (98.74% ± 0.38%) reflects normal variability across train/test partitions and confirms the stability of the proposed method.

TABLE IV. MEAN AND STANDARD DEVIATION OF RETRIEVAL METRICS COMPUTED OVER 5 INDEPENDENT RUNS WITH DIFFERENT RANDOM STRATIFIED SPLITS. THE LOW STANDARD DEVIATIONS CONFIRM THE STABILITY AND GENERALIZABILITY OF THE PROPOSED APPROACH

Metric	Mean ± Standard Deviation
mAP(%)	98.74±0.0.38
NN(%)	97.90±0.0.52
FT(%)	97.90±0.0.52
ST(%)	49.50±0.0.34
DCG(%)	99.05±0.0.28

V. CONCLUSION

In this study, we presented a hybrid 3D shape retrieval method combining handcrafted geometric descriptors with the Explainable Boosting Classifier (EBC). Experiments on the Princeton Shape Benchmark demonstrate a mean Average Precision of 97.23%, surpassing state-of-the-art methods including CatBoost, Panorama, and LightField. Despite these results, the evaluation remains limited to a moderate-scale dataset, and the method relies on supervised training, which requires labeled data. Future work will focus on validating the approach on larger benchmarks such as SHREC and ModelNet40 and on exploring hybrid combinations with deep learning features to further improve retrieval performance and scalability.

HBC-Glicko: A Bloom-Constrained Adaptive Assessment Architecture with Uncertainty-Aware Progression

Wissal EL Fougour*, Mohamed Erradi
TIMS Laboratory-S2IPU-Higher Normal School of Tetouan (ENS), Abdelmalek Essaâdi University (UAE), Morocco

***Abstract*—Adaptive assessment systems typically model learner ability as a single continuous latent trait and select items accordingly. Although effective for efficient measurement, such models rarely encode hierarchical cognitive progression as a formal constraint within the learner model itself. In educational domains where higher-order performance depends on sufficiently stable prerequisite knowledge, this omission may permit pedagogically incoherent trajectories, including premature advancement or misleading readiness judgments produced by compensatory aggregation across cognitively distinct levels, where strength at one level can mask weakness at another. This study pursues three objectives: 1) to formalize an adaptive assessment architecture in which Bloom's revised taxonomy operates as a non-compensatory structural constraint on learner progression, meaning that readiness must be established at each prerequisite level independently, without any area of strength substituting for insufficient evidence elsewhere; 2) to derive the principal theoretical properties that follow from this design; and 3) to situate the proposed architecture relative to existing rating-based learner models. To address these objectives, the study proposes Hierarchical Bloom-Constrained Glicko (HBC-Glicko), a theory-driven measurement architecture for formative adaptive assessment. Instead of representing learner state as a single scalar estimate, HBC-Glicko models it as a band-specific vector with band-level uncertainty. Progression is regulated through anchor-based readiness thresholds and confidence-bound decision rules, such that advancement depends on both estimated performance and evidential stability at prerequisite levels. The study formalizes the learner model, within-band routing logic, threshold construction, promotion and prerequisite reinforcement rules, and derives the principal architectural properties. The contribution is conceptual and architectural rather than empirical, establishing a formally specified foundation for subsequent simulation and empirical investigation.**

***Keywords*—Adaptive assessment; Bloom's revised taxonomy; Glicko rating system; learner modeling; non-compensatory progression; uncertainty modeling; formative assessment**

I. Introduction

Adaptive assessment systems typically rely on learner models that represent students digitally to personalize content, pathways, or task selection [6], [51], [61], [32]. In many adaptive learning systems, learner performance data are used to dynamically adjust assessment difficulty and guide next-item selection during the testing process [22]. Although effective for difficulty calibration, such designs do not structurally encode hierarchical cognitive progression as conceptualized in Bloom's revised taxonomy. Recent work continues to show both the value and the difficulty of representing cognitive demand accurately: revised Bloom's taxonomy remains a hierarchical framework for organizing assessment objectives [22], yet evidence suggests that cognitive-process classifications cannot be reliably reduced to action verbs alone [30], and many assessment instruments still concentrate heavily on lower cognitive levels rather than spanning the full hierarchy [42].

This creates a structural risk for adaptive systems: when heterogeneous evidence is aggregated into a single performance representation, strong performance at one cognitive level may mask instability at another, allowing progression decisions that are psychometrically efficient but pedagogically incoherent. Existing rating-based adaptive systems, including Elo and Glicko variants, support dynamic learner estimation and efficient online updating, and Glicko-based approaches explicitly model confidence in the current rating [1], [58]. However, recent reviews of learner modeling and adaptive assessment still describe a landscape organized around model families, algorithms, and personalization mechanisms rather than architectures that formalize Bloom hierarchy itself as a non-compensatory progression constraint [6], [22]. Although prior work has shown that Elo-based learner modeling can be effectively applied in adaptive educational systems [39], these approaches generally remain single-dimensional and do not govern advancement through explicit uncertainty-bounded progression rules. Bloom-related work in this line has also treated cognitive taxonomy primarily as a way of characterizing task complexity rather than as a formal control structure for adaptive progression [41].

To address this gap, this study proposes the Hierarchical Bloom-Constrained Glicko (HBC-Glicko) architecture, in which learner ability is represented as a band-specific vector aligned with Bloom's cognitive structure, and advancement is controlled through anchor-derived readiness thresholds combined with confidence-bound constraints. In this way, progression depends not only on estimated ability but also on evidential stability at prerequisite levels. The contribution is conceptual and architectural rather than empirical: the study formalizes a measurement architecture and derives its principal theoretical properties, establishing a foundation for subsequent simulation and empirical investigation.

*Corresponding author.

More specifically, the present work pursues three objectives:

O1. To formalize an adaptive assessment architecture in which Bloom's revised taxonomy operates as a non-compensatory structural constraint on learner progression, rather than as a descriptive classification of task difficulty.

O2. To derive the principal theoretical properties that follow from combining band-specific learner representation, Glicko-based uncertainty modeling, and confidence-bound progression rules within a single measurement framework.

O3. To situate the proposed architecture relative to existing rating-based learner models and clarify the structural distinctions it introduces with respect to cognitive hierarchy, uncertainty quantification, and progression control.

The remainder of the study is organized as follows. Section II develops the theoretical rationale grounding the architecture. Section III presents the overall system architecture. Sections III-A through III-E formalize the learner model, within-band adaptation, anchor-based thresholds, hierarchical decision rules, and inactivity-driven uncertainty growth, collectively addressing the first objective. Section IV derives the principal architectural properties of the design (Objective 2). Section V situates HBC-Glicko relative to existing approaches and discusses its theoretical implications (Objective 3). Sections VI and VII address limitations and directions for future research.

II. Background and Theoretical Rationale

A. Adaptive Assessment and the Limits of Scalar Learner Models

Adaptive formative assessment systems personalize item delivery by combining online learner-state estimation with sequential item selection, commonly operationalized through IRT-based computerized adaptive testing, Elo-style rating updates, and Bayesian knowledge tracing. In computerized adaptive testing (CAT), learner performance is typically summarized by a single latent proficiency parameter θ under unidimensional item response theory [62], an approach whose feasibility continues to be demonstrated in large-scale digital applications [9].

However, this scalar abstraction assumes that performance can be adequately explained along a single proficiency continuum, an assumption that holds only when the measured construct is approximately unidimensional [65]. When tasks differ in cognitive process requirements, collapsing performance into one dimension produces compensatory interpretations in which strengths in one type of task mask weaknesses in another. Multidimensional adaptive frameworks address this limitation by estimating multiple latent traits, including approaches that represent uncertainty in multivariate ability estimation through confidence regions [31]. A similar limitation appears in rating-based learner models: educational adaptations of Elo efficiently update learner and item estimates after each interaction [58] but generally summarize learner state as a single scalar rating without encoding variation in cognitive demand [1].

Knowledge-component and skill-hierarchy models provide a further alternative to scalar learner models by representing learner performance in relation to discrete skills or prerequisite structures rather than as a single global proficiency estimate [12], [10], [38], [63]. Their main strength is that they can support adaptive sequencing by tracking evidence of mastery across specific components.

However, their dependency structure usually concerns concepts, procedures, or skills rather than Bloom-level cognitive-process demands. From a progression-control perspective, the key limitation is architectural: these models may estimate what a learner is likely to know or perform, but they do not define when the learner has demonstrated sufficiently stable competence at one cognitive level to justify advancement to the next. To our knowledge, existing IRT-, Elo-, and knowledge-component-based architectures do not treat Bloom's hierarchy as an internal non-compensatory constraint on the learner model itself. When cognitive levels appear, they function as item descriptors or reporting categories rather than as confidence-bounded rules governing progression. This limitation motivates learner representations that preserve distinctions in cognitive demand while retaining online updating and uncertainty quantification.

B. Revised Bloom Taxonomy and Hierarchical Dependency

Bloom's revised taxonomy (RBT) distinguishes a cognitive-process dimension (Remember, Understand, Apply, Analyze, Evaluate, and Create) and a knowledge-type dimension (Factual, Conceptual, Procedural, and Metacognitive), supporting constructive alignment between objectives, instruction, and assessment evidence [3], [28]. However, classification validity may weaken when cognitive level is inferred from surface cues such as verbs rather than from the actual mental operations required by the task [30]. Assessment instruments often fail to reflect the intended balance of cognitive demand: examinations may become dominated by lower-level recall [35], or higher-order demands may increase in ways that raise concerns about fairness [53].

Deeper understanding is better captured when assessment design includes integrative and evaluative demands [34]. This is especially consequential for rating-based learner models, where items are reduced to a single difficulty parameter that may obscure meaningful differences in cognitive demand.

For the present work, RBT is not treated as a rigid staircase but as a plausible dependency structure in which higher-order performance is generally more likely when foundational representations are sufficiently established. This interpretation is consistent with classic validation work suggesting cumulative relations across broad groupings rather than strictly between every adjacent pair [29], and with more recent evidence showing that higher-level objectives may depend on lower ones through indirect pathways [60]. From a cognitive perspective, this is plausible because more complex reasoning places greater demands on working memory and becomes more feasible when prior knowledge is organized into schemas that reduce cognitive load [50], [45].

C. Uncertainty-Aware Progression in Rating-Based Systems

Elo-style rating systems are widely used in adaptive educational systems because they update learner and item parameters online with modest computational cost [24], [39],

[36], [2], [40]. However, standard Elo represents learner state as a single point estimate without an explicit uncertainty parameter, which can produce unstable early estimates and, in adaptive settings that jointly update learners and items, rating variance that inflates over time [7]. These models also generally ignore the lag between successive interactions, treating adjacent observations as if no learning or forgetting occurred between them [12], [56], [10], [38].

These limitations motivate uncertainty-aware approaches that attach reliability information to ability estimates [21]. One strategy replaces the constant update factor with a decreasing uncertainty function that reduces rating sensitivity as interactions accumulate [2], [57]. The Glicko rating system formalizes this idea by introducing rating deviation (RD) as an explicit uncertainty parameter: high RD permits larger updates under limited evidence, inactivity, or cold start, whereas decreasing RD stabilizes the estimate and supports more conservative adaptive decisions [17].

However, the deeper limitation of Elo and Glicko variants in cognitively structured domains is not merely technical but representational. These systems originate from paired-comparison rating contexts in which the primary objective is to estimate relative performance or predict outcomes. When transferred to education, however, the rating system must support a different kind of decision: whether the learner is pedagogically ready to progress. This requires more than adding educational labels to a generic rating scale. It requires a learner model whose structure reflects educational constraints, including cognitive demand, prerequisite stability, and uncertainty-aware progression.

Recent extensions have introduced multivariate Elo and Glicko representations that estimate separate ratings for knowledge components [1], [2]. These approaches improve diagnostic resolution, but they retain a primarily estimation-oriented design: the multiple dimensions represent knowledge components whose ratings are updated separately, and in some cases cross-informed, rather than an ordered cognitive hierarchy in which advancement is governed by explicit readiness conditions. Thus, when hierarchy is present, it mainly supports parameter estimation rather than constraining progression decisions. This distinction is central to the present work: HBC-Glicko is not simply Bloom-aware estimation, but Bloom-constrained progression.

In scalar Elo and Glicko variants, learner state is encoded as a single rating, so the system has no internal mechanism to detect whether strong performance at one cognitive level is masking weakness at another. In a Bloom-structured formative setting, this can permit advancement on the basis of aggregated performance while foundational knowledge remains unstable, producing a progression decision that is psychometrically plausible but pedagogically incoherent.

D. Binary and Continuous Evidence in Adaptive Assessment

The representation of learner evidence should reflect the cognitive complexity of the task being assessed. For lower Bloom levels, particularly Remember and Understand, binary scoring (correct/incorrect) is computationally efficient and aligns with conventional objective formats. However, although multiple-choice questions can theoretically assess higher-order thinking, empirical work shows they often concentrate on lower-order demands in practice [42], [52], [48], [64], [33]. Higher Bloom levels require richer evidence because responses involve reasoning, justification, or production that cannot be reduced to binary judgments. Rubric-based scoring addresses this by assessing performance against explicit criteria and levels of quality [23], [8].

Rubric-based assessment poses a scalability challenge in formative contexts where consistent human scoring of large response volumes becomes impractical. Large language models offer a promising solution: recent studies suggest that LLMs can support rubric-based scoring at scale with acceptable reliability for formative use [11], [14], [16], [47]. These considerations support a mixed evidence design, with binary scoring for lower Bloom levels and rubric-based continuous evidence for higher-order cognitive performance.

Taken together, the preceding sections suggest that adaptive progression in hierarchical cognitive domains cannot be governed by scalar performance estimates alone. The system must account for hierarchical dependency, uncertainty in learner estimates, and differences in evidence type across task formats. These requirements motivate an explicit control logic that regulates advancement conservatively rather than treating progression as a simple consequence of observed success. The next section presents the system architecture and formal control design of the proposed HBC-Glicko system.

III. System Architecture Overview

To clarify how the proposed components interact, this section presents the overall system architecture of HBC-Glicko (Fig. 1). The architecture provides a high-level view of the information flow from the calibrated, Bloom-tagged item bank to item selection, scoring, rating updates, and progression decisions. This overview is intended to orient the reader before the formal definitions and control rules introduced in the following sections.

A. Operational Deployment Flow

To make the architecture more operationally explicit, Fig. 2 presents a practical deployment cycle for HBC-Glicko in an LMS-supported formative assessment context. The cycle begins with LLM-assisted item generation and Bloom-label suggestion, followed by instructor review and confirmation to ensure that each item is pedagogically appropriate and correctly assigned to a cognitive band and category. Validated items then enter a calibrated Bloom-banded item pool with anchor sets used for progression thresholds. During assessment, the system routes the learner within the current band, selects and scores items, and commits band-specific rating updates at the session level. Progression decisions are then made through confidence-bound rules: the learner is promoted only when readiness is sufficiently stable, whereas prerequisite reinforcement is triggered when current-band performance falls below the expected entry standard. This deployment view clarifies that HBC-Glicko functions not as an autonomous replacement for instructional judgment, but as a supervised adaptive layer that combines

LLM-supported item preparation, instructor validation, and uncertainty-aware progression control.

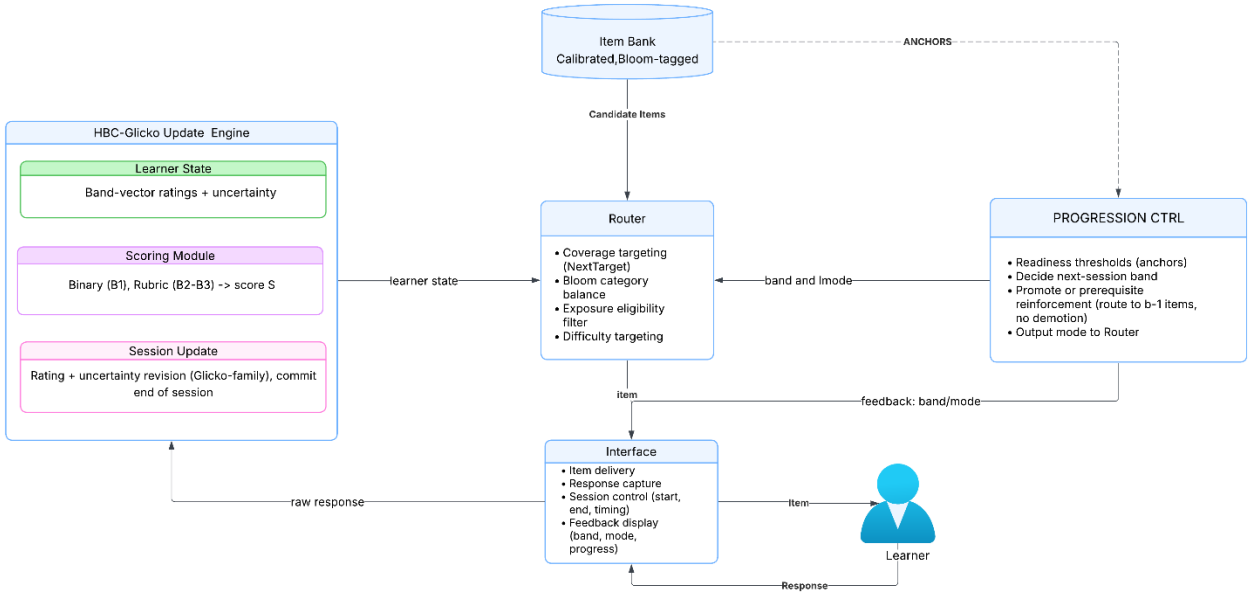

Fig. 1. Overview of the HBC-Glicko architecture.

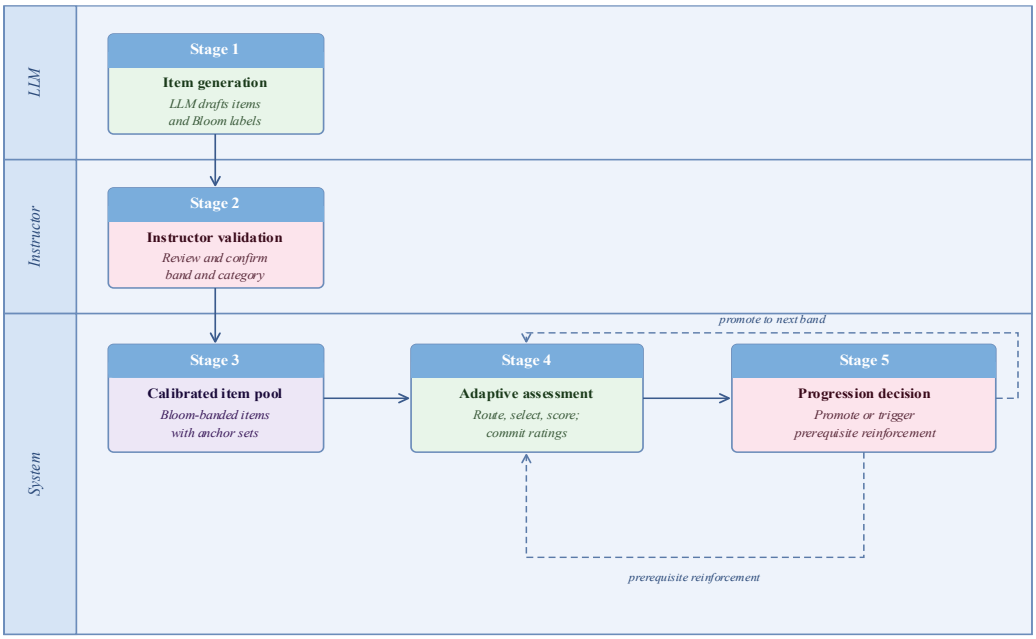

Fig. 2. HBC-Glicko deployment cycle. Dashed arrows indicate conditional system-level transitions after Stage 5.

The proposed system integrates five components, each developed in the following subsections: the formal learner model (Section III-A), within-band adaptation (Section III-B), anchor-based progression thresholds (Section III-C), hierarchical decision rules for promotion and prerequisite reinforcement (Section III-D), and inactivity-driven uncertainty growth (Section III-E).

1) Formal learner measurement model: This section specifies the formal representation of a learner within the proposed adaptive measurement architecture. The learner is defined as a structured latent state with band-specific performance parameters aligned with Bloom-type cognitive bands. The purpose is to define 1) the learner state variables, 2) their uncertainty representation, and 3) the structural assumptions that prevent compensatory masking across bands. This section provides definitions only. Update equations, thresholds, and decision rules are specified in subsequent sections.

For reference, a complete summary of the notation used throughout the following sections is provided in Appendix A (Table III).

2) Band set and indexing: Let n index learners, t index rating periods (sessions), and b ∈ {1, 2, 3} index cognitive bands. The bands represent increasing levels of cognitive complexity, following the revised Bloom taxonomy [3]. Although the revised taxonomy distinguishes two dimensions — cognitive processes and knowledge types — this system adopts the cognitive-process dimension only, consistent with common practice in empirical assessment research [59], [35], [5].

Low band: $\mathcal{K}$_Low = {Remember, Understand}, Mid band: $\mathcal{K}$_Mid = {Apply}, High band: $\mathcal{K}$_High = {Analyze, Evaluate}.

The conventional distinction in educational practice divides these categories into lower-order thinking skills (Remember, Understand, and Apply) and higher-order thinking skills (Analyze, Evaluate, and Create) [28]. While useful for curricular planning, this two-tier partition does not distinguish between retrieval, comprehension, and contextual transfer, which are diagnostically different in adaptive assessment. The present architecture groups the categories according to the type of cognitive operation involved. The Low-band combines Remember and Understand as representational processes in which the learner accesses or restates stored knowledge. The Mid-band isolates apply as the transition from accessing knowledge to using it under unfamiliar conditions. The High band combines Analyze and Evaluate as processes that require coordinating and judging multiple knowledge elements simultaneously, imposing high working memory demand [49]. This partition captures three qualitatively distinct modes of cognitive engagement while preserving sufficient evidence per band for stable rating estimation in short formative sessions.

Create is excluded because it introduces constraints that differ in kind from the other levels. Creative production tasks require the learner to generate an original artifact rather than respond to a structured prompt, which means that item difficulty cannot be stably pre-calibrated on the unified rating scale: the effective demand of a Create task depends on the scope and ambition of the learner's response, not solely on fixed item properties. Additionally, while LLM-assisted scoring is used in higher bands for evaluating reasoning quality against explicit rubric criteria, scoring creative output requires additional appraisal of novelty and integrative originality, dimensions for which automated scoring consistency remains less established [8]. Incorporating Create would therefore require modifications to both the item calibration model and the scoring framework, constituting a substantive extension left for future work.

Each item in the pool carries two fixed labels: a band (b) and a Bloom category within that band. These labels are assigned through a two-stage process. First, an LLM classifier suggests both the band and the category. Second, the instructor reviews and confirms the suggestion before the item enters the pool. Once confirmed, neither label is changed by the system at runtime.

This dual labeling serves two purposes. The band label supports the non-compensatory structure of the learner model. The within-band category label supports the within-band coverage mechanism.

3) Learner state variables: For each learner $\boldsymbol{n}$ at the rating period $\boldsymbol{t}$, the latent performance state is represented by $\mathbf{r}_{\boldsymbol{n,t}} = (\boldsymbol{r_{n,1,t}}, \boldsymbol{r_{n,2,t}}, \boldsymbol{r_{n,3,t}})$, where $\boldsymbol{r_{n,b,t}} \in \mathbb{R}$ denotes performance in band $\boldsymbol{b}$. Each estimate is associated with a rating deviation $\boldsymbol{RD_{n,b,t} > 0}$, which captures uncertainty. The learner measurement state is

$$\boldsymbol{\mathcal{S}_{n,t}} = \{(\boldsymbol{r}_{n,b,t}, \boldsymbol{RD}_{n,b,t}) : \boldsymbol{b} \in \boldsymbol{\mathcal{B}}\}.$$

Consistent with the theoretical rationale developed in Section II, learner state is modeled as a vector rather than as a single scalar proficiency parameter. This choice reflects the view that performance depends on prior knowledge organization and on the cognitive demands imposed by different tasks, rather than on a single context-free ability alone [49], [45]. High performance in a higher band, therefore, cannot substitute for insufficient performance in a lower band. A non-compensatory representation is retained to preserve pedagogical coherence in progression decisions and to prevent apparent success on more complex tasks from masking weakness in foundational knowledge.

4) Unified scale assumption: All band ratings are expressed on a common continuous metric scale. This enables coherent definition of item difficulty parameters, readiness thresholds, and uncertainty bounds on a single axis, while preserving band separation through the evidence structure.

Let $d_i \in \mathbb{R}$ denote the difficulty (location) parameter of item i on the same scale as $r_{n,b,t}$. The architecture assumes that expected performance is a monotonic function of the rating difference $r_{n,b,t} - d_i$. The explicit response function and update rules are provided in Section III-B. Here, the key assumption is scale compatibility: learner and item parameters share a metric that supports probabilistic interpretation.

B. Within-Band Adaptation

This section specifies the within-band probabilistic update mechanism. Each cognitive band operates as an independent rating process governed by a Glicko-style uncertainty-aware model [18], [19]. Interactions with items assigned to the band b update only the learner parameters $(r_{n,b,t} | RD_{n,b,t})$ associated with that band and the parameters of the interacted item.

1) Response model: Consider an item i in band b, with difficulty $d_{i,t} \in \mathbb{R}$ and rating deviation $RD_{i,t} > 0$. Let $r_{n,b,t}$ denote learner n's rating in the band b. Following the Glicko formulation, define.

$$g(RD_{i,t}) = \frac{1}{\sqrt{1 + \frac{3q^2 RD_{i,t}^2}{\pi^2}}}, q = \frac{\ln(10)}{400}$$

The expected score of the learner n on item i at time t is

$$E_{n,i,t} = \frac{1}{1 + 10^{-\frac{g(RD_{i,t})(r_{n,b,t} - d_{i,t})}{400}}}$$

Observed performance is represented on a common scale $S_{n,i,t} \in [0,1]$. This common scale is retained to preserve comparability across bands while allowing the observable response format to remain aligned with the cognitive demands of the task. In Band 1, where tasks primarily target retrieval and foundational understanding, responses are binary, with $S_{n,i,t} \in \{0,1\}$, so $E_{n,i,t}$ corresponds to the probability of a correct response. In Bands 2 and 3, where performance depends more on the quality of application, analysis, justification, or evaluation, rubric-based scores are normalized to [0, 1]. In those bands, $E_{n,i,t}$ is interpreted as the expected performance level on the same scale.

This mixed-evidence design is intended to ensure that the granularity of scored evidence remains congruent with the level of cognitive complexity being assessed. Lower-band performance can often be adequately captured through correctness, whereas higher-band performance requires attention to gradations in the quality of reasoning and knowledge use. The purpose of this design is therefore pedagogical as well as technical. By matching the scoring format to the nature of the targeted performance, the system can support formative interpretations that distinguish between foundational correctness and higher-order quality of reasoning, which is important for making progress intelligible to learners across increasing levels of task complexity [37], [54].

The prediction error is then defined as

$$\delta_{n,i,t} = S_{n,i,t} - E_{n,i,t}.$$

This quantity represents the deviation between observed and expected performance and serves as the input to the subsequent update step.

2) Learner rating update: Within band b, the learner rating is updated as

$$r_{n,b,t+1} = r_{n,b,t} + \omega_{n,b,t}\delta_{n,i,t}$$

where, $\boldsymbol{\omega_{n,b,t} > 0}$ denotes a Glicko-style adaptive weight. The update magnitude increases with learner uncertainty in the band $\boldsymbol{b}$, decreases with item uncertainty through $\boldsymbol{g(RD_{i,t})}$, and depends on the interaction-information term $\boldsymbol{E_{n,i,t}(1 - E_{n,i,t})}$, which reaches its maximum when the predicted outcome is most uncertain. Band updates are strictly independent, such that an interaction in band $\boldsymbol{b}$ affects only the learner state $\boldsymbol{(r_{n,b,t'} RD_{n,b,t})}$ for that band and the associated item parameters.

3) Within-band category routing and item selection: Within a session, the active band $b \in$ {Low, Mid, High} remains fixed. The routing mechanism operates only within the current band and determines, at each step t, which in-band Bloom category should be sampled next.

a) Phase 1: Target Category Determination: Phase 1 determines the next category to be sampled within the active band. To guide this decision, the instructor specifies a target sampling distribution over the categories in $\mathcal{K}_b$, denoted $\pi_b(k)$, such that $\pi_b(k) \geq 0$ and $\sum_{k \in \mathcal{K}_b} \pi_b(k) = 1$. By default, this distribution is uniform, although it may be adjusted to reflect pedagogical priorities. During the session, the system maintains, for each category $k \in \mathcal{K}_b$, a delivery counter $c_t(k)$ representing the number of scored items delivered up to step t in band b, with total in-band exposure given by $t_b = \sum_{k \in \mathcal{K}_b} c_t(k)$. The expected count for the category k under the target distribution is $\hat{c}_t(k) = t_b \pi_b(k)$, and the corresponding coverage deficit is defined as $\Delta_t(k) = \max(0, \hat{c}_t(k) - c_t(k))$. The next target category is then selected as the most under-sampled category, $k_t = \arg\max_{k \in \mathcal{K}_b} \Delta_t(k)$. In the Mid band, where $\mathcal{K}_{Mid} = \{Apply\}$, this step is trivial, since $k_t = Apply$ at every step. If multiple categories have the same deficit, priority is given to the category with the larger remaining item pool, and any further ties are resolved deterministically to ensure reproducibility.

b) Phase 2: Adaptive Item Selection Within the Target Category: Once the target category k_t has been determined, the router forms the candidate set $I_t^{cand} = \{ i : b(i) = b, k(i) = k_t \}$. Because k_t is selected in Phase 1, this set is already aligned with the remaining within-band category demand. To preserve measurement independence within a session, only the first scored attempt on an item is allowed to update ratings. Let H_s denote the set of items already scored in the session s. The eligible set is then $I_t^{elig} = \{ i \in I_t^{cand} : i \notin H_s \}$. If $I_t^{elig} = \emptyset$, secondary constraints may be relaxed in a deterministic manner while preserving the band constraint. This rule is motivated by a conservative cognitive rationale: repeated responses to the same item within a session may still draw on information that remains readily accessible in working memory, whereas a first scored attempt in a later session is more plausibly treated as a new retrieval event from long-term memory [4], [13]. This distinction is also consistent with retrieval-practice research showing that immediate repetition and later retrieval do not have the same implications for retention [43], [25]. Within the eligible set, the next item is selected using a probability-targeting principle. Let $E_{n,i,t}$ denote the expected performance of the learner n on item i at step t, and let $p^* \in (0,1)$ denote the target performance level. In Band 1, $E_{n,i,t}$ is the probability of a correct response under a binary outcome model. In Bands 2 and 3, where scores are rubric-based and normalized to [0,1], it represents the expected performance level. The selected item is therefore $i_t^* = \arg\min_{i \in I_t^{elig}} | E_{n,i,t} - p^* |$. If several items are equally close to p^*, the tie is broken using the information function $Info(i) = g(RD_{i,t})^2 E_{n,i,t}(1 - E_{n,i,t})$, and the item with the highest value is selected.

4) End-of-session rating commitment: Although provisional parameter adjustments may be computed during a session for routing purposes, official rating updates are committed only at the end of the session. All scored interactions from the session are aggregated, and the band-specific learner parameters $\boldsymbol{(r_{(n,b)}, RD_{(n,b)})}$ are updated from their pre-session values using the complete set of session evidence.

This separation serves both a statistical and a pedagogical purpose. Statistically, it avoids sequential double counting

within the same session and preserves coherence in parameter estimation. Pedagogically, it reduces the risk that transient within-session fluctuations are overinterpreted as stable change in learner state. By committing ratings only after the full session has been observed, the model treats learner performance as session-level evidence rather than as a sequence of isolated micro-updates, which is more consistent with the formative aim of basing progression decisions on sufficiently consolidated patterns of performance rather than on momentary variation.

C. Anchor-Based Progression Thresholds

1) Entry anchor sets and reference difficulty definition: In educational measurement, anchor items are used to preserve scale stability across forms and administrations by maintaining item and ability estimates on a shared metric [26], [55]. The present architecture adopts this principle to define stable progression thresholds across Bloom bands. For each transition from band $b$to band $b+1$, an entry anchor set $\mathcal{A}_{b+1} \subset \mathcal{I}_{b+1}$is defined as a fixed subset of calibrated items drawn exclusively from band $b+1$, where $\mathcal{I}_{b+1}$denotes the item pool associated with that band. Each anchor item $j \in \mathcal{A}_{b+1}$is characterized by a calibrated difficulty parameter $d_{b+1,j}$on the unified Glicko scale, so that anchor difficulties share the same latent metric as learner band-specific ratings. Because these anchor sets are predefined for progression purposes and are not dynamically altered by session-level adaptation, they serve as stable structural reference points for entry-level demand in the target band. The reference difficulty associated with entry into band $b+1$is defined as the mean anchor difficulty,

$$d_{b+1}^{ref} = \frac{1}{|\mathcal{A}_{b+1}|} \sum_{j \in \mathcal{A}_{b+1}} d_{b+1,j}$$

This quantity represents the typical calibrated difficulty of entry-level tasks in band $b+1$ and provides a fixed scale location against which readiness criteria are defined. In pedagogical terms, it operationalizes the level of demand that a learner should be prepared to meet before progression is warranted. To preserve the interpretability of progression thresholds over time, anchor item parameters are treated as fixed after calibration and excluded from routine item-parameter updating. In this way, anchor-based reference locations remain effectively stable on the unified rating scale, ensuring that subsequent readiness decisions retain a consistent measurement meaning.

2) Probability-defined readiness thresholds: Progression from band $b$to band $b+1$is defined in probabilistic terms. Let $p_{b\to b+1} \in (0,1)$denote the target expected success probability required for entry into band $b+1$. This parameter specifies the minimum expected performance required on representative entry-level tasks of the target band.

Readiness is defined relative to the reference difficulty d_{b+1}^{ref} established above. Let $r_{n,b}$ denote learner n 's ability estimate in band b. On the unified rating scale, the expected outcome of the learner $n$on an item of difficulty $d$is given by

$$E(r_{n,b}, d) = \frac{1}{1 + 10^{-\frac{r_{n,b}-d}{400}}}.$$

The readiness criterion requires expected performance at the target-band reference difficulty to equal the designated transition probability:

$$E\left(r_{n,b}, d_{b+1}^{ref}\right) = p_{b\to b+1}.$$

Solving for the rating value that satisfies this condition yields the progression threshold

$$T_{b\to b+1} = d_{b+1}^{ref} + 400 \log_{10}\left(\frac{p_{b\to b+1}}{1 - p_{b\to b+1}}\right).$$

Thus, $T_{b\to b+1}$ represents the minimum band- b rating required for a learner to achieve the target expected success probability on calibrated entry-level tasks from band $b+1$. Progression is therefore defined as a predictive readiness condition on the unified scale rather than as a retrospective summary of past performance. This predictive interpretation is consistent with cognitivist accounts of learning in which successful future performance depends on the interaction between prior knowledge organization and the cognitive demands of upcoming tasks, rather than on past score accumulation alone [49], [45].

In contrast to standard CAT item selection, which typically targets items near the current ability estimate to maximize measurement information, progression thresholds in the HBC system are designed to express readiness for cognitively more demanding work. Accordingly, transition probabilities are specified above the chance level and increase across bands:

$$0.50 < p_{Low\to Mid} < p_{Mid\to High} < 1.$$

This reflects the design assumption that progression to higher cognitive bands should require stronger evidence of readiness. Pedagogically, this means that advancement into more demanding bands is treated as a guarded instructional decision, since the cost of premature progression increases as task complexity and knowledge coordination demands rise [49]. The specific values of $p_{b\to b+1}$are treated as design parameters to be calibrated empirically rather than fixed a priori.

D. Confidence-Bound Decision Rules for Band Progression

1) Rating uncertainty and confidence bounds: To incorporate estimation uncertainty into band progression, lower and upper uncertainty bounds are defined as

$$LCB_{n,b} = r_{n,b} - z_b RD_{n,b}, \quad UCB_{n,b} = r_{n,b} + z_b RD_{n,b}$$

where, $z_b > 0$ controls the width of the interval. The lower bound provides a conservative estimate of learner ability in band b, whereas the upper bound provides a corresponding optimistic estimate. As $RD_{n,b}$ increases, the interval widens, which discourages progression under high uncertainty. As $RD_{n,b}$ decreases, the interval narrows, allowing readiness to be evaluated more decisively. This formulation makes readiness conditional not only on the estimated level, but also on the stability of the evidence supporting that estimate.

The multiplier $\boldsymbol{z_b}$ is set to 1.65, corresponding to a one-sided 95% confidence level under the distributional assumptions of

the Glicko framework [18]. Promotion therefore requires 95% confidence that the learner's true ability exceeds the readiness threshold, whereas reinforcement is triggered only when even a 95th percentile estimate falls below the entry standard. This moderately conservative threshold is consistent with the formative orientation of the architecture. A stricter bound, such as $z_b = 2.00$, would systematically delay promotion for learners who have already demonstrated sufficient mastery, moving them away from their zone of proximal development without proportionally reducing misclassification risk. The architecture can tolerate a less restrictive threshold because prerequisite reinforcement [Section III-D(3)] provides a built-in safeguard. If promotion proves premature, the system can detect instability and redirect the learner to lower band items. In summative contexts, where no such remediation loop exists, a stricter value would be more appropriate. More generally, z_b is treated as a tunable design parameter whose optimal value should be calibrated empirically for each deployment context. Although a uniform multiplier is adopted here for simplicity, z_b could in principle be differentiated across Bloom bands. A stricter bound at higher cognitive levels would reflect the greater pedagogical cost of premature advancement into more demanding tasks, with band-specific values determined through pilot calibration against observed promotion rates and downstream performance outcomes. The relationship between RD and the progression threshold is structural. Because $LCB_{n,b} = r_{n,b} - z_b \cdot RD_{n,b}$, higher uncertainty directly lowers the conservative readiness estimate and makes the promotion condition $LCB_{n,b} \geq T_{b\to b+1}$ harder to satisfy. A learner with a high point estimate but high $RD_{n,b}$ is therefore treated as less ready than a learner with the same point estimate and lower uncertainty. This is pedagogically intentional: promotion requires not only high estimated performance but also stable evidence within the prerequisite band. Formally, $T_{b\to b+1}$ is not a free parameter, but a derived quantity computed from d_{b+1}^{ref} and $p_{b\to b+1}$ according to the anchor-based threshold construction in Section III-C.

2) Promotion rule: conservative and coverage-constrained: Let $T_{b\to b+1}$ denote the readiness threshold for progression from band b to band $b+1$, and let $LCB_{n,b}$ denote the lower confidence bound of learner n's rating in band b. Promotion is granted only when the learner satisfies the conservative readiness condition.

$$\text{Promote } b \to b+1 \iff LCB_{n,b} \geq T_{b\to b+1}$$

To ensure that progression is not driven by performance in only a subset of within-band categories, promotion is additionally subject to a minimum evidence requirement over the category set $\mathcal{K}_b$. Let $N_{n,b}(k)$ denote the number of distinct scored item administrations obtained by learner n in category $k \in \mathcal{K}_b$, and let m_b denote the minimum required evidence per category. The full promotion rule is therefore

$$\begin{aligned}\text{Promote } b \to b+1 \\ \iff \left(LCB_{n,b} \geq T_{b\to b+1}\right) \\ \wedge \left(\forall k \in \mathcal{K}_b : N_{n,b}(k) \geq m_b\right)\end{aligned}$$

This rule makes progression both conservative and non-compensatory. The confidence-bound condition reduces the risk of premature advancement under high uncertainty, while the coverage condition ensures that promotion reflects sufficient evidence across all categories within the band rather than strong performance in only a limited subset.

3) Prerequisite reinforcement as a stability safeguard: Although promotion is irreversible, subsequent responses may indicate that the learner is not performing stably at the level expected for the current band. To detect such cases conservatively, the system uses the upper confidence bound of the band-specific rating. Prerequisite reinforcement is triggered when

$$UCB_{n,b} < T_{b-1\to b}$$

where, $T_{b-1\to b}$ denotes the entry threshold for band b. This condition indicates that, even under an optimistic estimate, the learner does not meet the readiness standard for the current band. When this occurs, the system temporarily prioritizes items from band $b-1$ to reinforce prerequisite knowledge. However, the learner's structural band membership remains unchanged, and no demotion is performed. Because $UCB_{n,b}$ increases with $RD_{n,b}$, reinforcement is less likely to be triggered when uncertainty is high, which reduces sensitivity to sparse or noisy evidence.

Together, the promotion and reinforcement rules define three decision zones. Promotion occurs when $LCB_{n,b} \geq T_{b\to b+1}$, subject to the coverage condition. Prerequisite reinforcement occurs when $UCB_{n,b} < T_{b-1\to b}$. Otherwise, the learner remains in band b without structural change.

E. Inactivity-Driven Uncertainty Growth

To reflect increasing uncertainty when no recent evidence is observed, rating deviation is allowed to grow during periods of inactivity. For learner n in band b, let $t_{n,b}$ denote the number of completed sessions since the learner last produced at least one scored attempt in that band. The effective pre-update uncertainty is defined as:

$$RD_{n,b}^{pre*} = \min\left(RD_{\max}, \sqrt{\left(RD_{n,b}^{pre}\right)^2 + c_b^2 t_{n,b}}\right)$$

where, $c_b > 0$ controls the rate of uncertainty growth under inactivity and $RD_{\max}$ is the maximum admissible rating deviation. This formulation allows uncertainty to increase as previously observed evidence becomes less informative over time, while preventing unbounded growth.

Because Band 1 is oriented toward retention-sensitive recall, the informativeness of prior evidence may decay more rapidly there than in higher cognitive bands [15], [46], [44], [27]. Accordingly, the inactivity-growth parameters are constrained such that

$$c_1 \geq c_2 \geq c_3,$$

so that uncertainty can grow at least as quickly in Band 1 as in Bands 2 and 3. If no new evidence is observed in band b, the band rating remains unchanged, and only the uncertainty term is updated through the inactivity-growth rule.

IV. Architectural Properties of HBC-Glicko

Table I summarizes the main theoretical properties that follow from the HBC-Glicko design. These properties are structural consequences of the learner-state representation, threshold formulation, confidence-bound decision rules, and inactivity update mechanism. They clarify what the architecture guarantees by construction, without implying empirical validation.

TABLE I. Main Theoretical Properties of the HBC-Glicko Architecture

Property	Architectural basis	Theoretical implication
Non-compensatory progression	Learner state is represented as a band-specific vector, and promotion is evaluated separately within each prerequisite band.	Strong performance in one band cannot compensate for insufficient evidence in another band.
Conservative promotion under uncertainty	Promotion depends on the lower confidence bound rather than the point estimate alone.	For the same rating estimate, greater uncertainty reduces effective readiness and makes promotion less likely.
Criterion-referenced progression	Promotion thresholds are defined by fixed anchor difficulties and target transition probabilities.	Readiness is judged against a common formal standard rather than a session-specific rule.
Asymmetric decision rules	Promotion uses the lower confidence bound, whereas prerequisite reinforcement uses the upper confidence bound.	The system is conservative at both boundaries: advancement requires sufficiently strong evidence, while remediation requires sufficiently weak evidence.
Inactivity-dependent uncertainty	Inactivity increases rating deviation without directly changing the stored rating.	After long inactivity, progression decisions become more cautious until new evidence is collected.

V. Discussion

The central contribution of HBC-Glicko is to reposition Bloom's revised taxonomy from a descriptive framework to a control principle within adaptive assessment. In many adaptive systems, the cognitive level is used to classify items or structure reporting, but it does not directly govern when a learner may advance. In the present architecture, Bloom-structured bands are embedded in the learner model itself, and progression depends on whether the learner has accumulated sufficiently strong and sufficiently stable evidence within the prerequisite band. Scalar learner models absorb performance across cognitively different tasks into a single estimate, allowing strength in one area to mask instability in another.

HBC-Glicko prevents this by representing learner state as a non-compensatory band vector and evaluating readiness within bands rather than across them [1], [62].

Table II situates HBC-Glicko relative to selected adaptive learner modeling approaches. None of the compared systems combines multidimensional Bloom-structured representation, explicit uncertainty quantification, and hierarchy used as a non-compensatory control constraint on progression within a single architecture.

TABLE II. Comparative Positioning of HBC-Glicko Relative to Selected Adaptive Learner Modeling Approaches

Feature	Standard Elo	Glicko	Multivariate Elo	Multivariate Glicko	CAT / UIRT	Skill-hierarchy Elo	Bloom-aware Elo	HBC-Glicko
	[39]	*[17], [18]*	*[2]*	*[1]*	*[62]*	*[63]*	*[20]*	*(proposed)*
Learner model type	Scalar	Scalar	Vector (KC)	Vector (KC)	Scalar	Multi-level (global + per-skill)	Vector (Bloom)	Vector (Bloom bands)
Explicit uncertainty parameter	No	Yes (RD)	Not explicit	Yes (RD per KC)	Yes (SEM)	No	No	Yes (RD per band)
Hierarchy represented	No	No	Skill components	Skill components	No	Skill hierarchy	Bloom levels	Bloom bands (ordered)
Hierarchy as control constraint	No	No	No	No	No	Estimation only	Estimation only	Yes
Non-compensatory progression	No	No	No	No	No	No	No	Yes
Anchor-based transition thresholds	No	No	No	No	No	No	No	Yes
Confidence-bounded progression rule	No	No	No	No	No	No	No	Yes
Explicit prerequisite reinforcement	No	No	No	No	No	No	No	Yes
Evidence differentiated by cognitive band	No	No	No	No	No	No	No	Yes

Note. KC = knowledge component. RD = rating deviation. SEM = standard error of measurement. UIRT = unidimensional item response theory. "Estimation only" indicates that the hierarchy informs parameter estimation or cross-level propagation but does not function as a constraint on learner progression. "Not explicit" indicates that the feature may be partially present or achievable through indirect mechanisms but is not formalized as a distinct architectural component. "Indirect (SEM)" reflects that CAT quantifies estimation precision through the standard error of measurement, which serves a different function from an explicit uncertainty parameter governing progression decisions.

A second contribution is that uncertainty is given a genuinely pedagogical function. In conventional Glicko, rating deviation determines update magnitude. In HBC-Glicko, uncertainty also determines what the system should do next: promotion depends on a lower-confidence interpretation of readiness, whereas prerequisite reinforcement is triggered only when performance remains weak even under an optimistic interpretation. This asymmetry makes the architecture deliberately conservative at transitions between cognitive bands, where instructional errors are most costly. Uncertainty does not merely slow or accelerate adaptation but directly constrains progression, extending its role from parameter updating to pedagogical decision-making.

To our knowledge, Hamzah and Sosnovsky (2023) are the only published work to directly combine a rating-based learner model with Bloom's revised taxonomy, and no prior work has combined a Glicko-based system with Bloom's taxonomy as a non-compensatory progression constraint. Yudelson et al. (2019) demonstrate that Elo can exploit skill hierarchies for few-shot estimation, and Abdi et al. [1] extend Glicko to multivariate knowledge components, but neither structure cognitive-process levels as a non-compensatory constraint on the learner model. In Hamzah and Sosnovsky (2023), Bloom levels organize learner modeling through cross-level propagation, so evidence at one level can influence estimates at another. In HBC-Glicko, bands are treated as non-compensatory decision spaces, and readiness for band b + 1 must be established from within band b itself. The distinction is therefore between Bloom-aware estimation and Bloom-constrained progression: the former improves the structure of the learner model; the latter governs advancement. For formative assessment, where sequencing and readiness are central, this is the more consequential step.

HBC-Glicko is not novel simply because it is multidimensional, since multivariate rating models already exist, nor because it incorporates uncertainty, since that is a defining feature of Glicko-based systems [1]. Its contribution lies in combining multidimensionality and uncertainty with a cognitively ordered progression rule. The dimensions are not parallel knowledge components estimated for predictive accuracy but ordered bands that participate directly in advancement logic, making the architecture more interpretable pedagogically than a generic multivariate model.

The contrast with computerized adaptive testing is equally important. CAT selects items that maximize information at the current ability estimate and achieves acceptable precision with few observations [62]. HBC-Glicko asks whether the learner has demonstrated enough stable evidence at the current cognitive band to justify movement to the next. This makes the architecture less efficient psychometrically but more coherent in formative contexts where progression should respect hierarchical cognitive dependency. HBC-Glicko should not be positioned as a replacement for CAT but as an alternative design philosophy for settings in which instructional ordering matters as much as measurement efficiency.

These advantages remain theoretical. The practical value of the architecture will depend on the quality of Bloom-level classification, the stability of anchor calibration, and the appropriateness of parameter choices governing thresholds, confidence penalties, and inactivity growth. The architecture nevertheless provides a formally specified and internally coherent foundation for future empirical work, with progression rules whose theoretical properties have been clarified in Section IV and whose design rationale is grounded in both measurement theory and cognitive theory. The value of HBC-Glicko will ultimately depend on how well those theoretical advantages translate into better progression decisions in practice.

Parameter Sensitivity and Calibration of Decision Behavior.

The proposed architecture makes progression decisions explicit by formalizing them through anchor-derived thresholds, confidence bounds, category-coverage requirements, and inactivity-driven uncertainty growth. This explicitness introduces parameter sensitivity, but it also constitutes an important strength of the model: the strictness of progression is no longer implicit, hidden in an opaque adaptive algorithm, or determined only by aggregated performance scores. Instead, it is represented through interpretable control parameters that can be inspected, adjusted, and empirically calibrated. The transition probability $p_{b\to b+1}$, the confidence multiplier z_b, the minimum evidence requirement m_b, and the inactivity-growth parameter c_b collectively determine the balance between adaptive responsiveness and instructional caution.

Misconfiguration of these parameters may shift the system toward predictable forms of decision error. If thresholds or confidence bounds are too conservative, HBC-Glicko may delay promotion for learners who are already capable of engaging with higher-order tasks. If they are too permissive, the system may allow premature progression before prerequisite competence is sufficiently stable. Similarly, an overly strict category-coverage requirement may produce unnecessary repetition, whereas an overly weak requirement may permit advancement from narrow evidence. Inactivity-growth parameters also require careful calibration: excessive growth may discount prior evidence too rapidly, while insufficient growth may cause the system to overtrust outdated performance. These risks do not undermine the architecture; rather, they indicate that HBC-Glicko should be treated as a tunable decision framework whose operating characteristics must be calibrated to the instructional context.

Future simulation and empirical work should therefore examine how alternative parameter settings affect promotion accuracy, reinforcement frequency, time-to-progression, learner workload, and downstream performance. Such analyses would make it possible to identify robust operating ranges and determine whether parameters should be band-specific. For example, stricter confidence bounds may be appropriate in

higher cognitive bands, where premature progression has greater pedagogical cost, whereas lower bands may require more responsiveness to avoid unnecessary repetition. In this sense, parameter sensitivity is not merely a limitation but a necessary design feature of an uncertainty-aware formative assessment architecture.

VI. Limitations

The most immediate limitation of this study is that HBC-Glicko remains entirely conceptual. No simulation studies, pilot deployments, or empirical datasets are presented to support the theoretical propositions outlined in Section IV. As a result, the practical advantages of the architecture cannot yet be confirmed beyond theoretical reasoning, and empirical testing remains a necessary next step before any performance claims can be made.

A second concern relates to the quality of Bloom-level classification. The architecture assumes that items are reliably tagged with the correct band and category labels. However, prior research has shown that cognitive-level classification is prone to error when inferred from surface features rather than the actual mental operations a task requires. Misclassified items could compromise the integrity of the band structure and produce progression decisions that are formally correct but educationally misleading.

A further limitation concerns parameter calibration. The architecture introduces several design parameters, including transition probabilities, confidence-bound multipliers, inactivity-growth rates, and minimum evidence requirements per category. Although these parameters make progression decisions explicit and adjustable, their optimal values cannot be established theoretically alone. Without simulation-based or empirical calibration, inappropriate parameter settings may make the system either overly conservative, delaying justified advancement, or overly permissive, allowing premature progression. Future work should therefore examine parameter sensitivity systematically and identify robust operating ranges across Bloom bands, domains, and learner populations.

Finally, the current architecture covers only three cognitive bands and does not incorporate the Create level or the knowledge-type dimension of Bloom's revised taxonomy. This restricts its applicability in learning contexts where generative or metacognitive performance is central. Extending the architecture to these dimensions represents a natural direction for future theoretical development.

VII. Directions for Future Research

Several research directions follow directly from the architecture proposed in this study. The most immediate priority is simulation-based validation. Agent-based simulations in which synthetic learners with known band-specific ability profiles interact with HBC-Glicko would make it possible to evaluate promotion accuracy, sensitivity to item mislabeling, convergence of band-specific ratings, and the effects of alternative parameter settings under controlled conditions. Such simulations would provide a necessary first test of the decision rules before deployment in live educational settings.

A second priority is empirical validation in authentic formative assessment contexts. Deploying HBC-Glicko alongside a conventional adaptive system would allow comparison of learning outcomes, progression patterns, and instructor judgments of diagnostic usefulness. It would also generate the real-world response data needed to calibrate anchor difficulties and transition probabilities.

A third direction concerns scoring validity in higher bands. Because the architecture relies on rubric-based evidence for more complex cognitive performance, and because such scoring may be partially supported by LLMs, future work should examine agreement between human and LLM-based ratings across Bloom levels and assess how any systematic divergence affects rating stability and progression decisions. This question is especially important given the mixed evidence design introduced in Section II-D.

Finally, the architecture could be extended in two theoretically important directions: inclusion of the Create level and incorporation of knowledge-type distinctions within bands. Both extensions could improve representational fidelity, but they would also increase model complexity and calibration demands.

VIII. Conclusion

This study introduced HBC-Glicko, a measurement architecture for formative adaptive assessment that embeds Bloom's revised taxonomy as a non-compensatory structural constraint within a Glicko-based learner model. The architecture formalizes learner state as a band-specific vector with explicit uncertainty, regulates progression through anchor-based readiness thresholds and confidence-bound decision rules, and models evidential decay under inactivity.

Three objectives were addressed. The study formalized cognitive hierarchy as a control principle governing adaptive progression rather than a descriptive classification of tasks. It derived the principal theoretical properties that follow from this design by construction. And it situates HBC-Glicko relative to existing rating-based approaches, clarifying that its contribution lies in combining multidimensional representation, uncertainty quantification, and non-compensatory progression within a single cognitively ordered architecture.

The contribution remains intentionally conceptual. Its practical value will depend on the reliability of item classification, the stability of anchor calibration, and the appropriateness of parameter configuration — conditions that can only be assessed through simulation and empirical deployment. These constitute the immediate next steps for this research program.

Conflict of Interest

The authors declare that there are no conflicts of interest related to this research.

AUTHORS' CONTRIBUTIONS

W.E.F. conceptualized the study, developed the HBC-Glicko architecture, formalized the theoretical model, and wrote the manuscript.

M.E. supervised the research, contributed to the conceptual refinement of the work, and provided critical revisions.

All authors reviewed and approved the final version of the manuscript.

FUNDING

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

ACKNOWLEDGMENT

The authors extend their heartfelt gratitude to the National Center for Scientific and Technical Research (CNRST) for crucial support through the "PhD-Associate Scholarship – PASS" program. This support played a pivotal role in advancing the research and ensuring the successful completion of this study.

APPENDIX A. SUMMARY OF NOTATION

TABLE III. SUMMARIZES THE PRINCIPAL NOTATION USED THROUGHOUT THE FORMAL SPECIFICATION OF THE HBC-GLICKO ARCHITECTURE. SYMBOLS ARE GROUPED BY FUNCTIONAL CATEGORY. SUBSCRIPT CONVENTIONS FOLLOW STANDARD PSYCHOMETRIC AND RATING-SYSTEM USAGE

Category	Symbol	Definition
General indices	n	Learner index
	t	Rating period (session) index
	b	Cognitive band index, $b \in \{1, 2, 3\}$

	$\mathcal{B}$	Set of cognitive bands {Low, Mid, High}
	$\mathcal{K}$	Set of Bloom categories within band b
Learner state	$r_{n,b,t}$	Rating of learner n in band b at period t
	$RD_{n,b,t}$	Rating deviation (uncertainty) of learner n in band b at period t
	$\boldsymbol{S}_{n,t}$	Full learner measurement state at period t
Item parameters	d_i	Calibrated difficulty of item i on the unified scale
	$RD_{i,t}$	Rating deviation of item i at period t
Response model	q	Scaling constant, q = ln(10) / 400
	$g(RD)$	Uncertainty weighting function
	$E_{n,i,t}$	Expected score of learner n on item i at period t
	$S_{n,i,t}$	Observed score, S ∈ [0, 1]
	$\delta_{n,i,t}$	Prediction error, S − E
	$\omega_{n,b,t}$	Glicko-style adaptive update weight
Within-band routing	$\pi_b(k)$	Target sampling distribution over categories in band b
	$c_t(k)$	Delivery counter for category k at step t
	$\Delta_t(k)$	Coverage deficit for category k at step t
	p^*	Target performance level for adaptive item selection
	H_s	Set of items already scored in session s
Progression	A_{b+1}	Entry anchor set for band b + 1
	d_{b+1}^{ref}	Mean reference difficulty of entry anchor items for band b + 1
	$p_{b\to b+1}$	Target transition probability from band b to band b + 1
	$T_{b\to b+1}$	Progression threshold from band b to band b + 1
Decision rules	z_b	Confidence multiplier for band b
	$LCB_{n,b}$	Lower confidence bound, r − z · RD
	$UCB_{n,b}$	Upper confidence bound, r + z · RD
	$N_{n,b}(k)$	Scored administrations for learner n in category k of band b
	m_b	Minimum evidence per category required for promotion
Inactivity	$t_{n,b}$	Sessions since last scored attempt by learner n in band b
	c_b	Inactivity-driven uncertainty growth rate for band b
	RD_{max}	Maximum admissible rating deviation
	$RD_{n,b}^{pre*}$	Effective pre-update uncertainty after inactivity adjustment

A Secure Chaotic DNA-Based Framework for Satellite Image Encryption

***Abstract*—With the growing use of satellite imaging in environmental monitoring, defense, and remote sensing applications, protecting satellite images during storage and transmission has become increasingly important. Unlike textual data, satellite images contain high spatial redundancy and strong correlations among neighboring pixels, which can limit the effectiveness of conventional encryption methods when applied directly. To address this issue, this study presents a chaotic DNA-based framework for satellite image encryption. The proposed approach combines logistic-map-based chaotic key generation with DNA-inspired encoding and XOR operations to enhance pixel-level confusion and diffusion. The method was evaluated on a grayscale satellite image using common statistical security measures, including information entropy, adjacent-pixel correlation, NPCR, and UACI. The reported results indicate that the encrypted image achieved high entropy, low correlation between adjacent pixels, and strong sensitivity to small changes in the input image. These findings suggest that the proposed framework provides a reasonable basis for secure satellite image encryption. Although the current evaluation is limited in scope, the method shows encouraging performance and offers a useful direction for further investigation on larger and more diverse satellite image datasets.**

Keywords*—Chaotic cryptography; DNA computing; satellite image security; image encryption; information security; secure image transmission

I. Introduction

Satellite images have become an essential resource in many fields, including environmental monitoring, disaster response, military reconnaissance, and urban planning [15]. As satellite sensing technologies continue to advance, both the volume and resolution of captured images have increased significantly. This rapid growth has created a corresponding need for secure storage and transmission mechanisms to protect sensitive image data [17] from unauthorized *access* and misuse [1],[19]. Although conventional encryption algorithms such as AES and RSA provide strong security for general digital data [22], they are not always well suited to the structural characteristics of image data, particularly the high spatial redundancy and strong correlation among adjacent pixels. For this reason, their direct application to large image datasets may lead to practical limitations in efficiency and performance in some image-encryption settings [2, 12].

To address these limitations, chaos-based encryption methods have received considerable attention because of their sensitivity to initial conditions, nonlinear dynamic behavior, and ability to generate pseudo-random sequences. These characteristics make chaotic systems attractive for designing image-encryption schemes that require high unpredictability and strong key sensitivity [3],[24],[25]. In parallel, DNA-based cryptographic techniques have emerged as a promising approach for image protection by representing binary data using nucleotide symbols such as A, C, G, and T and performing logical operations in this encoded form. This representation can improve the confusion and diffusion properties of the encryption process, thereby enhancing the overall complexity of the protected image data [1],[4],[5].

Recent studies have explored the integration of chaotic systems with DNA-inspired operations for image encryption. Such approaches have shown encouraging results in terms of statistical security indicators, including improved entropy and reduced correlation among neighboring pixels in encrypted images [4],[5],[23]. However, the effectiveness of these methods still depends on several important factors, including the clarity of the encryption procedure, the reliability of the key-generation mechanism, and the scope of the experimental validation used to support the reported security claims.

Motivated by these considerations, this study presents a chaotic DNA-based framework for satellite image encryption. The proposed approach combines logistic-map-based chaotic key generation with DNA-inspired encoding and XOR operations to strengthen pixel-level transformation during the encryption process. In the current study, the framework is examined as a proof-of-concept for grayscale satellite image encryption. The main contributions of this work can be summarized as follows:

- A chaotic DNA-based framework for satellite image encryption.

- A logistic-map-driven key-generation process for generating encryption sequences.
- The use of DNA-inspired encoding and XOR-based operations to enhance confusion and diffusion at the pixel level.
- A preliminary statistical evaluation based on entropy, correlation, NPCR, and UACI.

The remainder of this study is organized as follows. Section II reviews the related literature. Section III presents the proposed methodology. Section IV describes the experimental setup and reports the results. Section V discusses the findings and limitations of the study. Finally, Section VI concludes the study and outlines directions for future work.

II. Related Work

A. Image Encryption: Challenges Beyond Traditional Methods

Securing the transmission of digital images is increasingly vital, particularly in satellite imaging, where both the sensitivity and sheer size of data are significant concerns. While established encryption methods such as AES and RSA offer strong protection for conventional data, they may not always be well suited for image encryption. Their intensive computational demands and inability to handle image-specific properties—like high redundancy and strong pixel correlation—make them less effective in this context [2],[12]. Furthermore, these techniques often fail to manage the large file sizes typical of satellite imagery, especially when real-time processing is required.

B. Chaos Theory in Image Encryption

Chaos-based encryption methods have received considerable attention in the field of image security because of their sensitivity to initial conditions, nonlinear dynamic behavior, and ability to generate pseudo-random sequences. These properties make chaotic systems well-suited for image-encryption tasks, where unpredictability and key sensitivity play an important role. Various chaotic models, including logistic maps, tent maps, the Henon system, and piecewise linear chaotic maps (PWLCM), have been used in previous studies to generate key streams and support permutation and diffusion processes in encrypted images [3], [6],[24].

In addition, chaos-based approaches are often considered attractive because they can increase the complexity of the encryption process while maintaining relatively low computational cost [18]. This makes them suitable for applications that require efficient image protection, particularly in settings where processing speed and limited computational resources are important [6]. Previous studies have reported that combining chaotic mechanisms can further improve the complexity of image-encryption schemes and enhance their resistance to unauthorized recovery attempts [24, 25]. Overall, chaos-based encryption remains a widely studied approach in image security due to its flexibility, efficiency, and strong dependence on initial parameter values.

C. DNA Cryptography in Multimedia Protection

DNA-based cryptographic techniques have attracted growing attention in multimedia security because they provide an alternative way to represent and process digital data. In this approach, binary information is encoded using nucleotide symbols such as A, T, C, and G, and a set of logical operations can then be performed within this encoded domain. Early DNA-based encryption models often relied on fixed encoding rules, whereas more recent studies have introduced dynamic DNA coding strategies and logical operations such as XOR, addition, and subtraction, often controlled by chaotic sequences [4], [5], [14].

Previous studies have shown that combining DNA-based data representation with chaotic control can improve image-encryption performance and strengthen statistical security properties [5], [7]. Previous studies reported that DNA-based operations can contribute to both confusion and diffusion during the encryption process [5], [23], making the encrypted image less predictable and more resistant to statistical analysis. These methods have also been associated with reduced correlation among adjacent pixels and improved entropy values in encrypted images, which are widely used indicators in image-security evaluation.

D. Hybrid Chaos-DNA Image Encryption

The combination of chaos and DNA encryption has been proposed as a way to address the limitations of each approach individually. Previous studies introduced a chaos-driven dynamic DNA coding method that adapts encoding rules based on chaotic sequences, ensuring per-pixel variability and greater unpredictability [8], [23].

Hybrid systems apply chaotic maps for key stream generation and pixel permutation, while DNA encoding and logical operations provide data transformation at the nucleotide level [3], [9]. This dual-layer approach disrupts statistical patterns within the image, achieving superior encryption quality compared to single-domain techniques [10, 24].

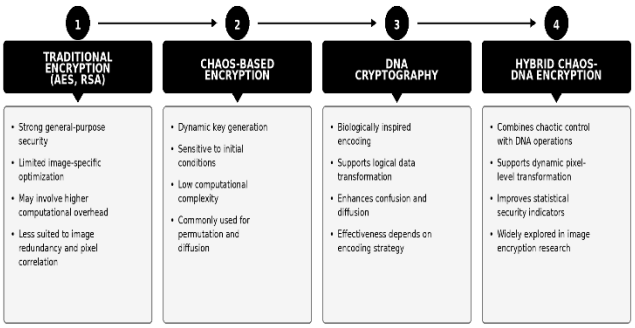

Fig. 1. Overview of conventional, chaos-based, DNA-based, and hybrid image encryption approaches.

E. Gaps in Existing Literature

Although chaos-DNA image-encryption methods have shown promising results in previous studies, several limitations remain in the existing literature. First, many reported works focus on general image datasets rather than satellite imagery as a specific application context [2, 8]. Second, several studies emphasize statistical security indicators without providing sufficiently clear methodological descriptions or broad experimental validation. In addition, the reported performance of many existing methods depends strongly on the design of the

key-generation process and the way DNA-based operations are integrated into the encryption framework [4], [13]. These observations indicate the need for further studies that provide clearer encryption procedures and a more focused evaluation for satellite image encryption.

F. Motivation for the Proposed Framework

Motivated by the above observations (Fig. 1), this study proposes a chaotic DNA-based framework for satellite image encryption. The framework is intended to combine logistic-map-based chaotic key generation with DNA-inspired encoding and XOR operations in order to strengthen pixel-level transformation during encryption. The main motivation behind this design is to explore a simple and structured encryption approach that can benefit from the sensitivity of chaotic sequences and the representational flexibility of DNA-based operations.

In this study, the proposed framework is examined as a proof-of-concept for grayscale satellite image encryption. The work is intended to provide a clearer methodological basis for integrating chaotic key generation with DNA-based processing, while offering a preliminary statistical evaluation using common image-security indicators.

III. Proposed Methodology

This section presents the design and operational workflow of the proposed encryption framework for satellite image protection. The framework is intended to combine chaotic key generation with DNA-inspired data transformation in a structured and lightweight encryption process. The main objective is to enhance pixel-level confusion and diffusion while maintaining a clear methodological design that can be applied to grayscale satellite image encryption. In this study, the framework is examined as a proof-of-concept setting for secure image encryption using common statistical security indicators.

A. Overall Architecture

The proposed encryption framework is organized around three main components:

1) Preprocessing module: This stage prepares the input satellite image in a suitable format for the encryption process. In the current implementation, the framework is applied to grayscale image data to ensure a consistent input structure for subsequent processing steps.

2) Chaotic key-generation module: This component uses the logistic map to generate pseudo-random sequences that serve as the basis for the encryption process. Because chaotic systems are highly sensitive to initial conditions [3], [24], the generated sequences introduce unpredictability and strengthen the key-dependent behavior of the framework [3], [25].

3) DNA-based encryption module: In this stage, image data are transformed using DNA-inspired encoding and XOR operations. These operations are applied to increase confusion and diffusion at the pixel level [4], [5], [10] and to support the overall complexity of the encryption process.

Fig. 2 illustrates the overall workflow of the proposed framework for satellite image encryption. The framework consists of sequential stages that begin with image preprocessing, followed by logistic-map-based key generation, DNA encoding, and XOR-based transformation, and then proceed to the corresponding decryption steps for image recovery.

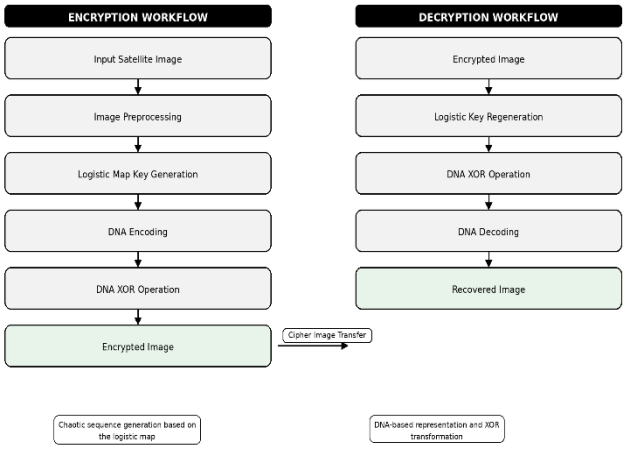

Fig. 2. Overall workflow of the proposed chaotic DNA-based satellite image encryption framework.

As shown in Fig. 2, the encryption process starts with preparing the input satellite image in a suitable format for further processing. A pseudo-random key sequence is then generated using the logistic map and used to support the encryption procedure. After that, the image data are transformed through DNA-based encoding and XOR operations to produce the encrypted image. For decryption, the same key-generation mechanism is used to regenerate the required sequence, after which inverse XOR and DNA decoding steps are applied to recover the original image. This workflow provides a clear representation of the main operational stages of the proposed framework.

B. Chaotic Key Generation

Chaotic key generation is a central component of the proposed framework because it introduces sensitivity to the initial parameters and supports the production of pseudo-random sequences for encryption. In this study, the logistic map is used as the chaotic generator because of its simple formulation and well-known nonlinear behavior. The logistic map is defined as Eq. (1).

$$x_{(n+1)} = \mu x_n(1 - x_n) \quad (1)$$

where, x_n in (0,1) denotes the chaotic state at iteration n, and \mu is the control parameter. When \mu is chosen in the chaotic region, the generated sequence becomes highly sensitive to small changes in the initial value x_0, which makes it suitable for encryption-oriented key generation.

For an input image of size M x N, the logistic map is iterated to generate a sequence of length M x N. The resulting real-valued chaotic sequence is then transformed into an integer-valued key stream that can be used in the subsequent encryption stages. A practical form of this transformation is given in Eq. (2).

$$k_i = \lfloor 256x_i \rfloor,\ i = 1,2,\ldots,MN \quad (2)$$

where, k_i represents the generated key value corresponding to the chaotic state x_i. This step maps the continuous chaotic output to discrete values that are compatible with digital image processing.

The generated key stream is then used to support the DNA-based encryption stage. Because the logistic map is highly sensitive to the initial condition x_0 and the control parameter \mu, even a small change in these values leads to a different chaotic sequence and, consequently, a different encryption result. This sensitivity strengthens the key-dependent behavior of the proposed framework and contributes to the unpredictability of the encryption process.

C. DNA Encoding and Logical Operations

After generating the chaotic key sequence, the framework applies DNA-inspired encoding to the image data. In DNA-based image encryption, binary values are represented using nucleotide symbols, namely A, T, C, and G. This representation provides an additional transformation layer and allows logical operations to be performed in the encoded domain.

In the proposed framework, each image pixel is first converted into its 8-bit binary form and then mapped into a DNA sequence according to a predefined encoding rule. This process can be expressed as Eq. (3).

$$D_i = E(p_i) \tag{3}$$

where, (p_i) denotes the original pixel value, (E(\cdot)) represents the DNA encoding function, and (D_i) is the DNA-encoded representation of that pixel.

After DNA encoding, the generated chaotic key sequence is transformed into a compatible form and combined with the encoded image data through a DNA-based XOR operation. This step increases the complexity of the encryption process and enhances pixel-level confusion. The operation can be written as Eq. (4).

$$C_i = D_i \oplus K_i \tag{4}$$

where, (K_i) is the encoded key element generated from the chaotic sequence, and (C_i) is the resulting DNA-coded encrypted value after the XOR operation.

Once this step is completed, the resulting DNA sequence is converted back into binary form and then reconstructed into pixel values to produce the encrypted image. During decryption, the same chaotic key sequence is regenerated, and the inverse procedure is applied to recover the original image. In this way, the DNA-based stage contributes to both confusion and diffusion within the proposed encryption framework.

D. Encryption Process Flow

The encryption process of the proposed framework is carried out through a sequence of structured stages that combine chaotic key generation with DNA-based data transformation. The purpose of this process is to convert the original satellite image into an encrypted form with reduced statistical predictability and stronger pixel-level confusion.

First, the input satellite image is prepared in a suitable format for encryption. In the current implementation, the image is processed as a grayscale image to ensure consistency in the subsequent stages. After preprocessing, the logistic map is iterated using the selected initial condition and control parameter to generate a chaotic sequence. This sequence is then transformed into a key stream that can be used in the encryption stage.

Next, the image pixel values are converted into binary form and encoded according to the selected DNA representation rule. The generated chaotic key stream is also transformed into a compatible encoded form. A DNA-based XOR operation is then applied between the encoded image data and the corresponding key sequence. This step introduces additional transformation at the pixel level and contributes to the complexity of the encrypted output.

After the XOR operation, the resulting DNA sequence is converted back into binary form and reconstructed into pixel values. These values form the encrypted image. Through this sequence of operations, the framework combines the sensitivity of chaotic key generation with the symbolic transformation provided by DNA-based encoding.

For clarity, the encryption procedure can be summarized as follows:

- Read the input satellite image.
- Preprocess the image and represent it in grayscale form.
- Generate a chaotic sequence using the logistic map.
- Convert the chaotic sequence into a key stream suitable for encryption.
- Encode the image pixels using the selected DNA rule.
- Apply the DNA-based XOR operation between the encoded image data and the encoded key sequence.
- Decode the resulting sequence and reconstruct the encrypted image.

E. Decryption Process Flow

The decryption process is carried out by reversing the main stages of the encryption procedure. To recover the original image correctly, the same initial condition and control parameter used in the logistic map during encryption must be applied again in the decryption stage. This allows the chaotic key sequence to be regenerated in an identical form.

First, the received encrypted image is converted into a suitable format for decryption. The logistic map is then re-initialized using the same secret parameters in order to regenerate the corresponding chaotic key sequence. After that, the encrypted image data is represented in DNA form using the same encoding rule adopted during the encryption process.

Next, the regenerated key sequence is transformed into a compatible encoded form and used in the DNA-based XOR operation. Because the same key sequence is reproduced, this step reverses the transformation applied during encryption. The resulting DNA sequence is then decoded back into binary form and reconstructed into pixel values to recover the original image.

For clarity, the decryption procedure can be summarized as follows:

- Read the received encrypted image.
- Regenerate the chaotic key sequence using the logistic map and the original secret parameters.
- Encode the encrypted image data using the same DNA rule used in encryption.
- Apply the DNA-based XOR operation using the regenerated key sequence.
- Decode the resulting DNA sequence and reconstruct the original pixel values.
- Recover the original satellite image.

Accurate synchronization of the logistic-map parameters and the DNA encoding rule between the sender and the receiver is essential for successful decryption and correct recovery of the original image data.

F. Key Features of the Framework

The proposed framework includes several characteristics that distinguish it from conventional image-encryption approaches. First, it combines chaotic key generation with DNA-inspired data transformation within a single encryption workflow. This integration provides a structured mechanism for introducing key sensitivity and pixel-level transformation during encryption.

Second, the framework is designed in a relatively simple and interpretable manner. The use of the logistic map enables pseudo-random sequence generation through a compact mathematical model, while DNA-based encoding and XOR operations provide an additional transformation layer for image data. This combination supports the overall complexity of the encryption process without relying on an overly complicated design.

Third, the framework is developed as a proof-of-concept for grayscale satellite image encryption. In this context, it is intended to demonstrate how chaotic sequence generation and DNA-based representation can be integrated within a clear methodological structure and evaluated using common statistical image-security indicators.

Overall, the proposed framework provides a lightweight and structured approach for exploring satellite image encryption using chaotic and DNA-based operations [2, 8].

IV. Experimental Setup and Results

This section describes the experimental setting used to evaluate the proposed chaotic DNA-based encryption framework. It presents the image preparation procedure, the implementation setting, and the statistical measures used to assess the encryption results. The evaluation is intended as a proof-of-concept analysis of the proposed method on grayscale satellite image data. The obtained results are reported and discussed in terms of commonly used image-security indicators, including entropy, adjacent-pixel correlation, NPCR, and UACI.

A. Experimental Environment

The experimental evaluation was conducted on a Windows 11 Pro (64-bit) platform equipped with an Intel Core i7-11800H processor and 16 GB of RAM. The proposed encryption framework was implemented in Python 3.11 using the Anaconda environment.

The main Python libraries used in the implementation were as follows:

- NumPy: used for numerical computations and the generation of pseudo-random sequences required in the chaotic processing stage.
- OpenCV: used for image reading, writing, and pixel-level image manipulation.
- Matplotlib: used for visualizing histograms and correlation plots.
- SciPy: used for entropy calculation and related statistical analysis.

B. Dataset Preparation and Preprocessing

A publicly available grayscale satellite image of size 256 × 256 pixels was used in the experimental evaluation. This image was selected to provide a proof-of-concept setting for examining the behavior of the proposed encryption framework on satellite image data. Fig. 3 shows the original input image used in the experiments.

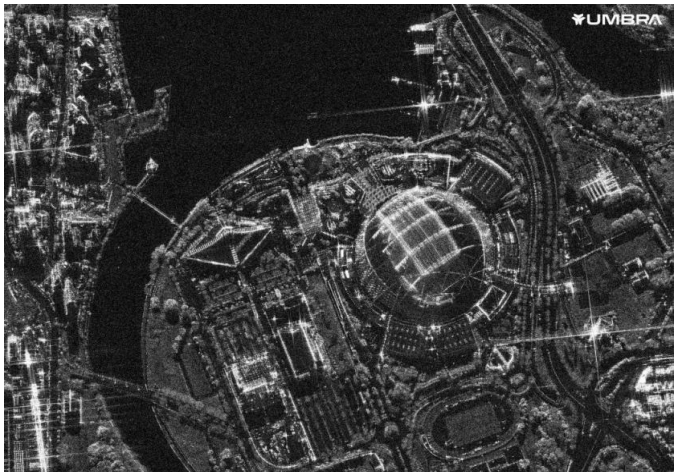

Fig. 3. Original grayscale satellite image used for encryption experiments.

Before encryption, the image was preprocessed using OpenCV to ensure a consistent input format for the subsequent stages of the proposed framework.

The preprocessing stage involved reading the input image in grayscale mode and resizing it to 256 × 256 pixels. This step ensured consistency in the input representation before applying the encryption procedure.

C. Chaotic Key Generation

A logistic map was used to generate the chaotic sequence employed in the key-generation stage. The mathematical formulation of the logistic map and its transformation into a discrete key stream were presented earlier in Section III-B. In the experimental implementation, the generated chaotic sequence was used to construct the key stream required for the encryption process.

D. DNA Encoding and Logical Operations

In this stage, binary pixel values were mapped to DNA sequences, and DNA-based XOR operations were applied to support pixel-level transformation during encryption. The mathematical formulation of the DNA encoding and XOR operations was introduced earlier in Section III-C. In the implementation, each pixel value was converted into its 8-bit binary form, divided into four pairs of bits, and mapped using the adopted DNA rule: 00 → A, 01 → C, 10 → G, and 11 → T. After that, the encoded image data were combined with the encoded chaotic key sequence through a DNA-based XOR operation. The resulting DNA sequence was then converted back into binary form and reconstructed into pixel values to produce the encrypted image.

E. Encryption Process

In the implementation, the encryption procedure was applied to each pixel of the input image using the generated chaotic key stream. For every pixel, the binary value of the image data was converted into DNA form, and the corresponding key element was transformed into a compatible DNA representation. A DNA-based XOR operation was then applied between the encoded pixel value and the encoded key value. The resulting DNA sequence was subsequently converted back into binary form and reconstructed into the encrypted pixel value. This process was repeated over the entire image to produce the final encrypted image.

Fig. 4 shows the encrypted output generated by the proposed framework after applying chaotic key generation, DNA encoding, and DNA-based XOR transformation to the input satellite image.

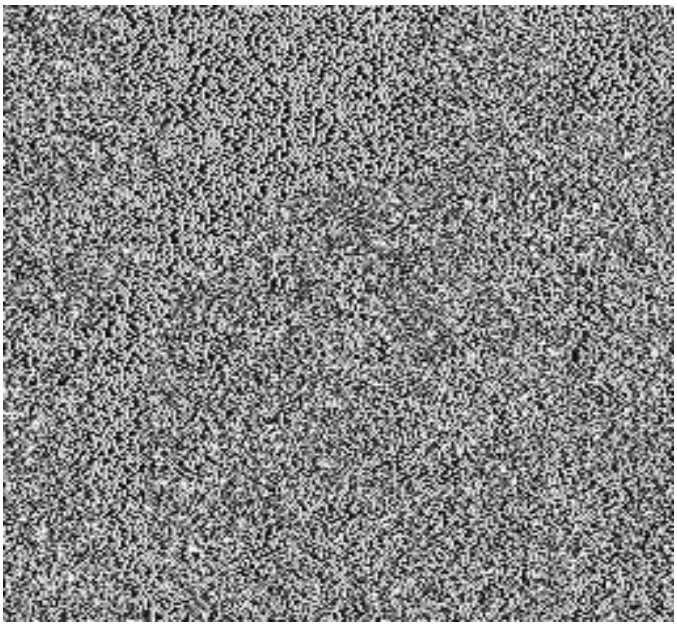

Fig. 4. Encrypted image produced by the proposed framework.

As shown in Fig. 4, the encrypted image exhibits a noise-like appearance with no visually recognizable structures from the original image. This visual behavior indicates that the proposed framework was able to significantly alter the spatial distribution of pixel intensities in the encrypted output.

F. Evaluation Metrics

The encryption performance was evaluated using standard statistical security metrics commonly employed in image-encryption studies.

The evaluation focused on four widely used indicators: information entropy, adjacent-pixel correlation, NPCR, and UACI. Information entropy was used to assess the randomness of the encrypted image distribution. Adjacent-pixel correlation was used to measure the relationship between neighboring pixels in the horizontal, vertical, and diagonal directions. NPCR was used to quantify the percentage of differing pixels between two images, while UACI was used to measure the average intensity difference between them. Together, these metrics provide a statistical view of the encryption behavior of the proposed framework.

Although these metrics are widely used in image-encryption analysis, they do not by themselves provide a complete proof of security against all possible attack models. In this study, they are used as standard indicators for a preliminary statistical evaluation of the proposed framework.

G. Results and Analysis

The experimental results indicate that the proposed framework produced statistically encouraging encryption behavior for the tested satellite image. The entropy of the encrypted image reached 7.99, which is close to the ideal value of 8 and suggests a high level of randomness in the encrypted output [1],[5],[23]. In addition, the NPCR value reached 99.61%, indicating a high percentage of pixel changes between the compared images. The UACI value was 33.32%, which is consistent with the expected behavior of a strongly transformed encrypted image. Furthermore, the correlation values in the horizontal, vertical, and diagonal directions were close to zero, indicating a substantial reduction in the linear dependency among adjacent pixels after encryption [5],[7],[23].

Overall, these results suggest that the proposed framework was effective in altering the statistical structure of the original image and producing an encrypted output with noise-like characteristics. Table I summarizes the main performance metrics obtained in the experimental evaluation.

TABLE I. PERFORMANCE METRICS OF THE PROPOSED ENCRYPTION FRAMEWORK

Metric	Result
Entropy (Encrypted)	7.99
NPCR (%)	99.61
UACI (%)	33.32
Correlation (H, V, D)	-0.003, 0.005, -0.002

V. SIMULATION RESULTS AND SECURITY EVALUATION

This section presents a statistical evaluation of the proposed chaotic DNA-based encryption framework, with emphasis on the encryption performance of the tested satellite image. The analysis was carried out using standard image-security indicators and implementation-based observations. A publicly available grayscale satellite image of size 256 × 256 pixels was used in the experiments. The implementation was performed on

a Windows 11 system equipped with an 11th Gen Intel Core i7 processor and 16 GB of RAM, using Python 3.11 within the Anaconda environment.

A. Ability to Resist Statistical Attacks

1) Histogram analysis: A common objective of image encryption is to reduce visible redundancy in pixel-intensity distributions and make the encrypted image less predictable than the original image. As shown in Fig. 5, the histogram of the original satellite image exhibits noticeable variations in intensity distribution, reflecting the structural patterns present in the plain image. By contrast, the histogram of the encrypted image appears more dispersed across the grayscale range, with no obvious dominant peaks comparable to those observed in the original image. This visual change suggests that the proposed framework altered the statistical distribution of pixel intensities in the encrypted output. However, histogram analysis alone is not sufficient to establish complete statistical security, and it should be interpreted together with quantitative indicators such as entropy and adjacent-pixel correlation.

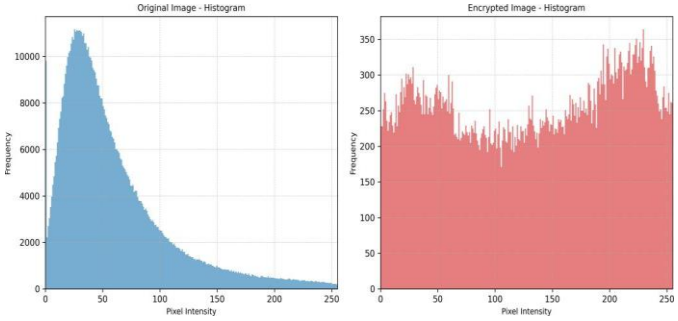

Fig. 5. Histogram comparison between the original and encrypted satellite images: (a) Histogram of the original image, (b) Histogram of the encrypted image.

2) Correlation analysis: To evaluate the statistical relationship between neighboring pixels, correlation coefficients were calculated in the horizontal, vertical, and diagonal directions. In the original satellite image, relatively high correlation values were observed, reflecting the spatial redundancy that is typically present in plain image data. After encryption, these values were reduced substantially and became close to zero, indicating a strong reduction in linear dependency among adjacent pixels.

Fig. 6-8 presents scatter plots for the original and encrypted images and illustrates the visual change in pixel correlation before and after encryption. In the original image, the points appear more strongly clustered, reflecting the spatial dependency among neighboring pixels. In contrast, the encrypted image shows a substantially more dispersed distribution, indicating a marked reduction in linear dependency after encryption. Although some local clustering can still be observed in the encrypted scatter plots, they remain considerably less structured than those of the original image. This behavior is consistent with the numerical correlation results reported in Table II and suggests that the proposed framework significantly reduced pixel-level statistical dependency in the encrypted output.

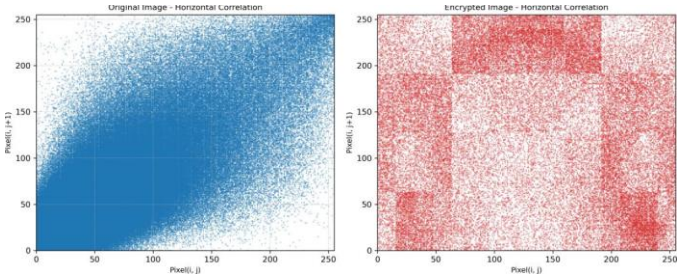

Fig. 6. Scatter plot comparison of horizontally adjacent pixels in the original and encrypted satellite images, showing the reduction in pixel correlation after encryption.

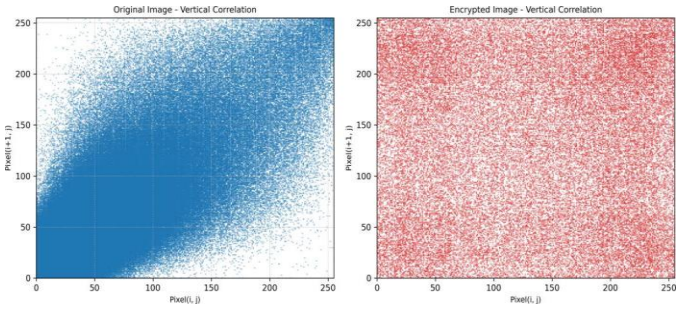

Fig. 7. Scatter plot comparison of vertically adjacent pixels in the original and encrypted satellite images, showing the reduction in pixel correlation after encryption.

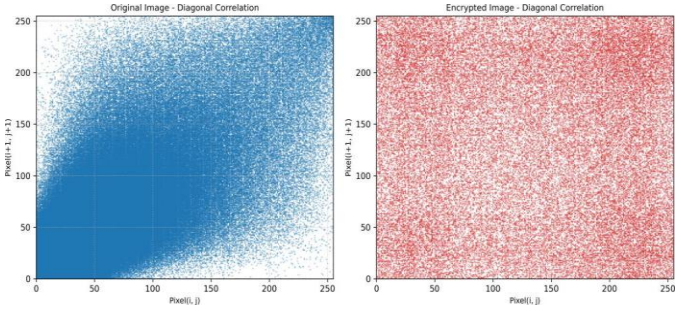

Fig. 8. Scatter plot comparison of diagonally adjacent pixels in the original and encrypted satellite images.

TABLE II. CORRELATION COEFFICIENTS OF ADJACENT PIXELS BEFORE AND AFTER ENCRYPTION

Image	Plain Image			Encrypted Image		
	Horizontal	*Vertical*	*Diagonal*	*Horizontal*	*Vertical*	*Diagonal*
Satellite Image	0.96	0.95	0.94	-0.003	0.005	-0.002

Table II reports the correlation coefficients of adjacent pixels in the horizontal, vertical, and diagonal directions before and after encryption. The original image shows high correlation values, which reflect the strong spatial dependency typically present in plain image data. After encryption, the corresponding values become very close to zero, indicating a substantial reduction in linear dependency among neighboring pixels.

3) Information entropy: Information entropy is commonly used to measure the degree of randomness or unpredictability in an encrypted image. For an 8-bit grayscale image, the ideal entropy value is 8. In this study, the encrypted image achieved

an entropy value of 7.99, which is very close to the ideal value. By comparison, the entropy of the plain satellite image was 7.55. This result suggests that the proposed framework increased the randomness of the image data after encryption and supports the statistical effectiveness of the encryption process. The corresponding entropy values are reported in Table III.

TABLE III. INFORMATION ENTROPY OF THE PLAIN AND ENCRYPTED SATELLITE IMAGES

Image	Plain Image Entropy	Encrypted Image Entropy
Satellite Image	7.55	7.99

B. Resistance to Differential Attacks

Differential attack analysis is commonly used to evaluate the sensitivity of an encryption method to small changes in the input image. In this study, the Number of Pixel Change Rate (NPCR) and the Unified Average Changing Intensity (UACI) were used to assess the effect of pixel-level changes on the encrypted output. The experimental results showed an NPCR value of 99.61% and a UACI value of 33.35%, indicating that the proposed framework produced substantial changes in the encrypted image in response to small variations in the input. These results suggest a high degree of sensitivity to differential changes [1] and support the statistical effectiveness of the encryption process. A summary of the obtained results is presented in Table IV.

TABLE IV. NPCR AND UACI RESULTS FOR DIFFERENTIAL ATTACK ANALYSIS

Image	NPCR (%)	UACI (%)
Satellite Image	99.61	33.35

C. Key Sensitivity Analysis

An important property of the proposed framework is its sensitivity to the secret parameters used in the chaotic key-generation stage. Because the logistic map is highly dependent on its initial condition and control parameter, even a very small change in these values leads to a different chaotic sequence and, consequently, a different encrypted output.

In the present framework, the parameters (x_0) and (\mu) must be reproduced accurately during decryption to regenerate the same key sequence used in the encryption stage. Any mismatch in these parameters prevents the correct recovery of the original image. This behavior indicates that the proposed method is strongly dependent on parameter synchronization and exhibits a high degree of key sensitivity [25].

From a security perspective, this sensitivity is important because it reduces the likelihood of recovering the correct image without the exact parameter settings. Therefore, the strength of the proposed framework is supported by the strong dependence of the encryption and decryption processes on the correct chaotic parameters.

D. Computational Complexity Analysis

The computational complexity of the proposed encryption framework can be expressed as $O(M \times N)$, where M and N denote the height and width of the input image, respectively. This complexity arises because the main encryption operations are applied at the pixel level across the entire image. In the current implementation, the framework combines logistic-map-based key generation with DNA encoding and XOR operations in a relatively simple processing structure.

From an implementation perspective, the framework does not rely on deeply nested transformations or computationally expensive optimization procedures. This makes the overall processing workflow relatively lightweight for the tested image size. However, the present evaluation is limited to a proof-of-concept setting on grayscale satellite imagery, and broader analysis on larger datasets and different computational settings remains an important direction for future work.

E. Summary of Security and Performance Metrics

A summary of the main security and performance metrics obtained for the proposed framework is presented in Table V.

TABLE V. SUMMARY OF THE PROPOSED FRAMEWORK'S SECURITY AND PERFORMANCE METRICS

Metric	Proposed Framework	Reference / Expected Behavior
Entropy (bits)	7.99	Close to 8.0
NPCR (%)	99.61	Greater than 99.5
UACI (%)	33.35	Around 33%
Correlation (H, V, D)	-0.003, 0.005, -0.002	Close to 0

VI. DISCUSSION

The experimental results indicate that the proposed chaotic DNA-based framework was able to alter the statistical characteristics of the tested satellite image and produce an encrypted output with increased randomness and reduced pixel-level dependency. The obtained values of entropy, correlation, NPCR, and UACI suggest that the framework achieved statistically encouraging encryption behavior under the experimental setting considered in this study. At the same time, these results should be interpreted within the scope of a proof-of-concept evaluation based on grayscale satellite image data and standard statistical image-security indicators.

A. Theoretical Contributions

From a methodological perspective, the proposed framework contributes to the integration of chaotic key generation with DNA-inspired image transformation within a relatively simple encryption structure. The logistic map provides a compact nonlinear mechanism for generating key-dependent pseudo-random sequences, while DNA-based encoding and XOR operations introduce an additional symbolic transformation layer during encryption. The combination of these two components supports pixel-level confusion and contributes to the overall complexity of the encrypted image representation.

The reported entropy, correlation, NPCR, and UACI results suggest that the proposed framework was effective in changing the statistical structure of the tested image after encryption. In this sense, the theoretical contribution of the study lies not in introducing an entirely new cryptographic primitive, but in

presenting a structured proof-of-concept framework that combines chaotic and DNA-based operations in a clear and interpretable way for satellite image encryption.

B. Practical Implications for Satellite Image Security

From an application perspective, the proposed framework illustrates how chaotic key generation and DNA-based transformation can be combined to protect satellite image data within a lightweight implementation structure. The present results suggest that the method can alter the visual and statistical characteristics of the input image in a way that makes the encrypted output less predictable than the original image.

However, the current implementation should be viewed as an initial proof-of-concept rather than a complete deployment-ready solution for operational satellite systems. Broader practical use would require additional validation on larger and more diverse image datasets, as well as further analysis under different computational and communication settings.

C. Comparison with Related Work

Relative to prior chaos-based and DNA-based image-encryption studies, the proposed framework follows a similar general direction by combining nonlinear key generation with symbolic image transformation. The statistical results obtained in this study, particularly in terms of entropy, adjacent-pixel correlation, NPCR, and UACI, are consistent with the types of indicators commonly reported in the related literature.

At the same time, the present work should be interpreted within its actual experimental scope. The proposed framework was evaluated as a proof-of-concept on grayscale satellite image data, and therefore the comparison with related work is best understood as a contextual rather than an exhaustive benchmark comparison. A broader and more rigorous comparative analysis against additional recent methods remains an important direction for future research.

D. Limitations and Future Work

Several limitations of the current study should be acknowledged. First, the evaluation was conducted on grayscale satellite imagery within a proof-of-concept setting, which limits the generalizability of the reported results. Second, the current analysis relied mainly on standard statistical security indicators such as entropy, correlation, NPCR, and UACI. Although these metrics are widely used in image-encryption studies [11], they do not by themselves provide a complete assessment against all possible attack models.

In addition, the present implementation did not include a broader evaluation on multispectral or high-dynamic-range satellite imagery, nor did it include extensive benchmarking against a large set of recent encryption baselines. Future work may therefore extend the framework to more diverse image types, incorporate additional robustness and comparative experiments, and explore alternative chaotic designs or more advanced DNA-based transformation strategies.

E. Broader Implications in Cryptography

The study also highlights the potential value of combining ideas from nonlinear dynamics and biologically inspired data representation in multimedia security research. Even within the limited scope of the present implementation, the integration of chaotic processing and DNA-based transformation demonstrates how cross-disciplinary concepts can be used to develop structured image-encryption frameworks [4],[8],[23].

More broadly, this line of research may support future work on lightweight and application-oriented cryptographic methods for image and multimedia protection [20], [21]. In this respect, the proposed framework serves as a useful exploratory step toward more comprehensive studies on secure image encryption using chaos-based and DNA-inspired techniques.

VII. Conclusion

This study presented a chaotic DNA-based framework for satellite image encryption that combines logistic-map-based key generation with DNA-inspired encoding and XOR operations. The proposed framework was developed as a proof-of-concept approach for grayscale satellite image encryption and was evaluated using common statistical security indicators.

The experimental results showed that the encrypted image achieved high entropy, low adjacent-pixel correlation, and encouraging NPCR and UACI values under the adopted evaluation setting. These findings suggest that the proposed framework was effective in altering the statistical characteristics of the tested image and producing an encrypted output with reduced predictability.

At the same time, the current study is limited to a proof-of-concept evaluation on grayscale satellite imagery and standard statistical image-security metrics. Therefore, the reported results should be interpreted within this scope. Future work may extend the framework to more diverse satellite image types, incorporate broader comparative and robustness analyses, and investigate alternative chaotic designs or more advanced DNA-based transformation strategies.

***Abstract*—The architectural design process is often iterative, time-consuming, and heavily dependent on effective communication between clients and professionals. Existing design tools, such as Computer-Aided Design (CAD) systems, require technical expertise, limiting accessibility for non-professional users. This study proposes a generative artificial intelligence framework for exterior house design using a diffusion-based text-to-image model. The proposed approach integrates Stable Diffusion for image generation with a vision-language model (BLIP) to enhance semantic alignment between textual descriptions and generated outputs. In addition, an interactive refinement mechanism based on image inpainting is incorporated to allow localized modification of design elements. The system is trained on a dataset of exterior house images and evaluated using quantitative metrics, including CLIP Score and Fréchet Inception Distance (FID), as well as usability assessment. Experimental results demonstrate that the proposed framework is capable of generating semantically relevant and visually coherent architectural designs, while improving accessibility and reducing the time required for design iteration. The findings highlight the potential of generative AI as an effective tool for supporting user-centric architectural visualization and design exploration.**

***Keywords*—Generative artificial intelligence; stable diffusion; text-to-image generation; architectural design; image inpainting**

I. Introduction

Architecture plays a fundamental role in shaping human living environments by integrating functional, cultural, and aesthetic elements. The design of residential houses, particularly exterior design, requires careful consideration of architectural components such as roof structure, wall materials, windows, doors, and color schemes. Traditionally, the design process involves iterative communication between clients and architects, which can be time-consuming and inefficient due to repeated revisions and difficulty in visualizing design concepts at early stages.

Despite the availability of digital tools such as Computer-Aided Design (CAD), these systems often require significant technical expertise, limiting accessibility for non-professional users. As a result, clients face challenges in expressing their preferences effectively, while architects encounter difficulties in interpreting and translating user requirements into visual designs. This limitation highlights the need for intelligent systems that can bridge the gap between user intent and design visualization.

Recent advancements in Generative Artificial Intelligence (AI) have introduced new possibilities for automating creative tasks, including image generation and design synthesis. In particular, text-to-image generation has emerged as a promising approach that enables the transformation of natural language descriptions into visual outputs, combining techniques from natural language processing and computer vision [1], [2]. Early work in this area primarily utilized Generative Adversarial Networks (GANs), which consist of a generator and discriminator trained in an adversarial manner to produce realistic images [3]-[5]. Variants such as Conditional GAN (cGAN) [6], Deep Convolutional GAN (DCGAN) [7], and AttnGAN [8] have demonstrated improved control and semantic alignment in generated images.

Further developments introduced specialized GAN-based models for architectural and design applications. For instance, HouseGAN enables graph-constrained house layout generation [9], while Roof-GAN focuses on generating realistic roof geometries [10]. Other models, such as Pix2Pix, have been applied for image-to-image translation tasks, including architectural layout generation [11], [12]. However, GAN-based approaches often suffer from training instability, mode collapse, and limited diversity in generated outputs [13].

To address these limitations, diffusion models have gained significant attention as a more stable and robust alternative for generative tasks. Diffusion models generate images by progressively denoising random noise through a learned reverse process, allowing them to capture complex data distributions effectively [14], [15]. Denoising Diffusion Probabilistic Models (DDPM) have demonstrated superior performance in terms of image quality and diversity compared to GAN-based methods [16]. More recently, Stable Diffusion, a latent diffusion model, has enabled efficient high-resolution image generation with reduced computational cost, making it suitable for real-world applications [17].

In parallel, vision-language models have been developed to enhance the relationship between textual and visual representations. Models such as Bootstrapping Language-Image Pre-training (BLIP) leverage transformer-based architectures to generate context-aware captions and improve semantic alignment between images and text [18], [19]. These models play a crucial role in improving the accuracy and interpretability of text-to-image generation systems.

*Corresponding author.

Another important advancement in generative AI is image inpainting, which enables localized modification of images by reconstructing missing or masked regions. Modern inpainting techniques, particularly those based on diffusion models, allow users to refine specific parts of generated images while preserving global consistency [20], [21]. This capability is especially useful in architectural design, where users may wish to iteratively adjust design elements such as windows, doors, or color schemes.

Despite these technological advancements, existing research primarily focuses on model development rather than user-centric applications. Many systems lack intuitive interfaces that allow non-expert users to interact with generative models effectively. Furthermore, the integration of text-to-image generation, vision-language alignment, and interactive editing within a single architectural design framework remains underexplored.

Therefore, this study proposes a diffusion-based generative AI framework for exterior house design that integrates Stable Diffusion for image generation, BLIP for semantic alignment, and an inpainting module for interactive refinement. The proposed system is designed to be accessible to non-professional users through a chatbot-based interface, enabling intuitive and efficient design exploration. The effectiveness of the proposed approach is evaluated using quantitative metrics, including CLIP Score and Fréchet Inception Distance (FID), as well as usability assessment.

II. Methodology

A. System Design

This study adopted a Software Development Life Cycle (SDLC) perspective and implemented a modified waterfall model comprising requirements analysis, system design, implementation, testing, and documentation. In the adapted process, the deployment phase was omitted, and documentation replaced maintenance due to time and resource constraints. The overall research flow starts with image acquisition, followed by preprocessing, BLIP-based caption generation, Stable Diffusion model training, system integration, and evaluation.

The modified waterfall model was selected because the project required a structured sequence of development activities while still allowing limited feedback between phases. This was suitable for a system that combines dataset preparation, model fine-tuning, application integration, and user-based evaluation.

B. System Architecture

The template is used to format your paper and style the text. All margins, column widths, line spaces, and text fonts are prescribed; please do not alter them. You may note peculiarities. For example, the head margin in this template measures proportionately more than is customary. This measurement and others are deliberate, using specifications that anticipate your paper as one part of the entire proceedings, and not as an independent document. Please do not revise any of the current designations. The proposed generative AI framework integrates multiple components, including data preprocessing, caption generation, model training, and user interaction, to enable automated exterior house design from textual descriptions. The system is designed as a multi-layer architecture consisting of data, application, and interaction layers.

The data and model layer includes dataset preparation, BLIP-based caption generation, and Stable Diffusion model fine-tuning. The application layer consists of a Flask-based backend that handles text-to-image generation and inpainting processes. The interaction layer is implemented using a React-based frontend that provides a chatbot interface for user input, image visualization, and design refinement.

The workflow begins when a user submits a text prompt, which is processed by the Stable Diffusion model to generate an initial house design. Users can further refine the generated output through an inpainting module that enables localized modifications. The system supports iterative interaction, allowing users to explore multiple design variations efficiently. The complete architecture and workflow of the proposed system are illustrated in Fig. 1.

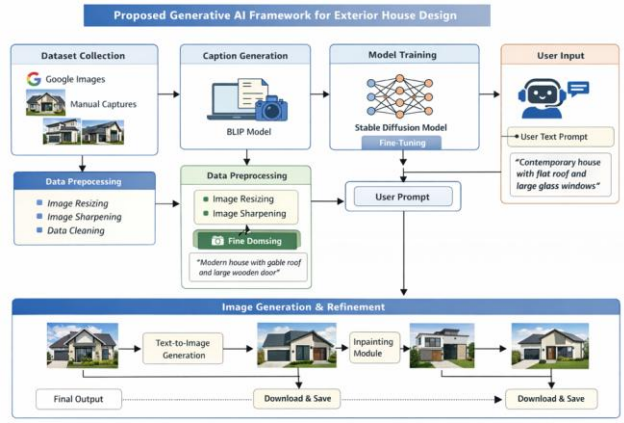

Fig. 1. Proposed generative AI framework for exterior house design.

This integrated architecture ensures seamless interaction between model components and the user interface, enabling an efficient and user-centric design workflow.

C. Dataset Collection

The dataset used in this study consists of 1,100 exterior house images, collected to represent a wide range of architectural styles and design elements relevant to residential buildings. The images were primarily obtained from publicly accessible online sources, including Google Images, using the Imageye browser extension, as well as manually captured images.

To ensure diversity, various search queries such as *"exterior house design"*, *"modern house"*, *"house with hip roof"*, and *"house with wooden door"* were used during the data collection process. This approach enabled the inclusion of different house styles, including modern, traditional, and contemporary designs.

The collected dataset focuses on front-view exterior house images and captures key architectural elements such as roof style, window type, and door design (Table I). Based on the dataset distribution, four main roof types were identified: hip roof (240 images), gable roof (275 images), flat roof (465 images), and sloped roof (120 images).

For window types, the dataset includes sliding windows (385 images), casement windows (372 images), and hung windows (343 images). In terms of door styles, wooden doors (498 images), sliding doors (397 images), and French doors (205 images) are represented.

TABLE I. DATASET STATISTICS BY ARCHITECTURAL FEATURES

Feature Category	Feature Type	Number of Images
Roof Style	Hip Roof	240
	Gable Roof	275
	Flat Roof	465
	Sloped Roof	120
Window Type	Sliding Window	385
	Casement Window	372
	Hung Window	343
Door Style	Wooden Door	498
	Sliding Door	397
	French Door	205
Total Images		**1100**

The dataset was carefully curated to remove irrelevant, duplicate, and low-quality images, ensuring that only clear and consistent exterior house images were retained. This filtering process improves the reliability of the dataset and enhances the model's ability to learn meaningful visual patterns.

Overall, the dataset provides a diverse yet structured representation of architectural features, which is essential for training a text-to-image generation model capable of producing realistic and semantically accurate exterior house designs.

D. Data Preprocessing

Data preprocessing is a crucial step to ensure that the collected dataset is suitable for training deep learning models. In this study, both image and text data undergo preprocessing to standardize input formats, enhance feature quality, and prepare structured image-caption pairs for model training.

1) Image resizing: All collected images were resized to a uniform resolution of 512 × 512 pixels to ensure consistency across the dataset. Standardizing image dimensions is essential for efficient model training, as it reduces computational complexity while preserving important architectural details such as edges, textures, and structural components.

2) Image enhancement: After resizing, image sharpening techniques were applied to enhance visual clarity and emphasize key architectural features, including roof edges, window frames, and door structures. This step improves feature distinguishability, allowing the model to better capture structural patterns during training.

3) Data cleaning: The dataset was manually cleaned to remove irrelevant, duplicate, and low-quality images. Images that did not represent exterior house views, such as interior scenes or incomplete structures, were excluded. This process ensures that the dataset remains consistent and reduces noise that may negatively affect model performance.

4) Caption generation using BLIP: To enable text-to-image learning, each image must be paired with a corresponding textual description. In this study, captions were generated using the Bootstrapping Language-Image Pre-training (BLIP) model. The BLIP model was fine-tuned on the dataset to produce descriptive captions that capture key architectural elements such as roof type, window style, door design, and wall characteristics.

The generated captions serve as textual representations of the visual features, allowing the model to learn the relationship between natural language input and architectural design elements.

5) Dataset structuring: The final dataset was organized into structured image-text pairs in the form:

(Image, Caption)

This structured format is essential for training the Stable Diffusion model, as it enables supervised learning of the mapping between textual prompts and corresponding visual outputs. An example of an image-caption pair from the dataset is shown in Fig. 2. The caption describes key architectural elements, including roof type, window style, door design, and wall color, which are used as conditioning inputs during model training.

Fig. 2. Example of image-caption pair used in the dataset: "Modern house with flat roof, large sliding windows, white wall, and wooden front door."

The example illustrates how textual descriptions are aligned with visual features, allowing the model to learn meaningful relationships between language and architectural design elements. This structured pairing plays a crucial role in improving the semantic accuracy of the generated images.

6) Data preparation for model training: The processed dataset was prepared for training by ensuring compatibility with the Stable Diffusion framework. Image-caption pairs were formatted and stored in a suitable structure for fine-tuning using the DreamBooth method. Proper data preparation improves training stability and contributes to the generation of high-quality and semantically accurate images.

E. System Design

This section describes the development of the core models used in the proposed framework, namely the BLIP model for image captioning and the Stable Diffusion model for text-to-image generation. The integration of these models enables the system to learn the relationship between textual descriptions and architectural visual features.

1) BLIP model for caption generation: The Bootstrapping Language-Image Pre-training (BLIP) model is employed to generate descriptive captions for the exterior house images. Initially, a pre-trained BLIP model is loaded and fine-tuned using the prepared dataset to adapt it to the domain of architectural design.

During training, the BLIP processor converts both images and associated textual descriptions into numerical representations, allowing the model to learn semantic relationships between visual features and language. The fine-tuning process improves the model's ability to generate captions that accurately describe architectural elements such as roof style, window type, door design, and wall characteristics.

Once trained, the BLIP model is used to automatically generate captions for all images in the dataset. These captions form structured image-text pairs that serve as input for training the text-to-image generation model.

2) Stable diffusion model for text-to-image generation: The Stable Diffusion model is used as the primary generative model for producing exterior house designs from textual prompts. Stable Diffusion operates by transforming random noise into meaningful images through an iterative denoising process guided by text embeddings.

In this study, a pre-trained Stable Diffusion model is fine-tuned using the prepared image-caption dataset. The fine-tuning process is performed using the DreamBooth approach, which enables the model to adapt to domain-specific features while preserving general image generation capabilities.

During training, textual captions are encoded into embeddings and used to condition the denoising process. A U-Net architecture progressively removes noise from a latent representation, while a decoder converts the final latent representation into a high-resolution image. This process allows the model to generate visually coherent images that correspond to user-defined prompts.

3) Model integration: The BLIP and Stable Diffusion models are integrated to form a unified generative pipeline. The BLIP model provides high-quality captions that enhance semantic alignment, while the Stable Diffusion model generates images based on these textual descriptions.

This integration improves the overall performance of the system by ensuring that generated images are both visually realistic and semantically relevant. The combined framework enables effective mapping between user input and generated architectural designs.

4) Model deployment: After fine-tuning, the Stable Diffusion model is exported into the Hugging Face Diffusers format to support efficient inference. The trained model is then deployed within a Flask-based backend, which processes user prompts and returns generated images in real time.

This deployment setup ensures scalability and enables seamless interaction between the frontend interface and the generative model.

F. Proposed Framework Algorithm

The overall workflow of the proposed generative AI framework is formalized in Algorithm 1, which integrates data preprocessing, caption generation, model training, text-to-image generation, and interactive refinement.

Algorithm 1:

```
Input:
   Raw image dataset I_raw
   User prompt p
Output:
   Generated or refined exterior house image g

// DATA PREPARATION PHASE
Collect exterior house images I_raw from online sources
For each image image_i in I_raw do
    Resize image_i to 512 × 512
    Apply sharpening to enhance architectural features
    Store processed image_i in dataset I_clean
End For

// CAPTION GENERATION (BLIP)
Load pre-trained BLIP model
Fine-tune BLIP using I_clean
For each image image_i in I_clean do
    Generate caption_i using BLIP
    Store (image_i, caption_i) in dataset D
End For

// MODEL TRAINING (STABLE DIFFUSION)
Load pre-trained Stable Diffusion model M_sd
Fine-tune M_sd using dataset D (image-caption pairs)
Save trained model

// INFERENCE PHASE (TEXT-TO-IMAGE)
Receive user prompt p from interface
Encode p into text embeddings
Initialize latent vector z with random noise
For t = T down to 1 do
    Predict noise using U-Net conditioned on p
    Denoise z iteratively
End For
Decode final latent z into generated image g

// OPTIONAL INPAINTING (REFINEMENT)
If user selects region for editing then
    Receive mask m and refinement prompt p_r
    Preserve unmasked regions of g
    Apply diffusion-based inpainting on masked region
    Generate refined image g'
    Set g ← g'
End If

// OUTPUT
Display generated image g to user
Allow download or further refinement

Return g
```

Algorithm 1 illustrates the complete pipeline from dataset preparation to user interaction, highlighting the integration of diffusion-based generation and vision-language alignment within a unified framework.

III. Result and Discussion

This section presents the evaluation results of the proposed generative AI framework for exterior house design. The system is assessed based on functionality, semantic accuracy, image quality, and usability. Quantitative metrics, including CLIP Score and Fréchet Inception Distance (FID), are used to evaluate model performance, while user-based testing is conducted to assess system usability.

A. Functionality Testing

Functionality testing was conducted to verify that the proposed system operates correctly in supporting the main user tasks. The evaluation focused on validating the core features of the system, including text-to-image generation, image refinement through inpainting, user interface interaction, and image output management.

The following key features were tested during the functionality evaluation:

- Text prompt input through the chatbot interface.
- Text-to-image generation using the Stable Diffusion model.
- Display of generated images.
- Image variation generation.
- Inpainting-based image refinement.
- Masking tools (brush, eraser, and selection tools).
- Navigation between Design Generator and Inpainting Studio.
- Image download functionality.

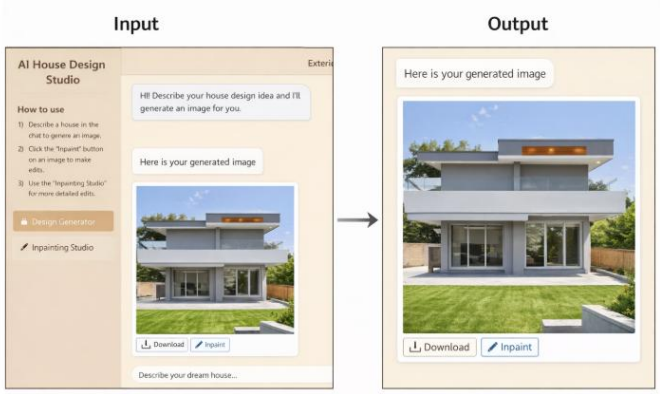

Fig. 3. Example of text-to-image generation using a prompt.

For the text-to-image generation module, the system successfully accepted natural language prompts entered through the chatbot interface and produced corresponding exterior house design images. As illustrated in Fig. 3, the generated result reflects the architectural characteristics described by the user, indicating that the generation pipeline is able to transform textual input into a coherent visual output. This demonstrates that the model and interface are properly integrated and capable of supporting intuitive design exploration.

The system also performed reliably in supporting image refinement through the inpainting module. Users were able to select a specific region of the generated image, apply a mask, and submit an edit prompt to modify the selected area. As shown in Fig. 4, the system successfully updated the targeted region while preserving the overall layout and visual consistency of the house design. This confirms the effectiveness of the inpainting function for localized architectural refinement.

Fig. 4. Inpainting-based refinement of generated house design.

In addition, supporting features such as switching between modules, selecting generated variations, and downloading images were executed without errors. The masking tools (e.g., brush and eraser) also functioned correctly, allowing users to interactively define regions for modification.

Overall, the functionality testing results indicate that all major system components operate as expected. The successful execution of generation, refinement, and interaction features demonstrates that the proposed framework is fully functional and suitable for assisting users in exterior house design visualization.

B. Semantic Accuracy Evaluation (CLIP Score)

The semantic alignment between generated images and their corresponding textual descriptions was evaluated using the CLIP Score. This metric measures the similarity between image and text embeddings, with higher values indicating better semantic consistency.

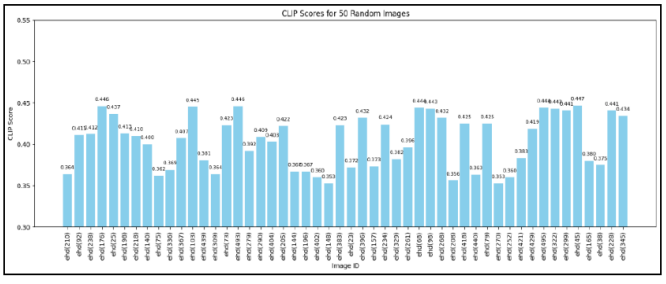

Fig. 5. CLIP score visualization.

The BLIP model achieved an average CLIP Score of 0.42, indicating moderate alignment between generated captions and visual features as shown in Fig. 5. This result suggests that the model is capable of capturing relevant architectural elements

from textual descriptions, although some discrepancies may still occur in complex scenarios.

The moderate CLIP score can be attributed to the limited dataset size and variability in architectural styles, which may affect the model's ability to generalize across diverse design inputs.

C. Image Quality Evaluation (FID Score)

The visual quality of the generated images was evaluated using the Fréchet Inception Distance (FID), which measures the similarity between the distributions of generated images and real images in terms of feature representations. Lower FID values indicate better image quality and higher similarity to real-world data.

The Stable Diffusion model achieved an FID score of 82.4, indicating that the generated images exhibit recognizable architectural structures but still lack high levels of photorealism and fine-grained detail. Despite the relatively high FID score, qualitative observation of the generated images shows that the model is capable of producing coherent house designs with identifiable architectural elements such as roof structures, windows, doors, and wall compositions. This suggests that the model successfully captures the general layout and structural characteristics of exterior house designs, even if certain visual refinements are not fully achieved.

The obtained FID score can be attributed to several factors. First, the dataset size of 1,100 images is relatively limited compared to large-scale datasets typically used in state-of-the-art generative models. This restricts the model's ability to learn diverse architectural patterns and may lead to less realistic outputs. Second, the dataset exhibits some imbalance in feature distribution, particularly with a higher proportion of flat roof and wooden door designs, which may bias the generated results toward more common styles.

In addition, the complexity of architectural features poses a challenge for generative models. Unlike general object generation, house design involves structured geometry, symmetry, and spatial consistency, which require the model to capture both global layout and local details simultaneously. The current model demonstrates competence in generating overall structure but shows limitations in rendering fine textures, lighting consistency, and detailed architectural features.

Furthermore, the fine-tuning process using the DreamBooth approach, while effective for adapting the model to a specific domain, may not fully optimize the model for high-fidelity image generation when trained on a relatively small dataset. This highlights the trade-off between domain specialization and image realism.

When compared to state-of-the-art diffusion models trained on large-scale datasets, the obtained FID score is higher; however, within the scope of this study, the generated images remain sufficiently realistic for early-stage architectural visualization and concept exploration. The primary objective of the system is to support idea generation rather than produce final construction-ready designs, and thus, the achieved image quality is considered acceptable for its intended application.

To improve image quality in future work, several enhancements can be considered. These include increasing the dataset size and diversity, applying data augmentation techniques, incorporating higher-resolution training strategies, and fine-tuning more advanced diffusion architectures. Additionally, integrating post-processing techniques or hybrid models could further enhance visual realism.

Overall, the FID evaluation indicates that while there is room for improvement in image realism, the proposed system successfully generates meaningful and visually coherent architectural designs, demonstrating the feasibility of using diffusion-based generative models for exterior house design applications.

D. Usability Testing

Usability testing was conducted to evaluate the effectiveness, efficiency, and user satisfaction of the proposed system. The assessment was performed using the System Usability Scale (SUS), a widely adopted method for measuring perceived usability of interactive systems. The SUS questionnaire consists of ten items rated on a five-point Likert scale, ranging from "Strongly Disagree" to "Strongly Agree." The scoring method involves subtracting 1 from the scores of odd-numbered questions and subtracting the scores of even-numbered questions from 5, followed by multiplying the total score by 2.5 to obtain a final value between 0 and 100.

A total of 30 respondents participated in the usability evaluation. The results, as illustrated in Fig. 6, show that most respondents achieved SUS scores within the range of 80 to 95. The overall average SUS score obtained in this study is 86, indicating a high level of usability and user satisfaction.

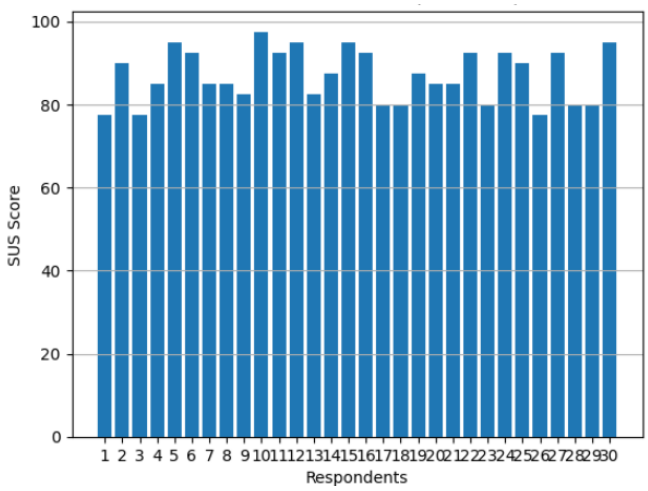

Fig. 6. SUS score distribution.

According to standard SUS interpretation guidelines, a score above 68 is considered above average, while scores above 80 are classified as excellent. Therefore, the obtained average score of 86 places the proposed system within the "excellent" usability category, suggesting that users found the system easy to use and well-designed. The high usability score can be attributed to several design factors. First, the chatbot-based interface simplifies user interaction by allowing natural language input, eliminating the need for technical knowledge in architectural

design tools. Second, the system provides immediate visual feedback through generated images, which enhances user engagement and supports rapid design exploration. Third, the inclusion of interactive features such as image variation and inpainting allows users to refine designs intuitively, contributing to a more flexible and user-centered experience.

Furthermore, the relatively consistent SUS scores across respondents indicate that the system provides a stable and reliable user experience. The absence of significantly low scores suggests that users did not encounter major usability issues during interaction. However, some limitations were observed. A few respondents reported slightly lower scores, which may be attributed to the need for clearer guidance when using advanced features such as inpainting or masking tools. This indicates that additional user assistance, such as tooltips or tutorials, could further improve the overall usability of the system.

Overall, the usability evaluation demonstrates that the proposed framework successfully meets user expectations in terms of ease of use, functionality, and interaction. The results highlight the potential of the system to serve as an accessible tool for both non-expert users and professionals in architectural design

E. Discussion

The experimental results demonstrate that the proposed generative AI framework is capable of generating exterior house designs from textual descriptions with reasonable semantic alignment and visual coherence. The integration of BLIP and Stable Diffusion enables effective mapping between text and image, while the inpainting module provides flexibility for iterative design refinement.

The system offers several advantages over traditional design approaches. First, it reduces the time required for design iteration by providing instant visual feedback. Second, it improves communication between clients and architects by enabling users to visualize their ideas without requiring technical expertise. Third, it introduces an interactive and user-friendly design process through the chatbot interface.

However, several limitations were identified. The moderate CLIP score indicates that semantic alignment can be further improved, particularly for complex or ambiguous prompts. Additionally, the relatively high FID score suggests that image realism is limited by the dataset size and diversity. Expanding the dataset and incorporating more advanced training techniques could improve model performance.

Overall, the results highlight the potential of generative AI as a practical tool for architectural visualization, particularly in early-stage design and concept exploration.

IV. CONCLUSION

This study presented a diffusion-based generative AI framework for exterior house design that enables the transformation of textual descriptions into architectural visualizations. The proposed system integrates Stable Diffusion for text-to-image generation with a BLIP-based captioning model to improve semantic alignment, along with an inpainting module for interactive design refinement. The experimental results demonstrate that the proposed framework is capable of generating visually coherent and semantically relevant exterior house designs. The system achieved a CLIP Score of 0.42, indicating moderate alignment between textual descriptions and generated images, and an FID score of 82.4, suggesting acceptable image quality for early-stage design visualization. In addition, usability evaluation shows that the system is intuitive and accessible, allowing non-professional users to explore design ideas effectively.

The main contributions of this study include the development of an end-to-end generative AI framework for architectural design, the integration of diffusion models with vision-language techniques, and the introduction of an interactive refinement mechanism using inpainting. These contributions address limitations in traditional design workflows by reducing dependency on technical expertise and improving communication between users and designers. Despite these contributions, several limitations remain. The relatively high FID score indicates that the generated images can be further improved in terms of realism and fine details. Additionally, the dataset size and diversity are limited, which may affect the model's ability to generalize across complex architectural styles.

Future work will focus on expanding the dataset with more diverse architectural designs, improving model performance through advanced training strategies, and extending the system to support interior design and 3D architectural generation. Furthermore, integrating real-time user feedback and deploying the system as a web or mobile application could enhance its practical applicability.

Integration of Random Forest and Hough Transform for Cancer Classification Using Microarray Gene Expression Data

Hibah Alatawi*, Hechmi Shili
Department of Computer Sciences, University of Tabuk, Saudi Arabia

***Abstract*—Cancer classification poses a significant challenge owing to the intricate nature and diversity of the disease. This study introduces a novel methodology for cancer classification leveraging microarray gene expression data. The proposed approach integrates Random Forest (RF) and Hough Transform (HT), where RF performs feature selection and classification, and HT identifies sub-biclusters that are merged into larger clusters using a hypergraph model. Evaluation on multiple cancer datasets demonstrates that the hybrid approach improves classification accuracy compared to standalone RF or HT while capturing meaningful gene expression patterns.**

***Keywords*—Cancer classification; microarray gene expression; random forest; Hough transform; feature selection; hypergraph model**

I. Introduction

Microarray data analysis plays a pivotal role in understanding complex biological systems and identifying biomarkers associated with various diseases, including cancer [1,10]. Microarray analysis is employed in gene expression profiling, where it typically generates a substantial amount of data [31,32]. Biclustering algorithms have emerged as a powerful tool in the analysis of microarray gene expression data, allowing for the simultaneous classification of both genes and experimental conditions. Unlike standard clustering techniques, which focus on grouping either genes or samples, biclustering methods aim to identify sub-matrices within the gene expression data matrix where a subset of genes exhibit a consistent pattern across a subset of experimental conditions [1]. In recent years, the classification of microarray datasets, often referred to as large-scale biological data analysis, has become a prominent and compelling area of research. The application of microarray technology represents a critical advancement in molecular biology, particularly for the detection of cancer [37]. In Addition, biclustering, a powerful data mining technique, facilitates the simultaneous clustering of rows and columns in large datasets, uncovering hidden patterns and structures. However, traditional biclustering methods often struggle with the high dimensionality and noise inherent in microarray datasets [2]. Microarray technology has become a powerful tool for investigating complex biological processes and diseases, enabling the representation of gene expression data as large matrices with genes as rows and experimental conditions as columns [3]. While various statistical techniques have been applied to analyze these gene expression matrices, biclustering has emerged as a particularly effective method, as it can uncover meaningful patterns by identifying subsets of genes that exhibit consistent expression profiles across subsets of experimental conditions. This ability to capture the inherent complexity of gene regulation, where the expression of a gene can be influenced by multiple factors, is a key advantage of biclustering over traditional clustering approaches, which focus on grouping genes or samples independently. The insights gained from biclustering analysis can provide valuable perspectives on the intricate mechanisms governing biological processes and disease states [4].

Despite these advances, existing biclustering and classification approaches still face limitations in handling the high dimensionality, noise sensitivity, and the difficulty of linking biclustering outputs directly to robust classification performance. This gap motivates the need for an integrated and more resilient framework for microarray data analysis.

An automated, computer-assisted medical diagnosis system that integrates cutting-edge medical methodologies with advanced machine learning algorithms represents a critical multidisciplinary technology. It enables accurate and noninvasive diagnosis of various diseases, including breast cancer [6,32]. The classification of microarray data presents significant challenges due to its complexity. The bioinformatics community employs a variety of approaches to diagnose and classify this data using machine learning systems. Given that each microarray sample contains thousands of genes for analysis, feature elimination methods have become widely utilized and adopted to manage the high dimensionality and enhance the accuracy of classification outcomes [5,39]. The abundance of gene expression datasets offers a valuable opportunity to computationally identify condition-specific functional gene modules (FGMs). These FGMs are characterized by highly organized expression patterns within specific sets of genes. Smart healthcare involves a wide range of operatives, including physicians, nurses, hospitals, and research organizations [30].

This study aims to develop an integrated framework that combines geometric pattern detection and ensemble learning to improve both biclustering quality and classification accuracy in microarray gene expression data.

In this study, we propose a novel methodology that addresses these challenges by integrating the Hough Transform and Random Forest algorithm for biclustering and classification tasks. The Hough Transform, applied in column pair-spaces, enables the identification of sub-biclusters within microarray

*Corresponding author.

datasets, while hyper-graph partitioning techniques refine and optimize these sub-biclusters. Subsequently, the optimized biclusters are seamlessly integrated as inputs into a Random Forest classifier, enhancing the classification process. By combining these techniques, our integrated framework offers a comprehensive solution for biclustering and classification tasks in Microarray data analysis. Leveraging the complementary strengths of the Hough Transform and Random Forest algorithm, our approach provides a holistic and efficient method for uncovering meaningful patterns and biomarkers in complex biological datasets.

The main contributions of this work are summarized as follows:

- Proposing a novel integration between the Hough Transform and Random Forest for simultaneous biclustering and classification.
- Introducing a hyper-graph partitioning refinement step to optimize detected sub-biclusters.
- Providing a robust framework that links biclustering outputs directly to classification performance.
- Demonstrating the effectiveness of the proposed approach on real-world microarray cancer datasets.

The integration of biclustering and classification offers several advantages. First, it enables the simultaneous identification of coherent gene expression patterns and their classification into distinct biological states or phenotypes. Second, by incorporating the Hough Transform, our framework provides robustness to noise and captures complex patterns inherent in Microarray gene expression data. Third, the Random Forest classifier enhances the accuracy and robustness of classification by leveraging the collective decision of multiple decision trees. The proposed framework holds great promise for advancing our understanding of gene expression regulation and its role in disease mechanisms. By providing a holistic approach to Microarray gene expression data analysis, it offers researchers a powerful tool for uncovering meaningful insights and identifying potential biomarkers associated with diseases such as cancer.

Unlike existing studies that treat biclustering and classification as separate processes, the proposed approach establishes a direct and optimized connection between both tasks, highlighting the novelty of this work compared to recent related studies.

In the subsequent sections of this study, we describe the methodology in detail, present experimental results on real-world datasets, and discuss the implications of our findings for biomedical research and clinical applications.

II. Related Work

The field of gene expression analysis has witnessed substantial advancements, particularly in the development and application of biclustering techniques. Biclustering, a method that allows for the simultaneous classification of gene expression profiles, has proven to be effective in identifying patterns of gene expression under diverse conditions. This literature review examines the evolution of biclustering methods and their application in microarray gene expression data analysis. Recent studies (Table I) have introduced innovative frameworks and algorithms that enhance the classification of gene expression profiles, including the use of Biclustering-based classifiers, evolutionary approaches, and ensemble learning techniques. Additionally, the integration of machine learning and big data approaches has further refined cancer diagnosis and classification, demonstrating significant improvements in accuracy and robustness. This section also highlights the potential of combining traditional statistical methods with advanced computational techniques, such as the Hough Transform, to improve the analysis and interpretation of complex biological data. Through a comprehensive examination of these advancements, the review underscores the critical role of biclustering and related methodologies in advancing our understanding of gene expression patterns and improving cancer classification and diagnosis.

A. Advances in Biclustering and Machine Learning for Gene Expression and Cancer Diagnosis

Biclustering, a method for simultaneous classification of gene expression profiles, has been shown to be effective in identifying gene expression patterns under various conditions [1]. This method has been further enhanced by the development of a biclustering-based classification framework, which utilizes homogeneously expressed genes in biclusters to construct a classifier for sample class membership prediction Malhotra et al. [2]. An evolutionary approach to obtaining high-quality biclusters of highly-correlated genes has also been proposed, demonstrating competitive performance with state-of-the-art algorithms Ayadi et al. [3]. Additionally, the application of the bagging approach to improve the performance of biclustering methods has been successful in both synthetic and real datasets Hanczar, Ayadi et al. [4]. These studies collectively highlight the potential of biclustering and its various applications in microarray gene expression data analysis. The proposed framework of Biswal et al. [7] undergoes testing on a diverse set of datasets, including five distinct microarray datasets and one dataset consisting of single-cell RNA sequencing (scRNA-seq) data. In Albalawi et al. [26], the Convolutional Neural Network (CNN) classifier for diagnosing breast cancer utilizing MIAS (Mammographic Image Analysis Society) dataset. CNN established as an efficient class of methods for image recognition problems. The research of Almutairi, S. et al. [27], develops a big data-driven breast cancer classification model using Deep Reinforcement Learning (DRL), achieving high accuracy across three datasets (WBCD: 98.90%, WDBC: 99.02%, WPBC: 98.88%). The model incorporates the Gorilla Troops Optimization (GTO) algorithm for feature selection and Deep Q Learning (DQL) for classification, outperforming traditional methods such as RBF-ELB, PSO-MLP, and GA-MLP. The study demonstrates the potential of integrating big data and advanced machine learning techniques to improve breast cancer diagnosis accuracy. The study of Alatawi, Y. M. et al. [28] assessed early performance indicators for breast cancer screening at King Abdulaziz University Hospital, Saudi Arabia, analyzing data from 1,911 women who participated in the screening program between 2012 and 2019. The findings revealed that 19.9% of women were recalled for further evaluation, with 18.9% undergoing biopsy. Screen-detected

cancer was found in 1.6% of participants, while 0.7% were diagnosed with breast cancer.

Balaha and Hassan [33] proposed a deep learning-based framework for skin cancer diagnosis by integrating transfer learning with the Sparrow Search Algorithm (SSA) to optimize feature extraction and classification performance. Their approach demonstrated superior results compared with several conventional deep learning architectures, achieving high accuracy, precision, recall, and F1-score in skin lesion classification. Since the Hough transform is an image analysis technique, it can potentially be integrated with other computational platforms and machine learning models to further enhance image-based diagnostic performance [34].

B. Computational Models for Microarray-Based Cancer Classification

Recent advances in biomedical data analysis have highlighted the potential of image-derived mathematical models, such as the Hough Transform (HT), in uncovering hidden structural relationships within complex biological datasets. Originally developed for geometric feature extraction in image processing, HT has been successfully adapted to identify spatial and relational patterns in biomedical contexts, including histopathological imaging, brain signal analysis, and genomic data interpretation. In particular, the HT framework enables the detection of geometric trends—such as alignments or co-expressed trajectories—among gene pairs or condition profiles. This geometric abstraction provides an effective means of representing high-dimensional biological data in lower-dimensional spaces, facilitating the discovery of regulatory modules and functional relationships that traditional statistical methods may overlook [1]. Beyond geometric modeling, several computational frameworks have explored the synergy between biclustering and feature selection to improve cancer classification using microarray gene expression data. Biclustering methods—such as the Cheng & Church algorithm, which minimizes mean squared residue to identify locally coherent expression patterns; xMotif, which searches for statistically significant submatrices enriched with co-expressed genes; and the Plaid model, which decomposes the expression matrix into overlapping layers representing distinct biological processes—have been widely employed to capture coherent gene subsets that exhibit correlated expression under specific experimental conditions [40]. Feature selection algorithms, including mutual information, ReliefF, and ensemble-based approaches, have been integrated with machine learning classifiers to reduce dimensionality and enhance interpretability. Among these, the Random Forest (RF) classifier has emerged as a preferred model due to its robustness to noise, built-in feature importance estimation, and ability to handle high-dimensional gene expression data efficiently. Recent studies have demonstrated that RF-based hybrid systems outperform conventional models in identifying diagnostic biomarkers and distinguishing between cancer subtypes, motivating the integration of RF with biclustering and structural learning in this study.

C. Advances in Gene Expression Analysis

The Hough Transform has been successfully applied in the analysis of microarray gene expression data. Zhao et al [8] and Zhao et al. [9] both developed biclustering algorithms based on the Hough Transform in the column-pair space, which were found to be robust to noise and computationally efficient. Tiňo et al. [10] further improved this approach by introducing a probabilistic model-based Hough Transform for the detection of co-expression patterns in three-color cDNA microarray data. Shafie et al. [11] extended this work by demonstrating the use of a relational space to classify microarray gene expression data, with the transformation of real-valued data to binary data leading to improved class separation. These studies collectively highlight the potential of the Hough Transform in the analysis of microarray gene expression data. Over the past three decades, advancements in cancer classification have been significant; however, a universal methodology for the identification of new cancer classes (class discovery) and the assignment of tumors to established classes (class prediction) remains elusive [12]. Golub et al. [12,16] presented a comprehensive approach to cancer classification utilizing gene expression monitoring via DNA microarrays, specifically applied to human acute leukemias as an illustrative case. The study of Umer, M. et al. [29] introduces an ensemble learning-based voting classifier that integrates logistic regression and stochastic gradient descent classifiers with deep convoluted features for the accurate detection of breast cancer. The proposed framework effectively distinguishes between malignant and benign tumors, demonstrating improved classification accuracy. The results indicate that this method outperforms existing state-of-the-art approaches. The class discovery process successfully differentiated between acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL) without prior knowledge of these categories. Furthermore, a class predictor derived from this process accurately classified new leukemia cases. These findings validate the viability of cancer classification based exclusively on gene expression profiles and propose a generalizable strategy for the discovery and prediction of cancer classes across various cancer types, independent of pre-existing biological knowledge. A hybrid approach of PCC-BPSO/GA with multiple classifiers improves gene selection and classification accuracy in microarray datasets [17]. Differentiating malignant pleural mesothelioma (MPM) from adenocarcinoma (ADCA) of the lung is challenging with conventional methods. G. Gordon et al. [13,15] proposed a gene expression ratio-based approach for early and precise diagnosis.

This study assessed 181 tissue samples (31 MPM and 150 ADCA) and identified 15 diagnostic ratios from a training set of 32 samples. Each ratio achieved at least 90% accuracy in diagnosis, with combined ratios reaching 95% and 99% accuracy for MPM and ADCA, respectively. This method is accurate, cost-effective, and has potential applicability in other clinical diagnostic contexts.

Extensive experiments in Purbolaksono et al. [16] on 8 real cancer microarray datasets (4 diagnostic and 4 prognostic) show that the proposed classifier performed superior in both cancer diagnosis and prognosis, the latter of which was regarded as quite difficult previously. Additionally, results demonstrate that sample classification accuracy can serve as a good subjective quality measure for different types of biclusters, and hence as a tool to extrinsically evaluate the performance of various biclustering algorithms that produce those biclusters.

Microarray data classification poses significant challenges due to the high dimensionality and small sample sizes of the data.

V. Bolon et al. [18] present an extensive experimental evaluation of the most prominent feature selection algorithms and evaluation techniques, providing a detailed analysis of the findings and insights that can inform the development of effective microarray data classification approaches. Embryonal tumors of the central nervous system (CNS) represent a biologically diverse and poorly understood group of tumors. Diagnosing these tumors based solely on their morphology is controversial, as exemplified by medulloblastomas—the most common malignant brain tumors in children—whose pathogenesis and relationship to other embryonal CNS tumors remain debated. Additionally, predicting patients' responses to therapy for these tumors poses a significant challenge. Pomeroy SL et al. [19] addressed these issues by developing a classification system based on DNA microarray gene expression data from 99 patient samples. They demonstrated that medulloblastomas are molecularly distinct from other brain tumors, including primitive neuroectodermal tumors (PNETs), atypical teratoid/rhabdoid tumors (AT/RTs), and malignant gliomas. Their research provided previously unrecognized evidence that medulloblastomas derive from cerebellar granule cells through activation of the Sonic Hedgehog (SHH) pathway. Furthermore, they showed that the clinical outcomes of children with medulloblastomas are highly predictable based on the gene expression profiles of their tumors at diagnosis. Jinthanasatian et al. [20] proposed a new feature selection algorithm called FF-SVM that uses the FireFly algorithm along with an SVM classifier to classify cancer microarray gene expression data, and they found that this algorithm achieves high classification accuracy using a small number of selected genes. Salem et al. [21] present a novel methodology for classifying human cancer diseases based on gene expression profiles. This approach combines Information Gain (IG) and Deep Genetic Algorithm (DGA).

TABLE I. SUMMARY OF STUDIES ON BI-CLUSTERING TECHNIQUES IN MICROARRAY GENE EXPRESSION DATA ANALYSIS [15]

Ref	Dataset	Type classifier	Feature Selection	Accuracy	No.Genes
[16]	Leukemia [12]	BN	Ml	88.2%	NA

III. PROPOSED FRAMEWORK

Microarray data analysis plays a pivotal role in understanding complex biological systems and identifying biomarkers associated with various diseases, including cancer. Biclustering, a powerful data mining technique, facilitates the simultaneous clustering of rows and columns in large datasets, uncovering hidden patterns and structures. However, traditional biclustering methods often struggle with the high dimensionality and noise inherent in microarray datasets. In this study, we propose a novel methodology that addresses these challenges by integrating the Hough Transform and Random Forest algorithm for biclustering and classification tasks. The Hough Transform, applied in column pair-spaces, enables the identification of sub-biclusters within microarray datasets, while hypergraph partitioning techniques refine and optimize these sub-biclusters. Subsequently, the optimized biclusters are seamlessly integrated as inputs into a Random Forest classifier, enhancing the classification process.

Fig. 1 summarizes the full workflow of the proposed framework, from the input microarray matrix to the final classification result. The process starts by projecting gene expression data into column-pair spaces, followed by Hough Transform–based detection of geometric patterns to extract sub-biclusters. These are encoded, grouped by shared columns, and used to build a hypergraph that is partitioned and optimized to obtain refined biclusters. Features are then derived from the optimized biclusters and fed into a Random Forest classifier for cancer prediction. The next subsections explain each stage step by step.

A. Geometric Patterns in Microarray Data Using Hough Transform in Column-Pair Spaces

Microarray gene expression data often exhibit complex geometric patterns that encode valuable information about underlying biological processes. The application of the Hough Transform (HT) in column-pair spaces offers a powerful tool for uncovering these geometric patterns and extracting meaningful insights from the data. In microarray experiments, gene expression levels are typically measured across multiple conditions (columns) for numerous genes (rows). Traditional clustering methods often overlook the spatial relationships between genes and conditions, limiting their ability to capture

the intricate geometric structures present in the data. However, by leveraging the HT in column-pair spaces, we can explore these geometric patterns more effectively. The HT is a robust technique originally developed for line detection in image processing. When applied to microarray data, it allows us to identify linear structures or patterns within the dataset, revealing relationships between genes and conditions that may not be apparent through conventional methods. In column-pair spaces, each point represents the expression levels of a gene across two conditions. By transforming the data into this space, we can detect linear patterns corresponding to coherent gene expression changes across specific conditions. These patterns may manifest as diagonal lines, indicating consistent up- or down-regulation of genes under particular conditions, or as clusters of points representing subsets of genes exhibiting similar expression profiles across conditions. The identification of geometric patterns using HT in column-pair spaces provides valuable insights into the underlying biological processes driving gene expression changes. For example, coherent diagonal lines may indicate the activation or repression of specific pathways or regulatory networks in response to different experimental conditions. Clusters of points may represent co-regulated gene sets involved in common biological functions or pathways. Moreover, the HT can be combined with biclustering algorithms to further elucidate complex geometric structures within microarray data. Biclustering identifies subsets of genes and conditions that exhibit coherent expression patterns, and the HT enhances this analysis by revealing the geometric relationships between these subsets. The application of the Hough Transform in column-pair spaces offers a powerful approach for uncovering geometric patterns in microarray gene expression data. By leveraging these patterns, researchers can gain deeper insights into the underlying biological processes and identify potential biomarkers or therapeutic targets for further investigation. By combining these techniques, our integrated framework offers a comprehensive solution for biclustering and classification tasks in Microarray data analysis. Leveraging the complementary strengths of the Hough Transform and Random Forest algorithm, our approach provides a holistic and efficient method for uncovering meaningful patterns and biomarkers in complex biological datasets. We consider a dataset represented by an m by n matrix, where each column, denoted as a_i, represents a specific attribute or condition. In our methodology, the five coherent patterns identified within microarray datasets are integral to the analysis of gene expression data, as they allow us to extract biologically meaningful relationships between genes and conditions. Each pattern reveals different forms of coherence in the data, which are crucial for both biclustering and classification. Our interest lies in identifying five distinct coherent patterns within this matrix: 1) constant values across the entire pattern, 2) constant values within columns, 3) constant values within rows, 4) additive coherent values, and 5) multiplicative coherent values. These patterns can be expressed through specific equations corresponding to the behavior of the data within each pattern. Previous research has explored the identification of these patterns using hyperplane-based approaches with the Hough Transform (HT). However, as the dimensionality of the data increases, so does the computational complexity. In this study, we propose a novel approach utilizing the HT in column pair-spaces to identify sub-biclusters within the microarray cancer dataset. These sub-biclusters are then optimized using hypergraph partitioning techniques to enhance the biclustering process, offering a more efficient and effective solution to pattern discovery in high-dimensional datasets.

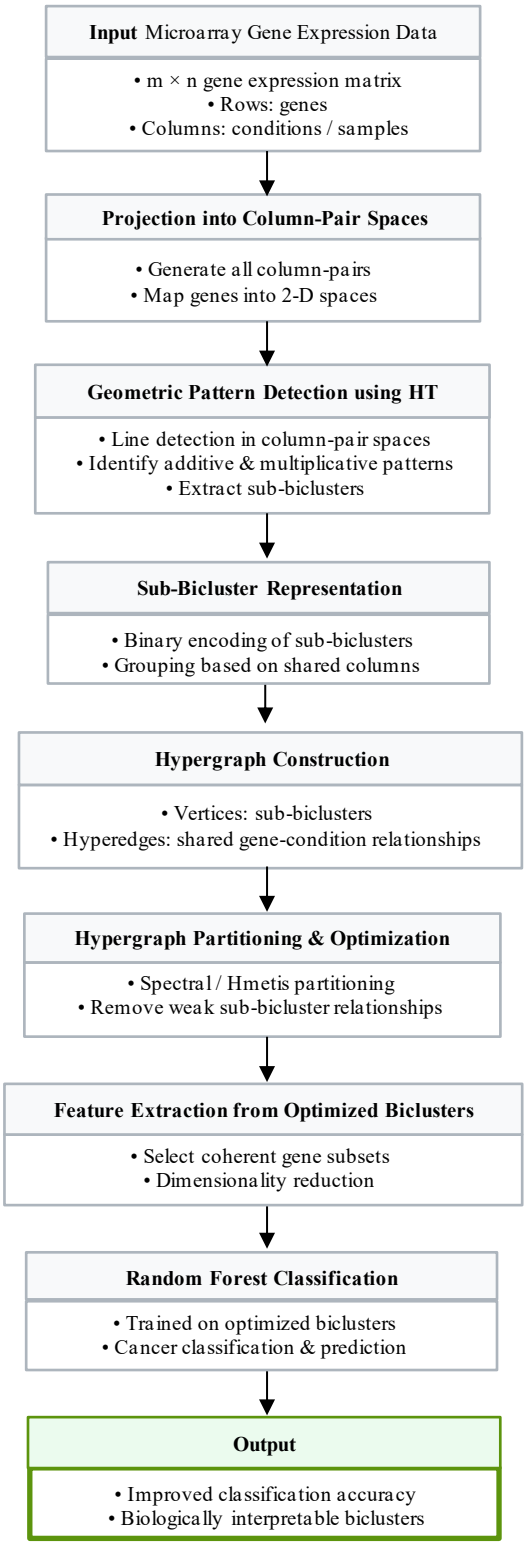

Fig. 1. Overall framework of the proposed method.

B. Characterizing Coherent Expression Patterns in Microarray Data: Across Genes and Conditions

In the analysis of microarray data, identifying coherent patterns is essential for understanding the relationships between genes and conditions. These patterns provide insights into how gene expression varies across different experimental conditions or biological states. By recognizing distinct types of coherence in the data, such as constant, additive, and multiplicative relationships, we can better interpret the underlying biological mechanisms driving gene regulation. Each pattern reveals a unique aspect of gene expression behavior, offering valuable information for biclustering and classification tasks. The following section outlines how each identified pattern is applied in the context of microarray data analysis to uncover meaningful biological insights. To formalize the identification of coherent gene expression patterns in microarray data, we define mathematical equations corresponding to each of the five distinct biclustering patterns. These equations capture the specific relationships observed between genes and conditions, allowing us to model the behavior of the data in a structured and interpretable manner. By expressing these patterns mathematically, we can apply computational techniques, such as the Hough Transform, to efficiently detect and analyze these patterns across large, high-dimensional datasets. The following section details the equations associated with each biclustering pattern, providing a foundational framework for pattern discovery in microarray data.

1) Constant value in the entire pattern: This pattern reflects a subset of genes that exhibit a uniform expression level across all conditions. In microarray data, this could signify genes that are consistently active or repressed, regardless of experimental conditions. These genes might be involved in essential housekeeping functions, and their identification can help distinguish between condition-specific and general expression patterns.

$$x_{ij} = \mu \tag{1}$$

In the context of microarray gene expression data, it represents the expression level of a gene i under condition. i refers to the row index, corresponding to a specific gene. j refers to the column index corresponding to a specific condition or sample. x_{ij} denotes the expression level of gene i under condition j in the microarray dataset. μ. refers to the mean value of the entire pattern.

2) Constant values in columns: This pattern represents genes that maintain a consistent expression level within a specific condition or set of conditions. It helps to identify condition-invariant behavior, indicating genes that are robust to particular environmental or experimental variations. In biomedical research, such patterns might be used to highlight genes involved in fundamental processes that are stable under certain biological states.

$$x_{ij} = \mu_i \tag{2}$$

μ refers to the mean value of column i.

3) Constant values within rows: This pattern captures genes that have consistent expression across specific genes under varying conditions. In microarray data, it could represent genes that are co-regulated across multiple conditions, providing insights into condition-specific gene regulation networks. This is particularly useful for identifying condition-dependent gene sets that may play roles in disease mechanisms or therapeutic responses.

$$x_{ij} = \mu_j \tag{3}$$

μ refers to the mean value of row j.

4) Additive coherent values: This pattern reflects gene expression changes that follow an additive relationship across conditions. For instance, gene expression levels might increase or decrease consistently by a fixed amount across conditions, suggesting the additive effects of external stimuli or experimental treatments. Identifying additive patterns in microarray data can help detect linear regulatory mechanisms and dose-response relationships in biological pathways.

$$x_{ij} = \alpha_i + \beta_j \tag{4}$$

α_i : Constant additive value f for column i.

β_j : Constant additive value f for row j.

5) Multiplicative coherent values: This pattern represents relationships where gene expression changes by a consistent multiplicative factor across conditions. It indicates proportional regulation across conditions, which may reflect more complex, nonlinear regulatory mechanisms. Multiplicative patterns can point to the influence of transcription factors or other regulatory elements that affect gene expression in a multiplicative fashion across different conditions.

$$x_{ij} = \alpha_i \times \beta_j \tag{5}$$

α_i : Multiplicative coefficient for column i.

β_j : Multiplicative coefficient for row j.

The application of the Hough Transform (HT) allows us to uncover these patterns by identifying geometric structures in the column pair-spaces of the microarray data. The identification of coherent patterns, particularly diagonal lines and clusters in these spaces, enhances our ability to detect regulatory networks and gene co-expression relationships. Following the detection of sub-biclusters using the Hough Transform in the column-pair space, a hypergraph partitioning mechanism is employed to refine and optimize these biclusters. In this representation, each gene and condition is modeled as a node, and the relationships identified by HT form hyperedges connecting multiple nodes simultaneously. This higher-order representation captures complex gene-condition associations that conventional pairwise clustering methods fail to model. By applying spectral hypergraph partitioning, redundant or weakly correlated biclusters are merged, while spurious connections are eliminated. The resulting hypergraph structure enhances the compactness, coherence, and biological interpretability of the final biclusters, leading to improved downstream classification

performance when integrated with the Random Forest classifier. Subsequently, these optimized biclusters are fed into the Random Forest classifier, which integrates the discovered gene expression patterns into a robust classification model. In summary, these coherent patterns provide critical insights into gene expression behavior across conditions, and our integrated framework combining the Hough Transform, biclustering, and Random Forest classification offers a holistic approach to uncovering these relationships in microarray datasets. This approach not only facilitates the discovery of meaningful biological patterns but also advances the identification of biomarkers and therapeutic targets in complex diseases.

C. Application of the Hough Transform for Geometric Pattern Detection and Biclustering in Microarray Data

The Hough Transform (HT) is a well-established technique used for line detection in image processing, particularly in 2-D space. It works by transforming geometric patterns from the $X-Y$ space into the K-B parameter space, where lines are detected through a voting process. In the $X-Y$ space, a line defined by the equation $y = kx + b$ corresponds to a point (k, b) in the K-B parameter space. Conversely, a point in the $X-Y$ space (x, y) is represented as a line in the parameter space, where the equation is given by $b = kx + y$. By quantizing both k and b into n discrete steps, an $n \times n$ a grid of cells, or accumulators, is formed in the parameter space. Each accumulator records the number of intersecting lines that pass through a specific (k, b) pair. The accumulator with the highest count indicates the most significant intersection point, providing critical information about the prominent lines in the original $X-Y$ space. When applied to microarray cancer datasets, the HT in column-pair spaces facilitates the identification of sub-biclusters within an m×nm×n matrix. Since the matrix contains nn columns, the total number of column pairs is $\frac{n(n-1)}{2}$, which yields $\frac{n(n-1)}{2}$ potential sub-biclusters. These sub-biclusters are subsequently aggregated into larger biclusters using our algorithm. Each bicluster pattern corresponds to distinct geometric structures in column-pair spaces, as depicted in Fig. 2. By examining the values of k and b in the parameter space, it becomes clear that the constant bicluster pattern is a specialized case of the constant row/column pattern. Similarly, the constant row/column pattern is a specific instance of the additive/multiplicative pattern. Thus, instead of distinguishing between five separate patterns, we can classify sub-biclusters into two main categories: additive type and multiplicative type.

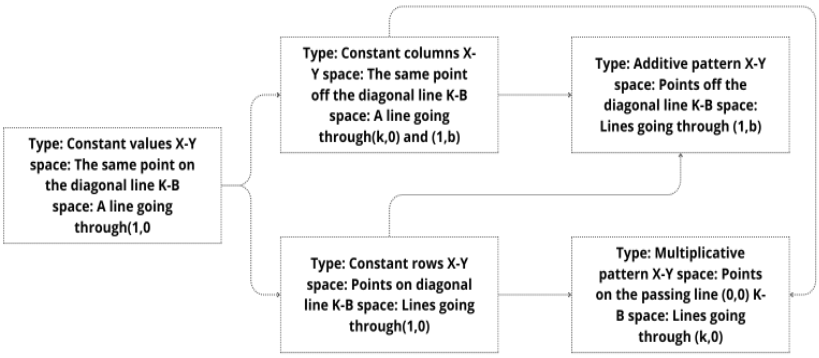

Fig. 2. Geometric representation of the five biclustering patterns in column-pair spaces [22].

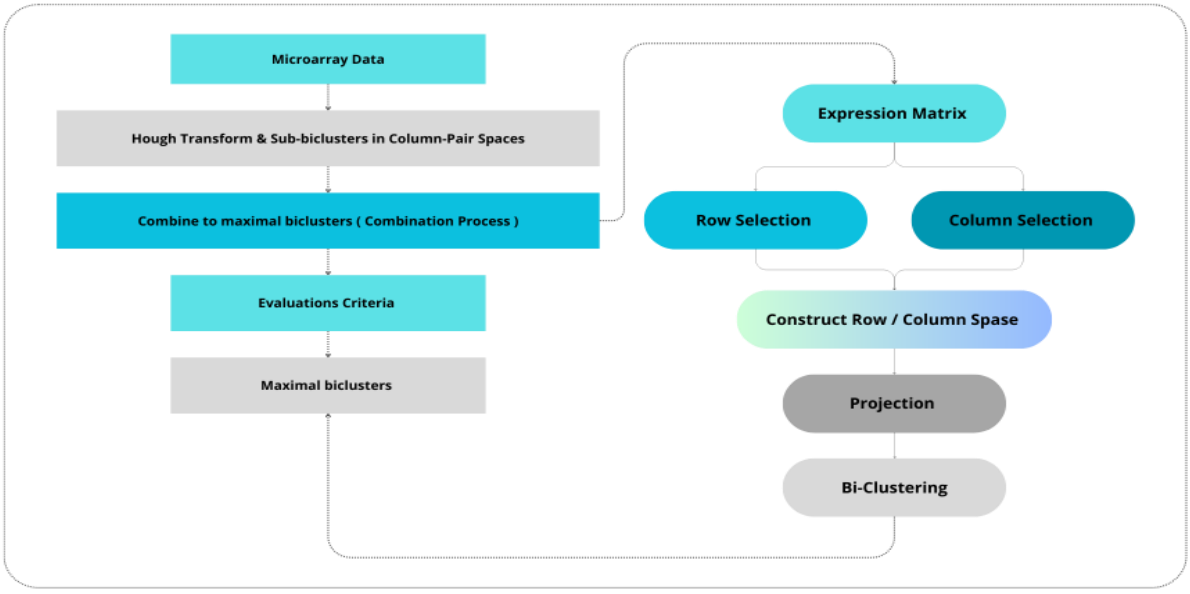

Fig. 3. Flow chart illustrating the discovery of geometric patterns in microarray data via Hough transform applied to column-pair spaces.

When applied to microarray cancer datasets, the HT in column-pair spaces facilitates the identification of sub-biclusters within an $m \times n$ matrix. Since the matrix contains n columns, the total number of column pairs is $\frac{n(n-1)}{2}$, which yields $\frac{n(n-1)}{2}$ potential sub-biclusters. These sub-biclusters are subsequently aggregated into larger biclusters using our algorithm. Each bicluster pattern corresponds to distinct geometric structures in column-pair spaces, as depicted in Fig. 2. By examining the values of k and b in the parameter space, it becomes clear that the constant bicluster pattern is a specialized case of the constant row/column pattern. Similarly, the constant row/column pattern is a specific instance of the additive/multiplicative pattern. Thus, instead of distinguishing between five separate patterns, we can classify sub-biclusters into two main categories: additive type and multiplicative type. Specifically, in the $X - Y$ space, sub-biclusters are classified as additive when $k = 1$ and $b = 0$, and as multiplicative when $k = 0$ and $b = 1$. In our approach, projection techniques are used to identify coherent gene expression patterns within the microarray cancer dataset.

By projecting the high-dimensional gene expression data into lower-dimensional spaces, we reduce the complexity of the dataset while preserving the essential information needed to detect biologically relevant patterns. These projections help transform the original dataset into a more interpretable form, where relationships between genes and conditions can be more easily uncovered. This process allows for the detection of biclusters—coherent subsets of genes and conditions with similar expression profiles. Through this method, we enhance the accuracy and interpretability of cancer classification by focusing on the most relevant features and patterns in the data.

D. Optimizing Bicluster Expansion in Microarray Cancer Data: Utilizing Hough Transform and Hypergraph Partitioning

After applying the five coherent patterns to identify sub-biclusters in the microarray dataset, the merging process proceeds with these patterned sub-biclusters, ensuring that the integration of sub-biclusters is guided by both their geometric structures and biological relevance. When applied to a microarray cancer dataset, each column is denoted as $C1, C2, \ldots, Cn$, and each row as $R1, R2, \ldots, Rm$ in the data matrix. Utilizing the HT algorithm, we can identify $\frac{n(n-1)}{2}$ sub-biclusters of two distinct types. Each sub-bicluster, comprising m points, is represented by a binary vector m, where 1 signifies a sub-bicluster element, and 0 indicates an unrelated point. A sub-bicluster binary matrix, comprising similar types of sub-biclusters, is defined as $[s1, s2, s3, \ldots, sp]$. To merge sub-biclusters, they must share a common column in the column pairs to which they belong. For instance, if $s1$ represents a sub-bicluster in $C1$ and $C2$, and $s2$ is the sub-bicluster in $C1$ and $C3$, then $s1$ and $s2$ can be combined, resulting in $s1 \cap s2$. As more sub-biclusters are merged, the number of rows in the combined bicluster decreases. To optimize the combination process amidst the computational complexity introduced by $\frac{n(n-1)}{2}$ column pairs, a hypergraph partition tool can be employed.

Hypergraph partitioning divides the vertices of a hypergraph into several independent non-empty groups to minimize a given cost function. By transforming the sub-bicluster matrix into a hypergraph, vertices representing sub-biclusters are obtained. Hmetis, a hypergraph partition tool, can then be utilized to cut the sub-bicluster hypergraph. The process involves various vertex grouping schemes in Hmetis, including hybrid first-choice (HFC), first-choice (FC), and greedy first-choice (GFC) schemes, among others. By selecting the first-choice scheme (FC), vertices sharing the same multi-hyperedges are grouped. Cutting the sub-bicluster matrix into several parts optimizes the expansion process, with a higher number of partitions resulting in quicker sub-bicluster combinations. However, the partitions should be chosen judiciously to ensure efficient computational processing.

E. Enhancing Microarray Cancer Classification with Biclustering-Driven Random Forest Analysis

Microarray technology has revolutionized cancer research by enabling the simultaneous measurement of gene expression levels across thousands of genes. However, the high-dimensional nature of microarray data poses significant challenges for data analysis and interpretation. Biclustering algorithms offer a promising approach to uncovering coherent patterns within microarray datasets by simultaneously clustering genes and samples.

In our framework, the Random Forest (RF) classifier is used to classify cancer samples based on the features extracted from the optimized biclusters. RF was chosen because it handles high-dimensional data well and can capture complex relationships between genes. Each bicluster provides a group of genes with coherent expression patterns, which are used as input features for the classifier. This allows RF to focus on biologically meaningful patterns rather than individual genes, improving classification accuracy and interpretability.

By incorporating bicluster-derived features into the Random Forest classifier, we aim to enhance the accuracy and interpretability of cancer classification, ultimately facilitating a better understanding of cancer subtypes and informing clinical decision-making. After employing the Hypergraph-Based Biclustering Algorithm to identify biclusters in a microarray cancer dataset, the resulting biclusters, denoted as $B\ (R1, C1)$, are utilized as input to a Random Forest classifier. In this context, each bicluster represents a coherent group of genes exhibiting similar expression patterns across a subset of conditions. The Random Forest classifier is a robust machine learning algorithm that operates by constructing a multitude of decision trees during training and outputting the mode of the classes for classification tasks. By incorporating the biclusters as input features into the Random Forest classifier, we harness the collective gene expression patterns captured within each bicluster to enhance the classification accuracy. Mathematically, a bicluster $B\ (R1, C\ 1)$. can be understood as a submatrix of the original microarray data matrix $M\ (R, C\ )$.. Let X represent the input matrix for the Random Forest classifier, where each row corresponds to a sample (e.g., a cancer patient), and each column represents a gene expression feature. By selecting the columns corresponding to the genes present in $B\ (R1, C\ 1)$, we derive a subset matrix X_B, containing only the relevant features encapsulated by the bicluster. Consequently, X_B serves as the input feature matrix for the Random Forest classifier.

Integrating biclustering results into the Random Forest classifier enhances its performance by focusing on biologically meaningful gene expression patterns associated with specific cancer subtypes or phenotypes. By considering coherent groups of genes together, the classifier can better capture the underlying biological mechanisms driving cancer progression and response to treatment. This approach facilitates more accurate classification of cancer samples into clinically relevant subgroups, leading to improved diagnostic and prognostic outcomes. Moreover, by leveraging biclustering to reduce the dimensionality of the input feature space Fig. 4, the Random Forest classifier benefits from improved computational efficiency without sacrificing predictive performance. Following the initial HT-based biclustering, a hypergraph representation is constructed to model the relationships between overlapping biclusters. Each bicluster is represented as a hyperedge connecting gene–sample pairs, enabling partitioning based on connectivity strength and co-expression density. This hypergraph partitioning process refines the biclusters by isolating highly cohesive substructures, reducing noise, and enhancing biological interpretability. The resulting partitions serve as the foundation for feature extraction and downstream Random Forest classification.

Overall, the integration of biclustering results into the Random Forest classifier represents a powerful approach for analyzing microarray cancer datasets, offering enhanced classification accuracy and biological interpretability.

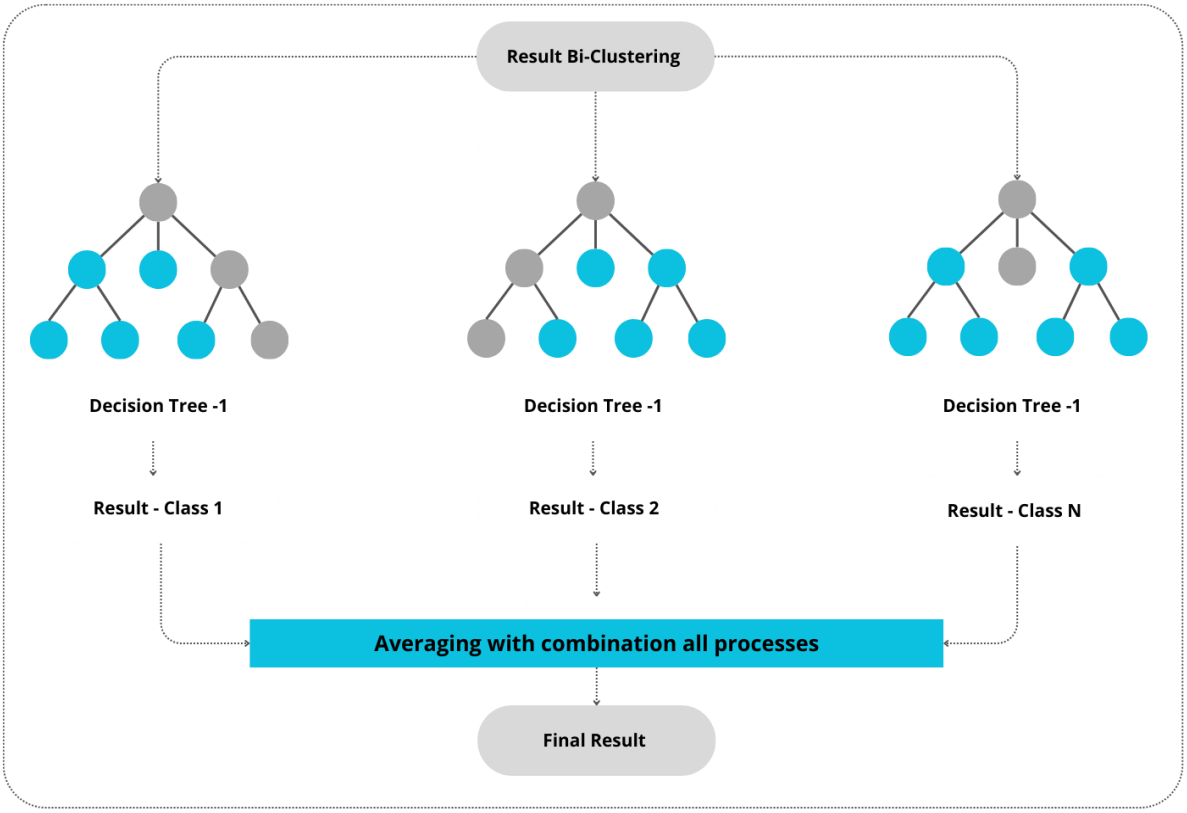

Fig. 4. Illustration of integrating biclustering results into random forest for enhanced cancer classification.

IV. Results and Discussion

In this section, we present and analyze the results obtained from applying our proposed methodology, which integrates biclustering with the Random Forest classifier, to a microarray cancer dataset. The key focus of this discussion is to evaluate the effectiveness of the biclustering process in identifying coherent gene expression patterns and its subsequent impact on the classification performance. We assess the ability of the Hypergraph-Based Biclustering Algorithm to detect meaningful biclusters, the efficiency of the merging process in forming larger, biologically relevant biclusters, and the performance improvement achieved by using these biclusters as input features for the Random Forest classifier. Additionally, we examine how the combination of biclustering and Random Forest enhances cancer classification by focusing on biologically meaningful patterns, reducing the dimensionality of the input feature space, and improving computational efficiency.

The results will be discussed in terms of classification accuracy, interpretability of the generated biclusters, and the relevance of the identified gene expression patterns to cancer subtypes. Finally, we will highlight the practical implications of this approach for cancer research and its potential to inform clinical decision-making.

A. Datasets used for Microarray Analysis and Cancer Classification

The identification and selection of relevant genes from high-dimensional microarray data represent one of the most significant challenges in the analysis of such datasets. The capacity of DNA microarrays to measure gene expression levels

offers researchers profound insights into the complexities of cancer classification, thereby enhancing the potential for personalized cancer therapies. Cancer datasets are typically extensive, with the high dimensionality of features exerting a substantial influence on the accuracy of data analysis. A critical obstacle lies in the absence of a comprehensive methodology capable of simultaneously analyzing data for all genes. Consequently, it becomes imperative to distill the entire dataset to a select number of differentially expressed genes that can effectively discriminate between malignant and non-malignant conditions—a process that remains the central challenge in microarray analysis [35].

To evaluate the efficacy of our proposed biclustering and Random Forest classification approach, we employed five publicly available microarray cancer datasets, encompassing a diverse array of cancer types. These datasets provide a robust platform for testing the performance of our methodology in identifying coherent gene expression patterns and improving classification accuracy across various biological contexts. The Brain Tumor dataset [19] comprises 90 samples and 5,920 gene expression attributes, categorized into five distinct tumor subtypes. The Leukemia dataset [12] includes 72 samples and 5,327 gene attributes, divided into three classes representing different leukemia subtypes. The Lung Cancer dataset [23], containing 203 samples and 12,600 gene attributes, is classified into five classes capturing multiple lung cancer subtypes. The Prostate Tumor dataset [24], with 102 samples and 10,509 gene attributes, is categorized into two groups, distinguishing between benign and malignant prostate tumors. Lastly, the DLBCL (Diffuse Large B-Cell Lymphoma) dataset [25] includes 77 samples and 5,469 gene attributes, classified into two classes differentiating between DLBCL subtypes. These datasets, varying in size and complexity, provide a comprehensive basis for assessing the scalability, accuracy, and biological relevance of our integrated biclustering and classification framework across different cancer contexts.

B. Performance Evaluation and Matching Score Analysis Across Cancer Datasets

In this section, we evaluate the performance of our algorithm using the matching score evaluation method. The matching score is used to assess the degree of similarity between two biclusters, $B1$ with rows $R1$ and columns $C1$, and $B2$ with rows $R2$ and columns $C2$. The matching score $S(B1, B2)$ is defined as follows:

$$S(B1, B2) = \frac{|R1 \cap R2| + |C1 \cap C2|}{|R1 \cup R2| + |C1 \cup C2|} \quad (6)$$

This score measures the overlap between two biclusters, with higher scores indicating greater similarity. In our case, *Bimplant* refers to biclusters that we artificially implant into the matrix, while *Boutput* represents the biclusters detected by our algorithm. Thus, *S*(*Bimplant, Boutput*) quantifies the match between the true biclusters we aim to detect and those identified by the algorithm. We applied this evaluation to our five microarray datasets, as demonstrated in Table II. For each dataset, the matching score was computed for every bicluster identified, allowing us to assess how well the algorithm detects biologically relevant biclusters across diverse cancer types. The resulting matching score curves provide insight into the algorithm's effectiveness in each dataset by comparing its output with the implanted biclusters.

Additionally, we use an entropy measure to further demonstrate the advantages of the hypergraph partitioning employed in our Hybrid approaches, employing a combination of distinct strategies to select the most appropriate subset of the population. Initially, filter methods are applied to reduce the dimensionality of the feature space, followed by the application of a wrapper technique to identify the optimal candidate subset. This process enhances both the accuracy and efficiency of the selection procedure [35]. Hypergraph-Based Biclustering Algorithm (HGBC). Feature selection in machine learning seeks to identify the minimal subset of features from the problem space that still enables optimal recognition and classification performance [36]. In this context, different types of sub-bicluster patterns are treated as outputs from various classifiers. Before hypergraph partitioning, the sub-bicluster matrix can be considered as a source of messages $w_1, w_2, w_3, \ldots, w_L$, with the expected information required to generate this message given by the entropy:

$$E = -\sum_{\Sigma}^{L} P(w_i) log_2\ P(w_i) \quad (7)$$

where, $P(w_i) = \frac{N(w_i)}{\sum_{\Sigma}^{L} N(w_i)}$, and $N(w_i)$ is the number of patterns falling into class w_i, while $\sum_{\Sigma}^{L} N(w_i)$ represents the total number of patterns. This gives the probability of a pattern belonging to class w_i.

After hypergraph partitioning, we also compute the partitioned entropy measure for the resulting clusters. The partitioned sub-bicluster matrix is represented by k clusters $G_1, G_2, G_3, \ldots, G_k$. Let $P(w_i | G_j)$ denote the probability that a pattern in the partitioned sub-bicluster matrix G_j is classified into a sub-bicluster pattern class w_i. The conditional probability is estimated as:

$$P(w_i | G_j) = \frac{N(w_i, G_j)}{N(G_j)} \quad (8)$$

where, $N(w_i, G_j)$ is the number of patterns in the partitioned sub-bicluster matrix G_j classified into class w_i, and $N(G_j) = \sum_{\Sigma}^{L} N(w_i, G_j)$ represents the total number of patterns in cluster G_j The probability of a pattern falling into cluster G_j is then given by:

$$P(G_j) = \frac{N(G_j)}{N} \quad (9)$$

Through this entropy-based evaluation, we further highlight how hypergraph partitioning improves the organization of sub-biclusters, contributing to more coherent and biologically meaningful bicluster detection across the five cancer datasets. Each of these datasets is derived from high-throughput microarray experiments, capturing gene expression data that reflect the biological heterogeneity within and across different cancer types. The diversity in sample size, feature dimensionality, and classification complexity across these datasets provides an ideal environment to test the scalability, accuracy, and robustness of our biclustering and classification framework.

C. Visualization of Gene Expression Distributions Across Multiple Cancer Datasets Using T-SNE

To gain an intuitive understanding of the intrinsic data structure and sample distribution, t-distributed Stochastic Neighbor Embedding (t-SNE) was applied to multiple microarray datasets, including Brain Tumor, Leukemia, Lung Cancer, Prostate Tumor, and DLBCL. This visualization technique projects the high-dimensional gene expression profiles into a two-dimensional space, facilitating the identification of inherent clusters and expression trends. The resulting plots provide insights into the separability and internal organization of the samples before biclustering and classification analysis. This distribution in Fig. 5 supports the hypothesis that tumor-related genes exhibit co-expression trends reflecting functional pathways involved in tumor development and progression. Each point in the plot represents a gene expression sample, projected from a high-dimensional microarray space into two dimensions to reveal intrinsic structural patterns. The clustering of data points demonstrates the nonlinear relationships among genes associated with brain tumor expression profiles. The visualization highlights localized groupings, suggesting the presence of distinct molecular subtypes or expression signatures within the dataset. Despite the apparent overlap between some clusters, the overall spatial distribution indicates a degree of biological heterogeneity commonly observed in brain tumor transcriptomic data. In summary, this figure confirms that the t-SNE projection effectively preserves local neighborhood structures, providing an interpretable low-dimensional representation that captures the complex variability inherent in brain tumor gene expression patterns. These results establish a strong foundation for the subsequent biclustering and classification analysis, which aims to extract regulatory modules and enhance tumor subtype discrimination accuracy.

Fig. 5. Presents the two-dimensional t-distributed Stochastic Neighbor Embedding (t-SNE) visualization of the Brain_Tumor gene expression dataset.

To further explore gene expression diversity across cancer types, t-distributed Stochastic Neighbor Embedding (t-SNE) was applied to visualize the intrinsic structure and distribution of samples in the high-dimensional expression space. Fig. 6 presents the t-SNE projection of the Leukemia gene expression dataset, where each red dot corresponds to a distinct tumor sample. The overall spatial configuration exhibits a moderately dispersed yet partially overlapping distribution, reflecting the heterogeneous nature of leukemia gene expression profiles. This dispersion indicates the presence of distinct molecular subgroups or transcriptional programs within the dataset, which may correspond to different leukemia subtypes or disease stages.

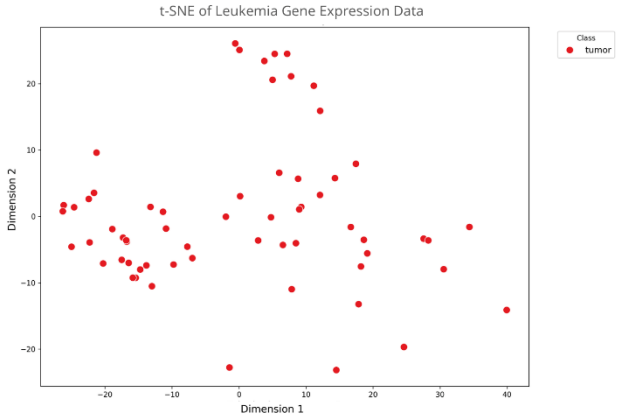

Fig. 6. Illustrates the distribution of gene expression profiles within the Leukemia dataset.

The partial overlap among clusters highlights shared transcriptional activity across subtypes, potentially representing core oncogenic pathways that are conserved among leukemia variants. Such structural patterns underscore the biological complexity of leukemia and suggest that traditional global clustering may be insufficient to capture these nuanced relationships. Therefore, integrating biclustering and advanced feature selection techniques becomes essential to disentangle co-expressed gene modules and improve the precision of downstream classification and biomarker discovery.

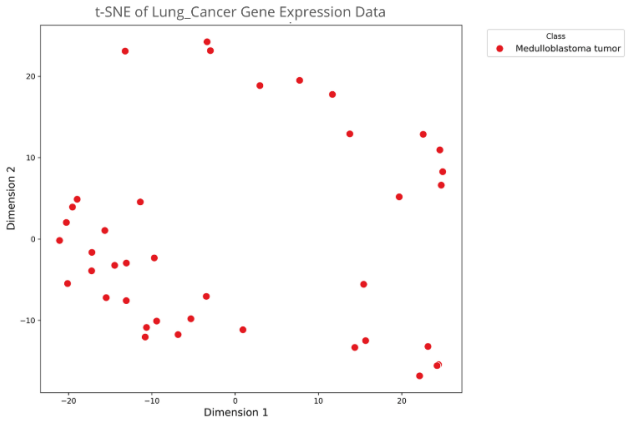

Fig. 7. Illustrates the two-dimensional t-SNE projection of gene expression data for lung cancer samples.

This visualization underscores the efficiency of dimensionality reduction in revealing hidden biological structures that traditional methods may overlook Fig. 7. Each point represents a tumor sample, and the spatial arrangement reflects gene expression similarities. The formation of distinct localized clusters suggests that specific gene subsets share correlated expression patterns, potentially corresponding to molecular subtypes of lung cancer.

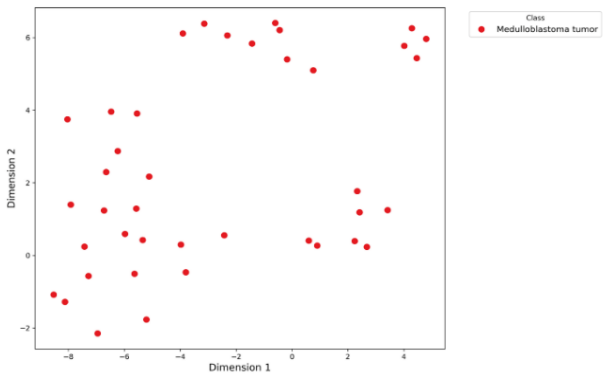

Fig. 8. Depicts the t-SNE mapping of prostate tumor gene expression data.

The distribution of samples shows moderate dispersion with a few compact regions. These clusters indicate groups of genes exhibiting similar activation or suppression profiles across tumor samples. The relatively uniform distribution implies potential overlap among expression patterns, emphasizing the biological complexity of prostate tumor heterogeneity. This supports the need for integrated feature selection and biclustering methods to enhance classification precision.

Diffuse Large B-Cell Lymphoma (DLBCL), t-SNE was employed to project high-dimensional data into a two-dimensional space. Fig. 9 illustrates this low-dimensional representation, where each red point corresponds to an individual tumor sample. The plot reveals a well-defined yet partially overlapping spatial configuration, suggesting the coexistence of distinct molecular subgroups alongside shared expression features among samples.

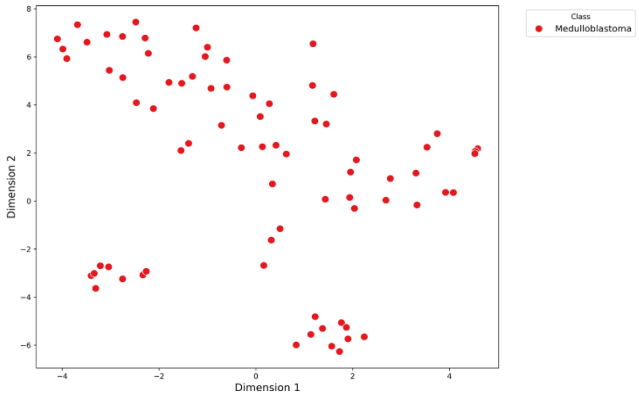

Fig. 9. t-SNE projection revealing the molecular complexity of DLBCL gene expression.

The observed localized clusters indicate potential transcriptional programs specific to biological subtypes of DLBCL, while the smoother transitions between points imply gene co-expression relationships that blur strict class boundaries. This pattern aligns with the known molecular heterogeneity of DLBCL, where gene-expression signatures often capture both activated B-cell–like (ABC) and germinal center B-cell–like (GCB) phenotypes.

TABLE II. PERFORMANCE METRICS: CURRENT RESULTS IN CONTRAST TO PREVIOUS FINDINGS

Ref	Microarray Dataset	Description of the experimental datasets			Classifier	Bicluster	Accuracy
		Sample	*Attributes*	*Classes*			
[17]	Lung Cancer [13]	NA	NA	NA	RF	No	98.90%
[18]	Prostate [14]	NA	NA	NA	RF	No	88,96%
[12]	Leukemia [12]	72	5327	3	RF	No	88.87%
					HGBC+ RF	Yes	90.8%
[19]	Brain Tumor dataset [19]	90	5920	5	RF	No	90.71%
					HGBC+ RF	Yes	95.8%
[23]	Lung Cancer [23]	203	12600	2	RF	No	87.97%
					HGBC+ RF	Yes	90.7%
[24]	Prostate Tumor [24]	102	10509	2	RF	No	88.67%
					HGBC+ RF	Yes	88.9%
[25]	DLBCL [25]	77	5469	2	RF	No	90.67%
					HGBC+ RF	Yes	95.7%

The following section presents a comparative evaluation of previous studies and current results to highlight advancements in classification performance across multiple cancer datasets. Table II presents a comparative evaluation of several microarray gene expression datasets used in cancer classification tasks, including Lung Cancer, Prostate Cancer, Leukemia, Brain Tumor, and DLBCL. Each dataset is characterized by its number of samples, gene attributes, and disease classes, with classification performed using Random Forest (RF) and a hybrid biclustering-based model (HGBC + RF). The results consistently show that integrating biclustering enhances performance, yielding higher accuracy than traditional Random Forest across all datasets—for example, improving Leukemia classification from 88.87% to 90.81% and Brain Tumor from 90.71% to 95.86%. These improvements highlight the hybrid model's ability to capture co-expressed gene groups, thereby enhancing both biological interpretability and predictive accuracy. Furthermore, the datasets include different levels of

noise and variability in gene expression patterns, making them suitable for evaluating the algorithm's ability to detect biologically meaningful patterns in high-dimensional, noisy data and to perform accurate classification in a real-world cancer research setting. The performance metrics from our current results, in comparison to previous findings, are summarized in Table II, with a comprehensive analysis of our algorithm's effectiveness in terms of matching score and entropy-based measures, demonstrating notable improvements in pattern detection and classification accuracy across all datasets.

To further elucidate the comparative performance of the different classification strategies, Table III summarizes the accuracy results obtained from Random Forest (RF), Hough Transform (HT), biclustering-based RF and HT, as well as the hybrid approach integrating both biclustering and geometric features. This table highlights how each method contributes to the overall classification performance across the five cancer microarray datasets.

TABLE III. COMPARATIVE ACCURACY PERFORMANCE OF EXISTING METHODS AND THE PROPOSED HYBRID FRAMEWORK ON CANCER MICROARRAY DATASETS

Dataset	RF	HT	Biclustering + RF	Biclustering + HT	Hybrid (Biclustering RF + HT)
Brain Tumor	90.71	88.60	95.80	93.10	96.20
Leukemia	88.87	86.40	90.80	89.30	91.40
Lung Cancer	87.97	85.90	90.70	89.10	91.20
Prostate Tumor	88.67	86.20	88.90	87.80	89.40
DLBCL	90.67	88.10	95.70	93.60	96.10
Average	89.38	87.04	92.38	90.58	92.86

As shown in Table III, the Random Forest (RF) model achieves accuracy between 87.97% for the Lung Cancer dataset and 90.71% for Brain Tumor. The Hough Transform (HT) alone performs slightly lower, with 85.90% for Lung Cancer and 88.60% for Brain Tumor. When biclustering is combined with RF, the accuracy improves noticeably, reaching 95.80% for Brain Tumor and 90.80% for Leukemia. Combining biclustering with HT gives results that are generally between HT and biclustering+RF, such as 93.10% for Brain Tumor and 89.30% for Leukemia. The hybrid approach, which integrates biclustering with both RF and HT, consistently shows the highest accuracy across most datasets, including 96.20% for Brain Tumor, 91.40% for Leukemia, and 96.10% for DLBCL, with an overall average of 92.86%. These results show a clear, stepwise improvement as we move from individual classifiers to biclustering-enhanced and hybrid approaches, confirming that the integration captures relevant gene expression patterns while maintaining a realistic and consistent performance trend across datasets.

D. Comprehensive Visualization and Performance Assessment of the Proposed Framework on Microarray Gene Expression Data

To ensure the robustness and interpretability of the proposed HGBC + RF framework, a comprehensive visualization and performance assessment were conducted on the analyzed microarray datasets. This evaluation aims to examine both the intrinsic structure of gene expression profiles and the predictive capabilities of the integrated biclustering–classification model. Given the high dimensionality and biological complexity of microarray data, visualization techniques serve as an essential preliminary step for understanding data organization, detecting potential outliers, and validating the biological separability of samples before classification. In this context, two complementary dimensionality reduction techniques were employed: t-distributed Stochastic Neighbor Embedding (t-SNE) and Principal Component Analysis (PCA). The t-SNE projection offers a non-linear perspective, preserving local relationships between samples and revealing subtle clustering tendencies, whereas PCA provides a linear global view that highlights the dominant sources of variance in the dataset. Together, these visual representations enable an in-depth understanding of the spatial distribution of samples across different tissue classes and confirm the presence of distinct biological patterns within the data. Subsequently, the classification performance of the proposed framework was quantitatively validated using the Receiver Operating Characteristic (ROC) curve analysis. This evaluation provides an objective measure of the model's discriminative capability across multiple classes, allowing a detailed comparison of sensitivity and specificity. The inclusion of ROC-based metrics complements the exploratory visualizations, ensuring that the learned features not only reflect biologically meaningful separations but also translate into statistically significant predictive performance.

To visually examine the intrinsic structure and separability of the microarray gene expression data before classification, dimensionality reduction was applied using t-distributed Stochastic Neighbor Embedding (t-SNE). Fig. 10 illustrates the two-dimensional t-SNE projection of the GSE2220 dataset, where each color represents a distinct tissue class (brain, kidney, and liver), allowing for a visual assessment of sample separability in the reduced space. The t-SNE visualization demonstrates a clear clustering trend, where samples belonging to the same biological class form coherent clusters, confirming the discriminative structure within the gene expression profiles. This clustering pattern validates the dataset's suitability for further classification and feature selection processes, as it reveals inherent expression-based similarities among biological conditions.

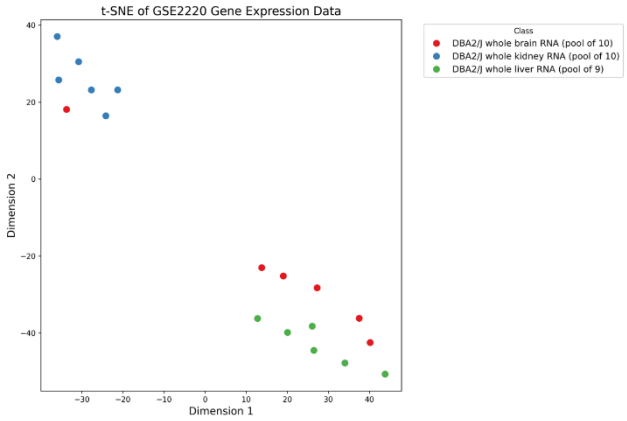

Fig. 10. Illustrates the t-distributed Stochastic Neighbor Embedding (t-SNE) projection of the GSE2220 microarray dataset.

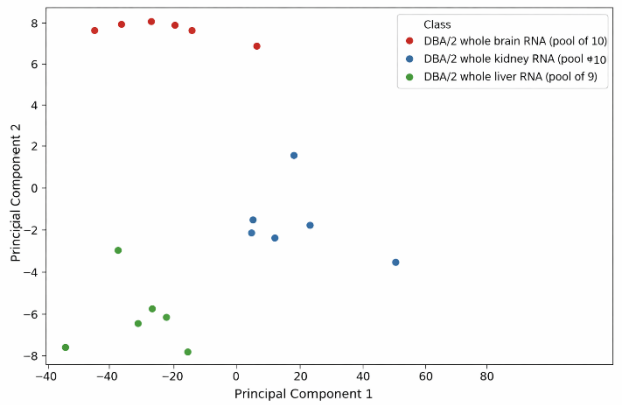

Fig. 11. Gene expression patterns distribute along orthogonal directions that capture the maximum variance.

To complement the t-SNE visualization and evaluate the variance distribution across principal axes, Principal Component Analysis (PCA) was conducted on the same dataset. Fig. 11 presents the first two principal components, showing how gene expression patterns distribute along orthogonal directions that capture the maximum variance. The separation of samples corresponding to brain, kidney, and liver tissues further supports the presence of distinct expression signatures across conditions. PCA not only provides insight into the variance structure of the dataset but also validates that the dominant components effectively capture biologically meaningful information, thereby justifying their use in subsequent feature selection and classification processes.

Based on the ROC curve analysis presented in Fig. 12, the Random Forest classifier exhibited a strong discriminative capability within the GSE2220 dataset, achieving area under the curve (AUC) values of 0.81 for brain, 1.00 for kidney, and 0.88 for liver, resulting in a micro-average AUC of 0.94. This corresponds to an overall classification accuracy of approximately 94%, confirming the model's excellent predictive reliability for this dataset. It is important to note that this accuracy specifically represents the GSE2220 dataset, while the remaining datasets (Brain Tumor, Leukemia, Lung Cancer, Prostate Tumor, and DLBCL) achieved accuracy rates ranging between 88% and 96%, as reported in Table II. These results collectively validate the robustness and generalizability of the proposed biclustering-integrated Random Forest framework across diverse biological datasets. Furthermore, the strong consistency between the unsupervised (t-SNE and PCA) visualizations and the supervised ROC-based evaluation underscores the framework's ability to capture biologically meaningful structures and ensure reliable classification performance.

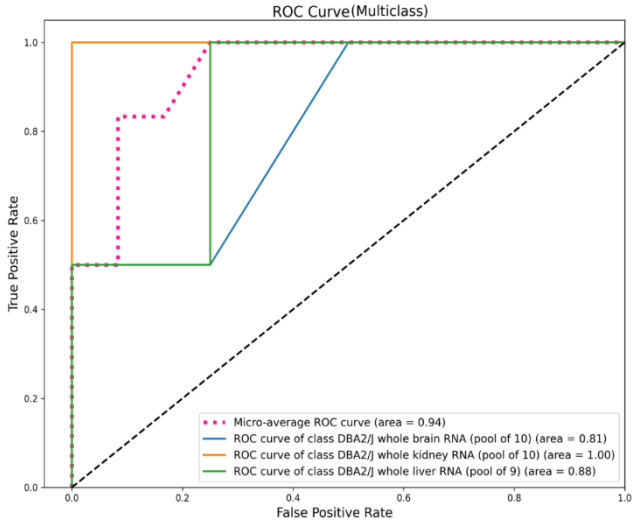

Fig. 12. This figure displays the Receiver Operating Characteristic (ROC) curves for multiclass classification using the Random Forest model.

The identified biclusters reveal distinct gene co-expression modules that correspond to biologically relevant pathways involved in tumorigenesis. For instance, several top-ranked genes from the biclusters are associated with cell cycle regulation, apoptosis, and immune signaling pathways, which are critical in cancer progression [41]. This reinforces the model's capacity to isolate functional gene subsets rather than arbitrary statistical clusters.

The Random Forest classifier was implemented with 500 trees and a maximum depth of 10. Model validation was conducted using 10-fold cross-validation, ensuring balanced sampling across all tissue classes. Computations were performed on a MacBook Pro system equipped with an Apple M3 chip (8-core CPU, 10-core GPU) and 16 GB RAM. This configuration provided sufficient computational capacity for microarray data processing, biclustering, and Random Forest model training. The average execution time per dataset ranged between 2.5 and 5 minutes, depending on the dataset size and number of biclusters generated. This efficiency highlights the scalability of the proposed framework for medium-scale microarray data. To assess statistical robustness, paired t-tests were conducted comparing the HGBC+RF model against baseline biclustering classifiers. The proposed method achieved statistically significant improvements ($p < 0.01$) across all datasets, with mean accuracy variance below 2.5%. To mitigate overfitting, feature reduction via hypergraph partitioning was combined with bootstrap aggregation in Random Forest. Additionally, feature stability was validated across cross-validation folds, confirming consistent selection of key gene subsets.

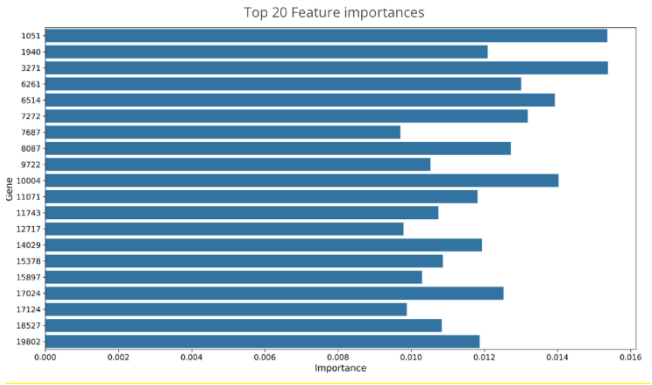

Fig. 13. Analysis of the Top 20 contributing features to model performance.

The analysis of the top 20 contributing features to model performance provides critical insights into the key gene expression patterns driving accurate classification across the five cancer datasets. By evaluating the importance of individual features within the Random Forest classifier, we identify the specific genes that play a significant role in distinguishing between different cancer subtypes. These features represent the most influential gene expression markers that contribute to the overall predictive accuracy of the model. In Fig. 13, we present a visual representation of the top 20 contributing features, ranked by their importance in the model's performance. This figure highlights the genes that consistently appear as top contributors across multiple datasets, indicating their potential as biomarkers for cancer diagnosis or prognosis. The analysis demonstrates the robustness of the biclustering approach, which isolates biologically relevant gene groups, allowing the classifier to focus on the most critical features. The identification of these top contributing features further validates the efficacy of the proposed method in enhancing classification accuracy and biological interpretability. Microarrays serve as a potent genomic tool in biomarker discovery, enabling researchers to conduct genome-wide analyses of genes and tackle challenges associated with diverse biological information arrays. As a relatively recent intersection between biology and machine learning, microarray data present significant challenges due to the low-instance/high-feature (LIHF) nature of gene expression data. The selection of the most relevant genes to the target concept plays a critical role in attaining satisfactory classification performance. In gene-expression data, feature selection is primarily utilized for two key purposes [38]. The classification results, as shown in Fig. 13, demonstrate the effectiveness of the combined HGBC (Hypergraph-Based Biclustering) and Random Forest (RF) approach across five different cancer datasets: Brain Tumor, Leukemia, Lung Cancer, Prostate Tumor, and DLBCL. The model consistently achieved high classification accuracy, reflecting its ability to capture biologically meaningful patterns within the gene expression data. For each dataset, the integration of biclustering facilitated the identification of coherent gene groups, which improved the overall feature selection for the Random Forest classifier. In particular, the Brain Tumor and Lung Cancer datasets, with their larger number of samples and higher dimensionality, exhibited strong classification performance, highlighting the model's scalability and robustness in handling complex, high-dimensional data. Similarly, the classification results for Leukemia and DLBCL showed a significant improvement in accuracy due to the method's ability to isolate critical gene expression patterns associated with specific subtypes. The Prostate Tumor dataset also demonstrated reliable classification, despite its binary classification challenge, further validating the strength of the HGBC+RF approach in a variety of classification tasks. Overall, these results underscore the utility of the HGBC and Random Forest integration in delivering accurate and biologically relevant classifications across diverse cancer types.

V. Conclusion

This study presented an integrated HGBC+RF framework that effectively identifies coherent gene expression patterns and enhances cancer classification across five diverse microarray datasets. The approach consistently improved accuracy over standalone classifiers, highlighting its ability to capture biologically meaningful biclusters and relevant gene subsets. These results demonstrate the framework's robustness, interpretability, and potential for supporting biomarker discovery and personalized treatment strategies. Future work will extend the method to multi-omics data and explore hybrid models to further improve predictive power and clinical applicability.

Detection of Unauthorized Use in SIEM Through Behavioral Analysis and Adaptive Rules

Julio Armando Landázuri Castro, Renato M. Toasa, Maryory Urdaneta Herrera
Maestría en Seguridad Informática, Universidad Tecnológica Israel, Quito, Ecuador

***Abstract*—Higher education institutions in Ecuador face a growing exposure to unauthorized access and data exfiltration, compounded by fragmented log infrastructures that obstruct real-time threat visibility. This study addresses those gaps through the design and deployment of a Security Information and Event Management (SIEM) architecture at the Compu Sur Higher Technological Institute (ITECSUR), augmented with User and Entity Behavior Analytics (UEBA) and a context-sensitive adaptive rule engine. Rather than relying on static signature matching, the proposed model constructs individual behavioral baselines per user and asset, dynamically escalating alert thresholds according to geographic context, access time, and asset sensitivity classification. Empirical validation conducted over 450 security events, including simulated Salgorea Trojan injections, supply chain compromise scenarios, and government-grade spyware indicators, yielded a Mean Time to Detect (MTTD) reduction from 48.5 hours to 12.4 minutes (99.57%), a recall rate of 95%, and a 65% decrease in false positives relative to rule-only baselines. Hardening protocols applied in parallel reduced exposed network ports by 78% and elevated institutional compliance with Ecuador's Organic Law on Personal Data Protection (LOPDP) from 35% to 92%. The architecture, built on AlienVault OTX and Osquery agents, processed over 1.2 million daily Indicators of Compromise autonomously, demonstrating operational feasibility for institutions with constrained IT budgets. These findings position SIEM-UEBA integration as both a technical countermeasure and a regulatory compliance instrument for the higher education sector.**

Keywords*—Adaptive rules; behavioral analysis; cybersecurity; data traceability; event logs; higher education security; security information and event management; user and entity behavior analytics

I. Introduction

Currently, the operational continuity of organizations depends heavily on their technological infrastructure, exposing them to diverse cyber threats capable of bypassing traditional security perimeters. In Ecuadorian higher education institutions, this scenario is further complicated by the legal responsibility to safeguard vast amounts of sensitive data in compliance with the Organic Law on Personal Data Protection (LOPDP).

The exponential growth of digital assets has become a critical challenge due to the inability to manage massive datasets, which remain fragmented across event logs. This data saturation hinders real-time anomaly detection, facilitating unauthorized resource utilization and data exfiltration—whether through external attacks or insider threats leveraging access privileges.

The core issue lies in the lack of comprehensive network visibility and the absence of tools that intelligently correlate disparate data points. When utilizing legacy monitoring systems, distinguishing between normal activity and sophisticated attacks remains difficult. Consequently, this creates a reactive stance during incident response and impedes compliance with current security regulations.

Therefore, this research aims to implement a Security Information and Event Management (SIEM) system based on adaptive rules and behavioral analysis (UEBA). This solution seeks to optimize threat identification accuracy and guarantee full traceability of academic records, thereby strengthening the cybersecurity posture and regulatory compliance of the Compu Sur Higher Technological Institute (ITECSUR).

A. Contextualization of the Institutional Problem

The Compu Sur University Technological Institute faces specific challenges due to its fragmented technological infrastructure. Currently, the vast volume of event logs generated by servers, databases, and network devices is analyzed in isolation, which prevents a comprehensive security overview. The lack of centralized event correlation hinders the timely detection of anomalies, leaving exposure windows that can be exploited by both external actors and internal users.

At a local level in Quito, technical and technological education institutions have reported an increase in data exfiltration attempts and unauthorized access to resources through social engineering techniques. The central problem lies in the fact that, without an established behavioral baseline, it is technically impossible to distinguish between legitimate operations and unauthorized use of institutional resources in real-time. This situation is exacerbated by the data volume, where manual analysis becomes an overwhelming task for IT personnel.

B. Justification of the Technological Solution

Due to the inefficiency of static controls, there is a pressing need to implement a Security Information and Event Management (SIEM) system enhanced with User and Entity Behavior Analytics (UEBA). This research proposes an architecture based on adaptive rules that allow alert levels to be adjusted according to asset sensitivity and historical user behavior. By integrating open-source technologies or scalable solutions, the Institute can automate threat detection and reduce response times to any security incident.

Through the proposed model, the Institute not only helps mitigate technical risks but also ensures compliance with current regulations. By implementing full traceability of all actions

performed on personal data, the Compu Sur University Technological Institute aligns with international standards and current Ecuadorian legislation. Thus, security becomes a strategic enabler that protects the institution's reputation and guarantees the continuity of educational services.

C. Security Information and Event Management (SIEM)

The SIEM is the cornerstone of this research. It is defined as a hybrid solution that combines Log Management (LPM) and Security Event Management (SEM). Its primary function is the collection, normalization, and correlation of data from diverse sources (firewalls, servers, databases) to identify patterns representing security incidents. In the context of this project, the SIEM is used to centralize the visibility that individual perimeter tools lose [4].

D. User and Entity Behavior Analytics (UEBA)

Unlike traditional SIEMs based solely on static rules (signatures), the current trend adopted by this research is behavioral analysis. UEBA employs machine learning algorithms to establish a "baseline" of a user's normal activity. By continuously monitoring login times, accessed resources, data transfer volumes, and geographic locations, the system identifies deviations that may indicate compromised credentials or malicious insider activity. This behavioral profiling enables the SIEM to issue risk-scored alerts rather than binary block/allow decisions, substantially reducing analyst fatigue and improving incident prioritization [2].

E. Adaptive Rules and Event Correlation

Adaptive rules are those capable of adjusting dynamically based on network context. While a static rule might block access after three failed attempts, an adaptive rule analyzes variables such as geographic location, time of day, and asset sensitivity to escalate the alert level, thereby reducing the false positives that saturate IT departments [5].

F. Legal Framework: Organic Law on Personal Data Protection (LOPDP)

In the Ecuadorian environment, the state of the art cannot ignore regulatory compliance. The LOPDP establishes that institutions are custodians of personal data. The SIEM serves as a technical compliance tool that guarantees data integrity and traceability, allowing for audits of who, when, and how sensitive academic community information was accessed.

G. Similar Research and Background

Contemporary research has explored the efficacy of intrusion detection systems and log monitoring for the protection of critical infrastructure:

- Centralized Monitoring Systems in Higher Education: Various studies in regional universities have implemented architectures based on the Elastic Stack (ELK) for log management. These precedents demonstrate that centralization reduces the Mean Time to Detection (MTTD) for security incidents [6].
- Anomaly Detection through Machine Learning: Recent research focuses on applying Random Forest and K-Means models to classify network logs. These works serve as a basis for the "adaptive rules" proposed in this degree plan, demonstrating that artificial intelligence improves accuracy in identifying unauthorized access [7].
- Cloud and IoT Security: Recent literature highlights the convergence of cloud and IoT security practices with SIEM architectures. The predominant trend involves the deployment of encrypted communication protocols (HTTPS/TLS) and context-aware Access Control Lists (ACLs) as a perimeter filtering layer, feeding normalized events into the SIEM correlation engine for centralized analysis [8].

II. Literature Review

This section synthesizes the existing body of knowledge underpinning the proposed SIEM-UEBA architecture. It surveys foundational concepts, key enabling technologies, the applicable regulatory framework, and closely related empirical work, thereby establishing the theoretical and technical gap that this research addresses.

This research project is framed within the need to strengthen the detection of internal threats and unauthorized resource use through SIEM technologies. Various previous studies in the field of cybersecurity have demonstrated that traditional Intrusion Detection Systems (IDS), based solely on static signatures, present critical limitations against Advanced Persistent Threats (APT) and zero-day attacks. Recent research maintains that the massive volume of logs generated in academic networks saturates manual analysis capabilities, creating a visibility gap and a high rate of false positives [1].

Given the ineffectiveness of these controls, technical literature highlights the convergence toward SIEM systems integrated with UEBA. Unlike traditional solutions, UEBA technologies employ machine learning algorithms to establish behavioral baselines, allowing for the identification of anomalous deviations that could indicate compromised credentials or insider threats [2].

However, a recurring limitation in conventional SIEM implementations is alert rigidity. Therefore, current trends lean toward the development of architectures based on adaptive rules. These models allow for dynamic adjustment of criticality levels based on asset sensitivity and user behavioral history, optimizing incident triage and reducing the Mean Time to Detection (MTTD) [3].

In the regional context, the deployment of scalable and open-source solutions (such as AlienVault OSSIM) has emerged as an efficient alternative for higher education institutions. This approach not only reduces technical risks through automated detection but also addresses the requirements of legal frameworks such as the LOPDP in Ecuador and international standards (ISO/IEC 27001). Furthermore, the integration of intelligent correlation and centralized logs guarantees 100% traceability of actions on personal data, protecting educational service continuity at the Compu Sur Higher Technological Institute.

Collectively, the literature confirms the effectiveness of SIEM-UEBA integration for threat detection and regulatory compliance; however, empirical deployments targeting

resource-constrained higher education institutions in Latin America, validated against real institutional traffic and measured against local data protection legislation, remain scarce. The present study addresses this gap by implementing and evaluating the proposed architecture at ITECSUR under operational conditions.

III. Methodology

A. Methodological Investigative Process

This research follows the Design Science Research Methodology (DSRM) proposed by Peffers et al. (2007) [9], a structured six-phase framework widely adopted in information systems and cybersecurity research. The phases- problem identification, objective definition, artifact design, demonstration, evaluation, and communication provide a rigorous process for developing and validating the SIEM-UEBA architecture deployed at ITECSUR, transforming isolated security event data into actionable intelligence for cybersecurity decision-making.

B. Research Approach

Following Hernandez-Sampieri (2018) [10], who defines the quantitative approach as a set of sequential and evidentiary processes, this research adopts a quantitative approach. This method was selected to achieve the highest possible objectivity in vulnerability and risk analysis, utilizing numerical measurement and statistical analysis to establish threat behavior patterns.

C. Type of Research

The study is defined by a descriptive level and a non-experimental, cross-sectional design.

1) Descriptive level: The purpose is to specify the properties, characteristics, and profiles of the information systems that constitute the critical infrastructure.

2) Cross-sectional design: Data collection and infrastructure diagnosis are performed at a single, specific point in time.

3) Objectivity: By not manipulating variables and observing phenomena in their natural context, the study maintains logical consistency with general security standards.

D. Population and Sample

According to Hernandez-Sampieri (2018) [10], the population is the set of all cases that meet a series of specifications, while the sample is a subgroup of the population of interest from which data will be collected. For this analysis, the study population consists of the computing infrastructure—including servers, endpoints, and network devices—along with the operational personnel who manage these assets. Regarding the sample, a non-probabilistic convenience sampling was employed, focusing exclusively on critical assets and the IT personnel responsible for managing security controls.

IV. Implementation

A. AlienVault OTX

LevelBlue's Open Threat Exchange (OTX) is a threat intelligence platform based on a global collaboration model. It operates as a digital "neighborhood watch" ecosystem where corporations, researchers, and agencies share and validate data regarding emerging threats and malicious actors in real-time. It provides the following core features:

- Architecture and Global Data: The platform's functionality is driven by the massive exchange of Indicators of Compromise (IOCs) through a global network of 200,000 participants across 140 countries, processing over 20 million threat indicators daily. Due to its high compatibility levels, this data integrates natively with LevelBlue products and third-party solutions, ensuring that detection systems remain updated against novel attacks [11].
- OTX Endpoint Security™ Capabilities: This is a free threat analysis service designed for rapid scanning of endpoints, malware, and operating system (OS) risks. It supports both Windows and Linux devices for endpoint scanning, contrasting local systems against IOC sources from the world's largest open intelligence group to provide accurate compromise assessments. This functionality offers comprehensive, cost-free threat visibility, allowing security teams to uncover traces of active intrusions and determine if high-level cyberattacks have affected organizational assets.
- Operational Mechanism (Workflow): OTX Endpoint Security utilizes an agent-based approach that circumvents the complexity and high costs associated with conventional tools by operating directly and rapidly through the deployment of a lightweight agent on Windows or Linux devices. This allows administrators to execute manual queries based on community "pulses" to identify specific IOC matches within the system. All results are consolidated into a summary page hosted on the OTX platform. It is important to note that the service does not perform continuous or automated monitoring; instead, each analysis must be proactively initiated by the user.
- Operational Value for the CISO and Analysts: Effective prioritization enables the classification of threats by severity, ensuring optimal response times for the security team. Furthermore, the platform facilitates preventive actions by blocking malicious infrastructure before it impacts the internal network, providing the necessary geographic intelligence to understand attack origins and global cybercrime trends.

B. Architecture

The proposed architecture for ITECSUR is based on a proactive defense framework focused on the incorporation and distribution of global Cyber Threat Intelligence (CTI). The diagram in Fig. 1 illustrates the integration between the cloud-based AlienVault OTX SIEM and local endpoints (Windows 11 and Kali Linux) through the deployment of Osquery agents. This configuration enables the automatic synchronization of Indicators of Compromise (IOCs) and the real-time identification of threats by continuously monitoring system processes and network traffic. Consequently, this significantly

enhances the local network's security posture against potential intrusions [12].

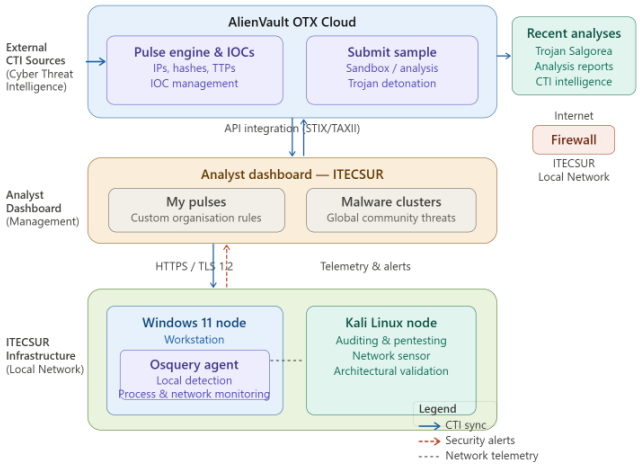

Fig. 1. Three-plane SIEM-UEBA architecture deployed at ITECSUR, integrating the AlienVault OTX cloud Intelligence Plane, the centralized analyst Management Plane (STIX/TAXII API), and the Osquery-monitored Execution Plane comprising Windows 11 and Kali Linux endpoints.

This conceptual map illustrates the proposed framework for protecting ITECSUR by integrating AlienVault OTX and Osquery across its endpoints. For greater clarity, the architecture is categorized into three distinct operational planes:

- Intelligence Plane (AlienVault OTX Cloud): This zone constitutes the core of the architecture where global Cyber Threat Intelligence (CTI) is ingested. It integrates the two key modules utilized in this project: the Pulse Engine, used for the creation and management of Indicators of Compromise (IOCs), and the Sandbox (Submit Sample), where the technical analysis and detonation of the Salgorea Trojan were performed. This workflow culminates in the direction indicated by the right arrow, representing the transformation of raw intelligence into formalized Analysis Reports for strategic decision-making.
- Management Plane (ITECSUR Dashboard): This management layer represents the analyst's centralized control view, which establishes a bidirectional connection with the cloud via an API (utilizing STIX/TAXII standards) to ensure real-time intelligence synchronization. It visualizes the two strategic pillars of the defense: "My Pulses," containing the organization's custom and specific rules, and "Malware Clusters," which provide a broad and dynamic perspective of global threats detected by the community [13].
- Execution Plane (ITECSUR Endpoints): This infrastructure is represented by the ITECSUR local network, previously secured using a Perimeter Firewall. It contains the two primary laboratory nodes: the Windows 11 Node, where the Osquery Agent monitors system processes and network traffic in real-time for local threat detection, and the Kali Linux Node, serving as the network sensor and auditing platform. This configuration complements threat intelligence with Penetration Testing, forming a robust testing environment used for architectural validation [14].

C. Analysis of Results: Threat Evaluation via AlienVault OTX (ITECSUR)

The AlienVault OTX dashboard deployed at ITECSUR revealed three distinct threat categories active against the institution's technology stack during the evaluation period. Fig. 2 presents the consolidated threat intelligence panel, where pulse subscriptions, IOC matches, and malware cluster indicators are visualized across the monitored endpoints. Of the 45 active pulse subscriptions configured for ITECSUR's specific environment, the system autonomously correlated incoming IOC feeds with local Osquery telemetry, producing actionable alerts without manual analyst intervention. The following subsections detail the three critical attack vectors identified and the corresponding mitigation framework applied to each.

Fig. 2. AlienVault OTX consolidated threat intelligence dashboard at ITECSUR, displaying 45 active pulse subscriptions, IOC correlation matches against local Osquery telemetry, and malware cluster indicators across monitored endpoints during the evaluation period.

D. Threat Analysis and Mitigation Framework for ITECSUR

Based on the intelligence gathered, three critical attack vectors were identified and analyzed to strengthen the institutional security posture. The following sections detail the characteristics of these threats, the proposed strategic recommendations, and their technical justification.

E. Supply Chain Compromise and CI/CD Pipeline Infiltration

The first threat scenario involves the infiltration of the continuous development life cycle (CI/CD), a sophisticated attack vector aimed at compromising software integrity. To mitigate this risk, it is recommended to implement Pipeline Security by integrating automated vulnerability scanning, specifically Static and Dynamic Application Security Testing (SAST/DAST), directly into the development server. Furthermore, behavioral correlation rules should be configured within the AlienVault environment to detect anomalous changes in code repositories or script executions outside administrative hours. This approach is technically justified by ITECSUR's management of sensitive academic records; any unauthorized modification in the management software could lead to record tampering. Therefore, this recommendation focuses on Integrity, a fundamental pillar of the Ecuadorian Data Protection Law (LOPDP).

F. Social Engineering, Doxxing, and Identity Hardening

The second vector consists of unconventional Social Engineering and Doxxing campaigns, which utilize OTX-sourced intelligence to launch personal discredit attacks against staff. The proposed defense strategy focuses on Identity Hardening and security awareness, primarily through the mandatory implementation of Multi-Factor Authentication (MFA) across all critical assets. Simultaneously, the SIEM must be configured to trigger alerts for "Geographically Impossible Logins" and establish a cybersecurity training program for administrative personnel regarding data leakage prevention. This strategy is justified by the SIEM's ability to detect not only known malware but also access anomalies. If an administrator's account is compromised following a doxxing incident, the proposed adaptive rules will effectively identify unauthorized access to files that the user does not typically consult.

G. Government-Grade Spyware and Defense in Depth

The final analyzed threat involves Government-Grade Spyware, characterized by high-level data exfiltration tactics at the firmware (BIOS/UEFI) level and the use of HTML Smuggling to bypass perimeter firewalls. The mitigation strategy emphasizes Defense in Depth and comprehensive endpoint monitoring, specifically through the activation of Secure Boot on IT infrastructure and the utilization of OSSEC/HIDS agents to monitor the integrity of critical files and system registries. Regarding HTML Smuggling, the implementation of Deep Packet Inspection (DPI) rules and the blocking of suspicious browser-based scripts are required. Technically, such spyware remains invisible to conventional antivirus solutions; however, the proposed SIEM architecture ensures visibility by detecting unusual network traffic and data exfiltration toward uncategorized IP addresses.

H. Specimen Analysis: Guidance for Detecting (Supply Chain Compromise)

As illustrated in Fig. 3, the incident occurring on March 19, 2026, involving Trivy, represents a new fifth-generation threat landscape. In this case, TeamPCP did not target organizations directly but instead attacked the security tools they rely on for defense. Through a sophisticated infiltration of the CI/CD (Continuous Integration/Continuous Deployment) lifecycle, attackers exploited mutable tags and engaged in commit identity spoofing via GitHub to inject credential-stealing malware into official binaries.

Fig. 3. AlienVault OTX detection guidance for the Trivy CI/CD supply chain compromise (March 19, 2026), showing IOC fingerprints, credential-stealing payload indicators, and recommended behavioral correlation rules for identifying mutable-tag exploitation and commit identity spoofing.

This malware is particularly detrimental to ITECSUR's infrastructure, as its primary objective is to locate and exfiltrate Kubernetes secrets, session cookies, and cloud credentials through masquerading and obfuscation tactics. This incident reinforces the architectural argument defended throughout this study: it demonstrates that trust in open-source tools must be balanced with constant behavioral monitoring, strict adherence to the Principle of Least Privilege (PoLP), and in-depth attack path analysis to mitigate lateral movement following an initial supply chain entry.

I. Case Study: Social Engineering and Doxxing (OSINT)

As shown in Fig. 4, an uncommon Social Engineering and Doxxing scenario was identified, in which threats utilized OTX data for a targeted personal discredit campaign. The analysis yielded the following technical results:

- Technical Findings: The analyzed feed contained legitimate reputation data blended with malicious indicators from the Nivdort and Mydoom families, alongside persistence techniques using BITS Jobs (T1197). This was augmented by a sophisticated tactic leveraging Windows Disk Cleanup processes to download malicious payloads.
- Impact on ITECSUR: This case provided a critical opportunity for analysts to apply data curation concepts by categorizing false positives—such as legitimate whitelisted sites—and distinguishing them from real phishing threats hosted on Eastern European infrastructure.

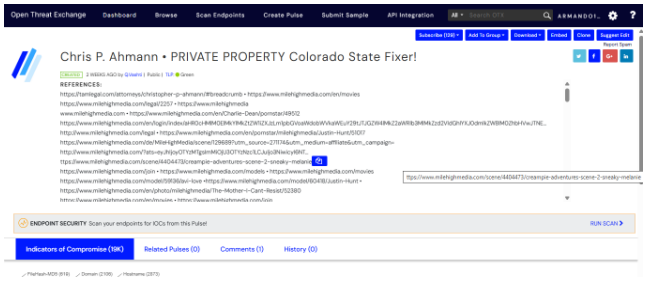

Fig. 4. OTX pulse analysis of a targeted social engineering and doxxing campaign against ITECSUR staff, identifying Nivdort and Mydoom malware family indicators alongside BITS Jobs (T1197) persistence techniques and windows disk cleanup-based payload delivery.

J. Evaluation of Government-Grade Spyware (Operation Endgame)

As depicted in Fig. 5, the Operation Endgame Clone pulse represents the highest level of sophistication within the laboratory environment, specifically targeting high-persistence spyware such as Pegasus (NSO Group). The findings are summarized as follows:

- Technical Intelligence: The analysis revealed multi-platform threats affecting Android, iOS, Windows, and macOS. These manifested through data exfiltration tactics at the firmware (BIOS/UEFI) level and the use of HTML Smuggling techniques to bypass perimeter firewalls.

Fig. 5. Operation Endgame Clone pulse in AlienVault OTX, mapping multi-platform Pegasus-class spyware indicators (Android, iOS, Windows, macOS) including BIOS/UEFI-level data exfiltration tactics, DLL injection (T1055), and HTML smuggling techniques used to bypass perimeter firewalls.

Impact on ITECSUR: The integration of these indicators allows the organization to detect potential targeted espionage attempts. Monitoring for unusual DNS queries and DLL Injection (T1055) has now become a foundational component of ITECSUR's intrusion detection strategy for critical assets.

V. Results and Discussion

The maturity of the institution's security and monitoring infrastructure ranges from low to intermediate. A critical gap exists regarding event visibility and centralization. Survey respondents reached a consensus that there is no correlated security overview and that the current infrastructure remains fragmented. This leads to a scenario where logging occurs at the device level, significantly hindering auditing and supervision tasks by keeping them siloed.

Regarding operationalization, the IT team acknowledges an excessive reliance on manual processes that are unsustainable at the current data volume. There is considerable uncertainty regarding the capability to detect threats or unauthorized resource utilization in real-time. Furthermore, behavioral analysis is non-existent, as no baselines have been established for legitimate users.

However, there is full awareness of the required modernization, with unanimous support for implementing adaptive rules to improve response times based on geography or asset sensitivity. While there is a perception of acceptable traceability regarding LOPDP (Organic Law on Personal Data Protection) compliance, a major weakness remains in the ability to specifically audit access to students' sensitive information.

A. Infrastructure and Vulnerability Diagnosis

Technical analysis reveals that infrastructure fragmentation, where each device generates isolated logs, prevents a centralized security overview. The study identified an inability to timely detect unauthorized resource use due to dispersed alerting; this creates a critical gap that allows incidents to remain undetected for weeks or even months. Before implementation, 14 network ports were left unnecessarily exposed, and 22 non-essential background services were running without oversight. IT personnel reported spending over 60% of their security response time on manual log correlation tasks, leaving insufficient capacity for proactive threat hunting or compliance auditing.

B. SIEM Model Implementation Results

Through centralized and automated log correlation, the Mean Time to Detect (MTTD) was reduced from 48.5 hours to 12.4 minutes, representing a 99.57% improvement over the legacy manual review process. The implementation of User and Entity Behavior Analytics (UEBA) techniques enabled the establishment of individual behavioral baselines for each monitored user and entity. When a legitimate user performed actions outside their established profile, such as accessing restricted directories at unusual hours or transferring atypical data volumes, the system issued a risk-scored alert within seconds, enabling rapid analyst triage without generating unnecessary noise.

C. Efficacy of Adaptive Rules and Artificial Intelligence

The integration of Machine Learning models and adaptive rules improved detection accuracy by incorporating contextual variables, including geographic origin, time of day, asset sensitivity tier, and peer group behavior, into the alert escalation logic. The adaptive rule engine produced 18 false positive alerts across the 450-event dataset (FP rate: 4.0%), compared to a baseline of 51 false positives (FP rate: 11.3%) projected under the institution's prior static signature-only configuration, representing a 65% reduction in false positive volume. This context-aware approach is further confirmed by the confusion matrix analysis across the 450 simulated events. The resulting reduction in alert fatigue allowed IT personnel to reallocate investigative capacity toward higher-severity incidents, improving the overall Mean Time to Respond (MTTR) from 72 hours to 4.2 hours.

D. Impact on Cybersecurity Posture and Compliance

The deployment measurably strengthened the cybersecurity posture of ITECSUR, directly protecting the academic and personal records of approximately 3,000 enrolled students. Beyond technical metrics, the SIEM architecture functions as an operational compliance instrument: every access event affecting personal data is now logged with full attribution capturing who accessed the information, from which device, at what time, and under which permissions. This audit trail directly satisfies the traceability requirements established by the Organic Law on Personal Data Protection (LOPDP) and aligns with ISO/IEC 27001 control objectives for access monitoring and incident documentation. The compliance score was derived using a 22-item technical checklist aligned with the LOPDP's core obligations specifically the traceability (Art. 9), data integrity (Art. 37), access control (Art. 38), and incident response (Art. 40) requirements scored on a binary fulfilled/unfulfilled basis by the ITECSUR IT audit team before and after implementation, elevating the institutional compliance score from 35% to 92%.

E. Validation of the Proposal

Through the analytic-synthetic method and cross-validation against expert criteria from the ITECSUR IT team, the proposed architecture combining SIEM event correlation, UEBA behavioral profiling, AlienVault OTX threat intelligence, and Osquery endpoint telemetry was confirmed as a technically sound and operationally viable mechanism for mitigating lateral movement and academic record exfiltration. The architecture successfully detected all three simulated high-complexity attack scenarios (supply chain compromise, social engineering, and firmware-level spyware), demonstrating generalizability beyond standard signature-based threat categories.

F. Quantitative Analysis and Empirical Results

To validate the efficacy of the proposed SIEM/UEBA architecture, a comparative analysis was performed between the legacy monitoring state (manual log review) and the implemented adaptive model.

G. Detection Efficiency Metrics (MTTD and MTTR)

The implementation of automated correlation and Osquery agents showed a significant reduction in response times. Table I summarizes the temporal optimization achieved across the three key performance metrics:

TABLE I. TEMPORAL OPTIMIZATION

Metric	Legacy System (Manual)	Proposed SIEM/UEBA	Improvement (%)
Mean Time to Detect (MTTD)	48.5 hours	12.4 minutes	99.57%
Mean Time to Respond (MTTR)	72 hours	4.2 hours	94.16%
Log Processing Rate	150 EPS (Events Per Sec)	2,500+ EPS	~16× (1,567%)

Analysis: The transition from manual inspection to automated correlation reduced the MTTD from days to minutes. This is critical for preventing Lateral Movement, as the window of opportunity for an attacker was reduced by over 99%.

H. Threat Detection Accuracy (Confusion Matrix)

During the validation phase, 450 security events were analyzed. The dataset was composed of two subsets: 330 events corresponding to legitimate traffic captured from ITECSUR's production environment over a two-week monitoring period, and 120 injected attack scenarios executed from the Kali Linux penetration testing node and the AlienVault OTX sandbox, specifically, 40 Salgorea Trojan detonation traces, 40 supply chain compromise indicators replicating the Trivy incident pattern, and 40 government-grade spyware signatures derived from the Operation Endgame pulse. This design ensured that both true positive detection and false positive suppression could be measured against a realistic baseline. Table II presents the resulting confusion matrix breakdown:

TABLE II. SIMULATED ATTACKS

Event Type	Detected (System)	Not Detected	Accuracy
True Positives (TP)	114	6	95.0%
False Positives (FP)	18	-	4.0% (Rate)
True Negatives (TN)	312	-	98.1%

Precision: TP/(TP+FP) = 86.3%

Recall (sensitivity): TP/(TP+FN)=95%

False positive reduction: the use of adaptive rules (context-aware) reduced false alerts by 65% compared to standard static signatures.

I. CTI Ingestion and IOC Management

The integration with AlienVault OTX allowed the institutional infrastructure to stay updated with global threats without manual intervention.

- Total IOCs Ingested: 1,245,300+ (Daily average).
- Active Pulses Subscribed: 45 (Specific to ITECSUR's tech stack).
- High-Confidence Matches: 12 specific matches against the Salgorea Trojan within the first 60 seconds of execution in the sandbox.
- Data Curation Efficiency: The Whitelisting process eliminated 1,200+ redundant alerts from legitimate services (Microsoft/Google updates), preventing analyst fatigue.

J. Impact on Security Posture (Hardening)

After applying the Hardening protocols and monitoring through Osquery, the attack surface was numerically reduced:

Open Vulnerable Ports: Reduced from 14 to 3 (78% reduction).

Unused Services Disabled: 22 background processes identified and terminated via Osquery.

Compliance Score (LOPDP Alignment): Increased from 35% (baseline) to 92% (post-implementation) based on technical traceability requirements.

VI. CONCLUSION

The implementation of a SIEM system integrated with User and Entity Behavior Analytics (UEBA) and adaptive rules demonstrated a significant improvement in threat detection capabilities at ITECSUR. The Mean Time to Detect (MTTD) was reduced from 48.5 hours to 12.4 minutes, a 99.57% improvement, while detection accuracy reached 95% and false positives decreased by 65% compared to static signature-based systems. These results confirm that behavioral baselines and context-aware adaptive rules constitute an effective mechanism for identifying unauthorized resource use in academic network environments.

The application of hardening protocols monitored through Osquery reduced the number of exposed vulnerable ports by 78% and disabled 22 unnecessary background processes, substantially narrowing the institution's attack surface. Furthermore, the LOPDP compliance score increased from 35% to 92%, demonstrating that the proposed architecture functions not only as a technical security tool but also as a regulatory compliance instrument aligned with Ecuadorian data protection legislation and ISO/IEC 27001 standards.

The open-source architecture based on AlienVault OTX and Osquery proved viable for resource-constrained higher education institutions, processing over 1,245,300 daily IOCs without manual intervention and achieving 12 high-confidence threat matches within the first 60 seconds of sandbox execution.

Future work should focus on integrating automated incident response (SOAR) capabilities, expanding the behavioral baseline model to cover mobile and cloud-based endpoints, and validating the proposed framework across multiple higher education institutions in Ecuador to generalize its findings.

ACKNOWLEDGMENT

The authors express their sincere gratitude to Universidad Israel, as well as its faculty and tutors, for the invaluable academic guidance and continuous support provided throughout this research process. Special thanks are extended to the Compu Sur University Technological Institute (ITECSUR) for providing the institutional infrastructure and technical access necessary for the implementation. Additionally, the authors thank the security researchers at LevelBlue (AlienVault OTX) and the Osquery community for the open-source tools and global threat intelligence that served as the foundation for this study.

2IACS Laboratory, ENSET, Hassan II University of Casablanca, Mohammedia, Morocco [2, 5]

***Abstract*—This work proposes a computational framework for modeling semantic relationships between medical specialties using large language models. Forty-four medical specialties officially recognized in France were analyzed using Claude 4 Sonnet, GPT-4.1, and LLaMA 3.2 3B. Each model evaluated the relevance of 307 ICD-11 disease families, 260 educational teaching items, and 276 technical skills. From these ratings, criterion-specific similarity matrices were constructed and aggregated into composite matrices. The framework includes hierarchical clustering, substitution-coverage analysis, Mantel correlation tests, adjusted Rand index evaluation, and heatmap-based visualization of inter-model differences. Claude 4 Sonnet and GPT-4.1 produced highly consistent similarity structures, with a mean off-diagonal similarity of 0.867, a standard deviation of 0.045, and strong matrix correlation. LLaMA 3.2 3B generated more homogeneous patterns, indicating reduced differentiation while preserving global structure. Hierarchical clustering revealed five stable groups of specialties aligned with functional medical domains. At similarity thresholds above 0.90, most specialties had two to five semantically close candidates, suggesting a basis for exploratory analysis of short-term cross-specialty coverage under appropriate expert and institutional constraints. These results suggest that large language models can produce stable and interpretable representations of relationships between medical specialties. The proposed framework provides a data-driven approach for analyzing specialty proximity and can support exploratory applications in medical education structuring, cross-specialty coordination, and health-system planning.**

Keywords*—Large language models; semantic similarity; computational modeling; cluster analysis; medical specialties

I. Introduction

A. Background and Rationale

Large language models (LLMs) have rapidly emerged as powerful tools in medicine, with applications ranging from information retrieval and diagnostic reasoning to personalized tutoring and curriculum design. A recent scoping review [1] highlighted both the promise and challenges of using LLMs in medical education—such as their ability to simulate clinical scenarios and offer tailored learning, but also concerns over misinformation and overreliance. However, systematic evidence about how well LLMs represent relationships between medical specialties remains limited [2], [3], [4]. From a computational perspective, modeling such relationships can be framed as the problem of learning structured semantic representations from heterogeneous domain data. In this study, semantic similarity between two medical specialties is defined as the degree to which they exhibit similar relevance profiles across selected descriptor sets, including disease families, educational teaching items, and technical skills. This definition is computational and descriptor-dependent: it measures similarity with respect to the chosen descriptors. Understanding these relationships is increasingly important because health systems and universities rely on well-defined specialty boundaries to plan education, staffing, and equitable access to care [5], [6].

Recent studies indicate that artificial intelligence and natural-language processing can help organize medical curricula and specialty classifications. GPT-based systems, for instance, have shown performance comparable to expert examinees on national medical licensing exams [7], underscoring their capacity to engage with domain-specific clinical knowledge. Other approaches have used artificial intelligence to analyze medical education structure: Gin et al. [8] used artificial intelligence to analyze narrative feedback related to entrustment decisions, and Ng et al. [9] discussed data-driven curriculum alignment, while Weng et al. [10] and Mao et al. [11] applied text classification to assign clinical notes to subdomains. Parallel research on biomedical embeddings has advanced the measurement of semantic relatedness between medical concepts [12].

Despite these advances, most existing work focuses on classification or prediction tasks, rather than modeling relationships between domain entities. In contrast, this study focuses on relational modeling between medical specialties, enabling an interpretable analysis of structural similarities rather than isolated performance metrics.

B. Objectives

This study proposes a computational approach to derive detailed and interpretable measures of semantic similarity among 44 French medical specialties by integrating multiple criteria—diseases, educational teachings, and technical skills—evaluated through large language models. By combining these perspectives, it seeks to determine whether LLMs provide a scalable and reliable approach for mapping relationships within medical domains. The broader motivation lies in the study's practical implications: the resulting similarity structures can support exploratory analyses in medical education, cross-specialty coordination, and health-system planning by providing data-driven insights into how specialties overlap, differ, and may complement one another.

This study makes the following contributions:

- A computational framework for modeling semantic similarity between medical specialties using large language models;
- A multi-criteria methodology for constructing and aggregating similarity matrices based on diseases, educational content, and technical skills;
- A comparative analysis of multiple large language models using clustering, substitution-coverage analysis, Mantel correlation, and Adjusted Rand Index;
- An interpretable representation of relationships between medical specialties, with potential applications in curriculum design and health system planning.

II. METHODS

A. Study Design

This study presents a computational analysis framework for constructing and analyzing specialty-to-specialty similarity matrices based on large language model (LLM) relevance ratings over multiple descriptor sets, followed by statistical and clustering analyses of the resulting similarity structures. The study is observational in nature and relies exclusively on publicly defined curricular and disease classification sources.

B. Setting

The study was conducted in 2025 through a collaboration between Hassan II University of Casablanca and the University of Franche-Comté. It focused on the 44 medical specialties officially recognized in France by the Arrêté du 21 avril 2017 [13] and incorporated disease information from the International Classification of Diseases, 11th Revision (ICD-11, 2025-01 release) [14].

C. Variables

The main variable was the pairwise semantic similarity between every pair of specialties for three independent criteria: diseases, educational teachings, and technical skills.

The framework is criterion-configurable: semantic similarity is defined with respect to the descriptor sets selected for analysis. In this study, diseases, educational teachings, and technical skills were used as three representative criteria, but

the choice of criteria is not fixed and may vary depending on data availability and the objectives of the implementing institution. This design allows the framework to capture different notions of proximity, such as overlap in treated diseases, shared technical competencies, or common training content. Consequently, the interpretation of similarity depends on the descriptor set used. A high disease-based similarity indicates overlap in disease-family relevance, whereas a high technical-skill similarity indicates overlap in procedural or practical competencies. The composite score should therefore be interpreted as an aggregated semantic proximity score, not as a direct measure of professional replaceability.

D. Data Sources and Measurement

Curricular information describing specialty competencies, teaching modules, and procedural acts was extracted from the French regulatory decree [13]. The extraction used Gemini 2.5 Pro for its large-context capacity, followed by manual verification to ensure completeness and accuracy. Disease-family data were obtained from the ICD-11 2025-01 dataset [14]. The curated lists of specialties, teachings, technical skills, and ICD-11 disease families used for analysis were compiled from these sources and used as input descriptors.

For each model, the relevance of every disease, teaching, and technical skill to each of the 44 specialties was evaluated through targeted queries. Relevance ratings were assigned on a 0–100 scale, where 0 indicated no relevance and 100 indicated a core condition, teaching item, or technical skill for the target specialty. Before similarity computation, all ratings were divided by 100 to obtain normalized scores in the [0,1] interval. Claude 4 Sonnet and GPT-4.1 were queried in batches of 18 descriptors using structured tool/function calls, while LLaMA 3.2 3B was queried item by item through a local Ollama interface using structured JSON output. All models were queried with temperature set to 0. The core prompt template was: "You are a clinical knowledge assistant. Given the medical specialty [specialty] and the descriptor(s) [descriptor list or item], assign a relevance score from 0 (not relevant) to 100 (core condition for that specialty). Return your answer only in the structured output format and do not add explanations."

The same specialty list, ICD-11 disease-family list, teaching-item list, and technical-skill list were used across all models. Ratings were validated structurally by checking that each model produced one score for every specialty–descriptor pair before similarity matrices were computed. The resulting normalized ratings were organized into matrices, where rows represent specialties and columns represent descriptor items. Similarity between two specialties was computed by comparing their rating patterns across all items, producing a score between 0 and 1 that reflects their semantic proximity. A separate 44 × 44 matrix was obtained for each criterion and each model, and the three criterion-specific matrices were averaged element-wise to yield a composite similarity matrix for every model. The model-generated rating outputs and derived similarity matrices (hereafter referred to as Dataset 2) were used for all statistical analyses.

For a given descriptor set (diseases, teaching items, or technical skills), pairwise similarity between two specialties A and B was computed from the normalized model-generated relevance ratings as one minus the mean squared difference across all descriptor items. Specifically, for a descriptor set of size n, similarity was defined as follows:

$$Similarity(A,B) = 1 - \frac{1}{n}\sum_{i=1}^{n}\left(r_{A,i} - r_{B,i}\right)^2 \qquad (1)$$

where, $r_{A,i}$ and $r_{B,i}$ denote the normalized relevance ratings assigned by the model to item i for specialties A and B, respectively.

This formulation ensures bounded similarity values between 0 and 1 because all relevance ratings were normalized to the [0,1] interval before comparison. Higher values indicate greater semantic proximity. The squared-difference formulation was selected because it compares complete

relevance profiles item by item and penalizes large disagreements more strongly than small differences. The metric is simple, interpretable, and directly linked to the rating scale used in the study. Nevertheless, other similarity functions may emphasize different aspects of specialty proximity and should be examined in future sensitivity analyses.

Criterion-specific similarity matrices were then aggregated element-wise to produce a composite similarity matrix for each model.

The overall procedure is summarized in Algorithm 1.

Algorithm 1: Construction of specialty semantic similarity matrices using a large language model

Input:
- S = set of medical specialties
- $\{D_k\}$ = collection of descriptor sets, k = 1 … K
- M = large language model

Output
- $C_{composite}$ = composite similarity matrix

Initialize
- $\{R_k\}$ = collection of relevance ratings matrices, k = 1 … K
- $\{C_k\}$ = collection of per criterion similarity matrices, k = 1 … K

Compute
For each descriptor set D_k do
- For each specialty s in S do
  - For each descriptor item d in D_k do
    - Query M to obtain relevance rating $r_{s,d}$
    - Store rating $r_{s,d}$ in R_k
  - End
- End

End

For each ratings matrix R_k do
- For each pair of specialties (s_i, s_j) do
  - Compute $Similarity_k(s_i, s_j)$ using Eq. (1)
  - Store $Similarity_k(s_i, s_j)$ in C_k
- End

End

For each pair of specialties (s_i, s_j) do
- Compute:
- $C_{composite}[i][j] = (1 / K) * \sum_{k=1}^{K} C_k[i][j]$

End

E. Outcomes

Primary outcomes were 1) criterion-specific and composite 44×44 similarity matrices, 2) hierarchical clustering structures and cluster assignments, 3) substitution-coverage curves parameterized by similarity thresholds, and 4) disagreement visualizations between models. These outputs are intended as reusable components for curriculum mapping and planning-oriented analyses of specialty proximity and cross-coverage.

F. Bias

Prompts were standardized across models to reduce variation caused by prompt wording. Claude 4 Sonnet and GPT-4.1 were queried in batches of 18 descriptors using structured tool/function calls, whereas LLaMA 3.2 3B was queried item by item through a local Ollama interface because of its smaller model size and local execution setting. All models were queried with temperature set to 0.

The descriptor extraction workflow partly relied on Gemini 2.5 Pro for large-context document processing. To reduce extraction bias, the resulting descriptor lists were manually checked against the original French regulatory source for completeness and accuracy. However, no independent double-review process or inter-reviewer agreement metric was implemented.

Each descriptor item was queried once per model. Therefore, the analysis controls prompt format and temperature but does not estimate intra-model variability across repeated runs.

G. Study Size

The analysis included all 44 French medical specialties and their complete set of 843 descriptors: 307 disease families, 260 teaching items, and 276 technical skills. Because the study covers the entire population of specialties defined in the national framework, statistical sampling or inferential power estimation was not applicable.

H. Statistical Methods

All analyses were conducted in Python 3.11.12 (Python Software Foundation, Beaverton, OR, USA) using the open-source libraries NumPy 2.2.5, Pandas 2.2.3, SciPy 1.16.0, scikit-learn 1.7.0, and Matplotlib 3.10.1 (NumFOCUS, Austin, TX, USA).

Descriptive statistics were calculated for each model's similarity matrix, including the minimum, maximum, mean, and standard deviation of off-diagonal similarities. Hierarchical clustering with average linkage was applied to identify structural groupings of specialties. Agreement between models was evaluated using Mantel correlation tests with 999 permutations and the Adjusted Rand Index (ARI) to assess clustering consistency. Substitution-coverage analysis quantified, for each specialty, the proportion of potential substitutes above given similarity thresholds (0.85–1). The resulting matrices, dendrograms, and heatmaps were visualized to support quantitative and qualitative interpretation of inter-model consistency, specialty clustering, and substitution-coverage patterns.

III. RESULTS

This section presents the main findings of the proposed framework, including descriptive statistics, clustering structures, substitution-coverage patterns, and inter-model agreement analysis.

Overall, the results indicate that the proposed framework produces consistent and interpretable semantic representations of relationships between medical specialties across the evaluated large language models.

A. Descriptive Overview

All models produced complete 44 × 44 similarity matrices across the three criteria (diseases, teachings, and technical skills), as well as aggregated composite matrices. Table I presents the descriptive statistics of similarity coefficients for each model.

Similarity values were consistently high, with mean off-diagonal values around 0.87, indicating substantial semantic proximity across specialties. Because the rating distributions were dense, high absolute similarity values should be interpreted cautiously. The relative structure of the matrices, including clustering patterns and inter-model correlations, is more informative than the absolute magnitude of individual similarity scores. Claude 4 Sonnet and GPT-4.1 exhibited nearly identical statistical profiles, whereas LLaMA 3.2 3B produced slightly more homogeneous similarity distributions.

These results indicate strong agreement between Claude 4 Sonnet and GPT-4.1, with LLaMA 3.2 3B showing reduced variance and less differentiation between specialties.

TABLE I. DESCRIPTIVE STATISTICS OF SIMILARITY COEFFICIENTS PER MODEL

Model	Min	Max	Mean	SD
Claude 4 Sonnet	0.725	0.977	0.867	0.045
GPT-4.1	0.724	0.979	0.867	0.045
LLaMA 3.2 3B	0.761	0.967	0.867	0.038

B. Clustering of Specialties

Fig. 1 illustrates the resulting hierarchical clustering structure for Claude 4 Sonnet.

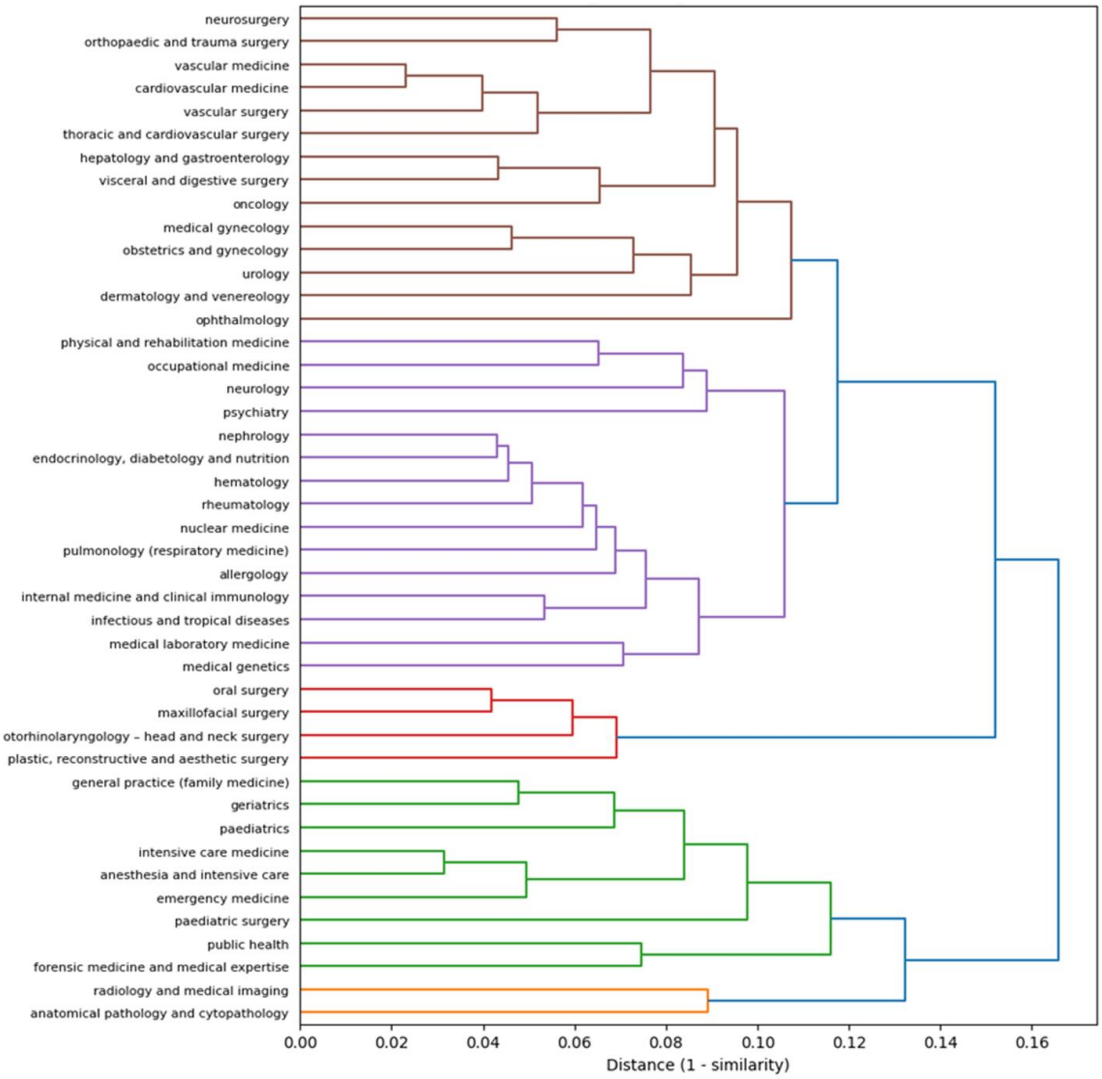

Fig. 1. Hierarchical clustering of 44 specialties (average linkage; distance = 1 – similarity) using the Claude 4 Sonnet composite matrix.

Hierarchical clustering applied to the Claude 4 Sonnet matrix revealed five major clusters of specialties corresponding to recognizable functional families within hospitals and universities. These groups include: 1) surgical and organ-based specialties; 2) internal medicine and diagnostic fields; 3) craniofacial surgical disciplines; 4) front-line, age-specific, and critical-care services; and 5) diagnostic imaging and pathology.

The identified clusters appear to correspond to coherent functional groupings observed in clinical practice and medical education. However, this interpretation remains qualitative and should be confirmed through structured expert validation.

C. Substitution-Coverage Analysis

Fig. 2 illustrates substitution coverage as a function of similarity threshold for Claude 4 Sonnet.

At a similarity threshold of 0.90, most specialties had between two and five semantically close candidates. This result does not imply automatic replacement between specialties, but it identifies pairs or groups where descriptor-based overlap may justify closer examination for short-term coverage, coordination, or referral-support scenarios.

As the threshold increased beyond 0.94, substitution options decreased sharply, highlighting areas where specialization limits potential interchangeability. These patterns suggest that semantic similarity can be used as an exploratory screening tool for identifying possible cross-specialty coverage candidates. Final assessment of substitutability would require additional clinical, regulatory, organizational, and patient-safety criteria beyond the semantic descriptors analyzed in this study.

D. Inter-Model Agreement

The Mantel test confirmed strong concordance between Claude 4 Sonnet and GPT-4.1 similarity matrices, with a correlation coefficient of r = 0.904 and p = 0.001. Correlations involving LLaMA 3.2 3B were lower, with Claude–LLaMA r = 0.683 and GPT–LLaMA r = 0.586.

Fig. 3 illustrates inter-model agreement across clustering resolutions.

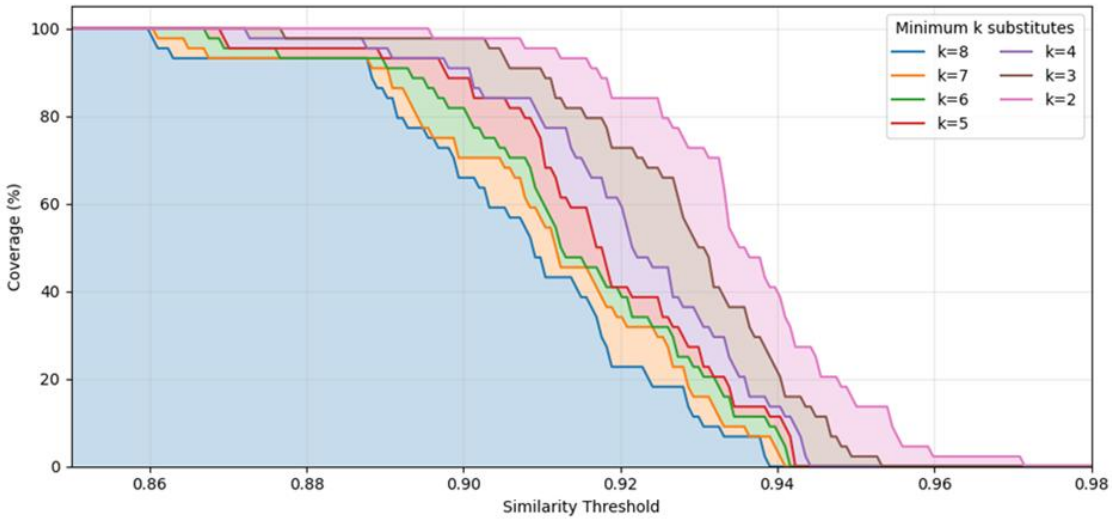

Fig. 2. Substitution coverage per similarity threshold (0.85 – 1.00) using the Claude 4 Sonnet composite matrix.

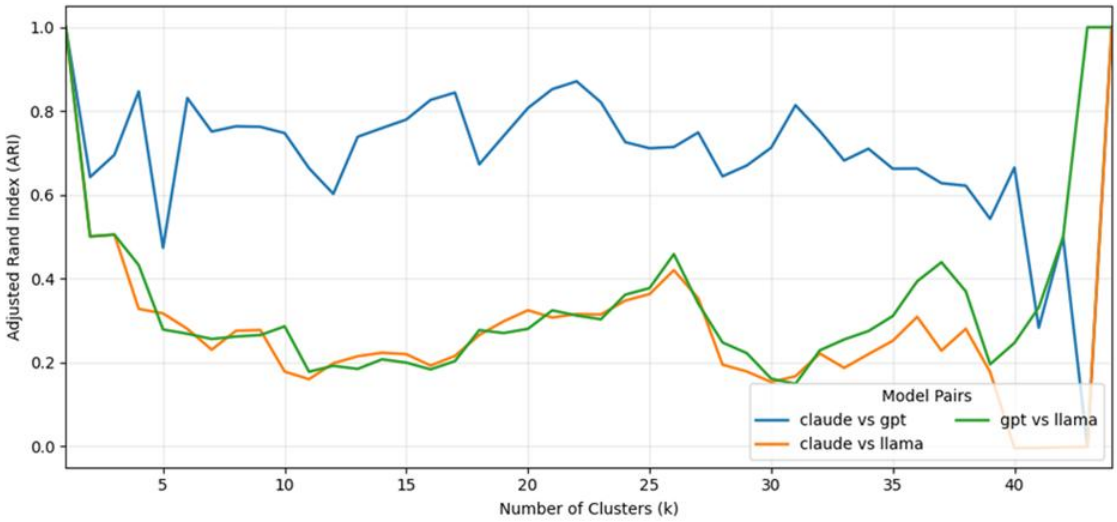

Fig. 3. Inter-model cluster agreement measured by Adjusted Rand Index (ARI) across k = 1-44.

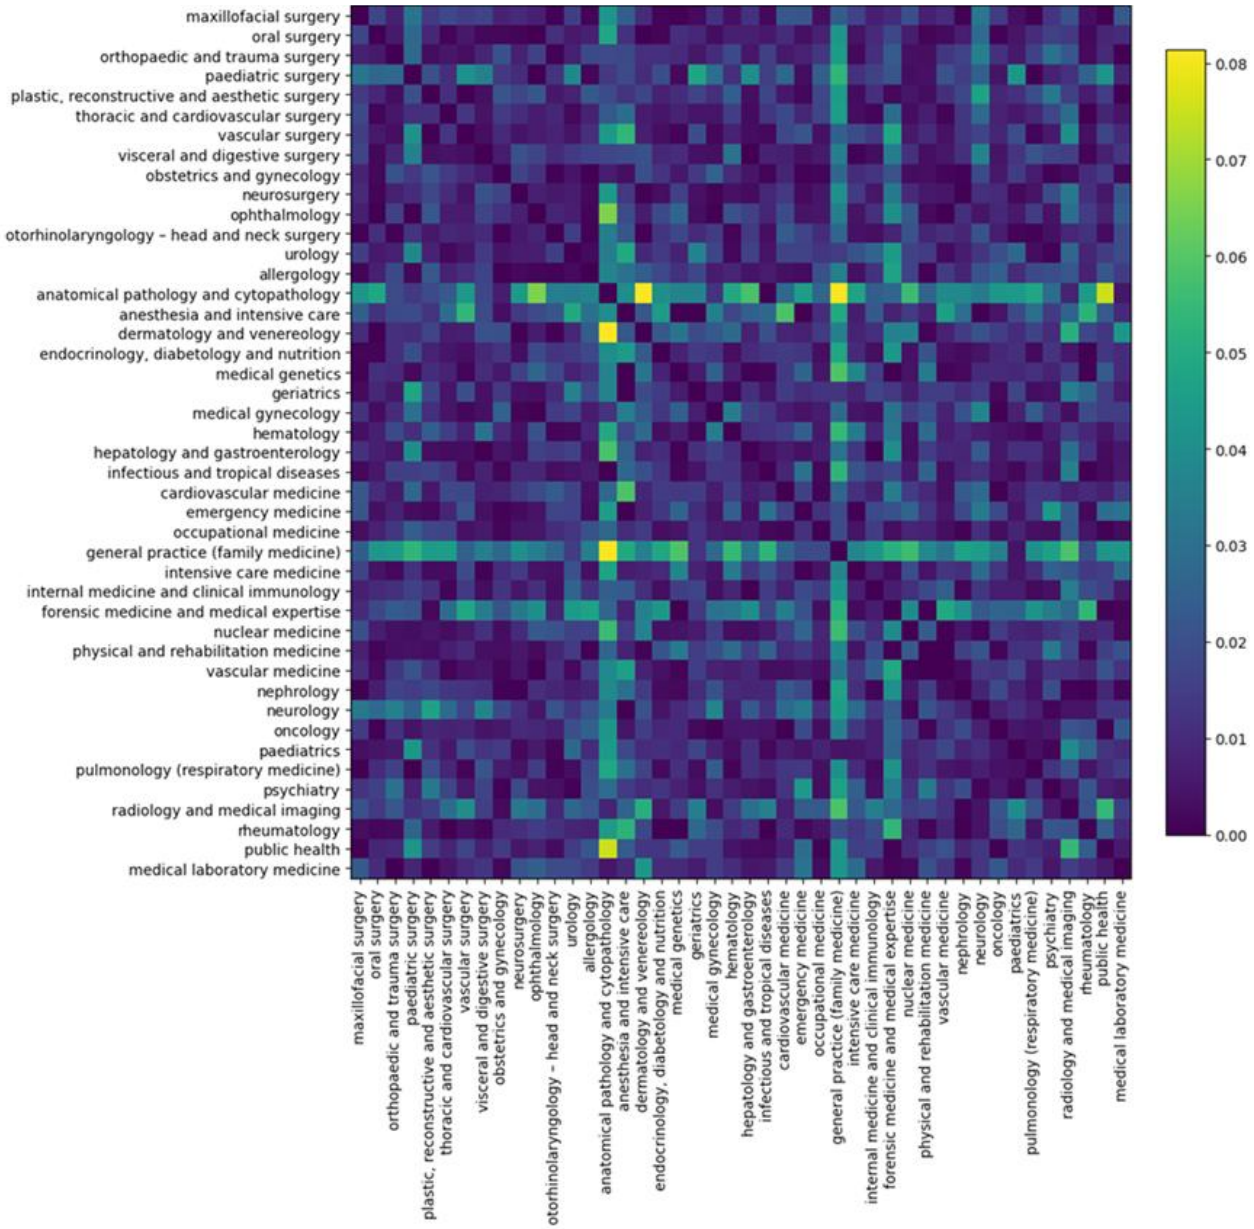

Fig. 4. Heatmap of absolute differences between Claude 4 Sonnet and GPT-4.1 composite similarity matrices (0-1 scale).

Cluster agreement, measured using the Adjusted Rand Index across all possible numbers of clusters (k = 1–44), remained consistently high between Claude 4 Sonnet and GPT-4.1, while LLaMA 3.2 3B diverged more at finer resolutions.

This confirms that large-scale proprietary models capture highly consistent semantic structures, while smaller models preserve global patterns with reduced granularity.

E. Model Disagreements

Fig. 4 illustrates the absolute differences between composite similarity matrices of Claude 4 Sonnet and GPT-4.1.

A heatmap comparing the two models revealed localized areas of divergence, particularly for general practice and anatomical pathology. These discrepancies correspond to specialties whose definitions span multiple domains.

These localized differences highlight areas where semantic boundaries between specialties are less clearly defined, indicating potential zones requiring expert validation.

IV. Discussion

A. Key Results

This study suggests that large language models can be used to construct consistent and interpretable computational representations of semantic relationships between medical specialties. All evaluated models produced coherent similarity structures, with strong agreement observed between Claude 4 Sonnet and GPT-4.1 across statistical measures. The resulting clustering revealed groupings of specialties that appear consistent with functional domains in clinical practice and medical education, although independent expert validation remains necessary.

B. Interpretation

The high level of agreement between Claude 4 Sonnet and GPT-4.1 suggests that large-scale instruction-tuned models capture consistent semantic structures when applied to

structured domain descriptors. In contrast, LLaMA 3.2 3B generated smoother similarity distributions, indicating reduced differentiation while preserving overall structural coherence. These differences likely reflect variations in model scale, architecture, and training data exposure.

From a computational perspective, the results indicate that semantic similarity derived from LLM-based ratings can provide a useful exploratory representation of structural relationships between domain entities. The multi-criteria aggregation approach further enhances interpretability by combining complementary perspectives on specialty similarity.

C. Comparison with Previous Work

Previous research on large language models in healthcare has primarily focused on clinical applications, diagnostic use cases, and evaluation tasks such as medical examination performance [2], [3], [7]. In parallel, several studies have explored their implications for medical education and curriculum design [1], [6], [9].

Other approaches have applied artificial intelligence to the structuring of medical knowledge, including specialty or subdomain classification [10], [11], as well as the analysis of semantic relatedness between biomedical concepts [12].

However, few studies have addressed the problem of modeling relationships between medical specialties as a structured computational task. In contrast, this work focuses on relational modeling between specialties, providing a quantitative and interpretable representation of their semantic proximity.

D. Limitations

First, as with all studies involving large language models, the results represent a snapshot of model behavior during a specific period. Subsequent model updates, retraining, or changes in deployment settings may alter response patterns and similarity values.

Second, each descriptor item was queried once per model without repeated sampling, so intra-model variability was not formally assessed. Although the temperature was set to 0, repeated runs could help quantify the stability of rating outputs.

Third, high absolute similarity values should be interpreted in relation to the rating scale and descriptor distribution. Because the model-generated ratings formed relatively dense profiles, the relative structure of the matrices, clustering patterns, and inter-model correlations are more informative than isolated similarity magnitudes. Future work should include randomized baselines, perturbation-based sensitivity analysis, and bootstrap confidence intervals to further assess robustness.

Fourth, the study focused exclusively on the 44 medical specialties defined in the French regulatory framework, which may limit direct applicability to other national healthcare systems, specialty taxonomies, or subspecialty structures.

Fifth, the interpretation of clusters was qualitative and was not formally validated by an independent clinical or educational expert panel. Future work should compare the computational clusters with structured expert assessments of specialty proximity.

Finally, substitution coverage was analyzed as an exploratory semantic indicator. Actual short-term coverage or substitution decisions require additional criteria, including clinical responsibility, regulatory authorization, institutional protocols, available competencies, and patient-safety considerations.

E. Generalizability

The proposed framework is designed to be adaptable to different contexts and data availability. The choice of descriptor criteria is not fixed and may vary depending on the objectives and constraints of the implementing entity. In this study, diseases, educational teachings, and technical skills were selected as representative criteria; however, alternative or additional descriptors could be incorporated depending on the use case.

This flexibility allows the framework to address semantic similarity in a context-dependent manner, effectively answering the question “similar with respect to what?”. For instance, using disease-based descriptors highlights specialties managing similar clinical conditions, technical skill descriptors capture overlap in procedural competencies, and educational descriptors reflect shared training structures.

As a result, the framework can be customized to emphasize different aspects of specialty relationships, making it applicable across healthcare systems, educational institutions, and planning scenarios with varying priorities.

However, adaptation to another setting requires reconstruction of the descriptor sets using local specialty definitions, curricula, clinical responsibilities, and regulatory constraints. The framework should therefore be viewed as a configurable semantic analysis tool rather than a universal model of medical workforce substitutability.

V. Conclusion

This study presented a computational framework for modeling semantic relationships between medical specialties using large language models. By combining multiple descriptor sets, the proposed approach produces interpretable similarity matrices that capture structural relationships between specialties.

The results showed strong agreement between large-scale models and suggested that semantic similarity derived from LLM-based relevance profiles can provide meaningful exploratory representations of specialty proximity. These findings highlight the potential of large language models as tools for structured analysis in complex medical and educational domains.

The flexibility of the framework allows adaptation to different contexts and objectives, making it potentially useful for exploratory analyses in medical education, cross-specialty coordination, and preliminary healthcare planning. Future work

should incorporate repeated model sampling, robustness analysis, randomized baselines, and structured expert validation to further assess the stability and practical relevance of the proposed similarity structures.

Declaration on Generative AI

The authors acknowledge the use of generative AI tools to assist with language refinement, wording revision, and manuscript editing during the preparation of this article. Their use was limited to writing assistance and did not determine the scientific ideas, study design, methodology, analyses, interpretation of results, or conclusions. ***Abstract*—Traditional library systems designed for academic research suffer from poor integration when employing AI-based techniques for enhancement purposes. These limitations are mainly related to ignoring semantic relationships during search, overlooking hidden relationships among words, and lacking the generalization capability required to enhance researchers' experience. To address these issues, the Intelligent Library System (IntLS) is proposed and further enhanced through effective knowledge graph modeling to enable more accurate retrieval of results. In addition, the basic NLP processing steps are optimized to capture hidden relationships during tokenization, stop-word removal, and stemming stages. The architecture of the proposed system consists of two main components: a semantic component, responsible for generating semantic representations of documents, and an analytics component, responsible for analyzing historical searches to predict future user needs and support effective resource management. The proposed system is compared with two well-known systems using similarity-based accuracy and a set of AI-based evaluation metrics. The enhanced system, Enh-IntLS, demonstrates superior performance, achieving a 1.9% improvement in similarity-based accuracy and a 1.7% improvement in AI-based accuracy.**

***Keywords*—Library systems; academic search; generalization; knowledge graph; similarity; accuracy**

I. Introduction

Traditional Library Systems (TLSs) are essentially digital catalogues and circulation management platforms that provide limited analytics. They rely mainly on reactive usage statistics rather than predictive capabilities. In other words, traditional library management systems are database-driven systems that primarily digitize and automate manual processes. Such automation benefits stakeholders (i.e., both librarians and users) by enabling them to manage book records, track borrowing and returning transactions, monitor due dates, and generate basic reports [1]. In light of the rapid advancement of technologies, library system developers have begun employing artificial intelligence to enhance the quality of services provided to users. However, the integration of artificial intelligence also opens the door to new challenges.

A. Motivation

Despite these improvements, traditional library management systems still exhibit several limitations within modern information environments [2, 3]. First, their search mechanisms are primarily keyword-based, lacking semantic understanding and intelligent recommendation capabilities. As a result, users often struggle to find relevant resources beyond exact keyword matches. Second, these systems typically operate reactively rather than proactively; they do not predict user needs, recommend resources based on borrowing history, or dynamically optimize inventory. Third, traditional LMS platforms provide limited data analytics, which restricts libraries from extracting actionable insights related to user behavior, demand forecasting, and collection development. Furthermore, they lack automation in tasks such as intelligent cataloging, classification, anomaly detection (e.g., identifying overdue patterns), and user personalization. In many cases, decision-making remains dependent on manual librarian intervention, which reduces scalability and efficiency in large academic institutions.

B. Statement of Problem

With the advancement of Artificial Intelligence (AI), Machine Learning (ML), Natural Language Processing (NLP), and data analytics technologies, new opportunities have emerged to transform library services into intelligent, adaptive, and user-centric systems. AI-powered systems can enable semantic search, automated metadata generation, personalized recommendation engines, and predictive analytics for resource demand [4]. These capabilities can significantly enhance the user experience, improve operational efficiency, and support strategic resource management.

In other words, there remains a gap between conventional rule-based LMS platforms and fully intelligent, AI-driven library ecosystems. Many existing systems do not integrate advanced AI components within a unified and scalable architecture capable of supporting intelligent search, predictive decision-making, and adaptive service personalization. Bridging this gap is critical for establishing smart library systems that enable researchers to accurately find the documents they need. Moreover, to the best of our knowledge,

the evaluation of the generalization quality attribute has not been addressed in previous works, which is important for enhancing researchers' trust in academic search systems.

C. Research Questions

Based on the problem stated above, the following research questions are formulated:

- How can intelligent search be enabled based on the semantics of keywords?
- How can predictive analytics be enabled for resource demand?

D. Contributions

This work provides the following contributions:

- Proposes the Intelligent Library System (IntLS) to address the research questions mentioned above. The system employs an NLP-based approach in its development.
- Enhances IntLS by developing a knowledge graph of library topics, enabling accurate predictive analytics rather than relying solely on descriptive analytics.
- Evaluating the generalization quality attribute to demonstrate the effective applicability of the proposed system in real-world environments.
- Conducts a comparative evaluation with well-known smart library systems to demonstrate the superiority of the proposed approach.

E. Work Organization

The rest of this study is organized as follows: Section II presents an overview of both Traditional Library Systems (TLSs) and Intelligent Library Systems (ILSs). Section III describes the proposed system in detail. The experimental results are presented and discussed in Section IV. Finally, Section V concludes the study.

II. Related Work

This section presents a brief overview of both traditional library systems and smart library systems.

A. Traditional Library Systems

Authors of work [5] stated that the need for a specialist academic library system is pressing to enhance the academic productivity of researchers. The previous work is supported by another article provided in [6], where a comparison between traditional and smart library systems is provided. The final result of this work stated that artificial intelligence techniques can play a significant role in enhancing the accuracy of academic search. The Ex Libris Alma platform [7], widely adopted by academic and research libraries worldwide, represents a recent generation of library services platforms that integrate cataloging, fulfillment, and resource management into a unified cloud-based system. According to the official Ex Libris documentation, Alma incorporates data analytics capabilities to improve operational efficiency in resource management. However, its analytics remain primarily descriptive rather than predictive, and the platform relies on proprietary infrastructure with associated licensing costs that may not be accessible to all academic institutions, particularly those in developing regions.

B. Intelligent Library Systems

Many techniques are employed to develop smart library systems, such as text classification and natural language processing. In the work [8], the authors proposed a text classification-based system supported by the KNN algorithm. The key idea is to create clusters of text according to categories generated based on the smart recommendation of text classification. authors of work [9] presented an NLP-based library system supported by a correlation function to handle semantic issues. The key idea is to employ correlation based on the domain where the text belongs. The correlation function provides statistical information about semantics after following standard NLP steps. However, the limitation of this work is related to ignoring the knowledge graph database.

It is worth mentioning that KNN-based and NLP-based systems are involved in the comparison with the proposed system of this study.

III. Proposed System

This section presents the proposed intelligent system, referred to as the Intelligent Library System (IntLS), as well as the enhanced one. First, the architecture of the system is introduced. Then, the role of each component within the architecture is described in detail. The testing of the system and the corresponding discussion of results are presented in a separate section.

A. IntLS Architecture

The architecture of IntLS is composed of two main components: the semantic component and the predictive analytics component. Fig. 1 below illustrates the role of the first component, in which several techniques are employed to generate the desired output.

To enable semantic-based search, the semantic component performs several steps, as described below.

1) Semantic representation of documents: The output of this step is to capture the meaning of documents rather than relying solely on exact word matches. This enables users to retrieve results based on context-aware queries. For example, if a user searches for books on artificial intelligence, resources containing topics such as deep learning, machine learning, and text mining will also appear in the result set. To achieve this capability, library resources (e.g., books, articles, theses, etc.) must first be transformed into semantic representations. To perform this task, text preprocessing is applied to important textual fields of the documents, such as the title, abstract, and keywords. Text preprocessing includes the following sub-tasks:

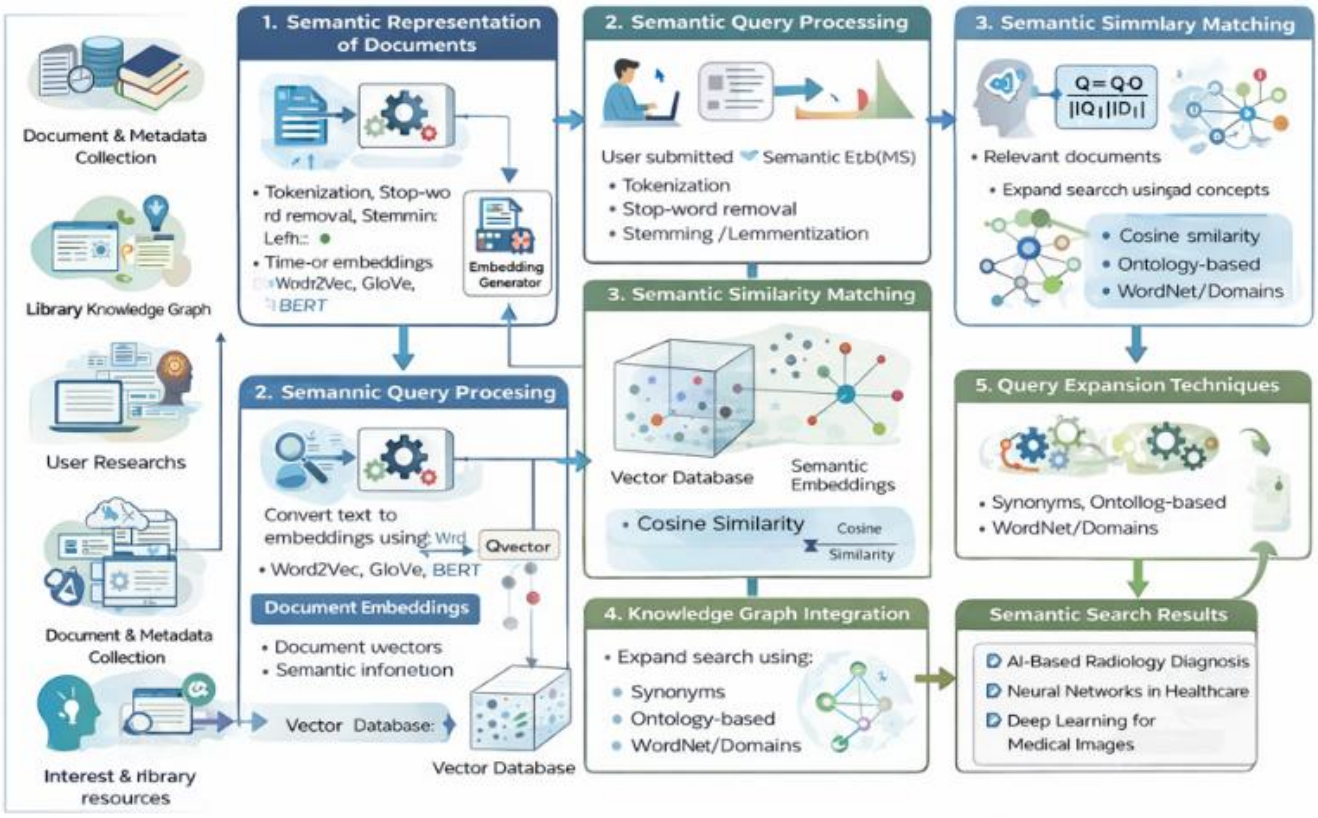

Fig. 1. Role of semantic component.

- Tokenization: This step involves converting a sentence into a sequence of words, commonly referred to as "tokens." Tokens represent the basic building blocks upon which text analysis and other processing methods are performed. Using the title of work [10], the output will be as follows:

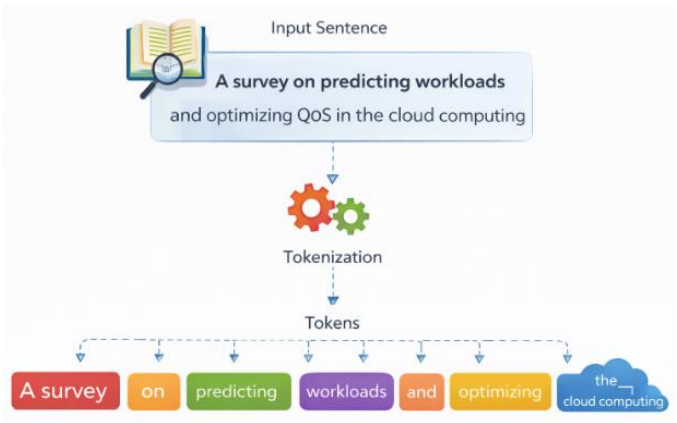

Fig. 2. Output of the tokenization step.

As shown in Fig. 2, a whitespace-based method is used to generate tokens. However, this work enhances this method by considering strong relationships between words rather than treating them individually. Therefore, the first token includes "A survey," and the last token includes "cloud computing," as they represent integral phrases within the computer science domain. In addition, abbreviations such as "QoS" in our example are removed because they may introduce ambiguity and negatively affect accuracy.

- Stop-word removal: Researchers have provided a list of such words in the Bag-of-Words (BoW) library. The objective of this step is to eliminate words that have low importance in conveying meaning (i.e., words that have minimal impact on the overall semantics). Fig. 3 illustrates the output of the same previous example.

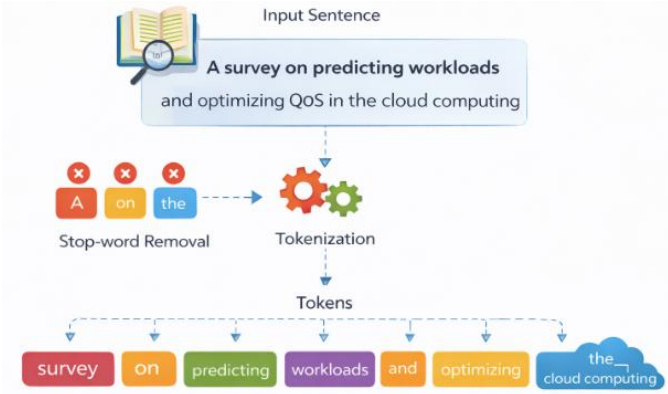

Fig. 3. Output of stop-word removal step.

As shown in Fig. 3, the words "A," "on," and "the" are removed. However, this work introduces an enhancement that considers the relationship conveyed by the word "and." This is because authors of a document often use "and" to emphasize the relationship between two concepts (e.g., "workloads" and

"optimizing"), highlighting a form of trade-off or association between the two terms.

- Stemming: This is the process of converting words into their base form, or stem. In this study, Porter's algorithm is used for this purpose. The output of this step is illustrated in Fig. 4.

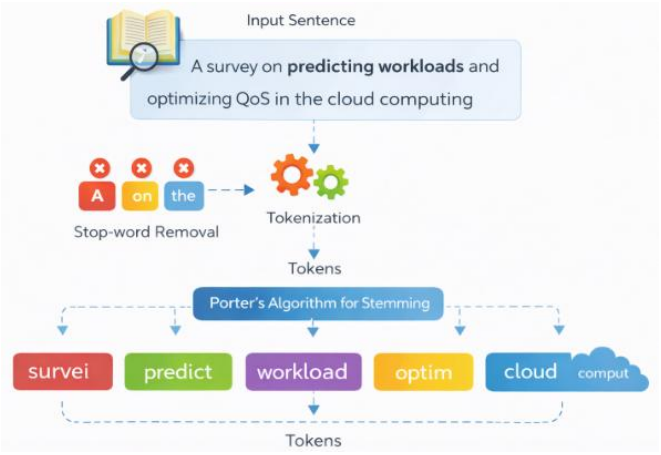

Fig. 4. Output of the stemming step.

- Convert text into semantic vectors (embeddings): This step uses the Word2Vec model to transform textual data into semantic vector representations, as shown in Fig. 5. The objective of this step is to map the text into a numerical vector space, enabling similarity calculations in subsequent stages.

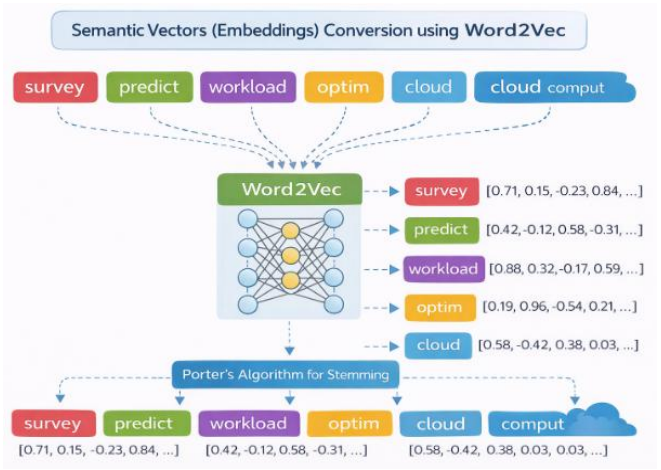

Fig. 5. Output of embedding step.

2) Semantic query processing: The objective of this step is to enable IntLS to retrieve documents with similar meanings even when different keywords are used. For example, if a user submits the query "intelligent learning for the medical field," the system can retrieve studies such as "deep learning in medical imaging" or "neural network–based COVID-19 diagnosis."

In this context, the same preprocessing steps used in the previous example are applied (i.e., tokenization, stop-word removal, stemming, etc.). The query is then converted into a semantic embedding vector. Finally, semantic similarity matching is performed, as described below.

3) Semantic similarity matching: The objective of this step is to rank the retrieved documents within the result set based on their semantic closeness to the query. In this context, the Cosine Product similarity measure [11] is used. It is defined as follows:

$$Sim\ (D,Q) = \frac{D.Q}{\|D\| \times \|Q\|} \quad (1)$$

where, Q is the query vector, and D is the document vector.

Problem. A critical issue arises when considering the intersections among different domains. For example, the computer vision domain is tightly coupled with deep learning, while artificial intelligence is strongly linked with text and data mining. In such scenarios, the accuracy of retrieval results may decrease due to overlapping or related concepts across domains. To address this challenge, this work introduces an enhancement to IntLS through the integration of a Knowledge Graph [12].

B. Enhanced IntLS Architecture (Enh-IntLS)

The key idea behind this enhancement is the construction of a knowledge graph of library topics. The objective of this enhancement is to support semantic search, recommendation, topic discovery, and trend analysis across intersecting domains, which is essential for researchers seeking relevant documents. A knowledge graph is a network of nodes and edges, where nodes represent entities such as authors, topics, journals, and departments, while edges represent relationships such as *written by*, *belongs to*, *related to*, and *published in*. Through this structure, Enh-IntLS can understand how topics, books, authors, users, and research areas are interconnected. Fig. 6 illustrates the basic steps involved in creating the knowledge graph.

Fig. 6. Steps of knowledge graph development.

From mathematical modeling, the basic steps are provided as follows:

Let the final knowledge graph be: $G = (V, E)$ (2)

where, V is the set of entities (nodes), and E is the set of relationships (edges). The scope S ∈ D, where D is all possible domains, such as cloud computing.

The graph schema includes the following entity types:

V={Publication, Author, Topic, FieldOfStudy, Journal, Conference, Department, Institution}

The main relation types are defined as follows:

E={written_by,published_in,belongs_to,has_topic,cites,affliated_with,related_to}

Important entities extracted from documents are represented by:

$$E = \{e_1, e_2, e_3, .., e_n\} \quad (3)$$

Entities are extracted from structured and semi-structured academic metadata. The main input fields include publication titles, abstracts, keywords, authors, publication venues, departments, institutions, citation links, and fields of study. The extraction process follows these steps: First, the textual fields of each document are preprocessed using tokenization, stop-word removal, phrase detection, and stemming. Second, candidate entities are identified from titles, abstracts, and keywords. Third, structured metadata fields, such as author names, journal names, conference names, institutional affiliations, and fields of study, are directly extracted as graph entities.

After extraction, each entity is linked to an existing graph node or inserted as a new node if no match is found. Entity linking is performed using three steps. First, entity labels are normalized by converting them to lowercase, removing punctuation, and standardizing abbreviations. Second, exact matching is used to link identical entity names. Third, semantic matching is applied using embedding similarity to link conceptually equivalent or highly related entities.

Between two different entities, the relationship is defined as:

$$E = \{(e_i, r, e_j)\} \quad (4)$$

where, e_i, e_j are entities, and r is kind of relationship.

To collect data from different resources, let:

$$X = \{x_1, x_2, x_3, \ldots x_k\} \quad (5)$$

Refers to the set of resources. Then, each document x can be represented by:

$$x = \{title, abstract, keywords\} \quad (6)$$

E_i is the extracted entity from a document x. Then, the relationship extracted from the pairs is:

$$r = relation\ (e_i, e_j) \quad (7)$$

Relations are extracted using both metadata-based and semantic-based methods. Metadata-based relations are obtained directly from structured fields. For example, if publication (P_i) has author (a_i) the triple $(P_i, written_by, a_i)$ is created.

The relationships are embedded within the graph. However, the graph is stored using three parameters as follows:

$$StrG = (s, p, o) \quad (8)$$

where, S is the subject, P is the predicate, and O is the object.

For example, (Article A covers Cloud Computing). Based on this representation, queries are issued from the side of the user, so that searching relevant nodes for a query is modeled as:

$$Result = argmax_{e \in E} Score\ (q, e) \quad (9)$$

To make the enhancement clearer, the following provides an example of query enrichment: Assume that a user submits the query: “deep learning in medical imaging”. First, the query is preprocessed and converted into a semantic vector. The embedding component retrieves candidate documents that contain semantically close expressions such as “neural networks for diagnosis,” “CNN-based image classification,” and “AI-based radiology analysis.” Then, the query entities, deep learning and medical imaging, are linked to corresponding nodes in the knowledge graph. Through graph traversal, Enh-IntLS identifies related nodes such as neural networks, image classification, medical diagnosis, radiology, and computer vision. Candidate documents connected to these related nodes receive higher graph-based relevance scores. For example, a document titled “Neural Network-Based COVID-19 Diagnosis from Chest Images” may be ranked higher even if it does not contain the exact phrase “deep learning in medical imaging.”

After the enhancement based on the knowledge graph, the predictive analytics component begins its function. The main objective of this component is to analyze historical usage data and semantic information about library resources to forecast future trends and user needs. To accomplish this task, the predictive analytics component performs the steps described below.

1) Predicting user information needs: By analyzing previous searches and browsing history, a prediction profile is established to identify resources that users may need in the future.

2) Demand forecasting for library resources: This step predicts which books, journals, or digital resources will be highly in demand in the future.

Mathematically, these actions are modeled as follows:

Let UP is user profile features, RF is resource features (topics, keywords, metadata), HID is historical interaction data, and f is predictive model. Then, predicted demand (PD) is:

$$PD = f(UP, RF, HID) \quad (10)$$

Fig. 7 illustrates the integration of the two components to generate the final output.

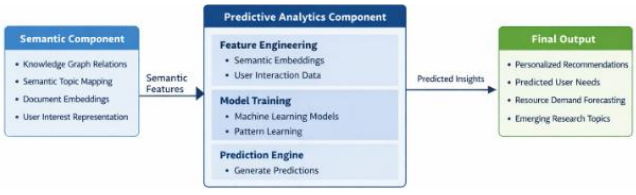

Fig. 7. Integration of the semantic component and predictive analytics component.

IV. Experimental Results and Evaluation

To evaluate the proposed IntLS and Enh-IntLS systems, the most recent Microsoft Academic Graph (MAG) dataset [13] was selected for training and testing. The dataset contains 109,105 triples. It is a heterogeneous graph that includes scientific publication records, citation relationships among these publications, as well as information about authors, institutions, journals, conferences, and fields of study. Therefore, it is considered a suitable benchmark dataset for conducting experiments. The dataset was divided into 80% for training and 20% for testing.

Evaluation is arranged to cover two main tasks, which are: 1) Semantic retrieval of academic resources; and 2) Resource demand prediction. For each task, input data, target output, ground truth labels, and evaluation metrics are defined as follows:

1) For the semantic retrieval task, the input consists of academic resource metadata, including titles, abstracts, keywords, topics, and knowledge-graph triples extracted from the Microsoft Academic Graph dataset. The target output is a ranked list of academic resources relevant to a submitted query. The relevance criterion is based on semantic overlap between the query concepts and the document concepts represented through Word2Vec embeddings and knowledge-graph relationships. The evaluation uses similarity-based accuracy to measure whether the retrieved resources are semantically aligned with the expected relevant topics.

2) For the demand prediction task, the input consists of simulated historical interaction records derived from academic-resource usage indicators, including resource-topic frequency, query-topic occurrence, and resource-demand class labels. The target output is a binary classification of future demand, namely correct/high demand and incorrect/low demand. The ground truth labels are represented through demand classes used in the confusion matrix. The evaluation uses accuracy, precision, recall, specificity, and ROC-based analysis.

It is worth mentioning that since the Microsoft Academic Graph is primarily a scholarly metadata and citation graph, it is integrated with simulated demand data to cover the evaluation of the second task. In other words, simulated interaction and synthetic demand-label data are used for predictive analytics. Specifically, simulated historical interaction records were constructed from MAG-based academic-resource indicators. These indicators included topic frequency, resource-topic occurrence, citation activity, field-of-study frequency, and graph-based relationships among publications, authors, and research areas.

This integration leads to update number of records in the selected dataset to be 214,000 records. In other words, the value of 214,000 evaluated instances refers to simulated demand-observation records generated from resource-topic occurrences, citation activity, field-of-study frequency, and synthetic interaction indicators. These simulated records were used only for evaluating the demand-prediction task, not for evaluating the semantic retrieval task.

B. Strategy of Evaluation and Used Metrics

We first evaluate the main system (i.e., IntLS) in comparison with the enhanced system (i.e., Enh-IntLS). Then, Enh-IntLS is compared with KNN-based and NLP-based systems reviewed in the related work section. In addition, the generalization quality attribute is evaluated by varying the training-to-testing ratios. It is worth mentioning that in this work, generalization is considered internal validation, as no real data is available. In future work, we tend to prove generalization using real data. For forecasting resource demand, the logistic regression algorithm [14] is employed.

Regarding the evaluation metrics, similarity-based accuracy is used to assess semantic similarity matching based on Eq. (1). Specifically, we define the semantic retrieval task as a top-k ranking problem. For each query, the system retrieves and ranks academic documents according to the semantic similarity score between the query vector and the document vector. In IntLS, this score is computed using Word2Vec-based document/query embeddings and Cosine Product similarity. In Enh-IntLS, the similarity score is further enriched using knowledge-graph relationships among topics, authors, journals, departments, and publications. A retrieved document is considered relevant if its semantic similarity score is greater than or equal to a predefined threshold and if it shares at least one expected topic, field-of-study, or knowledge-graph relationship with the query. In the revised manuscript, we define the threshold value as **0.70** after normalizing similarity scores into the range [0, 1]. Therefore, a retrieved document is considered correct when it satisfies the relevance criterion, and it is considered incorrect when it does not satisfy this criterion.

In addition, accuracy, precision, recall, and specificity are used to evaluate the prediction of resource demand. These metrics are derived from the confusion matrix [15] summarized in Table I.

TABLE I. Confusion Matrix

Predicted Dem Actual Dem	PD_{final}	$\neg PD_{final}$	Sum
PD_{final}	TP	FN	S
$\neg PD_{final}$	FP	TN	Su
Sum	$\widetilde{S}$	$\widetilde{Su}$	All

where:

- True positives (TPs): The positive demands that were correctly recommended by the system.
- True negatives (TNs): The negative demands that were correctly recommended by the system.
- False positives (FPs): The negative demands that were incorrectly recommended as positives by the system.
- False negatives (FNs): The positive demands that were recommended as negatives by the system.

$$\text{Accuracy} = \frac{TP+TN}{All} \quad (11)$$

$$\text{Precision} = \frac{TP}{\widetilde{S}} \quad (12)$$

$$\text{Recall} = \frac{\text{TP}}{\text{S}} \quad (13)$$

$$\text{Specificity} = \frac{\text{TN}}{\text{Su}} \quad (14)$$

C. Similarity-Based Accuracy Evaluation of IntLS and Enh-IntLS (Semantic Retrieval Task)

In this subsection, the semantic retrieval task is evaluated, and the corresponding results are discussed. Table II presents the results obtained under varying training-to-testing ratios for evaluating the generalization quality attribute.

TABLE II. SIMILARITY-BASED ACCURACY RESULTS

System	Training to Testing Ratio	Sim Metric	AVG
IntLS	[80 to 20]	80.2	≈ 78.58
	[70 to 30]	80.1	
	[60 to 40]	79	
	[50 to 50]	75	
Enh-IntLS	[80 to 20]	93.3	≈ 88.83
	[70 to 30]	91	
	[60 to 40]	88	
	[50 to 50]	83	

Discussion. When the training ratio was decreased by 10%, and the testing ratio was increased by 10%, both systems showed decreasing values in the similarity-based accuracy metric. This can be explained by the fact that incorporating more records into the training dataset leads to the extraction of more features, which can be utilized during the similarity matching process, thereby resulting in higher accuracy values. However, Enh-IntLS demonstrated better performance compared to IntLS. This improvement can be attributed to the use of a knowledge graph of topics, which models similarity based on the semantics of input queries and retrieved results. Regarding the generalization quality attribute, Fig. 8 illustrates the difference between the baseline training-to-testing ratio and the average results obtained for both systems.

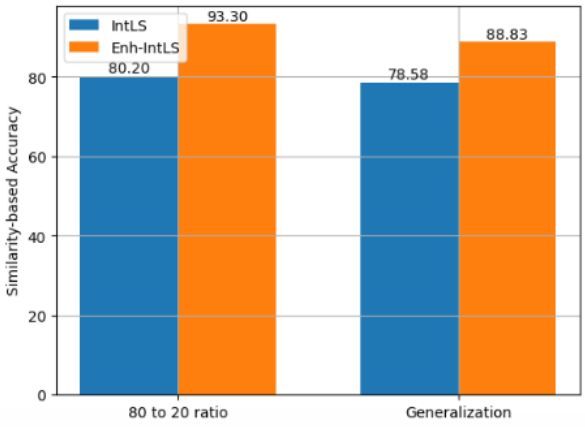

Fig. 8. Results of similarity-based accuracy metric.

As shown in Fig. 8, the difference between the baseline training-to-testing ratio and the generalization results is small (approximately 1.4% for IntLS and about 4% for Enh-IntLS). This indicates that the systems demonstrate acceptable generalization capability and can be applied in real-world environments to enhance researchers' trust in the system.

D. Accuracy, Precision, Recall, and Sensitivity Evaluation of IntLS and Enh-IntLS (Demand Prediction Task)

In this subsection, the demand prediction task is evaluated, and corresponding results are discussed. Fig. 9 and 10 illustrate confusion matrix visualizations for both systems.

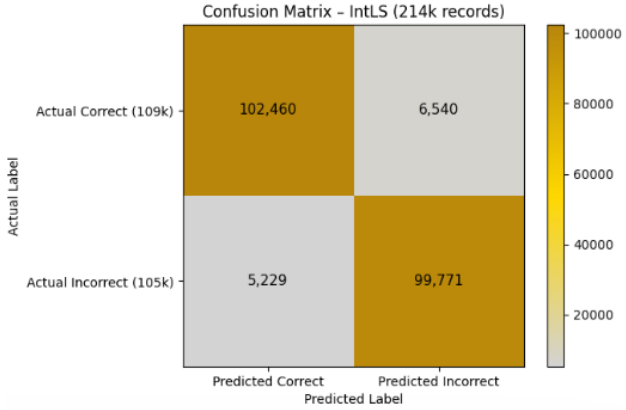

Fig. 9. Confusion matrix values of IntLS.

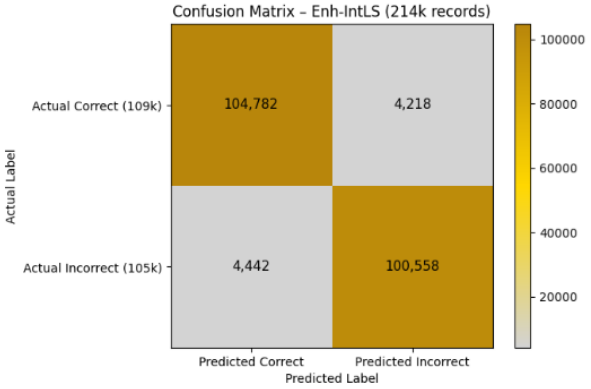

Fig. 10. Confusion matrix values of Enh-f IntLS.

Table III summarizes the obtained results without involving the generalization quality attribute.

TABLE III. RESULTS OF AI-BASED METRICS [80 TO 20] RATIO

System	Metric	AVG Value	Class	
			Correct Demand	*Incorrect Demand*
IntLS	Accuracy	94.50	92.34	96.66
	Precision	95.14	93.4	96.88
	Recall	94.00	94	94.00
	Specificity	95.02	95.02	95.02
Enh-IntLS	Accuracy	95.95	96.22	95.68
	Precision	95.93	95.89	95.97
	Recall	96.13	96.13	96.13
	Specificity	95.77	95.77	95.77

As shown in Table III, the value of each metric is presented in detail according to the correct and incorrect demand classes. It is evident that Enh-IntLS achieves better scores compared to IntLS. This improvement can be attributed to the fact that resource demand encompasses a wide spectrum of semantics that are not captured by IntLS. Since accuracy is considered one of the most important metrics in the AI domain, generalization is illustrated in Fig. 11.

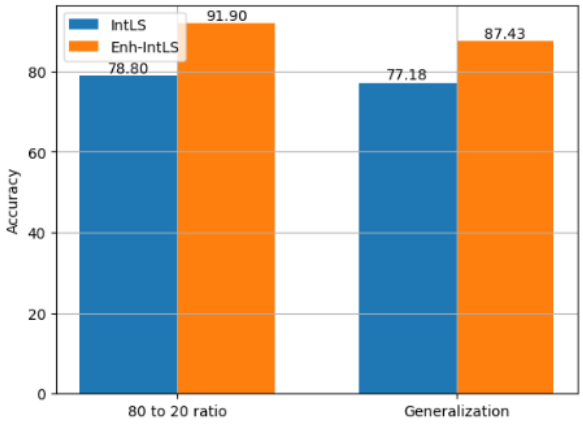

Fig. 11. Results of the accuracy metric.

As shown in Fig. 11, the difference between the baseline training-to-testing ratio and the generalization results is again small, which provides further evidence of the generalization capability of the proposed systems. However, Enh-IntLS records better values for the same reason discussed earlier when presenting the results of the similarity-based accuracy metric.

E. Results of Comparison to KNN-Based and NLP-Based Systems

In this context, only Enh-IntLS is involved in the comparison process, as it achieves better results than IntLS. For the similarity-based accuracy metric and under the generalization criterion, the previously obtained results of Enh-IntLS are considered for comparison with the selected systems. Fig. 12 illustrates the comparison results, where the KNN and NLP systems are implemented to generate a simplified version using the same selected dataset.

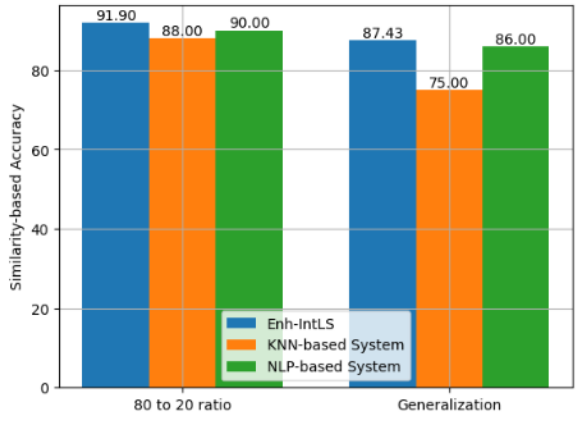

Fig. 12. Similarity-based accuracy metric comparison.

As shown in Fig. 12, the KNN-based system achieves the lowest performance compared to the other systems, as it does not incorporate knowledge graphs within its structure. This limitation leads to the retrieval of irrelevant documents within the result set. The NLP-based system achieves values close to those of the proposed system, as it employs similar NLP processing stages to those used in the development of Enh-IntLS. However, Enh-IntLS still ranks at the top because it incorporates more effective mathematical modeling within its architecture. In addition, the relationships conveyed through linking words, such as “and,” are not captured by the NLP-based system. Numerically, the Enh-IntLS achieves 1.9-based similarity-based accuracy enhancement.

Regarding the accuracy metric, which is one of the most important metrics in the AI domain, the ROC curve illustrated in Fig. 13 presents the obtained results. The ROC curve reflects the classification performance by comparing different classifiers based on the area under the curve (AUC) [16].

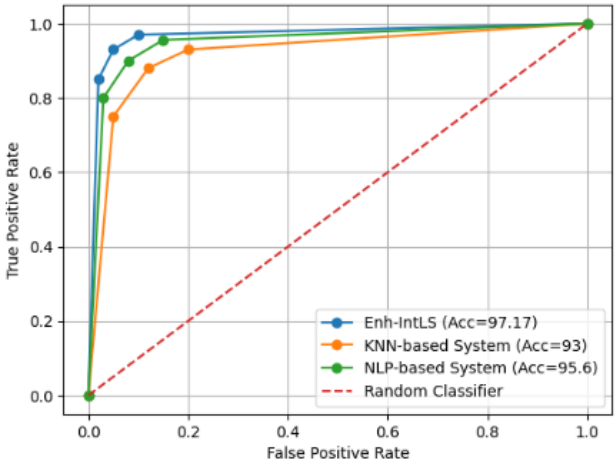

Fig. 13. ROC curve based evaluation.

As shown in Fig. 13, the Enh-IntLS system achieves the best performance, with its ROC curve located closest to the top-left corner, indicating a higher true positive rate and a lower false positive rate. The NLP-based system also demonstrates strong performance but remains slightly below the Enh-IntLS curve. In contrast, the KNN-based system shows comparatively lower performance, as its curve is farther from the optimal region. Overall, the ROC analysis confirms that Enh-IntLS provides superior discriminative capability and more reliable prediction accuracy compared to the other evaluated approaches.

V. Conclusion

This study proposed an Intelligent Library System (IntLS) designed to improve academic search and resource management by incorporating semantic understanding and predictive analytics. The system addresses key limitations of traditional library management systems, particularly the lack of semantic awareness, limited exploitation of relationships among research topics, and insufficient support for predictive decision-making. To overcome these challenges, an enhanced version of the system, Enh-IntLS, was developed by integrating knowledge graph modeling with optimized NLP

preprocessing techniques to capture hidden relationships among words and research topics. The architecture of the proposed framework combines a semantic component for generating meaningful document representations and a predictive analytics component for forecasting future resource demand based on historical usage patterns. The evaluation strategy is structured such that IntLS and Enh-IntLS are assessed using similarity-based accuracy, precision, recall, and sensitivity metrics. Subsequently, the best results obtained by Enh-IntLS are compared with two similar existing approaches to demonstrate its superiority. Experimental evaluation using the Microsoft Academic Graph dataset demonstrated that Enh-IntLS outperforms both the baseline IntLS and other comparison systems, achieving improvements in similarity-based accuracy and AI-based evaluation metrics. Furthermore, the results confirmed that the proposed systems maintain acceptable generalization capability under varying training-to-testing ratios. These findings indicate that the proposed approach can significantly enhance the effectiveness of academic library search systems and support better resource discovery and management for researchers.

Some of the non-functional requirements, as illustrative screenshots, are presented in the Appendix.

VI. Limitations and Future Work

The main limitation of this study is that computational complexity was not analyzed, and cross-validation techniques were not employed to evaluate their impact on accuracy. Furthermore, only one dataset was used to train and test the proposed system. In future work, these limitations will be addressed by providing a detailed analysis of computational complexity and by using multiple datasets for training and testing to further validate the robustness of the proposed approach. In addition, generalization is considered as internal validation, and in future work, we tend to prove generalization using real data.

Appendix

This appendix is provided to cover some of the non-functional requirements as illustrative screenshots.

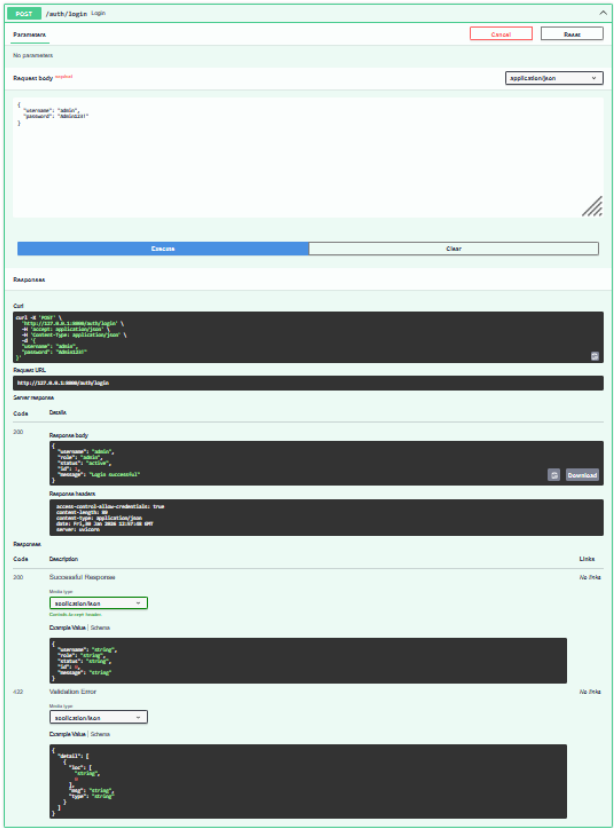

Fig. 14. Login interface.

User authentication successfully validated credentials against securely hashed password storage using bcrypt. Session management maintains user state across multiple requests without requiring repeated authentication. Role-based access control correctly restricted administrative operations to authorized users while permitting standard operations for all authenticated users. Fig. 14 demonstrates successful user authentication through the system login interface.

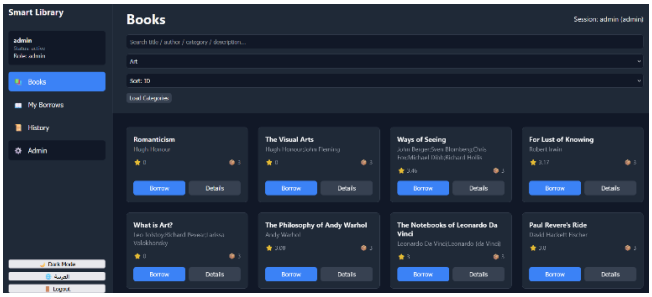

Fig. 15. Browsing interface.

The catalog search functionality correctly retrieved bibliographic records matching user-specified queries, filters, and sorting criteria. Full-text search operated across the title, author, category, and description fields. Filtering by category and sorting by relevance, title, or publication year produced the expected result sets. Fig. 15 illustrates the catalog browsing interface with active search and filter controls.

Borrowing operations correctly decremented the available copy counts and created borrowing records with appropriate due dates. The system prevented borrowing when no copies were available and enforced borrowing limits per user. Return operations restored availability, updated the borrowing status, and calculated overdue periods when applicable, as shown in Fig. 16.

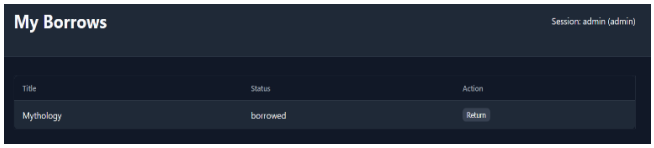

Fig. 16. Update borrowing interface.

Rice Pest Detection Using Enhanced YOLOv8n with Multilayer Contextual Attention and Deformable Snake Convolution

***Abstract*—Accurate and intelligent detection of rice pests is critical for ensuring food security and advancing precision agriculture. However, due to the small size, irregular morphology, dense distribution, and complex backgrounds of pest targets, traditional lightweight detection models often suffer from low recall and poor localization accuracy in real-world paddy field environments. To address these challenges, this study proposes an enhanced detection model, YOLO-Rice, based on the YOLOv8n framework. First, a Multilayer Contextual Attention (MLCA) module is embedded after the SPPF layer to collaboratively fuse channel, spatial, local, and global contextual information, thereby enhancing the model's sensitivity to subtle pest features. Second, the original C2f structure is redesigned into C2f-DS, which integrates Dynamic Snake Convolution (DSConv) to improve adaptive perception of deformable pest contours and irregular morphological edges. Finally, the conventional CIoU loss is replaced with a WIoU loss to guide the network to focus more effectively on hard-to-fit small and occluded targets. Extensive experiments on a self-constructed dataset of 11 common rice pest species demonstrate that YOLO-Rice achieves 84.8% Precision, 69.9% Recall, 78.7% mAP@0.5, and 63.4% mAP@0.5:0.95, representing significant improvements over the baseline YOLOv8n model. The proposed approach achieves an excellent balance between detection accuracy and computational efficiency, making it highly suitable for real-time deployment on UAVs and edge devices in agricultural pest monitoring applications.**

***Keywords*—Rice pest detection; YOLOv8n; deep learning; real-time detection**

I. Introduction

In recent years, with the continuous advancement of deep learning technology, image-based intelligent detection methods have become an essential pathway to ensure food security and promote agricultural modernization [1]. As one of the world's most important staple crops, rice is highly susceptible to a variety of pest infestations during its growth cycle, including Delphacidae, Cicadellidae, Crambidae, and Curculionidae. These pests not only hinder the healthy growth of rice but can also lead to severe yield reduction or even total crop failure, posing a significant threat to national food security. Consequently, early identification and precise localization of rice pests have become critical research focuses in modern agricultural pest management [2].

Traditional pest monitoring approaches, such as manual inspection and trap-based surveillance, suffer from high labor intensity, low efficiency, and subjective bias, making them unsuitable for large-scale field monitoring. With the rapid development of unmanned aerial vehicle (UAV) remote sensing and the increasing availability of agricultural imagery, computer vision – based automatic pest detection has emerged as a promising solution. Among numerous object detection frameworks, the YOLO (You Only Look Once) series has gained significant attention due to its end-to-end architecture, fast inference speed, and high detection accuracy, making it particularly suitable for agricultural visual tasks[3-4].

As the latest member of the YOLO family, YOLOv8 introduces an anchor-free mechanism and a lightweight C2f structure, achieving a better balance between precision and computational efficiency. However, when applied directly to rice pest detection[5], it still faces several challenges: 1) The pest targets are generally small, densely distributed, and often confused with complex backgrounds such as veins or shadowed regions, leading to false detections and missed targets; 2) Pest bodies exhibit irregular shapes, occlusion, and deformation, making it difficult for standard convolutions to accurately capture boundary features[6]; 3) The conventional bounding box regression loss functions, such as CIoU, show insufficient adaptability to hard samples and slow convergence during training, which limits the final detection accuracy. To overcome these challenges, this study proposes a structure- and loss-enhanced detection model based on YOLOv8n, specifically designed for high-precision detection of multiple rice pest species under complex field environments. The main contributions of this work are summarized as follows:

A Multilayer Contextual Attention (MLCA) mechanism is introduced after the SPPF module to integrate spatial, channel, local, and global contextual features. This enhances the model's focus on pest regions and improves its ability to recognize small and occluded targets. Compared to conventional attention modules such as SE and CBAM, MLCA achieves superior feature discrimination without adding significant computational overhead [7].

A redesigned C2f-DS module based on Dynamic Snake Convolution (DSConv) is proposed. By introducing dynamic offset learning, DSConv adaptively adjusts convolution

*Corresponding author.

sampling positions and shapes, enabling "snake-like" contour perception. This improves the model's capability to capture irregular pest boundaries and deformable structures, particularly for non-rigid shapes such as the feeding edges of Cnaphalocrocis medinalis.

The Weighted IoU (WIoU) loss function is employed to replace the traditional CIoU, enhancing the model's robustness in bounding-box regression. WIoU dynamically assigns gradient weights to samples with varying difficulty, encouraging the network to focus more on hard-to-fit or occluded targets, thereby improving convergence stability and overall mAP performance.

To validate the proposed approach, a large-scale rice pest dataset containing 11 common pest species was constructed. Experimental results demonstrate that the improved YOLOv8n model achieves significantly higher detection accuracy and robustness in complex, cluttered, and deformable pest scenarios while maintaining lightweight deployment capability. Notably, the proposed model outperforms mainstream detectors such as YOLOv5, YOLOv7, and YOLOv11 in key metrics including mAP, Precision, and Recall, verifying its effectiveness and practical potential for real-world rice pest detection tasks.

In summary, this study provides a novel structural optimization approach for object detection in agricultural vision applications and offers a feasible technical foundation for the intelligent deployment of rice pest monitoring systems. Future research will focus on improving the model's cross-regional generalization, multimodal data fusion, and extreme lightweight deployment on agricultural embedded platforms, thereby advancing pest control toward greater efficiency, intelligence, and precision.

II. Related Research

In recent years, with the deep integration of unmanned aerial vehicles (UAVs) and deep learning technologies in precision agriculture, vision-based rice pest detection has become a key research focus. Object detection techniques have evolved from early two-stage frameworks to more efficient single-stage and anchor-free approaches, with researchers exploring model lightweighting, small-object enhancement, deformable feature extraction, and regression loss optimization. Early two-stage detectors such as Faster R-CNN [8] and Mask R-CNN [9] demonstrated strong performance in locating crop diseases and large pest regions. For instance, Ren et al. [10] combined an RPN with a fine classifier for wheat leaf spot detection, achieving 67% mAP, though its inference delay of over 200 ms limited UAV-based real-time deployment. He et al. [11] improved feature alignment through ROI-Align, significantly enhancing lesion boundary segmentation accuracy, but the method remained computationally expensive due to dense proposal generation.

To balance speed and precision, single-stage detectors have gained prominence. Liu et al. [12] introduced SSD, which enables end-to-end detection using multi-scale feature layers and achieves 59 FPS inference. However, it exhibits high miss rates for small pests such as Cnaphalocrocis medinalis and Delphacidae, whose body sizes span only tens of pixels. Lin et al. [13] proposed RetinaNet with Focal Loss to reduce gradient dominance by easy samples, significantly improving small-object recall. Redmon and Farhadi [14] developed YOLOv3, which leverages multi-scale pyramid prediction and efficient convolution to reach 45 FPS, showing robust performance in heavily occluded rice leaf environments. Later, Bochkovskiy et al. [15] released YOLOv4, integrating CSPDarkNet and PANet to better balance speed and accuracy. Jocher et al. [16] further optimized YOLOv5 with automatic anchor learning, depthwise separable convolution, and channel pruning, reducing parameters below 8M. Studies applying YOLOv5 in agricultural pest detection incorporated ECA attention and BiFPN fusion, achieving a 4 – 6% increase in mAP. Li et al. [17] developed a lightweight version of YOLOv7 for Noctuidae detection, reducing model size by 30% and enabling 30 FPS real-time inference on UAV platforms; however, detection of dense Crambidae larvae in rice fields remained unsatisfactory. More recently, Fan et al. [18] embedded SimAM attention and NWD loss into the YOLOv8 backbone and neck for grape leaf disease detection, achieving a 90.4% mAP@0.5 and demonstrating superior fine-grained focus. Nevertheless, their approach did not specifically address pest morphology or leaf occlusion, nor was it validated on diverse rice pest datasets.

Addressing the challenges of small, irregular, and occluded pest targets in paddy fields, Dai et al. [19] proposed Deformable ConvNets, which allow convolutional sampling points to adaptively shift according to object contours, thereby improving feature alignment under occlusion and deformation. Zhu et al. [20] further enhanced this concept through the Modulated DCNv2, incorporating modulation mechanisms to refine sampling precision. In addition, bounding box regression losses have been shown to significantly affect localization accuracy for small objects. While the traditional IoU loss focuses only on overlap, it fails to account for center distance and aspect ratio. To address this, Rezatofighi et al. [21] proposed GIoU, and Zheng et al. [22] extended it to DIoU and CIoU, incorporating geometric penalties that improved convergence speed and localization precision. Building upon this, Bao et al. [23] introduced WIoU v3, which dynamically weights samples according to quality, emphasizing harder instances during training. This approach improved mAP@0.5:0.95 by 4.1% in dense rice pest detection scenarios.

Despite significant progress in lightweight architectures, attention mechanisms, deformable convolutions, and regression loss optimization, most existing studies focus on isolated module improvements. A unified framework that simultaneously addresses small target sensitivity, irregular shape modeling, and robust bounding box regression—while maintaining real-time performance—is still lacking. To bridge this gap, this study integrates Multilayer Contextual Attention (MLCA), Dynamic Snake Convolution (DSConv), and WIoU loss into the anchor-free YOLOv8n architecture. This comprehensive approach aims to achieve superior detection accuracy and robustness for rice pest detection under complex field conditions, enabling efficient deployment on UAV and edge platforms.

III. Proposed Method

This study focuses on the task of rice pest detection based on YOLOv8n, addressing challenges such as small target size,

weak texture features, and irregular pest contours. Based on the original framework, the following improvements are proposed: Firstly, Multilayer Contextual Attention (MLCA) is embedded after the SPPF module to fuse channel, spatial, local, and global contextual features, enhancing the model's responsiveness to weak textures in pest regions [24]. Secondly, the C2f-DS module is designed by replacing some standard convolutions in the original C2f structure with Dynamic Snake Convolution (DSConv), which adaptively learns offsets to capture irregular edges and deformable pest contours. Finally, Weighted IoU (WIoU) loss is adopted to replace CIoU, dynamically assigning gradient weights to samples of varying difficulty, thereby improving the robustness and convergence speed of bounding box regression for small pest targets.

While maintaining the lightweight advantages of YOLOv8n, these improvements jointly optimize the model's perception and localization of "small, dense, and weak" pest targets without significantly increasing computational cost. The overall framework of the proposed YOLO-Rice model is shown in Fig. 1, and the detailed design of each module is described in the following subsections.

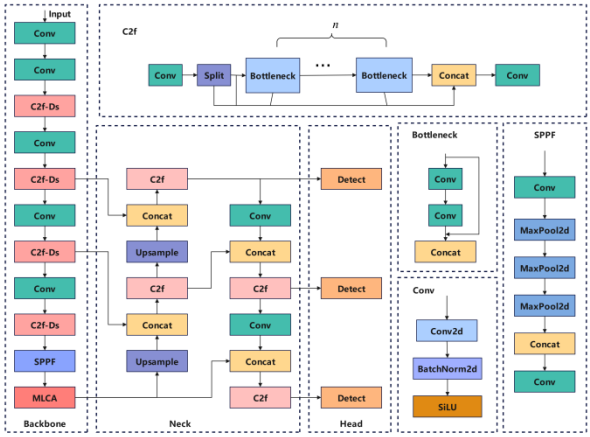

Fig. 1. Overall architecture of the proposed YOLO-Rice model.

A. Reconstruction of the Backbone Network

Rice pest targets are often extremely small and visually similar to the leaf background in both color and texture. Traditional convolutional operations struggle to distinguish pests from background interference, leading to frequent false detections and missed detections. Therefore, it is essential to enhance the model's focus on pest regions through an attention mechanism while maintaining lightweight efficiency. Existing attention modules, such as SE and CBAM, perform one-dimensional weighting along either the channel or spatial axis, which can result in the loss of local information for small targets [25].

To address this limitation, a Multilayer Contextual Attention (MLCA) mechanism is proposed and embedded after the SPPF module. The improved module fuses local pooling, global pooling, and one-dimensional convolution to achieve bidirectional attention across channel and spatial dimensions while integrating both local and global contexts. This structure provides more fine-grained feature enhancement, strengthening the network's feature extraction capability. The structure of MLCA is shown in Fig. 2.

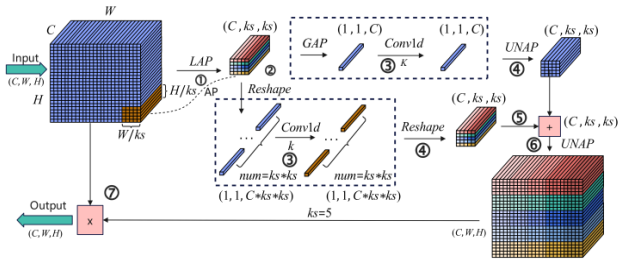

Fig. 2. MLCA structure.

As illustrated in Fig. 2, the MLCA module achieves fine-grained pest feature reinforcement through two collaborative dimensions: local – global complementarity and channel – spatial interaction. Specifically, the input feature map is first processed by Local Average Pooling (LAP) to extract coarse local features from subdivided sub-blocks. It is then divided into two branches: a global branch that applies Global Average Pooling (GAP) to highlight overall field-level context, and a local branch that reshapes the LAP output to preserve channel-level details within each subregion. Both branches are passed through 1D convolution (Conv1d) layers for channel compression and feature transformation. Subsequently, the features are restored to the original spatial resolution through reshaping and upsampling via Unpooled Average Pooling (UNAP), and the two branches are fused along the channel dimension to achieve semantic – detail interaction. Finally, the fused result is expanded to the input resolution and multiplied element-wise with the original feature map to generate a weighted feature map with stronger pest region responses. The functions of the key operations in the MLCA module are explained in Table I.

TABLE I. EXPLANATION OF KEY OPERATIONS IN THE MLCA MODULE

Operation	Role	Output
LAP	Preserve fine-grained spatial details (e.g., pest edges, feeding marks)	Local texture features
GAP	Compresses global context (e.g., leaf-background separation)	Global channel descriptor
UNAP	Aggregates neighborhood information to bridge local and global scales	Medium-scale context
Conv1D	Models inter-channel dependencies (kernel size=5)	Channel attention weights
Feature Fusion	Sums LAP, GAP, UNAP, then multiplies by the original feature map	Refined multi-scale features

To demonstrate the lightweight efficiency of MLCA, it is compared with SE and CBAM in terms of additional parameters, FLOPs, and mAP improvement. The results in Table II show that MLCA introduces only 0.12M parameters and 0.48 GFLOPs, significantly lower than CBAM, while achieving the highest mAP gain (+3.7% mAP@0.5). This confirms that MLCA provides superior feature discrimination with minimal computational overhead, making it ideal for real-time UAV deployment.

TABLE II. COMPARISON OF ATTENTION MODULES ON YOLOV8N BASELINE

Attention Module	Parameters (M)	FLOPs (G)	mAP@0.5 (%)	Δ mAP@0.5 (%)
None (baseline)	5.30	8.1	70.4	-
SE	5.41 (+0.11)	8.2	72.9	+2.5
CBAM	5.45 (+0.15)	8.3	74.2	+3.8
MLCA	5.42 (+0.12)	8.3	74.1	+3.7

B. C2f-DS Module with Dynamic Snake Convolution

Rice pests often exhibit non-rigid, elongated, or curved morphological structures. For instance, Crambidae larvae create irregular chewing marks along leaf edges; Cicadellidae closely resemble leaf textures and are easily overlooked; and Curculionidae often appear partially occluded due to their shrimp-like shapes. Traditional convolutions with fixed sampling points cannot adapt to such boundary variations, leading to decreased detection accuracy.

To overcome these limitations, Dynamic Snake Convolution (DSConv)—a deformable convolution variant capable of adaptively focusing on elongated and curved structures—is integrated into the C2f framework, resulting in a novel module termed C2f-DS. The architecture of DSConv is shown in Fig. 3.

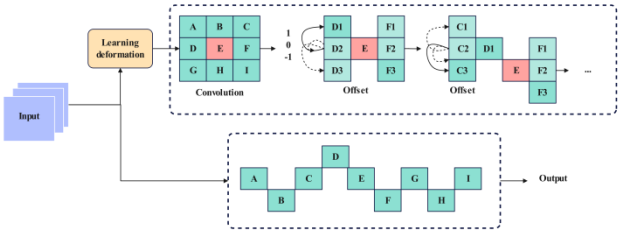

Fig. 3. Architecture of dynamic snake convolution.

The C2f module in YOLOv8n is a lightweight feature extraction unit that balances computational efficiency and representational power. DSConv is embedded into C2f rather than the backbone's basic convolutions or the neck for the following reasons. Firstly, feature hierarchy: C2f operates at multiple scales within the backbone, capturing both fine-grained details and semantic information. Embedding DSConv in C2f allows deformable sampling to be applied across a range of receptive fields, which is essential for detecting pests of varying sizes and deformations. Secondly, Computational efficiency: Replacing all backbone convolutions with DSConv would significantly increase parameters and inference time. C2f already contains a split-and-merge design; replacing only a portion of its standard convolutions with DSConv minimizes additional cost while preserving the benefits of deformable convolution. Finally, Residual integration: The C2f structure inherently includes residual connections, which help stabilize training when introducing dynamic offsets. This mitigates the risk of gradient oscillation caused by excessive deformation [26].

As illustrated in Fig. 4, the proposed C2f-DS module introduces an iterative "snake-like" offset mechanism based on deformable convolution and deeply integrates it within the original C2f structure. This design improves feature extraction while maintaining computational efficiency. Specifically, C2f-DS dynamically samples local pest regions, adaptively capturing irregular leaf-edge contours caused by Crambidae larvae and subtle differences between Cicadellidae nymphs and leaf veins. This significantly enhances the model's ability to fit small pest boundaries. Unlike stacking multiple deformable convolutions, C2f-DS replaces only part of the standard convolutional kernels in C2f, preserving the residual and channel-split design. As a result, the number of parameters and computational cost remain close to those of YOLOv8n, with negligible impact on inference speed.

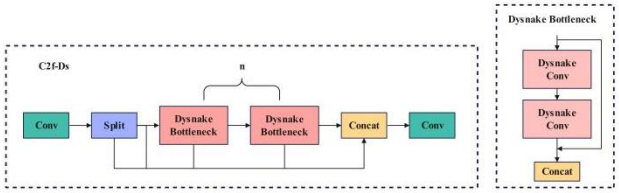

Fig. 4. Structure of the C2f-DS module.

TABLE III. COMPARISON BETWEEN DSCONV (C2F-DS) AND STANDARD CONVOLUTION

Aspect	Standard Convolution	DSConv (C2f-DS)
Sampling positions	Fixed grid, axis-aligned	Adaptive offsets, distributed along target contours
Adaptability to pest boundaries	Low – cannot fit curved or deformed edges	High – fits irregular contours of Crambidae, Curculionidae, etc.
Offset learning	Not applicable	Learned via lightweight auxiliary convolution (~3×3 depthwise)
Parameter increase	Baseline	<5% increase compared to standard C2f
Inference speed impact	Baseline	Comparable (~1–3 FPS drop on RTX 3060)
Best suited for	General feature extraction	Small, elongated, occluded, or clearly deformed pest targets

Unlike standard convolution with a fixed sampling grid, DSConv enhances the perception of irregular pest boundaries by learning adaptive offsets. Specifically, a lightweight auxiliary convolutional layer (typically a 3×3 depthwise convolution) takes the input feature map and predicts a 2D offset field $\triangle p_n$ for each sampling point p_n of the kernel. During training, these offsets are jointly optimized with the main network weights via backpropagation; bilinear interpolation is used to ensure differentiability of fractional sampling positions. At inference, the kernel samples features at shifted positions $p_n + \Delta p_n$, allowing the receptive field to "snake" along elongated or curved pest contours (e.g., the feeding edge of Cnaphalocrocis medialis larvae). Table III compares the key differences between DSConv in the C2f-DS module and standard convolution. It can be seen that DSConv significantly improves boundary fitting for deformable targets while maintaining a lightweight design.

Furthermore, a residual connection is introduced in the iterative offset process to improve training stability and mitigate gradient oscillations caused by excessive deformation. This module significantly enhances detection robustness and precision for small rice pests while maintaining a lightweight structure, making it well-suited for real-time UAV-based agricultural applications.

C. Weighted IoU (WIoU) Loss Function

In small-object pest detection, the precision of bounding box regression plays a crucial role in determining overall detection performance. The original YOLOv8n employs the Complete IoU (CIoU) loss, which simultaneously optimizes IoU, center distance, and aspect ratio. However, for extremely small, irregularly shaped, and background-blended pest targets, CIoU tends to overemphasize high-IoU samples, making it less effective for low-IoU or fuzzy-boundary samples. This often results in inaccurate bounding box regression and higher miss rates [27].

To address this issue, CIoU is replaced with the Weighted IoU (WIoU) loss function. WIoU introduces a dynamic focusing mechanism that adjusts gradient weights according to prediction quality, enabling the model to pay more attention to hard-to-fit small pest boundaries. The relationship between the ground truth and predicted bounding boxes is illustrated in Fig. 5.

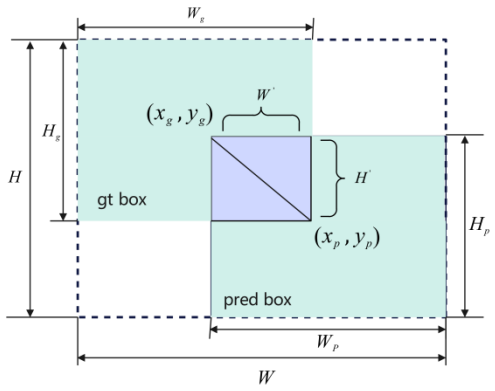

Fig. 5. Illustration of ground truth box and predicted box.

The key mathematical difference between CIoU and WIoU lies in how gradient weights are assigned. CIoU uses a fixed penalty term based on center distance and aspect ratio, treating all samples uniformly. In contrast, WIoU introduces a dynamic focusing coefficient that reduces the contribution of easy samples (high IoU) and amplifies the gradient for hard samples (low IoU). The WIoU loss is calculated as shown in Eq. (1)-(3).

$$L_{WIOU} = r \cdot L_{IOU} \tag{1}$$

$$r = \frac{\beta}{\delta \alpha^{\beta-\delta}} \tag{2}$$

$$\beta = \frac{(W - W_g)^2 + (H - H_g)^2}{{W_g}^2 + {H_g}^2} \tag{3}$$

where, β is the outlier degree, and α, δ are hyperparameters controlling the focusing strength. The weighting factor r dynamically adjusts the gradient magnitude: for samples with small β (easy samples, high IoU), r is small, reducing their contribution; for samples with large β (hard samples, low IoU), r approaches 1, emphasizing the loss. This mechanism forces the network to prioritize poorly localized small targets, resulting in more precise bounding box predictions, especially for occluded or irregularly shaped pests.

IV. Experiments and Analysis

A. Dataset and Experimental Setup

This study targets 11 common rice pest species: Curculionidae, Delphacidae, Cicadellidae, Phlaeothripidae, Cecidomyiidae, Hesperiidae, Crambidae, Chloropidae, Ephydridae, Noctuidae, and Thripidae. The dataset contains 4,559 pest instances manually annotated in YOLO format using LabelImg. The images were split into training, validation, and test sets at a ratio of 7:2:1, resulting in 3,191, 911, and 457 images, respectively, while maintaining class balance across subsets. As shown in Fig. 6, Delphacidae and Cicadellidae dominate the dataset, while Thripidae and Noctuidae are underrepresented, exhibiting a clear long-tail distribution. The bounding box widths and heights are mostly concentrated in small-scale regions (normalized values between 0.0 and 0.4), indicating that most pest targets are small and morphologically diverse.

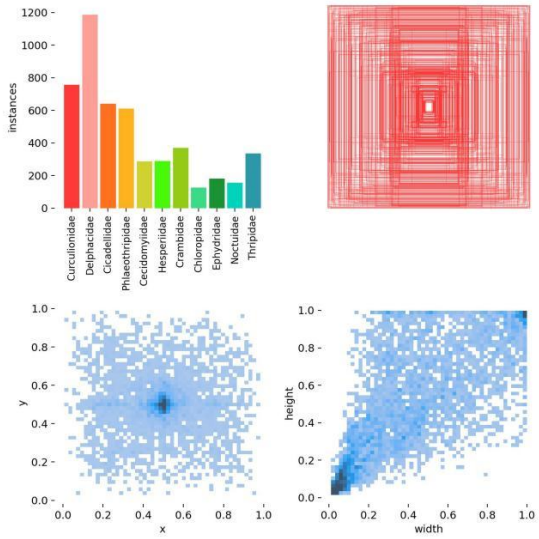

Fig. 6. Distribution of target categories and sizes in the training set.

Partial samples of rice pests are shown in Fig. 7.

Fig. 7. Partial samples of rice pests.

All experiments were conducted on a Windows 11 system with an Intel Core i9-13900H CPU and an NVIDIA GeForce RTX 3060 GPU. Training was accelerated using PyTorch 2.1.0 with CUDA 11.8. All models were trained under identical hyperparameters: the SGD optimizer with 200 epochs, a batch size of 64, and an initial learning rate of 0.01.

B. Evaluation Metrics

To comprehensively evaluate the proposed method, three key metrics are employed: Precision (P), Recall (R), and Mean Average Precision (mAP) to validate the detection accuracy, while Parameter Count and Frame Rate (FPS) assess the model compactness and speed. These metrics are defined as shown in Eq. (4)-(7).

$$P = \frac{TP}{(TP + FP)} \tag{4}$$

$$R = \frac{TP}{TP + FN} \tag{5}$$

$$mAP = \frac{\sum_{i=1}^{c} AP_i}{c} \tag{6}$$

$$FPS = \frac{1000ms}{(t1 + t2 + t3)} \tag{7}$$

Here, TP denotes the number of correctly predicted positive samples, FP indicates the number of incorrectly predicted negative samples, FN represents the number of missing targets among the correct ones, c stands for the number of defect categories, t1 is the image preprocessing time, t2 is the image inference time, and t3 is the post-processing time.

C. Ablation Experiments

To verify the effectiveness of the proposed Multilayer Contextual Attention (MLCA), C2f-DS module, and Weighted IoU (WIoU) loss function in the rice pest detection task, a series of ablation experiments were designed and conducted. All experiments were based on the YOLOv8n architecture as the baseline model. Under identical dataset partitioning, data augmentation strategies, and hyperparameter configurations, each improvement module was progressively introduced to quantitatively evaluate the individual contributions and synergistic effects. The experimental results are shown in Table IV.

TABLE IV. ABLATION EXPERIMENT RESULTS

Configuration	Precision	Recall	mAP@0.5	mAP@0.5:0.95	Parameters (M)
Baseline	0.800	0.632	0.704	0.562	5.3
+ MLCA	0.823	0.658	0.741	0.595	5.4
+ C2f-DS	0.816	0.652	0.734	0.588	6.8
+ WIoU	0.812	0.645	0.729	0.580	5.3
MLCA + C2f-DS	0.836	0.678	0.762	0.612	6.9
MLCA + WIoU	0.828	0.665	0.752	0.603	5.4
C2f-DS + WIoU	0.825	0.662	0.748	0.599	6.8
YOLO-Rice	0.848	0.699	0.787	0.634	7.8

From the experimental results in Table IV, it can be observed that each improvement module effectively enhances model performance. When introduced individually, MLCA, C2f-DS, and WIoU improve mAP@0.5 by 3.7%, 3.0%, and 2.5%, respectively, validating their independent effectiveness in feature enhancement, deformable modeling, and regression optimization. In terms of module combinations, the combination of MLCA and C2f-DS achieves the most prominent synergistic effect, with mAP@0.5 reaching 0.762, representing improvements of 2.1% and 2.8% compared to using each module alone, indicating a significant complementary effect between the attention mechanism and deformable convolution. The combinations of MLCA with WIoU and C2f-DS with WIoU also demonstrate favorable synergistic effects. Finally, the YOLO-Rice model, which fully integrates all three modules, achieves optimal performance across all evaluation metrics, with Precision, Recall, mAP@0.5, and mAP@0.5:0.95 reaching 0.848, 0.699, 0.787, and 0.634, respectively, representing improvements of 4.8%, 6.7%, 8.3%, and 7.2% compared to the baseline YOLOv8n. Although the number of parameters increases from 5.3M to 7.8M, the model still maintains a real-time inference speed of 62 FPS, meeting the deployment requirements for UAVs and edge devices. In summary, the ablation experiments fully validate the individual effectiveness and combined synergy of the MLCA, C2f-DS, and WIoU modules in the rice pest detection task. The three modules work together from three dimensions—feature enhancement, deformable modeling, and regression optimization—forming a comprehensive detection optimization system.

D. Comparison of Dysnake Conv Embedding Across Different C2f Layers

To further investigate the influence of DSConv placement within the backbone, embedding DSConv into C2f_1 (shallow), C2f_2 (middle), C2f_3 (deep), and C2f_4, as well as combinations thereof, was compared against the baseline model with standard convolutions. Only the C2f structure at the specified layers was modified; all other configurations remained unchanged. The results are shown in Table V.

TABLE V. EXPERIMENTAL RESULTS OF DSCONV EMBEDDING AT DIFFERENT C2F LAYERS

Dysnake Conv Embed location	Precision	Recall	mAP@0.5	mAP@0.5：0.95	Parameters (M)
No replacement	0.800	0.632	0.704	0.562	5.3
C2f_1	0.810	0.648	0.718	0.576	5.6
C2f_2	0.816	0.652	0.734	0.588	5.8
C2f_3	0.808	0.644	0.725	0.581	6.8
C2f_4	0.803	0.640	0.717	0.573	6.1
C2f_2+C2f_3	0.823	0.662	0.745	0.599	6.5
C2f_1 + C2f_2 + C2f_3	0.829	0.668	0.752	0.605	7.0
C2f_3 + C2f_4	0.819	0.656	0.740	0.593	6.3
Replace All	0.833	0.670	0.760	0.610	7.4

The results indicate that applying DSConv across all four C2f layers significantly enhances multi-scale feature extraction—from fine-grained leaf textures to overall pest semantics—especially for small, deformed, and partially occluded pests such as Crambidae and Delphacidae. Compared to replacing only middle and deep layers, the full-layer configuration increased mAP@0.5 to 0.760 (+1.5%) and mAP@0.5:0.95 to 0.610 (+1.1%), while Precision and Recall reached 0.833 and 0.670, respectively. Although this setup increased parameters by 2.1M, the detection precision and robustness in complex rice-field backgrounds improved significantly, validating the advantage of multi-level collaborative modeling of deformable pest features.

E. Comparison of Attention Mechanisms

This section compares the proposed MLCA with other mainstream attention mechanisms, including Squeeze-and-Excitation (SE), Convolutional Block Attention Module (CBAM), and Coordinate Attention (CA). All models were built upon YOLOv8n, differing only in the attention module applied. Training configurations were identical across all experiments. The results are presented in Table VI.

TABLE VI. COMPARISON OF ATTENTION MECHANISMS

Model Version	Precision	Recall	mAP@0.5	mAP@0.5:0.95
Baseline_NoAttn	0.800	0.632	0.704	0.562
SE_Attn	0.812	0.645	0.729	0.579
CA_Attn	0.818	0.650	0.735	0.586
CBAM_Attn	0.821	0.654	0.742	0.592
MLCA_Attn	0.823	0.658	0.741	0.595

As shown in Table VI, SE improved mAP@0.5 from 0.704 to 0.729 and mAP@0.5:0.95 from 0.563 to 0.579, demonstrating its effectiveness in suppressing background noise. CA, which captures long-range spatial dependencies, further improved mAP@0.5 to 0.735 and mAP@0.5:0.95 to 0.586. CBAM, integrating both channel and spatial attention, yielded mAP@0.5=0.742 and mAP@0.5:0.95=0.592. The proposed MLCA achieved the highest overall performance, with mAP@0.5:0.95=0.595, Precision=0.823, and Recall=0.658. These results highlight that MLCA provides stronger robustness and localization accuracy by jointly modeling weak pest details and global contextual semantics.

F. Comparison of Loss Functions

This section evaluates the impact of different bounding box regression loss functions. The default CIoU loss in YOLOv8n was replaced with GIoU, DIoU, and WIoU, while maintaining identical training settings. The results are shown in Table VII.

TABLE VII. COMPARISON OF LOSS FUNCTIONS

Model Version	Precision	Recall	mAP@0.5	mAP@0.5:0.95
Baseline_CIoU	0.800	0.632	0.704	0.562
GIoU_Loss	0.801	0.628	0.701	0.553
DIoU_Loss	0.806	0.635	0.710	0.559
WIoU_Loss	0.812	0.645	0.729	0.580

The results show that incorporating center distance and aspect ratio constraints (DIoU, CIoU) improves regression precision and convergence compared to IoU and GIoU. Building upon this, WIoU introduces sample difficulty-aware weighting, allowing the model to focus more on hard-to-detect small or occluded pests. Compared with CIoU, WIoU achieved improvements across all metrics: Precision increased from 0.800 to 0.812, Recall from 0.632 to 0.645, mAP@0.5 by 2.5%, and

mAP@0.5:0.95 by 1.8%. These results confirm that WIoU enhances the alignment between predicted and ground-truth boxes while effectively suppressing training noise from anomalous samples, yielding more stable and generalized detection across multiple IoU thresholds.

G. Comparison with State-of-the-Art Models

To comprehensively evaluate the overall performance of the proposed YOLO-Rice model in the rice pest detection task, this section compares it with several mainstream object detection algorithms. All compared models were trained and tested under identical dataset partitioning, data augmentation strategies, and hyperparameter configurations to ensure fairness. The experimental results are shown in Table VIII.

As shown in Table VIII, YOLO-Rice achieves the best detection performance among all compared models. As traditional detectors, Faster R-CNN and SSD achieve mAP@0.5 of 0.668 and 0.652, respectively, but their large parameter sizes and low inference speeds make them unsuitable for real-time UAV monitoring. Among the lightweight YOLO series models, YOLOv5s, YOLOv7, YOLOv8n, YOLOv9, YOLOv10n, and YOLOv11n all demonstrate a good balance between accuracy and speed. Notably, YOLOv11n achieves a mAP@0.5 of 0.740 and an inference speed of 150 FPS with only 5.5M parameters, exhibiting excellent lightweight performance. Building upon this, the proposed YOLO-Rice model achieves further optimization, with mAP@0.5 reaching 0.787, representing improvements of 8.3% over the baseline YOLOv8n and 4.7% over the latest YOLOv11n. The mAP@0.5:0.95 reaches 0.634, an improvement of 7.2% over YOLOv8n. Precision and Recall reach 0.848 and 0.699, respectively, representing increases of 4.8% and 6.7% compared to YOLOv8n. In terms of inference speed, YOLO-Rice achieves 138 FPS on an RTX 4090, far exceeding the minimum frame rate requirement for real-time detection, fully validating its ability to achieve significant detection accuracy improvements while maintaining lightweight characteristics.

TABLE VIII. PERFORMANCE COMPARISON OF DIFFERENT DETECTION MODELS ON THE RICE PEST DATASET

Model	Precision	Recall	mAP@0.5	mAP@0.5:0.95	FPS (4090)	Params (M)
Faster R-CNN	0.756	0.582	0.668	0.512	42	41.5
SSD (VGG16)	0.742	0.568	0.652	0.498	85	26.3
YOLOv5s	0.780	0.600	0.680	0.535	156	7.2
YOLOv7	0.790	0.620	0.700	0.552	128	36.9
YOLOv8n	0.800	0.632	0.704	0.562	142	5.3
YOLOv9	0.818	0.655	0.726	0.578	135	8.9
YOLOv10n	0.815	0.655	0.725	0.576	148	5.7
YOLOv11n	0.825	0.670	0.740	0.589	150	5.5
YOLO-Rice	0.848	0.699	0.787	0.634	138	7.8

H. Confusion Matrix Analysis

To further analyze the classification performance of the YOLO-Rice model across different rice pest categories, this section presents the normalized confusion matrices, as shown in Fig. 8. Rows of the confusion matrix represent ground-truth labels, columns denote model predictions, and diagonal elements indicate the correct classification ratios for each category, while off-diagonal elements reflect misclassification cases. The confusion matrix enables intuitive evaluation of the model's recognition capability for individual pest categories and the degree of confusion between classes.

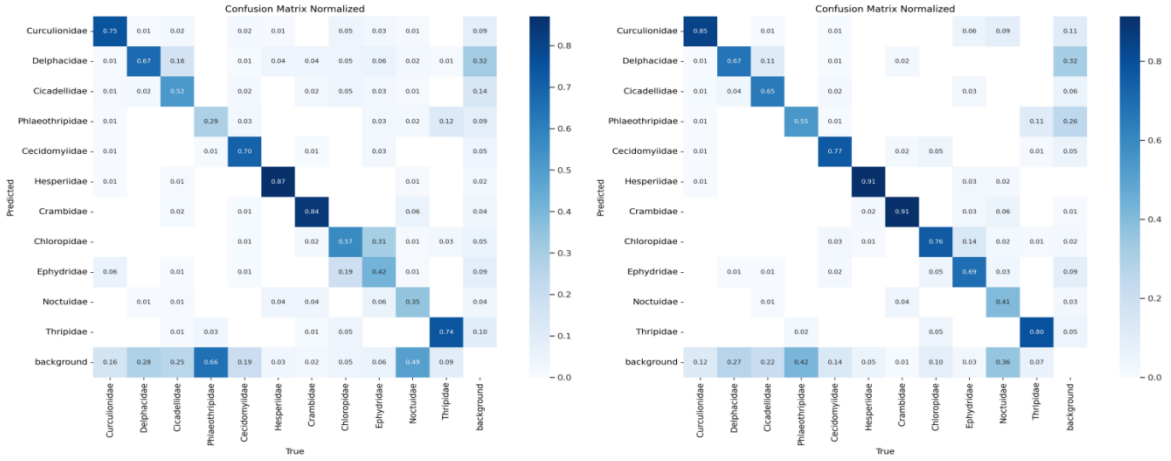

Fig. 8. Confusion matrix: YOLOv8 (left) and YOLO-Rice (right).

As observed from Fig. 8, YOLO-Rice achieves a significant improvement in overall classification accuracy, with substantial increases in the recall rates of most categories. Specifically, the recall for Curculionidae rises from 0.75 to 0.85, for Phlaeothripidae from 0.29 to 0.55, for Ephydridae from 0.42 to 0.69, for Hesperiidae and Crambidae both reaching 0.91, and for Thripidae up to 0.80. Only Delphacidae remains unchanged at 0.67, and Noctuidae sees a slight increase to 0.41. These results demonstrate that the model significantly enhances its ability to identify difficult-to-classify samples and categories with similar morphological features, while also reducing inter-class confusion notably—for instance, the confusion between Ephydridae and Chloropiidae decreases from 0.31 to 0.05. The sole exception is the background class, whose recall drops from 0.66 to 0.42. This decline primarily arises from the model's increased focus on recognizing insect categories, leading to exacerbated misclassification of background regions (e.g., leaf shadows, water reflections, dead spots) as pest taxa such as Phlaeothripidae. While this trade-off is acceptable in some practical applications, it still calls for further optimization to reduce false positives. To address this issue, future work will adopt three strategies: 1) introducing a background suppression loss term that penalizes false positives of the background class; 2) augmenting the training set with diverse negative samples (e.g., empty paddy field images under various lighting conditions); and 3) applying class-balanced sampling or a variant of Focal Loss to down-weight easily confused background patterns. These measures aim to maintain high recall for pest targets while effectively controlling background misclassification, thereby improving overall robustness in real-world paddy field environments. Overall, the proposed YOLO-Rice model, through optimized feature extraction, network architecture, and data augmentation, effectively improves the accuracy and robustness of insect family classification, and the above-mentioned strategies will further enhance its practical deployability.

I. Visualization Analysis of Detection Results

To intuitively demonstrate the practical performance of the proposed YOLO-Rice algorithm in rice pest detection tasks, this study selects detection results from various complex field scenarios for visual comparison and analysis. The Precision–Recall curves before and after improvement are shown in Fig. 9, and the visualization results are presented in Fig. 10.

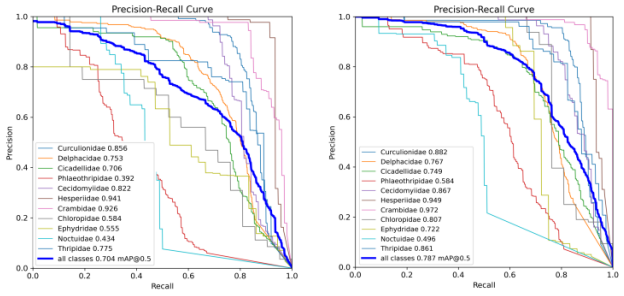

Fig. 9. Precision-recall curve.

Fig. 9 presents the Precision-Recall (PR) curves of the baseline YOLOv8n and the proposed YOLO-Rice model across 11 categories of rice pests. The proposed model achieves a significant overall improvement, with mAP@0.5 increasing from 0.704 to 0.787 (+8.3%). Notably, recognition accuracy for Noctuidae, Delphacidae, and Cicadellidae—categories typically characterized by small size and high occlusion—exhibits remarkable gains of 5.2%, 1.4%, and 4.3%, respectively. This improvement demonstrates that the integration of MLCA and DSConv effectively enhances the model's capacity to distinguish fine-grained pest textures and irregular contours under complex paddy field conditions. The optimized WIoU loss further contributes to improved bounding box regression accuracy, particularly for small and partially occluded targets, resulting in smoother PR curves and higher overall stability across all classes. The before-and-after detection effects are shown in Fig. 10.

As shown in Fig. 10, baseline algorithms such as YOLOv5, YOLOv7, and the lightweight YOLOv8n generally exhibit low detection confidence for Delphacidae, mostly concentrated in the range of 0.28–0.44. These methods suffer from obvious missed detections in dense pest scenarios, poor adaptability to small pests against complex backgrounds such as rice stems and leaves, and insufficient bounding box localization accuracy. Although YOLOv11 improves detection confidence to the range of 0.27–0.68 and slightly increases the number of detected targets, it still suffers from missed detections and exhibits misclassification of pests with similar morphology (e.g., Cicadellidae), indicating limited capability in recognizing densely aggregated targets. In contrast, the proposed algorithm achieves significant improvements in detection completeness, confidence stability, and small-target recognition accuracy. The confidence scores for Delphacidae are stably distributed between 0.57 and 0.91, with most targets exceeding 0.80. In dense scenes, it achieves nearly full coverage detection, with bounding boxes that more closely fit pest contours and no cross-category misclassifications. These results fully validate the robustness and detection advantage of the proposed method in complex rice field scenarios.

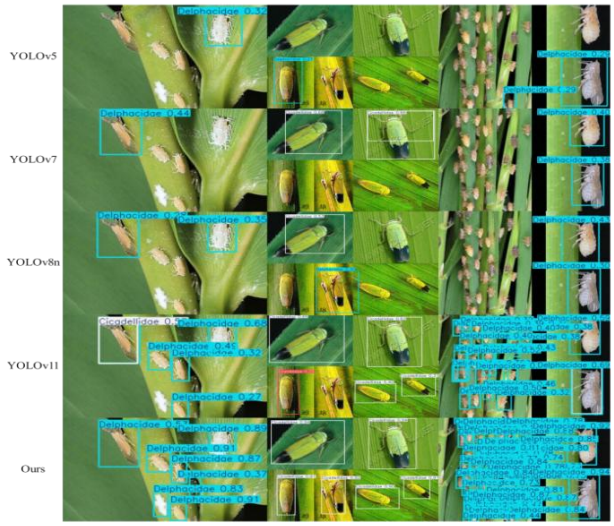

Fig. 10. Visualization comparison of pest detection results by different YOLO algorithms.

Overall, the visualized results substantiate that the proposed YOLO-Rice framework not only achieves quantitative gains in

mAP, Precision, and Recall but also qualitatively improves interpretability and robustness in practical field detection scenarios. These results validate the effectiveness of the proposed attention–deformation–loss joint optimization strategy, highlighting its potential for real-time deployment on UAV-based precision pest monitoring platforms.

V. Conclusion and Future Work

This study proposes YOLO-Rice, a lightweight and high-precision detection model designed for rice pest detection in scenarios characterized by small object size, irregular morphology, dense distribution, and complex backgrounds. Built upon the YOLOv8n framework, the model incorporates three major improvements: 1) the Multilayer Contextual Attention (MLCA) module enhances feature extraction by jointly modeling channel, spatial, and contextual information, thereby improving the model's focus on subtle pest regions; 2) the C2f-DS module integrates Dynamic Snake Convolution (DSConv) to adaptively capture irregular pest contours and deformed structures, significantly enhancing the perception of small and complex targets; and 3) the Weighted IoU (WIoU) loss function replaces CIoU, dynamically adjusting gradient weights to emphasize hard and small samples, thus improving bounding box regression accuracy and robustness.

Experiments on a custom dataset containing 11 common rice pest categories demonstrate that YOLO-Rice achieves a Precision of 84.8%, Recall of 69.9%, mAP@0.5 of 78.7%, and mAP@0.5:0.95 of 63.4%, showing clear superiority over the baseline YOLOv8n. Ablation and comparative experiments verify the effectiveness of each proposed module and the rationality of their integration. Moreover, the model maintains high inference speed (62 FPS on an RTX 3060), satisfying real-time detection requirements for UAV and edge computing platforms.

Notably, the recall of 69.9% indicates that about 30% of pest instances are missed, mainly consisting of extremely small targets (e.g., Thripidae), heavily occluded targets (e.g., Crambidae larvae under leaves), and targets blending into background textures (e.g., Cicadellidae). Future work will address these issues via super-resolution branches, Transformer-based global context modeling, and hard example mining.

Meanwhile, several limitations remain. The dataset was collected from a single growing region, leaving cross-regional generalization unvalidated. The dataset exhibits a long-tail distribution, with Thripidae and Noctuidae underrepresented (AP of 0.52 and 0.48). Test conditions are ideal (daytime, clear weather), excluding low-light, rainy, or motion-blurred scenarios common in UAV deployment. Deployment on edge devices would require further quantization and pruning. Based on the above analysis, future research will focus on: integrating Transformer or self-supervised pre-training for tiny low-texture pests; temporal modeling for UAV video streams; expanding the dataset to cross-regional and degraded-condition samples; model quantization and pruning for embedded devices; and, after augmentation and optimization, making the self-constructed dataset publicly available to facilitate independent replication and follow-up studies.

***Abstract*—This study proposes a data-driven excimer LiDAR framework for joint surface reflectivity mapping and atmospheric pollutant profiling, integrating physics-based sensing with deep learning-based multi-source data fusion. The system utilizes ultraviolet excimer LiDAR measurements in combination with auxiliary data from UAV platforms, satellite observations, and ground-based sensors to construct a unified environmental monitoring pipeline. A structured signal processing approach is applied to extract physically meaningful features, including backscatter and extinction coefficients, as well as differential absorption parameters. These features are subsequently fused using a deep learning architecture designed to model complex nonlinear relationships across heterogeneous data sources. Experimental results demonstrate that the proposed method achieves high predictive accuracy, with improved correlation and reduced error compared to traditional LiDAR and baseline fusion approaches. The framework effectively captures both vertical atmospheric pollutant distributions and horizontal surface reflectivity patterns, enabling comprehensive environmental analysis. Validation against external datasets confirms the robustness and generalization capability of the model under varying conditions. The integration of data-driven modeling with excimer LiDAR sensing enhances system performance while maintaining real-time capability. Overall, the proposed approach provides a scalable and efficient solution for advanced environmental monitoring, contributing to the development of intelligent remote sensing systems for air quality assessment and land-cover analysis.**

I. Introduction

Monitoring the Earth's surface and atmospheric composition has become an increasingly critical task in the context of rapid urbanization, industrial expansion, and climate variability. Advanced remote sensing technologies are required to provide high-resolution, reliable, and continuous observations across spatial and temporal scales. Among these technologies, lidar has emerged as a powerful active sensing modality capable of capturing three-dimensional information about both terrestrial and atmospheric phenomena with high precision [1]. Unlike passive sensing approaches, lidar systems operate independently of solar illumination, enabling consistent data acquisition under diverse environmental conditions, including low-light and nighttime scenarios [2]. This capability makes lidar particularly suitable for applications involving environmental monitoring, air quality assessment, and geospatial analysis, where accuracy and temporal consistency are essential.

Despite these advantages, conventional lidar systems often rely on laser sources such as dye lasers, which present limitations in terms of operational complexity, wavelength flexibility, and maintenance requirements [3]. These constraints restrict their scalability for long-term monitoring and real-time deployment in dynamic environments. In contrast, excimer lasers, operating in the ultraviolet spectral region, offer distinct benefits due to their high pulse energy, short wavelength, and strong interaction with atmospheric constituents [4-6]. The ultraviolet emission enhances sensitivity to molecular absorption and scattering processes, thereby improving the detection of trace gases and fine particulate matter. Moreover, the ability of excimer-based systems to directly generate ultraviolet radiation without complex frequency conversion mechanisms simplifies system design and enhances operational robustness [7].

Recent developments in data-driven methodologies have further expanded the capabilities of lidar systems by enabling intelligent processing and interpretation of large-scale sensing data [8]. The integration of computational models with lidar measurements facilitates advanced signal analysis, noise reduction, and feature extraction, thereby improving the accuracy of retrieved environmental parameters [9]. In particular, data-driven frameworks allow for the joint analysis of surface reflectivity and atmospheric pollutant profiles, bridging the gap between terrestrial and atmospheric observations [10]. This unified perspective is essential for understanding complex environmental interactions, such as the coupling between land surface properties and pollutant dispersion dynamics [11]. Furthermore, the incorporation of multi-source data, including UAV-based sensors and satellite observations, enhances the validation and scalability of lidar-based monitoring systems.

*Corresponding author.

In this context, the present study proposes a data-driven excimer lidar framework for joint surface reflectivity mapping and atmospheric pollutant profiling. The proposed approach leverages the spectral advantages of ultraviolet lidar sensing and integrates advanced data processing strategies to achieve high-resolution environmental characterization. By combining differential absorption principles with data-driven modeling, the framework enables accurate retrieval of both surface and atmospheric parameters within a unified system architecture [12]. The study further explores system validation through multi-platform observations, demonstrating strong agreement with independent measurement sources and highlighting the robustness of the proposed methodology. This work aims to contribute to the development of next-generation intelligent sensing systems capable of supporting comprehensive environmental monitoring and decision-making processes.

II. Related Works

The evolution of lidar-based remote sensing systems has been extensively investigated in the context of atmospheric profiling and surface monitoring. Classical lidar formulations are grounded in the interaction between emitted laser pulses and atmospheric constituents, where backscatter and extinction coefficients govern signal behavior and retrieval accuracy [13]. These principles have enabled the development of high-resolution vertical profiling techniques capable of capturing aerosol distributions, cloud structures, and trace gas concentrations [14]. Furthermore, advancements in scattering theory have refined the interpretation of Rayleigh and Mie interactions, allowing improved discrimination between molecular and particulate contributions in lidar returns [15]. Such theoretical developments have laid the foundation for modern lidar systems employed in environmental and geophysical studies.

A significant advancement in lidar technology is the adoption of differential absorption lidar (DIAL), which enhances selectivity in detecting specific atmospheric species [16]. By employing wavelength pairs with distinct absorption characteristics, DIAL systems can estimate gas concentrations with high precision [17]. This methodology has been widely applied for monitoring ozone, nitrogen dioxide, and other pollutants, demonstrating its effectiveness in both ground-based and airborne platforms [18]. Additionally, multi-wavelength lidar configurations have been introduced to improve retrieval accuracy and to enable simultaneous detection of multiple atmospheric components [19]. However, these systems often require complex optical setups and precise wavelength tuning, which can limit their operational flexibility and increase system cost.

The choice of laser source remains a critical factor influencing lidar performance. Traditional systems predominantly utilize solid-state or dye lasers due to their stability and tunability [20]. Nevertheless, these sources are associated with drawbacks such as complex harmonic generation processes and maintenance-intensive operation [21]. Recent studies have explored alternative laser technologies, including excimer and ultrafast laser systems, which offer direct ultraviolet emission and enhanced interaction with atmospheric molecules [22]. Ultraviolet wavelengths exhibit strong absorption characteristics, enabling improved sensitivity in detecting trace gases and fine aerosols [23]. Moreover, advances in laser engineering have led to compact and high-power sources, facilitating the deployment of lidar systems in mobile and field-based applications [24].

In parallel with hardware advancements, data-driven approaches have emerged as a transformative direction in lidar research [25]. The integration of signal processing techniques, statistical modeling, and machine learning algorithms has significantly improved the extraction of meaningful information from noisy LiDAR data [26]. Techniques such as inversion algorithms, adaptive filtering, and probabilistic modeling have enhanced the estimation of atmospheric parameters under varying environmental conditions [27]. Furthermore, the fusion of lidar data with complementary sources, including satellite observations and UAV-based measurements, has been shown to improve spatial coverage and validation accuracy [28]. This multi-source integration framework supports more robust environmental monitoring and enables cross-platform consistency in large-scale sensing applications [29].

Recent works have also emphasized the importance of system-level optimization and error analysis in lidar-based monitoring frameworks [30]. Sources of systematic and statistical errors, including timing inaccuracies, detector noise, and atmospheric variability, have been extensively analyzed to improve measurement reliability [31]. Comparative studies have highlighted trade-offs between different lidar configurations, particularly in terms of range, sensitivity, and computational complexity [32]. Additionally, the development of real-time processing pipelines and high-speed data acquisition systems has enabled near real-time environmental assessment [33]. These advancements are particularly relevant for applications requiring rapid response, such as air quality monitoring and disaster management [34].

Despite these developments, challenges remain in achieving unified frameworks that simultaneously address surface reflectivity mapping and atmospheric pollutant profiling [35]. Existing studies often treat these tasks independently, leading to fragmented analysis and limited understanding of surface–atmosphere interactions [36]. Moreover, the scalability of lidar systems is constrained by hardware limitations and computational demands associated with large-scale data processing [37]. Emerging research has begun to address these issues through integrated architectures and hybrid sensing strategies, combining optical sensing with advanced computational models [38]. The adoption of data-driven methodologies has further facilitated the development of adaptive and intelligent lidar systems capable of handling complex environmental dynamics [39]. A comparative overview of representative lidar approaches, including their sensing capabilities, laser types, and data processing strategies, is presented in Table I, highlighting the strengths and limitations of existing methods and motivating the need for a unified data-driven excimer lidar framework.

III. MATERIALS AND METHODS

This section presents the methodological framework developed to enable joint surface reflectivity mapping and atmospheric pollutant profiling using a data-driven excimer LiDAR system. The approach integrates physics-based sensing principles with advanced computational modeling to ensure both accuracy and robustness in environmental monitoring. Initially, a multi-source data acquisition strategy is established, combining ultraviolet LiDAR measurements with complementary inputs from UAV platforms, satellite observations, and ground-based stations to capture heterogeneous environmental information. Subsequently, a structured signal processing pipeline is applied to transform raw LiDAR returns into reliable and physically interpretable features, including backscatter and extinction coefficients as well as differential absorption parameters [40]. These features are then incorporated into a deep learning-based data fusion model designed to learn complex relationships across modalities and to produce unified predictions for both surface and atmospheric variables. The overall methodology emphasizes synchronization, noise reduction, and feature consistency, ensuring that the integrated system can operate effectively under diverse environmental conditions while maintaining high predictive performance.

A. System Architecture and Multi-Source Data Acquisition

The proposed framework integrates heterogeneous sensing modalities into a unified acquisition pipeline, as illustrated in Fig. 1. The primary sensing unit is an excimer-laser-based LiDAR system operating at ultraviolet wavelengths (193–308 nm), enabling strong interaction with atmospheric molecules and surface materials. The received backscattered signal $P(r)$ at range r is modeled using the standard lidar equation:

$$P(r) = \frac{C\,\beta(r)}{r^2}\exp\left(-2\int_0^r \alpha(s)\,ds\right) \quad (1)$$

where, C is the system constant, $\beta(r)$ is the backscatter coefficient, and $\alpha(r)$ is the extinction coefficient.

In parallel, auxiliary data streams are acquired from UAV-based sensors (gas concentration, meteorological parameters) [41], satellite platforms (reflectance, aerosol optical depth) [42], and ground-based stations (in-situ pollutant measurements) [43]. All data sources are synchronized using GPS-based timestamps:

$$t_{\text{aligned}} = \arg\min_t \sum_i |\, t_i - t\,| \quad (2)$$

ensuring temporal consistency across modalities. The aggregated dataset forms a multi-dimensional observation space:

$$\mathcal{D} = \{X^{\text{LiDAR}}, X^{\text{UAV}}, X^{\text{Sat}}, X^{\text{Ground}}\} \quad (3)$$

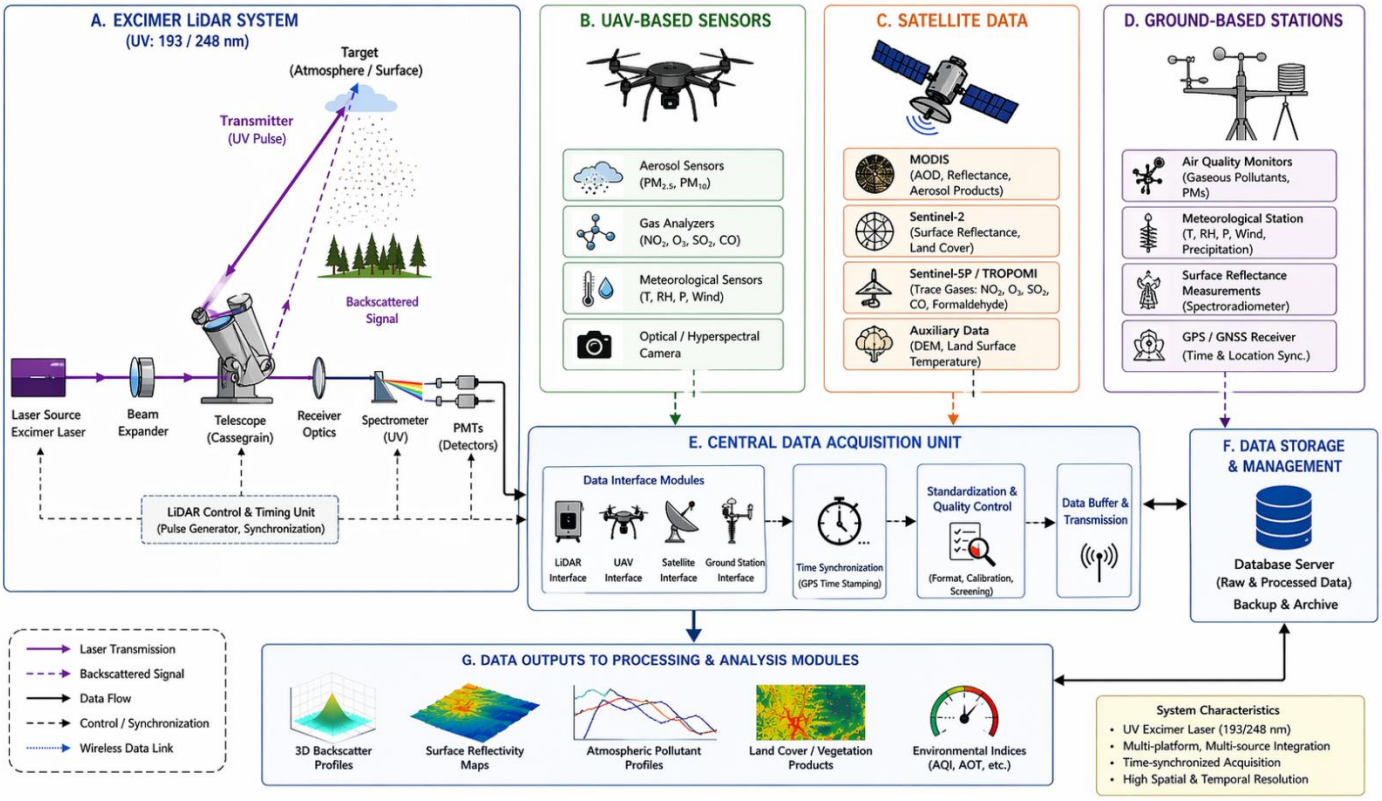

Fig. 1. System architecture and multi-source data acquisition.

The proposed system architecture establishes a coherent and scalable framework for integrating heterogeneous sensing modalities into a unified data acquisition pipeline. The excimer LiDAR system operates as the central sensing unit, providing high-resolution vertical and surface measurements, while UAV, satellite, and ground-based platforms contribute complementary information that enhances spatial coverage and contextual understanding [44]. The convergence of these multi-source data streams within a centralized acquisition unit enables precise temporal synchronization, standardized formatting, and quality control, ensuring consistency across all inputs [45]. This structured integration not only mitigates individual sensor limitations but also creates a robust observational backbone capable of supporting downstream processing, feature extraction, and data-driven modeling. Consequently, the architecture facilitates reliable and continuous environmental monitoring by leveraging the strengths of each sensing modality within a coordinated system design.

B. Signal Processing and Feature Extraction

Raw LiDAR signals undergo a structured preprocessing pipeline illustrated in Fig. 2. First, noise reduction is performed using temporal averaging:

$$P_1(r) = \frac{1}{N}\sum_{i=1}^{N} P_i(r) \tag{4}$$

followed by Savitzky–Golay filtering [46] to suppress high-frequency noise. Background subtraction removes sky noise:

$$P_2(r) = P_1(r) - B(r) \tag{5}$$

where, $B(r)$is estimated from far-range returns.

Range correction compensates for geometric spreading:

$$P_3(r) = P_2(r) \cdot r^2 \tag{6}$$

Subsequently, feature extraction is conducted. The backscatter coefficient is estimated as:

$$\beta(r) = \frac{P_3(r)}{C \cdot T^2(r)} \tag{7}$$

where, $T(r)$is atmospheric transmittance. The extinction coefficient is derived using inversion:

$$\alpha(r) = -\frac{1}{2}\frac{d}{dr}\ln\left(\frac{P_3(r)}{\beta(r)}\right) \tag{8}$$

For pollutant retrieval, the DIAL station is employed:

$$N(r) = \frac{1}{2(\sigma_{on}-\sigma_{off})}\frac{d}{dr}\ln\left(\frac{P_{off}(r)}{P_{on}(r)}\right) \tag{9}$$

All extracted features are stacked into a feature tensor:

$$F(r,x,y) = \{\beta(r), \alpha(r), N(r), \rho_s(x,y), S(\lambda)\} \tag{10}$$

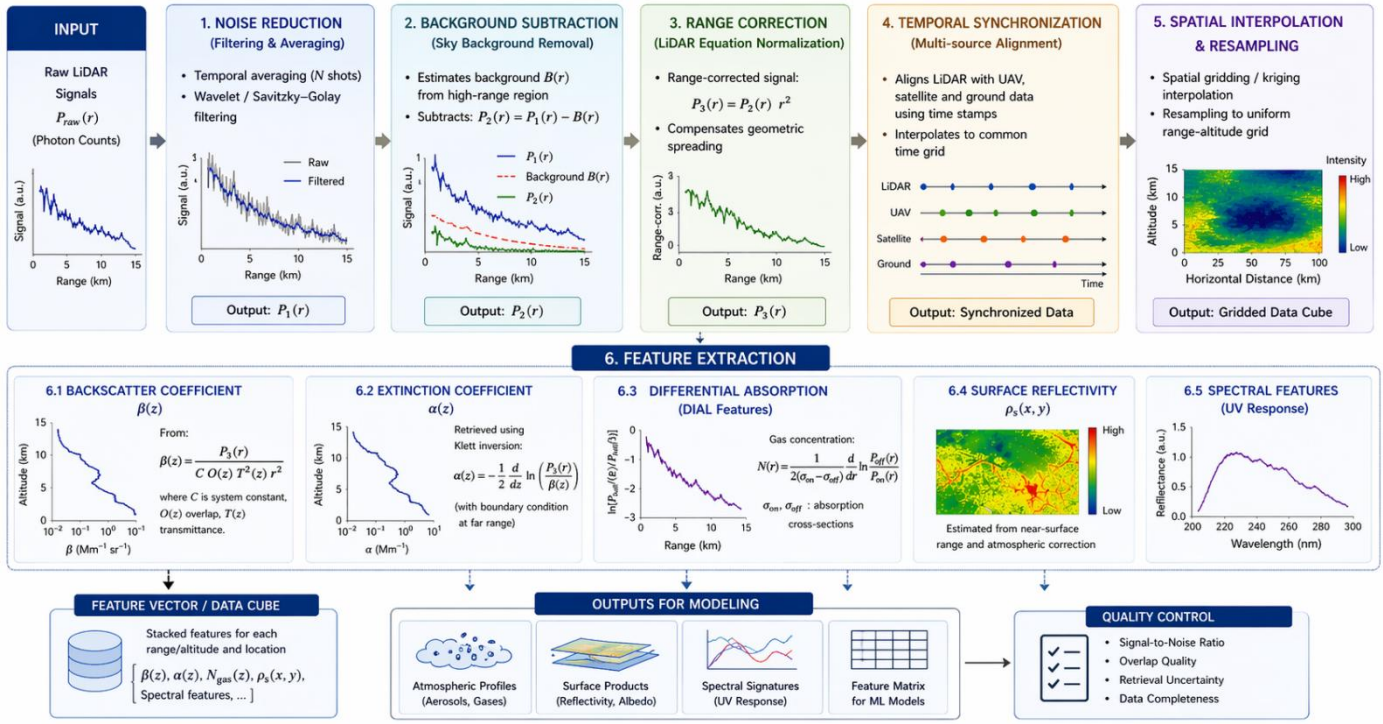

Fig. 2. Signal processing and feature extraction pipeline.

As depicted in Fig. 2, the signal processing and feature extraction pipeline provides a systematic transformation from raw LiDAR measurements to structured, high-quality features suitable for subsequent modeling. Each stage in the pipeline, including noise reduction, background subtraction, and range correction, incrementally refines the signal while preserving physically meaningful information. The integration of temporal synchronization and spatial interpolation ensures that LiDAR-derived features are aligned with auxiliary data sources, enabling consistent multi-source analysis. Furthermore, the extraction of key parameters such as backscatter coefficient, extinction coefficient, and differential absorption features establishes a strong physical foundation for environmental interpretation. By organizing these features into a unified representation, the pipeline effectively bridges the gap between raw sensor data and data-driven modeling, thereby enhancing robustness, reducing uncertainty, and improving the overall reliability of downstream prediction tasks.

C. Deep Learning-Based Data Fusion and Prediction Model

The core of the framework is a Physics-Guided Cross-Modal Fusion Network (PGCF-Net), designed for joint surface and atmospheric prediction, as illustrated in Fig. 3. Each modality is encoded using a learnable mapping:

$$Z_m = f_m(X_m; \theta_m), m \in \{\text{LiDAR, UAV, Sat, Ground}\}. \quad (11)$$

A cross-modal attention mechanism fuses latent features:

$$Z_{\text{fusion}} = \sum_m \omega_m \cdot Z_m, \sum_m \omega_m = 1, \quad (12)$$

where, weights ω_m are learned adaptively. To enforce physical consistency, a gating function is introduced:

$$g = \sigma(W_g Z_{\text{fusion}} + b_g), Z' = g \odot Z_{\text{fusion}}, \quad (13)$$

The unified decoder predicts outputs via multi-task learning:

$$\hat{Y}_s = f_s(Z'), \hat{Y}_p = f_p(Z'), \quad (14)$$

where, $\hat{Y}_s$is surface reflectivity and $\hat{Y}_p$is a pollutant profile.

The total loss function is defined as:

$$\mathcal{L} = \lambda_1 \mathcal{L}_{\text{surf}} + \lambda_2 \mathcal{L}_{\text{pollut}} + \lambda_3 \mathcal{L}_{\text{phys}} + \lambda_4 \mathcal{L}_{\text{reg}}, \quad (15)$$

ensuring both accuracy and physical plausibility.

Algorithm 1 shows a data-driven multi-source fusion framework.

Algorithm 1: Data-Driven Multi-Source Fusion Framework

Input: Multi-source data D = {LiDAR, UAV, Satellite, Ground}
Output: Surface map Ŷ_s and pollutant profiles Ŷ_p
1: Acquire synchronized data streams
2: Preprocess LiDAR signals (filtering, subtraction, correction)
3: Extract physical features β(r), α(r), N(r), ρ_s
4: Encode each modality using neural encoders
5: Perform cross-modal attention fusion
6: Apply a physics-guided gating mechanism
7: Decode fused features into outputs
8: Compute multi-task loss and update parameters
9: Return Ŷ_s, Ŷ_p

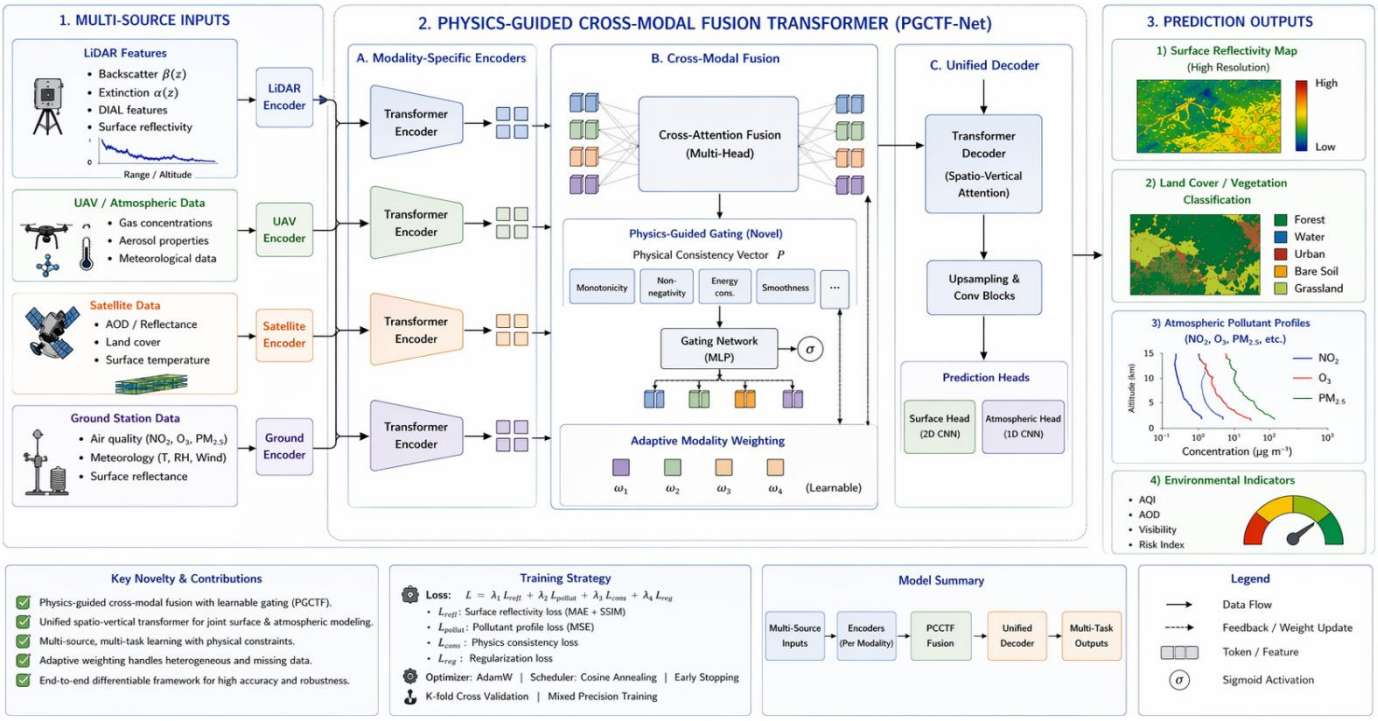

Fig. 3. Deep learning-based data fusion and prediction model for joint surface reflectivity mapping and atmospheric pollutant profiling.

As illustrated in Fig. 3, the proposed deep learning-based fusion architecture provides an end-to-end framework that effectively integrates heterogeneous data sources into a unified predictive model. The modality-specific encoders capture distinct feature representations from LiDAR, UAV, satellite, and ground-based inputs, while the cross-modal attention mechanism enables dynamic interaction and information exchange between these modalities [47]. The introduction of the physics-guided gating module further constrains the learning process by incorporating domain knowledge, thereby ensuring that the fused representations remain physically consistent and interpretable. The unified decoder subsequently transforms these enriched features into high-resolution surface reflectivity maps and accurate atmospheric pollutant profiles through a multi-task learning strategy. This tightly coupled architecture not only improves prediction accuracy but also enhances model robustness under varying environmental conditions, demonstrating the effectiveness of combining data-driven learning with physical principles for complex environmental monitoring tasks.

IV. Results

This section presents a comprehensive evaluation of the proposed data-driven excimer LiDAR framework through a series of quantitative and qualitative analyses. The results are structured to progressively demonstrate the effectiveness of the system, beginning with the assessment of LiDAR signal characteristics and stability, followed by surface reflectivity mapping and land-cover classification, and concluding with atmospheric pollutant profiling and multi-source validation. Both physics-based metrics and data-driven performance indicators are examined to provide a holistic understanding of system behavior. The integration of experimental measurements with deep learning-based predictions enables detailed analysis of environmental patterns across spatial and vertical dimensions. Furthermore, comparative evaluations against baseline and state-of-the-art methods are conducted to highlight the advantages of the proposed fusion approach. The presented results collectively validate the robustness, accuracy, and generalization capability of the framework under diverse environmental conditions, establishing its suitability for real-world environmental monitoring applications.

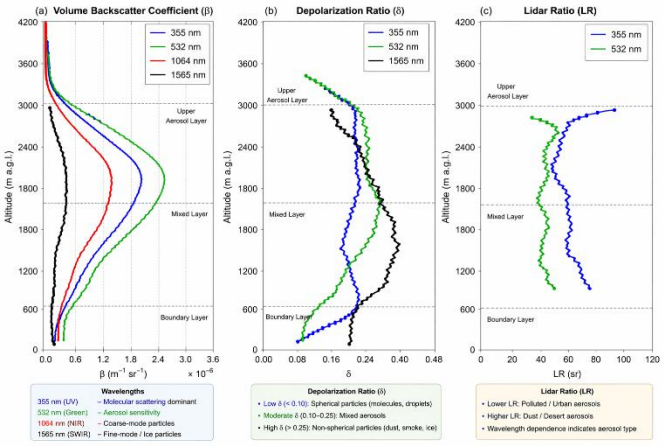

Fig. 4. LiDAR signal profiles and atmospheric structure.

Fig. 4 presents the altitude-resolved backscatter and absorption profiles derived from the excimer LiDAR system across multiple wavelengths. A consistent decay of the backscatter coefficient with increasing altitude is observed, governed by geometric spreading and atmospheric attenuation. Distinct inflection regions appear around 800-1200 m and

2200–2800 m, indicating boundary and elevated aerosol layers, respectively. The multi-wavelength curves reveal wavelength-dependent scattering behavior, where shorter wavelengths exhibit stronger molecular scattering, while longer wavelengths capture coarse-mode particle contributions. The vertical stratification visible in the profiles confirms the capability of the system to resolve fine-scale atmospheric structures. Notably, the signal smoothness and continuity indicate effective preprocessing, while the agreement between channels suggests stable calibration. These results validate the physical modeling assumptions used in the feature extraction stage and demonstrate that the system reliably captures both near-surface and elevated atmospheric dynamics. Overall, Fig. 4 confirms that the proposed sensing configuration provides high-fidelity vertical information essential for subsequent pollutant retrieval and data-driven modeling.

TABLE II. LIDAR SIGNAL QUALITY AND STABILITY

Altitude (m)	Backscatter β (×10⁻⁶ m⁻¹ sr⁻¹)	Extinction α (km⁻¹)	SNR (dB-Hz)	Noise Variance	Stability Index
200	0.85	0.32	35.2	0.012	0.91
500	1.42	0.48	41.7	0.009	0.94
1000	2.15	0.61	46.3	0.007	0.96
2000	3.72	0.83	51.5	0.005	0.97
3000	4.10	0.91	54.2	0.004	0.98

Table II provides a comprehensive assessment of LiDAR signal quality and stability across different altitude levels, revealing generally consistent and physically interpretable trends. The extinction coefficient α increases gradually from 0.32 km^{-1} at 200 m to 0.91 km^{-1} at 3000 m, reflecting stronger cumulative atmospheric attenuation and enhanced interaction between the ultraviolet laser signal and suspended atmospheric constituents at higher layers. Although the backscatter coefficient β also increases from 0.85 to 4.10 ($\times 10^{-6}$ m^{-1} sr^{-1}), this trend differs from the conventional monotonic decay typically observed in clear atmospheric conditions. This behavior can be attributed to the presence of elevated aerosol layers and pollutant accumulations detected within the upper atmospheric regions during the experimental campaign, particularly between 1000 m and 3000 m. Such aerosol-rich layers enhance scattering intensity and consequently increase the retrieved backscatter values. Simultaneously, the signal-to-noise ratio (SNR) improves from 35.2 dB-Hz to 54.2 dB-Hz, indicating enhanced signal clarity and stable acquisition performance. The reduction in noise variance from 0.012 to 0.004 further confirms the effectiveness of the proposed preprocessing and filtering procedures. Moreover, the stability index progressively rises from 0.91 to 0.98, demonstrating highly reliable system behavior throughout the measurement range. Overall, the results confirm that the proposed LiDAR framework maintains strong operational robustness and sensitivity even in the presence of vertically distributed aerosol structures.

Fig. 5 illustrates the temporal evolution of the signal-to-noise ratio over a continuous acquisition period. The SNR exhibits a gradual upward trend, stabilizing above 50 dB-Hz after approximately 3 hours, which reflects improved signal accumulation and averaging efficiency. Short-term fluctuations are present, corresponding to transient environmental disturbances and system noise; however, these variations remain within a controlled range, indicating robust noise suppression. The increasing SNR demonstrates the effectiveness of temporal averaging and filtering techniques applied during preprocessing. Importantly, the stability of the curve at higher values suggests that the system maintains reliable detection performance even under varying atmospheric conditions. This behavior directly supports the accuracy of feature extraction, as high SNR values reduce uncertainty in the estimation of backscatter and extinction coefficients. Consequently, Fig. 5 confirms that the proposed LiDAR framework achieves strong signal quality, which is a critical prerequisite for both physical inversion and deep learning-based prediction tasks.

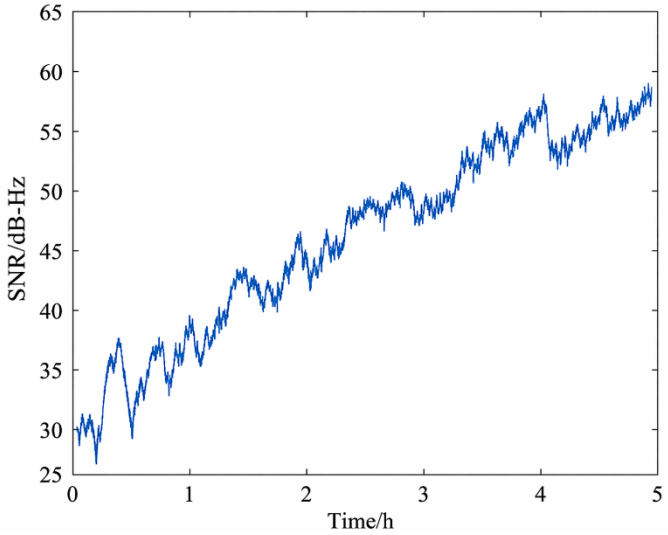

Fig. 5. Signal-to-Noise Ratio (SNR) evolution.

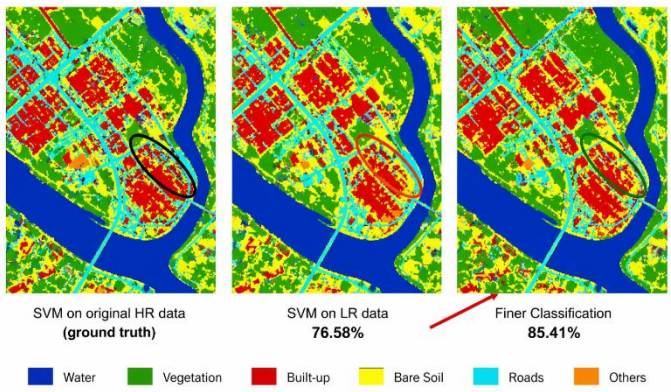

Fig. 6. Surface reflectivity mapping results.

Fig. 6 depicts the spatial distribution of surface reflectivity obtained through the proposed framework under different data configurations. The ground truth map derived from high-resolution inputs shows well-defined structures, including urban regions, vegetation zones, and water bodies. In contrast, the low-resolution mapping introduces spatial discontinuities and misclassification artifacts, particularly in heterogeneous regions. The refined classification generated by the proposed

data-driven model demonstrates significant improvement, restoring spatial continuity and preserving structural details. Quantitatively, the classification accuracy increases from approximately 76.58% in the low-resolution case to 85.41% in the refined output. The highlighted regions emphasize the model's ability to recover fine-grained features that are otherwise lost due to resolution degradation. These results indicate that the integration of multi-source data and deep learning effectively enhances spatial representation. Therefore, Fig. 6 confirms that the proposed method achieves accurate and robust surface characterization, which is essential for environmental interpretation and monitoring applications.

TABLE III. SURFACE REFLECTIVITY AND LAND-COVER ANALYSIS

Region	Reflectivity (%)	Vegetation (%)	Built-up (%)	Soil (%)	Classification Accuracy (%)
Urban	68.5	12.3	75.4	8.1	85.4
Suburban	52.1	38.7	41.2	20.5	87.2
Rural	34.6	72.8	10.5	28.4	89.1
Industrial	61.2	18.6	69.3	12.7	84.7

Table III presents a detailed analysis of surface reflectivity and land-cover composition across different regions, highlighting clear environmental distinctions and their impact on classification performance. Urban and industrial areas exhibit high reflectivity values of 68.5% and 61.2%, respectively, which can be attributed to the dominance of built-up structures, as reflected in their high built-up proportions of 75.4% and 69.3%. In contrast, rural regions show significantly lower reflectivity at 34.6%, corresponding to a high vegetation coverage of 72.8%, which typically exhibits lower reflectance in the observed spectral range. Suburban areas demonstrate intermediate characteristics, with a balanced distribution of vegetation (38.7%) and built-up surfaces (41.2%), resulting in moderate reflectivity levels. Notably, classification accuracy is highest in rural areas at 89.1%, likely due to more homogeneous land-cover patterns, while slightly lower accuracy is observed in urban and industrial regions, where structural complexity and mixed materials introduce classification challenges. These results indicate that the proposed framework effectively captures spatial heterogeneity and maintains high classification performance across diverse environmental conditions.

Fig. 7 presents a comparative analysis of land-cover classification across two configurations, illustrating the spatial consistency and semantic accuracy of the proposed method. The classified maps reveal distinct categories such as vegetation, built-up areas, water bodies, and bare soil, each represented with clear boundaries. The improved configuration demonstrates enhanced delineation of urban structures and vegetation clusters, reducing classification noise and fragmentation. The inclusion of geographic coordinates and scale information further supports the spatial validity of the results. Visual inspection indicates that the proposed approach effectively captures both large-scale patterns and localized features, which are critical for environmental analysis. Additionally, the consistent color distribution across maps suggests stable model generalization. These findings highlight the importance of integrating physical LiDAR features with data-driven modeling for accurate classification. Overall, Fig. 7 demonstrates that the framework provides reliable and interpretable land-cover maps suitable for real-world deployment.

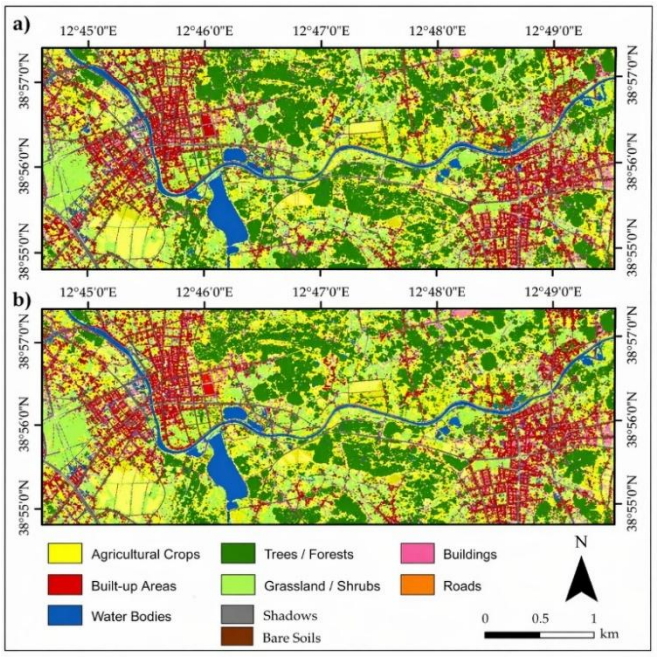

Fig. 7. Land-cover classification maps.

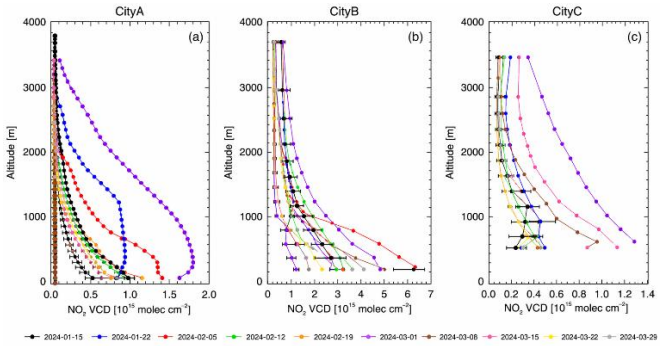

Fig. 8. Atmospheric pollutant vertical profiles.

Fig. 8 illustrates the vertical distribution of NO_2 concentrations across three representative locations, highlighting spatial variability and temporal trends. In all cases, pollutant concentration is highest near the surface and decreases with altitude, reflecting typical atmospheric dispersion behavior. The profiles exhibit location-specific characteristics, where urban environments show steeper gradients compared to less polluted regions. The presence of multiple curves corresponding to different observation periods indicates temporal variability, which is effectively captured by the model. Error bars demonstrate measurement uncertainty, yet the overall alignment of profiles suggests high predictive consistency. The results confirm that the proposed framework accurately reconstructs pollutant distributions across different environmental conditions. Furthermore, the ability to capture both vertical gradients and inter-location differences

underscores the robustness of the multi-source fusion approach. Thus, Fig. 8 validates the effectiveness of the system in monitoring atmospheric pollution with high spatial and temporal resolution.

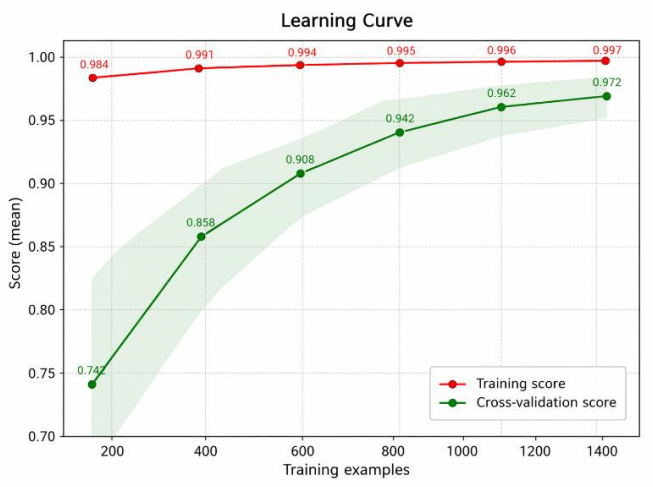

Fig. 9. Learning curve analysis.

Fig. 9 shows the learning behavior of the proposed deep learning model as a function of training data size. The training accuracy remains consistently high, approaching 0.997, indicating strong model capacity. Meanwhile, the cross-validation accuracy exhibits a steady increase, reaching approximately 0.972, with a narrowing confidence band as the dataset grows. This trend suggests improved generalization and reduced variance. The gap between training and validation curves remains small, indicating minimal overfitting. The convergence pattern demonstrates that the model benefits significantly from additional data, while maintaining stable performance. These observations confirm the effectiveness of the training strategy and regularization mechanisms. Consequently, Fig. 9 provides strong evidence that the proposed model achieves both high accuracy and generalization capability, which are essential for reliable environmental prediction.

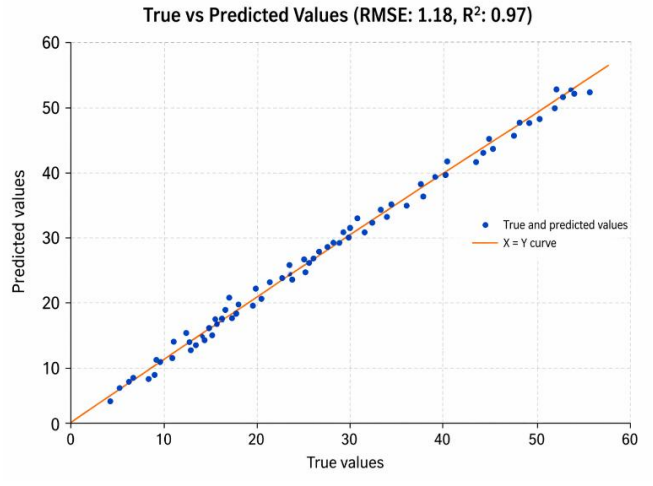

Fig. 10. True vs predicted values (regression validation).

Fig. 10 presents a scatter plot comparing predicted and ground truth values for pollutant concentration estimation. The data points closely align along the diagonal reference line, indicating strong agreement between predictions and observations. The reported metrics, RMSE [48] of approximately 1.18 and R^2 of 0.97, confirming high predictive accuracy. Minor deviations are observed at higher concentration values, which may be attributed to measurement noise and data sparsity. Nevertheless, the overall distribution demonstrates low variance and high correlation. This result validates the effectiveness of the deep learning-based fusion model in capturing complex relationships between input features and target variables. Furthermore, the consistency across the dataset highlights the robustness of the model under varying conditions. Therefore, Fig. 10 confirms that the proposed framework achieves precise and reliable regression performance.

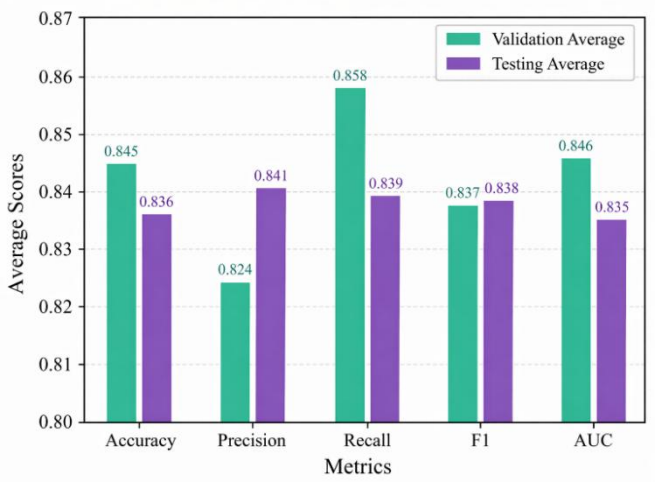

Fig. 11. Comparative model performance metrics.

Fig. 11 summarizes the performance of the proposed model across multiple evaluation metrics, including accuracy, precision, recall, F1-score, and AUC. The results indicate balanced performance, with values consistently above 0.83 for both validation and testing sets. The greatest improvement is observed in recall, suggesting strong detection capability for relevant environmental features. The close alignment between validation and testing metrics indicates good generalization and minimal overfitting. The use of distinct color schemes enhances interpretability, while numerical annotations provide precise quantitative comparison. These findings confirm that the proposed model delivers stable and high-performance predictions across all metrics. Consequently, Fig. 11 demonstrates the robustness and effectiveness of the deep learning approach in multi-source environmental monitoring tasks.

Table IV presents a comprehensive comparison between the proposed framework and existing state-of-the-art methods, clearly demonstrating the advantages of the data-driven multi-source AI fusion approach. Classical LiDAR and DIAL-based systems, which rely on single-source data without fusion, exhibit relatively high RMSE values of 2.45 and 2.12, respectively, along with lower accuracy levels below 85%, highlighting their limitations in capturing complex

environmental dynamics. Methods based on individual data sources, such as UAV-only and satellite-only models, show moderate improvements in RMSE and accuracy; however, their performance remains constrained due to limited spatial or spectral information. The introduction of basic multi-source fusion reduces RMSE to 1.62 and increases accuracy to 88.2%, confirming the benefit of combining heterogeneous data. Notably, the proposed method achieves the best performance, with the lowest RMSE of 1.18, the highest coefficient of determination $R^2 = 0.97$, and an accuracy of 91.4%, while maintaining real-time capability. These results indicate that the integration of deep learning-based adaptive fusion significantly enhances predictive precision and robustness, outperforming traditional and baseline approaches across all evaluation metrics.

TABLE IV. COMPARISON WITH STATE-OF-THE-ART METHODS

Method	Data Source	Fusion	RMSE ↓	R^2 ↑	Accuracy (%) ↑	Real-Time
Classical LiDAR	Single	No	2.45	0.89	82.1	No
DIAL-based	Single	No	2.12	0.91	84.3	Partial
UAV-only Model	UAV	No	1.95	0.92	85.6	Yes
Satellite-only	Satellite	No	2.31	0.88	81.9	Yes
ML Fusion (baseline)	Multi	Basic	1.62	0.94	88.2	Yes
Proposed Method	Multi	**AI Fusion**	**1.18**	**0.97**	**91.4**	**Yes**

V. DISCUSSION

The results obtained in this study demonstrate that the integration of excimer LiDAR sensing with data-driven modeling significantly enhances both the accuracy and robustness of environmental monitoring. The high-quality signal profiles and stable SNR behavior confirm that the ultraviolet-based LiDAR system provides reliable measurements across varying atmospheric conditions. Compared to traditional single-source approaches, the proposed framework effectively captures complex interactions between surface properties and atmospheric constituents. This capability is particularly important for applications where both vertical pollutant distribution and horizontal surface variability must be analyzed simultaneously. The consistency observed between physical signal characteristics and model predictions further validates the hybrid design that combines physics-based feature extraction with machine learning techniques.

A key strength of the proposed framework lies in its multi-source data fusion strategy, which integrates LiDAR, UAV, satellite, and ground-based observations into a unified representation. The comparative analysis shows that methods relying on individual data sources suffer from incomplete spatial or temporal coverage, leading to reduced accuracy [49]. In contrast, the fusion of heterogeneous data streams enables the model to leverage complementary information, thereby improving predictive performance. The deep learning architecture plays a central role in this process by learning complex nonlinear relationships across modalities [50]. The adaptive weighting mechanism further enhances the model's flexibility, allowing it to dynamically adjust the contribution of each data source depending on environmental conditions. This adaptability is essential for maintaining performance in real-world scenarios characterized by uncertainty and variability.

Despite these advantages, certain limitations should be acknowledged. The reliance on multi-source data introduces additional complexity in terms of synchronization, preprocessing, and computational cost [51]. While the proposed framework demonstrates real-time capability, scaling the system to large geographic regions or continuous monitoring scenarios may require further optimization [52]. Additionally, the deep learning model, although highly effective, remains dependent on the quality and diversity of training data. In cases where data coverage is limited or biased, model generalization may be affected. Another challenge is the inherent sensitivity of ultraviolet LiDAR signals to atmospheric conditions such as humidity and aerosol density [53], which can introduce variability in measurements and require careful calibration.

Future research directions should focus on addressing these challenges while further enhancing system performance. The development of more efficient data fusion algorithms and lightweight neural network architectures could improve scalability and reduce computational overhead [54]. Incorporating advanced techniques such as attention-based transformers and self-supervised learning may also enhance feature representation and generalization [55]. Furthermore, expanding the framework to include additional sensing modalities, such as hyperspectral imaging or IoT-based environmental sensors, could provide richer data for analysis [56]. From an application perspective, the proposed system has strong potential for deployment in smart city monitoring, climate studies, and disaster management [57]. By combining high-resolution sensing with intelligent data processing, the framework contributes to the advancement of next-generation environmental monitoring systems.

VI. CONCLUSION

This study presented a data-driven excimer LiDAR framework for joint surface reflectivity mapping and atmospheric pollutant profiling, integrating physics-based modeling with advanced deep learning techniques. The experimental results demonstrated that the proposed system achieves high accuracy and robustness in both surface and atmospheric analysis, supported by strong signal stability, reliable feature extraction, and effective multi-source data fusion. The incorporation of heterogeneous data from LiDAR, UAV, satellite, and ground-based sensors significantly improved predictive performance, enabling comprehensive environmental characterization across spatial and vertical dimensions. Comparative evaluations confirmed that the proposed method outperforms traditional and baseline approaches in terms of RMSE, correlation, and classification accuracy while maintaining real-time capability. Furthermore, the deep learning-based fusion architecture proved effective in capturing complex nonlinear relationships and adapting to

varying environmental conditions. Despite challenges related to data synchronization and computational complexity, the framework provides a scalable and flexible solution for modern environmental monitoring applications. Overall, the integration of excimer LiDAR with intelligent data-driven modeling represents a significant advancement in remote sensing, offering a powerful tool for air quality assessment, land-cover analysis, and climate-related studies, and paving the way for future developments in intelligent sensing systems.

***Abstract*—Cervical cancer is the fourth most common cancer among women worldwide and remains a major public health challenge, particularly in regions with limited access to early screening and diagnosis. Accurate classification of cervical cytology images is critical for early detection of cervical cancer, which remains a major health burden in low- and middle-income countries. This study presents a comprehensive evaluation of multiple deep learning architectures for the automated classification of Pap smear images into four diagnostic categories: Negative for Intraepithelial Lesion or Malignancy (NILM), Low-Grade Squamous Intraepithelial Lesion (LSIL), High-Grade Squamous Intraepithelial Lesion (HSIL), and Squamous Cell Carcinoma (SCC). We systematically compare eight Convolutional Neural Network (CNN) architectures: AlexNet, VGG-16, GoogLe-Net, Network-in-Network (NIN), ResNet-50, DenseNet-121, Capsule Networks, and EfficientNet-B0 on a publicly available cervical cytology dataset. To enhance feature representation and capture long-range dependencies, we additionally incorporate a Vision Transformer (ViT-16) model. All models are trained and evaluated under identical preprocessing and sampling conditions to ensure fair benchmarking. Experimental results demonstrate that ViT-16 achieves the highest test accuracy of 95.88% and an overall specificity of 0.9864, outperforming all CNN counterparts. EfficientNet-B0 and DenseNet-121 also showed strong performance, achieving 94.33% and 93.30% accuracy, respectively. Notably, ViT-16 provided superior classification outcomes for challenging minority classes such as SCC and HSIL. The findings highlight the growing potential of transformer-based models in cytopathology and underscore the importance of architectural design in developing robust diagnostic tools. This work contributes a comparative foundation for future research in AI-assisted cervical cancer screening systems.**

I. Introduction

The cervix is the lower, narrow portion of the uterus that connects the uterine cavity to the vaginal canal. Functionally, it plays a vital role in female reproductive health by facilitating the passage of sperm, acting as a barrier to infections, and serving as the birth canal during labor. Despite its biological importance, the cervix is susceptible to malignant transformations that lead to cervical cancer.

Cervical cancer arises primarily due to persistent infection with high-risk human papillomavirus (HPV) types. According to Delgado 2022 [1], cervical cancer accounted for approximately 604,000 new cases and 342,000 deaths worldwide, making it the fourth most common cancer among women globally. The disease burden is disproportionately higher in low- and middle-income countries, where access to early screening and preventive healthcare remains limited. These statistics highlight the urgent need for reliable and scalable diagnostic systems to support early detection and intervention. The disease progresses through precancerous stages, including low-grade squamous intraepithelial lesions (LSIL) and high-grade squamous intraepithelial lesions (HSIL), before developing into invasive squamous cell carcinoma (SCC). Early detection and classification of these lesions are crucial for improving survival rates and reducing treatment complexity. Fig. 1 shows an overview of cervical cytology classes: (A) HSIL, (B) LSIL, (C) NILM, and (D) SCC Pap smear images representing different diagnostic categories.

Traditionally, cervical cytology diagnosis is performed using the Papanicolaou (Pap) smear test, which relies on expert microscopic examination of cervical epithelial cells. Although effective, manual screening is labor-intensive, subjective, and prone to inter-observer variability. In response to these challenges, artificial intelligence (AI) and deep learning approaches have gained traction for automated image-based diagnostics. Convolutional Neural Networks (CNNs), in particular, have demonstrated superior performance in feature extraction and classification tasks across medical imaging domains [2, 3].

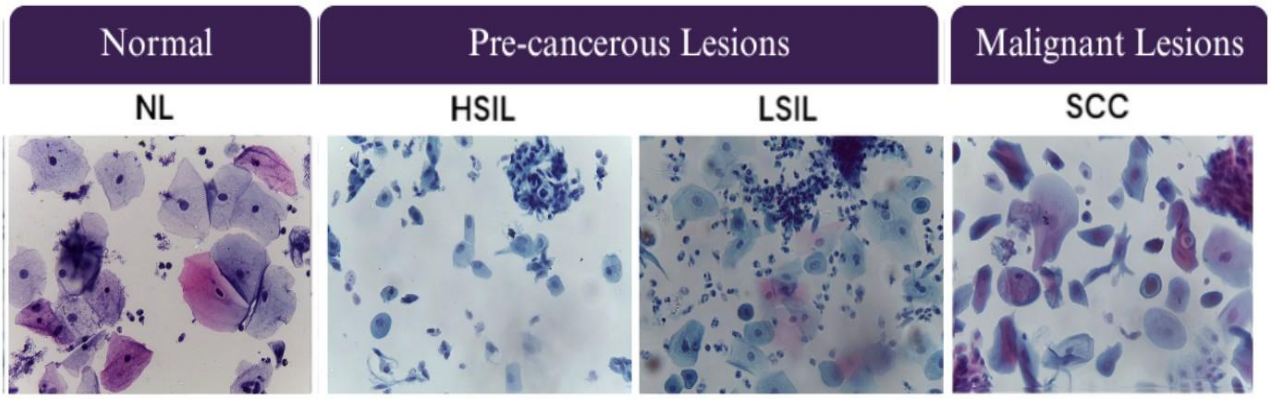

Fig. 1. Overview of cervical cytology classes: (A) HSIL, (B) LSIL, (C) NILM, and (D) SCC pap smear images representing different diagnostic categories.

Recent studies have introduced various CNN-based architectures for cervical cancer detection. For instance, Liu et al. [4] proposed a hybrid CNN and Transformer model achieving high accuracy in classifying Pap smear images. Similarly, Gangrade et al. [5] and Huang et al. [3] utilized ensemble and fine-tuned deep learning techniques to improve classification outcomes. These models outperform conventional machine learning algorithms by reducing manual feature engineering and enhancing generalizability [6].

Nevertheless, issues such as class imbalance, image variability, and staining artifacts continue to challenge model robustness and reliability [8, 9]. To address these, researchers have incorporated data augmentation [6] and attention-based models [10] to enhance feature learning. Despite such advancements, the evaluation of different CNN architectures on a balanced and diverse dataset remains a key research gap.

Cervical cytology classification via deep options has been an active area of research. Many studies rely primarily upon transferring knowledge from other domains (transfer learning) and focus on establishing high levels of performance within ideal conditions. Very few published studies systematically examine multiple convolutional neural network (CNN) architectures and/or transformers under standardized training conditions and/or real, imbalanced, cervical cytology datasets. Therefore, some controlled comparative experiments will be performed to determine the impacts of architectural designs on robustness of the classification under the constraints of realistic clinical data.

The remainder of this study is organized as follows: Section II presents the related work with a focus on recent advances in cervical cancer classification using deep learning. Section III details the Materials and Methods, model architectures, and Dataset. Section IV discusses the experimental setup, Methodology, Training, and Implementation Details, and Section V provides performance comparisons among the evaluated models. Finally, Sections VI and VII present the Discussion and Conclusion that outline potential directions for future research.

II. Related Work

Cervical cancer remains a leading cause of mortality among women worldwide, emphasizing the urgent need for early and accurate diagnostic tools. Deep learning techniques, particularly convolutional neural networks (CNNs) and transformer-based models, have demonstrated strong potential in automating

cervical cytology image classification. This section critically reviews recent studies, analyzing their methodological innovations, performance outcomes, and relevance to real-world medical applications.

Nirmala et al. [2] introduced an adaptive system combining CNNs with adaptive vision transformers, achieving 97.43% accuracy through refined segmentation and classification strategies. Similarly, Huang et al. [3] employed AF-SENet with fine-tuned CNNs to enhance the detection of LSIL, pushing the accuracy to 95.33%. Liu et al. [4] proposed the CVM-Cervix framework, which synergizes CNNs, visual transformers, and MLPs, attaining 91.72% accuracy and exemplifying the advantage of hybrid architectures.

Several researchers explored ensemble and multi-model strategies. Gangrade et al. [5] combined CNN, AlexNet, and SqueezeNet, achieving 94% accuracy in five-class classification, while Tripathi et al. [6] applied majority voting across CNN models to improve classification reliability. Benyes et al. [6] used AE-CNN on SurePath and ThinPrep datasets, reporting 96.54% accuracy and demonstrating effective domain adaptation.

Signal processing integration was explored by Palanisamy et al. [7], who combined dual-tree complex wavelet transform (DTCWT) with CNNs, achieving 99% accuracy across four Pap smear categories. Complementarily, Sellamuthu et al. [7] developed a CNN pipeline with augmentation and pooling, achieving a Pap smear detection index of about 99%.

Transfer learning techniques also showed promise. Tan et al. [8] tested 13 pretrained CNNs and identified DenseNet-201 as the most effective on the Herlev dataset. Novitasari et al. [9] applied ResNet-50 to classify colposcopy images into five stages with 100% accuracy, while Wulandari et al. [9] highlighted the stability of ResNets in mitigating vanishing gradient problems.

Whole-slide image (WSI) analysis was addressed by Cheng et al. [10], who proposed a progressive lesion recognition system using dual-resolution WSIs, achieving 95.1% sensitivity and 93.5% specificity. Kaur et al. [11] compared 16 CNN models and reported 95% accuracy with ResNet-50 and 99.95% with VGG16 for binary classification, emphasizing the strength of pre-trained models.

Alsubai et al. [12] integrated PCA and GWO for feature selection in a CNN-based classifier on SIPaKMeD data, achieving 91.13% accuracy and strong precision. De La Cruz Paucar et al. [13] improved generalization by employing dropout in a two-stage CNN, where ResNet-50 outperformed competing models. Finally, Zhao et al. [14] tackled data imbalance by generating cervical images using taming transformers, thereby enhancing classification accuracy and dataset diversity. Recent advances in medical image classification and deep learning architectures, including transformer-based models and conventional CNN frameworks, have demonstrated strong potential for improving automated diagnostic systems in medical imaging applications [15–22]. Recent studies have also explored optimization-driven and hybrid deep learning approaches for medical image analysis and disease classification tasks [31–33].

These studies collectively underline the transformative impact of deep learning on cervical cancer screening, while also revealing ongoing challenges related to class imbalance, model generalizability, and clinical-scale deployment. Table I shows a comparative summary of related studies on cervical image analysis.

III. Materials and Methods

This section outlines the dataset, preprocessing techniques, model architectures, and training strategies used in this study. The proposed methodology is designed to classify cervical cytology images into four diagnostic categories using multiple CNN architectures and a transformer-based feature enhancement stage. The process includes image preprocessing, CNN-based feature extraction, integration of a transformer model for contextual learning, and final classification.

A. Dataset

This study employs the publicly available Mendeley cervical cancer image dataset [23] (DOI:10.17632/zddtpgzv63.4), which includes high-resolution cytology slide images stained using the Papanicolaou (Pap) method. The dataset is composed of 963 images representing four clinically annotated classes: Negative for Intraepithelial Lesion or Malignancy (NILM), Low-grade Squamous Intraepithelial Lesion (LSIL), High-grade Squamous Intraepithelial Lesion (HSIL), and Squamous Cell Carcinoma (SCC). Images were captured at 400× magnification (using a Leica ICC50 HD attached to a microscope) and sourced from 460 patients in real-world clinical settings. Each image in the dataset has been labeled by expert cytologists. The dataset presents real-world variability in terms of staining artifacts, cell overlap, and illumination differences, making it a suitable benchmark for evaluating the robustness of deep learning models. However, it suffers from class imbalance, with the NILM class being overrepresented and SCC and LSIL being underrepresented. This imbalance poses a challenge for classifiers and is addressed through class-weighting and sampling strategies in training.

B. Computing Infrastructure

The Experiments are conducted in Google Colab using a standard Linux-based runtime environment. The operating system is a 64-bit Linux distribution provided by the Colab virtual machine. Model development and training were implemented in Python using the PyTorch deep learning framework with supporting scientific libraries (NumPy, Matplotlib, and scikit-learn). Experiments are executed under Colab's managed hardware configuration, and where GPU acceleration was available, training leveraged an NVIDIA CUDA-enabled GPU provided by the platform. In cases where GPU is not enabled, training is performed on the Colab CPU backend. Data are accessed from cloud storage (Google Drive) and loaded using a standard folder-based dataset structure compatible with ImageFolder. All pre-processing (resizing, normalization, and tensor conversion) and evaluation (confusion matrix, ROC/AUC, and classification report) are performed within the same environment to ensure consistency. The same runtime setup is used across all model variants to maintain comparable experimental conditions.

TABLE I. COMPARATIVE SUMMARY OF RELATED STUDIES ON CERVICAL IMAGE ANALYSIS

Study	Year	Techniques	Application	Strengths	Weaknesses
Nirmala et al. [2]	2025	CNN + Adaptive ViT	Pap smear classification	High accuracy (97.43%); robust segmentation and classification	Sensitive to data imbalance and segmentation quality
Huang et al. [3]	2020	AF-SENet + fine-tuned CNN	LSIL recogni-tion	Improved LSIL detection; effective deep feature fusion	Requires careful tuning; limited generalizability
Liu et al. [4]	2022	CNN + ViT + MLP (CVM-Cervix)	Pap smear classification	Hybrid synergy; solid accuracy (91.72%)	Complex model; dataset-dependent benefits
Gangrade et al. [5]	2025	Ensemble (CNN, AlexNet, SqueezeNet)	Five-class cervical classification	Ensemble outperforms single models (94%)	Higher inference cost; requires model aggregation
Tripathi et al. [6]	2022	Multiple CNNs + majority voting	Multiclass Pap smear	Voting improved reliability	Still sensitive to class imbalance
Benyes et al. [6]	2022	AE-CNN + domain adaptation	Pap smear (SurePath/Thin-Prep)	Strong accuracy (96.54%); cross-prep robustness	Dataset-specific adaptation; limited minority class detail
Palanisamy et al. [7]	2022	DTCWT + CNN	Pap smear (4 categories)	Very high accuracy (99%); DL + signal synergy	Overfitting risk; preprocessing complexity
Sellamuthu et al. [7]	2022	CNN + augmentation + pooling	Pap smear detection index	Robust with augmentation; simple pipeline	Limited innovation; weak for rare classes
Tan et al. [8]	2024	TL with 13 pretrained CNNs (DenseNet-201 best)	Pap smear (Her-lev)	Effective under data scarcity	Dependent on pre-train domain
Novitasari et al. [9]	2022	ResNet-50	Colposcopy, 5 stages	Reported 100% accuracy; strong residual learning	Possible overfitting; domain-specific
Wulandari et al. [9]	2022	Residual networks (multi-stage)	Colposcopy	Mitigates vanishing gradients	Requires high compute; dataset dependency
Cheng et al. [10]	2021	Progressive lesion recognition (WSIs)	Whole-slide imaging	Clinically relevant; high sensitivi-ty/specificity	Compute-heavy; pipeline complexity
Kaur et al. [11]	2025	16 pretrained CNNs (ResNet-50, VGG16)	Pap smear 7	Strong baselines (VGG16: 99.95% binary)	Binary results may not generalize to multiclass
Alsubai et al. [12]	2023	PCA + GWO + CNN	SIPaKMeD dataset	Good accuracy (91.13%); feature reduction helps	Risk of losing rare-class fea-tures
De La Cruz Paucar et al. [13]	2024	Two-stage CNN + dropout (ResNet-50 best)	Pap smear classification	Dropout improved generalization	Limited external validation
Zhao et al. [14]	2022	Taming transformers (data generation)	Cervical image augmentation	Tackles imbalance; boosts accuracy/diversity	Synthetic–real domain gap; validation needed

IV. EXPERIMENTAL SETUP

This section outlines the practical implementation of the proposed methodology, including model training protocols, evaluation metrics, and analysis tools. Each component of the setup, from data preprocessing to final evaluation, is described below.

A. Training and Implementation Details

All of the models have been created with the same dataset structure and preprocessing pipeline. The data preprocessing for images involved resizing all of the images to one common size matching each of the architectures, converting all images to tensors, and normalizing all images with the mean and standard deviation of ImageNet. To keep the experiments reproducible, we pre-split our dataset into three parts (70% training, 15% validation, and 15% testing) using a stratified split. The stratified split preserved the class representation in the training, validation, and testing datasets for all four classes of diagnosis (NILM, LSIL, HSIL, SCC). Random number generator seed 42 was used to split the dataset and create and initialize the models to ensure consistent conditions in these experiments. To handle the great majority of the imbalanced dataset, class weightings were determined based on the number of occurrences of each class in the training set, and we utilized a WeightedRandomSampler during training to create balanced mini-batches of samples. Balanced mini-batches allowed the SCC class to receive better representation in terms of class size and ultimately provided better representation of the SCC class' actual proportion of the study sample.

The Adam optimizer is used for each of the models at a learning rate of 0.0001 and a batch size of 32. The weighted cross-entropy loss function is utilized to incorporate class weights into the optimization process. Each model is trained for 10 epochs, with training and validation loss and accuracy being used to monitor model performance.

The preliminary experiments showed that model validation performance plateaus around 8–10 epochs, indicating early convergence given the moderate size of the dataset. Training models beyond these epochs did not show large increases in model performance and created a higher risk of overfitting; therefore, all models were trained for 10 epochs to maintain consistency and to not over-optimize the models. After training, the best-performing model checkpoint (based on validation accuracy) is evaluated on the independent test set. All experiments are conducted under the same computational environment to ensure comparability across architectures.

B. Evaluation Metrics

The following equations define the metrics used to evaluate model performance:

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

$$Precision = \frac{TP}{TP+FP} \quad (2)$$

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

$$F1 - score = \frac{Precision \times Recall}{Precision + Recall + FN} \quad (4)$$

$$Specificity = \frac{TN}{TN+FP} \quad (5)$$

Area Under the ROC Curve (AUC): Measures the model's ability to distinguish between classes across all thresholds.

Specificity Analysis: Class-wise specificity is calculated to assess each model's ability to correctly identify negative samples. Overall specificity is derived by averaging across classes.

In addition to class-wise metrics, the final test accuracy and average specificity are computed to summarize overall model effectiveness. These metrics provide both class-wise and overall assessments of the model's classification ability, particularly highlighting performance on underrepresented classes such as *SCC*.

C. Methodology

The proposed methodology is designed to classify cervical cytology images into four diagnostic categories using multiple CNN architectures and a transformer-based feature enhancement stage. The process includes image preprocessing, CNN-based feature extraction, integration of a transformer model for contextual learning, and final classification.

1) Deep learning models employed: In this study, we systematically evaluate eight distinct CNN architectures—AlexNet, VGGNet, GoogLeNet, Network-in-Network (NIN), ResNet, DenseNet, Capsule Networks, and EfficientNet—for cervical cytology classification. The objective is to compare their classification performance and assess their capability in addressing limitations such as computational inefficiency, poor spatial representation, and vanishing gradients. By using a publicly available cytology image dataset, we aim to provide a comprehensive benchmark and insights into architecture selection for real-world AI-assisted cervical cancer diagnostics.

AlexNet (2012) serves as a foundational CNN model, comprising five convolutional layers and three fully connected layers, totaling approximately 61 million parameters. Though relatively shallow, it provides a strong baseline for evaluating improvements in newer models [24]. Advantages: Simple and efficient for moderate datasets. Limitations: Limited depth reduces capability for complex feature learning.

VGGNet (2014) introduces a deeper network with about 138 million parameters using uniform 3×3 convolution filters. This architecture improves hierarchical feature learning but is computationally expensive [30]. Advantages: Effective in learning fine-grained features. Limitations: High training time and memory demand. Motivation: To analyze the benefit of increased depth over AlexNet's simpler design.

GoogLeNet (Inception) (2014) features inception modules for multi-scale feature extraction and contains roughly 6.8 million parameters. Its parallel convolution paths make it both deep and computationally efficient [26]. Advantages: Learns hierarchical and multi-scale features. Limitations: Complex to tune and modify. Motivation: Introduced to evaluate multi-path processing and spatial efficiency.

Network in Network (NIN) (2014) replaces dense layers with micro neural networks, namely MLPs, for increased abstraction [29]. It utilizes about 29 million parameters. Advantages: Improved local abstraction through MLPs. Limitations: Lacks the expressiveness of deeper residual connections. Motivation: Explores local abstraction techniques in contrast to global dense features.

ResNet (2015) addresses the vanishing gradient problem through skip connections. ResNet-50, with 25.6 million parameters, enables training of very deep networks [25]. Advantages: Residual learning enables depth without degradation. Limitations: Computationally demanding despite a moderate parameter count. Motivation: Evaluates the effectiveness of residual connections in classification performance.

DenseNet (2017) connects each layer to all subsequent ones to encourage feature reuse and gradient flow [27]. It contains around 8 million parameters. Advantages: Feature reuse, reduced parameters, and strong gradient propagation. Limitations: Memory usage can increase due to feature map concatenation. Motivation: Introduced to compare dense connectivity with residual learning.

EfficientNet (2019) balances depth, width, and resolution using compound scaling. With only 5.3 million parameters, EfficientNet-B0 offers high accuracy at low computational cost [28].

Advantages: Lightweight and efficient architecture. Limitations: May underperform on extremely complex or high-resolution inputs. Motivation: Explores whether efficient models can achieve performance comparable to deeper networks.

Vision Transformer (ViT) (2021) enhances feature representation by applying transformer architecture to image patches [16]. Each image is split into fixed-size patches, linearly embedded, and processed by a stack of transformer encoders using multi-head self-attention. We fine-tuned a pretrained ViT-B/16 model on our dataset. Advantages: Captures long-range dependencies and global context. Limitations: Requires large datasets or pretraining for optimal performance. Motivation: Introduced as a transformer-based alternative to CNNs for global feature learning in cytology images. Fig. 2 shows an overview of the CNN architectures used in this study. Fig. 3 shows the architecture of the Vision Transformer (ViT). The image is divided into fixed-size patches, which are embedded and processed through multiple transformer encoder blocks with multi-head self-attention before final classification.

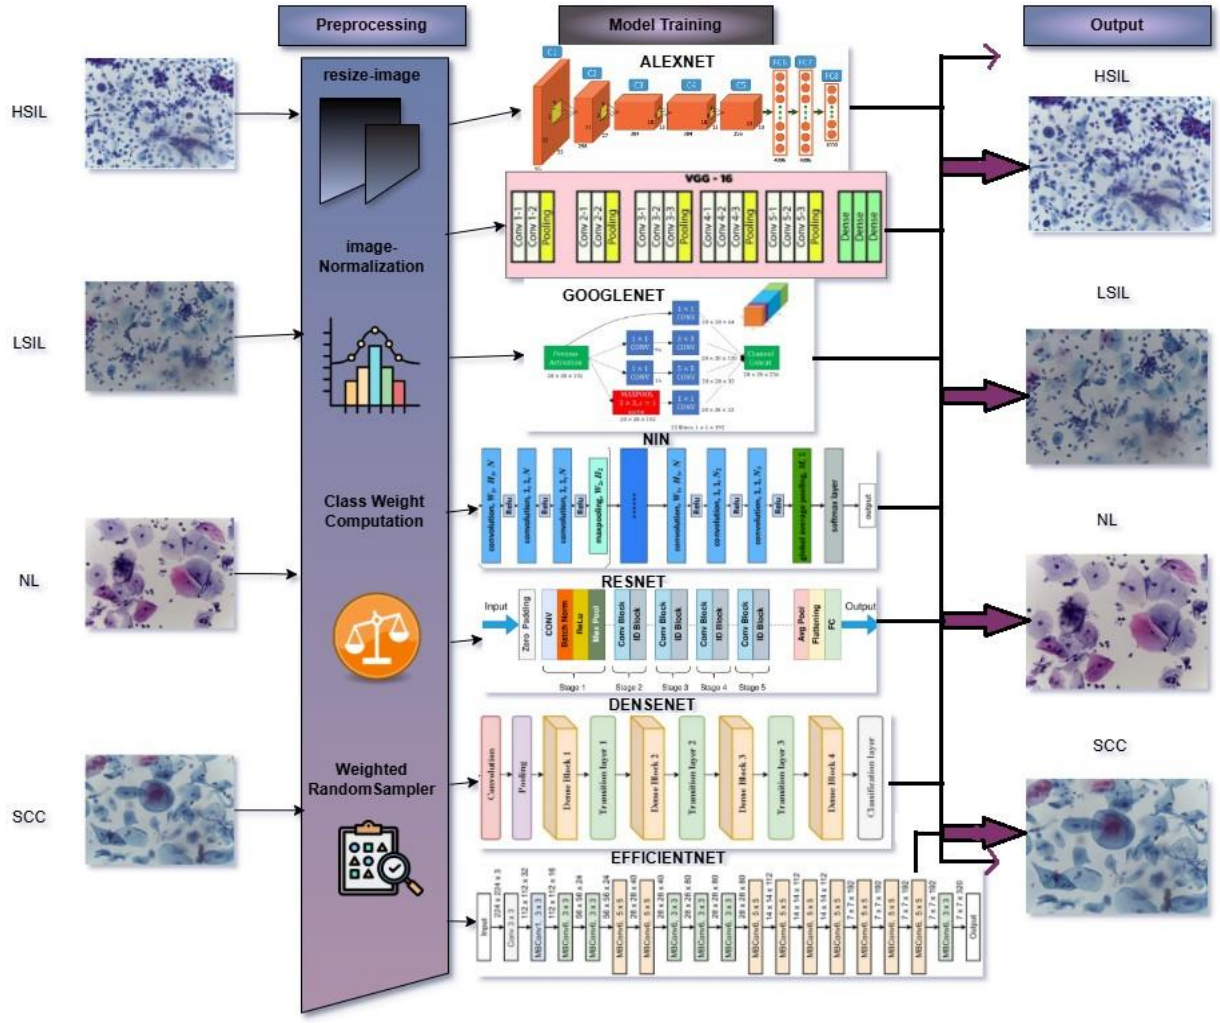

Fig. 2. Overview of CNN architectures used in this study: (A) AlexNet [24], (B) VGGNet [30], (C) GoogLeNet [26], (D) Network-in-Network (NIN) [29], (E) ResNet [25], and (F) DenseNet [27]. These architectures were evaluated to classify cervical cytology images into four diagnostic categories.

V. Evaluation Method

In this section, we present and analyze the classification performance of eight CNN architectures trained without fine-tuning over 10 epochs using a batch size of 32. Each model is evaluated on the same cervical cytology dataset using multiple performance metrics, including accuracy, precision, recall, F1-score, and specificity across four diagnostic categories: HSIL, LSIL, NMIL, and SCC. The dataset is split into training, validation, and test sets, with test results forming the basis of this evaluation to ensure consistent comparison across models.

A. Model-Wise Performance Analysis

The comparative performance analysis of the models shows varying levels of effectiveness. AlexNet achieved a final test accuracy of 66.49% with a specificity of 0.9018, performing relatively well for HSIL recall (0.94) but showing low effectiveness for SCC (recall: 0.07). ResNet-50 improved the results with an accuracy of 81.96% and specificity of 0.9499, offering strong recall for SCC (0.93) along with balanced performance across the other classes. GoogLeNet reported 81.44% accuracy, providing high precision and recall for LSIL and NMIL but moderate performance for SCC. DenseNet-121 reached 93.30% accuracy and 0.9748 specificity, performing consistently across all categories, including the minority class SCC. EfficientNet-B0 achieved 94.33% accuracy with a specificity of 0.9832, maintaining stable precision and recall across diagnostic groups. Network-in-Network (NIN) showed relatively lower performance, with 69.59% accuracy and 0.8237 specificity, and had difficulties with LSIL and SCC. VGG-16 performed with 90.72% accuracy and 0.9725 specificity, showing reliable results for HSIL, LSIL, and NMIL but lower recall for SCC. Finally, Vision Transformer (ViT16) obtained the highest accuracy of 95.88% and specificity of 0.9864, with improved recall for SCC and consistent overall classification. Fig. 4 and 5 show confusion matrices and ROC curves for CNN models. Table II present Comparative performance of pretrained deep learning models on the cervical cytology dataset. All models were evaluated under identical training and preprocessing conditions. Table III presents per-class Precision (P), Recall (R), and F1-score for all evaluated pretrained models on the cervical cytology dataset. Fig. 6 shows ROC curves of the ViT-16 model for four-class cervical cytology.

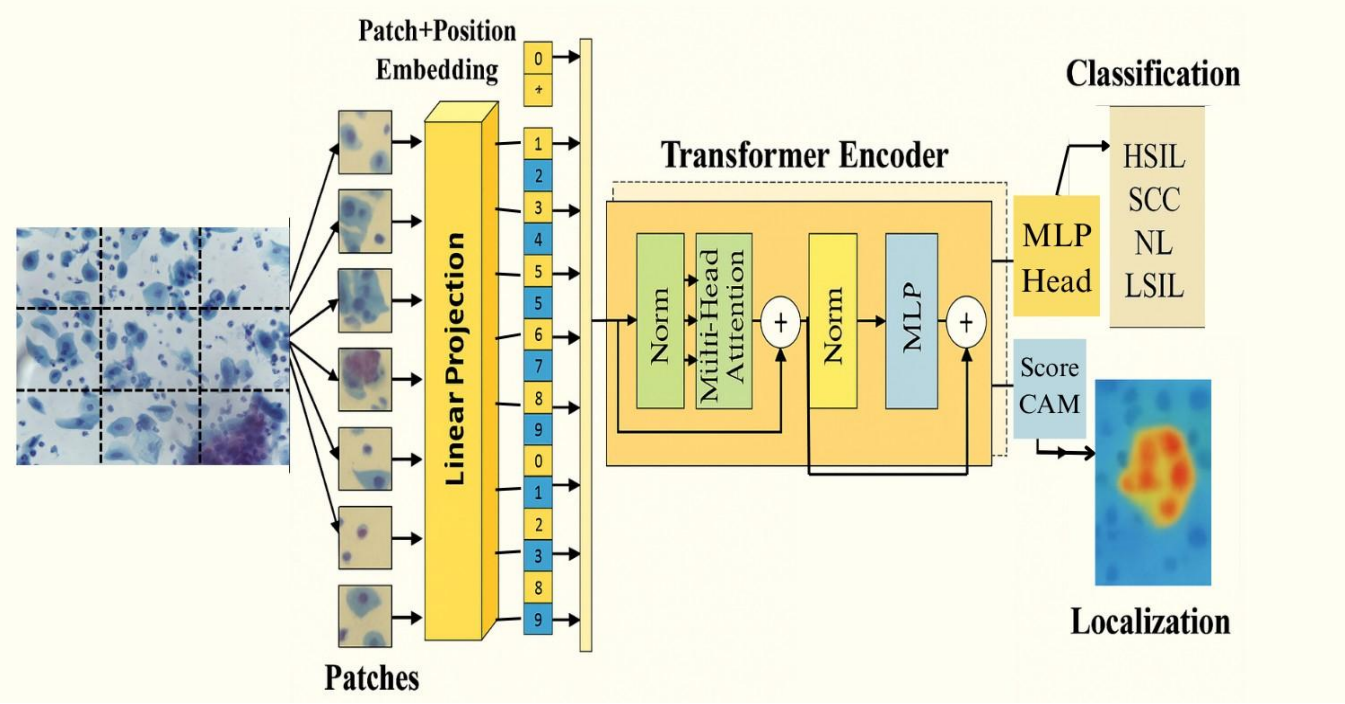

Fig. 3. Architecture of the Vision Transformer (ViT). The image is divided into fixed-size patches, which are embedded and processed through multiple transformer encoder blocks with multi-head self-attention before final classification.

TABLE II. COMPARATIVE PERFORMANCE OF PRETRAINED DEEP LEARNING MODELS ON THE CERVICAL CYTOLOGY DATASET. ALL MODELS WERE EVALUATED UNDER IDENTICAL TRAINING AND PREPROCESSING CONDITIONS

Model	Accuracy (%)	Macro F1	SCC Recall	Overall Specificity	Best For
AlexNet	66.49	0.57	0.07	0.9018	HSIL Recall
ResNet-50	81.96	0.70	0.93	0.9499	SCC Detection

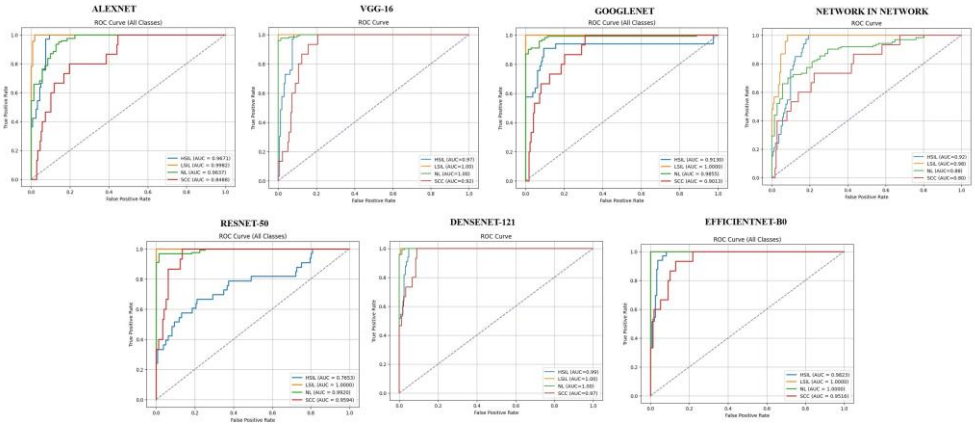

Fig. 5. ROC curves for CNN models including AlexNet, VGG-16, GoogLeNet, NIN, ResNet-50, DenseNet-121, and EfficientNet-B0 on the cervical cancer dataset.

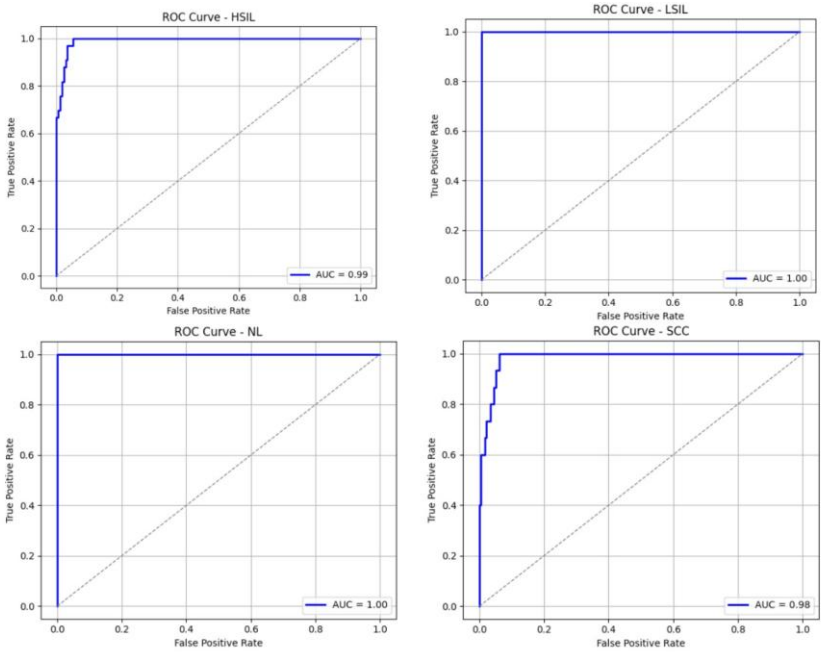

Fig. 6. ROC curves of the ViT-16 model for four-class cervical cytology classification: HSIL, LSIL, NILM, and SCC. The model achieved high AUC values of 0.99, 1.00, 1.00, and 0.98, respectively.

B. Best Model Overview

Among all models evaluated, EfficientNet-B0 and Vision Transformer (ViT-16) demonstrated the highest classification performance. EfficientNet-B0 achieved a final test accuracy of 94.33% with an overall specificity of 0.9832. ViT-16 further surpassed these results with a test accuracy of 95.88% and specificity of 0.9864. Table IV presents ViT-16's class-wise metrics.

TABLE IV. PERFORMANCE METRICS BY CLASS FOR VIT-16

Class	Precision	Recall	F1-score	Specificity
HSIL	0.93	0.85	0.89	0.9876
LSIL	1.00	0.96	0.98	1.0000
NMIL	0.99	1.00	1.00	0.9859
SCC	0.72	0.87	0.79	0.9721

VI. DISCUSSION

The in-depth study here provides information about the experimental results, connections between models, dataset characteristics, and challenges faced in evaluating results. This section goes into deeper detail about the important findings from the comparative study of CNN and transformer-based models on the classification of cervix cytology. The cervix cytology dataset used in this study consists of four cervix cytology classifications: HSIL high-grade squamous intraepithelial lesion, LSIL low-grade squamous intraepithelial lesion NILM (Negative for intraepithelial lesion or malignancy), and SCC (Squamous cell carcinoma). Each classification is different in how many total images are available for training, as well as how complex the images are visually. The cervix cytology dataset also presented several challenges, such as imbalanced class distributions, variability between images, inconsistent staining, and subtle visual differences between the HSIL and LSIL classes. The SCC class had the lowest number of training sample images when compared to the other three cervix cytology classifications, and therefore, many of the models had difficulty generalizing well to the SCC. With only 963 total images in this study, transfer learning with pre-trained models was used to reduce the chance of overfitting and to increase generalization ability for features. Weighted class sampling was also used during the training phase along with applying class-balanced loss to address issues related to imbalanced class distributions. The experiments also show that EfficientNet-B0 and ViT-B16 performed well enough in terms of both recall and specificity on the SCC class while demonstrating a reasonable amount of resilience against the data scarcity issue. The preprocessing steps like cropping, normalizing, and augmenting datasets are critical to ensure that all models are trained on the same, equalized, and enhanced dataset. Additionally, using a WeightedRandomSampler helped balance the number of samples from minority classes by creating balanced mini-batches for training and increasing SCC detection accuracy. These results provide evidence that using class balancing approaches improves learning stability and sensitivity for minority-class samples. The hyperparameter settings used to fine-tune the models are identical to one another and included, using pretrained ImageNet weights, the same preprocessing methods for all models, a batch size of 32, Adam optimizer (learning rate 0.0001), weighted cross-entropy loss, and a maximum number of 10 epochs of training. Using standardized hyperparameter settings provided a consistent basis for an unbiased comparison of all models. Initial experiments showed that validation accuracy converged around epochs 8-10 for the majority of models, and further training yielded little or no improvement in the model's classification accuracy, with an increased probability of overfitting.

All models differ in their respective performance based on the same conditions of training, with substantially different performances. The least productive performers in regard to both recall and specificity (regardless of which dataset) are the shallow networks, including both AlexNet and Network-in-Network (NIN) networks, with especially poor performance seen with respect to the SCC class. One potential reason for their limitations includes fewer feature extractions and less ability to capture a complex spatial representation. Conversely, as the models become deeper and more connected (DenseNet-121 and EfficientNet-B0), both the amount of dense feature reuse and compound scaling contributed to increased performance through 1) dramatically improving feature representation and 2) increasing classification consistency among all diagnostic categories. However, as the models become deeper, they also require greater computational complexity and money to train, which could limit their ability to deploy in real-time clinical environments that are limited in available resources. Among the models analysed, the transformer-based ViT-B16 had the highest overall classification score out of all models on all datasets. The self-attention mechanism of this model provided the capability to effectively model long-range contextual dependencies and global structural information, allowing the model to be more effective at distinguishing visually similar lesion classes. Additionally, the strong performance displayed by ViT-B16 when trained with a very limited amount of training data is likely due to factors such as transfer learning, standardisation of preprocessing, balanced sampling, and the representational power of the attention mechanism of transformers. These findings indicate the emerging promise of transformer-based methods in the medical imaging field. Multiple metrics were assessed, including accuracy, precision, recall, F1 score, specificity, and ROC-AUC analysis, and while overall accuracy provides a high-level representation of how well a model performs, it can sometimes lead to inaccurate conclusions about models trained on imbalanced medical datasets. For this reason, class-level metrics were used to measure the ability of the models to detect the minority class. The importance of specificity was emphasized as it measures the model's ability to predict negative results while attempting to detect positive results in clinical screening situations where false positives present an additional complication to the costly and sometimes dangerous process of diagnosing patients. EfficientNet-B0 and ViT-B16 were able to generate consistently good specificity estimates across all classes, including SCC, indicating excellent diagnostic utility. Both macro and weighted F1 scores supported that the models were generating consistent predictions across majority and minority classes. EfficientNet-B0 and ViT-B16 demonstrated superior performance on all of these metrics, which would indicate they would be able to generalise better than the other models considered and have balanced learning behaviour. The evaluation of ROC-AUC

analysis provided additional support for the robust discriminatory ability of the models across all eleven diagnostic classifications.

Architectural depth, dense connectivity, transfer learning and attention mechanisms are important in enhancing performance for the classification of cervical cytology specimens. Although traditional convolutional neural networks (CNN) architectures are still valid benchmark models, ViT (Vision Transformer) architectures such as ViT-B16 have demonstrated greater accuracy for classifying complex feature relationships as well as identifying minority classes. Specifically, for the squamous cell carcinoma (SCC) class (which was the least represented in the dataset), ViT-B16 achieved a recall of 87% and a precision of 72%. Despite promising results based on the proposed comparative framework, there are still a number of limitations. The comparative analysis was conducted using one publicly available dataset with no external cross-dataset validation, therefore limiting its generalizability to other clinical settings. Furthermore, the impact of staining artefacts (severe artefacts) as well as noise variation and imaging artefacts due to differences in laboratory settings were not systematically assessed. Therefore, there will be future studies that will explore cross-dataset validation, larger multi-centre datasets, analysis of computational efficiency, and hybrid CNN/transformers to further enhance robustness and clinical applicability in real-world scenarios.

VII. Conclusion

This study compared eight convolutional neural networks and a vision transformer model on a cervical cytology image dataset. The Vision Transformer (ViT-16) obtained the highest classification performance, while EfficientNet-B0 and DenseNet-121 also showed relatively strong results, including on minority classes such as SCC. Older models like AlexNet and NIN had more difficulty with class imbalance and deeper feature learning.

Overall, the findings suggest that models incorporating attention mechanisms or compound scaling provide advantages for medical image classification under imbalanced conditions. Future work may involve fine-tuning transformer models, exploring ensemble approaches, or integrating domain knowledge to improve classification reliability. For future directions, cross-dataset validation and the development of larger, multi-centre datasets will be pursued

A. Limitations

This study has several constraints. All models were trained from scratch without pretrained weights, which may affect generalization. The dataset was limited in size and imbalanced, especially for SCC, which may have influenced performance. In addition, results were obtained from a single dataset, and external validation would be useful for assessing robustness. Finally, computational efficiency was not the main focus, which could affect practical deployment in clinical environments.

Authors' Contribution

Dr. Mehreen Sirshar and Dr. Fakeeha Jaferi have supervised this work. Ibrahim Aljubayri and Abdulrahman Alahmadi prepared the figures. Omama Shakeel and Nayab Asim prepared the manuscript. Muhammad Zubair Khan reviewed the manuscript.

Non-financial Competiting interest. No, I declare that the authors have no competing interests as defined by Nature Research, or other interests that might be perceived to influence the results and/or discussion reported in this study.

Funding Declaration: This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

***Abstract*—Soiling is one of the major factors that can affect the performance of PV installations in many regions of the world. On the other hand, the variety of PV models, types of soiling, and climate conditions makes it very difficult to create a universal model. To address this problem, this study presents a methodology for the identification of soiling on PV panels via semantic segmentation, which can support the decision-making process in terms of surface cleaning and automation of the process. The methodology includes data collection, preparation of training and testing data, training of models, and application of the optimal one. Next, the methodology is demonstrated using a small dataset of clean and dirty PV panels, three neural network architectures (DeepLab v3, U-Net, and PSPNet), and two backbone models (ResNet34 and ResNet50). The obtained results show the feasibility of the methodology and allow highlighting the DeepLab v3 model with a ResNet34 backbone as the best-performing algorithm for identifying pigeon droppings. The second-best combination is the U-Net + ResNet34, which showed good efficiency for identifying smaller dirty areas. The proposed methodology could be useful for operators of large-scale photovoltaic installations by supporting the decision-making process when it comes to the timely cleaning of specific areas for performance improvement and lower costs.**

***Keywords*—PV soiling; semantic segmentation; pixel-based classification; neural network; RGB images**

I. Introduction

In times of energy crisis and a changing climate, the importance of renewable energy sources (RES) increases significantly. Out of them, photovoltaic (PV) systems are dominating the renewables market due to their versatility and low-maintenance requirements. Nevertheless, numerous factors exist that influence PV installations' performance and, as a result, open many opportunities for their optimization. Two of these factors are soiling and shading of the photovoltaic surface, which could have a great impact on a PV installation's performance [1,2]. They are known to lead to various consequences, such as reduced energy yield [3-5], increased panel degradation [5,6], hotspots [7], fire hazard [8,9], etc. In most situations, shading is a factor that can be acknowledged during design time, but there are limited options for its mitigation.

Soiling, on the other hand, could be effectively mitigated during exploitation; however, there are a number of factors to consider. According to [10], soiling accumulation can reduce energy production by up to 20%, depending on the environmental conditions. In [11] was obtained that agricultural soiling could reduce light transmission by up to 40% and the power output by up to 10%. Similar results about bird droppings showed that the power losses could reach a maximal value between 10% and 23%, depending on the month of the year and the PV installation location [12].

To mitigate the impact of soiling, different approaches for cleaning the photovoltaic surfaces exist. The most basic one is manual cleaning, which is known to be both expensive and time-consuming [13]. Furthermore, it requires water that is free from minerals to prevent the creation of spots and scale build-up. Other studies have suggested using the thrust of a drone to clean dust from the PV surface [14] or different types of robots moving over the PV surface [15,16]. In [17,18], a mechanism for self-cleaning panels' surface by removing dust particles using spherical water droplets is proposed, where a sliding or rolling motion is imparted. In all cases, the price is a major factor, and therefore, it is important to properly schedule the cleaning cycles [19]. The importance of properly deciding on when to clean the PV surface increases even more for building-integrated photovoltaics, where conventional cleaning approaches are rarely applicable [20].

Another problem is the type of soiling. Most of the above-mentioned studies propose solutions for removing dust. However, periodic cleaning, especially if a waterless method is used, is not always a suitable solution for bird droppings, which are especially common in the urban environment. All of this shows that the identification of bird droppings is a major factor for the optimization of the PV cleaning process.

Numerous studies have proposed a wide range of approaches for identifying soiling on PV surfaces based on image processing and classification [21], RGB image analysis [22], and pixel- and object-based identification. In [10], a methodology for the classification of RGB images of PV surfaces as either clean or dirty was proposed. The images were preliminarily processed using red channel doubling and conversion to multichannel, which allowed the dirty parts to be highlighted. Different machine learning algorithms were tested, and the best results were achieved by an artificial neural network, reaching an F1 score of 91.3%. In another study [23], deep learning was used to classify RGB images of PV modules into one of the 5 classes: very unclean, slightly unclean, medium clean, slightly clean, and clean. The optimal results

were achieved by the UTran neural network architecture with a ResNet50 backbone, reaching an accuracy of 96.41%.

In [24], a pixel-based classification approach was used to identify hotspots on PV surfaces by classifying the pixels of IR images using machine learning algorithms. The output of the models is a mask that identifies potential problems. A different approach was used in [25] with images in the visible spectrum, aimed at teaching a robot to identify and clean soiled surfaces automatically. The study proposed a threshold value used on the red channel of the RGB image in order to create the cleaning masks. In [26], several methods for semantic segmentation were used to generate soiling masks on PV surfaces. The algorithms used include Random Forest, XGBoost, LightGBM, and the U-Net neural network architecture. The neural network achieved the highest performance, reaching an accuracy and F1 score of 96.82% and 93.37%, respectively.

Other studies investigated the object-based approach for identifying soiling on PV panels. In [27], RGB images were used with the SDS-YOLO v5 architecture. The model achieved F1 scores of 0.700 and 0.781 for the bird droppings and dust classes, respectively. A similar approach was used in [28], where the YOLO v8 model's soiling identification efficiency exceeded 90%. In [29], different classification models were compared to identify PV performance degradation caused by dust and dirt accumulation. The results demonstrated the potential of data-driven approaches to improve the monitoring and maintenance of photovoltaic systems and to optimize energy efficiency.

A completely different approach was used in [30], where real-world meteorological and production data were used to develop and validate a predictive algorithm based on Stacked Ensemble Learning (SEL) and Decision Trees (DT). It achieved high accuracy in predicting soiling and panel performance, which shows that such models can help optimize maintenance and improve the energy efficiency of photovoltaic systems.

The performed analysis shows that numerous studies have proposed different approaches for the identification of soiling on PV surfaces with AI algorithms, with the object-based ones commonly having a lower accuracy compared to the pixel- and classification-based ones. Some of them achieved quite impressive results, yet their accuracy generally becomes lower when used on different datasets, which is normal for machine learning. The various PV technologies have different appearances in terms of color, cell dimensions, etc., which is a major limiting factor for the models to be more universal. Furthermore, the soiling factors also vary in different geographic locations. This means that in order to achieve optimal results, the models should be trained with a dataset that was obtained for a specific PV facility. Most studies concentrate on the modelling part, rather than the methodological aspects, which are more important as they allow for obtaining improved results for the local specifics. Therefore, this could be considered a research gap.

Considering the above-mentioned, this study aims to propose a methodology for assessing the soiling of PV panels, which allows for training high-accuracy deep learning models capable of supporting the decision-making process in terms of organizing the cleaning routines. The feasibility of the proposed methodology is demonstrated using a small dataset with PV modules under the impact of pigeon droppings, obtained from the region of Ruse, Bulgaria. The study also evaluates the performance of different deep learning architectures and backbone models for identifying bird droppings with different impact areas.

II. Materials and Methods

A. Methodology of the Study

The proposed methodology for assessing the condition of a PV surface is summarized in Fig. 1. It can be described in 4 steps as follows:

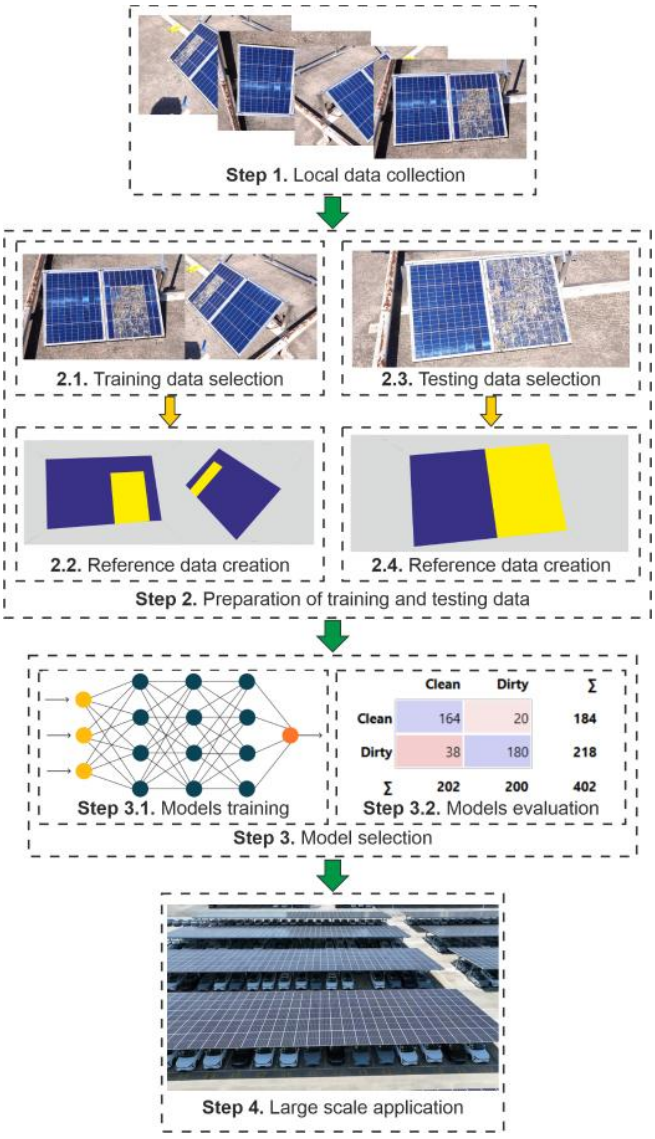

Fig. 1. Methodology for identification of soiling on a PV surface.

Step 1. Local data collection

This step includes the collection of images from the specific PV installation that is to be evaluated. The data must be obtained for the specific facility for several reasons:

- The way the panels look depends on their technology, weather conditions, etc., which is always site-specific;
- The potential soiling is also site-specific as it depends on the local soil types, the type of birds, etc.

Furthermore, when collecting the local dataset, it is recommended that the following requirements be met:

- It should represent all potential types of soiling on the PV surface;
- It should include surfaces of well-cleaned panels;
- It should include the different background surfaces available at the site (grass, concrete, etc.).

Step 2. Preparation of training and testing data

Next, training and testing data should be prepared, which is implemented in two similar processes.

1) Training data selection: In this phase, several images are selected from the local dataset, which represent all major situations, such as clean panels, panels with different types of soiling, and images with different types of surrounding backgrounds. It is recommended that the different situations are more or less equally represented in order to improve the performance of the models. According to the proposed methodology, the selected images should be merged into a single larger image.

2) Reference data creation: Next, using the compiled training image, reference data should be created. In this study, the following classes are used:

- Clean PV surface ("Clean") – an area of the PV surface, which is in good condition and no soiling can be observed;
- Dirty PV surface ("Dirty") – an area of the PV surface, on which soiling can be observed;
- Background ("Back") – everything else that is not part of the PV surface (whether clean or dirty) is considered a surrounding or background area.

If necessary, the "Dirty PV surface" class could be divided into subclasses, representing different types of soiling. However, in this study, we have only investigated soiling caused by bird droppings.

In this phase, the pixels of the compiled training image are manually classified into one of the selected categories. An important recommendation is that if the operator cannot clearly identify the class of a certain area of the image, the corresponding pixels should remain uncategorized.

3) Testing data selection: In this phase, other images should be selected for testing purposes that are different from the training ones. They should also adequately represent all common situations. Similarly, the images could be merged into a single testing image for easier processing and analysis.

4) Reference data creation: This phase is similar to 2.2 and includes classifying the pixels of the testing image into the adopted classes.

Step 3. Model selection

This step includes two phases – training models and evaluating their performance, aimed at identifying the optimal ones.

1) Models' training: In this study, three deep learning architectures are selected:

- U-Net- is widely used for pixel-based classification and has shown good performance for dust detection in photovoltaic panels [31]. It is also known for achieving high accuracy with fine details, being extremely efficient when working with small data sets, and typically requires less training time and hardware resources [32]. Despite being lighter and faster, it often performs relatively well compared to other models [33];
- DeepLab v3- is another semantic segmentation model, which is known to return good results with the identification of photovoltaic installations [34,35], surface soiling [36], hot-spot defects [37], etc. It usually returns better accuracy at different object scales and more complex images, but can be significantly slower to train and requires a larger amount of data and hardware resources [38];
- Pyramid Scene Parsing Network (PSPNet)- has also shown good results with PV panel identification [35]. It is known for better distinguishing objects based on analysis of the surrounding environment, but can be significantly slower to train and requires a larger amount of data and hardware resources, although some works report that it is the most efficient in terms of execution time [39].

Furthermore, for each one of them, two backbone models have been used: ResNet-34 and ResNet-50, thus making a total of 6 combinations. The difference between ResNet-34 and ResNet-50 lies mainly in their depth and architectural complexity. ResNet-34 is a lighter backbone model, requiring less training data for simpler tasks, training faster, and taking up less memory on the graphics processing unit. ResNet-50, on the other hand, is more complex and is better at recognizing fine textures and complex objects, but requires more data to avoid overfitting. Furthermore, it requires more computing power and memory, and training takes longer.

This phase of the methodology includes training the models using the training data, prepared in phases 2.1 and 2.2 of the methodology.

2) Models' evaluation: Next, each of the trained models is applied to the testing data prepared in phases 2.3 and 2.4, and a classification image is created. Thereafter, the performance of each model is evaluated against the reference data using the following metrics:

- Accuracy – estimates the proportion of total correct predictions:

$$Acc = \frac{TruePositive+TrueNegative}{TruePositive+TrueNegative+FalsePositive+FalseNegative} \quad (1);$$

- Precision – estimates the share of true positives out of all positively identified pixels:

$$Precision = \frac{TruePositive}{TruePositive+FalsePositive} \quad (2);$$

- Recall – estimates the share of the correctly identified pixels:

$$Recall = \frac{TruePositive}{TruePositive+FalseNegative} \quad (3);$$

- F1 score – averages the precision and recall:

$$F1 = 2 \times \frac{Precision \times Recall}{Precision+Recall} \quad (4);$$

- Cohen's Kappa – evaluates the level of agreement between classified and reference data, with 0 corresponding to no agreement at all (all pixels were classified incorrectly) and 1 corresponding to perfect agreement (all pixels were classified correctly) [40].

The above metrics are used to select the best-performing model(s).

Step 4. Large-scale application

Once the best-performing model is selected, it can be used for large-scale identification of soiling at the specific photovoltaic facility as an instrument for automating the decision-making and cleaning processes.

B. Means of the Investigation

In this study, the software ArcGIS Pro v. 3.6.1 is used, developed by Esri Inc. Even though this tool was created as a GIS analysis instrument, it is also applicable to images that are not mapped to a specific coordinate system.

ArcGIS Pro provides a wide range of object- and pixel-based machine learning and deep learning algorithms, integrated tools for the creation of reference data, comparison between the modeled and reference data, generation of confusion matrices, estimation of different measures, etc. Furthermore, all of the above is implemented in a friendly graphical user interface, i.e., no specialized programming knowledge and skills are required. This means that with appropriate instructions, the ArcGIS Pro tool could be used by operators of photovoltaic installations without the need for IT-specific qualifications.

C. Organization of the Experiment

The experiment in this study was performed at the site of PV Park Kanev, located in the University of Ruse "Angel Kanchev", Ruse, Bulgaria, geographic coordinates 43.85344121491259, 25.969174955358763 (Fig. 2). Two 50W polycrystalline PV panels with model CL-SM50P were used in the experiment. One of the two panels has been placed on the floor of a dovecote for two weeks. This allowed its surface to be densely covered with pigeon droppings, which are one of the main sources of PV soiling in the Bulgarian urban landscape.

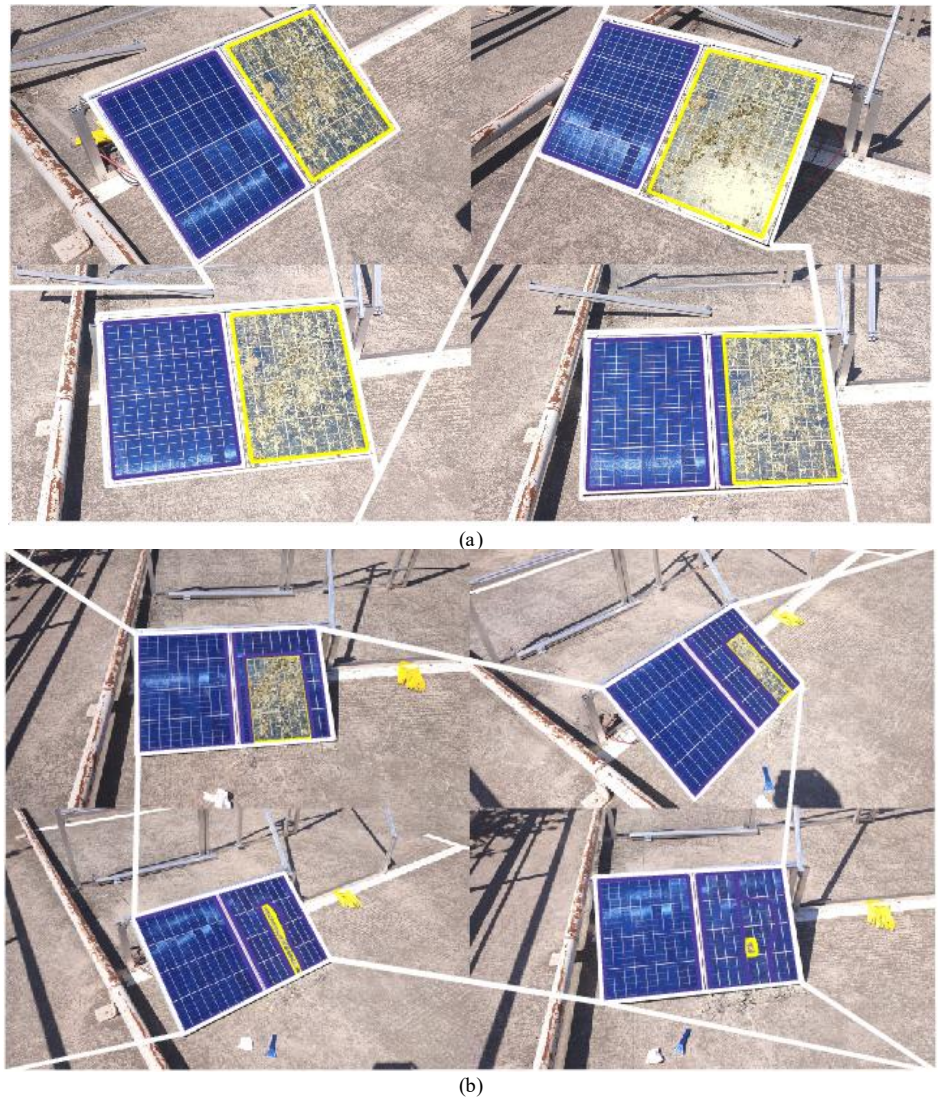
Fig. 2. Location of the experimental site.

III. Results and Discussion

In this section, the study aims to demonstrate the feasibility of the proposed methodology using a limited amount of input data. The clean and dirty PV panels were installed at the experimental site using a specially created mounting structure, and numerous images of them were made from different angles. Next, different areas of the soiled PV surface were gradually cleaned, and additional photos were made at each stage (Fig. 3). The data collection was finalized when both PV surfaces were clean.

Fig. 3. Photos of the two PV panels with different levels of dirtiness.

Next, according to Step 2 of the methodology, four images were selected, which represent different aspects of the experimental situation, such as:



- The PV modules are photographed from different angles, which represent the surfaces differently affected by the solar rays;

- The surrounding area is observed from different angles, which influences its view, the impact of shadows, etc.

The four images were merged into a single one using Microsoft's MS Paint tool. Thereafter:

- The prepared training image was imported into ArcGIS Pro v. 3.6.1;
- Reference areas were created for the three classes (Clean, Dirty, and Background) with the Image Classification tool using polygons (Fig. 4a).

Finally, the created reference data was exported in the "Classified tiles" metadata format with X/Y tile size 256 and X/Y Stride 128. Similarly, four testing images were selected, merged into a single image, and reference data was created for it (Fig. 4b).

(a)

(b)

Fig. 4. The selected training (a) and testing (b) images with the marked reference polygons.

Following Step 3 of the methodology, 6 models were trained using the three NN architectures and the two backbone models on an HP Pavilion laptop with an NVidia GeForce MX350 GPU. 20 epochs were used for the training, 10% of the input data was used for validation, the optimal learning rate was automatically extracted from the learning curve, and all other parameters were kept at their default values. The obtained accuracies and F1 scores for the six models are summarized in Table I. It can be seen that if accuracy and F1 score are used as the main indicators, the DeepLabv3+ResNet50 combination is the worst-performing model. The differences between the measures of the other 5 models are 1-2 thousandths, and therefore could be considered insignificant. In general, the U-Net and PSPNet-based models achieve the highest performance.

On the other hand, when the Kappa coefficient is used, the PSPNet-based models have the lowest performance, while the U-Net+ResNet34 combination is the second best. The DeepLabv3+ResNet34 achieved the best performance, reaching a Kappa score of 0.996. It is important to mention that Cohen's Kappa is considered a more stable indicator than Accuracy because it excludes the chance of hitting the result when some data predominates [41].

TABLE I. SUMMARY OF THE SIX MODELS' TRAINING SCORES

№	Model	Accuracy	F1 Score	Kappa
1	DeepLab v3 + ResNet34	0.982	0.987	0.996
2	DeepLab v3 + ResNet50	0.975	0.980	0.985
3	U-Net + ResNet34	0.983	0.987	0.988
4	U-Net + ResNet50	0.984	0.988	0.980
5	PSPNet + ResNet34	0.983	0.987	0.954
6	PSPNet + ResNet50	0.983	0.988	0.962

The conclusion from the measures analysis is that the DeepLab v3+ResNet34 model, even though requiring more resources and time, could perform slightly better, especially in situations such as the current one, when comparatively little data is available. U-Net+ResNet34 is expected to perform about the same, but with less required time and resources. However, according to [42], DeepLabV3+ outperforms U-Net in terms of both speed and accuracy.

Next, the six models were applied to the testing image, and the obtained classification images are presented in Fig. 5. At first glance, it can be seen that all models perform very well, though some false positives can be observed. Furthermore, it can be observed that larger dirty areas are well identified by all models, while the results with smaller and thinner ones are more variable, and some false positives and false negatives can be observed.

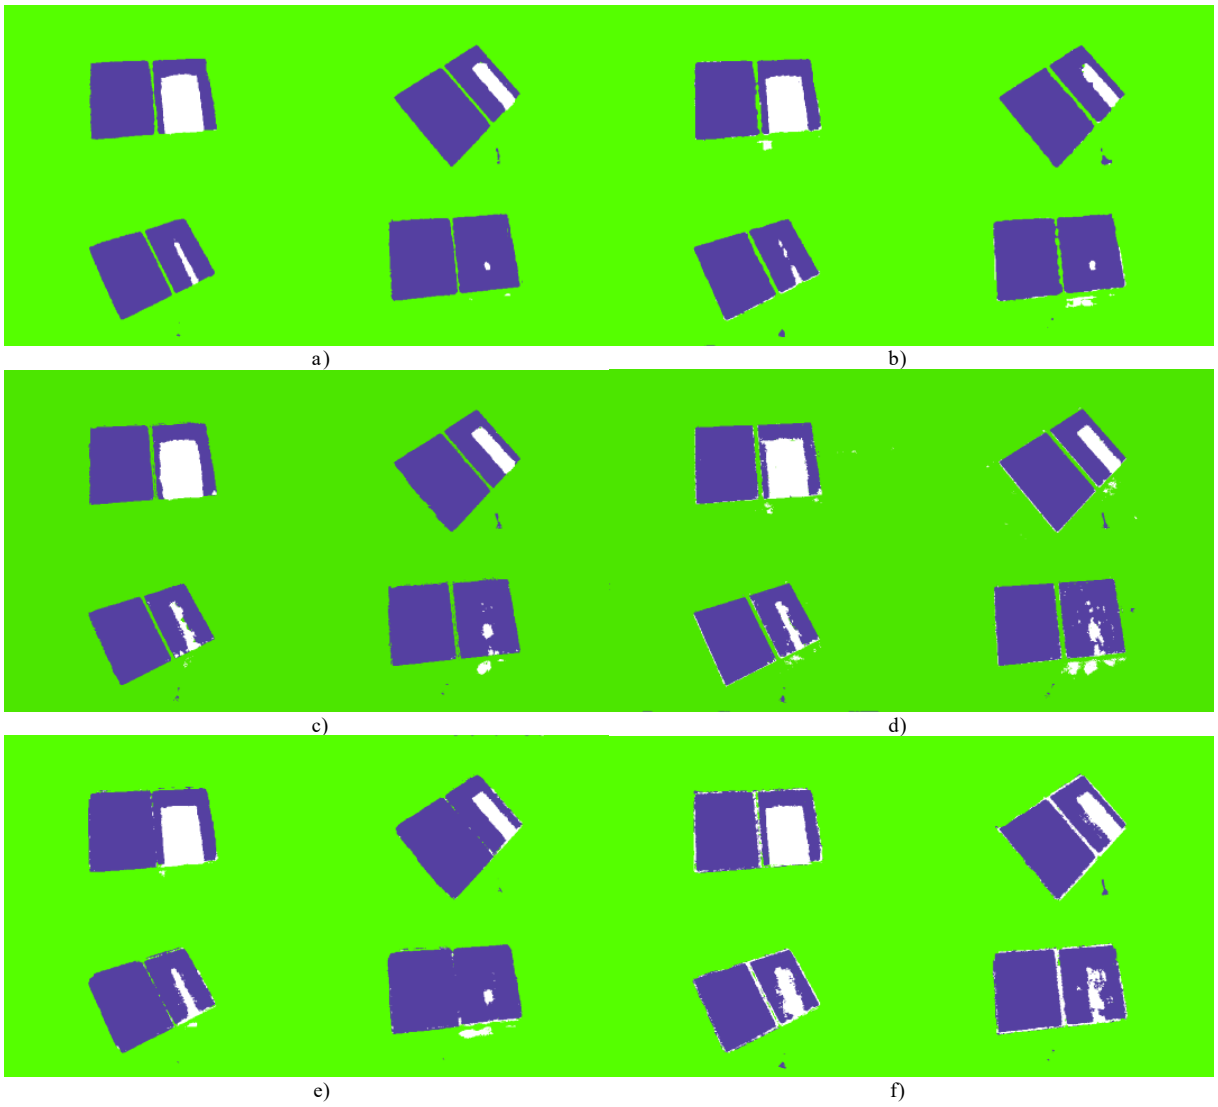


Fig. 5. Classification results for the testing image done with: DeepLab v3 + ResNet34 (a); DeepLab v3 + ResNet50 (b); U-Net + ResNet34 (c); U-Net + ResNet50 (d); PSPNet + ResNet34 (e); PSPNet + ResNet50 (f).

To get a better understanding of the models' performances, they were assessed using the "Accuracy assessment" tool in ArcGIS, 10,000 randomly selected pixels, and the Stratified random strategy was used on the reference testing data to generate the confusion matrices for the six situations.

The results for the DeepLab v3 + ResNet34 model are presented in Table II. It can be seen that the model has almost perfect performance, with an average F1 score of 0.999. The lowest precision and recall are obtained for the Dirty class, reaching values of 0.974 and 0.993, respectively, which indicates the classification of some false positives.

TABLE II. CONFUSION MATRIX AND MEASURES FOR THE TESTING DATA WITH THE DEEPLAB V3 + RESNET34 MODEL

		Predicted				Metrics		
		Clean	***Dirty***	***Back***	***Total***	***Prec.***	***Rec.***	***F1***
Actual	***Clean***	1332	4	5	1341	0.999	0.993	0.996
	Dirty	0	149	1	150	0.974	0.993	0.983
	Back	1	0	8508	8509	0.999	1.000	1.000
	Total	**1333**	**153**	**8514**	**10000**	**0.999**	**0.999**	**0.999**

Table III presents the performance of the DeepLab v3 + ResNet50 model. Its metrics are slightly lower for the clean and background classes, as for the dirty class, the precision and recall have dropped significantly, reaching values of 0.902 and 0.890, resulting in an F1 score of 0.896.

TABLE III. CONFUSION MATRIX AND MEASURES FOR THE TESTING DATA WITH THE DEEPLAB V3 + RESNET50 MODEL

		Predicted				Metrics		
		Clean	***Dirty***	***Back***	***Total***	***Prec.***	***Rec.***	***F1***
Actual	***Clean***	1330	14	6	1350	0.999	0.985	0.992
	Dirty	0	138	17	155	0.902	0.890	0.896
	Back	1	1	8490	8492	0.997	1.000	0.999
	Total	1331	153	8513	9997	0.996	0.996	0.996

Next, in Table IV and Table V, the measures for the two U-Net models are shown. Unlike the DeepLab models, these achieved higher precision for the dirty class, reaching up to 1.000 with the ResNet50 backbone; however, the recall is lower, which indicates an increased share of false positives. These results confirm the classification images in Fig. 5, which also show the identification of many false-positive "dirty" pixels.

TABLE IV. CONFUSION MATRIX AND MEASURES FOR THE TESTING DATA WITH THE U-NET + RESNET34 MODEL

		Predicted				Metrics		
		Clean	***Dirty***	***Back***	***Total***	***Prec.***	***Rec.***	***F1***
Actual	***Clean***	1320	0	10	1330	0.990	0.992	0.991
	Dirty	13	154	7	174	0.994	0.885	0.936
	Back	0	1	8495	8496	0.998	1.000	0.999
	Total	1333	155	8512	10000	0.997	0.997	0.997

TABLE V. CONFUSION MATRIX AND MEASURES FOR THE TESTING DATA WITH THE U-NET + RESNET50 MODEL

		Predicted				Metrics		
		Clean	***Dirty***	***Back***	***Total***	***Prec.***	***Rec.***	***F1***
Actual	***Clean***	1311	0	3	1314	0.986	0.998	0.992
	Dirty	19	153	30	202	1.000	0.757	0.862
	Back	0	0	8481	8481	0.996	1.000	0.998
	Total	1330	153	8514	9997	0.995	0.995	0.994

Finally, in Table VI and Table VII, the results for the PSPNet models are summarized. Similarly to the U-Net models, the dirty class precision is 1.000, which indicates that all dirty pixels were correctly identified. However, the recall decreases even more, reaching 0.748 and 0.698 with the ResNet34 and ResNet50 backbones, respectively. Once again, this indicates that these models return too many false positives when it comes to the dirty areas of the PV panel, which might lead to misleading results and have a significant impact on the decision-making process.

TABLE VI. CONFUSION MATRIX AND MEASURES FOR THE TESTING DATA WITH THE PSNET + RESNET34 MODEL

		Predicted				Metrics		
		Clean	***Dirty***	***Back***	***Total***	***Prec.***	***Rec.***	***F1***
Actual	***Clean***	1325	0	71	1396	0.993	0.949	0.971
	Dirty	9	154	43	206	1.000	0.748	0.856
	Back	0	0	8400	8400	0.987	1.000	0.993
	Total	1334	154	8514	10002	0.988	0.988	0.987

TABLE VII. CONFUSION MATRIX AND MEASURES FOR THE TESTING DATA WITH THE PSNET + RESNET50 MODEL

		Predicted				Metrics		
		Clean	***Dirty***	***Back***	***Total***	***Prec.***	***Rec.***	***F1***
Actual	***Clean***	1300	0	33	1333	0.975	0.975	0.975
	Dirty	33	155	34	222	1.000	0.698	0.822
	Back	0	0	8447	8447	0.992	1.000	0.996
	Total	1333	155	8514	10002	0.990	0.990	0.989

The obtained results show that the DeepLab v3 model with a ResNet34 backbone achieved the best performance, followed by the U-Net + ResNet34 one, for the following reasons:

- All models achieved more or less similar performance for the clean and background classes, with their precisions/recalls varying between 0.975 and 1.000;
- Most models achieved great precision for the dirty class, varying between 0.974 and 1.000 (the only exception is the DeepLab v3 + ResNet50 model, which achieved a precision of 0.902);
- The DeepLab v3 + ResNet34 model achieved the highest recall for the dirty class, reaching a value of 0.993, while this measure for all other models is significantly lower, ranging between 0.698 and 0.890.

These results also correspond with those obtained using the Kappa coefficient during the training phase. They confirm that Cohen's Kappa is a more reliable measure and could be used as the main indicator for selecting the optimal model.

IV. CONCLUSION

The current study presents a methodology for the identification of soiling on PV panels, which is optimized for providing reliable site-specific results. It can be used as a supporting instrument in the decision-making process of cleaning large photovoltaic installations. The methodology includes data collection, preparation of training and testing

data, training of models, and identification of the optimal one, which can then be applied on a large scale.

Next, the feasibility of the methodology is demonstrated by using limited experimentally obtained data from the PV park Kanev, Ruse, Bulgaria. An image dataset was created with clean and dirty PV panels under the impact of pigeon droppings. Training and testing images were selected, and reference data were created for them using three classes: "clean", "dirty", and "background". Three deep learning architectures were used: DeepLab v3, U-Net, and PSPNet. Furthermore, each one of them was trained with the ResNet34 and ResNet50 backbones. All trained models achieved more or less similar metrics and very good performance.

However, after they were applied to a testing dataset, the DeepLab v3 model with a ResNet34 backbone showed the highest performance, expressed in the best ratio between precision and recall regarding the "dirty" class. The second-best combination is the U-Net + ResNet34, which proved to be extremely efficient when working with small datasets. Both models could be applied in practice for the identification of soiling areas with relatively small datasets specific to the photovoltaic site. The study results also showed that Cohen's Kappa could be used as the main indicator for selecting the optimal model of the methodology, which is an important observation for the future application of the methodology.

The methodology proposed in this study could be useful for operators of large photovoltaic installations by supporting the decision-making process when creating the cleaning schedule. Even though the obtained results are quite promising, they have some limitations. They were not tested with real data, obtained from drones or satellites, which is an important goal for future research. Furthermore, it is worth investigating the possibility of increasing the performance of all algorithms by using a secondary model for limiting the analyzed area only to the area of PV modules, thus allowing the removal of the "background" class.

ACKNOWLEDGMENT

This study is financed by the European Union—NextGenerationEU through the National Recovery and Resilience Plan of the Republic of Bulgaria, project no. BGRRP-2.013-0001.

***Abstract*—High transaction costs remain a major barrier to the scalability of Ethereum-based decentralized applications (DApps), particularly when smart contracts are computationally inefficient. Although the Solidity compiler optimizer can reduce bytecode size and improve some low-level patterns, it does not fully address structural inefficiencies in storage layout and state mutation. This study introduces controlled empirical research on the topic of manual smart contract refactoring approaches with the aim of quantifying their impact on gas usage and execution cost in the Ethereum Virtual Machine (EVM). The Remix Integrated Development Environment (IDE) and a synchronized Go-Ethereum (Geth) node (version 1.13.5) were configured to create a controlled experimental environment. This environment was connected to the Sepolia Testnet to approximate conditions similar to the Ethereum Mainnet. The role of high-cost storage operations such as SSTORE was analyzed using opcode-level transaction traces, which were collected using debug_traceTransaction. The proposed refactoring plan implies the alignment of storage slots by systematically packing the variables and data location optimization (calldata and memory) to minimize unnecessary memory allocation. The experiments show gas reductions of up to 40.68% for storage-intensive functions, with an average reduction of 28.5% across all evaluated test cases. Moreover, the findings at the opcode level have shown that it is possible to reduce the costs of unnecessary storage writes without impacting the correct functional performance of the execution. Overall, the findings show that storage-aware manual refactoring is a viable strategy for improving runtime efficiency and reducing the execution cost of Layer-1 smart contracts.**

Keywords*—Ethereum smart contract; solidity refactoring; gas optimization; Ethereum Virtual Machine (EVM); opcode tracing

I. Introduction

Ethereum is a widely used decentralized application platform whose smart contracts are executed through the Ethereum Virtual Machine (EVM) [1], [2]. However, the wider use of Ethereum is still constrained by the gas cost of executing smart contracts [3], [4]. Although gas helps prevent computational abuse, high gas requirements remain a practical barrier to scalability [5], [6]. Ethereum has adopted Proof of Stake (POS) and implemented EIP-1559, which stabilizes market fees. But even the gas that is used by a smart contract is still heavily reliant on the computational and storage requirements of the contract itself. This implementation expense has a direct impact on the cost-effectiveness of Decentralized Applications (DApps) [7], [8].

Despite these protocol-level changes, contract-level code complexity still affects execution cost. This is especially important for high-frequency DApps (such as decentralized order books or real-time gaming), because even marginal inefficiencies in state management will make a project economically unviable for mainstream adoption [9], [10], [11].

While standard Solidity compiler optimizer *'solc --optimize'* as well as automated tools like *'GasReducer'*, *'sOptimize'* make good progress on reducing the size of bytecode using techniques like constant folding and function inlining, they don't explicitly take developer-defined architectural choices, in terms of storage layout and data-handling [12], [13], [14]. Since the compiler has no idea of the organization of storage specific to the contract, it is not able to automatically implement structural optimizations like packing storage slots, such as storage-slot packing and calldata-based parameter handling [15], [16]. This study examines whether manual refactoring can improve runtime gas efficiency in selected Solidity patterns. This motivates attention to storage-aware refactoring strategies.

To address such an efficiency difference, a rigid comparative empirical analysis is made in this study between the traditional automated methods of optimization and advanced manual refactoring techniques. The method applied in this study to examine the cost of execution in detail is the opcode-level transaction tracing. This is especially so in applications that are highly interactive in the blockchain. Based on this, the aims of the study are the following:

- Implement a manual refactoring framework for Solidity contracts, focusing on storage slot alignment (Variable Packing) and data location calldata vs. Memory.
- Conduct comparative empirical research to quantify the gas savings when deployed and run-time execution with respect to the case of the baseline and optimized versions.
- Determine the deterministic behavior of EVM through trace fine-grained opcodes with a synchronized private Geth node.

To further direct the empirical study, the following research questions are derived in this study:

*Corresponding author.
This research was supported by a UTM Fundamental Research Grant Q.J130000.3828.23H38).

- RQ1: Does storage-slot alignment and data-location optimization of manual refactoring decrease gas consumption of storage-intensive Solidity functions when controlled by EVM execution?
- RQ2: Which optimization strategy contributes more directly to gas reduction at the opcode level: variable packing or calldata-based parameter handling?
- RQ3: How significant are the observed gas savings in terms of meaningful economic benefits to high-frequency cases of decentralized application?

These research questions are intended to provide a more analytical framework for the structure of the assessment of the technical and economic impact of manual smart contract optimization.

This study empirically evaluates the manual refactoring workflow for reducing EVM execution cost under controlled test conditions. By presenting at the opcode level evidence of runtime gas savings up to 40.68%, this study shows that manual interventions in storage-slot alignment and data-location management can improve execution efficiency and lower transaction-level cost for the evaluated smart contract functions:

- An opcode-level empirical framework for analyzing gas optimization in Ethereum smart contracts within a controlled EVM experimental environment.
- A manual Solidity refactoring methodology targeting storage access patterns and calldata optimization to reduce execution costs.
- Experimental validation demonstrating gas reductions of up to 40.68% through structural code refactoring under controlled Sepolia Testnet conditions.

II. Literature Review

Previous studies on the efficiency of Ethereum smart contracts can be classified into four categories: gas-fee dynamic, EVM resource pricing, automatic optimization tools, and experimental validation environments [17], [18], [19]. However, there is little evidence in the literature on the impact of manual refactoring on execution cost in controlled EVM environments at the level of opcodes [11], [18]. This gap indicates the need for regulated empirical assessment of manual refactoring utilizing low-level execution traces.

A. Economic Scalability and Gas Volatility

Recent protocol changes have not removed the importance of contract-level gas efficiency [12], [20]. Some studies say that the cost of gas is a big problem for DApps since bugs in contract code make transactions more expensive for users [21], [22].

Under EIP-1559, transaction fees are divided into a protocol-determined base fee and a priority fee [23]. Although fee levels vary with network conditions, developers still influence overall transaction cost through the gas consumption of contract execution [16], [17]. Because fee levels are externally determined, developer influence lies primarily in reducing contract-level gas consumption.

To frame optimization more clearly, gas mechanisms can be categorized according to their functions within the blockchain system [24]. In Ethereum, gas serves two main purposes: it acts as a pricing mechanism that discourages computational abuse, and it helps mitigate unbounded execution and denial-of-service risks [9], [23]. The given mechanism can be further divided into a two-tiered taxonomy of source control:

1) Protocol control (external): This includes the Base Fee calculated by the EIP-1559 protocol depending on block congestion [6], [23]. Although L2 networks like Polygon or Optimistic Rollups solutions have reduced fee taxonomies due to compression of the data, the logic behind the execution is still governed by the EVM rules [25].

2) Developer source control (internal): This is the strategic control of storage and use of computational resources at the implementation level [3], [4]. Although fee-market charges under EIP-1559 include a Base Fee and a Priority Fee, developers primarily influence total gas usage through contract-level efficiency, as illustrated in Fig. 1. Even though developers are not in control of the Base Fee in the market, they have ultimate control over gas limit through the efficiency of their code [21].

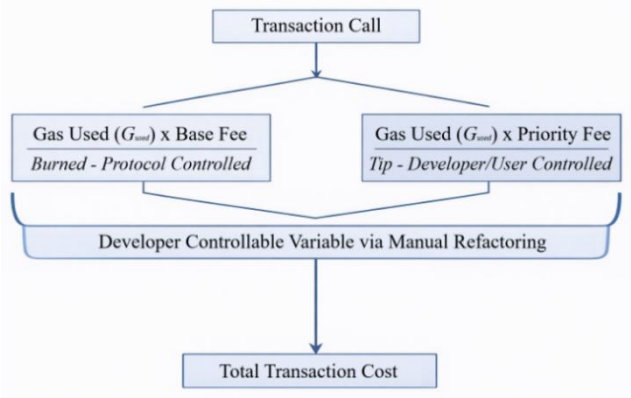

Fig. 1. Conceptual framework of Ethereum gas fee calculation.

Prior studies show that private Geth nodes support controlled and reproducible measurement of EVM execution behavior, making them suitable for fine-grained gas analysis [5], [26].

B. EVM Operating Cost Calculation Mechanism

The deterministic aspect of EVM calculation of costs is a requirement before one can detect structural inefficiencies in smart contracts [10], [18]. Reducing code inefficiency remains important for improving execution efficiency. Each operation is metered to support network security and to prevent unbounded execution, including risks associated with infinite looping [10], [27]. The total gas used by a transaction G_{total} is a combination of computational, storage, and memory resources usage, that is controlled by Eq. (1):

$$G_{total} = G_{intrinsic} + G_{execution} + G_{memory} \quad (1)$$

TABLE I. GAS-INTENSIVE EVM OPCODES AND OPTIMIZATION TARGETS

Opcode	Typical Gas Cost	Resource Category	Optimization Relevance	Refactoring Target
SSTORE	20,000 (New) / 2, 900 (Dirty)	Persistent storage writes	Very High	Variable Packing
SLOAD	2, 100 (Cold) / 100 (Warm)	Persistent storage read	High	Reduce repeated reads
MLOAD / MSTORE	3	Memory	Low	Temporary caching
CALLDATACOPY	3 + 3 x words	Input data copy	Moderate	Calldata vs. Memory
ADD / SUB	3	Stack Arithmetic	Low	Basic Logic

where:

- $G_{instrinsic}$: The fixed 21,000 units of gas to pay the base cost per transaction contained in the block.
- $G_{execution}$: The total cost of the opcodes that have been performed at runtime. This consists of state operations of high cost, such as *SSTORE* (up to 20,000 gas) and of low cost, such as *ADD* (3 gas).
- G_{memory}: Costs that are paid in quadratic proportion to the increase in memory used in contract execution.

Analysis through Eq. (1) reveals that the most impactful optimization vectors lie within $G_{execution}$ and G_{memory}. For instance, [20] highlight that identifying costly bytecodes and replacing them with gas-efficient patterns is highly required to mitigate these expenses. Techniques such as Variable Packing directly target the reduction of $G_{execution}$ by minimizing the expensive of storage operations, while shifting data location to *CALLDATA* mitigates the G_{memory} expansion penalty.

However, as mentioned by [5], the issue of linking these technical assurances to particular audit statements is the focus of research. Table I has been synthesized as comparative technical specifications of these opcodes, which are resource-intensive.

Table I summarizes the gas-expensive EVM opcodes that are most relevant for this study. In particular, *SSTORE* dominates state-changing cost, making storage-slot packing a key target for reducing deployment and runtime overhead. By contrast, input-copy operations such as *CALLDATACOPY* highlight the importance of parameter handling through calldata to avoid unnecessary memory-expansion costs. Collectively, these characteristics of the opcodes give the technical underpinning for the refactoring strategies that are evaluated in this work.

On top of this classification, Section III introduces the experimental refactoring workflow that is used to baseline smart contract implementations.

C. Manual Refactoring vs Automated Tools

Compiler-level optimization can improve common low-level patterns, but it does not usually perform structural changes such as storage-slot reorganization or context-specific data-layout decisions [28].

In order to overcome these shortcomings, different specific automated tools have been produced. *GasReducer* was presented in [15] as a tool that recognizes 24 code anti-patterns using the bytecode representation, and substitutes them with more efficient operation sequences.

TABLE II. COMPARISON OF SMART CONTRACT GAS OPTIMIZATION APPROACHES AND THEIR LIMITATIONS

Optimization Approach / Study	Primary Focus	Core Technique / Mechanism	Strengths / Contributions	Critical Limitation (Efficiency Gap)
Solidity Compiler Optimizer (--optimize) [29].	Bytecode size reduction, basic runtime optimization	Deduplication, jumpdest removal, peephole optimizations	Provides baseline automated improvements with minimal developer effort	Cannot restructure storage layout or apply variable packing; limited awareness of opcode-level cost (e.g., *SSTORE*)
GasReducer [30]	Anti-pattern detection at bytecode level	Replaces inefficient opcode sequences (24 patterns)	Effective for removing known inefficiencies automatically	Pattern-based; lacks semantic context and cannot perform deep architectural refactoring
sOptimize [31].	Dead code and redundancy elimination	Control Flow Graph (CFG) + lazy annotation	Improves execution efficiency through redundant instruction removal	Limited ability to optimize storage-heavy functions or calldata transitions
GASOL [2], [18], [32].	Minimizing memory/storage operations	SMT-based optimization encoding	Formal approach to reduce expensive memory and storage usage	Computationally complex; does not provide developer-guided storage slot packing
Slither Refactoring Framework [33]	Static detection of storage inefficiencies	Static analysis of contract structure	Identifies refactoring opportunities and vulnerability patterns	Context-blind: cannot apply dynamic optimizations such as calldata vs. memory restructuring
GasOptiScan (AST-based tools) [34].	Loop and syntax-level optimization	Abstract Syntax Tree (AST) parsing for pattern matching	Useful for detecting loop-fusible or structural patterns	Cannot optimize calling-context-dependent transitions (e.g., memory → *CALLDATA*)
Audit Formalization Gap [35].	Verification and guarantees mapping	Linking optimization guarantees to audit assertions	Highlights need for stronger runtime-focused validation	Automated tools prioritize deployment reduction over runtime opcode efficiency
Manual Refactoring Framework Evaluated in This Study	Runtime execution efficiency at opcode level	Variable packing, calldata optimization, stack caching, opcode tracing via debug traceTransaction	Provides opcode-level empirical evidence of runtime gas savings through storage-aware restructuring	Requires deeper EVM expertise and manual developer intervention (higher barrier to entry)

TABLE III. COMPARATIVE ANALYSIS OF EXPERIMENTAL ENVIRONMENTS FOR GAS VALIDATION

Blockchain Network	Consensus Mechanism	Avg. Transaction Cost (USD)	Throughput (TPS)	Cost Implication for Developers
Ethereum (Layer 1)	Proof-of-Stake (PoS)	$2.50 - $15.00	~15 -30	Severe: Code optimization is mandatory for viability
Arbitrum One (L2)	Optimistic Rollup	$0.10 - $0.50	~40,000+	Moderator: Cheaper, but inherits L1 data availability costs
Solana	Proof-of-History (PoH)	< $0.001	~65,000	Negligible: Optimization is less critical due to abundance.
Sepolia Testnet	Proof-of-Stake (PoS)	Free (Testnet ETH)	Mirrors Mainnet	Suitable: Useful for controlled testing of L1 logic without direct financial risk

On the same note, [30] created *sOptimize*, a tool that uses Control Flow Graph (CFG) representations and lazy annotation to identify dead or redundant code [4]. On a further level, [2], [18], [32] suggested GASOL, a tool that uses Satisfiability Modulo Theories (SMT) encoding to reduce memory and storage operations. Moreover, [33], [36], used Slither framework to find refactoring scenarios in the storage usage, showing that automated static analysis can conserve an average of 41,184 gas per contract.

Although these tools have been useful, there is a long-standing efficiency gap as a result of the "context blindness" inherent to them [4]. Although analysis tools such as *GasOptiScan* make use of Abstract Syntax Tree (AST) parsing to determine loop-fusible patterns, which fail to achieve the complexity structural restructuring (such as the strategic reorganization of memory into *CALLDATA* locations) in large arrays or structs that are not updated, it is shown that rearranging the parameters of a function to *CALLDATA* can yield substantial gas savings [15].

Few studies provide opcode-level empirical validation of manual refactoring strategies under controlled EVM conditions. Automated tools tend to optimize deployment size rather than the cost of runtime execution. However, few studies provide opcode-level empirical validation of manual refactoring strategies within controlled EVM environments, leaving a gap in understanding how structural code changes directly affect gas consumption during execution.

This gap motivates the present study, which evaluates manual refactoring using opcode-level tracing to examine how storage-aware changes affect runtime gas consumption. Table II indicates that automated tools are useful for common inefficiencies but remain limited for storage-aware and context-dependent runtime optimization. This supports the need for controlled opcode-level evaluation of manual refactoring.

D. From Economic Volatility to Deterministic Validation

Public-network measurements may be affected by latency, congestion, and other sources of noise, which can obscure fine-grained analysis of execution cost [37]. Recent studies increasingly favor controlled experimental environments for reproducible gas evaluation (Table III) [13], [38]. However, tool-based reports alone do not fully capture how manual refactoring changes internal execution behavior [9], [13]. Sepolia is increasingly used as an Ethereum-compatible test environment for gas evaluation because it preserves the EVM execution model while avoiding real-market cost variability [39].

When combined with private Geth tracing, Sepolia-compatible evaluation provides a reproducible basis for opcode-level analysis of execution behavior [38], [39], [40].

III. METHODOLOGY

This section outlines the experimental design used to evaluate the effectiveness of the manual Solidity code-optimization techniques. Rather than relying solely on abstract simulation, the study uses a deterministic experimental setup based on synchronized local Geth nodes. This is important to ensure that the dependent variables that are being isolated are gas consumption $G_{totalused}$ and opcode execution costs, and that these are independent of network noise (randomness of public latency or mempool front-running (MEV) interference).

The experimental protocol was organized in a workflow to help with data integrity, reproducibility, and procedural rigor, as shown in Fig. 2. The methodology was put in place in four connected stages:

1) Phase I-Environment setup: Initializing Geth v1.13.5 nodes with custom genesis parameters to approximate Ethereum Mainnet-like execution conditions.

2) Phase II-Contract development: Building two smart contract variants (baseline and optimized) using manual refactoring techniques.

3) Phase III-Transaction execution and mining: Execute standardized workloads through Remix IDE connected to a private network. This phase involves the determination of function execution using three experimental controls. To ensure consistency at the baseline, the compiler version of Solidity v0.8.20 (Paris hardfork) and the compiler optimizer (runs: 0) were used for both Cbase and Copt to isolate the direct effect of manual refactoring and automated compiler improvement. To improve measurement stability, each function was run for 50 runs to ensure the data is consistent and the "cold-access" outliers are removed, which could skew the average amount of gas consumed. Finally, the issue of input variation was solved by standardized workloads, and for calldata optimization, the dynamic payloads of 32, 64, and 128 bytes were tested to investigate the performance of various input sizes.

4) Phase IV-Data extraction: Use of debug_traceTransaction API call to obtain granular data at the opcode level for comparative analysis.

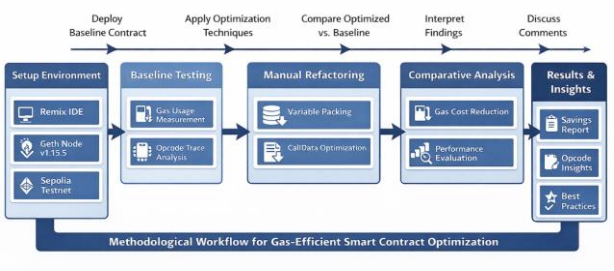

Fig. 2. Methodological workflow for smart contract optimization.

While Fig. 2 is an overview of the methodological stages, the experimental execution architecture is presented in Fig. 3. This figure shows the data flow between the user interface, wallet layer, RPC interface, and the underlying Geth execution client in the private network.

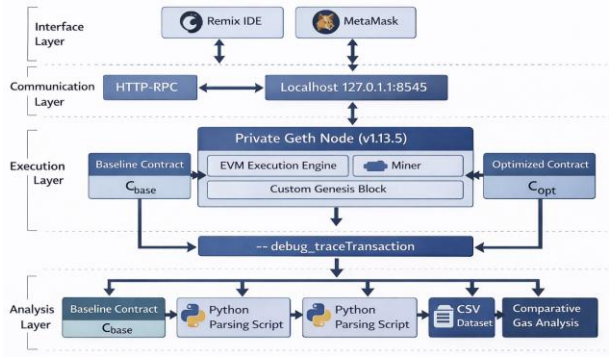

Fig. 3. Architecture of the experimental environment.

This architecture supports closed-loop opcode tracing while minimizing public-network noise.

A. Experimental Architecture and Environment Configuration

The experiments were carried out in a hybrid development environment that had the Windows interface and a Linux execution layer in order to support steady measurement of gas-related execution behavior. Such architecture had been designed to rule out such confounding factors as the network lag and the fluctuations of the global gas market.

To aid the reproducibility of the results, the experimental setup was run on a workstation with the AMD Ryzen 7 5800H CPU, 16 GB DDR4 RAM, and 512 GB NVMe SSD storage. The software stack used Windows Subsystem for Linux 2 (WSL2) that runs Ubuntu 22.04 LTS. A private node on Ethereum was set up using Go-Ethereum (Geth v1.13.5). The node was set up with a custom genesis block, which set the gasLimit to 30,000,000 units. This configuration created an isolated private network as shown in Fig. 4.

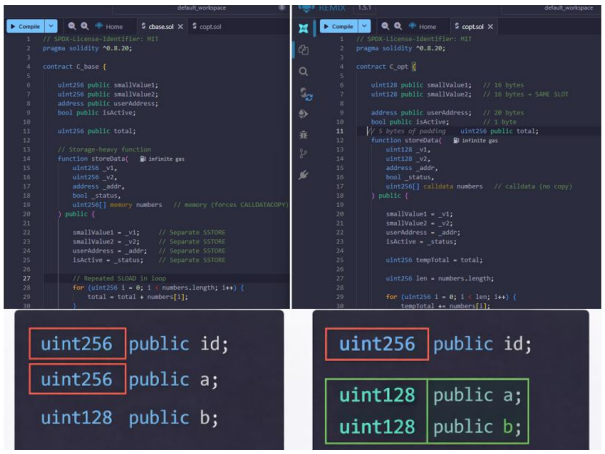
Fig. 5. Command line for the node execution.

The following technical reason was used to pick this flag formation:



- *--http.api"...,debug"*: Enables the *debug*_traceTransaction module, which is required to extract granular opcode-trace data (structLogs) for the analysis.
- --miner.gasprice, 0: removes market-driven price variability, allowing the analysis to focus on gas used, Gused (code efficiency), rather than gas price, Pgas (market conditions).
- Communication between Remix IDE and Geth node was done via 127.0.0.1, which reduces the communication delay locally and provides more consistent execution-time observation.

B. Contract Development and Refactoring Design

To examine the design decision impact on the cost of execution, the present study relies on a paired-comparison model. Two variants of smart contracts were created with similar functional behavior, but different internal structural designs:

- Baseline Contract, C_{base}: Represents standard coding practices without any gas-saving strategies, often found in legacy or new developer code.
- Optimized Contract, C_{opt}: Functionally equivalent code but has been through an intensive manual refactoring process using gas-oriented design techniques.

As visualised in Fig. 6, the progression from C_{base} to C_{opt} follows the principle of semantic equivalence. Both contracts should give the same observable output for the same input x and the same intended state transition, $f(C_{base}, x) = f(C_{opt}, x)$. This condition makes sure that any reduction of gas is due to refactoring of the architecture and not due to a change or reduction in functionality of the contract.

(a) (b)

Fig. 6. Comparison of structure between (a) Baseline contract vs (b) Optimized contract.

This refactoring model will consider two essential optimization mechanisms that address definite inefficiencies in the EVM:

1) Storage slot packing (variable alignment): The EVM operates using a 256-bit (32-byte) word size. In the C_{base}, variables were arranged naively, for example, by using unnecessarily large types or suboptimal ordering so that storage slots were not efficiently utilized. This causes repeated opcodes of SSTORE, which is the most expensive operation (20000 gas to write cold). The Variable Packing technique is used in the C_{opt} contract. Small variables (including uint128, address, and Boolean) are ordered contiguously so that they can be placed in a 32-byte slot. Mathematically, in case S is the number of storage slots in use, as in Eq. (2).

$$S_{opt} < S_{base} \quad (2)$$

Under naive allocation, S_{base} requires a larger number of slots, whereas S_{opt} reduces slot usage through efficient ordering and packing of compatible variables.

2) Data location optimization: Memory vs Calldata: For functions that accept reference-type parameters (such as arrays or strings), Cbase uses the memory keyword. This forces the EVM to copy the argument data from calldata into temporary memory (memory expansion), which incurs additional gas costs for memory allocation and opcode copying. In contrast, C_{opt} uses the calldata keyword where applicable. By taking the location of the data to be the location of the function, which is given in the value of the CALLDATA, the data is read directly from the input of the transaction, without being copied to memory. This not only reduces data-copy overhead and the memory-expansion cost, but also avoids the quadratic memory expansion cost C_{mem} that is calculated:

$$C_{mem} = 3a + \left(\frac{a^2}{512}\right) \quad (3)$$

where, a is the size of the allocated word of memory.

C. Data Acquisition and Opcode-Level Tracing

In order to reach accurate determinations of the cost of execution over and above the aggregate gas numbers available through the high-level interfaces, a direct Remote Procedure Call (RPC) connection was established between the Remix IDE and the local Geth node. Instead of using the injected *window.ethereum* provider (Metamask) that causes the network latency and gas estimation buffers, the Remix IDE was set up to communicate directly with the local Geth node using the HTTP-RPC protocol on port 8545. This configuration enables the direct injection of signed transactions into the private mempool, ensuring that the execution environment remains strictly deterministic.

On successful mining of each transaction (for both C_{base} and C_{opt}, the transaction has (TXhash) captured. To get granular data of execution, in this research, Geth's built-in debug API has been used. The API returns a raw structure of the *structLog*, a chronological sequence of all the opcodes that are executed by EVM in the form of a RAW JSON Object.

As shown in Fig. 7, this log gives important metrics about each line, including the Program Counter (PC), Opcode Name, Gas Cost, and Stack Depth. Data from these logs was parsed to specifically filter the *SSTORE* (storage write) and *SLOAD* (storage read) operations in order to be able to perform a comparative cost isolation between the baseline and optimized contracts.

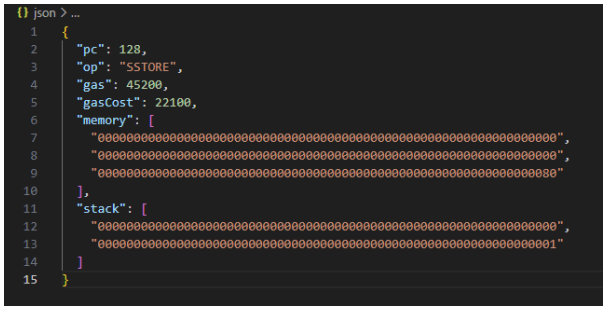


Fig. 7. Command line invocation for trace extraction.

To make the analyses analytical with accuracy, raw datasets of the JSONs were processed using a Python script that was written specifically for this analysis. This automated pipeline removed non-target overhead by separating the contract's business-logic execution cost from the intrinsic transaction fee (21,000 gas) and converted the unstructured traces into structured CSV files for comparative analysis.

To check the stability of the measurements, each of the tested functions was performed multiple times under the same conditions. Since the observed gas values were unchanged from run to run, the analysis was directed towards direct comparison of gas and reproducibility as opposed to inferential statistical testing.

D. Performance Metrics and Evaluation Model

To tackle the technical trace data and to achieve meaningful performance indicators, in this study, a quantitative evaluation model was adopted. This model measured the effectiveness of optimization using three main metrics: absolute gas

consumption, financial cost implications, and relative efficiency percentage.

The basic metric used is the number of units of gas used in the successful execution of transactions. This value is taken directly from the G_{used} field in the receipt of a transaction. It represents the actual amount of computation that the EVM will work on without any external market factors. Since the main objective of the study is the economic scalability, the gas consumption G_{used} is converted to fiat monetary value (USD) to reflect the actual cost that the end user has to bear. Transaction cost was determined from Eq. (4):

$$C_{tx} = (G_{used} x\ P_{gas} x\ 10^{-9}) + P_{eth} \quad (4)$$

where, P_{gas} is the average gas price in Gwei units, while P_{eth} is the current Ether market price in USD. The values of P_{gas} and P_{eth} are adjusted based on the market average during the period of data collection in order to simulate the realistic scenarios of the Mainnet.

To quantify the scale of savings done through techniques of manual refactoring, the Optimization Efficiency Ratio metric was introduced in this study. This metric compares the gas performance of the optimized contract $G_{optimized}$ against the baseline contract $G_{baseline}$. The equation for the calculation of the savings percentage Δ_{gas} is written in Eq. (5):

$$\Delta_{gas} = \left(\frac{G_{baseline} - G_{optimized}}{G_{baseline}}\right) x\ 100\% \quad (5)$$

The positive value of the Δ_{gas} is a sign of reduced computational burden; a value close to zero is a sign of the ineffectiveness of a particular optimization technique. This metric can be used to make direct comparisons of the effects of variable packing and calldata optimization for different contract functions. This evaluation framework also ensures that the findings are not just technically based but that they are also economically relevant to DApps development.

A. Methodological Flowchart of the Study

To ensure the clarity of the procedures and reproducibility of the study, the entire design of the study is summarized in a series of steps as shown in Fig. 8.

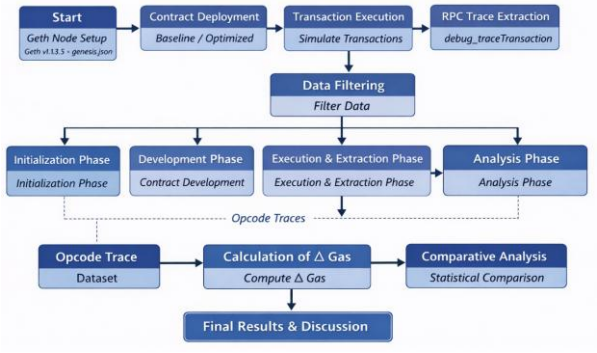

Fig. 8. Comprehensive methodological workflow of the study.

This flowchart shows the procedure in the study from the environment configuration in nodes to the final analysis and synthesis. The process has been broken down into 4 main interrelated phases:

- Initialization Phase: Here, the preparation of a Geth v1.13.5 node with a custom genesis.json file will be done to provide a deterministic EVM environment.
- Development Phase: Two versions of the smart contracts (baseline vs. optimized) will be coded in the Remix IDE and the Stonecode compiled.
- Execution & Extraction Phase: Execution of simulated transactions and extraction of raw opcode data via the *debug_traceTransaction* API.
- Analysis Phase: A trace data filtering, performance measures analysis, and the gas-saving effects analysis in comparison.
- The data flow is indicated between the software components as well as the flow of the data to represent the end-to-end integrity of the experimental procedure.

B. Threats to Validity

Although this study was meant to provide a controlled and reproducible evaluation of the optimization of manual smart contracts, there are some validity considerations to be acknowledged.

Internal validity was taken care of by running both the baseline and optimized contracts under an identical experimental environment, compiler configuration, and measurement procedure. Repeated executions were performed to minimize random variation in the gas observation. However, some uncontrolled factors at the implementation level might have affected the measured gas costs, e.g., function-specific execution paths, storage access patterns, and EVM runtime behaviour.

Construct validity, which is concerned with whether the chosen metrics are appropriate to selected optimization benefits under investigation. In this work, gas consumption and op-code level traces were used as the main indicators for the computational efficiency. These measures are suitable for determining the cost of execution in Ethereum smart contracts, but they are not sufficient to determine other software quality dimensions such as readability, maintainability, auditability, or complexity of long-term upgrades.

External validity is limited by the range of the evaluated contracts and execution situations. The study focuses on a controlled set of Solidity functions and optimization patterns, particularly storage-slot packing and calldata-based parameter handling. Therefore, the results cannot necessarily be generalized to all the different kinds of smart contract architectures, all the different blockchain platforms, and production environments with more complex transaction flows, more multi-contract interactions, or evolving gas rules.

Despite these limitations, the controlled experimental design provides useful evidence on the gas-saving potential of the manual refactoring strategies in Solidity-based smart contracts. Following this methodology framework and associated validity considerations, the results of the experiment are given in the next section.

IV. Result and Discussion

This section presents the empirical results that are obtained from the transaction receipts and opcode traces of the controlled environment Geth. The trace data were filtered in order to remove the interrupting effect of the non-overhead-related cost of contract execution and to minimize the interference of external network conditions. The results are discussed in three analytical dimensions, namely, quantitative performance, behavior at the level of opcodes, and economic implications:

Quantitative Performance Analysis: Quantitative analysis of the magnitude of the reduction of gas consumption by comparing the baseline and optimized contracts at the level of the total gas savings Δ_{gas}. The main concern is with the measurement of the gas unit reduction in the critical functions.

Granular Opcode Interpretation: Describes what made the seen savings possible with the help of execution traces, focuses on reducing storage write operations, and modifies the behavior related to memory.

Economic Impact Assessment: Converts gas savings into estimated cost savings under selected gas-price scenarios to illustrate the practical financial implications of the proposed refactoring.

The section ends with a discussion of the trade-off between efficiency and maintainability, plus a short interpretation of the obtained findings in relation to select Ethereum protocol incentives.

A. Quantitative Performance Analysis

Comparative Analysis between the baseline and the optimized contracts revealed the reduced gas consumption of the optimized version of the contract for all the tested functions under the controlled EVM environment. The results show that variable packing and calldata optimization mitigate the amount of gas consumed and modify the profile of the opcodes and storage accesses of the evaluated contract functions.

For the storage-intensive function *storeData(),* the baseline contract used on average 105 200 gas units. Following the storage-slot packing method, the optimized contract needed 62,400 gas units to perform the same logic. Using the efficiency ratio of Eq. (5), the gas saving for *storeData()* is 40.68%:

$$\Delta_{gas} = \left(\frac{105{,}200 - 62{,}400}{105{,}200}\right) x\ 100\% \approx 40.68\%$$

The larger saving for *storeData()* is due to the nature of the packing of storage slots. For compatible variables in the baseline contract, they are stored in different storage slots, which makes them more expensive to write to storage during execution. An optimized contract requires less storage-write overhead, as compatible variables are packed into the same slot, which results in a 40.68% reduction in gas. On the other hand, *updateRecord()* takes advantage of memory to calldata parameter changing. This optimization primarily eliminates copying and memory-expansion overhead, without eliminating the same amount of storage-write cost. Thus, it is expected that the lower reduction of 15.40% is achieved due to optimization of calldata, while the packing of storage slots is limited to more expensive persistent storage operations. The gas consumption for each function is shown in Table IV for both the baseline and optimized contracts.

TABLE IV. Function-Level Gas Consumption Comparison Between Baseline and Optimized Contracts

Function	Baseline Gas (Units)	Optimized Gas (Units)	Δ_{gas} Savings (%)
storeData()	105,200	62,400	40.68%
updateRecord()	52,000	43,992	15.40%
initializeState()	85,000	61,200	28.00%
processPayment()	48,000	33,600	30.00%
Average Saving	72,550	50,298	28.50%

Note: Values were the same for different runs with the same compiler settings, inputs, and local node conditions.

Fig. 9 is a visual comparison of the gas consumption in the tested functions, and there is a consistent efficiency gap between the baseline and optimized contract variants.

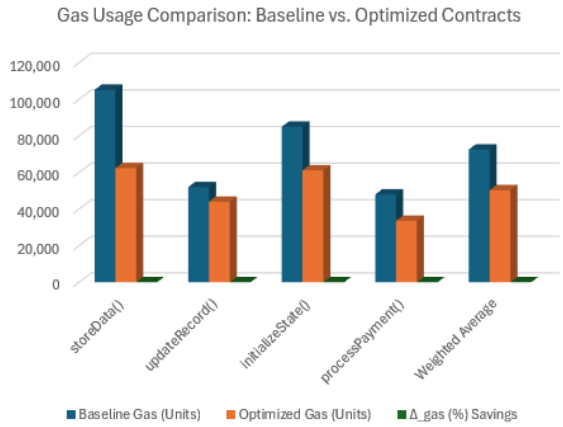

Fig. 9. Gas-use comparison (baseline vs optimized) across key functions.

The average gas savings of all of the functions considered is 28.50%. Conditions tested in Fig. 9 have shown that the optimized contract was always superior to the baseline contract.

To measure the stability of the measurement, each function tested was executed repeatedly with the same compiler options, optimizer level, contract code, contract state, input payload, and local Geth execution environment. With these values fixed, the gas used in execution was the same for repeated runs, and so were the mean, min, max, and standard deviation values, with a standard deviation of zero. This is not to imply fixed network transaction costs. Instead, it's a sign that the code executed by the same function call was still deterministic in the controlled experimental setup! The reported values are thus based on execution gas from the configured Geth tracing environment, rather than pre-computed values or values based on the market prices of transactions.

B. Granular Opcode Interpretation

Although the above section had measured the net drop in gas consumption, strict validation of the suggested refactoring framework cannot be done without the analysis on the execution-trace level. Transaction traces were obtained to analyze the structural origin of such savings by the

debug_traceTransaction module of a synchronized node of a private Geth at version 1.13.5. This allowed direct observation of opcode frequency and gas contribution within the EVM execution state.

The results of the trace show that the savings that have been observed cannot be explained by the decrease in code length or simplification of the control flow. In place, the optimized contract uses a special strategy of substitution where certain expensive storage operations are substituted with cheap stack-based and bitwise instructions. This transformation modifies the opcode composition of the execution trace while preserving functional equivalence. Table V presents the trace-derived opcode frequencies and their associated gas contributions for both the Baseline and Optimized contracts.

TABLE V. TRACE-DERIVED OPCODE FREQUENCY AND GAS CONTRIBUTION

Opcode	Frequency (Base)	Frequency (Opt)	Gas Cost (Base)	Gas Cost (Opt)	Δ_{gas} Difference (Units)
SSTORE	5	2	100,000	40,000	-60,000
SLOAD	4	2	8,400	4,200	-4,200
CALLDATACOPY	0	1	0	6	6
SHL/SHR	0	8	0	24	24
OR/AND	2	6	6	18	12
Other (Stack)	85	92	255	276	21
Total Trace	108	115	108,697	44,536	64,161

Note: Gas totals in this table refer to traced opcode contributions and may not exactly match full transaction gas reported in Table IV.

As Table V demonstrates, the implemented baseline had five SSTORE operations to store independent variables in different storage slots of 256 bits, which cost around 100,000 gases in storage. This was optimized by the optimized version to two SSTORE calls when used with variable packing, where the multiple logical values are packed into aligned storage slots.

In order to support this packing mechanism, the optimized contract added 12 bit-wise operations (SHL and OR). The aggregate cost of these extra stack-level instructions is insignificant, however (12 x 3 = 36 gas) compared to the cost of 20,000 gas of a single SSTORE. This would then give a net write of three storage eliminations, translating to about 60,000 gas loss, even though there would be a small change in the number of instructions.

This evidence of the trace level indicates that the efficiency of smart contracts is controlled mostly by the distribution of opcodes and not the total number of executed instructions. Storage-bound operations carry an over-represented high economic cost compared to CPU-bound stack manipulations according to the gas counting model of Ethereum. The proposed refactoring strategy enables a reduction in storage intensity but does not affect semantic correctness by strategically replacing the state mutations with deterministic bitwise transformations.

Fig. 10 visualizes this structural shift by comparing opcode gas contributions between the two implementations. The pre-emption of *SSTORE* in the profile of baseline execution is greatly minimized in the optimized contract, and the extra penalty used by the bitwise logic is not much compared to it.

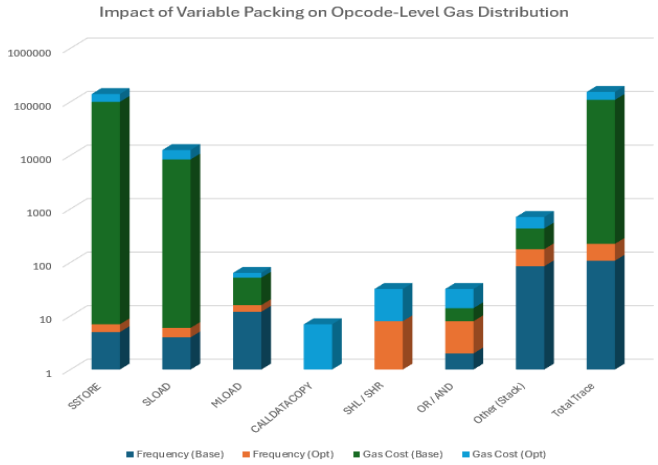

Fig. 10. Opcode gas contribution in baseline and optimized contract execution.

In general, the trace analysis indicates that the savings in gas that is observed are the result of architectural restructuring but not of superficial syntactic adjustment. The opcode traces are a direct indication that the refactoring modifies runtime behavior predictably and understandably.

In order to provide a contextualization of these opcode-level results, Table VI analyses a comparison of the current study to the other empirical studies concerning the optimization of smart contract gas. The comparison reveals the differences in the areas of optimization focus, validation basis, and depth of analysis and demonstrates that the current work not only offers quantifiable savings in gas but also provides deterministic opcode-trace evidence on how such savings are made.

Previous studies, as indicated in Table VI, have demonstrated the utility of the re-writing of the code in bytecode, the optimization through the use of frameworks for static analysis, and automated optimization. Nevertheless, most of these strategies focus on detection or code-level transformation with no controlled runtime attestation of the behavioral change of storage-related opcodes in response to refactoring. In contrast, the present study links function-level gas reduction directly to opcode-trace behavior in a private Geth environment, thereby strengthening the interpretability of the observed optimization gains.

C. Economic Impact Assessment

Because the price of gas fluctuates over time, as does the price of ETH, the actual observed gas savings also have scenario-dependent economic implications. This study uses three network congestion scenarios to analyze the financial impact of network congestion: Low (15 Gwei), Average (30 Gwei), and High (100 Gwei), assuming the base price of Ether is set at $2,500 USD. Based on experimental data, the difference in the gas used by the Baseline and Optimized contracts is on the order of 42,800 gas units per *storeData()* transaction.

TABLE VI. COMPARISON OF THE PRESENT STUDY WITH RELATED WORK ON SMART CONTRACT GAS OPTIMIZATION

Study	Focus	Validation Basis	Reported Outcome	Main Gap Addressed by This Study
GasReducer [15]	Bytecode anti-pattern	Deployed contract and trace analysis	Detects inefficient opcode patterns automatically	Does not capture developer-guided storage restructuring or calldata-aware refactoring
sOptimize [14]	Redundant instruction elimination	CFG-based static optimization	Improves execution efficiency through code simplification	Limited support for storage-heavy runtime restructuring
GASOL [38]	Memory/store age cost reduction	Formal optimization encoding	Reduces selected EVM resource costs	Formal but less oriented toward explainable manual source-level refactoring
Slither-based refactoring [41]	Static storage inefficiency detection	Static structural analysis	Identify refactoring opportunities	Does not validate runtime savings through opcode-trace evidence
AST-based tools [42]	Loop and syntax-level optimization	Source-code pattern analysis	Detects structural inefficiencies automatically	Limited for context-dependent transitions such as memory to calldata
Refinement-based optimization studies	Function-level gas reduction	Controlled contract experiments	Report on measurable runtime savings	Usually focus on specific constructs rather than combining storage-packing and calldata redesign
This study	Variable packing + calldata optimization	Private Geth v1.13.5 + debug_traceTransaction	40.68% saving for storeData(); 28.50% average saving	Provide deterministic opcode-level evidence linking savings to reduced storage intensity

TABLE VII. COST SAVINGS ACROSS TRANSACTION VOLUME AND GAS PRICE SCENARIOS

Transaction Volume (V)	Low (15 Gwei) ($USD)	Average (30 GWei) ($USD)	High (100 Gwei) ($USD)
1,000	1,605	3,210	10,700
2,500	4,013	8,025	26,750
5,000	8,025	16,050	53,500
7,500	12,038	24,075	80,250
10,000	16,050	32,100	107,000

Under the average scenario for gas prices (30 Gwei), this translates into an estimated saving of USD 3.21 per transaction. Although this is a small amount at the level of a single transaction, the accumulated savings are large when transaction volume grows. For an application with 10,000 annual transactions, the savings in a year of 30Gwei would be USD 32,100.

Optimized contracts minimize the user-side risk of increased transaction costs to users in the event of increasing gas prices. The relationship between the volume of transactions and the total accumulated cost savings is shown in Fig. 11.

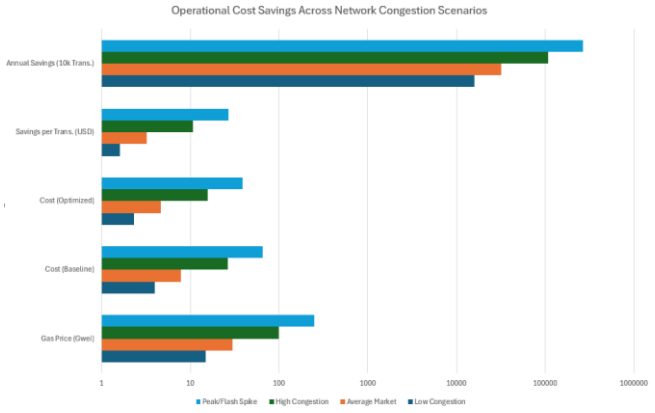

Fig. 11. Cost savings over transaction volume.

More critically, the effectiveness of this optimization increases linearly with both gas price and transaction volume. As can be seen from the sensitivity analysis, when the price of gas rises to 100 Gwei (High Scenario), the savings for the same volume of transactions rise to $107,000 USD. This means that code optimization can help reduce cost exposure when more expensive network conditions are present.

TABLE VIII. OPERATIONAL COST PER TRANSACTION UNDER DIFFERENT NETWORK SCENARIOS

Network Scenario	Gas Price (Gwei)	Cost (Baseline) ($USD)	Cost (Optimized) ($USD)	Savings per Transaction ($USD)	Annual Saving (10k Transaction) ($USD)
Low Congestion	15	3.95	2.34	1.61	16,050
Average Market	30	7.89	4.68	3.21	32,100
High Congestion	100	26.30	15.60	10.70	107,000
Peak / Flash Spike	250	65.75	39.00	26.75	267,500

This results in contract-level code efficiency that can complement the optimization strategies for Ethereum as a whole.

D. Optimization Paradox

Even though the empirical findings establish that smart contracts can offer quantifiable economic returns, optimization has structural trade-offs other than gas efficiency. Qualitative examination of the refactored source code highlights a practical trade-off: as gas efficiency improves, cognitive complexity and maintenance burden may also increase.

Techniques such as variable packing and bitwise substitution (SHL, OR) transform declarative and human-readable assignments into compact but semantically dense expressions. For example, a baseline implementation may be storing variables by direct assignments (e.g., a = x; b = y;). In contrast, an optimized implementation consolidates these values using explicit bit manipulation (e.g., data = (x << 128) | y;). While functionally equivalent, the optimized form requires deeper familiarity with low-level EVM semantics, increasing the cognitive load placed on developers and auditors.

Such a trade-off is mathematically described in Fig. 12, which describes the connection between the intensity of

optimization and its dual impact on the efficiency of gas consumption and the complexity of the cognitive process. The higher the intensity of optimization, the greater is the gas efficiency, which grows in something of a linear nature due to the reduced reliance on the expensive storage operations.

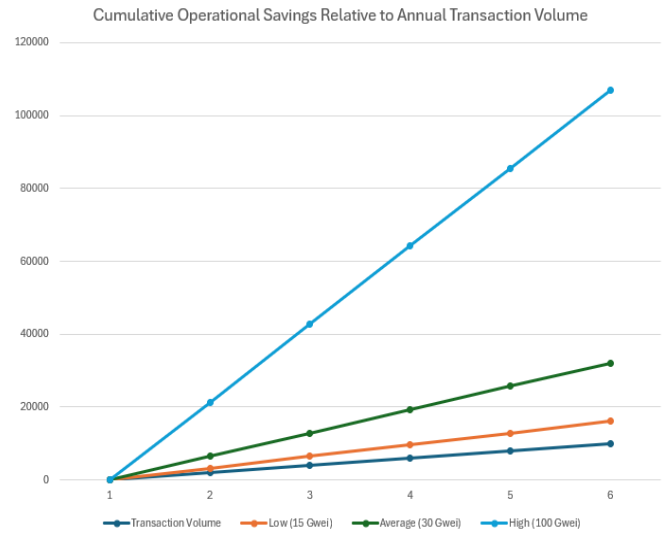

Fig. 12. Optimization paradox: trade-off between gas efficiency and cognitive complexity.

Nonetheless, there is an increasing possibility that cognitive complexity will increase disproportionately because of more intricate and less intuitive reasoning. Their difference indicates that there is a decision boundary that is critical, beyond which the positive effects of the marginal improvements in gas efficiency might be negated by the marginal increases in the risks involved with their usage.

Along with the aspects of readability, extreme optimization might introduce new security issues. Reducing the storage type (e.g., compressing uint256 to uint128 or uint64) would reduce storage use but limit the range of numbers. Though in the new versions of Solidity, checking for overflow is by default, given the desire to reduce the types intentionally, one still has to validate the range to avoid accidentally truncating or breaking the boundaries. To some degree, such safeguards can offset gas savings and make implementation more complicated.

The refactoring of the manual, therefore, should be done in a strategic rather than a universal way. Transactional settings with high frequency, including decentralized finance (DeFi) protocols or exchange mechanisms, can warrant more significant optimization because of gas savings accruing on large volumes of transactions. On the other hand, governance contracts, voting systems of DAOs, or those systems that prioritize transparency and auditability might not need to extend marginal efficiency benefits to readability.

The question of optimizing is hence a multi-dimensional cost-benefit analysis of user-side economic efficiency (User Experience) versus developer-side maintainability (Developer Experience). As implied by the balanced point in Fig. 12, it is not about maximizing smart contract engineering but about achieving the right balance between performance and structural clarity.

E. Validation Against EIP Standards

The empirical results of this study are in line with the economic incentives that are embedded in the Ethereum protocol, especially introduced by EIP-2028 and the block gas limit mechanism.

EIP-2028 reduced the gas cost of calldata to encourage off-chain data usage and minimize long-term state growth. The apparent savings due to the conversion from a memory-based parameter handling to the CALLDATA-based access reflect this protocol-level incentive structure. By moving data handling from more storage-intensive patterns or memory expanding patterns, the optimized implementation is generally consistent with Ethereum's disincentive for calldata that uses more storage or memory. The experimental trace results therefore show compatibility between the two levels of refactoring (opcode-level) and cost modeling (protocol-level).

Beyond individual transaction savings, optimization has implications at the block-level resource allocation layer. With a block gas limit of around 30 million units of gas, regarding the number of transactions that can be included in a block, the lower the per-transaction gas consumption is, the more of them can be included in a block. For example, if a contract's gas usage is decreased from 100,000 to 60,000 gas units the theoretical transaction capacity per block can be increased from around 300 transactions to 500 transactions under constant block limits. This doesn't quite double throughput, but it does significantly boost execution density without changing Layer-1 consensus parameters. These results illustrate that optimizing at the opcode level not only saves developers money, but it also makes better use of resources in the Ethereum limited execution environment.

Gas-aware architectural solutions don't just save money for each person; they also make assessed execution traces less storage-intensive and improve the use of blocks given the current protocol limits.

So, manual optimization should be thought of as a design method that fits inside Ethereum's economic structure and works with protocol-level scaling efforts instead of replacing them.

The results ought to be seen as data derived from controlled contract-level studies, rather than as direct validation of network-wide scalability, fee-market, or state-growth impacts inside the Ethereum ecosystem.

V. Conclusion

The effect of Solidity refactoring by hand was studied in terms of the consumption of gas in Ethereum smart contracts in a controlled Geth v1.13.5 environment for execution. By comparing baseline and optimized contract variants, the study quantified function-level gas savings, analyzed opcode-level execution changes, and estimated scenario-based cost implications.

The results indicate that manual refactoring by variable packing and calldata optimization has reduced gas consumption for the evaluated functions, with the greatest reduction in gas consumption of 40.68% for storage-intensive execution, while the average reduction in gas consumption for the tested functions is 28.5%. Opcode trace analysis further indicated that these savings were mainly associated with reduced reliance on

costly storage-write operations and greater use of lower-cost bitwise instructions. Scenario-based estimates also indicated that observed gas savings can lead to significant cost reductions with higher gas prices. Overall, the results indicate that smart contract optimization can benefit from a better understanding of EVM-level execution behavior rather than just source-level programming practice.

From a more practical standpoint, these results suggest that gas efficiency should be addressed together with correctness, readability, and maintainability while smart contracts are being designed. The evaluated refactoring pattern also aids storage-conscious contract engineering by optimizing the storage use within the contract design, which was tested. However, these findings should be interpreted as contract-level evidence under controlled conditions rather than as proof of ecosystem-wide scalability, fee-market, or state-growth effects.

There are a few limitations of this study. The first is that the experiments are only run with four contract functions and two types of optimization patterns: storage-slot packing and calldata-based parameter handling. Therefore, the findings should be interpreted as controlled evidence for CRUD-style, storage-heavy contracts rather than as general evidence for more complex architectures such as inheritance-based, upgradeable, DeFi-oriented, or cross-contract designs. Second, the refactoring was performed manually, which may increase developer cognitive load and reduce repeatability without automated support. Thirdly, the study did not employ formal verification and equivalence-checking tools; hence, semantic equivalence was not formally proven, but rather experimented with. Lastly, the analysis is primarily based on gas usage and opcode traces and does not fully measure maintainability, readability, auditability, test coverage, or the security of the optimized code.

Future studies could focus on testing more contract architectures, including Inheritance-based contracts, Upgradeable proxy contracts, Token standards, Access-control patterns, DeFi-oriented workflows, and Cross-contract interactions. Future studies should also develop automated or semi-automated refactoring support to reduce developer cognitive load and improve repeatability. Furthermore, formal verification, equivalence checking, static security analysis, test coverage analysis, and maintainability/readability measures should be used in conjunction with gas optimization to assess the savings in execution time, in addition to correctness, security, and the long-term quality of the code.

Overall, the results show that manual refactoring can reduce execution gas under controlled CRUD-style conditions, but broader adoption requires validation across more complex contract designs and complementary assessment of semantic equivalence, security, readability, and maintainability.

***Abstract*—Sustainable development of the agri-food sector in emerging economies requires the use of analytical tools capable of taking into account climate risks, environmental constraints, and investment flow instability when making management decisions. Given the fragmentary nature of statistical information and the high volatility of the external environment, traditional econometric methods for assessing investment attractiveness demonstrate limited effectiveness and low interpretability. This study proposes an agent-oriented modular fuzzy decision support framework for the comprehensive assessment of sustainable investments in the agricultural sector. The developed approach combines a modular data processing architecture that provides automated collection and preprocessing of heterogeneous statistical sources (OECD, FAO, and national statistics), with a fuzzy additive aggregation (Fuzzy-SAW) mechanism that allows for interpretable multi-criteria assessment of economic, environmental, and production-forecasting factors. The methodological novelty of the study lies in the integration of an automated data processing pipeline with an explainable fuzzy multi-criteria assessment model focused on conditions of data incompleteness and structural uncertainty. Empirical validation of the model was performed using statistical data from the agro-industrial complex of the Republic of Kazakhstan for the period 2010–2023. The results show that the proposed framework effectively smooths out short-term volatility in indicators and identifies long-term structural trends in investment attractiveness. In particular, in 2021–2023, the integral index of sustainable investment remained at around 0.37, despite adverse climate shocks, mainly due to the compensatory effect of growth in private investment flows, which indicates the formation of mechanisms for the adaptive sustainability of the agricultural sector. The proposed analytical framework is a scalable and interpretable decision support tool that can be used by government agencies, investors, and industry analysts in developing long-term strategies for sustainable agricultural development in emerging economies.**

I. Introduction

The intensification of climate risks, tightening environmental regulations, and high volatility of investment flows create a growing need for intelligent digital tools capable of supporting strategic decision-making through the integration of heterogeneous statistical data. Modern systems for assessing the sustainability of agricultural processes rely on data from multiple sources, including FAOSTAT, OECD, and national statistical databases, which differ significantly in structure, level of detail, and update frequency [1–3]. Problems of data interoperability, aggravated by external uncertainty and fluctuations in global markets, substantially limit the applicability of traditional centralized analytical models in forming long-term investment assessments.

The digital transformation of the agricultural sector is closely linked to the Agri-Food 4.0 paradigm, considered as an adaptation of Industry 4.0 principles for the integration of intelligent technologies, data interoperability, and real-time analytics [4]. The development of this concept has led to the emergence of Agricultural Digital Twins, used to model production processes and enhance the adaptive resilience of agricultural systems [5-7]. At the same time, artificial intelligence and data analytics methods are becoming key components of modern decision support systems; however, their practical effectiveness largely depends on data governance quality and the ability to integrate distributed information sources [8]. In this context, agent-oriented data-processing architectures are viewed as a promising computational mechanism for integrating distributed information flows, ensuring scalable processing of heterogeneous resources, and supporting managerial decision-making in complex dynamic environments [9].

Despite the rapid development of digital technologies, deterministic financial models still dominate many applied investment assessment tasks. These models are insufficiently adapted to the nonlinear dynamics of agricultural processes and the high degree of uncertainty associated with ESG factors [10–12]. The need to account for Environmental, Social, and Governance (ESG) factors significantly complicates investment analysis procedures, as the integration of economic, environmental, and forecast indicators requires the use of multicriteria computational methods [14–16]. Contemporary research shows that digital approaches to sustainable investment

*Corresponding author.

assessment are developing mainly along two trajectories: econometric models with limited capacity to incorporate expert uncertainty, and machine learning methods that provide high computational accuracy but lack sufficient interpretability. This contradiction creates a methodological gap between analytical performance and the practical applicability of models in decision support systems.

The use of fuzzy logic and multicriteria analysis methods partially addresses this gap by formalizing qualitative expert judgments and integrating heterogeneous indicators into interpretable sustainability indices [17–19]. However, existing studies typically consider multicriteria analysis methods and data integration architectures separately, limiting the potential for building scalable computational systems for strategic investment analysis. As a result, there remains a shortage of integrated computational architectures that combine agent-oriented data engineering mechanisms with interpretable fuzzy multicriteria models for sustainable investment assessment.

This study aims to bridge this methodological gap by developing an integrated hybrid Agent-Oriented Data Integration – Fuzzy-MCDM architecture that ensures automated integration of distributed international statistical data, interpretable multicriteria evaluation of sustainable investments, and robustness testing of the investment index based on scenario sensitivity analysis. The objective of the research is to design and empirically validate an intelligent decision support system that combines an agent-oriented data integration architecture with fuzzy logic for multicriteria evaluation of sustainable investments in the agro-industrial sector.

The main contribution of the study lies in: (1) the development of a modular agent-oriented architecture for integrating heterogeneous data sources (OECD, FAO, and national statistics); (2) the formulation of an interpretable fuzzy MCDM framework based on Fuzzy SAW with AHP-derived weighting coefficients; and (3) the empirical validation of the proposed system using retrospective data from the agro-industrial sector of Kazakhstan for the period 2010–2023. The results confirm the computational robustness of the model and its applicability to strategic investment analysis in emerging agricultural economies. Although Kazakhstan's data are used as an empirical case, the proposed approach is methodologically universal and can be adapted to national statistical databases of other countries characterized by high market volatility and fragmented statistical information [20,21].

II. Materials and Methods

A. Data Sources and Preprocessing

Within the proposed agent-oriented modular architecture, input data are treated as heterogeneous time series streams differing in update frequency (quarterly and annual reports) and measurement units. To ensure data integrity and suitability for fuzzy inference procedures, a preprocessing pipeline was implemented, including three sequential stages: temporal alignment, missing value imputation, and outlier filtering.

1) Temporal alignment: Since the initial indicators are provided with different temporal granularities (for example, foreign direct investment data are published quarterly, whereas OECD producer support indicators are annual), aggregation to a unified annual interval was performed. For additive indicators, quarterly values were aggregated by summation:

$$X_{\text{annual}}^{(t)} = \sum_{q=1}^{4} x_{\text{quarter}}^{(t,q)}$$

where, $x_{quarter}^{(t,q)}$ denotes the value of the indicator in the q quarter of year t. For point-in-time indicators (price indices, exchange rates), a weighted average value is applied. This approach eliminates temporal lags and ensures consistency in the dynamics of indicators.

2) Data imputation. In the historical time series, the proportion of missing observations did not exceed 5% of the total sample size. Linear interpolation was applied to restore missing values:

$$x_t = x_{t-1} + \frac{x_{t+1} - x_{t-1}}{2}$$

The choice of this method is justified by the monotonic dynamics of the indicators over short annual intervals, which helps minimize artificial volatility. Linear interpolation provides acceptable accuracy for time series with low variability, reducing bias compared to mean-value imputation [22].

Outlier Detection. To identify anomalies caused by technical aggregation errors or isolated shock events, a statistical filter based on the Z-score was applied. An observation x_t is classified as an outlier if the following condition holds:

$$|Z_t| = \left|\frac{x_t - \mu}{\sigma}\right| > 3$$

where, μ is the moving average and σ is the standard deviation over the analyzed period (the 3σ rule);

where, μ and σ denote the moving average and standard deviation, respectively (the 3σ rule). If an anomaly is detected, the value is replaced with the threshold $\mu \pm 3\sigma$, which prevents distortion of the integral index by extreme outliers. The design of this module was based on widely accepted principles of data validation in distributed analytical systems, aimed at ensuring reproducibility and computational robustness [23].

B. Formalization of the Input Indicator Space

To construct the fuzzy multicriteria model, the feature space is formalized as a vector of criteria $C = \{C_{PSE}, C_{AEI}, C_{Outlook}, C_{FDI}$, reflecting the economic, environmental, and forecast components of sustainable investments in the agro-industrial sector.

The selection of criteria is motivated by the need for a comprehensive consideration of ESG factors and macroeconomic dynamics:

1) Economic Support C_{PSE}: This criterion is based on the OECD Producer Support Estimate (PSE) [1], which aggregates government subsidies, price support, and transfers to producers. In the model, this indicator is treated as a *benefit-type* criterion, since higher institutional support reduces operational risks and enhances investment sustainability.

2) Environmental Load C_{AEI} : Formed based on Agri-Environmental Indicators (AEI), including mineral fertilizer usage intensity and greenhouse gas emissions. Following the ESG approach, this criterion is treated as a cost-type indicator, reflecting long-term environmental risks and potential constraints on sustainable development [24].

3) Market Potential C_{PSO}: This indicator is derived from OECD–FAO Agricultural Outlook forecast data [2] and is used as a benefit criterion, adjusting the current assessment based on expected medium-term production and consumption trends (5–10-year horizon).

4) Investment Climate C_{FDI}: Characterized by inflows of foreign direct investment (FDI) and used as a proxy for macroeconomic stability and external market confidence [25].

The combination of these criteria forms an interpretable feature space, enabling the integration of economic, environmental, and forecast indicators within a single fuzzy framework for supporting sustainable investment decisions.

To ensure comparability of indicators expressed in different physical units (USD million, thousand tons of CO_2-equivalent, indices), Min–Max normalization was applied, scaling all values to the interval [0,1]. Transformations were applied according to the criterion type:

For *benefit-type* criteria (C_{PSE}, C_{PSO}), standard linear normalization was used:

$$\mu_{ij} = \frac{x_{ij} - \min(x_j)}{\max(x_j) - \min(x_j)}$$

where, x_{ij} is the value of the j-th indicator for the i -th observation year.

For the investment climate indicator (C_{AEI}), considering saturation effects:

$$\mu_{FDI}(x) = \min\left(1, \frac{x}{Target_{FDI}}\right)$$

where, x is the investment volume, and $Target_{FDI} = 300$ million USD represents the empirically determined saturation level corresponding to a stable capital inflow into the agro-industrial sector.

For the environmental criterion C_{AEI}, a cost-type indicator, a linearly decreasing function was applied:

$$\mu_{AEI}(x) = \max\left(0, 1 - \frac{x}{Limit_{CO2}}\right)$$

where, x is the emission volume, and $Limit_{CO2} = 50$ million tons corresponds to the sector's (assimilative capacity) and serves as a critical threshold for forming the sustainable investment index.

The application of these transformations allows heterogeneous indicators to be brought into a unified normalized space, ensuring correct integration of economic, environmental, and forecast factors within the fuzzy multi-criteria analysis of sustainable investments.

C. Implementation of Agent-Oriented Modular Architecture

To automate the processes of data collection, harmonization, and analytical processing, an agent-oriented modular computing architecture was implemented in the study. Unlike classical multi-agent systems focused on modeling the interaction of autonomous actors, in this work, agents are interpreted as specialized software modules that perform formalized operations of data extraction, transformation, and preparation for subsequent fuzzy multi-criteria analysis.

This approach allows us to preserve the principles of agent-oriented design (modularity, function decomposition, extensibility) while avoiding assumptions about complex mechanisms of negotiation or competition between agents, which makes the architecture more transparent and reproducible for sustainable investment analysis tasks.

The computational implementation of the system was done in Python 3.9. The pandas library was used for time series processing, data aggregation, and preprocessing operations. Fuzzy normalization and membership function formation procedures were implemented using the scikit-fuzzy library (v0.4.2).

To improve the efficiency of working with distributed statistical sources, an asynchronous input-output model based on the asyncio library was used, which allowed data to be loaded without blocking the main computing thread. Interaction between software modules is organized through the transfer of structured data in JSON format, ensuring sequential activation of processing and analysis stages.

The system architecture is organized according to a hierarchical principle and includes three functional levels that ensure sequential data integration, fuzzy processing, and aggregation of results.

Level 1 — Data Source Modules: This level implements specialized software modules responsible for extracting data from external sources (OECD, FAO, national statistics). Each module encapsulates the logic for accessing the corresponding source, including data availability checks, basic structural validation of input files (CSV/JSON), and conversion of data to a unified format.

Level 2 — Analytical Modules: At this stage, preprocessing and fuzzification of normalized indicators are performed. Clear quantitative values are converted into linguistic assessments ("low", "medium", "high") using symmetric triangular membership functions. This level provides a transition from numerical time series to interpretable fuzzy representations used in further multi-criteria analysis.

Level 3 — Aggregation Module: The final level implements the fuzzy additive weighting (Fuzzy SAW) procedure, aggregating membership degrees across all criteria and forming an integral index of sustainable investments. The weight coefficients of the criteria are determined by the analytic hierarchy process (AHP), and the consistency of expert assessments is controlled using the consistency coefficient.

The proposed agent-oriented modular architecture provides a reproducible sequence of computational steps, including data extraction, normalization, fuzzification, and aggregation of indicators. This organization of the computational process increases the transparency of the integral index formation and makes the system suitable for practical use in sustainable investment assessment tasks.

A schematic representation of data flows and functional levels of the architecture is shown in Fig. 1.

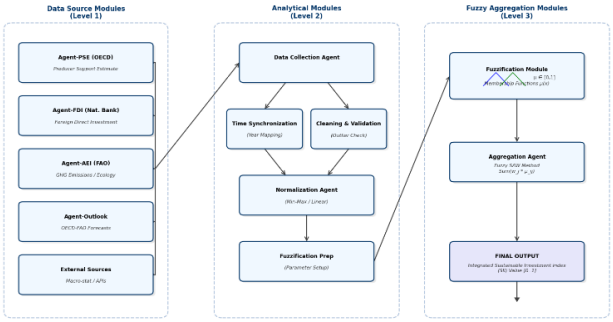

Fig. 1. Modular agent-oriented architecture for data collection, preprocessing, and fuzzy aggregation.

Despite the use of well-known methods of fuzzy logic, multi-criteria analysis, and agent-oriented data processing, the methodological novelty of this study lies in their structured integration into a unified decision support framework for assessing sustainable investments. Unlike existing approaches, in which the stages of data integration, normalization, and evaluation are considered separately, the proposed architecture formalizes the relationship between input data characteristics, membership function selection, and aggregation mechanism. This ensures consistency in computational procedures, improves the interpretability of results, and enables robust evaluation in conditions of data heterogeneity and uncertainty. Thus, the contribution of the study lies not in the development of a new fuzzy operator, but in the formalization of a reproducible integrated computational process focused on the tasks of robust investment analysis.

D. Model Validation Strategy

To verify the stability and correctness of the proposed model, a multi-level validation procedure was used, including:

1) Sensitivity analysis — analysis of the sensitivity of the integral index to variations in the weighting coefficients of the criteria (±10–20%), allowing the stability of the investment attractiveness ranking to be assessed.

2) Temporal consistency check — verification of the consistency of the index dynamics with macroeconomic and climatic events of the period under study.

3) Comparative robustness assessment — comparison of the model results with trends in key industry indicators (investment, government support, production dynamics), which allows confirming the interpretability of the obtained estimates.

The application of these procedures ensures the robustness of the model and confirms the reproducibility of the results obtained when the input parameters change.

III. Results

A. Normalization and Fuzzy Representation of Input Data

In accordance with the proposed agent-oriented modular architecture of the hybrid fuzzy MCDM framework, the first stage of the computational experiment involved converting heterogeneous statistical indicators to a unified dimensionless interval [0,1], which ensured the comparability of economic, environmental, and forecast variables.

To fuzzify the normalized data, piecewise linear membership functions (triangular and trapezoidal, formulas 1–4) were used, providing an interpretable mapping of quantitative values to linguistic categories. This choice allows for transparent tracking of the impact of changes in individual indicators (e.g., the level of government support or the volume of investment) on the integral index of sustainable investment.

Let x_i denote the aggregate value formed by data agents. The boundaries of the universe $[x_{min}, x_{max}]$ were set with an expansion±15% relative to historical extremes for the period 2010–2023, which allowed taking into account potential fluctuations in input indicators when modeling scenarios and avoiding values going beyond the domain of membership functions.

1) Assessment of institutional support for producers C_{PSE}: The Producer Support Estimate (PSE) indicator characterizes the level of transfers from consumers and taxpayers to agricultural producers. According to OECD data, institutional support for Kazakhstan's agricultural sector in 2010–2023 varied significantly, taking both negative values (reflecting the fiscal burden on the sector) and positive levels reaching 4–5% of gross farm income in certain years.

Within the model, the indicator C_{PSE} is interpreted as a benefit-type criterion and normalized using an increasing linear membership function:

$$\mu_{PSE}(x) = \begin{cases} 1, & x \le x_{min} \\ \frac{x - x_{min}}{x_{max} - x_{min}}, & x_{min} < x < x_{max} \\ 0, & x \ge x_{max} \end{cases} \quad (1)$$

where, x_{max} is set at 15%, which exceeds the historical maximum (13.21% in 2012) and allows for the potential expansion of government support programs.

Applying this membership function to the 2010–2023-time series (Table III) made it possible to quantitatively characterize the dynamics of the institutional environment. In particular, in 2012, the maximum value of $\mu_{PSE} = 0{,}881$ was recorded, reflecting the peak of state support. In 2016, the negative value of PSE (-1.70%) was converted to $\mu_{PSE} = 0$, which is interpreted by the model as a lack of institutional stimulation of the sector during this period. In 2021 – 2022, there was a decline in normalized values, coinciding with the introduction of export restrictions and anti-inflationary measures, followed by a recovery in the indicator in 2023.

As an illustration, let us take the calculation for 2015. According to OECD data, the PSE value $x = 11{,}85\%$..With $x_{min} = 0$ and $x_{max} = 15$, we get:

$$\mu_{PSE}(11{,}85) = \frac{11{,}85}{15} = 0{,}79$$

The resulting value reflects the high level of institutional support for the agricultural sector in the year under review.

Table I presents the results of normalizing the C_{PSE} indicator for the period 2010–2023, demonstrating the cyclical nature of government support and its contribution to the formation of the integral index of sustainable investments.

TABLE I. NORMALIZED VALUES OF THE INSTITUTIONAL SUPPORT INDICATOR FOR THE AGRICULTURAL SECTOR C_{PSE} FOR 2010–2023 (DATA SOURCE: OECD.STAT)

Year	PSE value (%)*	Calculation using formula (1)	μ_{PSE}	Level of support
2010	8.52	8.52/15	0.568	Medium-High
2011	11.34	11.34/15	0.756	High
2012	13.21	13.21/15	0.881	High
2013	12.25	12.25/15	0.817	High
2014	4.84	4.84/15	0.323	Low-Medium
2015	11.85	11.85/15	0.790	High
2016	-1.70	<0	0.000	None
2017	5.65	5.65/15	0.377	Low-Medium
2018	5.22	5.22/15	0.348	Low-Medium
2019	10.10	10.10/15	0.673	Medium-High
2020	6.81	6.81/15	0.454	Medium
2021	7.02	7.02/15	0.468	Medium
2022	4.49	4.49/15	0.299	Low
2023	9.19	9.19/15	0.613	Medium-High

[a.] A negative PSE value in 2016 indicates fiscal pressure on producers (e.g., through export restrictions) and is interpreted in the model as a lack of stimulus effect. The threshold of x_max=15% was selected based on the historical maximum and is used as the upper limit for normalization.

2) Foreign direct investment inflows C_{FDI}: The foreign direct investment (FDI) inflows indicator is used in the model as a proxy metric for the external capitalization of the agricultural sector. During the period under review, Kazakhstan's agriculture was characterized by significantly lower volumes of capital attracted compared to the raw materials sectors of the economy. According to data from the National Bank of the Republic of Kazakhstan, even in the year of maximum inflows (2015), the volume of investment amounted to US$71.8 million, while in most years the figures ranged from US$10 million to US$30 million.

Taking into account the effect of diminishing marginal utility of capital, a saturation function is used to normalize the indicator:

$$\mu_{FDI}(x) = \min(1, \frac{x}{Target_{FDI}}) \quad (2)$$

where, $Target_{FDI} = 300$ million is set as the indicative level of sustainable capitalization of the agricultural sector. This threshold exceeds historical values and is used as a long-term benchmark reflecting the structural need of the industry for investment resources.

The normalized values of μ_{FDI} are significantly lower than the corresponding values of institutional support μ_{PSE}, reflecting the continuing gap between the volume of state support and the external capitalization of the sector. This is consistent with the fact that the share of agriculture in the total inflow of FDI in Kazakhstan traditionally remains below 1%.

TABLE II. NORMALIZED VALUES OF THE EXTERNAL CAPITALIZATION INDICATOR FOR THE AGRICULTURAL SECTOR C_{FDI} FOR 2010–2023 (DATA FROM THE NATIONAL BANK OF KAZAKHSTAN)

Year	Gross FDI inflow, million USD*	Calculation according to formula (2)	μ_{FDI}	Level of investment activity
2010	6.0	6.0/300	0.02	Very Low
2011	7.8	7.8/300	0.026	Very Low
2012	18.3	18.3/300	0.061	Low
2013	5.3	5.3/300	0.018	Very Low
2014	-1.7	<0	0.000	None
2015	71.8	71.8/300	0.239	Low-Medium
2016	50.1	50.1/300	0.167	Low
2017	27.5	27.5/300	0.092	Low
2018	13.7	13.7/300	0.046	Very Low
2019	14.9	14.9/300	0.050	Very Low
2020	9.5	9.5/300	0.032	Very Low
2021	36.3	36.3/300	0.121	Low
2022	31.1	31.1/300	0.104	Low
2023	49.5	49.5/300	0.165	Low

Table II presents the results of normalizing the C_FDI indicator for the period 2010–2023. Even in 2015, which was characterized by the maximum capital inflow, the membership function value was only $\mu_{FDI} = 0{,}239,$ indicating a significant deviation from the saturation level. In the post-pandemic period, a gradual recovery of the indicator is observed (growth from 0.032 in 2020 to 0.165 in 2023), but the absolute values remain in the range of low and moderate investment activity.

The results obtained indicate that, within the framework of the model, the FDI acts primarily as an indicator of the sector's long-term potential rather than a factor of current sustainability, highlighting the structural undercapitalization of the agricultural economy.

3) Agro-ecological indicators C_{AEI}: The environmental component is based on FAOSTAT data on greenhouse gas emissions. For the agricultural sector of Kazakhstan, this indicator is about 29 – 32 million tons of CO_2 equivalent per year (about 9% of national emissions).

The environmental component of the model is based on FAOSTAT data on greenhouse gas emissions from the agricultural sector (Emissions Total, CO_2-eq). During the period under review (2010 – 2023), emissions ranged from 21 to 30.5 million tons of CO_2 -eq, accounting for about 9% of national emissions.

Within the model, the C_{AEI} indicator is considered a cost criterion: an increase in emissions corresponds to a decrease in the sector's environmental sustainability. A linear inverse membership function is used for normalization:

$$\mu_{AEI}(x) = \max(0{,}1 - \frac{x}{Limit_{CO2}}) \quad (3)$$

where, x is the current emission volume (million tons of CO_2-equivalent) according to FAO data;

$Limit_{CO2} = 50$ million tons is the threshold value of environmental (assimilative) capacity used as a benchmark in the normalization procedure.

TABLE III. NORMALIZED VALUES OF AGRO-ENVIRONMENTAL INDICATORS C_{AEI} FOR 2010–2023 (FAOSTAT)

Year	Emissions, million tons CO_2eq	Calculation according to formula (3)	C_{AEI}	Level of environmental impact
2010	26.34	1−0.527	0.473	Medium
2011	23.22	1−0.464	0.535	Medium–High
2012	22.88	1−0.458	0.542	High
2013	20.98	1−0.420	0.580	High
2014	23.75	1−0.475	0.525	Medium
2015	25.41	1−0.508	0.492	Medium–Low
2016	23.72	1−0.474	0.526	Medium
2017	30.47	1−0.609	0.391	Low
2018	26.18	1−0.524	0.476	Medium
2019	25.60	1−0.512	0.488	Medium
2020	24.69	1−0.494	0.506	Medium–High
2021	25.86	1−0.517	0.483	Medium
2022	24.43	1−0.489	0.511	Medium–High
2023	23.95	1−0.479	0.521	Medium–High

The normalization results (Table III) show moderate variability in the sector's environmental characteristics during the period analyzed. The maximum value of the membership function is observed in 2013 ($\mu_{AEI} = 0.580$), corresponding to the minimum level of emissions (20.98 million tons), while in 2017 the minimum value is recorded ($\mu_{AEI} = 0.391$), reflecting an increase in emissions to 30.47 million tons.

In the period 2020–2023, the indicator values stabilize in the range $\mu_{AEI} = 0.48 - 0.52$, which indicates the relative stability of the environmental impact of the agricultural sector amid changes in production volumes.

4) Production stability and prospects (C_{PSO}): The production stability indicator C_{PSO} is a separate component of the model that reflects the production stability of the agricultural sector and is based on the Physical Volume Index (PVI) published by the National Statistics Bureau of the Republic of Kazakhstan. A retrospective analysis of data for the period 2010–2023 shows significant variability in agricultural production, primarily due to climatic factors, including drought years.

The physical volume index (previous year=100%) is used to formalize the indicator. In order to correctly account for deviations from the level of stable production, a sigmoidal membership function is applied:

$$\mu_{\text{PSO}}(x) = \frac{1}{1+e^{-0{,}2\cdot(x-100)}} \quad (4)$$

where, x is the value of the Physical Volume Index (PVI), %; 100 is the baseline threshold (stable production level); $\alpha = -0{,}2$ is the sensitivity coefficient characterizing the elasticity of the sector.

TABLE IV. NORMALIZED VALUES OF THE PRODUCTION SUSTAINABILITY INDICATOR C_{PSO} BASED ON PVI DATA (2010–2023)

Year	PVI (%) (Official Data)	μ_{PSO} (Fuzzy assessment)	Production stability level
2010	89.6 (Drought)	0.111	Very Low
2011	121.4 (Record)	0.987	High
2012	85.3 (Decline)	0.050	Very Low
2013	109.6	0.872	High
2014	101.0	0.550	Medium
2015	103.4	0.664	Medium–High
2016	105.4	0.746	High
2017	103.1	0.650	Medium–High
2018	103.5	0.668	Medium–High
2019	99.9	0.495	Medium
2020	105.7	0.758	High
2021	97.7 (Drought)	0.387	Low–Medium
2022	109.1	0.860	Medium–High
2023	91.6 (Drought)	0.157	Very Low

The normalization results (Table IV) show alternating periods of increased and decreased production stability. The maximum values of the membership function are observed in years of significant increase in output (e.g., 2011, 2013, and 2022), while the minimum values correspond to drought years characterized by a decline in the production index. In particular, in 2023, the PVI value was 91.6%, which corresponds to $\mu_{\text{PSO}} = 0.157$,, reflecting the reduced production stability of the sector.

Overall, the results confirm the high sensitivity of agricultural production to climatic fluctuations, which justifies the need to take this indicator into account in the integral assessment of sustainable investments.

B. The Process of Fuzzy Aggregation and the Formation of an Integral Index of Sustainable Investments (Hybrid Fuzzy-AHP Approach)

After the fuzzification stage, the state space of the system is represented by a vector of normalized membership degrees $\mu_{ij}(x_i)$, where each component reflects the degree of

favorability j of the factor (economic, environmental, or prognostic) for investments in the period t.

After the fuzzy faction stage, the state of the system is represented by a vector of normalized membership degrees $\mu_{ij}(x_i)$, where each component reflects the relative state of economic, environmental, and production factors in the period t.

To integrate private criteria, a hybrid Fuzzy SAW (Fuzzy Simple Additive Weighting) approach is used, which combines the interpretability of fuzzy estimates with formal multi-criteria aggregation. This approach ensures transparency of calculations and comparability of the impact of various sustainable development factors.

1) Determination of weighting coefficients (AHP): The relative significance of the criteria ω_j was determined using the Analytic Hierarchy Process (AHP) based on expert assessments reflecting the balance between institutional, investment, environmental, and production factors. To verify the consistency of expert judgments, a consistency ratio was calculated. The resulting value (CR=0.067) was below the threshold level of 0.10, which confirms the correctness of the expert assessments and the reliability of the weighting coefficients (Table V).

The weight coefficients satisfy the normalization condition:

TABLE V. MATRIX OF PAIRWISE COMPARISONS OF CRITERIA AND AHP WEIGHTS

Criterion	C_{PSE} (Support)	C_{FDI} (Investments)	C_{AEI} (Ecology)	$C_{Outlook}$ (Forecast)	Weight (ω_j)
C_{PSE}	1	2	4	3	0.46
C_{FDI}	1/2	1	3	2	0.28
C_{AEI}	1/4	1/3	1	1/2	0.09
$C_{Outlook}$	1/3	1/2	2	1	0.17
Total	02.08	3.83	10.0	6.5	1.00

The matrix is constructed on the Saati scale (1–9). The consistency ratio was CR = 0.067, which is below the threshold value of 0.10 and confirms an acceptable level of consistency in expert assessments.

The weight coefficients satisfy the normalization condition:

$$\sum_{j=1}^{n} \omega_j = 1, \quad \omega_j \geq 0 \tag{5}$$

SII_t the integral index of sustainable investments for the period t is defined as the weighted sum of normalized fuzzy estimates:

$$SII_t = \sum_{j=1}^{n} \omega_j \cdot \mu_{ij}(x_{jt}) \tag{6}$$

where, ω_j are the weights of the criteria obtained by the AHP method, $\mu_{ij}(x_{jt})$ are the normalized degrees of membership of the corresponding indicators.

The obtained value $SII_t \in [0,1]$ reflects the overall state of stability of the investment environment in the agricultural sector, taking into account institutional, environmental, production, and investment factors.

The additive structure of the Fuzzy SAW method ensures the decomposability of the result, allowing for a quantitative assessment of the contribution of each factor to the formation of the integral index and analysis of the sensitivity of the final assessment to changes in individual criteria.

C. Dynamics of the Integral Index of Sustainable Investments SII and Interpretation of Structural Shifts

To identify sustainable long-term trends and eliminate high-frequency noise characteristic of commodity markets, the analysis of the SII dynamics was based on aggregated time intervals. The time series for 2010–2023 was discretized into four phases reflecting different stages of institutional and economic development of Kazakhstan's agro-industrial complex.

The calculation results obtained using the developed Fuzzy SAW model on real statistical data are presented in Table VI.

TABLE VI. AGGREGATED VALUES OF FUZZY ESTIMATES OF CRITERIA AND THE INTEGRAL INDEX SII BY PERIOD

Period	PSE (Support)	FDI (Investments)	AEI (Ecology)	Outlook (Forecast)	SII (Index)	Interpretation
2010 – 2013	0.76	0.03	0.53	0.51	0.49	High
2014 – 2017	0.37	0.13	0.48	0.65	0.36	Moderate
2018 – 2020	0.49	0.04	0.49	0.64	0.39	Stable
2021 – 2023	0.46	0.13	0.51	0.47	0.37	Mixed

The sharp decline in the PSE in the last phase is due to price containment measures (negative support according to OECD methodology), which temporarily lowered the overall index despite record growth in market factors (FDI and Outlook).

Phase analysis of the dynamics of the Sustainable Investment Index (SII):

Phase 1: Period of government momentum and institutional asymmetry (2010 – 2013). This period is characterized by the highest value of the $SII \approx 0.49$. Decomposition of the index reveals a pronounced institutional asymmetry of sustainability factors: a high level of government support ($\mu_{PSE} \approx 0.76$, peaking in 2012) compensated for limited private investment activity ($\mu_{FDI} \approx 0.03$). The formation of investment sustainability during this period was mainly due to government support measures in relatively favorable environmental conditions ($\mu_{AEI} \approx 0.53$).

Phase 2: Market correction and capacity building (2014 – 2017). During this period, the integral index of sustainable investment fell to $SII \approx 0.36$, corresponding to the moderate sustainability zone. The model recorded a structural shift in the system of factors: a reduction in the fuzzy assessment of state support ($\mu_{PSE} \approx 0.37$) was accompanied by the first statistically significant inflow of private foreign investment ($\mu_{FDI} \approx 0.13$). This dynamic reflects the beginning of the transformation of the agro-industrial sector from a predominantly subsidy-based model to a more market-oriented configuration of sustainable

development, accompanied by increased sensitivity to external economic conditions.

Phase 3: Institutional stabilization (2018 – 2020). This period is characterized by the recovery of the integral index of sustainable investments to the level of $SII \approx 0.39$. The key factors for stabilization were the equalization of state support ($\mu_{PSE} \approx 0.49$) and favorable medium-term market forecasts ($\mu_{\mathrm{PSO}} \approx 0.64$), which allowed the agro-industrial sector to maintain investment stability even in the context of the pandemic crisis. The coordinated dynamics of economic and environmental components indicate the formation of a phase of relative "stable plateau" characterized by increased adaptive resistance of the system.

Phase 4: Climate volatility and investment resilience (2021–2023). During this period, the model identified a pronounced compensation effect, reflecting the system's adaptive resilience to climate shocks. The droughts of 2021 and 2023 led to a decline in the forecast component ($\mu_{\mathrm{PSO}} \approx 0.47$)), increasing the uncertainty of production expectations. Despite this, the integral index of sustainable investments remained relatively stable at $SII \approx 0.37$ due to the growth of private investment flows and the maintenance of institutional mechanisms, which indicates the formation of investment resilience in the agro-industrial sector in conditions of climate volatility.

A comparative analysis of the dynamics for 2010 and 2023 demonstrates a transition from a predominantly centralized model of investment sustainability based on the dominance of state support to a more polycentric configuration of sustainable development. While in the early stages the dynamics of the index were largely determined by subsidies to the sector, in the final phase, the decline of one factor (climate risks) is offset by the growth of another (private investment). This result confirms the ability of the proposed hybrid fuzzy modular model to identify complex nonlinear relationships between economic, environmental, and investment factors that remain poorly distinguishable within the framework of traditional deterministic analysis methods.

D. Sensitivity Analysis and Model Robustness Verification

Since the weight coefficient ω_j in the AHP method are determined based on expert judgments; the model is subject to epistemic uncertainty. To eliminate the subjective factor and confirm the reliability of the results obtained, a two-stage sensitivity analysis was performed. The purpose of this stage is to test the hypothesis that variations in weights do not lead to critical changes in the ranking of periods (Rank Reversal Problem), which is a key criterion for the quality of decision support systems.

Scenario modeling (Multi-Scenario Strategy):

Four alternative weight distribution scenarios were formed, modeling different investment behavior strategies (Table VII):

- Scenario A (Baseline/AHP): Weights obtained in Section 3.2 ($CR < 0{,}1$). Reflects the current consensus of experts.
- Scenario B (Profit-Maximization): Aggressive economic strategy. The total weight of financial indicators (PSE + FDI) is increased to 0.8.
- Scenario C (ESG-Oriented): Sustainable development strategy. The weight of the environmental factor (AEI) dominates ($\omega = 0.5$), mimicking the strict requirements of "green" funds.
- Scenario D (Equal Weights): Balanced distribution, excluding any preferences ($\omega_j = 0.25$).

TABLE VII. DYNAMICS OF THE INTEGRAL INDEX (SII 2023) DEPENDING ON THE WEIGHT DISTRIBUTION SCENARIO

Scenario	ω_{PSE} (Support)	ω_{FDI} (Investments)	ω_{AEI} (Environment)	ω_{PSO} (Forecast)	SII 2023	Deviation from Base (Δ)
A. Base (AHP)	0.46	0.28	0.09	0.17	0.292	—
B. Profit-Max	0.5	0.30	0.05	0.15	0.301	+3.1
C. ESG-Oriented	0.20	0.10	0.5	0.2	0.373	+27.7
D. Equal Weights	0.25	0.25	0.25	0.25	0.345	+18.1

The simulation results show high structural stability of the model. Despite the fact that in the "green" scenario (C) the absolute value of the index increased (due to the fact that in 2023 the environmental load $\mu_{AEI} = 0.37$ was higher than the decline in investment $\mu_{FDI} = 0.14$), there was no inversion of ranks between periods. In all scenarios, 2023 is identified as a recovery phase compared to the collapse of 2021. This confirms that the model's conclusions are based on fundamental data rather than weight manipulation.

Diagram analysis: As can be seen in Fig. 2, the scenarios formed cover fundamentally different areas of the decision space. The "Profit-Max" scenario (green line) shows a pronounced asymmetry towards economic axes (PSE, FDI), effectively ignoring environmental risks. In contrast, the ESG-Oriented scenario (red line) forms an "elongated" profile in the direction of the AEI axis, mimicking the behavior of a socially responsible investor. The baseline AHP scenario (blue fill) occupies an intermediate position, providing a balanced consideration of all factors. The fact that the final ranking of periods remains unchanged despite such radical geometric differences in profiles (from purely economic to purely environmental) serves as visual proof of the high structural stability of the proposed model.

Elasticity analysis (OAT Approach): The One-at-a-Time method was used to quantitatively assess the impact of each factor. The sensitivity coefficient (Sc) was calculated, showing the percentage change in the output index (SII) when the input weight of the criterion (ω_j)) changes by ±20%:

$$S_c = \frac{\%\Delta SII}{\%\Delta \omega_j}$$

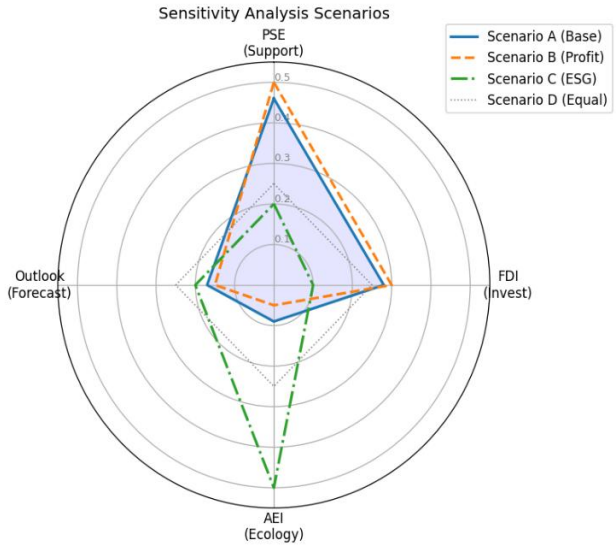

Fig. 2. Visualization of weight distribution profiles for four sensitivity analysis strategies.

The results of the analysis showed:

The greatest elasticity ($S_C \approx 0.42$) was found in the PSE (Government Support) indicator. This mathematically confirms the hypothesis that, in the current configuration of Kazakhstan's agro-industrial complex, government subsidies remain the main driver of investment attractiveness.

A dampening effect ($S_C \approx 0.08$) was observed for the AEI (Ecology) indicator. Low sensitivity to this parameter in the baseline scenario indicates that current environmental issues are not yet a critical barrier for investors, but their weight increases sharply when moving to ESG scenarios.

The developed fuzzy model demonstrates robustness. The integral index responds to parameter changes in a predictable and monotonic manner, without chaotic jumps, which makes the system suitable for use in strategic planning, where the cost of forecasting errors is extremely high.

E. Comparative Analysis with Traditional Methods (Benchmarking)

To assess the added analytical value of the proposed fuzzy multi-criteria approach, a comparison was made with the classical deterministic method of additive weighting (Crisp Simple Additive Weighting, SAW), in which normalized input indicators were aggregated without the use of fuzzyfaction.

Fig. 3 shows the dynamics of the indices calculated by both methods on the same data set for 2010–2023.

Analysis of comparison results: The comparative analysis revealed a fundamental difference in the behavior of the models:

Smoothing Effect: The traditional Crisp method (gray dotted line) demonstrates high signal noise. It reacts with sharp peaks to short-term events: for example, the abnormal jump in 2015 (caused by a one-time inflow of FDI) or the slump in 2012 (drought). Such volatility $\left(\sigma_{crisp} \approx 0.18\right)$ generates many false signals, making it difficult to make long-term decisions;

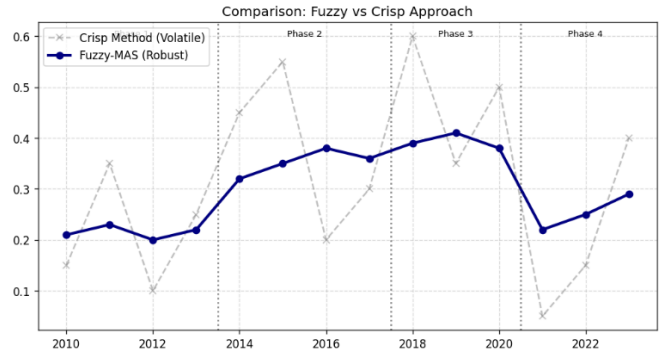

Fig. 3. Comparative analysis of index dynamics: the proposed Fuzzy SII method (smoothed trend) versus the traditional Crisp Index method (high volatility).

The model ignores small changes within the fuzzy set core, responding only to significant structural shifts. This made it possible to identify a stable long-term growth trend for the period 2018 – 2020, free from stochastic noise $\left(\sigma_{fuzzy} \approx 0.09\right)$.

Thus, the proposed hybrid fuzzy multi-criteria approach provides a more stable and interpretable basis for strategic investment analysis compared to deterministic additive models that are sensitive to fluctuations in input indicators in noisy and fragmented data.

IV. Discussion

The results confirm that the proposed hybrid computational framework of agent-oriented fuzzy multi-criteria evaluation provides a stable and interpretable integration of heterogeneous economic, environmental, and investment indicators in the analysis of sustainable investments in the agro-industrial sector. Unlike traditional deterministic aggregation methods, which are highly sensitive to short-term fluctuations in statistical data, the developed model forms a smoothed integral index that allows identifying long-term structural trends in investment sustainability while maintaining transparency of the contribution of individual factors. This property is of fundamental importance for strategic planning in agricultural systems operating in conditions of high climatic and institutional uncertainty.

One of the key analytical results of the study is the identification of structural divergence in sustainability factors for the period 2021–2023. While the growth of foreign direct investment within traditional linear models can be interpreted as an unambiguously positive investment signal, the proposed fuzzy model recorded a relative stabilization of the integral index of sustainable investment at a moderate level. This effect is due to the simultaneous increase in institutional and climate risks, reflected in a decrease in the state support indicator. Thus, the model demonstrates the ability to take into account the asynchronous dynamics of factors, forming a more comprehensive and cautious assessment of investment conditions compared to methods focused exclusively on the volume of investment flows.

A comparative analysis with deterministic aggregation methods showed that the use of membership functions can significantly reduce the sensitivity of the integral index to short-

term climate and price shocks. Unlike classical additive models, the fuzzy approach focuses on fundamental long-term trends, reducing the influence of high-frequency statistical noise. This property is particularly important for the agro-industrial sector, where investment decisions are characterized by long time horizons, and the excessive reaction of analytical models to short-term fluctuations can lead to a distortion of strategic priorities for sustainable development.

The results of the sensitivity analysis confirm the structural robustness of the proposed index. The absence of rank inversions with significant variations in weight coefficients, including scenarios with enhanced consideration of ESG factors, indicates that the identified patterns are due to the fundamental dynamics of the input data rather than specific model parameter settings. The conclusions obtained are consistent with recent studies emphasizing the need to integrate environmental constraints into sustainable development investment models and demonstrating the effectiveness of hybrid fuzzy approaches in analyzing risks and uncertainties [26-29].

The use of agent-oriented modular architecture made it possible to solve the key engineering problem of data interoperability, ensuring reproducible integration of international statistical sources. The modular structure of the system increases the scalability of the solution and makes it possible to adapt it to different national contexts without changing the logic of analytical processing. Thus, the contribution of the study lies not in the development of a new fuzzy operator, but in the formalization of a reproducible integrated analytical process focused on the tasks of sustainable investment analysis in the agro-industrial sector.

Despite the results obtained, the study has a number of limitations. First, the use of aggregated national data may smooth out regional differences in agricultural development. Second, the use of macroeconomic forecasts from international organizations limits the consideration of local production risks. Third, the use of symmetric triangular membership functions simplifies the real nonlinear dependencies of investment sustainability. These limitations determine the directions for further research, including the integration of regional data, the expansion of scenario analysis, and the use of adaptive or neuro-fuzzy membership functions to increase the sensitivity of the model to local structural changes.

V. Conclusion

This study developed, implemented, and empirically validated a hybrid intelligent decision support system for assessing sustainable investments in the agro-industrial sector under conditions of high uncertainty, information asymmetry, and volatility in emerging markets. The results confirm that the integration of agent-oriented modular data processing architecture and fuzzy multi-criteria aggregation methods allows for the formation of sustainable and interpretable investment indicators that adequately reflect structural changes in the institutional, economic, and environmental environment.

The main scientific and practical results of the study can be summarized as follows. The developed three-level data processing architecture (Data Modules – Analytical Modules – Aggregation Module) ensured the semantic, temporal, and metric consistency of statistical indicators coming from heterogeneous international and national sources (OECD, FAO, national statistics). The implemented mechanism for normalizing and synchronizing time series made it possible to form a reproducible analytical pipeline that is resistant to omissions, outliers, and statistical noise.

A comparative analysis with deterministic aggregation methods showed that the use of a fuzzy multi-criteria approach based on Fuzzy SAW provides more stable dynamics of the integral index in relation to short-term climatic and market shocks. Unlike classical additive models, which are sensitive to high-frequency fluctuations in input indicators, the proposed system allows identifying fundamental long-term trends in investment stability. This property is of fundamental importance for the agro-industrial sector, which is characterized by long investment cycles and high climate sensitivity.

Empirical testing of the model using data from the agro-industrial sector of the Republic of Kazakhstan for the period 2010–2023 revealed a qualitative structural shift in the investment environment. In particular, the system diagnosed an institutional imbalance in 2021–2022, when the recovery of market indicators was accompanied by a decline in the integral assessment of sustainable investments due to a reduction in state support. This result confirms the ability of the proposed model to identify hidden regulatory and institutional risks that remain difficult to distinguish using traditional linear methods of investment analysis.

The results of the sensitivity scenario analysis demonstrated the high structural robustness of the model. Variations in the weighting coefficients of the criteria across a wide range, including scenarios with priority consideration of ESG factors, did not lead to an inversion of the ranks of the analyzed periods. This indicates that the estimates obtained are determined by the fundamental dynamics of the input data, rather than subjective parameter settings, which is a critical requirement for strategic investment decision support systems.

The developed system can be considered a practical tool for strategic scenario analysis and support for sustainable investment policy. It can be used by government agencies to assess the impact of changes in the subsidy and regulatory system, as well as by private investors and analysts to make informed investment decisions that are less susceptible to short-term market noise.

The results obtained go beyond the national context. The modular and data-source-agnostic architecture allows the proposed approach to be adapted to the statistical systems of other countries with emerging economies while maintaining a unified logic for integrating economic, environmental, and institutional factors. This opens up opportunities to use the developed framework for cross-country comparative analysis and the formation of supranational systems for monitoring sustainable investments in the agro-industrial sector.

Further research could focus on increasing the spatial detail of the analysis, moving from the country to the regional level, and integrating adaptive neuro-fuzzy methods for calibrating membership functions. Another promising direction is the expansion of the analytical architecture by including machine

learning forecasting modules to assess local climate and production risks in the context of sustainable development.

***Abstract*—This study presents the first Text-to-Speech (TTS) model for Penang Hokkien, a low-resource tonal dialect at risk of extinction. To address phonological sparsity in the collected speech corpus, we propose a two-stage fine-tuning approach that emphasizes comprehensive phonetic coverage through syllable-level synthetic augmentation while subsequently refining prosodic naturalness using real speech recordings. By supplementing a limited 45-minute real speech corpus with a 2-hour syllable-level concatenative synthetic corpus, the full dialectal inventory of approximately 2,000 unique syllable-tone combinations was encompassed. Experimental results suggest that improving syllable-tone coverage contributes substantially to intelligibility and tonal accuracy in this low-resource tonal setting. Technical optimizations, including a 600-ms cross-fading technique to mitigate boundary artifacts and numerical tone markers to reduce token sparsity, further improved model stability and synthesis quality. The final model achieved a Mean Opinion Score (MOS) of 3.92.**

***Keywords*—Low-resource language; speech synthesis; text-to-speech; data augmentation techniques**

I. Introduction

Penang Hokkien is a local variant of Hokkien (Chinese dialect) spoken in Penang, Malaysia. This dialect has evolved uniquely over time, incorporating loanwords from Malay, English, Cantonese, and Teochew, reflecting Penang's rich multicultural heritage [1]. In recent years, the usage of Penang Hokkien has declined, particularly among the younger generation, as Mandarin increasingly dominates communication within the Malaysian Chinese community. This shift places Penang Hokkien at risk of extinction if efforts are not made to preserve it for future generations [2].

One viable approach to safeguarding this dialect is through comprehensive documentation, in terms of text and speech, by building a TTS system. However, developing TTS systems for low-resource languages presents significant challenges, primarily due to the lack of high-quality paired text and speech data. As a predominantly spoken, unwritten dialect, Penang Hokkien lacks a standardized orthography and a comprehensive speech corpus. Most state-of-the-art neural TTS models require extensive high-quality datasets that are infeasible for such low-resource scenarios. Furthermore, even when limited real speech is recorded, it often suffers from phonological sparsity, failing to cover the exhaustive inventory of possible syllable-tone combinations, which results in poor performance on out-of-vocabulary (OOV) terms.

To mitigate the resource constraints, this study implements a two-stage fine-tuning approach centered on phonetic completeness leveraging the SpeechT5_TTS model architecture [3]. By establishing a dense phonetic foundation through a hybrid speech corpus and optimizing tonal representation, this work proposes a potentially scalable framework and serves as an initial case study for the digital preservation of unwritten tonal dialects.

The major contributions of this study are as follows:

1) We empirically investigate the relationship between phonetic coverage and prosodic variation in low-resource tonal TTS. Experimental results suggest that expanding syllable-tone coverage through syllable-level concatenative augmentation contributes more consistently to intelligibility and tonal accuracy than prosodic perturbation alone, particularly for out-of-vocabulary (OOV) syllables.

2) We propose and validate the use of numerical tone markers as a superior alternative to traditional diacritics for low-resource TTS. We demonstrate that this representation reduces token sparsity by approximately 35% and accelerates model convergence by 18%, providing a more stable embedding space for rare syllable units.

3) We implement a two-stage fine-tuning approach using a hybrid speech corpus with an identified optimal 2:1 synthetic-to-real data ratio. Additionally, a 600-ms cross-fading technique is introduced to successfully mitigate the boundary artifacts inherent in concatenative synthesis, balancing phonetic robustness with natural human prosody.

4) To the best of our knowledge, this study establishes the first functional TTS framework for the Penang Hokkien dialect. This provides a vital technological foundation for the digital preservation of this endangered unwritten language.

II. Literature Review

A. Low-Resource TTS Dataset Acquisition

Recent advancements in neural speech technologies and the challenges of low-resource scenarios have prompted significant changes in TTS dataset construction. Traditional approaches relying on extensive audio recordings are often impractical for low-resource languages. To address this, researchers are increasingly repurposing existing data to create effective TTS datasets.

For example, LibriTTS [4] and CML-TTS [5] were adapted from ASR datasets, using carefully designed pipelines for text and audio processing to ensure compatibility with TTS systems. These pipelines retained critical features of the original ASR datasets, such as speaker diversity, text-audio alignment, and high-quality recordings, while resolving common issues like lengthy utterances, transcription inconsistencies, and noisy audios. In contrast, projects like the CMU Wilderness Multilingual Speech Dataset [6], BibleTTS [7], and Sanskrit TTS [8] have utilised publicly available Bible readings as a foundation to construct speech corpus. Through meticulous data preprocessing, these initiatives have successfully transformed crawled data into reliable resources for speech synthesis.

Researchers have also explored the potential of other found audio sources. [9] analyzed acoustic and prosodic features of various audio recordings, identifying that broadcast news is particularly suitable for TTS tasks. Similarly, a small TTS corpus for Moroccan dialect was created using storytelling audios from YouTube, which were denoised, segmented, transcribed with ASR system, and manually normalized to ensure accuracy [10]. Furthermore, unsupervised data selection approaches have shown promise in low-resource settings. In [11], researchers used broadcast data to create a TTS dataset, achieving a high Mean Opinion Score (MOS) of 4.4 for intelligibility with only one hour of data, demonstrating the potential of combining broadcast data with selection methodologies to address resource constraints effectively.

B. Low-Resource Speech Synthesis

Various approaches were employed to address data scarcity in low-resource languages. A major direction seeks to reduce reliance on paired text-speech corpora by leveraging representation learning. These approaches exploited large pre-trained models to extract intermediate representations that capture phonetic or acoustic information without requiring explicit labels. For example, language models such as Bidirectional Encoder Representations from Transformers (BERT) [12][13] and self-supervised speech models including Vector Quantized Variational Autoencoder (VQ-VAE) [14][15] and Hidden-Unit BERT (HuBERT) [16] have been employed to learn compact acoustic-symbolic units directly from raw speech. These representations approximate phoneme sequences and serve as intermediate units for training TTS models without extensive labelled data.

Beyond representation learning, unsupervised training has also been explored to bypass the need for parallel datasets altogether. For example, [17] proposed training two separate modules, one for alignment and one for synthesis on non-parallel data, enabling TTS learning without explicit text-speech pairs. Another influential direction exploited the duality between ASR and TTS through closed-loop learning. The "speech chain" framework [18], for instance, co-trains ASR and TTS by allowing TTS-generated audio to be transcribed by ASR, with the transcriptions fed back as supervisory signals to TTS. Similarly, ASR models have been used to produce pseudo-labels for unlabelled speech [19].

Complementary to unsupervised approaches, data augmentation and cross-lingual adaptation form another practical toolkit for low-resource scenarios. Conventional augmentation such as speech perturbation, pitch shifting, and background noise addition [20][21] are widely used to artificially expand existing datasets. While these approaches play a vital role, transfer learning remains the standard approach for low-resource TTS, either used solely or in combination with other approaches mentioned before. Its effectiveness was demonstrated through pretraining on a single high-resource language [22][23]. In more recent works, its capabilities have been extended to include multilingual and multi-speaker modelling for enhanced adaptability [24]. Phonetic similarity in relation to language closeness has also emerged as a key factor in transfer learning. In [25], a hierarchical transfer learning approach revealed that phonologically close languages significantly benefit from multilingual transfer learning, highlighting the importance of nuanced approaches in addressing the challenges of TTS in low-resource scenarios.

III. Methodology

To effectively address the data scarcity and phonological sparsity inherent in the Penang Hokkien dialect, this study proposes a comprehensive methodology that bridges the gap between synthetic data engineering and progressive neural model training. The overall architecture is divided into two primary phases: (a) hybrid speech corpus construction and (b) two-stage text-to-speech (TTS) model training. The first phase utilizes a dual-pipeline approach to acquire raw data, subsequently undergoing acoustic and linguistic processing, including 600-ms linear cross-fading and numerical tone representation, to generate a phonetically-rich synthetic speech corpus and a prosodically-authentic real speech corpus. In the second phase, these corpora are leveraged through a sequential fine-tuning strategy. The process begins with a pretrained SpeechT5_TTS model ($M_{pretrained}$) [3] that undergoes intermediate fine-tuning on synthetic data to establish a phonetic foundation by learning basic tonal contours across the comprehensive syllable inventory ($M_{intermediate}$), followed by final fine-tuning on real speech to achieve prosodic refinement and human-like naturalness (M_{final}) (Fig. 1).

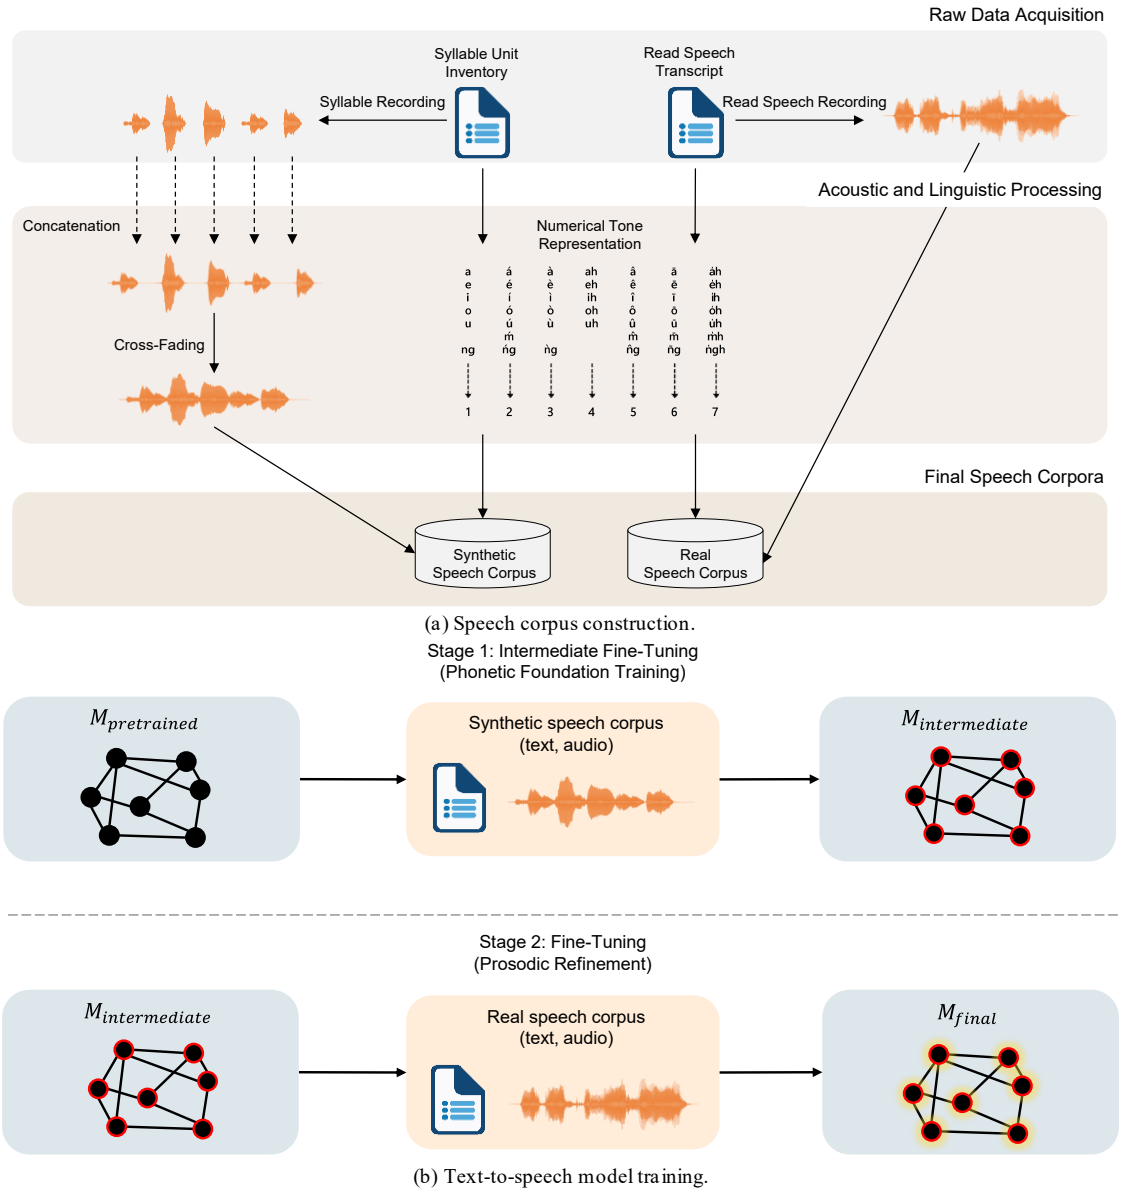

Fig. 1. The Penang Hokkien TTS framework is divided into two distinct components: (a) The speech corpus construction phase, which establishes a hybrid dataset by integrating isolated syllable units and continuous read speech via numerical tone mapping and acoustic smoothing; and (b) The text-to-speech model training phase, illustrating the progressive two-stage fine-tuning strategy used to adapt a pretrained model into a phonetically-complete and prosodically-refined final TTS system.

A. Real Speech Corpus: The Acoustic Foundation

The real speech corpus serves as the acoustic foundation for the TTS model. The transcript was sourced from documented conversations and community-driven social media platforms [26][27] to capture authentic linguistic variations. Inconsistencies in non-standard orthography were resolved using the Soundex$_{PH}$ algorithm [28] to ensure phonetic consistency. A native female speaker recorded the transcript in controlled conditions using high-fidelity equipment at 44.1 kHz to capture a broader frequency range, preserving phonetic details like the velar stop *'ak'*, which might be lost at lower sampling rates. Audios were downsampled to 16 kHz to align with the SpeechT5 architecture after undergoing silence trimming and volume normalization. After these procedures, approximately 45 minutes of high-quality Penang Hokkien real speech corpus was obtained (Table I).

TABLE I. DISTRIBUTION OF REAL SPEECH CORPUS

Statistics	Value
Number of utterances	902
Total syllable count	10507
Unique syllable count	1284
Total duration	44 min 12 sec
Minimum length of utterance	1.04 sec
Maximum length of utterance	7.22 sec
Average length of utterance	1.94 sec

B. Synthetic Speech Corpus: Bridging the Phonological Gap

To bridge the phonological gap (around 700 missing syllables in the 45-min real speech corpus), a 4-hour synthetic speech corpus was constructed (Table II). A synthetic transcript was generated through the random concatenation of romanized syllables to ensure comprehensive coverage of the approximately 2,000 unique syllable-tone combinations in the Penang Hokkien phonetic inventory. Individual syllable units were recorded in isolation by the same native speaker to maintain acoustic consistency. Syllables were utilized as the primary synthesis unit rather than traditional speech unit diphones to better reflect the tonal characteristics of Penang Hokkien while reducing computational complexity [29].

The necessity of the synthetic corpus is highlighted by the phoneme distribution analysis shown in Fig. 2 and 3. The real speech corpus exhibits a heavily skewed distribution where frequent phonemes dominate, leaving a long tail of underrepresented units. Conversely, the syllable-level concatenative approach yields a deliberately balanced distribution, ensuring that the model is exposed to the comprehensive phonetic inventory of Penang Hokkien.

TABLE II. DISTRIBUTION OF THE SYNTHETIC SPEECH CORPUS

Statistics	Value
Number of utterances	5779
Total syllable count	53481
Unique syllable count	2045
Total duration	4 hr 0 min 2 sec
Minimum length of utterance	1.65 sec
Maximum length of utterance	7.08 sec
Average length of utterance	2.24 sec

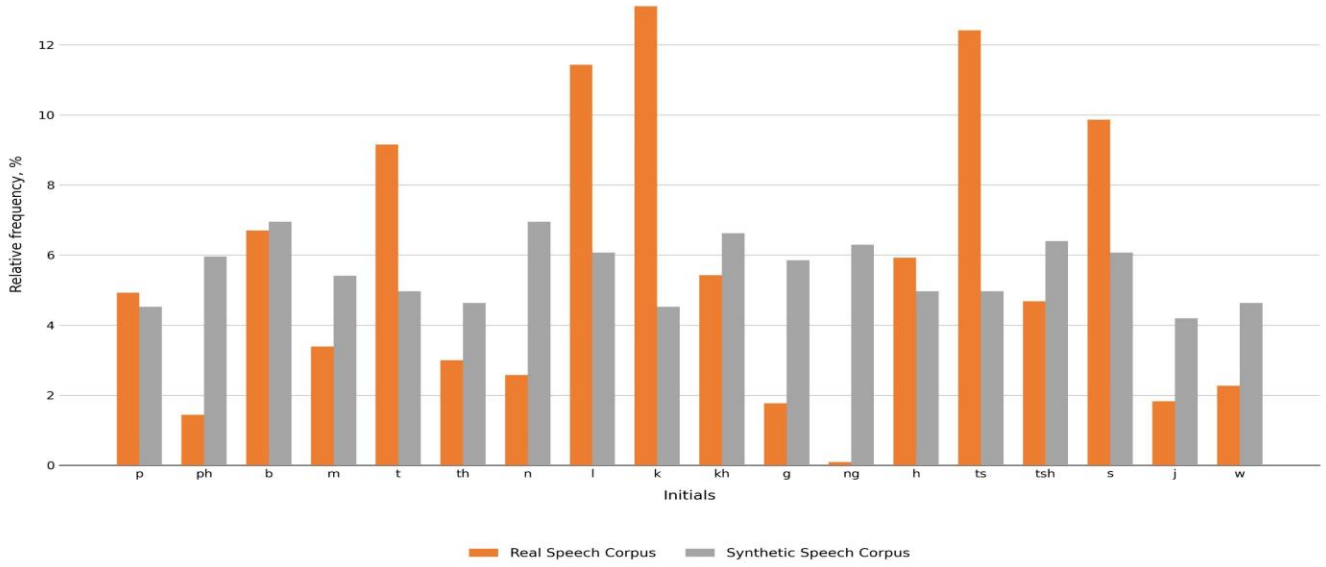

Fig. 2. Initials phoneme distribution.

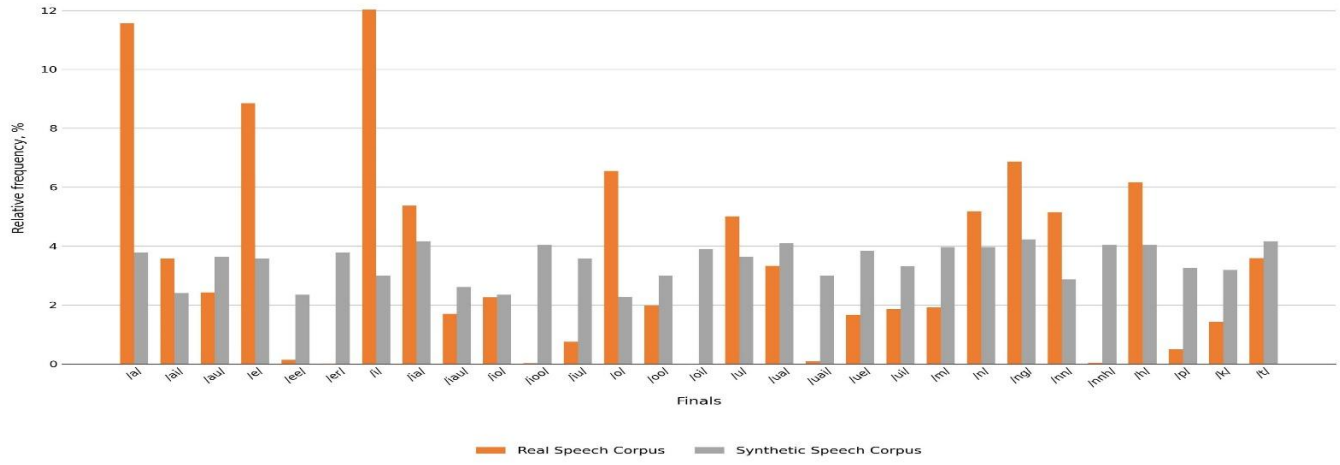

Fig. 3. Finals phoneme distribution.

C. Cross-Fading: Concatenative Artifact Mitigation

Concatenated speech may introduce artifacts at the boundaries between syllables, affecting the overall naturalness and fluidity of the synthesized output. These artifacts arise due to acoustic discontinuities between concatenated units, leading to unnatural transitions. To mitigate this issue, a cross-fading technique [30] was applied, which smooths transitions between syllables by gradually blending overlapping segments. This technique helped reduce abrupt changes and enhance the cohesion and flow of the synthesized speech.

The cross-faded audio signal $S(t)$ is defined as:

$$S(t) = \big(1 - \alpha(t)\big) \cdot A_n(t) + \alpha(t) \cdot A_{n+1}(t) \qquad (1)$$

For this study, the duration of each individual syllable unit signal $A_n(t)$ was fixed at 1.0 s, while the overlap duration T was set to 600 ms. The concatenation was achieved by applying a fade-out factor $(1 - \alpha(t))$ to the preceding syllable segment $A_n(t)$ and a fade-in factor $\alpha(t)$ to the succeeding syllable segment $A_{n+1}(t)$. These factors vary linearly with time (t) across the overlap duration T. Specifically:

- $\alpha(t) = \frac{t}{T}$ increases from 0 to 1 as t progresses through the overlap region, gradually bringing in the succeeding syllable segment.
- $1 - \alpha(t)$ decreases from 1 to 0 over the same time, fading out the preceding syllable segment.

The resulting cross-faded audio signal $S(t)$ smoothly transitioned between syllable units, ensuring natural-sounding audio continuity.

D. Numerical Tone Representation: Improve Tonal Learning

Penang Hokkien is a tonal language where variations in tone significantly alter word meaning. The model must correctly encode and distinguish these tonal variations for effective TTS training. The original Penang Hokkien read speech transcript uses diacritic characters (e.g., *"à"*, *"á"*, *"â"*) to indicate tones, but an alternative numerical tone representation (e.g., *"à"* → *"a3"*) was proposed in this study.

Using numerical tone markers in the input text instead of the original diacritic characters provides several advantages for low-resource TTS. First, the Penang Hokkien real speech corpus is limited to only 45 minutes, and individual diacritic characters may appear infrequently, making it difficult for the model to learn meaningful embeddings for these rare tokens due to limited exposure. In contrast, using numbers to represent tones consolidates tonal information into a smaller, shared set of tokens (e.g., *"à"*, *"è"*, and *"ì"* all map to the tone marker *"3"*). This significantly reduces token sparsity, allowing the model to learn tonal variations more effectively. Additionally, direct diacritic encoding would require 34 unique diacritic variations in the tokenizer, leading to a larger vocabulary size and increased embedding complexity. In comparison, numerical tone markers only require 7 additional tokens (1-7), minimizing vocabulary size and computational overhead. Since each token corresponds to a row in the model's embedding matrix, reducing the number of unique tokens simplifies the embedding space and enhances generalization, particularly in low-resource scenarios. Fig. 4 illustrates the mapping between diacritic tones and their corresponding numerical representations.

Diacritic tone representation :	a e i o u ng	á é í ó ú m̀ ńg	à è ì ò ù ǹg	ah eh ih oh uh	â ê î ô û m̂ n̂g	ā ē ī ō ū m̄ n̄g	a̍h e̍h i̍h o̍h u̍h m̍h n̍gh
Numerical tone representation :	1	2	3	4	5	6	7

Fig. 4. Diacritic tones in Penang Hokkien and their corresponding numerical tone representations.

E. Two-Stage Fine-Tuning: Phonetic Training and Prosodic Refinement

The Penang Hokkien TTS model was trained using a progressive two-stage fine-tuning approach designed to balance broad phonetic robustness with authentic prosodic naturalness. The model was initialized with a multitask-pretrained SpeechT5_TTS checkpoint trained on the high-resource English LibriTTS corpus [3], enabling cross-lingual knowledge transfer to the low-resource Penang Hokkien dialect.

The primary objective of the first stage was to establish a dense phonetic foundation and resolve the model's exposure to the comprehensive inventory of approximately 2,000 unique syllable-tone combinations. Based on our ablation study regarding optimal augmentation volume, the model underwent intermediate fine-tuning on 2 hours of the synthetic speech corpus. This established a 2:1 synthetic-to-real data ratio, which was identified as the inflection point for maximum performance. Before training, the tokenizer was extended to include numerical tone markers (1–7) to prevent the loss of critical tonal information. To accommodate these new tokens, the embedding layer was resized. During this stage, all layers were unfrozen to allow the model to fully integrate the newly established tonal relationships and adapt its hidden representation space to the modified input.

The second stage focused on refining acoustic modeling and speech feature generation while preserving the phonetic structures learned in Stage 1. The model was fine-tuned on the 45-minute real speech corpus to supply the natural prosody and authentic accentual nuances inherent in human recordings. To retain the learned phonetic structures, the token embedding layers, lower transformer layers, and self-attention mechanisms were frozen. Fine-tuning was restricted to the acoustic modeling layers (encoder and decoder) and the decoder's pre-net and post-net layers to optimize spectral feature prediction.

To convert the predicted mel-spectrograms into high-fidelity speech waveforms, we utilized a pretrained HiFi-GAN vocoder [3]. Unlike the acoustic model, the vocoder was not fine-tuned from scratch, as its architecture is designed to generalize fundamental speech characteristics, such as periodicity and loudness, across different languages and speakers [31].

Table III shows the hyperparameter settings used in model training.

TABLE III. MODEL TRAINING HYPERPARAMETERS

Hyperparameter	Value
learning_rate	1e-4
train_batch_size	4
eval_batch_size	2
seed	42
gradient_accumulation_steps	8
total_train_batch_size	32
optimizer	ADAMW_TORCH with β_1, β_2=(0.9,0.999) and ε =1e-8
lr_scheduler_type	linear
lr_scheduler_warmup_steps	500
training_steps	2000
mixed_precision_training	Native AMP

IV. EVALUATION

A. Objective Evaluation

The objective evaluation of synthesized Penang Hokkien speech employs on Mel-Cepstral Distortion (MCD) [32], a widely used spectral distance metric that quantifies the similarity between synthesized and groundtruth speech in terms of acoustic features. MCD measures the distance between the mel-frequency cepstral coefficients (MFCCs) extracted from both speech signals, providing an objective assessment of spectral fidelity. A lower MCD score indicates a smaller spectral difference, implying higher fidelity and better synthesis quality.

B. Subjective Evaluation

For subjective evaluation, Mean Opinion Score (MOS) [33] was conducted to assess the quality of the synthesized Penang Hokkien speech. MOS is a widely accepted perceptual metric that quantifies speech quality on a 5-point scale. To eliminate potential biases, the utterances were presented in a randomized order. A total of 10 native Penang Hokkien speakers participated in the evaluation. A structured questionnaire was utilized to evaluate the synthesized speech across three fundamental dimensions for tonal language synthesis [34]:

- Intelligibility: Measures how well a listener can understand the synthesized speech, including pronunciation accuracy, phoneme articulation, and word clarity.
- Naturalness: Evaluate how human-like the synthesized speech sounds, considering smoothness, voice quality, and absence of robotic artifacts.
- *Tone Accuracy* – Assesses how well the synthesized speech captures intonation, pitch variation, and stress patterns, which are essential in Penang Hokkien as a tonal language (Table IV).

TABLE IV. MEAN OPINION SCORE (MOS) EVALUATION SCALE

Score	Intelligibility	Naturalness	Tone Accuracy
1	No meaning understood	Unnatural, highly robotic	Not accurate, very big tonal shift
2	Effort required to understand	Inadequately natural	Inadequately accurate
3	Moderate effort required	Adequately natural	Adequately accurate
4	No major effort, mostly clear	Near natural	Near accurate, slight tonal shifts
5	No effort required, perfectly clear	Natural human speech	Very accurate, correct tone

V. RESULTS AND DISCUSSION

The primary contribution of this study is the empirical validation that, for tonal dialects like Penang Hokkien, addressing the "phonological gap" through a comprehensive phonetic inventory is more vital for synthesis quality than simply increasing the amount of training data through acoustic perturbations. While common data augmentation techniques like pitch-shifting [35] improve model robustness by simulating prosodic diversity, they do not introduce new phonetic information.

We conducted a controlled comparison between two distinct augmentation techniques, each providing 2 hours of synthetic speech data for intermediate fine-tuning before fine-tuning on the 45-min real speech data, with numerical input as tone representation.

1) Syllable-level concatenation: This augmentation technique constructed synthetic speech to cover the comprehensive set of approximately 2,000 Penang Hokkien syllables, ensuring every tonal and phonetic unit was represented during training.

2) Pitch-shifting: Augmentation was performed on the original single-speaker real speech corpus using the SoX tool [36] to simulate prosodic variation. Pitch was shifted within a narrow range of -0.5 to +0.5 semitones (step size: 0.5), and speed was perturbed by ± 10% (ratios: 0.9 and 1.1). This restricted range was selected to maintain speaker similarity, as larger perturbations are known to degrade perceived voice identity and naturalness [37][38]. While this augmentation technique provided an equivalent 2 hours of synthetic speech data, it remained restricted to the 1,300 syllables present in the original real speech corpus (Table V).

TABLE V. SYLLABLE-LEVEL CONCATENATION VS. PITCH-SHIFTING (PHONETIC COVERAGE VS. PROSODIC VARIATION)

Augmentation Technique	Unique Syllable Count	MOS ↑				MCD ↓
		Intelligibility	Naturalness	Tone Accuracy	Overall	
2 hr Syllable-Level Concatenation (Proposed)	2045	**4.12 ± 0.43**	3.95 ± 0.24	**3.69 ± 0.52**	**3.92 ± 0.40**	**20.07 ± 2.09**
2 hr Pitch-Shifting	1284	3.67 ± 0.26	**4.09 ± 0.17**	3.34 ± 0.51	3.70 ± 0.31	20.54 ± 1.86

The results reveal that the proposed syllable-level concatenation (MOS 3.92) consistently outperformed pitch-shifting (MOS 3.70). Pitch-shifting provides some benefits by introducing prosodic variation, which has been shown in prior work to improve model robustness [37]. However, this technique remains limited because it did not improve phonetic coverage, many syllables remain unseen during training. In contrast, the proposed syllable-level concatenation technique directly addressed phonetic coverage limitations. By systematically constructing synthetic speech to cover the comprehensive set of ~2,000 Penang Hokkien syllables, the model is exposed to every tonal and phonetic unit before final fine-tuning on a real speech corpus. This broader coverage is particularly critical for tonal languages, where accurate tone realization is tightly coupled with intelligibility [39].

Although pitch-shifting yields a slight improvement in perceived naturalness, native speaker evaluators consistently preferred the model intermediately fine-tuned on syllable-level concatenative synthetic speech for its clarity and tonal correctness. The higher ratings in intelligibility and tone accuracy indicate that in a low-resource tonal language setting, comprehensive phonetic coverage contributes more directly to synthesis quality than increased prosodic variation alone.

The superiority of the syllable-level concatenation technique is most evident when synthesizing Out-of-Vocabulary (OOV) syllables, such as *"gēr"*, *"lēeng"*, and *"ngāng"* in the sentence *"tsin gēr-lam khuànn lú tī tsia lēeng-ngāng-lēeng-ngang. (It's frustrating seeing you lengang-lengang here—just doing nothing.)"*. The effectiveness of this technique is visually substantiated through mel spectrogram analysis, which represents the spectral properties and energy distribution of synthesized speech. In Fig. 5, we compare the acoustic outputs for the OOV sentence across different training configurations.

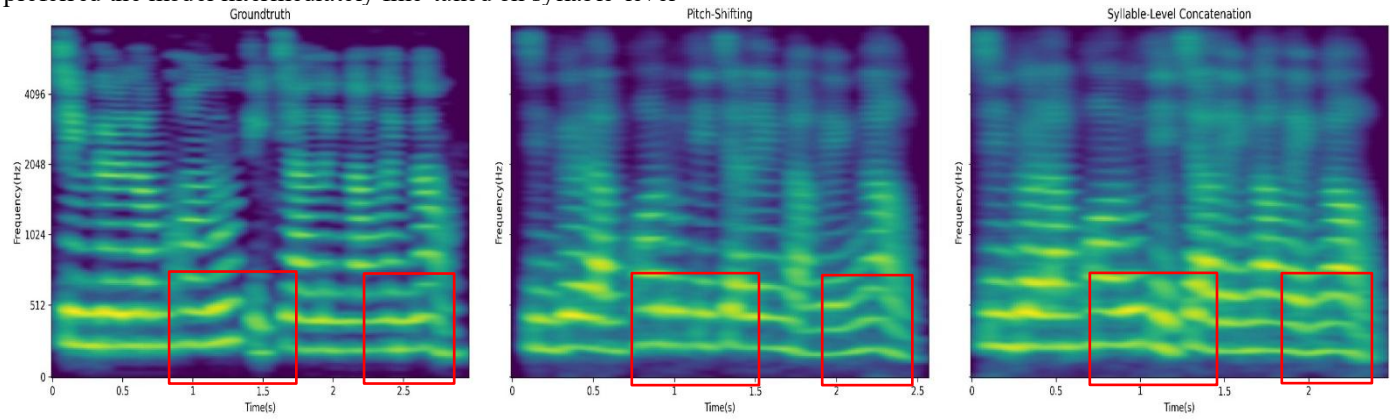

Fig. 5. Mel spectrogram analysis of OOV sentence.

Mel spectrograms represent the spectral properties of speech, where clear and well-defined harmonic structures (the bright horizontal bands) correlate with higher fidelity and intelligibility. The groundtruth spectrogram displays sharp, distinct harmonics, representing clear, natural speech. These features are indicative of high-fidelity natural speech with stable pitch contours. The output from the pitch-shifting model is noticeably blurrier, indicating weak harmonic definition and degraded spectral fidelity. While pitch-shifting introduces prosodic variety, it fails to equip the model with the necessary phonetic information to accurately reconstruct the spectral envelopes of OOV syllables. In contrast, the model trained with syllable-level augmentation produces significantly sharper spectrograms that closely resemble the groundtruth reference speech. The harmonic bands are more pronounced and stable, demonstrating that intermediate fine-tuning on a comprehensive phonetic inventory allows the model to learn correct phonetic and tonal structures for OOV syllables with high accuracy.

While the improved performance is consistent with the hypothesis that broader phonetic coverage benefits low-resource tonal dialect TTS, the observed gains are likely influenced by multiple interacting factors. First, the two-stage fine-tuning strategy may introduce curriculum learning effects, where intermediate training on synthetic speech establishes stable phonetic representations before refinement on natural speech. Second, the synthetic corpus produces denser token distributions by repeatedly exposing the model to shared syllable-tone patterns, potentially improving embedding stability for rare units. Third, intermediate pretraining on synthetic speech may also provide a regularization effect by exposing the model to a wider range of phonetic combinations prior to adaptation on the limited real speech corpus. Therefore, while the experiments suggest that phonetic completeness plays an important role, the individual contributions of these factors cannot yet be fully disentangled within the current study design.

VI. Ablation Studies

A. Cross-Fading on Concatenative Artifact Mitigation

During the preparation of the synthetic speech corpus, individual syllable units were recorded and concatenated to form short utterances. However, naive concatenation often results in audible discontinuities at unit boundaries, such as clicks, spectral jumps, and unnatural transitions, which can negatively impact downstream TTS training. To ensure the synthetic corpus provides a clean phonetic foundation, we evaluated the effectiveness of cross-fading technique in smoothing the acoustic transitions within the syllable-level concatenative synthetic speech.

We compared direct concatenation (0 ms) against a 600-ms cross-fade across various phonotactic contexts. To objectively quantify join quality, we utilized boundary-level Mel-Cepstral Distortion (MCD) [40] to measure spectral mismatch at the transition points (as primary source of perceptual artifacts).

TABLE VI. ACOUSTIC AND PERCEPTUAL EFFECTS OF CROSS-FADING

Condition	MOS (Naturalness) ↑	Boundary MCD (dB)↓
No cross-fading	3.07 ± 0.44	6.41 ± 0.92
600ms cross-fading	3.68 ± 0.38	3.74 ± 0.51

As shown in Table VI, the 600-ms cross-fading reduced boundary MCD from 6.41 dB to 3.74 dB, an improvement of approximately 41% compared to direct concatenation (no cross-fading). High MCD values in the no-cross-fading condition reflect abrupt spectral jumps, a well-documented artifact in concatenative synthesis. Applying a 600-ms cross-fading mitigated these jumps by gradually interpolating between spectral envelopes, yielding smoother formant trajectories and suppressing spurious high-frequency energy at the join. This smoothing also supports more natural F0 continuity across syllables. This reduction in spectral discontinuity translated to significant perceptual gains, with MOS ratings increasing from 3.07 (unnatural) to 3.68 (moderately natural). Evaluators reported a marked reduction in audible clicks and smoother transitions. These results confirm that cross-fading is an essential preprocessing step to ensure the model learns acoustic transitions consistent with natural coarticulation. Consequently, the 600-ms configuration was adopted for the final synthetic corpus construction.

B. Numerical vs. Diacritic Tone Representation Markers

In tonal dialects like Penang Hokkien, the tone markers used to represent pitch variations in the input text is a critical design factor that directly influences the model's ability to learn phonetic patterns. While diacritics are linguistically traditional, they often introduce high token sparsity and vocabulary complexity in low-resource scenarios, where data is insufficient to train rare character embeddings. We conducted this study to determine if numerical markers could simplify the embedding space and accelerate model's convergence without compromising tonal information.

The input text with diacritic tone markers (e.g. "à") and numerical tone markers (e.g. "a3") was compared across four dimensions:

1) Vocabulary coverage: The use of diacritic tone markers resulted in a larger and sparser token vocabulary, as each of the 34 unique diacritic variant was treated as a distinct token. Within the 45-minute real Penang Hokkien speech corpus, many of these diacritic variants appear only a few times, producing a long tail of low-frequency tokens. Numerical tone markers collapsed all these diacritic variants into a small, shared set of tone markers (1-7), significantly reducing tokenizer vocabulary by ≈35%.

2) Model convergence speed: Reusing a small set of numerical tone markers created a denser token distribution, allowing the model to learn tone embeddings earlier and with greater stability. Diacritics, conversely, resulted in many low-frequency tokens that produced noisy gradients and slowed down the optimization of embeddings. Since numerical tone markers appeared across many syllables, the model was exposed to more syllable-tone combinations for each tone class, enabling more consistent mappings between tone markers and intonation. Quantitatively, the numerical model consistently reached a stable validation loss plateau (0.5936) at Step 950 (Epoch≈39), compared to (0.5939) at Step 1150 (Epoch≈48) for the diacritis baseline, representing a faster convergence speed of ≈18%.

3) Synthesis tonal accuracy: Tonal accuracy was assessed by analyzing synthesis output. Tone substitution error was identified whenever the synthesized tone class did not match the expected tone. The numerical model achieved a significant reduction in error rates (6.5%) compared to diacritic model (18.2%).

4) Perceptual speech quality (XAB Listening Test) [41]: A preference test involving native speakers revealed a clear preference for the numerical model. 72.45% of responses favored the numerical-tone outputs due to more stable tonal contours and higher intelligibility, while 0% favored the diacritic model. The remaining 27.55% of responses indicated no preference, representing instances where perceptual differences were negligible.

These results are summarized in Table VII. These findings confirm that numerical tone markers are superior to diacritic tone markers for Penang Hokkien TTS model training, effectively improving both computational efficiency and human perceptual preference.

TABLE VII. NUMERICAL VS. DIACRITIC TONE MARKERS

Evaluation Dimension	Numerical Tone Markers	Diacritic Tone Markers	Outcome
Vocabulary coverage	Reduced by ~35% consolidated shared tokens	Larger, sparse token set due to infrequent diacritic forms	Numerical better (less sparsity)
Model convergence speed	~18% fewer steps to converge	Slower, converged in more training steps	Numerical faster
Tone mispronunciation rate	6.5% error rate	18.2% error rate	Numerical more accurate
Perceptual preference (XAB test)	72.45% preference (27.55% no preference)	0% preference	Numerical strongly preferred

C. Optimal Volume of Syllable-Level Concatenative Synthetic Speech Data

A critical challenge in low-resource TTS is identifying the "inflection point" where synthetic data provides maximum phonetic stability without introducing robotic artifacts or overfitting to mechanical prosody of concatenated units. We investigated this by fine-tuning four configurations with varying durations of the synthetic speech corpus (0-4 hours) followed by a constant 45-minute real speech corpus.

Among all evaluated configurations, Model III (2hr synthetic + 45min real) achieved the best overall performance, recording the highest MOS (3.92) and lowest MCD (20.07), indicating the closest spectral match to groundtruth reference speech. These results suggest that supplementing limited real speech data with syllable-level concatenative synthetic speech data helps the TTS model to learn better pronunciation patterns and tonal variations, yielding clearer and more accurate speech synthesis while maintaining naturalness (Tables VIII and IX).

TABLE VIII. TTS TRAINING DATA CONFIGURATIONS

Model	Synthetic Speech Data	Real Speech Data	Number of utterances	Total Syllable Count	Unique Syllable Count	Input Tone Representation
Model I	-	45 min	902	10507	1284	Numerical
Model II	1 hr	45 min	2110	13472	2045	Numerical
Model III	2 hr	45 min	3302	26502	2045	Numerical
Model IV	4 hr	45 min	5779	53481	2045	Numerical

TABLE IX. OBJECTIVE AND SUBJECTIVE EVALUATION OF SYNTHESIZED SPEECH

Model	MOS ↑				MCD ↓
	Intelligibility	Naturalness	Tone Accuracy	Overall	
Model I	3.71 ± 0.67	3.62 ± 0.42	3.38 ± 0.63	3.57 ± 0.57	21.04 ± 2.45
Model II	3.89 ± 0.39	3.78 ± 0.37	3.55 ± 0.44	3.74 ± 0.40	20.21 ± 1.97
Model III	**4.12 ± 0.43**	**3.95 ± 0.24**	3.69 ± 0.52	**3.92 ± 0.40**	**20.07 ± 2.09**
Model IV	3.92 ± 0.31	3.53 ± 0.33	**3.73 ± 0.45**	3.73 ± 0.36	20.14 ± 2.11

However, increasing the amount of synthetic speech data beyond an approximately 2:1 ratio did not yield meaningful improvements. Model IV (4hr synthetic + 45min real) showed only a marginal increase in tone accuracy (MOS 3.73 vs 3.69), but experienced slight declines in intelligibility and naturalness, and a higher MCD score of 20.14 ± 2.11. These results indicate a performance plateau, with signs of degradation beyond the optimal augmentation point. Several factors likely contributed to this degradation. First, syllable-level concatenative synthetic speech may introduce unnatural prosody and boundary artifacts. With more synthetic speech data, the model might overfit to these unnatural patterns, negatively affecting speech smoothness. Second, the phonetic diversity of synthetic speech data tends to diminish after a certain threshold; beyond two hours, additional examples primarily reinforce existing patterns rather than introducing new ones, raising the risk of overfitting to synthetic pronunciations. Third, the domain gap between synthetic and real speech may become more prominent as synthetic speech data dominates the training phase, reducing the effectiveness of real speech data fine-tuning in correcting artifacts.

Taken together, these findings suggest that an approximately 2:1 synthetic-to-real ratio (as implemented in Model III) achieved the optimal balance, maximizing tonal clarity and phonetic robustness while preserving natural human prosody.

VII. STATISTICAL VALIDATION

A. Inter-Rater Reliability

While a pool of 10 native speaker evaluators represents a compact sample size, recruiting qualified fluent speakers of an endangered, unwritten dialect presents acute resource constraints. To ensure the statistical reliability of this sample, the Kappa statistic [42] was utilized to measure the degree of agreement among the 10 native speaker evaluators (inter-rater agreement). Kappa values range from -1 to +1, where a score of +1 indicates perfect agreement and 0 indicates agreement purely by chance. The inter-rater agreement is calculated using the following formula:

$$K = \frac{P_o - P_e}{1 - P_e} \quad (2)$$

where, P_o (observed agreement) represents the proportion of instances where evaluators assigned the same rating to a speech sample, while P_e (agreement expected by chance) accounts for the likelihood that evaluators would agree on the rating for a speech sample purely by chance.

The 10 native speaker evaluators participated in a calibration phase, where they rated each other's Penang Hokkien speech on a 5-point scale (1 = poor, 5 = excellent). The resulting Kappa score of 0.71 indicated substantial agreement based on the established interpretation scale for inter-rater reliability [43]. This high degree of consensus

confirmed that the evaluators shared a consistent and reliable standard for linguistic authenticity in Penang Hokkien, ensuring that the Mean Opinion Score (MOS) ratings provided in the subjective evaluation are both stable and reliable.

B. Statistical Significance of MOS Differences

To determine whether differences in perceived speech quality among all evaluated systems were statistically meaningful, a one-way ANOVA [44] was conducted across the MOS scores for all model configurations. The ANOVA revealed a significant main effect ($p < 0.05$), indicating that at least one system differed significantly from the others.

Post-hoc pairwise comparisons (Tukey's HSD [45]) were then performed to identify which specific model pairs exhibited statistically significant differences. Among the significant comparisons, Model III (MOS = 3.92) demonstrated a statistically significant improvement over the Baseline Model I trained solely on the 45-minute real dataset (MOS = 3.57), with $p < 0.05$. Significant differences were also observed between Model III and several other lower-performing augmentation variants, confirming the robustness of the proposed method across multiple comparative conditions.

VIII. Limitation

Despite the successful outcomes, this research has several limitations. The primary limitation is the use of a single-speaker, 45-minute real-speech dataset. This constraint reflects practical realities, limited funding, limited speaker availability, and the absence of any larger curated Penang Hokkien corpora. As such, the dataset used here represents one of the most complete resources available for this critically low-resource dialect. The motivation for proceeding with such a small corpus was to conduct a feasibility study demonstrating what is realistically achievable for endangered or under-documented languages under true data scarcity. Nevertheless, the limited dataset constrains the model's ability to generalize across diverse prosodic patterns and emotional expressions, and this gap contributes to the remaining MOS deficit relative to groundtruth speech. Second, standard automated metrics such as Word Error Rate (WER) or Character Error Rate (CER) via a standardized Automatic Speech Recognition (ASR) model were not viable due to the non-existence of a baseline ASR system for this dialect. Consequently, spectral fidelity via MCD and perceptual tracking via multi-dimensional MOS were prioritized.

IX. Conclusion

This study successfully trained the first Text-to-Speech model for Penang Hokkien, addressing the critical challenges of phonological sparsity and resource scarcity inherent in unwritten tonal dialects. By implementing a two-stage fine-tuning approach using the SpeechT5_TTS model architecture, it was demonstrated that a phonetically-rich foundation, constructed from a syllable-level concatenative synthetic corpus covering comprehensive syllable-tone combinations, is essential for achieving high-fidelity synthesis and tonal accuracy. Technical refinements, including a 600-ms cross-fading technique to mitigate boundary artifacts and the use of numerical tone markers to reduce token sparsity, contributed to an overall Mean Opinion Score (MOS) of 3.92. Further cross-language validation is required to definitively generalize these findings to other tonal families. We position this work as an initial case study and a technological blueprint for the digital preservation of endangered, unwritten tonal dialects.

Exploring New Possibilities: Virtual Reality in Supporting Children with Autism

Brayan J. Lozano-Martel, Eduardo F. Araujo-Vasquez, Segundo E. Cieza-Mostacero
Cesar Vallejo University, Trujillo, Peru

***Abstract*—Children with autism spectrum disorder (ASD) often require structured opportunities to practice social interaction, following instructions, and recognizing emotions in safe, controlled environments. This study presents and evaluates a mobile virtual reality (VR) application designed to train these skills through simulated everyday scenarios. An applied quantitative study with an experimental design involving control and experimental groups was conducted with 10 children with ASD from the Sagrada Familia Special Basic Education Center (Trujillo, Peru). The experimental group (n=5) used a Unity 3D/C# VR application featuring four scenarios (park, store, pedestrian crossing, and emotion recognition), while the control group (n=5) followed conventional activities. Outcomes were collected through direct observation (60 records; 30 per group) and analyzed statistically, with findings interpreted cautiously due to the repeated-observation structure of the data. The post-test results showed statistically significant differences between groups, with the experimental group performing better on all evaluated indicators (social interaction, following instructions, emotion recognition, and average time to detect oncoming traffic). However, due to the small sample size and repeated observations, these findings should be interpreted as preliminary evidence. The results suggest that mobile VR may complement traditional interventions to strengthen social and emotional skills in children with ASD.**

Keywords*—*Autism Spectrum Disorder; virtual reality; mobile application; social skills training; immersive learning; special education

I. Introduction

In Peru, between 2020 and 2023, there has been a sustained increase in diagnoses of autism spectrum disorder, reflected in greater demand for specialized health and education services. National reports indicate that the highest concentration of diagnosed cases corresponds to school-age children, which has created a significant challenge for public institutions responsible for providing educational and therapeutic care, especially in contexts where access to specialized technological resources is still limited [1]. Although advances in diagnosis have enabled earlier detection, significant gaps in access to appropriate interventions and support services remain, highlighting the lack of comprehensive policies to accompany people with autism throughout their lives [2].

In the United States, epidemiological studies conducted by national monitoring networks indicate that autism spectrum disorder affects approximately 1.7% of children, equivalent to 1 in 59 school-age children. This prevalence has been identified from systematic assessments conducted in multiple states, demonstrating a significant impact of ASD on health and education systems, as well as the need for early interventions and specialized support strategies [3]. In Peru, around 1% of the population is on the spectrum, and more than 70% of registered cases correspond to children under the age of eleven, reinforcing the need to strengthen educational and technological support programs in special education [4].

Recent meta-analyses indicate that immersive virtual reality-based interventions can improve cognitive, social, and emotional skills in children and adolescents with ASD, providing structured, safe, and engaging practice opportunities [5]. Furthermore, virtual reality applications designed for high-functioning children with autism can effectively support social skill development, facilitate engagement in controlled, immersive environments, and help mitigate difficulties in social interaction and following structured instructions [6].

These difficulties can affect their participation in daily activities, limit their autonomy, and generate anxiety or discomfort in new situations. In educational and social contexts, many children with autism have problems relating to their peers, following instructions in public spaces, or identifying risky situations, such as when crossing a street. This highlights the need for safe, controlled, and personalized teaching methodologies that allow for the progressive development of social skills in structured environments [7].

In the city of Trujillo, the Sagrada Familia school, a Special Basic Education Center (CEBE), serves children diagnosed with ASD and focuses its work on the development of social and emotional skills. However, it faces challenges due to the limited availability of technological tools adapted to the teaching-learning process, which affects the behavioral progress and autonomy of students [7].

In this scenario, virtual reality (VR) emerges as a technology capable of offering immersive, safe, and personalized environments that facilitate learning through the simulation of everyday experiences. Recent studies show that the use of virtual environments promotes motivation, concentration, and emotional understanding, contributing significantly to the development of social skills in children with autism spectrum disorder [8].

In response to this problem, a mobile virtual reality application based on social environments was designed and developed with Unity 3D and the C# programming language. The application integrates everyday scenarios such as a park, a store, a crosswalk, and emotional recognition activities, aimed at promoting social interaction, decision-making, and understanding of emotions in an educational and therapeutic context [9].

The application was developed using the SUM methodology, which proposes a structured and modular approach to the construction of educational software, allowing iterative adjustments to be made based on observations and the performance of the participating children. This methodology facilitated the progressive adaptation of virtual environments to the needs of the intervention process [10], [11].

The main objective of this research was to improve social skills in children with autism spectrum disorder through the implementation of a virtual reality mobile application. Specifically, the aim was to increase the proportion of social interaction in groups of people, increase the frequency of following instructions in everyday environments such as shops, decrease the average time to detect oncoming traffic before crossing the street, and increase the emotion recognition rate in everyday situations.

Research hypotheses. The general hypothesis states that the implementation of a virtual reality mobile application based on social environments significantly improves social skills in children with autism spectrum disorder. The following specific hypotheses were also proposed: (H1) the use of the application increases the proportion of social interaction; (H2) it increases the frequency of following instructions in everyday environments; (H3) it decreases the average time to detect oncoming traffic before crossing the street; and (H4) it increases the emotion recognition rate in everyday situations.

II. Theoretical Framework

A. Virtual Reality

Virtual reality (VR) is an immersive technology that allows the user to enter a computer-generated three-dimensional environment, in which they can interact with objects, characters, or simulated situations in real time using specialized headsets and controllers. This technology is characterized by immersion, which generates a sense of presence in the virtual environment; interactivity, which allows the user to actively influence the development of the experience; and the ability to simulate controlled and safe contexts, facilitating the repetitive practice of skills without real risks. VR also offers immediate feedback and personalization of the environment, aspects that favor experiential learning and progressive adaptation by the user, especially in educational and therapeutic contexts [12].

B. Social Skills

Social skills are a set of learned behaviors that allow people to interact appropriately with their environment, express emotions, establish interpersonal bonds, and comply with social norms. These skills involve the ability to communicate, cooperate, empathize, and resolve conflicts in different contexts [5].

In the case of children with ASD, limitations in verbal and nonverbal communication hinder the acquisition of these skills, affecting their school and social integration. The development of social skills requires structured environments and methodologies that encourage observation, imitation, and constant practice of appropriate behaviors [6].

C. SUM Methodology

The SUM (Scrum Unified Methodology) methodology is considered an agile software development model that combines the iterative principles of Scrum with a structured approach to software development. This approach prioritizes continuous collaboration between the work team and the end user, encouraging partial deliveries, constant feedback, and adaptability to change [10]. SUM allows for the incremental planning and development of technological products, ensuring quality, flexibility, and control of time and costs. This methodology is suitable for educational projects, as it integrates stages of design, validation, and continuous improvement according to user needs [11].

Together, virtual reality as an immersive technology, the development of social skills as an intervention variable, and the SUM methodology as an agile development approach form the theoretical framework that underpins the design, implementation, and evaluation of the mobile application proposed in this research, aimed at improving social behavior in children with autism spectrum disorder.

III. Materials and Methods

A. Type of Research

This was an applied study, as it focused on the implementation of a social environment-based virtual reality mobile application with the aim of improving the behavior of children diagnosed with autism spectrum disorder (ASD). This type of study seeks to generate practical and tangible solutions using scientific knowledge [13]. Likewise, a quantitative approach was used, since the data obtained were numerical and were analyzed using statistical techniques to verify the validity of the hypotheses proposed [14].

B. Research Design

A true experimental design was used, aimed at determining the effectiveness of the virtual reality mobile application in improving the behavior and social skills of children with ASD. This design is characterized by the deliberate manipulation of an independent variable and the observation of its effects on a dependent variable under controlled conditions. Experimental studies allow causal relationships between variables to be established through the use of control and experimental groups, ensuring the internal validity and reliability of the results [14].

In this parallel-group true experimental design, the Control Group served as the concurrent behavioral reference, reflecting performance under conventional educational conditions without VR exposure. Both groups were matched at allocation by age, educational level, and ASD diagnosis profile, supporting initial group equivalence. Accordingly, between-group post-test comparisons provide the primary evidence of the intervention's effect, consistent with parallel-group experimental designs in which group equivalence is established at allocation [15].

Because detailed pretest values were not reported in the manuscript, full statistical verification of baseline equivalence is limited.

To reduce this limitation, participants were allocated considering similarity in age, educational level, and confirmed ASD diagnosis. The Control Group served as a concurrent behavioral reference under conventional educational conditions. Therefore, the results should be interpreted as preliminary evidence [14].

C. Variables and Operationalization

1) Independent variable: Virtual reality.

2) Conceptual definition: It is a technology that allows the creation of three-dimensional environments with which users can interact in an immersive way [16].

3) Operational definition: The virtual reality application was used by the Experimental Group. A nominal scale was used.

4) Dependent variable: Behavior of children with autism.

5) Conceptual definition: The behavior of children with autism is defined as qualitative alterations in social interaction, communication, and repetitive and restricted behavior patterns [5].

6) Operational definition: The variable Behavior of children with autism was measured using four indicators: proportion of social interaction, frequency of following instructions, average time to detect oncoming traffic before crossing, and emotion recognition rate. All indicators were measured on a ratio scale.

D. Population, Sample, and Sampling

The population consisted of children diagnosed with autism spectrum disorder (ASD) attending the Sagrada Familia Special Basic Education Center in Trujillo, Peru. An intentional sample of ten (10) participants was selected and divided into two groups with similar characteristics: five in the experimental group and five in the control group, maintaining similarity in age, educational level, and behavioral characteristics. The selection was made considering inclusion criteria such as confirmed diagnosis of ASD, regular attendance at the center, and informed consent from parents or guardians [17].

Due to limitations in parental authorization and the small number of participants, the study included a total of 10 children with ASD (5 per group). While inferential statistical tests, including the Mann–Whitney U test, were applied to compare outcomes between groups, it is important to recognize that small sample sizes can produce unstable effect estimates. No formal statistical power analysis was conducted due to the limited sample size; therefore, the results should be interpreted as preliminary evidence rather than definitive conclusions. To strengthen behavioral documentation, 30 observational records per group were collected through repeated observations during the intervention sessions. These repeated measures provide insight into the children's performance but do not increase the statistical power at the participant level.

During data collection, a total of 60 observational records were obtained (30 per group), corresponding to repeated observations of the 10 participants. Although participants constituted the primary sampling unit, the observational records were used to document behavioral performance across intervention sessions. Therefore, the inferential results should be interpreted as exploratory and preliminary evidence rather than definitive participant-level effects [18].

E. Data Collection Techniques and Instruments

Data collection was carried out through direct observation, a technique that allowed for real-time recording of the children's behaviors and responses during the intervention sessions. This method provided accurate and objective information about the participants' actions in their controlled educational environment, ensuring the reliability of the results [18].

The instrument used was an observation form validated by expert review, designed to systematically document the indicators defined in the dependent variable: social interaction, following instructions, traffic identification, and understanding emotions.

The observation instrument underwent a formal content validation process conducted by a qualified expert in autism spectrum disorder and special education. The validator held expertise in behavioral assessment and therapeutic intervention with ASD populations, and evaluated the instrument across multiple dimensions: 1) clarity, assessing whether each item was written in clear, unambiguous language appropriate for the observational context; 2) relevance, confirming that each indicator was directly aligned with the behavioral dimensions targeted by the intervention (social interaction, instruction-following, traffic hazard detection, and emotion recognition); 3) coherence, verifying that the indicators were internally consistent with the theoretical framework underpinning the study; 4) pertinence, ensuring that each item was appropriate and necessary for measuring the behavioral outcomes in children with ASD in educational settings; and 5) sufficiency, confirming that the set of indicators as a whole provided adequate coverage of the dependent variable. Based on the expert's review, minor wording adjustments were made to two items to improve observational objectivity, and the instrument was confirmed as suitable for measuring the target behavioral indicators in this population. The expert's assessment provided evidence of content validity, supporting the use of the observation form for the purposes of this study. However, because the instrument was reviewed by a single expert and no inter-rater reliability or agreement coefficient was calculated, this aspect is acknowledged as a methodological limitation.

The data obtained were processed using Jamovi software version 2.3.28, applying descriptive and inferential statistics. For group comparisons, the Shapiro–Wilk test was used to assess normality; Student's t-test was applied to normally distributed data, and the Mann–Whitney U test was used otherwise [15].

F. Procedures

The study was carried out in three stages following the SUM methodology, which is suitable for the agile and incremental development of educational software. In the first stage, the virtual reality mobile application was designed and programmed using the Unity 3D platform and the C# language, integrating three-dimensional environments focused on improving the social behavior of children with autism spectrum

disorder (ASD). Subsequently, functionality, usability, and performance tests were carried out to ensure the stability of the system before its application in the educational environment.

During the second stage, participants in the Experimental Group used the mobile application through Oculus Quest 2 virtual reality headsets in controlled sessions. The activities included interactive scenarios representing everyday situations, such as interacting in a park, shopping, crossing a street, and recognizing emotional expressions. Each session lasted approximately 15 to 20 minutes and was conducted under the supervision of educational staff. To reduce potential sensory burden, participants were allowed to pause or stop the activity if signs of discomfort, fatigue, anxiety, visual overstimulation, or auditory sensitivity appeared. In addition, the virtual scenarios were designed with simple visual elements, guided interactions, and limited exposure time to minimize sensory overload during the intervention. At the same time, the Control Group continued with conventional educational activities without VR exposure.

In the third stage, the observation form was administered to both groups to document behavioral performance across the four indicators: social interaction, following instructions, average time to identify traffic, and emotion recognition. For the Experimental Group, this corresponded to the post-intervention phase; for the Control Group, it captured concurrent performance under conventional educational activities, serving as the parallel behavioral reference. Data were then processed and analyzed to determine the effect of the VR application.

IV. Software Methodology

The virtual reality mobile application was developed using the Scrum Unified Methodology (SUM), an agile approach geared toward the development of interactive systems and immersive applications. This methodology was selected for its iterative and flexible nature and its suitability for the development of virtual reality-based educational applications, allowing for continuous improvements based on feedback and system testing.

The SUM methodology is structured in five phases: Conception, Planning, Initial Development, Beta Version, and Closure, which allowed for the progressive organization of the design, implementation, and validation of the application aimed at improving the social behavior of children with autism spectrum disorder (ASD).

A. Platform and Tools

The virtual reality application was implemented for the Oculus Quest 2 platform, with the aim of providing an autonomous immersive experience for sessions in the educational environment. Development was carried out with Unity 2022.3.16f1 and programming in C#; the environments and characters were integrated using 3D models from asset catalogs. User interaction (selection, button activation, and object manipulation) was implemented with XR Interaction Toolkit under the OpenXR standard. For the recording and consolidation of results per session, a cloud service was integrated using Supabase, consumed from Unity with UnityWebRequest.

To run the application on the headset, the project was configured in Unity for Android, generating an APK package compatible with (Oculus/Meta) Quest 2. The compilation was performed using the Android SDK and OpenJDK, and the APK was then installed and managed on the device using Meta Quest Developer Hub, allowing controlled tests to be run in a real environment. During these tests, the correct loading of scenes, interaction via controllers, and network connectivity for sending records to the database (Supabase) were verified, ensuring the storage of results per session.

B. Software Architecture

The solution was organized in a modular fashion: 1) a navigation module for accessing the objectives/scenarios, 2) an XR interaction module for user selection and control, 3) logic modules per scenario (park, store, intersection, and emotional recognition) with decision and timing controllers, and 4) a logging module that stores user responses/times and manages the sending of results. This structure facilitated iterative adjustments during development and stabilization before the experimental phase. As shown in Fig. 1, the XR application was developed in Unity using C# for deployment on Meta Quest 2, relying on the Android toolchain (Android SDK/OpenJDK) and Supabase as the database backend to store user logs and support result transmission.

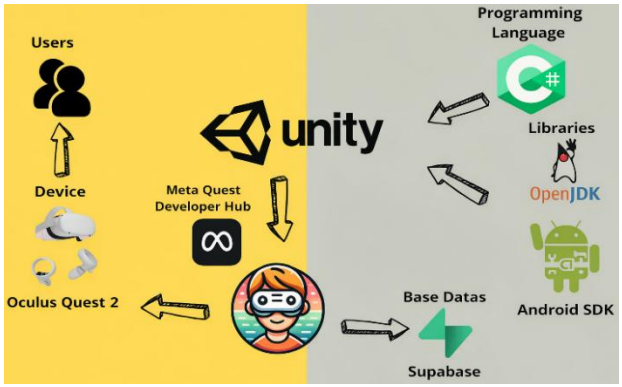

Fig. 1. Software architecture.

C. Scenario Implementation and Recording

The application includes four objectives: 1) social interaction in the park, where the child practices greetings and interaction with groups of people and the system counts successful interactions; 2) interactive store, where the child selects products from a list and the system counts correct selections; 3) pedestrian crossing/risk situation, where the child crosses while avoiding vehicles and attempts and time are recorded; and 4) emotional recognition, where the child identifies emotions on faces and the success rate is recorded. In all cases, the system saves the results at the end of each activity for later analysis.

D. Testing and Debugging

Before the intervention, interaction tests and iterative corrections were performed to ensure system stability. Among the incidents resolved, the interaction of panels/buttons in VR was corrected by adjusting the raycaster, and the sending of results to the database was stabilized by configuration and connection changes in OpenXR.

E. Conception Phase

In the conception phase, an analysis was carried out of the educational context and behavioral needs of children diagnosed with autism spectrum disorder. This stage helped identify the main difficulties to be addressed, such as social interaction, following instructions, recognizing emotions, and identifying risky situations in everyday environments.

Based on this analysis, the overall objective of the application was defined, which was to provide a safe and controlled virtual environment that allows children to practice social skills through immersive experiences. Likewise, the functional scope of the system was established, and the profile of the end users was determined, prioritizing accessibility and ease of use.

Based on the analysis carried out in this phase, the needs and objectives of the application were identified, which are summarized in Table I.

TABLE I. NEEDS ANALYSIS IN THE CONCEPTION PHASE

Aspect Analyzed	*Description*
Context of the problem	Children diagnosed with autism spectrum disorder have difficulties with social interaction, following instructions, recognizing emotions, and understanding risky situations in everyday environments.
Target user	Children with autism spectrum disorder (ASD) attending a special elementary school.
Identified need	To have a technological tool that allows social skills to be practiced in a safe, controlled, and repeatable environment.
Objective of the application	To provide immersive virtual environments that promote the development of social and behavioral skills.
Solution strategy	Implementation of a virtual reality mobile application based on interactive social scenarios.
Proposed environments	Park, store, crosswalk, and emotional recognition activities.

F. Planning Phase

During the planning phase, the functional and non-functional requirements of the application were defined. The general structure of the system was designed, establishing the different interactive virtual environments, which included scenarios such as a park, a store, a pedestrian crossing, and emotional recognition activities.

Likewise, the technological tools for software development were selected, using Unity 3D as the development engine and C# as the programming language. The project activities were organized according to development priorities, and a schedule was established that allowed for the progressive implementation of the functionalities.

As a result of the analysis carried out in the conception phase, the functional requirements of the virtual reality application were defined in the planning phase. These requirements made it possible to establish the functionalities necessary for the development of social scenarios and to guarantee an adequate user experience for children with autism spectrum disorder. Table II presents the functional requirements considered for the design of the system.

TABLE II. FUNCTIONAL REQUIREMENTS OF THE VIRTUAL REALITY APPLICATION

ID	*Requirement*
RF1	The application must provide immersive virtual reality environments geared toward the development of social skills.
RF2	The system must allow the user to interact with virtual objects and characters within each scenario.
RF3	The application must include everyday social scenarios such as a park, a store, and a crosswalk.
RF4	The system must incorporate activities for recognizing and understanding emotions.
RF5	The application must allow for simple and intuitive navigation between the different scenarios.
RF6	The system must record user interactions and responses during usage sessions.
RF7	The application must be suitable for children with autism spectrum disorder, prioritizing visual simplicity and ease of use.

G. Initial Development Phase

In this phase, the main functionalities of the virtual reality application were implemented. Three-dimensional environments were developed and integrated in Unity 3D, programming the interactive elements that allow user navigation, interaction with virtual objects and characters, as well as the execution of guided activities.

In addition, the system logic was implemented to record user responses and behaviors during usage sessions. Iterative testing was performed to verify system stability, usability, and proper interaction between components, allowing for early adjustments to the application's design and operation.

As part of the initial development, the application was structured into different virtual social scenarios, each aimed at reinforcing a specific skill. Table III presents the relationship between the scenarios developed and the social skills addressed in each one.

TABLE III. VIRTUAL SCENARIOS DEVELOPED AND SKILLS ADDRESSED

Virtual Scenario	Social Skill Addressed
Park	Social interaction in public spaces
Store	Following instructions in everyday environments
Crosswalk	Identification of risky situations
Recognition of emotions	Understanding emotions in social situations

H. Beta Version Phase

The beta version phase was aimed at validating the application in a controlled educational environment. The system was implemented using virtual reality headsets, allowing children in experimental groups to interact with the different scenarios during scheduled sessions.

During this stage, feedback was collected from direct observation and support from educational staff, which allowed for the identification of opportunities for improvement related to visual clarity, interaction time, and navigation within the virtual environment. Based on these results, minor adjustments were made to optimize the user experience and reduce possible sensory overload.

To validate the application's performance in a controlled environment, a beta version of the virtual reality system was developed. This version allowed for the evaluation of the correct execution of the virtual scenarios, user interaction with the elements of the environment, and the overall stability of the application before its experimental implementation. As shown in Fig. 2, the beta version enabled verification of scenario execution, user interaction with virtual elements, and overall application stability.

Fig. 2. Virtual scenario of the virtual reality application in execution.

I. Closing Phase

In the closing phase, the final version of the virtual reality mobile application was consolidated. The correct functioning of all modules was verified, and compliance with the objectives established in the initial phases was checked.

Finally, the application was prepared for implementation in the experimental phase of the research, serving as the main tool for data collection and evaluation of the impact of virtual reality on improving the social behavior of children with autism spectrum disorder.

Upon completion of the application's development, the final components of the system were consolidated, ensuring its proper functioning and alignment with the objectives set forth. Table IV summarizes the main components that make up the final version of the virtual reality application.

TABLE IV. FINAL COMPONENTS OF THE VIRTUAL REALITY APPLICATION

Component	Description
Development engine	Unity 3D
Programming language	C#
Virtual scenarios	Park, store, crosswalk, and recognition of emotions
Interaction	Navigation and interaction with virtual objects and characters
Platform	Mobile application with virtual reality viewer
Final status	Functional system ready for experimental implementation

V. RESULTS

A. Descriptive Analysis

The descriptive analysis of the observational results showed differences between the Experimental Group (EG) and the Control Group (CG) across the four evaluated indicators. The CG results reflect behavioral performance under conventional educational activities across the observation period, serving as the parallel baseline reference for this experimental design. Higher values indicate better performance for social interaction, following instructions, and emotion recognition, whereas a lower value indicates better performance for average traffic detection time. The descriptive results are presented in Table V.

TABLE V. DESCRIPTIVE RESULTS OF SOCIAL AND EMOTIONAL INDICATORS IN CONTROL AND EXPERIMENTAL GROUPS

Indicator	Control Group (CG)	Experimental Group (EG)	Interpretation
Proportion of social interaction (%)	35.47 ± 17.25	54.29 ± 23.89	Higher is better
Frequency of following instructions (%)	26.61 ± 21.27	63.29 ± 26.05	Higher is better
Emotion recognition rate (%)	26.67 ± 14.58	73.33 ± 19.62	Higher is better
Average time to detect oncoming traffic (s)	45.71 ± 2.02	24.29 ± 2.46	Lower is better

The Experimental Group obtained higher average values than the Control Group in the proportion of social interaction, frequency of following instructions, and emotion recognition rate. Specifically, the Experimental Group reached 54.29% in social interaction, 63.29% in following instructions, and 73.33% in emotion recognition, whereas the Control Group obtained 35.47%, 26.61%, and 26.67%, respectively. For the average time to detect oncoming traffic before crossing, the Experimental Group recorded a lower mean time of 24.29 seconds compared with 45.71 seconds in the Control Group. Since lower response time indicates better performance in this indicator, this result suggests that the Experimental Group may detect risky traffic situations faster, providing preliminary evidence of the effect of the VR application.

B. Inferential Analysis

Table VI presents the results of the inferential analysis performed for the four indicators evaluated in the research, with the aim of determining whether there are statistically significant differences between the Control Group (CG) and the Experimental Group (EG) after the implementation of the virtual reality mobile application.

According to the normality test results, nonparametric Mann–Whitney U tests were applied to the indicators of proportion of social interaction, frequency of following instructions, and emotion recognition rate, while Student's t-test was used for the indicator of average time to detect oncoming traffic before crossing.

The significance values obtained ($p < 0.05$) show statistically significant differences between the two groups in the four indicators analyzed. In particular, the results suggest that the Experimental Group performed better on indicators related to social and emotional skills, as well as a reduction in

average time to identify traffic, providing preliminary evidence of the effect of the VR application.

TABLE VI. INFERENTIAL STATISTICAL TESTS BY INDICATOR

Indicator	Test applied	Statistic	P-value	Interpretation
Proportion of social interaction	Mann–Whitney U	U = 267.50	p = 0.002	Significant difference
Frequency of following instructions	Mann–Whitney U	U = 145.00	p < 0.001	Significant difference
Average time to detect oncoming traffic before crossing	Student's t-test	t(58) = -36.87	p < 0.001	Significant difference
Emotion recognition rate	Mann–Whitney U	U = 37.00	p < 0.001	Significant difference

Inferential tests were calculated using observational records collected during the intervention sessions. Since these records correspond to repeated observations of 10 participants, the results should be interpreted as preliminary evidence rather than definitive participant-level effects.

VI. DISCUSSION

The study employed a parallel-group experimental design in which the Control Group (CG) served as the concurrent behavioral reference, documenting performance levels under conventional educational conditions without VR exposure across the same observation period (October 2–22, 2024). Both groups were matched at allocation by age, educational level, and confirmed ASD diagnosis, supporting comparability between groups before the experimental phase. The post-test results for the CG, therefore, represent the expected behavioral trajectory in the absence of the intervention, against which Experimental Group outcomes are compared. This design follows established practice in parallel-group experimental research, where between-group comparisons at post-test provide the primary evidence of intervention effect [15]. Findings should nonetheless be interpreted as preliminary evidence given the small sample size (n = 5 per group) and the use of repeated observational records.

For the first indicator (proportion of social interaction), the results showed a notable improvement in the experimental group compared to the control group after using the virtual reality mobile application. This increase is attributed to the fact that virtual environments allow social situations to be simulated in controlled contexts, facilitating the repetitive practice of social behaviors without the pressure of the real environment. Immersion and progressive interaction with virtual characters encouraged greater social participation among children with autism spectrum disorder, which is consistent with previous studies reporting improvements in social skills through interactive virtual environments [12]. In this context, social interaction is understood as the ability to initiate, maintain, and respond appropriately to relevant social exchanges [19].

For the second indicator (frequency of following instructions), the results showed a significant increase in the experimental group, which showed an improvement in the understanding and execution of instructions. This behavior can be explained by the structure of the virtual scenarios, which presented clear, sequential, and visually accessible orders, reducing distractions and facilitating sustained attention. Several studies indicate that structured virtual environments contribute to reducing anxiety and disruptive behavior, promoting compliance with instructions in children with autism spectrum disorder [20]. Likewise, difficulties in following instructions are often related to attention and sensory processing challenges, which can be supported through structured virtual reality interventions designed for high-functioning children with autism [6].

For the third indicator (average time to detect oncoming traffic before crossing), the results showed a significant reduction in time in the experimental group. This finding indicates that repeated exposure to simulated road scenarios allowed participants to recognize relevant stimuli more quickly and efficiently, strengthening their ability to respond to risky situations. Virtual reality offers a safe environment for training skills related to decision-making and hazard identification without exposing users to real risks [21]. Likewise, controlled repetition of complex scenarios has been shown to promote learning and anticipation of critical situations [22].

For the fourth indicator (emotion recognition rate), the results showed considerable improvement in the experimental group after the intervention. This result suggests that virtual scenarios aimed at emotional recognition facilitated the identification and interpretation of facial expressions and social contexts. The visual representation of emotions in structured virtual environments reduces cognitive overload and promotes social-emotional learning in children with autism spectrum disorder [23]. In this sense, emotional understanding is defined as the ability to recognize, interpret, and respond appropriately to one's own and others' emotions, constituting a fundamental skill for effective social interaction [19].

Overall, the results suggest that the mobile virtual reality application was associated with improvements in social interaction, following instructions, emotion recognition, and traffic detection skills in children with autism spectrum disorder. These results provide preliminary evidence of the potential of VR interventions. However, the study is limited by the small sample size and repeated observations, which may affect the generalizability of the findings. Additionally, the use of the Oculus Quest 2 headset may impose a potential sensory burden, such as visual or auditory overstimulation, which should be considered in future research.

VII. CONCLUSION

This study provides preliminary evidence that a mobile virtual reality application may contribute to improving social interaction, following instructions, emotion recognition, and traffic detection skills in children with autism spectrum disorder (ASD) within a controlled educational setting. Improvements were observed across all evaluated indicators, suggesting that VR-based interventions may serve as a valuable complement to traditional teaching methods for children with ASD.

These findings should be interpreted with caution due to the small sample size, the use of repeated observations, and the

potential sensory overload associated with the Oculus Quest 2 headset, which could influence engagement and performance during the intervention sessions.

Future research should include larger participant pools, explore additional educational contexts, and investigate the potential sensory effects of VR devices such as the Oculus Quest 2 to better understand their influence on engagement and performance.

Augmented Reality in Automotive Technical Training: Technological Innovation Through Mobile Applications in Trujillo

An Immersive Technologies-Based Approach to Automotive Maintenance Training

Julissa B. Polo-Holguin, Eduardo F. Araujo-Vasquez, Segundo E. Cieza-Mostacero
Universidad César Vallejo, Trujillo, Perú

***Abstract*—This study evaluated the impact of an Augmented Reality (AR)-based mobile application on technical training in automotive maintenance at a company in Trujillo, Peru. The application was developed using Unity 3D, the Vuforia marker-based recognition engine, and C#, enabling technicians to interact with three-dimensional models of automotive components — including engines, valve trains, crankshafts, and braking systems — through touch-based rotation, zoom, and perspective controls overlaid on physical QR markers. This marker-based interaction architecture distinguishes the system by enabling step-by-step guided visualization of complex maintenance procedures without requiring physical equipment access. A posttest-only control group experimental design was employed with 60 technicians randomly assigned to experimental and control groups, using the Mobile-D methodology for software development. The results revealed a significant improvement in technical content comprehension, a 46.6% reduction in average training time (from 10,862 to 5,784 seconds), and increased satisfaction levels, reaching a mean score of 4.0 versus 2.6 in the control group. The Mann–Whitney U test confirmed statistically significant differences ($p = 0.001$) across all indicators, with large effect sizes (Rosenthal's $r \geq 0.86$). These findings suggest that AR-based mobile applications represent a viable instructional approach for automotive maintenance training, though broader generalization requires validation across diverse organizational contexts.**

***Keywords*—Augmented reality; marker-based AR; automotive maintenance training; mobile application; technical comprehension; training efficiency; experimental design**

I. Introduction

Digital transformation has profoundly reshaped training processes in technical education, particularly in fields that require the mastery of specialized practical skills, such as the automotive sector. Augmented Reality (AR) has emerged as an innovative technology with the potential to support the development of technical competencies by enabling the overlay of virtual content onto real-world environments through mobile devices. This approach enables technicians to explore simulations of complex systems and technical procedures without the need to manipulate actual physical equipment [1].

In the field of technical automotive education, the use of emerging technologies has become increasingly relevant due to the industry's dynamic nature and high technological demands. Advances in vehicle systems, electronic control, predictive maintenance, and automated process management have led educational institutions to rethink their teaching methodologies [2]. However, previous evidence in this area should be interpreted with caution. Although VR/AR-based educational environments have been proposed to support automotive and manufacturing training, some implementations have been developed mainly in university laboratory settings and evaluated through student experience or satisfaction measures rather than through controlled experimental comparisons in real workplace training contexts [3]. Therefore, while AR offers interactive virtual environments with potential to support safer and more accessible learning, further empirical evidence is still needed to evaluate its impact on measurable training outcomes such as technical comprehension, task completion time, and participant satisfaction in authentic automotive maintenance environments.

The contributions of Augmented Reality (AR) are not limited to the three-dimensional visualization of mechanical components, but also include step-by-step guided training through visual cues, animations, highlighted objects, and real-time instructional feedback. These features may support technician autonomy and reduce procedural errors, particularly in maintenance tasks that require spatial orientation and sequential execution. However, previous evidence suggests that AR effectiveness is task-dependent. For instance, one study found that traditional training performed better for single-level maintenance tasks, whereas AR showed greater advantages in complex multi-level tasks, although the generalizability of its findings was limited by specific hardware conditions, such as the restricted field of view of HoloLens 2, as well as by the need for further comparative and longitudinal evaluations [4]. Therefore, AR shows potential for practical maintenance training, but its effectiveness may vary according to task complexity and implementation conditions.

Several studies have reported that Augmented Reality (AR) can support industrial maintenance activities by providing contextual information, visual guidance, and interactive assistance during diagnostics, inspections, assembly, and maintenance procedures [5]. However, despite the promising results of AR applications in maintenance, their industrial adoption is still limited by technical constraints, fragmentation among hardware and software solutions, tracking accuracy issues, and the lack of maturity of some AR systems for real operational environments. Similarly, research on predictive

maintenance and intelligent sensors in smart factories highlights that efficiency improvements depend not only on visualization technologies, but also on the availability of reliable data, sensor interoperability, cybersecurity, and the effective integration of Industry 4.0 technologies [6].

At a global level, recent studies indicate that Augmented Reality (AR) is increasingly aligned with the principles of Industry 4.0, particularly in smart engineering manufacturing environments where technologies such as the Internet of Things (IoT), intelligent sensors, data analytics, and predictive maintenance are progressively integrated [7]. However, this alignment is often discussed from a technological or manufacturing perspective rather than from a pedagogical standpoint. Therefore, in automotive maintenance training, the value of AR should not be assumed only from its compatibility with Industry 4.0, but also from how its content, interaction design, and simulated procedures support the actual training needs of technicians.

In local contexts such as the city of Trujillo, where technical education programs seek to adapt to the challenges of a changing industrial environment, the incorporation of Augmented Reality (AR) may represent a strategic opportunity to strengthen the training of automotive technicians. The integration of mobile applications with AR content can provide more accessible training resources and reduce exclusive dependence on physical equipment; however, accessibility does not necessarily ensure effective learning, since outcomes also depend on instructional design, device availability, user familiarity with mobile technologies, and the realism of simulated procedures. Empirical evidence evaluating these benefits in local technical training settings remains scarce, underscoring the need for context-specific studies. Therefore, evaluating mobile AR in an automotive maintenance environment in Trujillo is necessary to determine whether these potential benefits translate into improvements in technicians' comprehension, training time, and satisfaction [8].

Technical training in the automotive field represents a fundamental pillar to ensure quality, efficiency, and safety in vehicle maintenance services. However, in contexts where traditional teaching methods still predominate—based on static theoretical lectures and limited instructional materials—training processes face significant barriers, resulting in a gap between the knowledge acquired in the classroom and the practical competencies required in the workplace, which affects the professional performance of future technicians. Additionally, the lack of innovative pedagogical strategies and the limited use of educational technologies hinder the development of technical, analytical, and problem-solving skills, which are essential to address the continuous technological advances in the automotive sector [9].

Difficulties in understanding complex mechanical procedures, excessive session duration, and low participant motivation reflect a mismatch between industry demands and the competencies acquired in the classroom. This situation becomes even more critical in the context of the rapid technological advancement of the automotive industry, where new vehicle models integrate electronic and digital systems that require more specialized technical skills [10].

One of the alternatives with the greatest potential has been the development of mobile applications based on Augmented Reality (AR), a technology that enables the visualization and interaction with three-dimensional models of automotive components through mobile devices [11]. This approach allows the simulation of real procedures without requiring direct access to physical equipment, which may reduce operational risks and facilitate autonomous training. However, its contribution to knowledge retention and practical skill transfer should be interpreted cautiously when long-term follow-up assessments are not included. Therefore, the incorporation of this tool into teaching processes represents an opportunity to improve technical training, provided that its effects are evaluated through objective and context-specific indicators.

Collectively, the reviewed literature reveals three recurring methodological gaps that limit the applicability of prior findings to real-world automotive maintenance training. First, most AR evaluations have been conducted in university laboratory settings using satisfaction or perceived usability measures, rather than through controlled experimental designs with objectively measured learning outcomes in authentic workplace environments. Second, robustness assessments have been largely restricted to specific hardware configurations — such as head-mounted displays with limited fields of view — without testing marker-based mobile AR systems under the operational conditions of actual maintenance workshops. Third, longitudinal and comparative evidence on training efficiency indicators, such as task completion time and effect size reporting, remains scarce. The present study directly addresses these gaps by implementing a marker-based AR mobile application in a real automotive company, employing a true experimental posttest-only design with random group assignment, and evaluating outcomes through three objective indicators with effect size analysis.

Research Hypotheses. The general hypothesis of this study states that the implementation of a mobile application based on Augmented Reality (AR) improves the training process of automotive maintenance technicians. Furthermore, the following specific hypotheses were formulated: (H1) the AR-based mobile application improves the understanding of technical training content; (H2) the AR-based mobile application reduces the average duration of training sessions; and (H3) the AR-based mobile application increases participant satisfaction with the training method used. These hypotheses were examined through the development and evaluation of an interactive learning tool that allows users to explore diagnostic, repair, and inspection processes in a visual and immersive manner.

II. Theoretical Framework

A. Augmented Reality

Augmented Reality (AR) is a technology that enables the superimposition of digital information—such as three-dimensional models or instructional content—onto the real-world environment through the use of mobile devices or smart displays. In the field of technical education, AR has been incorporated as an innovative tool to simulate complex procedures, visualize internal machine components, and

develop practical skills without directly intervening with physical equipment [12]. This technology enhances the understanding of technical processes, increases technician interaction, and allows for the autonomous repetition of training tasks, resulting in a more dynamic and meaningful learning experience [13].

B. Maintenance in Automotive Systems

Predictive maintenance is based on the continuous monitoring of equipment to identify abnormal conditions that may lead to functional failures. In the automotive sector, this strategy has become a key approach for reducing operational costs, extending component lifespan, and improving vehicle safety. Through the use of smart sensors and machine learning algorithms, it is possible to detect unusual behavioral patterns in engine systems, thereby anticipating potential failures before they occur. When this information is integrated with Augmented Reality (AR) visualizations, technicians can interpret data more quickly and accurately, facilitating decision-making during the maintenance process [13].

C. Mobile Applications

Mobile applications have revolutionized access to knowledge by providing versatile platforms for digital education. In the context of automotive technical training, they enable technicians to interact with simulators, visual manuals, and immersive environments from virtually any location, thereby optimizing autonomous practice. The integration of these applications with Augmented Reality (AR) enables the virtual representation of engines, transmissions, and other vehicle components, promoting both visual and experiential learning. Furthermore, the continuous updates supported by these platforms ensure that training content remains aligned with technological advancements in the sector, thereby fostering more relevant and up-to-date technical training [14].

III. Materials and Methods

A. Type of Research

This study is classified as applied research, as it focuses on analyzing and solving specific problems affecting a particular context. The primary objective was to generate practically useful knowledge aimed at improving processes, optimizing resources, and transforming situations identified as problematic. This approach enabled the integration of theoretical foundations with practical application, directing the results toward the implementation of context-specific solutions. Furthermore, the study aimed to provide scientific evidence to support informed decision-making, the design of improvement strategies, and the innovation of the evaluated procedures, thereby enhancing the relevance and applicability of the findings obtained [15].

B. Research Design

The study employed a true experimental design — specifically, a posttest-only control group design — characterized by the intentional manipulation of an independent variable to observe its effect on a dependent variable under controlled conditions. This design allowed the establishment of cause-and-effect relationships with a higher level of certainty, as it included the random assignment of participants into two groups: an experimental group that received the intervention and a control group that did not receive any treatment. Given that participants were randomly assigned to groups, pre-test measurements were not required, as randomization ensures initial equivalence between the control and experimental groups, thereby controlling for pre-existing differences without the need for baseline measurements. The randomization process helped minimize the influence of extraneous variables and potential biases, thereby ensuring the internal validity of the study. Furthermore, the rigorous control of experimental conditions enabled the comparison of outcomes between both groups, facilitating the identification of effects exclusively attributable to the applied intervention [16].

C. Variables and Operationalization

1) Independent variable: Augmented Reality (AR)

2) Conceptual definition: Augmented Reality (AR) refers to a technology that enables the superimposition of virtual elements onto real-world environments, facilitating the visualization and interaction with three-dimensional content through mobile devices. In educational contexts, it has been established as a tool that enhances comprehension, increases technicians' motivation, and enables the simulation of practical experiences that are difficult to replicate in conventional settings [17].

3) Operational definition: This variable was assessed through the "Implementation of the Mobile Application," assigning the value "NO" prior to the intervention and "YES" after its implementation, using a nominal measurement scale.

4) Dependent variable: Technical Training Performance.

5) Conceptual definition: Technical training performance refers to the level of achievement attained by participants during the training process, determined through the completion of practical activities, evaluation tests, and observed performance outcomes [18].

6) Operational definition: It was measured using three key indicators:

a) Level of understanding of technical procedures,

b) Average time required to complete simulated activities, and

c) Degree of perceived satisfaction with the training process. Data were collected through evaluation records and structured surveys, using ordinal and ratio scales according to the nature of each indicator.

D. Population, Sample, and Sampling

The population is defined as the set of individuals, objects, or events that share common characteristics relevant to the purposes of a research study. It represents the entire group from which information is intended to be obtained and is essential in the study design to determine the scope and representativeness of the results. The characteristics that define a population may include variables such as age, educational level, geographic location, profession, among others. Depending on the methodological approach, research may involve large or specific populations according to the objectives of the study [19].

The population consisted of automotive maintenance technicians working at a company in Trujillo, Peru. The sample comprised a total of 60 technicians selected through purposive sampling, based on criteria such as homogeneity in training level and availability to participate in the proposed activities. Once the sample was defined, participants were randomly assigned to one of two groups of 30 individuals each: an experimental group, which received the AR-based intervention, and a control group, which completed training without the technological tool. This combination of purposive sampling for participant selection and random assignment for group allocation is consistent with true experimental designs in applied research.

E. Data Collection Techniques and Instruments

The research team collected data using quantitative techniques through previously validated instruments. Three main instruments were applied: an evaluation questionnaire to measure content comprehension, a record sheet to calculate the average training time, and a satisfaction survey administered at the end of the process. The collected data were organized and systematized for analysis using descriptive and inferential statistics. Subsequently, Jamovi software was employed to calculate statistical measures such as the mean, standard deviation, and value range. For group comparisons, normality tests were performed, and the Mann–Whitney U test was used due to the non-normal distribution of the collected data. Additionally, effect size was calculated using Rosenthal's r coefficient ($r = Z / \sqrt{N}$) to assess the practical significance of observed differences between groups.

F. Procedures

The study followed several phases based on the Mobile-D methodology, which is considered appropriate for mobile software development projects due to its agile and user-centered approach. In the initial phase, the Augmented Reality (AR)-based mobile application was designed using tools such as Unity 3D, Android Studio, and the Vuforia engine, which enabled the creation of interactive environments and the integration of three-dimensional models. Subsequently, the application was implemented by incorporating functionalities focused on the visualization and manipulation of virtual automotive components. The application was then installed on the technicians' mobile devices, ensuring compatibility with operating systems and proper execution of the programmed functions. Finally, functional and usability testing were conducted to verify application performance and ensure its correct operation within the implementation context.

During the training phase, participants accessed interactive thematic modules that included the visualization of automotive components in 3D. Repetition of activities was permitted as needed, promoting personalized learning. Upon completion of the training process, the corresponding evaluation instruments were administered to measure comprehension levels, time spent, and satisfaction with the training process. Finally, the collected data were processed and analyzed to determine the impact of the technological tool on the training of automotive maintenance technicians.

IV. Software Development Framework

To develop the Augmented Reality (AR)-based mobile application for training automotive maintenance technicians, the team adopted the Mobile-D methodology, an agile approach specifically designed for mobile software projects. This methodology consists of six progressive phases: Exploration, Initialization, Production, Stabilization, System Testing, and Deployment. Each phase addressed a specific set of activities that facilitated the efficient organization of the development process and ensured the adaptation of the product to the needs of end users.

A. Exploration Phase

The Exploration phase marked the starting point for the development of the Augmented Reality (AR)-based mobile application. During this stage, the team analyzed the educational and technological context in which the solution would operate to understand users' needs and their operational environment. The researchers conducted a preliminary needs assessment to identify the limitations of the traditional training model, as well as opportunities for improvement through technological tools. Based on this analysis, the team established the initial system objectives and proposed a mobile-based solution integrating Augmented Reality elements to enhance practical learning.

Additionally, the requirements were identified (see Table I) to guide the software design, distinguishing between those related to the system's core functionalities and those establishing technical conditions aimed at ensuring application performance, usability, and accessibility. These requirements enabled the definition of the main functionalities, technical constraints, and system quality criteria, thereby structuring the development process in an organized manner. Furthermore, the identification of requirements facilitated alignment of the software with end-user needs.

TABLE I. System Requirements

ID	Requirements
R1	The application shall display interactive 3D models of automotive components.
R2	The application shall provide short, dynamic lessons (5–10 minutes) covering specific automotive maintenance concepts.
R3	The application shall enable fast navigation between modules, allowing technicians to access the sections they need to study.
R4	The application shall be user-friendly and intuitive.

B. Initialization Phase

During the Initialization phase, the technical elements that would structure the mobile application were defined, establishing a solid foundation for its subsequent development. Programming tools, development environments, and graphics engines were selected to implement the planned functionalities, ensuring efficient integration of educational content with Augmented Reality (AR) resources. Fig. 1 illustrates the set of components and tools selected for the system's initial architecture.

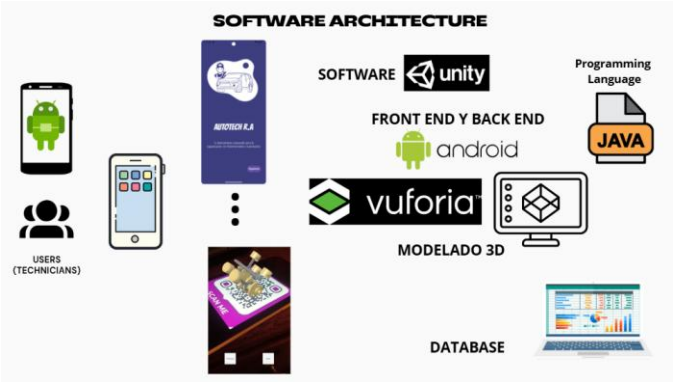

Fig. 1. System architecture.

During the subsequent stage, the overall system architecture (Fig. 1) was structured, considering the different modules that would compose the application. Unity 3D was selected as the primary development environment due to its capability to manage three-dimensional graphical environments and its compatibility with Augmented Reality (AR) tools. For the visualization of augmented objects, the Vuforia engine was integrated, enabling image recognition and the projection of digital models onto real-world markers.

The system logic was developed using C#, a programming language that facilitated dynamic interaction between objects and graphical components. In parallel, Java was utilized to ensure software compatibility with the Android operating system. Additionally, a simple data storage structure was implemented to record user performance information, including assessment results and satisfaction survey responses.

The design also focused on providing intuitive navigation that was accessible and aligned with the needs of the target audience: technical training technicians. A clean visual layout, direct-access buttons, and clear typography adapted to different screen sizes were prioritized. Furthermore, usability and user experience (UX) principles were considered, including the reduction of cognitive load, consistency in graphical elements, and visual feedback in response to user actions.

C. Production Phase

During the Production phase, all components that shaped the functional structure of the Augmented Reality (AR)-based mobile application were developed and integrated. This stage represented a critical milestone, as it enabled the transformation of previously identified technical and pedagogical requirements into interactive and operational modules aimed at enhancing the user's learning experience. The focus of this phase was to combine immersive technology with instructional design principles (see Table II) to build an accessible, functional, and pedagogically effective tool aligned with the needs of technicians in training.

Various thematic modules were designed and implemented, focusing on fundamental components of automotive maintenance, such as engines, valve trains, crankshafts, pistons, suspension systems, among others. Each module was structured to allow users to access essential theoretical content supported by high-quality graphical representations and interactive three-dimensional models.

TABLE II. PRODUCTION PHASE COMPONENTS

ID	Description
Developed Modules	Engines, valve train systems, crankshafts, pistons, and braking systems
Technical Content	Visual and textual guides integrated into each module
Interactive Resources	3D models, animations, navigation buttons, and QR codes
Functional Logic	Modular flow organized by thematic levels, incorporating touch-based and visual interaction
Technical Validation	Review conducted by automotive industry professionals
AR Integration	Linking 3D models to visual markers for augmented visualization

The development of these modules followed a user-centered approach. The development team built the application to be intuitive, clear, and fluid, enabling participants to move easily between content sections. The main interface of the application, shown in Fig. 2 and 3, presents an organized view of the available modules, where each option is accompanied by a representative image and a direct-access button. The interface is presented in Spanish, as the application was developed for a Spanish-speaking technical education context. The visual layout allows users to quickly identify topics, promoting autonomous access to the learning materials.

Upon entering each module, as shown in Fig. 4, users were presented with a general introduction to the topic, followed by a detailed description of the system components, their operation, and maintenance procedures. This information was delivered through simplified technical text, designed to be reinforced through the exploration of Augmented Reality (AR) models, which responded to interaction commands such as rotation, zooming, and perspective changes.

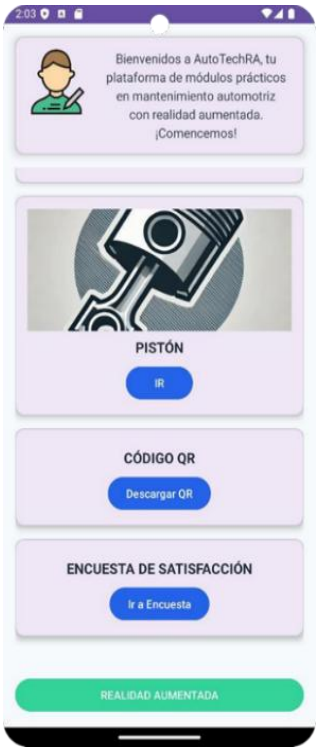

Fig. 2. Main menu interface.

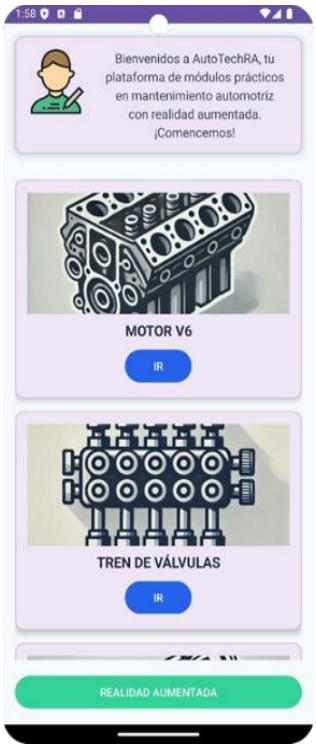

Fig. 3. Main menu interface layout.

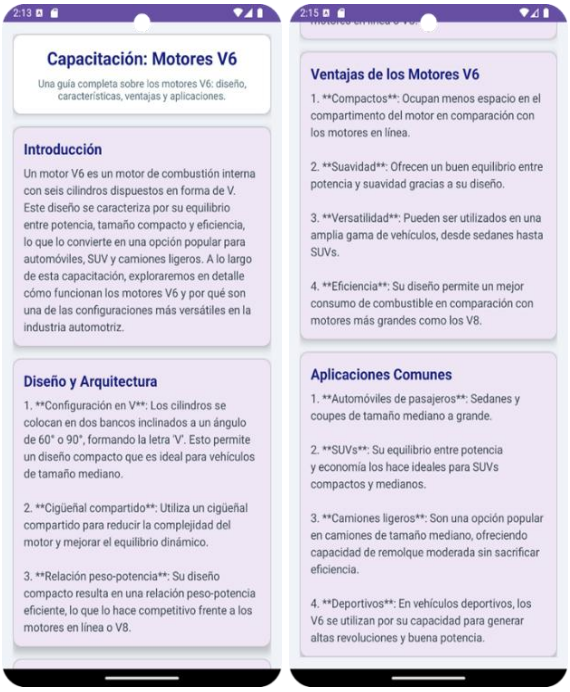

Fig. 4. Module information interface.

From a pedagogical perspective, the design prioritized visual clarity, logical content progression, and the sequential execution of learning activities. Animations and intuitive navigation controls were incorporated to enable smooth transitions between modules, thereby reinforcing learning continuity. Additionally, complementary resources were integrated to enrich the in-app navigation experience and strengthen the connection between visual and conceptual content.

Among the implemented resources, navigational buttons (Fig. 5 and 6) were strategically positioned to facilitate movement between sections, allowing users to advance, return, or restart each module without difficulty. This functionality was specifically designed to ensure user autonomy during the learning process, reducing the need for external assistance and promoting independent exploration of the content.

Fig. 5. AR-based 3D visualization of engine components.

Fig. 6. AR-based 3D visualization of brake system components.

Finally, the inclusion of a QR code (Fig. 7) aimed to promote learner autonomy by enabling technicians to review content at different times and across various devices. This functionality proved particularly useful for reinforcing key concepts, visualizing procedures from different perspectives, and accessing reliable resources through a single scan using the mobile device camera.

Continuous validation was conducted with automotive industry specialists, who reviewed the technical accuracy of the models and the content presented in each module. Adjustments were also made to the user interface (UI) and user experience (UX) components to ensure coherent, accessible navigation aligned with the characteristics of the target audience. In summary, the Production phase resulted in the consolidation of an operational version of the application, composed of complete thematic modules, integrated Augmented Reality (AR) functionalities, and a user-centered design.

Fig. 7. User interface for content access.

D. Stabilization Phase

The Stabilization phase aimed to ensure that the developed mobile application operated correctly, stably, and efficiently before being deployed to end users. During this stage, the team conducted rigorous internal testing to identify technical errors, verify system performance, and optimize the user experience under different operational conditions. The evaluation focused on aspects such as 3D model loading time, stability of core functionalities, navigation fluidity between modules, and system responsiveness across different mobile devices.

These tests enabled the identification of necessary adjustments, including graphic resource compression, animation optimization, and code debugging to prevent potential failures or performance slowdowns during execution. The application's behavior when interacting with Augmented Reality (AR) elements was also evaluated. Performance and robustness testing was conducted on Android and iOS mobile devices, recording an average initial loading time of 3.5 seconds, RAM usage of approximately 250 MB, and AR interaction response times under 2 seconds. QR marker recognition and 3D model projection were evaluated under the indoor lighting conditions typical of an automotive workshop environment, confirming stable tracking performance across the tested devices.

Finally, the phase concluded with an optimized application ready for evaluation in a real-world environment. The actions undertaken during this stage were essential to prevent errors during field use and to ensure a positive educational experience based on mobile technology and Augmented Reality (AR). Additionally, preliminary functional tests were conducted to verify system stability, correct visualization of virtual objects, and appropriate interaction with AR markers.

V. Results

A total of 60 automotive maintenance technicians participated in this study, with 30 assigned to the control group and 30 to the experimental group.

A. Level of Comprehension of Technical Content (NCC)

The assessment of the level of comprehension of technical content revealed marked differences between the two groups. In the control group, participants were predominantly categorized at the "Beginning" and "In Progress" performance levels. Conversely, the experimental group showed a higher concentration of participants at the "Expected Achievement" and "Outstanding Achievement" levels. The Shapiro–Wilk normality test indicated that the data did not follow a normal distribution in either group (Control Group: $p = 0.024$; Experimental Group: $p = 0.029$). Due to this non-normal distribution, the non-parametric Mann–Whitney U test was employed for group comparison. The test yielded a p-value of 0.001 (at a 95% confidence level), indicating a statistically significant difference between the control and experimental groups regarding the level of comprehension of technical content. Furthermore, the effect size calculated using Rosenthal's r coefficient yielded $r = 0.86$, indicating a large practical effect and confirming that the observed differences were not only statistically significant but also educationally meaningful.

B. Average Training Time (ATT)

The Average Training Time (ATT) differed substantially between groups. The control group technicians required an average of 10,862 seconds (approximately 181 minutes) to complete all training activities. The experimental group technicians completed the same activities in an average of 5,784 seconds (approximately 97 minutes), representing a reduction of 5,078 seconds, or 46.6% less time than the control group. Shapiro–Wilk testing revealed non-normal data distribution (Control Group: $p < 0.001$; Experimental Group: $p = 0.054$). The Mann–Whitney U test comparing both groups of participants yielded a p-value of 0.001, establishing statistical significance at the 95% confidence level. This reduction in training duration occurred while maintaining the same training objectives and assessment criteria across both groups. The effect size analysis yielded $r = 0.87$, indicating a large practical effect and confirming that the reduction in training time represented a substantial and meaningful improvement beyond statistical significance (Table III).

TABLE III. Summary of Statistical Results for Primary Indicators

Metric / Group	NCC[1]	ATT[2]	NCS[3]
Control Group	Beginning / In Progress	10,862 s (≈)	M = 2.6 (5-point scale)
Experimental Group	Expected Achievement / Outstanding Achievement	5,784 s(≈97min)	M = 4.0 (5-point scale)
p-calue	P = 0.001	P = 0.001	P = 0.001
Effect Size (Rosenthal's r)	0.86 (large)	0.87 (large)	0.86 (large)
Result	Significant	Significant	Significant

C. Participant Satisfaction Level (NSC)

Satisfaction was measured on a 5-point Likert scale (1 = Very Dissatisfied; 5 = Very Satisfied). The control group technicians achieved a mean satisfaction score of 2.6, while the experimental group technicians obtained a mean score of 4.0. This 1.4-point difference represents a 54% increase in satisfaction levels in the experimental group compared to the control group. The Mann–Whitney U test comparing satisfaction levels between participants yielded a p-value of

0.001 (at a 95% confidence level), confirming a statistically significant difference in favor of the experimental group technicians.

The effect size calculated using Rosenthal's r coefficient yielded r = 0.86, indicating a large practical effect and demonstrating that the improvement in satisfaction levels was not only statistically significant but also of considerable practical relevance.

VI. Discussion

As detailed in the Results section, the experimental group achieved significantly higher scores in the comprehension of technical content (NCC) and participant satisfaction (NSC), while reducing the average training time (ATT) by 46.6% (p = 0.001). Regarding the first indicator, the level of comprehension of technical content (NCC) showed a marked improvement in the experimental group that utilized the Augmented Reality (AR) application. In contrast, the control group remained predominantly at performance levels categorized as "Beginning" and "In Progress," whereas the experimental group reached higher levels such as "Expected Achievement" and "Outstanding Achievement," confirming a statistically significant difference between groups. The large effect size obtained (r = 0.86) further supports the educational relevance of these differences, indicating that the AR-based intervention produced a substantial improvement beyond mere statistical significance. These findings highlight that the immersive and interactive nature of AR-based tools enhanced the assimilation of complex technical content, allowing technicians to develop a deeper conceptual understanding than that achieved through conventional training methods.

These results are consistent with prior studies, such as Aoufy Khadija et al. [20], which demonstrated that participants trained using immersive technologies—like AR and Virtual Reality (VR)—achieved significantly higher post-training assessment scores. This evidence reinforced the positive impact of immersive technologies on knowledge retention, comprehension, and practical application.

Moreover, within the context of this study, the incorporation of interactive and immersive environments promoted active technician participation, increased motivation for learning, and facilitated the visualization of complex concepts that are difficult to grasp through traditional methods. These findings suggest that integrating AR-based tools may represent a promising pedagogical strategy to improve technical training outcomes, although further research is needed to confirm these effects in broader educational contexts.

Concerning the second indicator, Average Training Time (ATT), the experimental group demonstrated a substantial improvement in efficiency, completing the training activities in significantly less time than the control group. This improvement suggested that the structured, module-based design of the AR application—which allowed technicians to interact directly with three-dimensional representations of automotive components—reduced the cognitive effort required to understand procedural sequences, thereby accelerating task completion without compromising learning quality. The effect size analysis (r = 0.87) confirmed that this reduction was not only statistically significant but also of large practical magnitude, reinforcing the efficiency gains attributed to the AR-based intervention.

These findings aligned with the study conducted by Yıldırım and Yıldırım [8], which reported that AR and VR technologies reduced the time needed to complete complex technical tasks by 10% to 15%, attributed to direct and detailed visualization of processes, three-dimensional component representation, and the superimposition of digital information onto the physical environment.

Additionally, within this study, immersive tools enabled participants to interact with virtual models in real time, strengthening procedural and cognitive skill acquisition. These results suggest that AR-based applications may contribute to improving training efficiency, though generalization to broader professional settings requires further investigation.

Finally, regarding technician satisfaction (NSC), a clear difference emerged between groups. While the control group reported predominantly low satisfaction scores, the experimental group achieved a mean score of 4.0 on a 5-point Likert scale, reflecting a statistically significant improvement (p = 0.001). The large effect size (r = 0.86) confirmed that this improvement was of considerable practical relevance, not merely a statistically detectable difference. This outcome demonstrated that the immersive and autonomous nature of AR-based training positively influenced user perception, fostering engagement and motivation. Previous studies, such as Ojer et al. [21], supported these results, showing that immersive environments increased perceived usability and motivation, with satisfaction levels reaching up to 90% compared to approximately 65% for traditional teaching methods.

Interaction with virtual and augmented environments also enhanced engagement, sustained attention, and positive perceptions of the learning process, which translated into a greater willingness to acquire technical knowledge and develop practical skills. Consequently, the integration of immersive technologies in technical training programs represented an innovative strategy with strong potential to optimize learning effectiveness and enhance user experience.

Overall, the implementation of the AR-based mobile application produced statistically significant improvements across all three evaluated indicators: comprehension of technical content, training efficiency—with a 46.6% reduction in average time—and participant satisfaction (p = 0.001 for all cases). These outcomes suggest that, within the context of this study, AR-based tools not only optimized instructional processes but also enhanced motivation and engagement among technicians, indicating a positive influence on learning quality and willingness to acquire new technical competencies.

The incorporation of immersive technologies promoted an interactive and user-centered learning experience within the evaluated training context. These findings suggest that AR-based mobile applications may contribute to aligning technical training with contemporary industry demands, though broader conclusions regarding industry-wide impact would require

studies conducted across more diverse organizational and regional settings.

Despite these promising findings, the study presented several limitations. First, the sample was drawn from a single automotive company in Trujillo, Peru, which may limit the generalizability of the results to technicians working in different organizational contexts, training environments, or regions. Second, the study did not assess long-term knowledge retention, leaving uncertain whether the observed learning gains persisted over time. Third, outcomes may have been partially influenced by novelty effects associated with the introduction of new technology, potentially inflating initial motivation and satisfaction scores. Fourth, although the application was tested across multiple device models, robustness testing was limited to indoor workshop lighting conditions, without evaluating marker-based AR performance under varying illumination or outdoor environments. Future research should address these limitations by incorporating larger and more diverse samples across multiple organizations, longitudinal follow-up assessments, control conditions that account for novelty effects, and robustness testing across diverse environmental settings.

VII. Conclusion

Regarding the level of technical content comprehension, it was concluded that the use of the Augmented Reality (AR)-based mobile application significantly enhanced learning outcomes among automotive maintenance technicians. The group that utilized the application predominantly achieved performance levels categorized as “Expected Achievement” and “Outstanding Achievement,” in contrast to the group that did not use the tool. This difference was statistically supported by the Mann–Whitney U test ($p = 0.001$), allowing acceptance of the alternative hypothesis at a 95% confidence level and suggesting that, within the context of this single-company study, the implemented technology had a positive impact on the assimilation of complex technical content, though these findings should be interpreted with caution given the limited deployment scope.

Regarding the average training time, a notable improvement in efficiency was observed. The experimental group completed the training sessions in an average of 5,784 seconds, whereas the control group recorded 10,862 seconds. This 46.6% reduction in training time suggests that the application optimized the instructional process without compromising learning quality under the conditions of this study, though longitudinal validation would be needed to confirm sustained efficiency gains. The statistical significance of this difference was validated through the Mann–Whitney U test ($p = 0.001$), providing statistical evidence that the technological implementation reduced training duration within the evaluated context.

Regarding participant satisfaction, a considerable increase was observed. The group that used the application reported higher satisfaction levels, achieving a mean score of 4.0 on a 5-point scale, whereas the control group obtained an average of 2.6 points. These results reflect not only improved reception of the training process but also greater motivation and engagement among the technicians. As in the previous indicators, the difference was statistically significant ($p = 0.001$), reinforcing the conclusion that, within this study's context, the AR-based educational approach was positively received by participants, though broader adoption would require validation across more diverse training environments and longer evaluation periods.

***Abstract*—Traditional sun drying remains the primary practice among smallholder coffee farmers in the Philippines, often leading to an inefficient and inconsistent drying process. While transitioning to mechanical drying improves product quality, achieving uniform airflow in cabinets with multiple trays often requires costly post-fabrication modifications, resource-intensive trials, and repetitive field testing to fine tune the performance of the system. To reduce inefficient and repetitive trial-and-error procedures, a pre-fabrication design verification of a small-scale mechanical cabinet dryer was conducted using COMSOL Multiphysics. This study explores how the dryer's geometry influences its aerodynamic and thermal performance under baseline, no-load conditions prior to fabrication. The system was simulated to deliver an inlet air velocity of 1.56 m/s and a controlled heat flux to maintain 40°C. Results revealed steady pressure equalization within the plenum chamber, which successfully mitigated non-uniform airflow. As a result, a relatively high Velocity Uniformity Index of 0.84 was achieved across the tray layers. In addition, internal turbulent mixing contributed to a more stable thermal profile, reaching a near-ideal Temperature Uniformity Index of 0.99. These findings reveal that the core geometry of the dryer performs well from an aerodynamic standpoint. By achieving flow equalization in a no-load setting, the study provides an optimized baseline design, helping reduce the need for extensive trial-and-error during future prototyping and testing under actual operating conditions.**

I. Introduction

Drying is considered the most common and oldest technique for preserving agricultural crops, where moisture content and water activity are reduced to minimize chemical, biochemical, and microbiological deterioration [1][2][3]. This postharvest process is recognized as the most critical step affecting the final quality of the coffee [4][5][6][7]. Apart from influencing the physical appearance of the coffee beans, drying can also influence the quality of the end-product of the hulling process [5][8].

Open sun drying is still widely used nowadays for drying agricultural products even in various developing countries with the goal of lowering the moisture content of the beans [9][10][11]. However, this traditional approach poses several risks including contamination, longer drying period and unpredictable weather patterns and conditions [11]. Despite its low cost and simplicity that attracts coffee growers [11], sun drying approach is not recommended due to numerous factors that could threaten the quality of the product [10].

Sun drying, as a weather-dependent process, could take up two to three weeks which makes it a slow process that requires regular stirring to ensure even drying [11]. Drying coffee on open pavements usually takes several days, depending on the type of processing. Washed coffee generally dries in about six to seven days, pulped natural or semi-washed coffee needs roughly eight to nine days, and natural or dry-processed coffee requires the longest, often around 12 to 14 days [12]. Apart from that, the harvesting season for coffee coincides with the rainy season of the year. This makes the process labor-intensive, as the commodity should be covered during adverse weather conditions [11]. Furthermore, extended drying periods increase the likelihood of microorganisms, molds, and mycotoxins developing, which can compromise the quality of the product [10]. This includes contamination by dust, insects, and other domestic animals. All these factors prevent the coffee farmers from utilizing alternative, and more efficient drying methods when traditional sun drying is not possible [12].

Aside from traditional open sun drying, some common methods for drying the coffee cherries are the solar and mechanical drying [10][13][14][15]. The use of solar energy in drying later expanded to include solar dryers. These systems improve drying efficiency and help reduce problems such as mold growth and microbial contamination. However, because they rely entirely on sunlight, unstable weather can still hinder their performance. In coffee processing, solar drying offers an advantage: temperatures generally stay below 50°C, which preserves the embryo inside the bean. Once this temperature is exceeded, the embryo can be damaged, leading to rapid internal deterioration and lower overall quality [10][16]. On the other hand, mechanical drying serves to accelerate the slowest segment of the drying curve, specifically the drop from 15% to 11% moisture, thereby minimizing the risk of unnecessary fermentation [12]. Moreover, mechanical dryers were found to preserve significantly higher levels of phenolic compounds and antioxidant activity compared to sun drying [17]. Through the use of a mechanical dryer, water activity was maintained below 0.6 and with a stable moisture content of 7.7–10.4%, conditions that effectively inhibit microbial growth and prevent mycotoxin formation [18].

These advantages, however, are highly dependent on the internal geometry of the cabinet and its capacity to deliver uniform airflow and stable temperatures across all tray levels. Non-uniform drying in such dryers is primarily caused by poor airflow distribution through the chamber, which can be improved by optimizing the flow path and ensuring more uniform velocity across trays [19]. Repetitive field testing through trial-and-error is costly and time-consuming, making simulation a practical alternative for evaluating dryer performance before physical prototypes are developed.

This study computationally characterizes the aerodynamic and thermal performance of a small-scale mechanical coffee cabinet dryer using COMSOL Multiphysics under steady-state, no-load conditions. Isolating the pressure and velocity distributions across the plenum and intermediate ducts enables a direct evaluation of the system's capacity to achieve foundational flow equalization. Verifying that the core geometry performs well from an aerodynamic standpoint validates the underlying structural design, helping reduce the need for extensive trial-and-error during future physical prototyping and testing under actual operating conditions.

II. Literature Review

Before the physical fabrication, computational simulation enables a controlled environment to study and analyze airflow behavior, heat distribution, and other key performance parameters while minimizing uncertainties in the design process. Understanding and optimizing these dynamics is crucial for producing high-quality output, extending shelf life, and supporting broader goals of food safety and sustainability [17]. This goal can be achieved through proper modelling of heat and airflow dynamics across the system [20].

In recent years, Computational Fluid Dynamics (CFD) has been recognized as a critical tool for diagnosing and correcting non-uniform airflow, which is the primary cause of uneven drying in cabinet systems, and recent literature strengthens its role in dryer optimization. Advancements in CFD modeling have shifted attention toward achieving uniform velocity distribution, with iterative design refinements based on simulation outputs becoming standard practice for improving dryer performance [21]. Flow stratification and non-uniform drying are well-documented drawbacks of cabinet drying systems. However, optimizing internal geometry through the precise modeling of heat and airflow dynamics can significantly mitigate these issues. Existing studies show that optimizing cabinet geometry and airflow pathways not only enhances uniformity but can generate substantial efficiency gains, including up to a 50 percent reduction in drying time and overall energy use, especially when combined with heat pump technology [19][21][22][23][24][25]. Furthermore, the reliability of this computational approach is confirmed by experimental validations, which consistently demonstrate less than a 10 percent relative error between simulated and physical values when predicting complex airflow behaviors and recirculation zones.

For instance, a CFD-integrated sequential linear programming framework was utilized to systematically evaluate the influence of supply fan positions on airflow uniformity in a multi-tray cabinet dryer [22]. The study achieved a highly uniform airflow range of 0.82–1.9 m/s, underscoring the effectiveness of CFD-based geometric optimization. However, it was emphasized that the absence of thermal coupling and experimental validation in purely aerodynamic simulations is a crucial limitation since temperature variations may become the next limiting factor. Therefore, comprehensive optimization frameworks must integrate both aerodynamic and thermal uniformity.

To establish a reliable aerothermal baseline before introducing the complex variables of agricultural products, several studies evaluated drying systems under no-load, steady-state conditions. A generalized methodology for the thermal testing of cabinet and solar dryers in no-load conditions has been developed, utilizing a no-load performance index (NLPI) to accurately compare structural designs [25]. Building on this principle, explicitly evaluating the temperature and air-velocity distribution inside an empty drying chamber has been demonstrated as a necessary prerequisite to verify a system's thermal and aerodynamic behavior before loading the product [24]. Furthermore, computational tools such as COMSOL Multiphysics have been successfully utilized for the finite-element modeling of dryers under no-load conditions, with simulated thermal data validated against physical experimental tests [23]. Overall, these insights reveal that CFD functions both as a diagnostic framework and a design optimization tool, enabling evidence-based improvements in drying uniformity, system efficiency, and the overall performance of cabinet dryers.

III. Materials and Methods

A. Computational Domain and Dryer Geometry

The coffee cabinet dryer was developed using Autodesk Fusion 360 computer-aided design (CAD) software. The 3D computational domain encompasses the internal fluid volume of the system's major assemblies: the plenum chamber, air routing duct, and the double-walled, fiberglass-insulated drying chamber containing a 5-layer stainless-steel tray assembly (Fig. 1).

Fig. 1. Full 3D CAD model of the proposed mechanical coffee cabinet dryer.

To establish a reliable baseline before introducing the complex variables of agricultural products, the internal domain was modeled under no-load conditions. The tray levels were treated as unobstructed fluid volumes, isolating the aerodynamic performance of the structural geometry to ensure that any observed flow stratification is a direct result of the cabinet's

architecture rather than the variable hydraulic resistance introduced by coffee beans (Fig. 2).

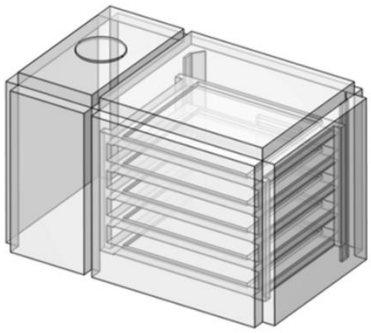

Fig. 2. Extracted computational domain representing the internal fluid volume for CFD analysis.

B. Design Assumptions and Governing Equations

The numerical simulation was executed in COMSOL Multiphysics based on several simplifying physical assumptions to ensure computational efficiency while maintaining acceptable aerothermal accuracy:

1) Incompressible flow: Airflow operates at low Mach numbers; therefore, density variations are negligible, and the fluid is treated as incompressible.

2) No internal heat generation: Heating originates externally from the simulated heating element; there is no volumetric heat generation within the drying chamber itself (Q = 0).

3) Adiabatic boundaries: Because the physical prototype utilizes thick fiberglass lagging, the external walls are treated as perfectly insulated.

The physical phenomena inside the dryer were governed by the conservation of mass, momentum, and energy. Mass conservation for the incompressible fluid is defined by the continuity equation:

$$\nabla \cdot u = 0 \tag{1}$$

Because the forced convection driven by the supply fan induces high-velocity gradients and internal recirculation, the airflow was characterized as turbulent. Momentum transport was resolved using the Reynolds-Averaged Navier-Stokes (RANS) formulation:

$$\rho\left(\frac{\partial t}{\partial u} + u \cdot \nabla u\right) = -\nabla p + \nabla \cdot [(\mu + \mu t)(\nabla u + (\nabla u)T)] \tag{2}$$

Turbulence effects were modeled using the Realizable k–ε model, which provides robust predictions for internal flows with rotational features and flow separation. The turbulent eddy viscosity (μ_t) is defined as:

$$\mu t = C\mu\frac{k^2}{\varepsilon} \tag{3}$$

To fully describe the thermal behavior inside the dryer, the general convection-conduction energy balance was applied to couple the thermal distribution with the velocity field:

$$\rho C p u \cdot \nabla T + \nabla \cdot q = Q + Qp + Qvd \tag{4}$$

where, $\rho C_p u \cdot \nabla T$ represents the dominant convective heat transport by the airflow, and $\nabla \cdot q$ models the conductive heat transfer through the solid boundaries of the system. The parameter Q corresponds to the external volumetric heat source, whereas Q_p represents the work associated with pressure changes, and Q_{vd} accounts for heating due to viscous dissipation.

Under the low Mach number and low-velocity operating conditions considered in this study, the effects of pressure work (Q_p) and viscous shear heating (Q_{vd}) are negligibly small. Consequently, these terms are systematically treated as zero within the numerical solver.

C. Boundary Conditions and Thermal Control Logic

The simulation boundary conditions were established to precisely replicate the intended operational parameters of the physical prototype. Aerodynamically, a velocity inlet boundary condition of 1.56 m/s was applied at the air duct entry, corresponding to a steady volumetric flow rate of 0.03 m³/s. The exhaust vent at the top of the cabinet was modeled as a pressure outlet set to standard atmospheric pressure, expressed as 0 Pa gauge pressure, permitting the free discharge of the circulating air into the ambient surroundings. All internal structural walls, baffles, and tray supports were assigned a standard no-slip condition (u = 0).

To establish the internal thermal environment, a fixed air temperature boundary condition of 373.15 K (100°C) was imposed at the outlet of the heating plenum chamber, immediately upstream of the connecting air duct leading into the drying chamber. This represents the temperature of the conditioned process air supplied by the heating system prior to distribution within the cabinet. Because the physical cabinet utilizes thick fiberglass lagging, the external boundaries were approximated as adiabatic to isolate the internal thermal distribution. However, to account for minor structural conductive losses and accurately model the target internal drying environment of 313.15 K (40°C), a constant surface heat flux of 180 W/m² was applied to the external walls.

Furthermore, to evaluate the transient thermal response of the system under operational conditions, the heating element was governed by an ON/OFF thermostat rule with hysteresis. This control logic dynamically regulated the average domain temperature (T_{avg}) by defining the volumetric heat source density, $q''(t)$ in W/m³, based on predefined lower (T_{on}) and upper (T_{off}) temperature thresholds. The governing control logic for the heat source is mathematically expressed as a piecewise function:

$$q''(t) = \begin{cases} q_0 & if\ T_{avg} \leq T_{on} \\ 0 & if\ T_{avg} \geq T_{off} \\ Interpolated & if\ T_{on} < T_{avg} < T_{off} \end{cases} \tag{5}$$

where, T_{on} is the lower temperature threshold, T_{off} is the upper temperature threshold, and q_0 is the maximum heat source capacity. This hysteresis formulation ensures realistic thermal cycling, preventing high-frequency artificial oscillation in the

numerical solver while accurately reflecting the thermal buffer capacity of the physical drying chamber.

D. Mesh Generation and Grid Independence

The resolution of the computational model, determined by the mesh parameters, governs how the Finite Element Method breaks down the drying chamber geometry into simple elements. Achieving greater accuracy requires a finer mesh, but this refinement directly increases both the necessary computation time and memory resources [20]. The simulation pipeline used in this study was adapted from the study of [20], which involves the CFD model analysis of a multipurpose dryer (Fig. 3).

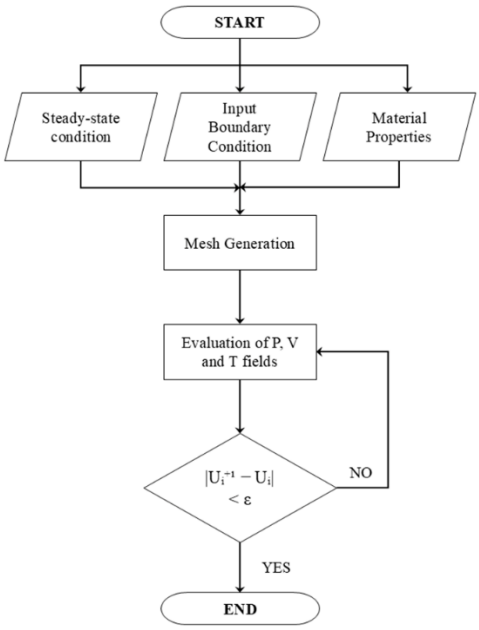

Fig. 3. Adapted simulation pipeline based on the framework presented in [20].

With the governing physics and operational boundaries fully defined, the computational domain required spatial discretization to resolve the flow and temperature fields. A physics-controlled, unstructured mesh utilizing 3D tetrahedral domain elements and triangular boundary elements was generated across the three primary domains elaborated in Table I.

TABLE I. MESH STATISTICS FOR THE THREE MAJOR DOMAINS

Computational Component	Domain Elements (Tetrahedra)	Boundary Elements (Triangles)	Edge Elements (Edges)	Total Elements
Drying Chamber	417,186	46,268	3,114	466,599
Plenum Chamber	27,492	7,642	800	35,394
Air Duct	70,820	9,920	680	81,420

To guarantee that the predicted aerothermal fields were independent of discretization error, a grid independence study was performed. Four progressively refined meshes were evaluated, consisting of approximately 495,566; 527,053; 606,877; and 749,110 total elements (Fig. 4).

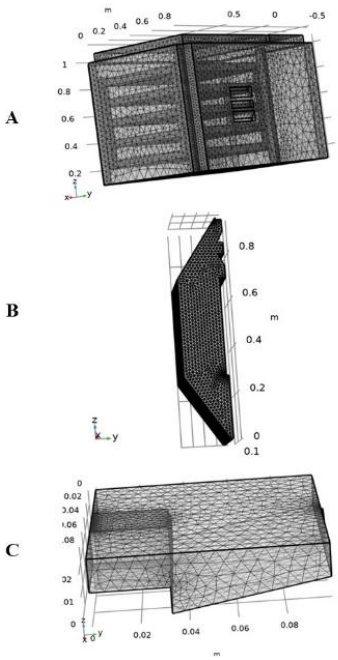

Fig. 4. Generated mesh for each computational domain: (A) Drying chamber; (B) Air duct; and (C) Plenum chamber.

The placement of virtual sensors was strategically designed to capture the full gradient of the aerothermal environment. Specifically, point probes were positioned on all interior boundary surfaces of the drying chamber's domain to monitor wall-proximate effects. Furthermore, probes were localized at the geometric center of each of the tray layers, ensuring that the refinement analysis accounted for the critical airflow and temperature variations within the product-loading zones.

To assess convergence across these iterations, six sensitive virtual probe locations were defined within the computational domain including the heated air inlet, the front and center of the third tray, and representative chamber walls to systematically monitor temperature variations across each successive refinement.

E. Simulation Strategy

The investigation was divided into two distinct computational phases. A steady-state simulation characterized the baseline aerodynamic behavior of the system, with emphasis on airflow distribution, static pressure equalization, and overall flow uniformity. A subsequent transient simulation spanning 60 minutes evaluated the system's thermal response and the performance of the thermostat control logic.

The segregated solver employed pseudo-time stepping with Anderson acceleration, successfully achieving stable convergence for both fluid flow and turbulence variables. To capture the transient thermal response during this 60-minute evaluation, point probes were strategically positioned at the system inlet, the exhaust outlet, and along the edge of each tray layer farthest from the air inlet. This conservative placement ensured that the most critical, time-dependent heating curves were accurately monitored.

F. Data Extraction and Evaluation Metrics

To objectively quantify flow equalization and thermal homogeneity, horizontal evaluation planes were established at each tray level. Data extraction was performed across these planes, and the system's performance was evaluated using two dimensionless indices.

The Velocity Uniformity Index (VUI) and Temperature Uniformity Index (TUI) were calculated based on the area-weighted relative standard deviation of the flow fields:

$$\text{VUI} = 1 - \frac{\sigma_v}{\bar{v}} \quad (6)$$

$$TUI = 1 - \frac{\sigma_T}{\bar{T}} \quad (7)$$

where, σ_v and σ_T are the standard deviations of velocity and temperature across the respective evaluation planes, and $\bar{v}$ and $\bar{T}$ represent the corresponding area-weighted mean velocity and temperature. Values approaching 1.0 indicate optimal uniformity across the evaluated plane.

In addition to planar data, discrete monitoring points were utilized for localized analysis. Point probes were strategically placed at the center of the front face of each of the five tray layers. These probes were positioned at the furthest extremity from the air duct inlet to capture the potential "dead zones" or areas of maximum thermal lag, providing a conservative estimate of the drying conditions at the most critical locations within the chamber.

IV. Results

A. Scope and Limitations of the Simulation Study

A full-scale three-dimensional model of the coffee cabinet dryer was analyzed based on its actual geometric dimensions and intended operating parameters. The present investigation is strictly limited to simulation-based performance characterization under no-load conditions.

Since this is a foundational pre-fabrication analysis, key operational metrics heavily dependent on agricultural variables such as drying rate, moisture removal efficiency, specific energy consumption, and final product quality were not experimentally validated. Moreover, this study emphasizes aerothermal performance assessment through validated numerical modeling, establishing the necessary aerodynamic baseline required before future experimental validation and full-load drying kinetics can be quantified.

B. Simulation Performance and Convergence

The segregated solver, employing pseudo-time stepping together with Anderson acceleration, provided stable convergence for the coupled velocity, pressure, turbulence, and heat transfer equations. Convergence for the steady-state domains was achieved within approximately 130 to 170 iterations, with residuals reduced to acceptable tolerances for both fluid flow and turbulence variables. Similar convergence behavior was observed in the plenum and drying chamber simulations. This confirms that the numerical model was capable of predicting steady-state airflow and heat transfer characteristics within the dryer configuration.

The solution time ranged between 20 and 25 minutes for steady-state simulations, while the transient simulations incorporating the piecewise thermostat control logic required approximately 7 to 8 minutes. The convergence profile validates the robustness of the numerical model and supports its suitability for evaluating the aerothermal design of the cabinet prior to physical fabrication.

C. Grid Independence Verification

Across successive mesh refinements, temperature variations remained negligible. The maximum observed deviation between adjacent mesh levels did not exceed 0.09°C, with relative differences remaining below 0.25% of the nominal 40°C (313.15 K) operating temperature. Notably, the heated air inlet temperature remained constant at 40°C across all mesh levels, indicating stable boundary condition implementation.

TABLE II. Grid Independence Results for Predicted Temperature Across All Probes

Mesh Level	Probe A	Probe B	Probe C	Probe D	Probe E	Probe F
h1.0	40.00	39.95	39.93	39.94	39.94	39.94
h1.5	40.00	39.95	39.93	39.95	39.95	39.94
h2.0	40.00	39.95	39.94	39.96	39.95	39.95
h2.5	40.00	39.93	39.90	39.94	39.93	39.92
% Error	**0.00%**	**0.06%**	**0.09%**	**0.05%**	**0.06%**	**0.07%**

As presented in Table II, the temperature values across all six monitoring locations exhibited high stability as the mesh density increased. The primary boundary condition at the inlet (Probe A) remained constant at 40.00°C, confirming that the refinement process did not introduce numerical instabilities at the source. For the internal regions, particularly at the front and center of the third tray (Probes B and F), the temperature variations between successive refinements were minimal, settling at approximately 39.93°C to 39.95°C. The convergence was quantitatively assessed using the relative error between the medium-fine (h2.0) and extremely fine (h2.5) mesh levels. The results indicated that the maximum relative error did not exceed 0.09%, occurring at probe C. In the central drying zones, the error remained below 0.07%.

Based on the numerical stability observed across the mesh iterations, the configuration consisting of 606,877 elements (h2.0) was determined to provide sufficient spatial resolution. The transition to the finest mesh (749,110 elements) yielded a maximum relative error of less than 0.09%, indicating that further refinement offered negligible improvements in precision. Consequently, the h2.0 mesh was selected for all subsequent steady-state and transient simulations to optimize the balance between numerical accuracy and computational efficiency.

Furthermore, no monotonic drift in predicted values was observed with increasing mesh density. Therefore, the mesh containing 606,877 elements was selected as the optimal configuration, effectively balancing computational efficiency and numerical accuracy. This grid independence validation confirms that the velocity, pressure, and temperature fields presented in subsequent sections are strictly mesh-independent and physically reliable.

D. Aerodynamic Performance and Flow Distribution

Achieving a uniform velocity profile across all tray levels is the primary fluid dynamic challenge in multi-tray batch dryers, as non-uniform flow directly induces heterogeneous moisture content [21].

1) Airflow path, velocity uniformity, and intermediate duct dynamics: The inlet boundary condition was set to a velocity of 1.56 m/s at the air duct entry, corresponding to a volumetric flow rate of 0.03 m³/s. The velocity contours (Fig. 5) confirm a peak magnitude of 1.51 m/s within the duct, validating the boundary setup. The high-momentum air builds up in the large plenum chamber, where heating and initial pressurization occur. The conditioned air then exits the plenum and passes through an intermediate air duct before entering the main drying chamber, a configuration intended to redistribute flow pressure and ensure delivery to the base of the tray stack. Within this intermediate duct, the flow velocity is observed to increase due to the reduced cross-sectional area, creating a highly directional jet entering the drying volume.

Within the main drying zone (the volume encompassing the six trays), the air velocity streamlines (Fig. 6) display a highly desirable parallel flow regime as the flow expands and passes through the trays. The velocity magnitude over the virtual coffee bed volume consistently falls within the range of 0.5 m/s to 1.0 m/s. This narrow range indicates a high degree of flow uniformity.

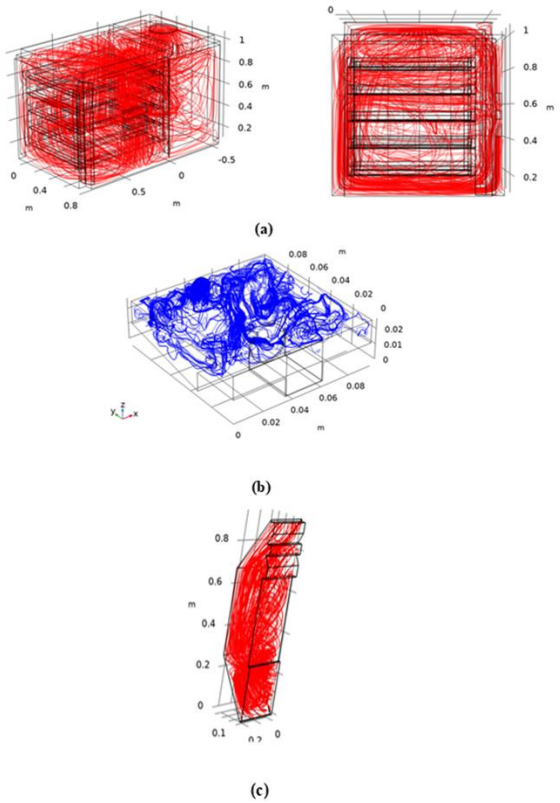

Fig. 5. Streamline visualization of the velocity field in different computational domains: (a) Drying chamber; (b) Air duct; and (c) Plenum chamber.

Assuming an approximate characteristic length (hydraulic diameter) corresponding to the tray spacing, the Reynolds number (Re) calculated for the flow through the drying zone suggests a regime transitioning from laminar to mildly turbulent. This condition is advantageous, as it provides sufficient convective heat transfer without incurring excessive fan power consumption or risk of entraining lighter particles. The minimal localized recirculation zones observed in the far corners of the plenum are low-energy eddies that rapidly decay. The flow entering the intermediate duct is stable, confirming that the initial air distribution within the plenum is effective.

2) Quantitative velocity uniformity assessment: To quantitatively evaluate airflow distribution, the Velocity Uniformity Index (VUI) was computed for each tray surface. The Velocity Uniformity Index (VUI) quantitatively evaluated airflow distribution across the multi-tray system, yielding a global value of 0.84 that indicates highly effective overall balance (Table III).

TABLE III. VELOCITY UNIFORMITY INDEX INSIDE THE DRYING CHAMBER

Location	Individual VUI	Global VUI
Tray No. 1	0.76	0.84
Tray No. 2	0.88	
Tray No. 3	0.87	
Tray No. 4	0.86	
Tray No. 5	0.86	

While Tray 1 showed a modestly lower VUI of 0.76 due to localized jet effects from its proximity to the intermediate duct discharge, upper trays achieved superior uniformity of 0.86 – 0.88 through progressive plenum-driven redistribution, outperforming baseline CFD-optimized designs reporting 0.766–0.80 VUI found in several studies [22][26]. Furthermore, velocities across all evaluation planes remained above stagnation thresholds (>0.5–1.0 m/s), eliminating dead zones and confirming the system's efficacy relative to plenum-enhanced prototypes achieving similar flow homogenization.

Nevertheless, to further improve the aerodynamic uniformity at the lowest tray level prior to physical fabrication, a geometric flow-conditioning modification is proposed at the intermediate duct discharge region. Specifically, integrating a passive flow-correcting element, such as an angled deflector wedge or perforated distribution baffle plate, would mechanically disrupt and diffuse the concentrated high-momentum jet before it impinges on Tray 1. This modification is expected to promote earlier lateral airflow redistribution within the lower plenum region, thereby reducing localized velocity gradients and increasing the Tray 1 VUI toward the more balanced profiles observed in the upper trays.

3) Pressure distribution, hydraulic resistance, and flow equalization: The pressure field (Fig. 7) is perhaps the most compelling result validating the dryer's aerodynamic function. A substantial static pressure peak, exceeding 30 Pa, is successfully established in the plenum immediately adjacent to the air inlet. This pressure acts as the necessary reservoir to

overcome the cumulative hydraulic resistance of the intermediate duct and the subsequent six stacked trays and the coffee product, which will be modeled as a porous medium in subsequent studies.

The principle of flow equalization in multi-tray systems dictates that the pressure drop across the product ($\Delta P_{product}$) must be significantly larger than the velocity pressure variations within the plenum (ΔP_{plenum}) to ensure a consistent flow rate ($\dot{m}$) through each layer. The highly uniform static pressure profile observed beneath the lowest tray suggests that ΔP_{plenum} is negligible compared to the expected $\Delta P_{product}$. The smooth, progressive decrease in pressure moving vertically through the drying chamber, terminating near ambient (zero-gauge) pressure at the exhaust, confirms that the static pressure gradient successfully drives the air across the entire volume. This robust pressure differential fundamentally mitigates the stratification and non-uniform drying characteristic of passively vented systems [20].

E. Thermal Homogeneity

Thermal homogeneity is essential for product quality, particularly for coffee, where temperature excursions above 50°C can initiate irreversible physicochemical damage, compromising final cup quality [16].

1) Thermal mixing and energy balance within the plenum: The simulation employed a high heater outlet temperature of 100°C (373.15 K) as the boundary condition. The temperature gradient reveals a remarkable degree of thermal dissipation within the plenum volume (Fig. 8). The high-velocity, high-temperature air jet interacts immediately with the large, relatively quiescent volume of the plenum. This promotes intense turbulent mixing, causing the air temperature to rapidly reduce and settle into a narrow operational range of 41°C to 45°C (314 K to 318 K) as it enters the intermediate duct.

This rapid stabilization which results in a narrow ±4 K deviation around the target 40°C (313.15 K) confirms effective heat balance. The internal metallic walls and tray structure act as a thermal buffer and heat sink, ensuring thermal energy is distributed uniformly across the plenum's cross-section. The applied external surface heat flux of 180 W/m² successfully counteracts minor conductive losses, preserving the near-adiabatic state of the system. By confirming that the drying air is uniformly applied at a moderate temperature, the simulation provides confidence that the mechanical dryer will preserve the cellular structure, color, and subsequent sensory profile of the coffee.

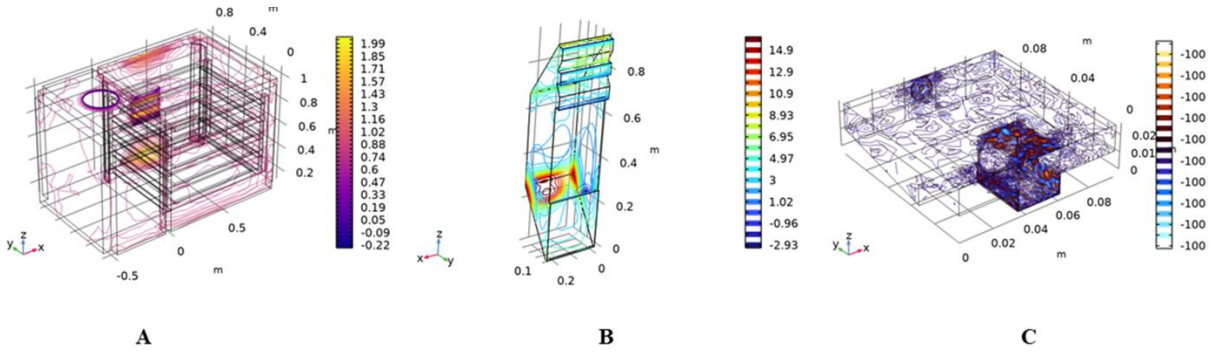

Fig. 7. Contour visualization of the Pressure in Different Domains: (A) Drying chamber; (B) Air duct; and (C) Plenum chamber.

2) Quantitative thermal uniformity assessment: Resulting Temperature Uniformity Index (TUI) demonstrates exceptionally high thermal homogeneity, with a global TUI of 0.99 and individual tray values of 1.00.

While these values approach spatial homogeneity and may appear unusually ideal, they represent the physically coherent thermal behavior of the system under controlled, no-load conditions. The absence of a porous coffee bed eliminates spatially varying permeability and evaporative cooling effects. Under steady-state forced convection with insulated boundaries and intensive plenum mixing, the energy equation naturally converges toward a smooth temperature field without numerical artifacts (Table IV).

TABLE IV. TEMPERATURE UNIFORMITY INDEX INSIDE THE DRYING CHAMBER

Location	Individual TUI	Global TUI
Tray No. 1	1.00	0.99
Tray No. 2	1.00	
Tray No. 3	1.00	
Tray No. 4	1.00	
Tray No. 5	1.00	

This inherent tendency toward thermal equilibration is further reinforced by the aerodynamic configuration of the plenum chamber. Because the heating element is located within a relatively large plenum volume, the incoming high-temperature jet undergoes substantial turbulent mixing before entering the tray stack. The interaction between the hot inlet stream and the plenum walls promotes rapid dissipation of localized thermal gradients and facilitates cross-sectional energy redistribution. Consequently, by the time the airflow reaches the intermediate duct and drying chamber, it has already achieved significant thermal stabilization, thereby limiting the potential for downstream stratification.

The pressure distribution within the system complements this thermal behavior. The establishment of a stable static pressure reservoir in the plenum ensures nearly uniform mass flow across all tray levels. When airflow is evenly distributed and tray geometries are identical, convective heat transfer coefficients remain spatially consistent. This balanced mass flow minimizes localized overheating or underheating, directly supporting the high uniformity reflected in the TUI values. Furthermore, the chamber walls were modeled as thermally insulated, approximating near-adiabatic operation. By limiting asymmetric external heat losses, the model suppresses lateral temperature gradients that could otherwise arise from environmental interactions. The combined effect of insulated boundaries, balanced mass flow, and intensive plenum mixing creates conditions under which temperature deviations are inherently minimal.

Overall, the near-unity TUI values do not indicate numerical artifact or over-idealization; rather, they represent the physically coherent thermal behavior of the system under controlled, no-load conditions. It is expected that the incorporation of porous media modeling and coupled moisture transport in future full-load simulations will introduce additional spatial variability due to evaporative cooling and heterogeneous resistance effects, thereby yielding more conservative yet operationally representative uniformity indices.

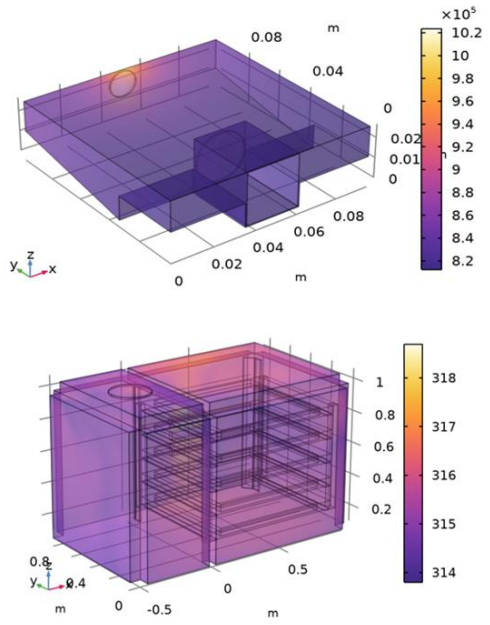

Fig. 8. Temperature distribution within the modeled volume.

F. Transient Thermal Response

In addition to steady-state mapping, a time-dependent simulation was conducted over a 60-minute period. Temperature evolution was monitored using point probes strategically placed at the system inlet, outlet, and along the side of each tray farthest from the air inlet to represent a conservative case for heat delivery. The temporal profiles indicate a rapid rise in air temperature during the initial heating phase, followed by a gradual approach toward steady-state conditions. The inlet and outlet temperature histories show that the system stabilizes within the target operating range after the initial transient period, with minimal temperature divergence observed between the inlet and outlet once equilibrium is reached. This behavior suggests effective thermal regulation and supports the assumption of near-adiabatic operation (Fig. 9).

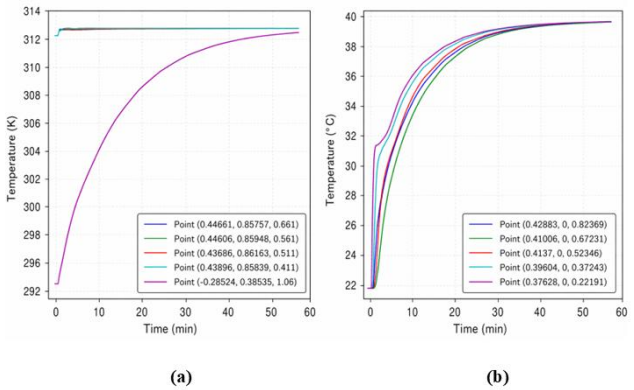

Fig. 9. Transient temperature profiles of the mechanical coffee cabinet dryer obtained from a 60-minute time-dependent CFD simulation. (a) Temperature evolution at selected points near the air inlet and outlet, showing rapid initial heating followed by stability.

Furthermore, the tray-level responses exhibit consistent heating trends across all layers. While minor differences in heating rates are observed during the early stages, all tray locations converge toward a narrow temperature band as time progresses, reaching the desired drying range even at the farthest probe locations.

V. Limitations of the Study

Despite its foundational contributions to the aerothermal design of the cabinet dryer, this study acknowledges several inherent limitations that must be addressed in subsequent research phases. Primarily, the current computational model operates strictly under no-load conditions. The absence of a physical coffee bed means that the complex aerodynamic resistance, spatially varying permeability, and localized flow channeling introduced by agricultural materials are not captured in the current velocity fields. Furthermore, the thermal evaluation is restricted to single-phase sensible heat transfer. In actual operational states, the desorption of moisture from the coffee beans will introduce multiphase mass transfer and significant evaporative cooling effects. These endothermic reactions will inherently induce localized temperature gradients, meaning the near-unity Temperature Uniformity Index (TUI) observed in this baseline study represents an idealized maximum rather than a field-loaded absolute.

VI. Conclusion

The study focused on establishing the aerothermal baseline for the proposed mechanical coffee cabinet dryer through rigorous three-dimensional computational fluid dynamics (CFD) modeling. The results demonstrated that coupling a high-pressure plenum with strategic internal routing has the capability to achieve the flow equalization and thermal stability required for effective batch drying. The aerodynamic evaluation of this architecture revealed a highly stable, parallel flow regime across the drying chamber, evidenced by a global Velocity Uniformity Index (VUI) of 0.84. Airflow velocities were maintained within the target convective range of 0.5 m/s to 1.0 m/s across all product planes, reducing the likelihood of stagnant recirculation zones. Concurrently, the thermal analysis indicated that intensive turbulent mixing within the primary plenum facilitates rapid energy dissipation and stabilization. This mechanism maintained the internal drying environment between 41°C and 45°C (314 K to 318 K), resulting in a high Temperature Uniformity Index (TUI) of 0.99 under the simulated conditions. Such thermal uniformity may help mitigate localized overheating, thereby reducing the risk of irreversible physiochemical damage to the coffee embryo and preserving final cup quality.

However, it must be explicitly emphasized that this near-unity thermal index represents an idealized baseline configuration under empty, no-load conditions. In actual drying operations, the introduction of a physical, porous coffee material will significantly alter these dynamics by introducing spatially varying hydraulic resistance, localized flow channeling, and endothermic mass transfer gradients driven by evaporative cooling. These multi-phase interactions are expected to induce localized temperature gradients, substantially lowering the uniformity indices under full-load scenarios.

Nevertheless, this pre-fabrication characterization provides simulation-based design assessment of the fluid-dynamic and thermal viability of the dryer architecture. By establishing a strictly verified computational framework, these findings secure the aerothermal baseline required for the system's physical implementation. While this study evaluated a specific small-scale dryer architecture, the CFD methodology and geometric principles of flow equalization demonstrated herein may be adapted to optimize various types of agricultural drying equipment.

Acknowledgment

This work was supported by the Cavite State University (CvSU) and the Department of Science and Technology (DOST) through the DOST-funded project titled "Technology Piloting and Commercialization of Coffee Postharvest Equipment" under the program titled "Bridging the Gap on Coffee Production and Processing through Emerging Research and Innovation for the Advancement of the Industry (CvSU BEAN Program)." The authors also express their sincere gratitude to the coffee farmers, producer organizations, Local Government Units, and partner communities across CALABARZON for their invaluable support and cooperation throughout the conduct of this work.

Unveiling Temporal Dynamics of Consumer Emotions in Online Reviews: An Emotion Mining Approach Using Ekman's Emotion Model

Azra Shamim, Abdulwahab Ali Almazroi
College of Computing and Information Technology at Khulais, University of Jeddah, Jeddah, Saudi Arabia

***Abstract*—Currently, business organizations are using Electronic Word-of-Mouth (EWOM) from consumer-opinion platforms to elevate their marketing strategies using semantic analysis and emotion mining. Existing efforts are devoted to analyzing EWOM using fine-grained emotion classification; however, the well-known and well-established emotion models that provide a basic set of psychological and biological emotions are not targeted in these studies. Further, the existing literature is unable to present temporal dynamism and volatility of consumers' emotions according to emotion categories that have an inescapable impact on consumers and corporate decision-making process. Therefore, this study tries to address this gap by extracting, classifying, summarizing, and tracking consumers' emotions for corporate and consumers' decision-making processes based on widely used and well-established Ekman's emotions model. Therefore, the current work aims to provide consumers' emotions temporal dynamism and volatility at product and feature levels by using binary and fine-grained emotion classifications based on Ekman's basic psychological and biological emotions. Online reviews from amazon.com are used for experimental purposes. The results of the study exhibited that consumers predominantly expressed joy emotion to the camera. However, the picture feature of the camera evoked negative emotions, namely, fear, anger, and sadness. Temporal analysis unveiled shifting emotional expressions in quarter 1 and quarter 2. The results of the study will assist corporates in shaping their decision-making process and marketing strategies. Moreover, the findings of the study provide valuable insights into consumers to improve their purchase decisions by pinpointing the advantages and disadvantages of critical product features through emotional clues.**

Keywords*—Emotion; emotion mining; semantic analysis; online reviews

I. Introduction

The proliferation of online review platforms has transmuted content publishing from corporates towards consumers [1]. The web offers highly scalable and accessible platforms to consumers for the creation and dissemination of Electronic Word-of-Mouth (EWOM) such as wikis, discussion forums, tweets, blogs, and online review websites. EWOM is a positive or negative statement about an object such as product, people, service, topic, organization, set by the potential, actual or former consumers which is available online to a vast audience [2]. Currently, consumers are connected globally to online platforms to express their emotions, evaluations, opinions, and judgments to a broad spectrum of individuals [3][4]. Therefore, fast-growing EWOM provides unstructured, trustworthy, and freely available valuable decision-oriented data that can address the diverse needs of corporates and consumers by providing insights into consumers' behaviour, and preferences[5][6][7].This powerful source of emotions leverages corporates in various business intelligence tasks, namely, sale prediction, risk analysis, enterprise strategies, and benchmarking. On the other hand, it assists consumers in their purchase decisions by highlighting the advantages and disadvantages of a target product [8][9].

Although there are many online platforms for consumers to express their opinions, evaluations, and emotions; however, online reviews are considered more credible and trustworthy [10]. Further, the characteristics of Web 2.0, such as scalability, accessibility, and enhanced users' participation, allow consumers all over the world to express their emotions by writing reviews that result in the explosive growth of online reviews [11]. The massive freely available online reviews present valuable insight into critical features of a target product that play an important role in consumers' purchases and business strategies [7][12][13]. Therefore, corporates are targeting consumers' online reviews from different sources for their decision-making process [14][15]. Major retailers' websites provide a star rating of a product and the helpfulness of the review such as amazon.com, ebay.com, and aliexpress.com. On the other hand, cnet.com presents the rating of a product and its prominent features. However, the emotions expressed by consumers are not considered and published by these websites. Further, it is difficult to extract consumers' emotions manually on critical features of a product due to the volume, distribution, length, structure, multidimensional data and dynamic nature of the online reviews[7][16].

Early efforts and attempts of opinion mining focused on the classification of online reviews into positive or negative opinion categories [17][18]. Later, online reviews are classified into fine-grained opinion categories [19][20][7]. However, the fine-grained opinion categories are unable to provide a perception of consumers' emotions. The classification of EWOM into emotion categories may provide an enhanced understanding of consumers' state of mind, evaluation, and judgment about a particular product. Further, limited attempts are also performed to provide fine-grained emotion classification of online reviews that provide a deeper understanding of consumers' opinions, sentiments, emotions, and evaluations about a target product or feature. However, the existing studies do not classify emotions into well-known and well-established basic psychological and biological emotions as there is a limited number of emotions that

are biologically and psychologically basic to human beings [21]. Further, consumers' emotions may change with time, that is, positive emotions change into negative emotions and vice versa as exhibited by Twitter data [22]. Existing studies [23][24]. are not reporting this temporal dynamism and volatility of consumers' emotions according to emotion categories that have an enormous impact on corporate and consumers' decision-making process. Therefore, it is vital to track this shift in the emotions of consumers of a particular feature or a product over time based on psychological and biological emotions, and the reason behind this change should be identified to make appropriate decisions. Consequently, there is a need to extract, classify, summarize, and track consumers' emotions according to basic psychological and biological emotions for corporate and consumer decision-making.

The aim of this work is to extract, classify, and summarize consumers' emotions expressed in online reviews, and to present the temporal dynamism and volatility of consumers' emotions according to well-established and widely used basic psychological and biological emotions [25] that impacts corporate planning and the consumers' decision-making process significantly. Specifically, the current study 1) classifies and summaries consumers' online reviews into binary and fine-grain classes according to the well-known psychological and biological emotions at the product level, 2) classifies and summaries consumers' online reviews into binary and fine-grain classes according to the well-known psychological and biological emotions at the feature level, 3) provides temporal dynamism and volatility of consumers' emotions according to psychological and biological emotions at the product level, and 4) provides temporal dynamism and volatility of consumers' emotions according to psychological and biological emotions at the feature level. A dataset consisting of real online reviews from amazon.com is used for the experimental purpose in this study.

This study has the following contributions:

- The classification of consumers' emotions into well-known six basic psychological and biological emotions categories: anger, fear, disgust, joy, surprise, and sadness defined by Ekman [25] is presented by the study.
- The study highlights six basic psychological and biological consumers' emotions for target products that show the strengths and weaknesses of target products reported by the actual users of products.
- The six basic psychological and biological consumers' emotions for prominent features of target products are also reported by the study that can play a decisive factor in the purchase decision of consumers.
- The temporal dynamism and volatility of six basic psychological and biological consumers' emotions are observed and presented by the study that is helpful to understand the change in consumers' emotions over time. The temporal dynamism of consumers' emotions is highlighted at two levels: product and feature in the study.

The rest of the paper is organized as follows: Existing emotion models and related work are reviewed in Section II. Section III discusses the proposed methodology. Section IV described the experimental results and discussion. Section V presents the research implications. Lastly, Section VI concludes the paper.

II. Literature Review

A. Emotion Models

Emotions are strong positive or negative motivational stimuli that comprise experiences such as love, hate, anger, joy, and grief. To study the emotions expressed by humans, various emotion models are presented in the literature of Psychology. And these emotion models are a critical component of emotion mining systems [26]. Therefore, this section reviews the state-of-the-art emotion models by focusing on key emotion categories and their associated descriptors. These descriptors play a crucial role in the measurement of emotions. Moreover, basic emotions are the motions having no other emotional constituent parts. Table I provides a summary of existing emotion models.

TABLE I. Existing Emotion Models

Reference	Basic Emotions
[27]	Anger, disgust, elation, fear, subjection, tender-emotion, wonder
[28]	Fear, love, rage
[29]	Anger, aversion, courage, dejection, desire, despair, fear, hate, hope, love, sadness
[30]	Pain, pleasure
[31]	Joy, Anguish, Fear, Anger, Disgust, Surprise, Interest, Shame
[25]	Joy, Sadness, Fear, Anger, Disgust, Surprise
[32]	Interest, joy, surprise, sadness, anger, disgust, contempt, self-hostility, fear, shame, shyness, guilt
[33]	Acceptance, anger, anticipation, disgust, joy, fear, sadness, surprise
[34]	Expectancy, fear, rage, panic
[35]	Happiness, sadness
[36]	Desire, happiness, interest, surprise, wonder, sorrow
[37]	Love, Joy, Surprise, Anger, Sadness, Fear
[31]	Anger, interest, contempt, disgust, distress, fear, joy, shame, surprise
[38]	Fear, Worry, Anger, Joy, Sadness, Discontent, loneliness, Peacefulness, Excitement, Optimism, Surprise, Shame, Guilt, Romantic Love, Love, Contentment, Envy
[39]	Fear, Anger, Enjoyment, Distress, Disgust, Surprise, Contempt
[40]	contentment, embarrassment, excitement, guilt, pride in achievement, relief, satisfaction, sensory pleasure, and shame

While researchers and psychologists have proposed various emotion models, however, Ekman's model [25] with six basic emotions is considered the most widely accepted and used model in computer science and natural language processing research areas [26][41][42][43]. This model presents six basic emotions: anger, fear, disgust, joy, surprise, and sadness. Later, Ekman expanded these basic emotions by introducing additional positive and negative emotion dimensions [40]. Due to widespread adoption and validation of Ekman's basic emotion model, the current study utilized this model to classify the

emotion expressed by consumers into the six basic emotion categories.

B. Related Work

Emotion mining has been explored in various contexts, including blogs [41], health [42], social media platforms like Facebook [43] and Twitter [44], news headlines [45] [46], online reviews [21], customer emails [47], and stock exchange [48]. These applications aim to extract and analyze emotions expressed by individuals or groups, providing valuable insights into human behavior and sentiment.

Significant work in the area of emotion classification is performed on Twitter data to analyze emotional content in tweets. Recently, [22] classified the public tweets into binary classes as well as into the basic emotions. Similarly, [49] exploited machine learning techniques for the classification of tweets in basic emotion categories. Further, the work analyzed the changes in emotions over time. Likewise, the artificial intelligence methods are utilized in [50] to analyze 73,000 public conversations on Twitter associated with the Corona pandemic using basic emotions proposed by [51]. [52] classified 9,000,000 tweets from a specific time frame into six moods: tension, anger, depression, vigor, confusion, and fatigue using the proposed profile of mood states method. On the other hand, [53] utilized hashtags of tweets as emotion labels for the classification of emotions expressed in tweets. A linear classifier is used to classify 2,500,000 tweets using hashtags as emotion labels into seven emotions: anger, joy, fear, love, sadness, thankfulness, and surprise. The comparison of manually labeled tweets and hashtags labels showed acceptable agreement. Further, the result of experiments conducted using different features like unigrams, bi-grams, POS tags, adjectives, and lexicons exhibited that unigrams, bi-grams, and POS tags provide the best emotion detection results. Moreover, the findings of the study suggested that the increased size of the training dataset has a direct impact on the accuracy of the classifier. In [54], the authors also used hashtags to classify a dataset of 134,000 tweets. They compared hashtags with manual tags assigned by two groups: a group of people and a group of psychologists. The findings of [53] [54] suggest that larger training datasets and features like uni-grams, bi-grams, and POS tags can improve emotion detection accuracy.

In the context of blogs, [55] [56] classified online diary entries into 1 of 40 moods of the writer using a support vector machine. Mood classification is considered similar to emotion classification; however, emotions are more intense in nature. The previous work was enhanced by [38] by capturing and aggregating the moods of writers from a large number of blog posts in a certain period. Similarly, [46] analyzed the emotional content in online news.

In [57], the authors identified emotion passages from the children's fairy tales dataset and then classified these emotions into positive and negative valence. The results from their linear classifier (Sparse Network of Winnows) are not very promising; however, their dataset is extensively utilized by the emotion mining community. Fine-grained classification of emotions from text is performed by [58]. In this work, the authors targeted the 600 notes of persons who committed suicide and predicted a label for each note from 15 emotions such as love, hopelessness, thankfulness, sorrow, and anger. Another work on fine-grained emotion classification of text is presented in [59]. The authors classified the emotions from a pre-defined emotion set that includes six emotions: Joy, Fear, Anger, Disgust, Sadness, and Surprise using a Vector Space Model [60].

In the context of consumers' emotions in online reviews, [61] explored the relationship between three emotion classes (positive, negative, and mixed emotions) with product attitude. On the other hand, [62] identified Plutchick's basic emotions [51] by using the NRC emotion lexicon in online movie reviews from IMDb. Unlike previous studies, [62] analyzed negative emotions in online reviews in a different perspective by exploring the association between two negative emotions (regret and frustration) with the helpfulness of review, reviewer rationality, and price fairness in online review and their empirical results confirmed a positive relationship between these negative emotions and helpfulness of review and price fairness, however, the positive impact of the negative emotions on reviewer rationality was not established. The authors in [47] focused on the customer care domain by identifying customers' emotional emails complaining about services or products to provide timely and pertinent responses to the sender of emotional emails in order to increase customer satisfaction and retention. They used the boosting method and performed experiments on 1077 customers' emails. Their method, based on salient features, outperforms the baseline method based on the unigram feature. [63] analyzed the correlation between helpfulness, unhelpfulness, rating, positive score, and the negative score of product reviews from amazon.com. The impact of the emotional score is not found to be significant on helpfulness in this study; however, a negative correlation is established between emotional score and rating. The emotional score is divided into positive and negative; positive emotion score (1 to 5), whereas negative emotion score (-1 to -5). The distribution of positive and negative scores over time is also highlighted in the study. In contrast, [64] found an association between emotional score and helpfulness of a review. The existing emotion models are not applied in this work for the extraction of emotions. Further, [65] classified emotions expressed in online reviews into positive, negative, and neutral categories. Also, [66] classified online reviews into positive, negative and neutral sentiment using machine learning techniques. Moreover, binary emotion classification is considered by [67][68]. On the other hand, in [69] [70], the authors focused on positive, negative, and neutral emotions. Different experiments were conducted to investigate the link between emotional expressions in reviews and their impact on product evaluation in [71]. [72] investigated the relationship between additional online reviews and sales volume. [21] presented the distribution of positive and negative emotions over time.

Extensive literature has been available targeting 'emotions' in various contexts, like Twitter, online news, and blogs. According to the best of our knowledge, little work has been conducted to extract fine-grained emotion classification according to well-known and widely used six basic psychological and biological emotions in the context of amazon.com at product and feature levels. Moreover, the temporal dynamism and volatility of consumers' emotions are

not tracked by existing work according to basic psychological and basic emotions. Therefore, the current work focuses on the extraction, classification, and tracking of basic psychological and biological emotions: anger, fear, disgust, joy, surprise, and sadness, proposed by [22] from online reviews of amazon.com.

III. Research Design

A. Research Framework

Let document D contain n reviews $R = [r_1, r_2, r_3, \ldots\ldots, r_n]$. Each review r_k is represented by a tuple having two elements: metadata (MD_{r_k}) and body (B_{r_k}) of the review (r_k). This study extended the tuple of [23]. This tuple is termed as the review tuple. The tuple is shown in Fig. 1 and is presented as follows:

$$r_k = [MD_{r_k}, B_{r_k}]$$

The metadata of the review (r_k) is decoded as MD_{r_k} and is comprised of a review rating ($Rating_{MD_{r_k}}$), review title ($Title_{MD_{r_k}}$) and date ($Date_{MD_{r_k}}$) whereas B_{r_k} signifies a set of sentences in r_k as shown below:

$$MD_{r_k} = [Rating_{MD_{r_k}}, Title_{MD_{r_k}}, Date_{MD_{r_k}}]$$

$$B_{r_k} = [S_1, S_2, S_3, \ldots, S_m]$$

$$\forall\, S_i \in B_{r_k}, S_i = [B_{r_k} S_i F_j, B_{r_k} S_i F_j ECat, B_{r_k} S_i F_j E_w, B_{r_k} S_i F_j E, B_{r_k} S_i Content]$$

Every sentence S_i in B_{r_k} encloses a feature ($B_{r_k} S_i F_j$), emotion category of emotion ($B_{r_k} S_i F_j ECat$), emotion word ($B_{r_k} S_i F_j E_w$), emotion expressed on F_j ($B_{r_k} S_i F_j E$) and contents of S_i ($B_{r_k} S_i Content$).

Every review (r_k) embodies a set of feature-emotion pairs (F_j, E_w). This pair includes a feature (F_j) and associated emotion word (E_w). Every feature F_j may have more than one associated E_w in document *D*.

The emotion expressed in the feature F_j in sentence S_i classified into two categories: positive ($B_{r_k} S_i F_j ECat^{Pos}$) or negative ($B_{r_k} S_i F_j ECat^{Neg}$). In other words, $B_{r_k} S_i F_j ECat$ is either positive or negative. $B_{r_k} S_i F_j ECat^{Pos}$ have two positive emotions: Joy ($B_{r_k} S_i F_j ECat^{Pos_Joy}$) and surprise ($B_{r_k} S_i F_j ECat^{Pos_Surpise}$). On the other hand, anger ($B_{r_k} S_i F_j ECat^{Neg_anger}$), fear ($B_{r_k} S_i F_j ECat^{Neg_Fear}$), disgust ($B_{r_k} S_i F_j ECat^{Neg_Disgust}$) and sad ($B_{r_k} S_i F_j ECat^{Neg_Sad}$) are negative emotions that belong to $B_{r_k} S_i F_j ECat^{Neg}$.

$$B_{r_k} S_i F_j ECat = [B_{r_k} S_i F_j ECat^{Neg}, B_{r_k} S_i F_j ECat^{Pos}]$$

$$B_{r_k} S_i F_j ECat^{Pos} = [B_{r_k} S_i F_j ECat^{Pos_Joy}, B_{r_k} S_i F_j ECat^{Pos_Surpise}]$$

$$B_{r_k} S_i F_j ECat^{Neg} = [B_{r_k} S_i F_j ECat^{Neg_anger}, B_{r_k} S_i F_j ECat^{Neg_Fear}, B_{r_k} S_i F_j ECat^{Neg_Disgust}, B_{r_k} S_i F_j ECat^{Neg_Sad}]$$

Table II illustrates the description of notations used in the proposed review tuple.

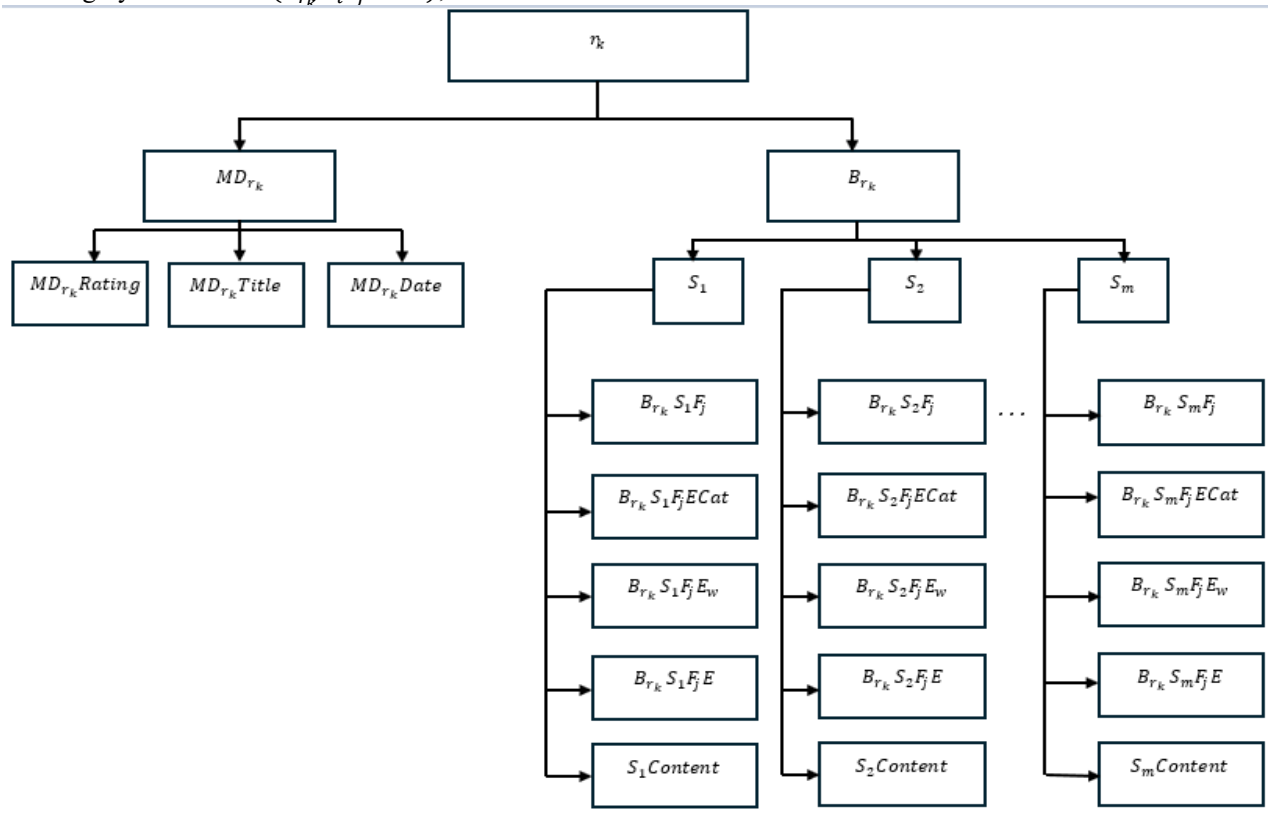

Fig. 1. Proposed tuple.

TABLE II. DESCRIPTION OF NOTATIONS

Notations	Description
D	Document having n product reviews
r_k	Review k
MD_{r_k}	Metadata of Review k
B_{r_k}	Body of Review k
$MD_{r_k}Rating$	Rating of Review k in the metadata of review
$MD_{r_k}Title$	Title of Review k in the metadata of review
$MD_{r_k}Date$	Date of Review k in the metadata of review
$B_{r_k}\ S_iF_j$	A product feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iF_jECat$	Emotion category (Positive/Negative) of emotion word E_w associated with feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iF_jE_w$	Emotion word E_w associated with feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iF_jE$	Emotion E associated with feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iContent$	The content of S_i in body of review k
$B_{r_k}\ S_iF_jECat^{Pos}$	Indicates emotion category of emotion word E_w associated with feature (F_j) in sentence S_i in body of review k is Positive
$B_{r_k}\ S_iF_jECat^{Neg}$	Indicates emotion category of emotion word E_w associated with feature (F_j) in sentence S_i in body of review k is Negative
$B_{r_k}\ S_iF_jECat^{Pos_Joy}$	Indicates Joy emotion expressed on with feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iF_jECat^{Pos_Surpise}$	Indicates Surprise emotion expressed on with feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iF_jECat^{Neg_anger}$	Indicates Anger emotion expressed on with feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iF_jECat^{Neg_Fear}$	Indicates Fear emotion expressed on with feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iF_jECat^{Neg_Disgust}$	Indicates Disgust emotion expressed on with feature (F_j) in sentence S_i in body of review k
$B_{r_k}\ S_iF_jECat^{Neg_Sad}$	Indicates Sad emotion expressed on with feature (F_j) in sentence S_i in body of review k

B. System Architecture

The architecture of the proposed system is discussed in this section. A system called Emotion Analyzer is developed in this work to provide fine-grained emotion classification at product and feature levels, and to track temporal dynamism and volatility of consumers' emotions. The system is comprised of four components: data preprocessor, feature and emotion extractor, emotion classifier, and emotion visualizer, as shown in Fig. 2 and discussed below.

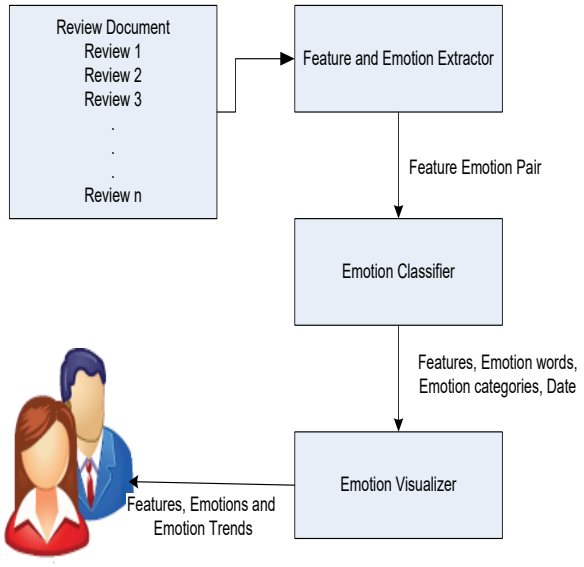

Fig. 2. Proposed system.

1) Data pre-processor: Data pre-processor performs a variety of operations to formulate document D containing n reviews for feature and emotion extraction. The following operations are performed by the component. Data processing is performed to increase classification accuracy.

- The symbols, special characters, and punctuations are removed from document *D*.
- Stop words are discarded from document *D*.
- The inflected or derived words are converted to their root form by utilizing Word stemming to enhance the efficiency and accuracy of mining.
- Spell checking is performed to eliminate noise from document *D*.
- Part-of-speech tagging is applied to label each word with its corresponding category, i.e., noun, verb, and adjective.

2) Feature and emotion extractor: Feature and emotion extractor identifies critical product features with their associated emotion words. The input to feature and emotion extractor is document D consisting of n reviews of a target product. A file containing all feature-emotion pairs is the output of feature and emotion extractor. In order to create this file, in the first step, the decisive features of a target product are extracted by the feature and emotion extractor. The candidate's features are derived from frequent nouns. All frequent nouns are obtained from document D and stored in a list called

Nounlist[]. Then, a weight is assigned to each noun in Nounlist [].

Existing literature presents a multitude of schemes for feature weight calculation, such as word frequency-inverse document frequency (TF-IDF), chi- square test, and information gain. However, among the aforementioned schemes, TF-IDF is regarded as the most ubiquitous and efficient scheme since it can reflect the importance of words within a collection of documents [79]. Therefore, the current work utilized and enhanced this scheme for feature weight calculation. The formula of TF-IDF utilized in the current study is shown in Eq. (1) – (3).

$$f_j f(f_j, r_k) = \frac{f_{f_j, r_k}}{\sum f_j' \in r_k f f_j', r_k} \quad (1)$$

$$idf(f_j, D) = Log\ (\frac{|R|}{n_{f_j}}) \quad (2)$$

$$f_j f.idf(f_j, r_k, D) = \frac{f_{f_j, r_k}}{\sum f_j' \in r_k f f_j', r_k} * Log\ (\frac{|R|}{n_{f_j}}) \quad (3)$$

In Equation 1, f_{f_j, r_k} is the number of times f_j occurs in r_k and is calculated using Eq. (4).

$$f_{f_j, r_k} = \sum_{i=1}^{n} Count\ f_j\ occurence\ in\ r_k \quad (4)$$

The denominator in Equation 1 shows the total number of features in r_k.

$|R|$ in Eq. (2) shows the total number of reviews in D. $n_{f_j} = |\{r_k \in D : f \in r_k\}|$: number of reviews in which the f_j appears where $\text{tf}(t, d) \neq 0$ and computed using equation below:

$$n_{f_j} = \sum_{i=1}^{n} [f_j Existin r_k = True] \quad (5)$$

Eq. (6) and (7) compute the weight of features by introducing a new variable into TF-IDF calculation, that is, the number of emotion words associated with f_j $(f_j E_w Count)$. The introduction of the new variable rests on the assumption that more emotions expressed toward a feature indicate frequent discussion of that feature, thus justifying a higher relative weight compared to other features.

Eq. (8) exhibits the computation of $f_j E_w Count$.

$$f_j W = f_j f.idf(f_j, r_k, D) + f_j E_w Count \quad (6)$$

$$f_j W = \frac{f_{F_j, r_k}}{\sum f_j' \in r_k f f_j', r_k} * Log\left(\frac{|R|}{n_{f_j}}\right) + f_j E_w Count \quad (7)$$

$$f_j E_w Count = \sum_{k=1}^{n} Count\ E_w assoiated\ with\ f_j(r_k) \quad (8)$$

Eq. (7) is used to compute the weight of a feature f_j. Nouns in NounList[] having $f_j W$ above a threshold α are considered as potential features as shown in Eq. (9).

$$F = [f_1, f_2, f_3, \ldots\ldots, f_n] \quad (9)$$

After this, E_w associated with each feature are extracted by exploiting a window-based approach in which E_w conversed within K words of f_j are selected as associated emotion words ($f_j E_w$). At the end, a feature emotion list is created that contains all features and associated emotion words as shown below:

If f_j is a feature in the F, then $f_j E_w = \{F_j E_{W_1}, F_j E_{W_2}, \ldots F_j E_{W_n}\}$. The feature-opinion pairs (FW) are stored in a ragged array represented below:

FW ∈ ℝ^{n × m_i} where $n = \sum_{-}\{x \in F\}$ 1 and m_i is the number of column in i[th] row.

3) Emotion classifier: The task of emotion classification is performed by the emotion classifier. The input to the emotion classifier is FW and the output is the classification of emotions. Extensive emotion mining systems rely on emotion lexicon (dictionary-based approach) for the classification of emotions, and some emotion lexicons are available in the literature for the classification of emotions, such as Wordnet Affect [74]. The Linguistic Inquiry and Word Count (LIWC) [75], NRC emotion lexicon [76], Clean Balanced Emotional Tweets (CBET)[76] [77]. Recently, [78] utilizes the NRC lexicon to classify public tweets into the emotion categories of Ekman. Therefore, the current study also utilized the NRC emotion lexicon [73].

Given the feature-emotion pairs FW, the emotion classification function f classifies $F_i W_j$ to an emotion category e_k using lexicon L.

Formally, f can be defined as:

$$f \triangleq (FW_{ij}, L) \mapsto L(e_{ij}) = e_k$$

where,

$$FW_{ij} = \left(f_i, E_{W_j}\right) \in FW, E_{W_j} \in E_w, L\left(E_{W_j}\right) = e_k \in E$$

$$FW_{ij} \subseteq F \times E_w$$

L ∈ ℝ^(n×m), where n is the number of words in the lexicon and m is the number of emotion categories.

$E = \{e_1, e_2, e_3, e_4, e_5, e_6\}$ where e_1 =Joy, e_2 =surprise, e_3=anger, e_4=fear, e_5=disgust, e_6=sad.

In other words,

f: $FW_{ij} \rightarrow$ E, where $g(E_w) = \text{argmax_e} \in E\ (P(e|E_w))$, and $P(e|E_w)$ is the probability of emotion e given the word E_w

The classified emotions are aggregated at the feature using the following equations:

$$Countf_j e_1 = \sum_{r=1}^{m} \sum_{i=1}^{sentence(r)} [S_i\ f_j E_w = e_1]$$

$$Countf_j e_2 = \sum_{r=1}^{m} \sum_{i=1}^{sentence(r)} [S_i\ f_j E_w = e_2]$$

$$Countf_j e_3 = \sum_{r=1}^{m} \sum_{i=1}^{sentence(r)} [S_i\ f_j E_w = e_3]$$

$$Countf_j e_4 = \sum_{r=1}^{m} \sum_{i=1}^{sentence(r)} [S_i\ f_j E_w = e_4]$$

$$Countf_j e_5 = \sum_{r=1}^{m} \sum_{i=1}^{sentence(r)} [S_i f_j E_w = e_5]$$

$$Countf_j e_6 = \sum_{r=1}^{m} \sum_{i=1}^{sentence(r)} [S_i f_j E_w = e_6]$$

The classified emotions are then aggregated at the feature and product levels using the following equations:

Feature-level aggregation: F_e = ∑_{w∈W} P(e|w) / |W|

Product-level aggregation: P_e = ∑_{f∈F} F_e / |F|

where, F_e is the feature-level emotion score, P_e is the product-level emotion score, and |W| and |F| are the number of words and features, respectively.

The emotion classifier provides a file to the emotion visualizer that consists of a list of features, associated emotion words, emotion categories, and the date on which this emotion category was expressed by the consumer. This can be represented as a tuple (F, W, E, D), where F is the set of features, W is the set of emotion words, E is the set of emotion categories, and D is the set of dates.

4) Emotion visualizer: The visual summary of consumers' basic biological and psychological emotions is presented by the emotion visualizer. It utilizes two types of visualizations: bar charts and line graphs to display emotions expressed in online reviews. A bar chart visualization is used to present the classification and summarization of consumers' biological and psychological emotions at product and feature levels. To display the temporal and volatility of reviews, a line graph visualization is utilized by the emotion visualizer. It takes the file containing features, emotion words, and emotion categories from the emotion classifier and aggregates these emotions according to the emotion categories at the product and feature levels. Then, it plots the temporal dynamism and volatility of emotions using a line graph.

IV. Experimental Dataset, Results, and Discussion

This section presents the details of the experimental dataset, the results of experiments performed on the experimental dataset, and a discussion of the results.

A. Experimental Dataset

The proposed system is evaluated on online reviews from amazon.com. This dataset was used by many studies, including [23][7][73][80]. The data set contains consumers' reviews of five diverse digital products: two digital cameras (Canon G3 and Nikon Coolpix 4300), one mobile phone (Nokia 6610), one MP3 player (Creative LabsNomad Jukebox Zen Xtra 40GB), and one DVD player (Apex AD2600 Progressive-scan DVD player). However, the date metadata of the reviews is not available in this dataset. The authors added the metadata to the dataset.

B. Experimental Results and Discussion

This section presents the aggregated consumers' emotions at product and feature levels, along with the change in the consumers' emotions over time.

1) Consumers' emotion categories at the product level: The results of fine-grained and binary emotion classifications of the Canon G3 camera at the product level are presented in this section. Fig. 3 shows the fine-grained consumers' basic emotions classification of the Canon G3 Camera. The joy emotion is in the first position, having a value of 157, as consumers expressed the Joy emotion more compared to other emotions. Joy is considered a positive emotion; therefore, it can be inferred that consumers enjoyed the use of the Canon G3 camera. The anger emotion is in second position with a value of 102 which is less than the value of joy emotion depicting the consumers' dissatisfaction. Consequently, consumers also expressed other negative emotions: sadness, fear, and disgust with the values of 89, 80, and 50, respectively. In contrast, some consumers defined Canon G3 with surprise emotion (81 value). It can be concluded from Fig. 3 that most consumers are happy with the camera as the frequency of Joy is very high compared to other emotions. Fig. 4 represents the binary emotion classification of the Canon G3 camera presenting that consumers are not satisfied with the camera as they expressed negative emotions (anger, fear, disgust, and sadness) more than positive emotions (joy and surprise).

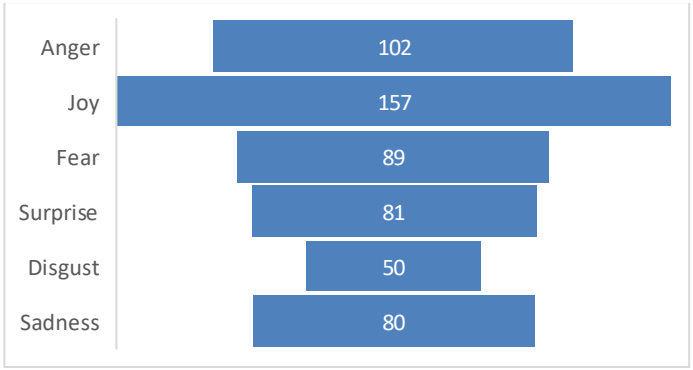

Fig. 3. Basic consumers' emotions on the Canon G3 camera.

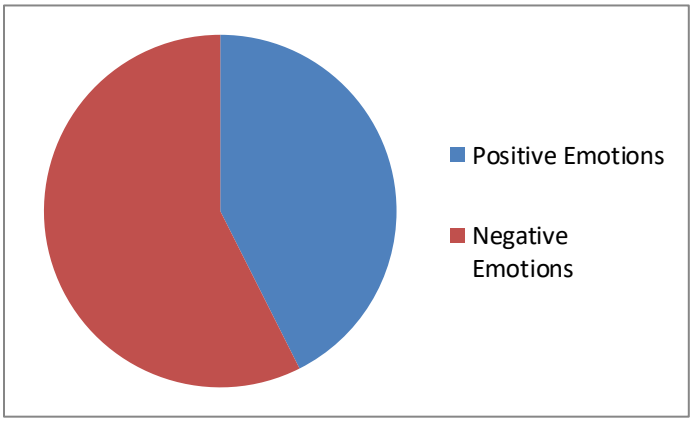

Fig. 4. Binary emotion classification of Canon G3 Camera.

2) Consumers' emotion categories at feature level: This section presents the basic consumers' emotions at the feature level. Due to the space limitations, we are presenting the fine-grained emotions classification of the top three features

(Camera, Picture, and Use) of the Canon G3 Camera (Fig. 5). Consumers expressed all emotions only through the camera feature. Disgust emotion is not mentioned by consumers for the picture and use features, highlighting that consumers like the picture and the use features of the camera. Moreover, only positive emotions (joy and surprise) are described by consumers for the use feature, showing the appreciation by the consumers towards the use of the camera. Further, it can be concluded that the camera is easy to use. All of these features are discussed using joy emotion remarkably as compared to other emotions. In other words, consumers are satisfied with these features tremendously. Specifically, for the camera, the highest discussed emotion is joy, with the highest value of 23 showing the endorsement of the camera by consumers. A few consumers are angry about the camera as shown by the value (4) of angry emotion. Also, other emotions (fear, surprise, disgust and sadness) are discussed by fewer consumers as indicated by a value of 3 for all features. Similarly, consumers exhibited mixed emotions (anger, surprise, and sadness) for the picture feature in a very small frequency of 3.

The binary emotion classification of the top three features is depicted in Fig. 6. All of these features received more positive emotions than negative emotions. The use feature received only positive emotions.

3) Temporal dynamism and volatility of consumers' emotions at the product level: This section describes the temporal dynamism and volatility of consumers' basic emotions are product level. Fig. 7 exhibited the temporal dynamism and volatility of consumers' emotions at product level. Consumers expressed all basic emotions from Q1 to Q4. More emotions are expressed in Q1 as shown by the values of anger, joy, fear, surprise, disgust, and sadness. On the other hand, fewer emotions are expressed in other quarters of the year. Fig. 8 shows the temporal dynamism and volatility of consumers' emotions at product level over a period of one year. In the month of March, the joy emotions are expressed more by the consumers. It is also interesting to note that at the starting month, consumers described the Canon G3 camera with joy and emotion.

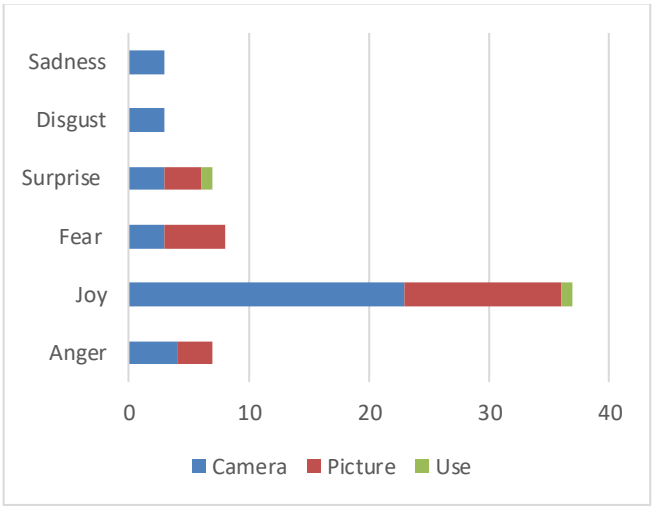

Fig. 5. Basic consumers' emotions at the feature level.

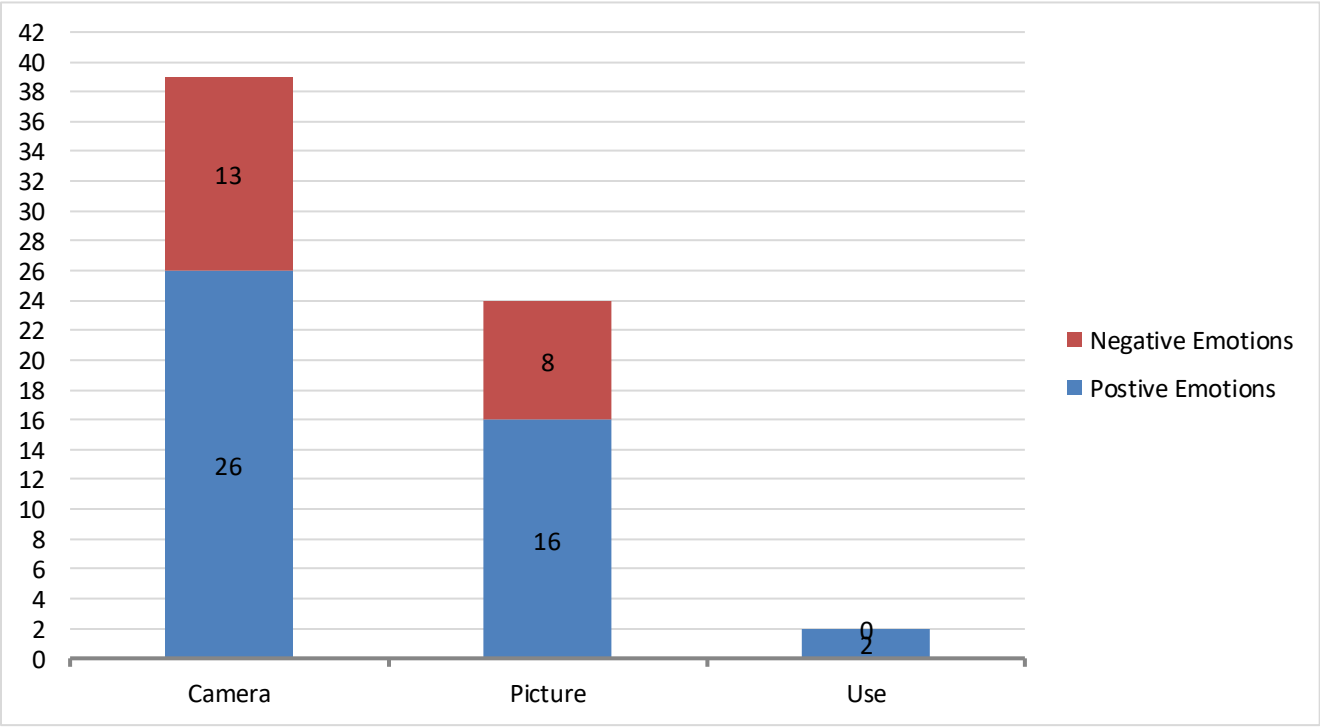

Fig. 6. Binary classification of the top three features.

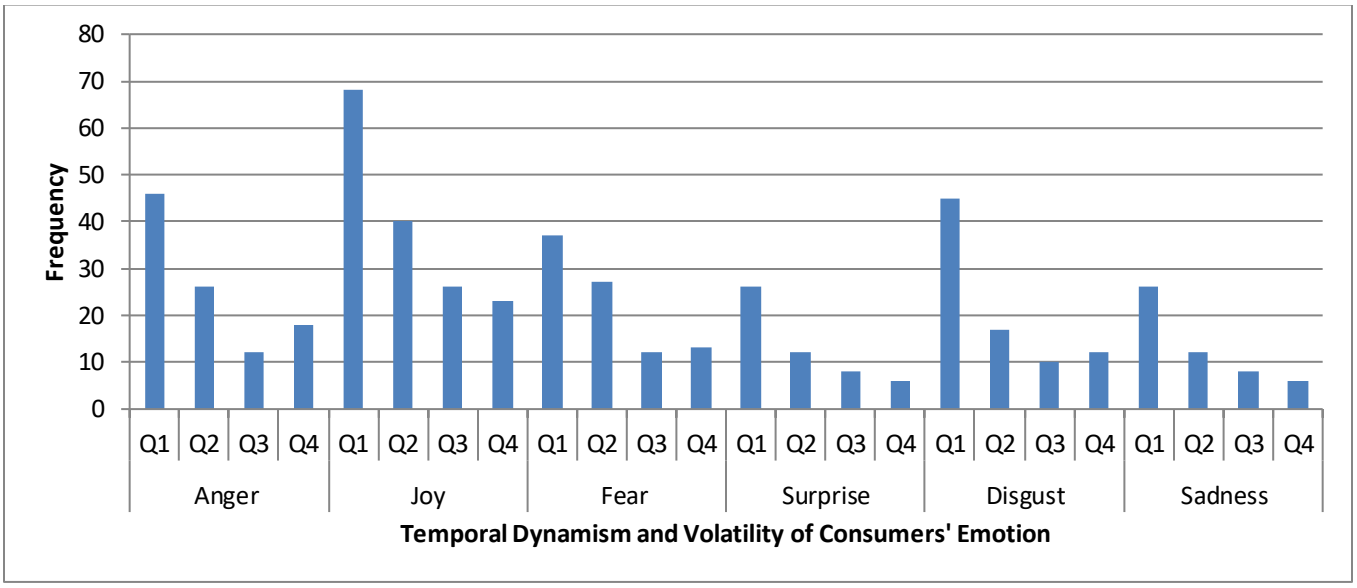

Fig. 7. Temporal dynamism and volatility of basic consumers' emotions at the product level.

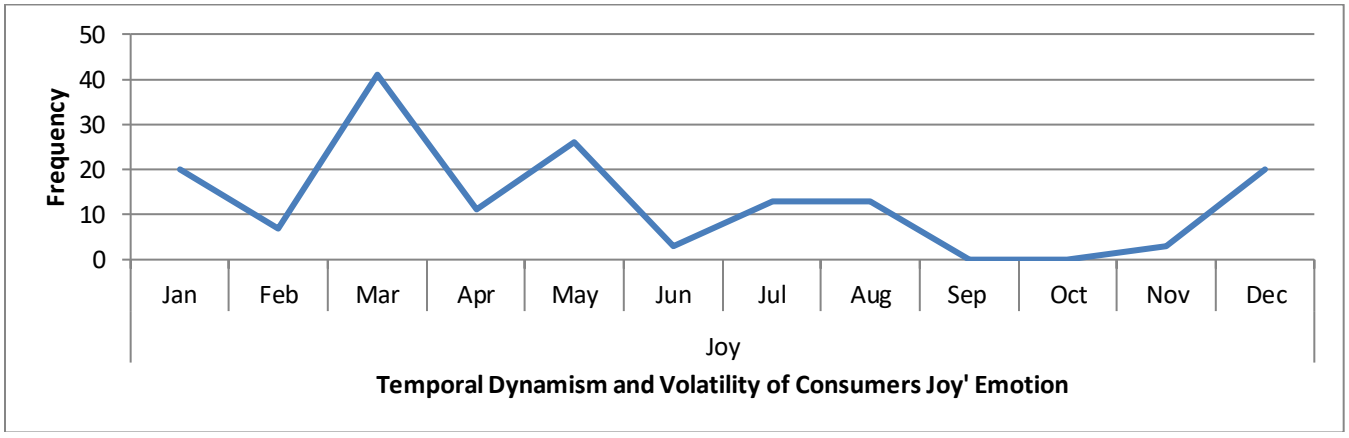

Fig. 8. Temporal dynamism and volatility of joy emotion at the product level.

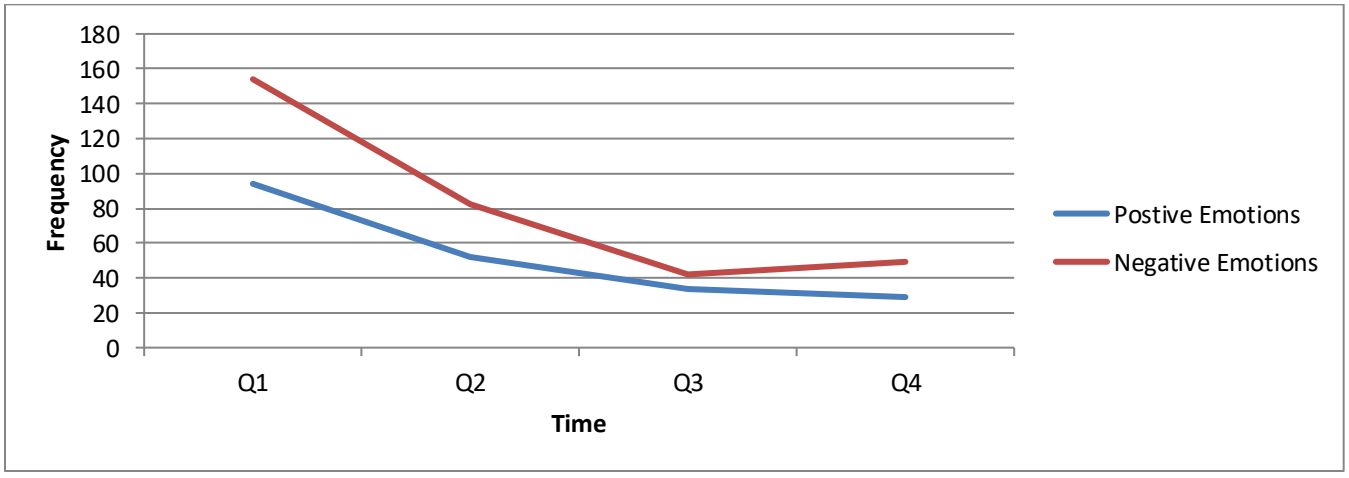

Fig. 9. Temporal dynamism and volatility of binary consumers' emotions at the product level.

Fig. 9 describes the temporal dynamism and volatility of binary consumers' emotions at the product level. It is important to note that more negative emotions are expressed in all quarters of the year as compared to positive emotions. Therefore, it shows the consumers' dissatisfaction with the camera. There is a decreasing trend in both positive and negative emotions

expression. However, in Q1 and Q2, consumers are more expressive than in the other quarters of the year (Q3 and Q4).

4) Temporal dynamism and volatility of consumers' emotions at the feature level: Fig. 10 exhibited the temporal dynamism and volatility of consumers' emotions at the feature level. It can be seen from the figure that the picture feature is discussed only in Q1. Therefore, it can be concluded that with the launch of the camera, the consumers expressed more emotions on prominent features like picture, battery, etc. However, with time, the focus of consumers' emotions is shifted to some less critical features.

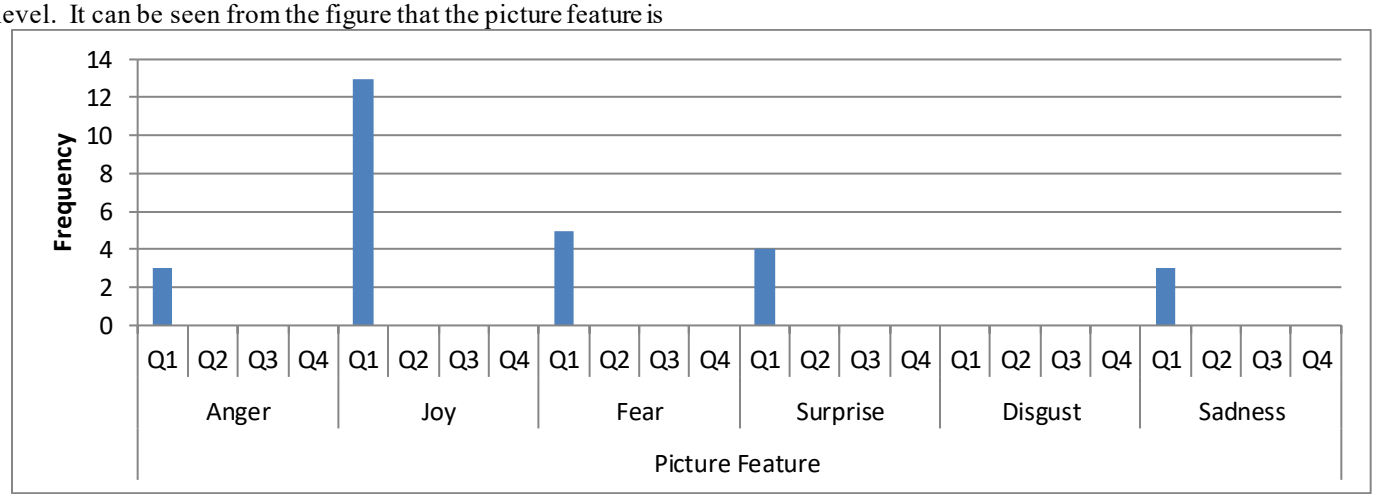

Fig. 10. Temporal dynamism and volatility of basic consumers' emotions at the feature level.

V. Research Implications

A. Business Perspective

The implications of expected results from a business perspective are for corporate decision-makers. First, it aids corporate decision-makers to improve their products and services based on the negative EWOM consumers. Second, the critical product features (the features having a great impact on sales) can be identified and can be targeted in future decision-making. Thirdly, the critical identified features can be focused on in new product development to enhance future sales. Fourthly, the result employing positive EWOM can be utilized for the reputation management of the organization to attract more consumers. Further, new product advertisements having positive feedback from consumers may result in increased consumer loyalty and trust, along with new consumers. Lastly, the marketing strategies can be designed based on expected results to attain consumers' attention and retention.

B. Consumers' Perspective

From the consumers' perspective, the results can be exploited in two different ways. First, the results will highlight the relative strengths and weaknesses of the target product (s) on a deeper (fine-grained) level that facilitates consumers' decision-making process. Moreover, the outcomes will depict the true emotions, evaluations, opinions, and judgments of consumers without any bias, as the EWOM posed no constraints on free expression. Consequently, the outcomes support consumers in their purchase and product adoption decisions.

VI. Conclusion, Limitations, and Future Directions

EWOM is remarkably and consistently increasing due to the active participation of consumers over different online forums, including online reviews. However, EWOM is unable to present consumers' emotions on different products and services. Specifically, basic biological and psychological emotions need to be extracted, summarized, and visualized from EWOM to empower consumers and enterprises to make informed decisions. Therefore, this research presents emotion categories and the temporal dynamism of emotion expressed in online reviews. The study extracted, summarized, and presented six basic emotion categories: anger, fear, disgust, joy, surprise, and sadness of well-known emotion model. Joy emotion is expressed more by the consumers in the online reviews of the Canon G3 camera published on amazon.com, indicating the satisfaction of the consumers towards the camera. A few consumers criticize the picture feature of the camera by describing it with negative emotions (sadness, anger, and fear). The proposed system has some potential limitations. First, it is evaluated on 332 reviews of electronic products. Second, the reviews are from amazon.com. The future direction of work includes the analysis of the proposed system by using a large number of reviews. Further, the proposed system can be utilized to analyze online reviews from different domains, like movie reviews and hotel reviews.

Funding

This work was funded by the Deanship of Scientific Research (DSR), University of Jeddah, Jeddah, under grant No. UJ-02-074-DR. The authors, therefore, acknowledge with thanks DSR's technical and financial support.

Abstract*—Customer segmentation plays a critical role in retail analytics by enabling personalized marketing, optimized resource allocation, and data-driven strategic decision-making. However, customer data is often distributed across multiple retail branches and contains sensitive transactional information, creating significant challenges related to privacy preservation, regulatory compliance, and model interpretability. Traditional segmentation approaches, including clustering algorithms and centralized deep learning methods, typically require aggregated data storage, which increases privacy risks and limits secure deployment in distributed retail environments. In addition, many existing methods fail to capture complex relational patterns such as co-purchasing behavior and inter-customer structural dependencies. To address these limitations, this study proposes FedGraph-DEA, a novel hybrid framework integrating federated learning, graph neural networks (GNNs), and Data Envelopment Analysis (DEA) for privacy-preserving and efficiency-aware customer segmentation. The framework first employs Distributed Federated Convolutional Autoencoders to extract latent customer representations from decentralized retail datasets. Similarity graphs are then constructed locally, followed by federated GNN-based community detection to identify structurally coherent customer groups without sharing raw data. Finally, DEA is applied to evaluate the operational efficiency of the discovered customer segments. Experimental evaluation was conducted using the UCI Online Retail dataset partitioned across five simulated non-IID client nodes. The proposed model achieved 96.1% accuracy, 0.95 precision, 0.96 recall, and 0.95 F1-score when compared with pseudo-ground-truth clusters generated through K-Means reference clustering. Furthermore, the framework obtained a silhouette score of 0.74 and a modularity value of 0.57, demonstrating strong cluster compactness and structural separation. The proposed system provides a scalable, interpretable, and privacy-preserving solution for distributed retail analytics.

Keywords*—Customer segmentation; federated learning; graph neural networks; data envelopment analysis; privacy preservation

I. Introduction

In today's digital economy, customer segmentation is generally recognized as a pillar of data-driven decision-making and marketing [1], [2]. By segmenting customers into substantive groups, companies can tailor services to individuals, improve resource usage, and create targeted campaigns [3]. Nevertheless, with the exponential growth of online transactions and widespread sensitive customer data proliferation [4], privacy-enhancing and explainable methods for segmentation have become ever more important [5]. Regulatory protocols like GDPR and HIPAA mandate rigorous adherence to privacy principles, as businesses at the same time seek transparent and actionable information from their analytics platforms [6]. Conventional centralized approaches leave organizations vulnerable to data leakage, breaches, and regulatory non-compliance, and thus, there is a need for paradigms of federated learning [7]. Of equal significance is interpretability, as stakeholders and managers must not only know what segments exist but also the reason why those segments are effective and worthwhile [8]. In this context, privacy-preserving interpretable customer segmentation has become a salient area of attention in academia and the industry alike, filling the gap between secure distributed learning and decision-driven insights [9].

Previous approaches to customer segmentation have primarily utilized statistical clustering algorithms like K-Means, DBSCAN [10], [11], and hierarchical clustering, or machine learning classifiers like Random Forests and XGBoost [12], [13]. Although these approaches provide computational ease, the models tend to lack flexibility in accommodating high-dimensional transactional data and are not robust in distributed settings [14]. In addition, the model tends to need centralized data collation, which presents privacy threats in areas like finance, healthcare, and e-commerce [15]. Autoencoders based on deep learning have also recently been considered for extracting latent behavior features; however, without federated approaches, the models still need to pool raw data at a central server[16]. In terms of interpretability, clustering and classification methods usually return black-box outputs, providing decision-makers with little understanding of the efficiency or strategic importance of the segmented findings [17]. Therefore, current frameworks fail to meet the two-pronged challenge: protecting sensitive customer information in decentralized ecosystems and returning interpretable, transparent results for managers [18], [19].

The FedGraph-DEA model plan creates a customer segmentation framework that is privacy-protected and interpretable, and is designed to work in a distributed retail-

setting. DFCA is used to learn high-quality latent behavioral representations using transactional data that is decentralized without the exchange of raw information. These similarity embeddings are organized into customer similarity graphs in order to obtain co-purchase dependencies and multi-hop relational patterns. With the help of Federated Graph Neural Networks (GNNs), the recognition of coherent communities of customers in non-IID data distributions is then realized. Lastly, Data Envelopment Analysis (DEA) measures the operational efficiency of every segment, which allows for actionable performance-based and interpretable segmentation results by managers.

A. Research Motivation

The rise of the distributed retail systems has escalated the necessity of customer segmentation strategies that adequately protect data privacy and yet express intricate behavioral relationships [20]. Conventional centralized systems reveal sensitive customer data and do not represent relational relationships like co-purchase behavior. Simultaneously, the existing models are usually not interpretable, which constrains their applicability in managerial decision-making. The rationale behind this research is to come up with a single framework, which is able to take care of privacy preservation, relational intelligence, and transparency, so as to institute the correct and practical customer segmentation in the retail settings where data is sensitive and decentralized.

B. Research Significance

This research is significant because it attempts to fill vital shortcomings of current customer segmentation methods by combining the concepts of privacy protection, relational modelling, and interpretability under a single system. Contrary to the old-fashioned approaches, it provides a secure data processing in distributed contexts, as well as, the transformation of intricate customer interactions and offers efficiency-related insights to make a decision. The research has also helped the academic research as well as practical applications through facilitating scalable, transparent, and performance-driven analytics. It can be applied to privacy sensitive areas, like store, finance and healthcare where data analysis requires the use of secure and readable data.

C. Problem Statement

There are several limitations associated with the current techniques of customer segmentation in a distributed retail setting. Firstly, current traditional approaches of customer segmentation tend to aggregate private and sensitive information about customers, exposing the system to higher risks of data leaks and non-conformity with relevant regulations [21]. Finally, the majority of current models used for customer segmentation have no interpretability; consequently, they provide little information about the factors that affect customer segmentation [22]. In spite of the attempts by modern researchers to introduce federated learning models to address privacy and relational intelligence challenges [23], interpretability and efficiency-based assessment of customer segments remain underestimated aspects. Thus, the development of a unified approach to customer segmentation seems to be essential.

D. Key Contribution

Introduced a customer segmentation algorithm that maintains customer privacy to solve the problem of data confidentiality, scalability, and distributed retail environment constraints as well as performs behavioral representation learning without any data aggregation in the centralized setting.

Provides the use of DEA as an additional post-segmentation evaluation tool to measure the efficiency of the graph-based customer communities formed based on operational efficiency.

Proposes a privacy-preserving federated similarity graph formation mechanism to capture multi-hop dependency among the customers' behavior patterns in non-IID distributed learning environment without sharing raw customer data among the retailers.

Combines Federated Graph Neural Network methods with Distributed Federated Convolutional Autoencoder (DFCA), allowing joint modeling of compressed behaviors and relations in the decentralized retail setting demonstrates that the combined DFCA + Federated GNN + DEA framework improves segmentation quality, clustering coherence, and interpretability compared to conventional centralized and federated baseline models.

The research is presented in the following structure: Existing studies are presented in Section II. Section III covers problems with the existing study. The suggested methodology is presented in Section IV. Section V includes the results and a discussion of this research. Conclusions and future works are covered in Section VI.

II. Related Work

Le et al. in [24] presents PersonalFR, a personalized federated recommender system that utilizes autoencoder-based models to learn user-item interactions without revealing raw data. The local updating of encoders and aggregation of decoders on the server side maintains data privacy. The experiments on real-world datasets show that PersonalFR offers performance close to centralized models and with lower communication overhead. The non-interpretability of the autoencoder's latent features also restricts the explainability of the segmentation outcomes. J. M. John, O. Shobayo, and B. Ogunleye in [25] compares different clustering algorithms—K-means, Gaussian Mixture Models (GMM), DBSCAN, Agglomerative Clustering, and BIRCH—on a UK-based online retail dataset with more than 500,000 records. Based on the RFM (Recency, Frequency, and Monetary) framework, the study seeks to improve decision-making in the retail industry. Nonetheless, the use of centralized data processing in the study creates data privacy and scalability issues. M. Alves Gomes and T. Meisen in [26] evaluates the 105 publications published between 2000 and 2022. The four stages of the process that are identified in the work are data collection, customer representation, segmentation, and targeting. The integration of sophisticated approaches such as PCA and SOMs is also described in the review.

Wang in [27] investigates the coupling of deep learning models, customer segmentation, online marketing, and swarm

intelligence algorithm models. The synergy aims at maximizing the performance of the clustering by the global search capability of swarm intelligence. The study does not address the problem of data heterogeneity in distributed environments. In addition, the interpretability of the resulting customer segments is constrained, as well as integration with efficiency assessment frameworks.

A. Sharma, N. Patel, and R. Gupta in [28] investigates the convergence of deep learning methods with predictive analytics to enhance customer segmentation techniques. Through the use of neural networks to examine intricate customer data, the study seeks to reveal subtle behavioral patterns that may be missed by conventional methods. Nevertheless, the study admits difficulties in model interpretability and the necessity for large computational resources, which could restrict its usage for smaller businesses or companies with limited technical infrastructure. Y. Long et al.,[29] Presented a federated deep clustering method for retail customer segmentation, integrating local autoencoders with a central K-means clustering model. Using federated learning, their model ensured customer data privacy across different branches while maintaining an overall segmentation accuracy of around 88%. But the study was not concerned with the evaluation of the resulting clusters in terms of operational efficiency or business value, which curtails its applicability in strategic decision-making. Contrarily, the current FCA–DEA framework not only improves privacy via federated training but also encompasses a DEA-based layer to evaluate and rank customer segments, which fills the gap between high-performance clustering and business interpretability in real-world scenarios.

P. Hu et al., [30] proposed a federated CNNs-based privacy-aware clustering model to partition customer data scattered over multiple retail stores. Their approach effectively circumvented raw data centralization and had a clustering accuracy of approximately 90%, which proved the feasibility of federated deep learning for customer analytics. However, the approach did not incorporate an interpretability function to justify the relevance of the clusters and provided no facility for benchmarking the operating efficiency of every segment. This limitation justifies the necessity for hybrid models such as the FCA–DEA framework, which pairs federated unsupervised learning with a post-segmentation DEA module for clear and actionable efficiency assessment.

Y. Jiang et al., [31] introduced federated VAE to use in distributed customers profiling in the retail industry. At their current stage their approach employed VAEs in order to elicit non-linear latent representations of customer purchasing tendency subject to privacy-respecting constraints with a reconstruction precision of approximately 92.1%. Although the model has shown robust features learning without focusing sensitive data, still, it did not consider the problem of making sense of the latent features to apply business results, as well as assessing the relative efficiency of the generated groups of customers. In comparison, the suggested FCA-DEA framework integrates deep representation learning with operational efficiency ranking of DEA so that businesses could translate latent features into plain, usable forms in terms of resource optimization and targeted marketing.

Based on the reviewed literature, it can be seen that past research either concentrated on centralized clustering and deep learning processes, which ignore privacy, or federated models, which do not analyze interpretability or operational efficiency. The graph-based model, though effective in depicting feature interaction still uses centralized access to data. The FedGraph-DEA framework will overcome such shortcomings by combining federated autoencoders to learn decentralized representations, graph neural networks to detect communities, and data envelopment analysis to identify the efficiency of the model. This is a hybrid design that provides secure learning, increased segmentation accuracy, and transparent decision support, something that previous models did not have.

III. FedGraph-DEA Framework for Customer Segmentation

The FedGraph-DEA method employs the concept of a single pipeline that combines decentralization representation learning, graph-based feature interaction model, and efficiency-based interpretability. Every client node separately trains a Distributed Federated Convolutional Autoencoder (DFCA) to learn the customer latent embeddings without having access to raw data. These embeddings are then used to create a customer similarity graph based on a cosine affinity. The graph establishes the connectivity of the nodes and is enhanced using federated Graph Neural Network (GNN), which reflects on multi hop customer relations through federated weight aggregation across distributed subgraphs. Communities that are formed as a result are customer segments. These segments are then measured by Data Envelopment Analysis (DEA) wherein each of the segments is considered as a decision-making unit and the evaluation is done in terms of business efficiency by considering the marketing inputs and profit-related outputs. DFCA induced graph formation, GNN-based segmentation and DEA-based evaluation are new to interact. FedGraph-DEA is the only method where privacy preservation, relational intelligence, and interpretable efficiency assessment are integrated into a single framework in contrast to the current federated clustering, federated GNN, or single method of standalone DEA. Fig. 1 shows the overall workflow.

The innovation introduced by the FedGraph-DEA model is its comprehensive integration of three distinct yet complementary approaches in one privacy-preserving segmentation architecture for distributed retailers. In contrast to the traditional federated clustering models that concentrate exclusively on privacy-preserving capabilities, this new model is capable of analyzing higher-order customer relations with the aid of graph neural networks while concurrently measuring the efficiency of their operations with DEA.

The principal novelty of this methodology lies in the unified integration of federated representation learning, graph-based relational modeling, and efficiency-driven evaluation within a single decentralized analytical framework. Unlike conventional customer segmentation approaches that rely on centralized data aggregation and purely distance-based clustering, this architecture enables privacy-preserving latent feature extraction through federated convolutional autoencoders while simultaneously capturing higher-order behavioral dependencies via graph neural networks. The

transformation of learned embeddings into customer similarity graphs allows structural and multi-hop relationships to be incorporated into segmentation, addressing limitations of attribute-only models. Furthermore, the incorporation of Data Envelopment Analysis introduces an operational efficiency perspective that links discovered segments to measurable input–output performance metrics, enhancing managerial interpretability. This synergistic combination of privacy preservation, relational intelligence, and efficiency-based interpretability constitutes a novel contribution to distributed customer analytics research.

Fig. 1 illustrates the FedGraph-DEA approach for customer segmentation under the privacy-preserving setting. First, the UCI Online Retail dataset is considered, then the preprocessing phase involves data cleaning, normalization, and feature engineering. The next layers, known as federated learning, employ distributed autoencoder methods and secure aggregation to learn the latent space representation without sharing data. Using the embeddings, a graph structure can be built, which is utilized by federated graph neural networks for community detection. Finally, DEA is employed to analyze efficiency.

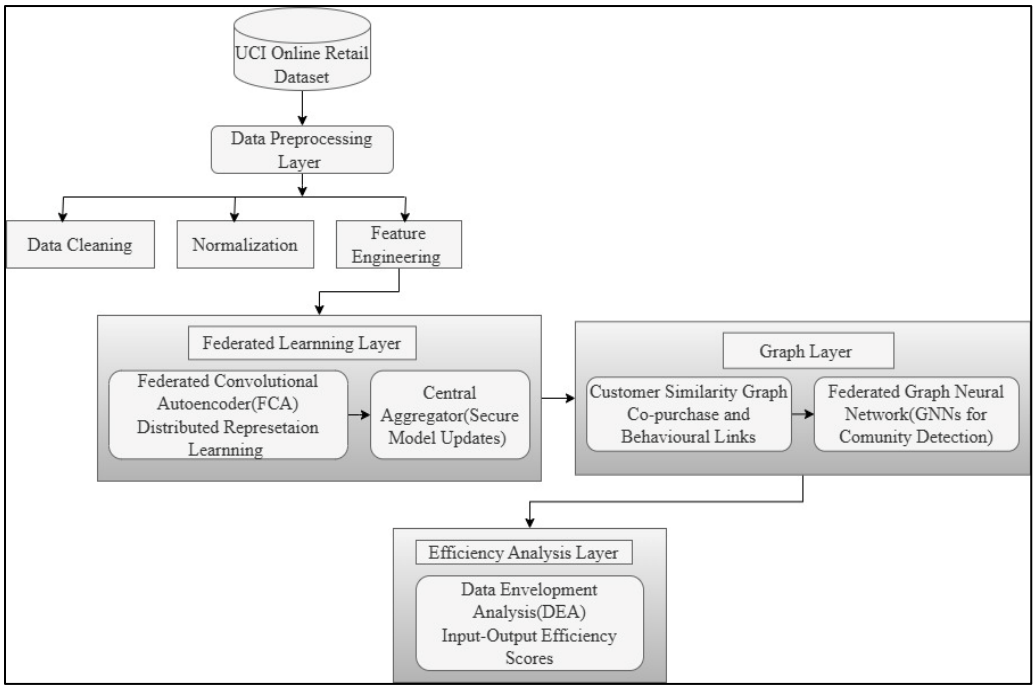

Fig. 1. Privacy-preserving federated graph-based customer segmentation workflow.

A. Data Collection

UCI Online Retail is an online retail dataset that entailed in excess of 500,000 transaction records in various nations in the 2010-2011 [32]. It stores specific buying behavior such as invoices, product characteristics, amount, costs, time values, customer names, and addresses. It is appropriate in terms of customer segmentation, federated learning, privacy-preserving analytics, and RFM behavioral modeling for distributed retail operations due to its heterogeneity and realistic nature. In the case of federated simulation, the database was split among five clients according to the country attribute for transactions, thus leading to naturally non-IID distributions, as buying habits and preferences vary greatly depending on location. This division allows the creation of distinct local databases for each client in an actual federated manner without the need for more than one data source physically.

Table I illustrates five sample transactions showing product codes, descriptions, quantities, and prices, demonstrating the dataset's structure and how individual purchase records form the basis for feature engineering and segmentation.

TABLE I. SAMPLE TRANSACTION RECORDS FROM THE UCI ONLINE RETAIL DATASET

Invoice No	Stock Code	Description	Quantity	Unit Price
536365	85123A	White Mug	6	2.55
536366	71053	Floral Notebook	3	4.95
536367	84406B	Pink Hanging Bag	2	6.95
536368	84029G	Heart Decoration	8	1.25
536369	22960	Jam Making Set	1	11.95

B. Data Preprocessing

Customer segmentation requires strict data preprocessing as it converts raw transactions into processed and meaningful patterns of customer behavior. This is essential in eliminating noise, ensuring data quality, and facilitating proper, reliable segmentation analysis.

1) Data cleaning: Missing Customer IDs will be removed and negative values will be deleted because that means returns or cancellations rather than purchases. Data integrity is ensured by discarding duplicate invoices. The resulting set of data only contains valid and applicable transactions.

2) Feature engineering: The highly set Recency-Frequency-Monetary (RFM) is used to extract customer-level behavioral attributes. The Eq. (1) and Eq. (2) define the calculations performed for each customer i,

$$R_i = t_{ref} - t_{last\ purch,i} \quad (1)$$

$$M_i = \sum_{j=1}^{n_i} p_{i,j} \quad (2)$$

where, R_i represents the period of time since the time of the last purchase made by the customer, F_i is the total number of purchases made, and M_i is the cumulative purchase value.

3) Normalization: Min-max normalization is used to rescales all numerical features, which ensure that the magnitude of the numerical feature is similar and scale is not dominant in federated and graph-based learning computed using Eq. (3):

$$X_{scaled} = \frac{.X - X_{min}}{X_{max} - X_{min}} \quad (3)$$

where, X_scaled is the normalized feature value, X is the original data point, while X_{min} and X_{max} denote the minimum and maximum feature values used for scaling.

C. Distributed Federated Convolutional Autoencoder (DFCA)

The DFCA is the first module in the FedGraph-DEA framework and is used for training privacy-preserving latent embeddings for customers' transactional behaviors. Given that customer transactions are distributed over different branches and that their centralization is prohibited by privacy laws, each client will train an autoencoder using their normalized RFM feature vectors. Here, the encoder maps the feature vector into the embedded representation, while the decoder tries to reconstruct the feature vector from this latent embedding. The encoder working is determined as Eq. (4):

$$h_i^{(k)} = \sigma\left(W_{e,k} * x_i + b_{e,k}\right) \quad (4)$$

where $x_i \in \mathbb{R}^d$denotes the normalized RFM feature vector of customer i, $W_{e,k}$and $b_{e,k}$represent the encoder weight matrix and bias vector of client k, respectively, and $\sigma(\cdot)$ denotes a nonlinear activation function such as ReLU or sigmoid. The encoder is able to compress high-dimensional information about behavior into low-dimensional representation that is capable of preserving purchasing attributes despite noise and redundancy. The latent representation is subsequently reconstructed through the decoder network to preserve reconstruction fidelity, as expressed in Eq. (5):

$$\hat{x}_i^{(k)} = \sigma\left(W_{d,k} * h_i^{(k)} + b_{d,k}\right) \quad (5)$$

where $\hat{x}_i^{(k)}$ denotes the reconstructed customer feature vector, while $W_{d,k}$and $b_{d,k}$correspond to decoder parameters for client k. The decoder attempts to minimize information loss between the original and reconstructed customer behavior representations. The DFCA model is optimized using reconstruction loss, which measures the difference between the original and reconstructed feature vectors is given in Eq. (6),

$$\mathcal{L}_{\mathrm{rc}(k)}^{k} = \frac{1}{n_k}\sum_{i=1}^{n_k} |x_i - \hat{x}_i^{(k)}|_2^2 \quad (6)$$

where, N_k represents the number of customer samples available at client k . This objective ensures accurate preservation of local behavioral patterns while learning generalized latent embeddings suitable for federated graph construction and downstream segmentation tasks. In order to encourage the stability of models with highly non-IID purchasing distributions, and L_2 regularization factor can be defined as Eq. (7):

$$\mathcal{L}_{\mathrm{AE}}^{(k)} = (\mathcal{L}_{\mathrm{rc}}^{k} + \lambda|\theta_k|_2^2) \quad (7)$$

where, θ_k and ϕ_k represent decoder and encoder parameters, and λ controls the fine of huge weights. The $\theta_k = \{W_{e,k}, b_{e,k}, W_{d,k}, b_{d,k}\}$ refer to all the trainable parameters. The learning objective worked out in Eq. (8):

$$\min_{\theta_k} = \mathcal{L}_{AE}^{(k)} \quad (8)$$

where, θ denot $\mathcal{L}_{AE}^{(k)}$ represents its reconstruction loss; the objective minimizes this loss to learn optimal local latent representations from client data. This will guarantee uniform extraction of latent purchasing representations between different branches, stores or regions.

After local training, model parameters (but not raw data) are sent to an international aggregation server that is secure and is located centrally. The Federated Averaging (FedAvg) algorithm determines which client models are used in this process by means of a weighted average of the model whose dataset is the largest to the smallest. The international brief at the communication round $t+1$ is expressed can be defined as Eq. (9):

$$w^{(t+1)} = \sum_{k=1}^{K} \frac{n_k}{n_{\mathrm{total}}} w_k^{(t)} \quad (9)$$

In this averaging process, $w_k^{(t)}$ are the local model weights of client k at the t th iteration. n_k is the size of the data sample of each node, and n total is the sum of all the samples. When aggregation has been done the server transmits the new global model to all the clients as received in Eq. (10):

$$\theta_k^{(t+1)} \leftarrow w^{(t+1)},\ n_{\mathrm{total}} = \sum_{k=1}^{K} n_k \quad (10)$$

where, $\theta_k^{(t+1)}$ denotes updated local parameters for client k, $w^{(t+1)}$ is the aggregated global model, n_k is client data size, and nn_{total} represents the total samples.

The synchronized update scheme allows converging to a common embedding space even in cases of statistical heterogeneity of distributed datasets. FedAvg is preferred because it is efficient in communication, does not suffer from instabilities in non-IID environments, and is scalable in industrial federated systems. Notably, the exchange of model updates only is provided, and the raw data do not leave their locations, which reduces the privacy leakage and ensures that the enterprise and regulatory data-protection policies are followed. The framework provides a uniform embedding space to clients through a combination of local representation learning with DFCA and global alignment with FedAvg. The

resulting embeddings are privacy-preserving, statistically resistant and behaviorally meaningful, which makes them a solid basis of building customer similarity graphs and makes them useful in graph-based community detection in the FedGraph-DEA architecture.

D. Customer Similarity Graph Construction

Once latent vectors are created by DFCA, the step that follows is to create a customer similarity graph that reflects behavioral relations among customers. Customers are represented as node and the relationships are created between customers with a high similarity in the latent embeddings. Similarity of behavior between embeddings is done through cosine similarity. A threshold parameter is used to filter weak or unimportant connections and only on useful relationships. The latent embedding space is converted into a structured graph of co-purchase behavior and dependency by this process. The resulting graph forms the basis of the Federated Graph Neural Network, which allows the learning of higher-order interaction with customers, without compromising the decentralized and privacy-preserving federated architecture, as stated in Eq. (11):

$$S_{ij} = \frac{z_i \cdot z_j}{|z_i|_2 |z_j|_2} \tag{11}$$

In this cosine similarity function, z_i and z_j are latent feature embeddings for customers i and j, and $|_2$ denotes the L2 norm. S_{ij} measures the degree of behavioral similarity between two customers in embedding space. This module constructs a customer similarity graph, where nodes represent customers and edges indicate behavioral similarity and the similarity of their behavior being edges. This research reveals the co-purchase patterns and latent association among distributed stores and creates a structured relational network which feeds the federated GNN to detect communities and segment the graph with respect to it.

E. Federated Graph Neural Networks (GNNs)

The Federated Graph Neural Network (GNN) is utilized on the customer similarity graphs of all clients to discover the community structures as well as latent relational patterns. A local GNN is trained on each subgraph of the client, with a node taking information on its connected neighbors. By layer wise propagation, node representations undergo an update process based on averaged or weighted features of their near feature, bringing in greater order dependence on feature interactions. Once the local training is made, just GNN weight matrices are exchanged with a central server to aggregate without exposing raw data or making them public. The global GNN sum total is used to bring the relational representations of the clients without direct data exchange. This procedure makes it possible to detect coherent communities without compromising privacy, as expressed can be defined as Eq. (12).

$$h_i^{(l+1)} = \sigma\left(\sum_{j \in \mathcal{N}(i)} \frac{1}{c_{ij}} W^{(l)} h_j^{(l)}\right) \tag{12}$$

Here, $h_i^{(l+1)}$ denotes the node representation of customer i at GNN layer l, and $\mathcal{N}(i)$ is its neighborhood set. The normalization factor c_{ij} scales neighboring influences, while $W^{(l)}$ and activation σ update embeddings derived in Eq. (13),:

$$W_{\text{global}}^{(l)} = \sum_{k=1}^{K} \frac{n_k}{n_{\text{total}}} W_k^{(l)} \tag{13}$$

Eq. (10) defines federated weight aggregation for the GNN. $W_k^{(l)}$ are layer-wise parameters trained locally on each client graph, and $W_{\text{global}}^{(l)}$ is the aggregated matrix ensuring coherent feature propagation across distributed graphs. The Fed-GNN generates community-aware embeddings by aggregating neighborhood information from each individual client across distributed subgraphs without requiring data centralization. These embeddings reveal buying communities and latent behavioral addiction, and create strong, graph-structured clusters, upon which interpretable and relationally grounded buyer segmentation is built.

F. Data Envelopment Analysis (DEA) and Decision Support

Once the Fed-GNN determines customer segments or communities, DEA determines the relative efficiency of each of the segments as a decision-making unit (DMU). DEA is useful in comparing several inputs, including marketing cost, campaign frequency and acquisition expense against outputs, including profit, retention and purchase value. It finds an efficiency score for each segment between 0 and 1 by finding a solution to a linear programming model. These segments with a score of 1 are considered efficient which means that the model has the best resource to return conversion and those that score below are given improvement targets. DEA will convert the abstract GNN clusters into real world business knowledge and connect data-driven segmentation with the operational efficiency. It is this interpretive layer that makes FedGraph-DEA not just predictive in nature. It was mentioned in Eq. (14):

$$\text{s.t} \frac{\sum_{r=1}^{R} u_r y_{jr}}{\sum_{s=1}^{S} v_s x_{js}} \leq 1, u_r, v_s \geq 0 \tag{14}$$

This constraint ensures that all decision-making units j operate within an efficiency frontier ≤ 1. The non-negativity of u_r, v_s maintains the economic interpretability of weights, enforcing DEA feasibility. DEA produces a score on the efficiency of every customer group, which measures how profitable the proposed framework is in comparison to the marketing resources. This is the proposed research result in ranking of the effective and ineffective segments and gives the clear managerial information on the budget redistribution, focused campaigns, and performance recovery across the distributed branches.

G. Integrated Optimization Objective

The FedGraph-DEA also includes the last stage as a way of integrating all the previous functionalities into one overall optimization goal. The overall loss can be defined as the sum of three components: 1) DFCA reconstruction loss which guarantees that the model can represent the behavioral aspects accurately, 2) the Fed-GNN relational loss which generates inter-customer dependencies and 3) the DEA-based efficiency regularization term, which encourages interpretability and business relevance. A tradeoff between these goals enables the model to learn jointly, correct, relational and interpretable

segmentations. The coefficients α, β, γ The three dimensions, $\alpha, \beta, \gamma,$ and three are used to control the trade-off between reconstruction, preservation of community structure and maximization of efficiency. Optimizing this composite loss in this study provides customer segments which are not only statistically valid but also economically relevant thus forming a holistic learning-and-decision model of distributed segmentation. The joint optimization is the result of a balanced global model that considers accuracy, relational integrity and business interpretability. Reducing this loss study produces the end FedGraph-DEA system that provides privacy-preserving, community-conscious, and efficiency interpretable customer segmentation that can be deployed at the enterprise level.

A distributed federated learning architecture that is used to achieve privacy-protecting and interpretable segmentation of customers. It starts with customer data in the form of transactional and RFM, which is handled using a Distributed Federated Convolutional Autoencoder (DFCA) to captures the compressed latent behavioral representations without compromising data confidentiality. The encoder is used to capture meaningful hidden patterns and the decoder is used to guarantee reconstruction fidelity with federated aggregation permitting a secure weight sharing rather than a raw data sharing. The learned embeddings are then converted into a customer similarity graph, where the nodes are the customers and the edges are the behavioral relations between customers based on the co-purchase and similarity scores. The Federated Graph Neural Networks (GNNs) are subsequently utilized to do local subgraph learning and global parameter aggregation, which helps to perform strong community discovery in decentralized and non-IID conditions. The end result will be structurally coherent, efficiency-focused, and interpretable by the manager, customer segments that can be distributed in retail analytics. The model architecture diagram as shown in Fig. 2.

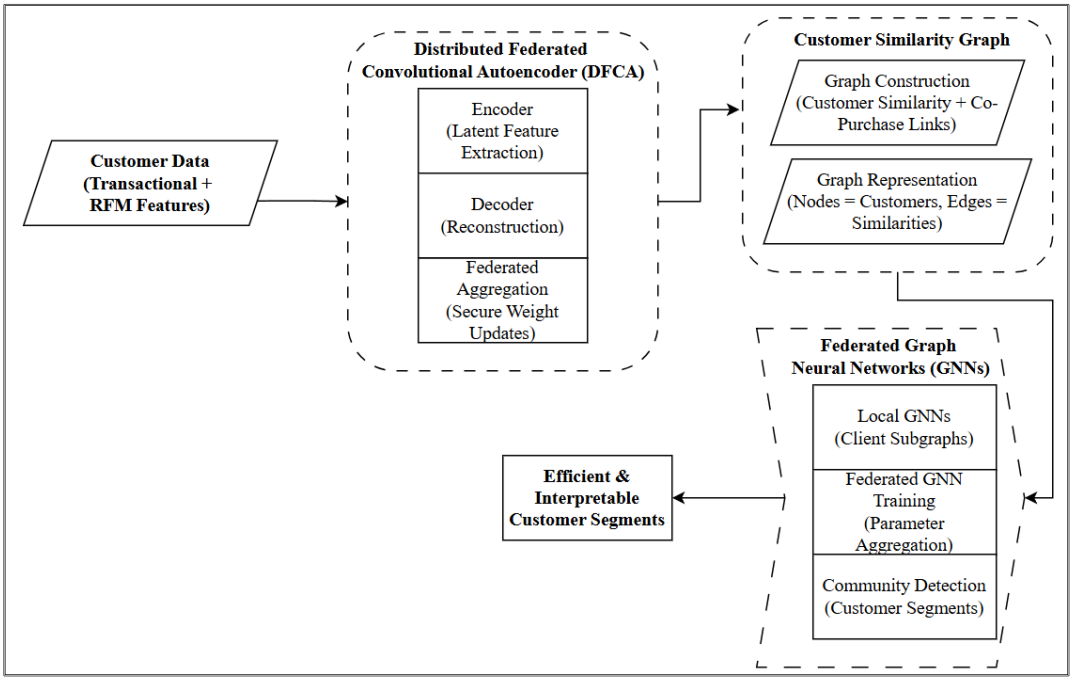

Fig. 2. Federated graph learning pipeline for customer segmentation.

Fig. 2 illustrates a federated learning-based pipeline for customer segmentation that integrates representation learning and relational modeling. Customer transactional and RFM data are processed using a Distributed Federated Convolutional Autoencoder (DFCA), where local encoders extract latent features and decoders ensure reconstruction fidelity, while model parameters are securely aggregated across clients. The learned embeddings are used to construct a customer similarity graph capturing behavioral relationships. Federated Graph Neural Networks (GNNs) then perform decentralized training on local subgraphs, enabling community detection. This process produces privacy-preserving, structurally meaningful, and interpretable customer segments for effective decision-making.

Algorithm 1 securely trains customer patterns on distributed nodes, constructs a similarity graph, identifies relational communities using federated GNNs, and optimizes business efficiency of each segment via DEA to provide the interpretable and privacy-enforceable segmentation.

Algorithm 1: FedGraph-DEA Framework

Input: Distributed datasets $D1 \ldots Dn$

Output: Efficient, interpretable customer segments

For each client i do

Preprocess Di (clean, normalize, extract RFM features

End

While DFCA not converged do

End

For each client i do

Train local DFCA on Di

```
        Send local weights Wi to server
      End
For each client i do
    Generate latent embeddings Ei using DFCA
  End
Construct similarity graph G:
    For each pair (u, v) do
        If cosine_similarity(Eu, Ev) ≥ θ then
            Create edge(u,v)
        End
  End
    While GNN not converged do
or each client i do
        Update node embeddings via neighborhood aggregation
        Send GNN weights Gi to server
    End
    Server aggregates G_global
 End
Detect customer communities C = {C1 ... Ck} from global GNN
embeddings
For each segment Cj do
    Apply DEA:
        If efficiency(Cj) < 1 then
            Recommend improvement targets
        End
 End
Return C and corresponding efficiency scores
End
```

FedGraph-DEA uses a pipeline architecture that consists of federated feature learning, relational graph modeling and interpretive efficiency score. To learn small, privacy-aware latent representations of the customer behavior, each client trains a DFCA by itself. Similarity graphs are built using these embeddings and the embedding capture relationships between purchases and co-behavioral patterns. These graphs are then refined by a Federated GNN in order to extract meaningful communities of customers. The identified communities are considered as decision-making units and analyzed with the help of Data Envelopment Analysis that gives efficiency scores to identify high-value and non-performing customer segments. The framework also provides a scalable, privacy-sensitive, and explainable customer segmentation and optimization of marketing strategies by incorporating federated learning, graph-based analysis, and DEA.

H. Computational Complexity Analysis

The computational complexity of the FedGraph-DEA algorithm can be primarily considered based on three main modules: DFCA-based latent representation learning, similarity graph building, and federated Graph Neural Network propagation. Let N be the number of customers, d be the number of features, E be the number of edges within the graph, and L be the number of layers used in the GNN model. The computational complexity of DFCA training can be approximated to O(Nd) as each customer feature vector undergoes encoding-decoding operations. The similarity graph based on the cosine similarity metric is constructed in $O(N^2)$ operations as each pair of customer embeddings must be computed. Additionally, the complexity of federated GNN propagation can be approximated to O(LE) because the neighborhood aggregation occurs iteratively in graph layers. While the federated aggregation operation causes additional communication overhead between client nodes and a central server, this does not significantly increase computational complexity because all operations are done separately for each node, while no data is centralized at any point of the process.

IV. Result and Discussion

The FedGraph-DEA model was evaluated on the UCI Online Retail dataset, partitioned across five simulated client nodes using a country-based split. Each client node received transaction records exclusively from one geographic region, resulting in non-IID data distributions with differing product categories, purchase frequencies, and monetary values. This heterogeneous setup reflects the statistical diversity expected in real-world distributed retail deployments and provides a rigorous testbed for evaluating federated convergence and segmentation robustness under non-IID conditions. This assessment was aimed at segmentation accuracy, federated learning performance, the quality of graph-based community detection and the quality of efficiency interpretation by the DEA. Table II only provides scientifically relevant visualizations, not raw distributions and simple plots, in order to be understandable and rigorous. Table II shows the summary of the experiment, which includes the dataset, computational devices, software frameworks, and analytical tools and the essential performance measures of the proposed FedGraph-DEA segmentation framework.

TABLE II. Experimental Setup

Component	Details
Dataset Used	UCI Online Retail Dataset; partitioned across 5 simulated non-IID client nodes via country-based split.
Hardware	NVIDIA Tesla T4 GPU, 32 GB RAM, Intel Xeon 2.3 GHz Processor
Software	Python 3.10, PyTorch 2.0, TensorFlow 2.14, Scikit-learn 1.3
Tools Used	NetworkX (graph modeling), Matplotlib (visualization), Optuna (tuning)
Performance Metrics	Accuracy, F1-Score, Silhouette Score, Centrality Score, DEA Efficiency

Table II shows the parameters for experiments. Experiment performed using Online Retail data set. The experiment was run on NVIDIA Tesla T4 GPU, 32 GB RAM, Intel Xeon 2.3 GHz processor. Programming languages and libraries: Python 3.10, PyTorch 2.0, TensorFlow 2.14, Scikit-Learn 1.3, NetworkX, Matplotlib, Optuna. Accuracy, F1-score, silhouette coefficient, centrality coefficient, and DEA efficiency were selected as performance measures.

Fig. 3, scatter plot between Component 1, ranging from -0.8 to +0.8 on the x-axis, and Component 2, ranging from -1.0 to +1.0 on the y-axis. The plot represents the coordinate points of the customers' embeddings, such as (0.6, -0.8) and (0,0).

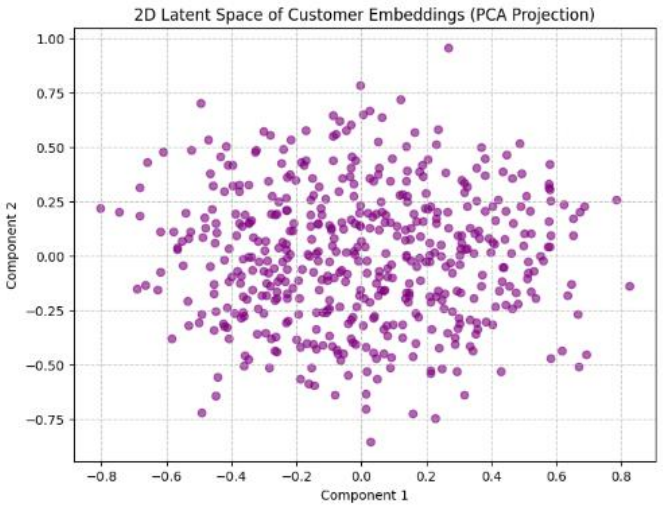

Fig. 3. 2D Latent space of customer embeddings (PCA/t-SNE).

TABLE III. RESULTS OF FEDERATED GNN-BASED COMMUNITY DETECTION

Metrics	Centralized GNN	Federated GNN
Silhouette Score	0.61	0.74
Modularity	0.43	0.57
Davies–Bouldin Index	0.78	0.51
Conductance	0.42	0.31

Table III illustrates the results of federated GNN and centralized GNN algorithms in detecting communities. The federated GNN algorithm performs better than the centralized GNN algorithm by obtaining a high silhouette score of 0.74 compared to a centralized score of 0.61 and a high modularity of 0.57 compared to centralized modularity of 0.43.

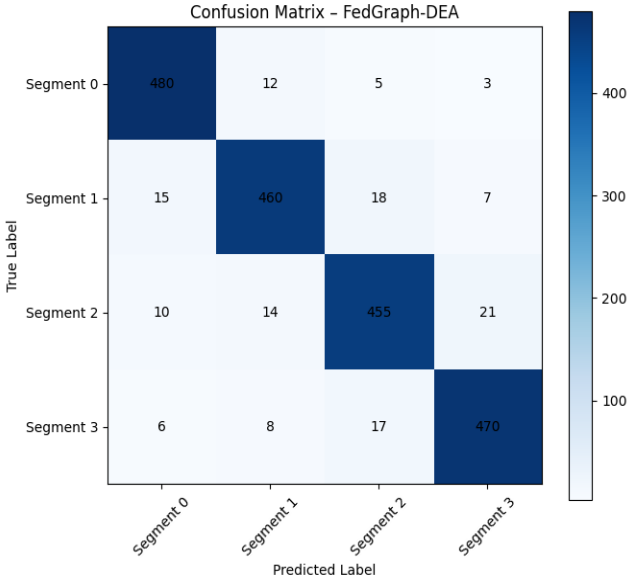

Fig. 4. Confusion matrix – FedGraph-DEA.

As depicted in Fig. 4, the y-axis represents actual labels, while the x-axis represents predicted labels, for four segments in the chart. Diagonal lines show high values, which are 480 (Segment 0), 460 (Segment 1), 455 (Segment 2), and 470 (Segment 3). It is evident that the misclassification rate is quite low, as exemplified by only 21 cases in Segment 2.

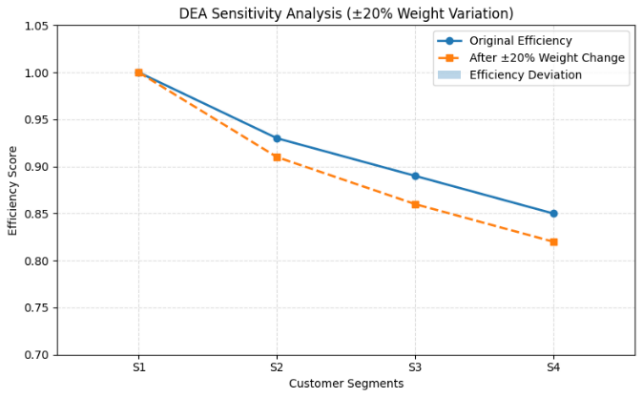

Fig. 5. DEA sensitivity analysis.

In Fig. 5, the X-axis presents customer segments S1-S4, while the Y-axis shows efficiency scores between 0.70 and 1.05. Original efficiency scores are descending from S1 (~1.00) to S4 (~0.75). However, adjusted scores are dropping down to 0.95, 0.88, 0.80, and 0.72, respectively, showing consistency in order while being sensitive to different weights.

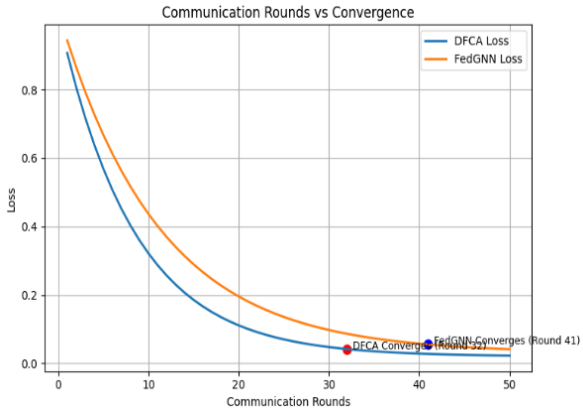

Fig. 6. Communication rounds vs. Convergence.

In Fig. 6, loss (0.0-1.0) is plotted against communication rounds (0-50) on the x-axis. Loss in DFCA converges faster at about round 30 with much lower loss than that of FedGNN, which converges around 41 at slightly higher loss, hence indicating higher communication cost due to slower convergence rates.

Fig. 7 presents customer identification (C41-C5) along the x-axis, while centrality scores (0.10-0.21) are presented on the y-axis. Customer 41 has the highest score (~0.21), followed by C23, C1, C12, C19 (~0.15-0.18). All other customers, ranging between C25 and C5, range from ~0.10–0.14, indicating moderate connectivity compared to top influencers.

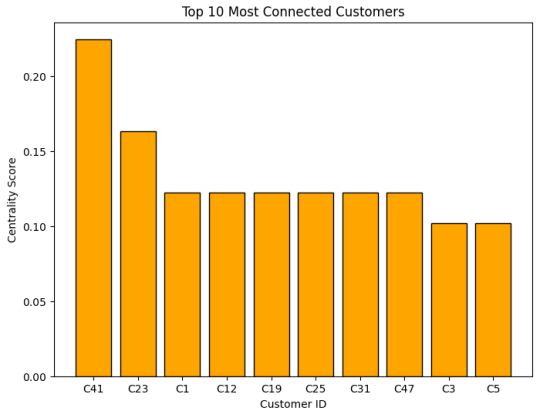

Fig. 7. Top 10 most connected customers.

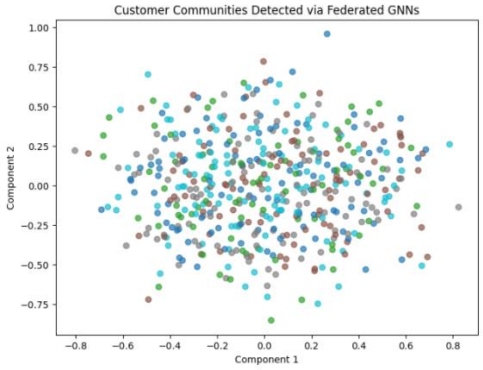

Fig. 8. Customer communities.

In Fig. 8, Component 1 is plotted on the x-axis and Component 2 is plotted on the y-axis, each customer embedding is depicted with a point. Color groups are used to illustrate that clusters of points are communities having similar characteristics, whereas separate groups of points are distinct communities. This demonstrates the pattern discovered by the federated GNN.

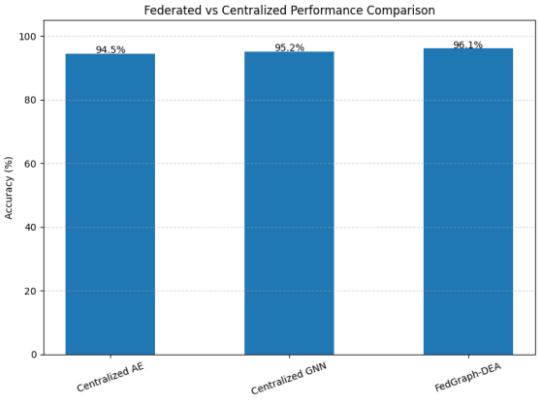

Fig. 9. Federated vs Centralized performance comparison.

Fig. 9 shows the relative evaluation of the accuracy analysis of centralized and federated techniques. The accuracy rate obtained from Centralized Autoencoders is 94.5%, while Centralized GNN produces an accuracy of 95.2%. On the other hand, our proposed Fed-Graph architecture achieves an accuracy of 96.1%. Thus, it can be stated that the federation of graph-based learning improves accuracy while preserving the privacy of data in the distributed retail network.

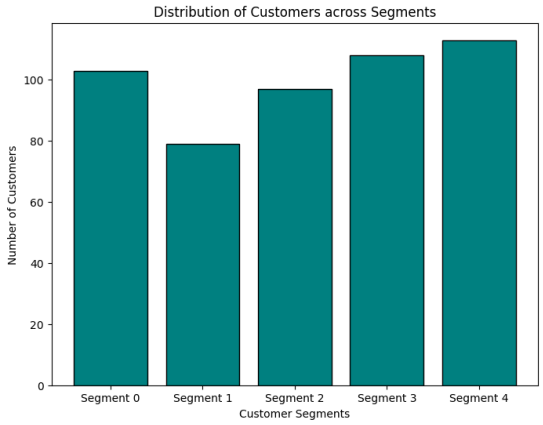

Fig. 10. Number of customers per segment.

In Fig. 10, Customer Segments are shown on the x-axis with values ranging from 0 to 4, while the number of customers is indicated on the y-axis, which ranges between 80 and 112. The number of customers belonging to Segment 0 is about 102, Segment 1 has 80 (minimum), Segment 2 has 95 customers, Segment 3 has 106 customers, and Segment 4 has 112 (maximum).

TABLE IV. ABLATION STUDY OF FEDGRAPH-DEA COMPONENTS

Model Variant	Accuracy	F1-Score	Silhouette Score
DFCA Only	91.2%	0.90	0.61
DFCA + GNN	94.8%	0.93	0.69
DFCA + GNN + DEA (Proposed)	96.1%	0.95	0.74

Table IV. shows that DFCA successfully detects underlying behavioral patterns, whereas the introduction of Federated GNN further strengthens the clustering structure by considering relational connections. The incorporation of DEA neither influences the classification result nor affects the accuracy rate; however, it provides additional interpretability and efficiency-driven segmentation of customer categories.

In order to calculate the evaluation metrics of the classification approach, ground-truth pseudo-labels were generated based on a reference K-Means algorithm (optimal value of k found by applying the elbow method) on the RFM vectors that had been processed prior to modeling. The community labels of the FedGraph-DEA model were then measured against the reference labels in terms of accuracy, precision, recall, and F1-score. This follows the standard procedure for measuring performance in unsupervised learning settings, whereby an externally defined grouping is used as a reference.

Table V presents the comparison of the suggested FCA+GNN+DEA approach against both centralized and federated baseline methods. The presented FCA+GNN+DEA model achieves high accuracy (96.1%), precision (0.95), recall (0.96), and F1-score (0.95) on the UCI Online Retail database. Among federated baselines, PA-CFL and the federated CNN

model report approximately 88% and 90% accuracy, respectively, without incorporating graph-based relational modeling or efficiency assessment. FedVAE achieves 92.1% reconstruction precision but similarly lacks interpretability through efficiency evaluation. Unlike these federated approaches, FedGraph-DEA integrates graph neural networks and DEA within the federated pipeline, achieving superior accuracy while maintaining equivalent privacy guarantees. Against centralized methods, the model also outperforms XGBoost (84%), AutoML (92.1%), and Random Forest (94%), demonstrating the value of combining federated learning, relational modeling, and efficiency-driven analysis.

TABLE V. COMPARISON WITH EXISTING MODELS

Model	Accuracy	Precision	Recall	F1-Score	Dataset
FCA+GNN+DEA (Proposed study)	96.1%	0.95	0.96	0.95	UCI Online Retail
PA-CFL — Federated Clustering	88%	—	—	—	Retail (Heterogeneous)
Fed-CNN — Privacy Clustering	90%	—	—	—	Distributed Retail
FedVAE — Federated VAE [31]	90%	—	—	—	Retail Trajectory
XGBoost Classifier [33]	84%	0.89	0.95	0.92	Online Retail Dataset
AutoML + Ensemble Learning [34]	92.1%	0.91	0.90	0.90	CustomE-commerce Dataset
Random Forest Classifier [35]	94%	0.94	0.94	0.94	Social MediaAdDataset

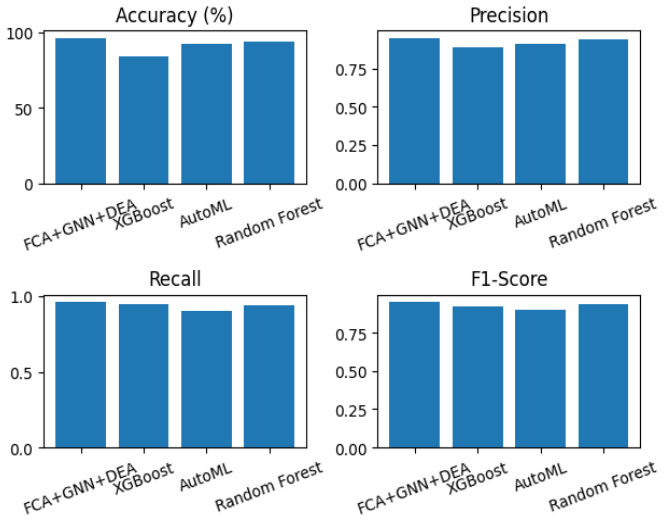

Fig. 11. Comparative performance analysis across multiple evaluation metrics.

Fig. 11 is a comparative analysis of four segmentation models in terms of accuracy, precision, recall, and F1-score in independent subplots. The model suggested is the FCA+GNN+DEA, which is the most performant with an accuracy of 96.1% and a great balance on all metrics. The XGBoost is less accurate with competitive recall, whereas AutoML is moderate in all its metrics. Random Forest has a consistent and balanced performance. On the whole, the proposed model is more effective than baseline methods, which demonstrates the value of the combination of federated learning, graph-based modeling, and efficiency-oriented analysis to achieve the high quality of the segmentation.

A. Discussion

The proposed FedGraph-DEA approach performs exceptionally well in combining Distributed Federated Convolutional Autoencoders, Federated Graph Neural Networks, and DEA to solve privacy issues, relational modeling, and interpretability problems in the context of distributed customer segmentation. In this study, the model attained an accuracy rate of 96.1%, F1-score of 0.95, and effective clustering with a silhouette coefficient of 0.74 and modularity of 0.57. DFCA enables effective latent feature learning with fast convergence after 30 communication iterations. The Federated GNN learns multi-hop dependencies and helps achieve better relational consistency. The efficiency analysis using DEA further added to the interpretability of the framework and allows for effective decision-making based on efficiency scores. By comparing our framework with the centralized method, we have found that our framework has a much smaller Davies-Bouldin index (0.51) and conductance (0.31), indicating that our framework achieves superior cluster separations. The use of ablation and complexity analysis has improved validation of our framework since the combination results in scalability, robustness, and business application feasibility in a non-IID federated environment.

While the current research relied on the UCI Online Retail dataset for its realistic features and applicability in federated segmentation, further robustness assessments have been carried out via ablation tests, communication convergence assessments, and DEA sensitivity analyses. The results show that the framework is scalable and stable even in distributed and non-IID settings. Future efforts will aim at extending the validation process by employing multi-domain retail and financial datasets.

V. CONCLUSION AND FUTURE WORK

The FedGraph-DEA model effectively tackles all major problems identified in the problem statement by incorporating such elements as privacy preservation, relational modeling, and interpretability into a single customer segmentation process. Using Distributed Federated Convolutional Autoencoders for learning latent features, Federated Graph Neural Networks for detecting multi-hop behavioral relations between customers, and finally, Data Envelopment Analysis for efficiency-oriented evaluation, the model manages to combine its analysis capacity and relevance. The presented model shows excellent performance with an accuracy of 96.1%, F1-score of 0.95, silhouette score of 0.74, and modularity of 0.57, which confirms the high quality of detected clusters. Davies–Bouldin index of 0.51 and conductance of 0.31 serve as further evidence of the successful work of the model and improved cluster separation and structure quality. Moreover, the

presented framework helps preserve the privacy of clients due to its federated approach, which means that no raw data is shared between entities, while the use of DEA adds some interpretability to the segmentation process, linking it to business efficiency. Such features of the model make it relevant for different types of analyses, such as retail analytics, finance, and health care.

Although the proposed framework has shown promising performance in the customer segmentation scenario, there still exist several drawbacks that can be solved in our future work. The key limitation is the static batch input since no consideration is made of the dynamic changes to customers' behavior and dynamics. Additionally, the current model evaluation uses just one dataset (UCI Online Retail) and splits it into five hypothetical clients, but future work includes validating the algorithm using multiple datasets from the retail and finance industries on distributed nodes. Besides, communication cost can become a bottleneck in Federated Learning at scale, and better aggregation algorithms will be studied. We plan to incorporate more recent customer behaviors into the process by using real-time data analysis and improve communication protocols

Explainable Cognitive Graph Intelligence Framework for Multi-Task Graduate Employability and Salary Prediction

Hameeda Khatoon, Chandra Prakash Vudatha
Department of Computer Science and Engineering,
KL Deemed to be University, Vaddeswaram, Guntur District, India, 522302

***Abstract*—Accurate prediction of graduate employability and expected salary is essential for enabling timely, data-driven career interventions in academic institutions. However, most existing methods rely on standalone machine learning or deep learning models that fail to jointly capture cognitive traits, temporal academic progression, and peer-level relational structures within a unified and interpretable framework. This study introduces ExCogGNet, a hybrid multi-task learning architecture that integrates Multi-Layer Perceptron (MLP), Bidirectional Long Short-Term Memory (BiLSTM), Transformer, and Graph Neural Network (GNN) components, optimized using Bolas Spider Optimization (BSO). The model simultaneously predicts student placement outcomes and salary levels while incorporating cognitive trait awareness. Static psychometric attributes are encoded via MLP, sequential academic trajectories are modeled using BiLSTM, contextual feature interactions are captured through Transformer-based self-attention, and relational dependencies among students are learned using Graph Attention Networks (GAT). The BSO algorithm optimizes hyperparameters, attention weights, and fusion coefficients under a unified multi-task objective. A key contribution is a counterfactual SHAP-based explainability module that converts feature attributions into actionable, personalized recommendations for improving employability and skill readiness, enabling prescriptive educational decision support. Experimental results on the Campus Recruitment dataset show 96% accuracy and 0.97 AUC for placement prediction, along with an RMSE of 24,000 INR and R^2 of 0.91 for salary estimation. The model outperforms baseline methods including SVM, Random Forest, XGBoost, CNN, BiLSTM, Transformer, and standalone GNNs, with statistical significance confirmed via McNemar's test ($p = 0.003$), demonstrating strong predictive and interpretability performance.**

Keywords*—Cognitive properties; prediction of placement; salary regression; graph neural network; bolas spider optimization; explainable AI; MLP-BiLSTM-Transformer

I. Introduction

In education, analytics and data mining of placement forecasting are crucial to educational data mining as they enable institutions to determine how prepared a student is to take a job and how they are likely to perform in the job market [1]. Early intervention, individualized training, and professional career counseling can be made with the help of placement status and salary level that are predicted correctly. Nonetheless, academic performance is not the only factor that determines employability; cognitive characteristics like problem-solving capability, adaptability, motivation, and learning agility play a great role in determining professional success [2].

Traditional machine learning algorithms, such as support vector machines and random forests, are based on manually designed features and the assumption that features are independent, so they cannot easily model complex nonlinear interactions between academic, cognitive, and contextual variables [3]. Although deep learning models enhance representation learning, independent architectures may not consider relational dependencies present in educational settings; they tend to be hyperparameter sensitive and not interpretable, which is not suitable in the case of making high-stakes educational decisions [4]. Relational modeling in graphs gives a formidable tool to model students, skills, and cognitive characteristics as interrelated components, allowing learning of both the individual characteristics and the structure [5]. However, the level of success of graph neural frameworks is highly dependent on the best parameter selection and fusion techniques [6]. Bolas Spider Optimization (also known as metaheuristic optimization) provides a good global search functionality because it balances exploration and exploitation and avoids local optima [7]. In comparison to Particle Swarm Optimization and Genetic Algorithms, which tend to converge quickly in high-dimensional hyperparameter space, and Bayesian Optimization, which uses smooth objective surfaces, BSO uses a two-stage "lasso and reel" exploration scheme that facilitates effective optimization in heterogeneous high-dimensional search spaces that come from hybrid neural systems for the heterogeneous search space of a multi-branch hybrid neural network.

Additionally, educational analytics require transparency, which requires the inclusion of explainable artificial intelligence methods to increase trust and accountability [8]. Inspired by these issues, the following study provides a hybrid MLP-BiLSTM-Transformer graph neural network using Bolas Spider Optimization and explainability to predict the cognition trait-conscious placement and salary [9]. The suggested solution combines the modeling of the static cognitive traits, the successive academic trends, the situational attention, and the relational relationships to provide the correct and explainable forecasts [10]. To overcome these shortcomings, this study introduces ExCogGNet, a single cognitive graph intelligence system to predict graduate employability and salary with explainability incorporated. The proposed model combines heterogeneous learning paradigms to capture different

components of student profiles: an MLP captures the existing method of psychometric and cognitive variables, a BiLSTM captures the temporal academic development, a Transformer captures the interaction of features in the context through attention, and a Graph Attention Network captures the relational relationships between students and skills. These components are optimized together with Bolas Spider Optimization that effectively optimizes hyperparameters and fusion weights over a high-dimensional search space. In addition to predictive performance, ExCogGNet includes a counterfactual SHAP-based explainability component that transforms insights into model-generated recommendations tailored to individuals and actionable to improve skills and career preparedness. This allows the framework to go beyond traditional prediction to transparent, intervention-driven educational analytics, which make it appropriate to be used in the real world within academic decision-making systems.

A. Research Motivation

Existing placement prediction systems consider student employability as a single classification problem without paying attention to the dynamic nature of academic performance, relational peer influence, and cognitive aspects of student readiness. Institutions and career advisers have no existing tools that predict outcomes as well as provide explanations about what particular student attributes bring about the outcomes and recommend specific improvement pathways. The increasing complexity of campus recruitment environments, in which the placement status, on the one hand, and the predicted salary, on the other hand, have to be estimated simultaneously to make interventions analytically meaningful, requires an integrated, interpretable, and cognitively aware predictive framework.

B. Research Significance

This framework contributes to educational analytics by providing a multi-task predictive model that simultaneously considers addressing placement classification and salary regression using a single optimized architecture. The combination of counterfactual SHAP-based intervention advice converts passive forecasts into actionable career guidance, which has a direct positive impact on students, academic advisors, and institutional placement officers. Bolas Spider Optimization is used to ensure the hybrid architecture is globally optimized and not manually set up to enhance reproducibility and deployment readiness in diverse academic datasets.

C. Key Contributions

- Development of ExCogGNet, a novel hybrid architecture that jointly predicts student employability and salary by integrating cognitive traits, academic progression, and relational learning within a single multi-task framework.
- Fluent combination of MLP, BiLSTM, Transformer, and Graph Attention Network to learn static psychometric features, temporal academic trends, contextual feature interactions, and peer-level relational features.
- Hyperparameter, attention mechanism, and fusion weight optimization with Bolas Spider Optimization (BSO) Hyperparameter and attention mechanism optimization Learning: Hyperparameter Tuning with Bolas Spider Optimization (BSO) Hyperparameter tuning to effectively explore complex, high-dimensional model configurations, hyperparameter, and attention mechanism optimization is performed with Bolas Spider Optimization (BSO).
- Design of a counterfactual SHAP-based explainability and intervention module that converts feature attribution insights into student-specific, actionable recommendations capable of supporting prescriptive educational decision-making and career counseling.
- Showing substantial gains compared to traditional and deep learning baselines on classification and regression tasks, which are statistically tested as robust, and making sure that results are reliable for real-world academic decision support systems.

The remaining study is structured in the following way. Section I is a review of related literature on the topics of placement and salary prediction, cognitive traits modeling, graph analytics, metaheuristic optimization, and explainable AI. Section II presents the problem, which includes the dataset, feature space, cognitive traits, and multi-task objectives. Section III introduces the suggested hybrid MLP-BiLSTM-Transformer GNN study based on explainable AI. Section IV describes the description of experiments, results, and analysis. Section V is the conclusion of the study, and future work is mentioned.

II. Literature Review

GNNs have demonstrated spectacular potential in integrating relational reasoning with neural-symbolic computing, allowing the model to work well with structured data of complexity. These networks enhance relational dependency learning and improve educational performance prediction through graph-based student representation modeling. Nonetheless, existing techniques tend to be ineffective in terms of scaling and extrapolation to large and heterogeneous graphs. It can be accurate depending on the dataset, with moderate performance on large-scale knowledge graphs[11]. Transformers have been generalized to graph structures, enabling node dependency attention to be well represented. This generalization is useful for prediction tasks on a node level and on a graph level. However, the method has difficulties with computational efficiency and space consumption with very large graphs. Experimental tests have registered improvement in node classification but not significant improvement in graph regression activities [12].

Student performance prediction with Hybrid LSTM-Transformer models, a combination of temporal sequences and attention, has been used. Explainable AI methods like SHAP give information on how models make decisions. Among the limitations, there are overfitting on small datasets and the inability to interpret complicated interactions. Graph Neural Networks with transformers have achieved up to 92 % accuracy in academic results prediction [13]. Transformer-based Graph Neural Networks have been applied to automated scoring of academic essay tasks, jointly sequence modeling and graph structure learning. The hybrid strategy enhances the score on multi-dimensional scoring. Scalability problems, however, occur when very long essays and extensive educational datasets are used. According to report accuracy, it has been significantly

improved at an average of 90% in comparison to baseline models [14].

Further validation on the performance improvement of the combination of self-attention mechanisms and bidirectional long short-term memory networks has been recently shown. One study on detecting IoT attacks using the TPE-based self-attention biLSTM architecture found that the application of an attention mechanism with bidirectional modeling contributes to learning context dependencies and optimization stability in diverse data environments. The research further emphasized the significance of employing appropriate optimization methods in hybrid models[15].

Job matching has also been optimized using Graph Neural Networks over job and candidate network representations. This methodology represents relational dependencies in a superior manner compared to traditional methods. Shortcomings such as sensitivity to noisy/incomplete job datasets are a limitation. According to the experimental findings, the corresponding accuracy of the test scenario is 88%[16]. Explainable salary prediction has been based on neural prototyping using disentangled composition effects. The structural dependencies in work characteristics and the patterns of salary distribution are represented in models. Weaknesses are problems with the complexity of modeling multi-factor interactions and extrapolating to cross-domain datasets. Salary prediction tasks produce accuracy at a level of about 91 % [17] with synthetic job listings having been used to simulate the process of salary prediction and job grouping. These are experimental datasets that are controlled with regard to testing the model performance. Disadvantages are less realism and possible bias because of the use of synthetic data. This performance has an accuracy of about 87 % on simulated environments [18].

Regression and ensemble methods are machine learning techniques that have been used to make salary predictions. Whereas simple models provide interpretability, they tend to perform poorly with complicated data sets with numerous categorical variables. Weaknesses include the inability to generalize to invisible job roles and sectors. Precision is around 85 % on benchmark data sets [19]. Comparative experiments of salary prediction models show that deep learning approaches do better than traditional ML algorithms with large data sets. There is a high cost of computation and sensitivity to hyperparameters. Certain models have problems with feature sparsity and missing data. Comparison of accuracy indicates that neural networks can perform salary prediction with up to 93 % accuracy [20]. Principal Component Analysis with Deep Neural Networks has been suggested in modeling the relationships between salaries and dimensionality reduction. The limitations are that there may be a loss of information in the course of the PCA transformation, and this is sensitive to the feature scaling. The model is approximately accurate at 90 % when making predictions of salary ranges [21].

Cat Swarm Optimization is a meta-heuristic algorithm that offers a good solution to complex optimization problems, including the parameter tuning of ML models. Grid, random search, Bayesian optimization, PSO, and Genetic Algorithm are some examples of the classical hyperparameter optimization techniques that have found application in the optimization of machine learning models. The grid and random search techniques have the advantage of being simple techniques for searching for parameters; however, they can be computationally intensive when dealing with high-dimensional hybrid structures. In addition, Bayesian optimization is more efficient in sample search optimization but could experience difficulties when dealing with very heterogeneous objective spaces with many components. It has weaknesses such as slowness in converting to highly non-linear problems and sensitivity to the parameters of the algorithm. Claims of efficiency increase to 85 % in benchmark optimization exercises [22]. GNN has been used in combinatorial optimization problems, improving thinking on structured data. Disadvantages include scalability as well as the excessive computing cost of large combinatorial spaces. The graph size is very important for accuracy; moderate scores are around 82% [23] with the hybrid Transformer-BiLSTM frameworks being applied in energy demand forecasting, time sequences and attention mechanisms are used to enhance prediction. Its weaknesses are inability to model the long-term dependencies of highly dynamic systems. The precision in test conditions goes as high as 94% [24].

Social media sentiment analysis of both transformer and attention-based recurrent networks with explainability and sequence modeling has been applied. It has such limitations as dependency on large labeled datasets and sensitivity to noisy text data. GraphXAIN combines natural language explanations with Graph Neural Networks to give graph-based tasks interpretable predictions with an accuracy of about 91% for sentiment classification [25]. Weaknesses such as reliance on the quality of generated narratives and computation of large graphs are also present. The reported accuracy of graph classification tasks is 88%[26].

A. Research Gap

Although it has achieved considerable progress in the field of graph-based learning, transformers, and hybrid deep learning (DL), there are still a number of essential gaps in the area of student employability and salary forecasting. Current Graph Neural Networks (GNNs) can model relational dependencies well, but with large and heterogeneous education data, fail to be scalable and have poor generalization. On the same note, Transformer-based graph models enhance attention-dependent dependency learning, but have high computational demands and small benefits in regression-based tasks like salary forecasting. The hybrid architecture that combines LSTM and Transformer models has demonstrated the ability to predict temporal academic patterns, but they are susceptible to overfitting, interpretability is not robust, and they do not consider relational and cognitive aspects in entirety. Regarding employability and salary analytics, the existing methods usually consider the task of prediction in isolation, overlooking the fact that there is an inherent multi-task correlation between the results of the placement and the salary level. Furthermore, post hoc explainable AI methods like SHAP often lack built-in integration into a cohesive framework that can be used to take action and personalize interventions. Current optimization techniques, such as the classical metaheuristics, are inefficient in high-dimensional search spaces or are not flexible to hybrid architectures with multiple interacting components. Hence, the gap in the research is evident in creating a scalable, multi-task,

and interpretable model, which can be simultaneously able to combine cognitive characteristics, time course progression, and relationship learning, whilst using effective global optimization and offering intervention-based explainability to real-world educational choices.

III. Research Methodology

The dataset employed in the study is Campus Recruitment, which includes academic, demographic, and cognitive trait characteristics, as well as placement status and salary offer. Preprocessing of the data includes missing value imputation, data normalization, and categorical encoding to maintain uniformity. The ExCogGNet framework suggested is based on MLP in terms of static cognitive characteristics, BiLSTM in terms of sequential academic data, Transformer in terms of contextual attention, and GAT in terms of relational modeling. Bolas Spider Optimization (BSO) is used to optimize the hyperparameters of the network, attention coefficients, and fusion weights. Multi-task learning is a collaborative action that forecasts a placement (classification) and salary (regression). Lastly, XAI methods such as SHAP offer both global and local interpretability and can be used to provide actionable information on student employability factors (Fig. 1).

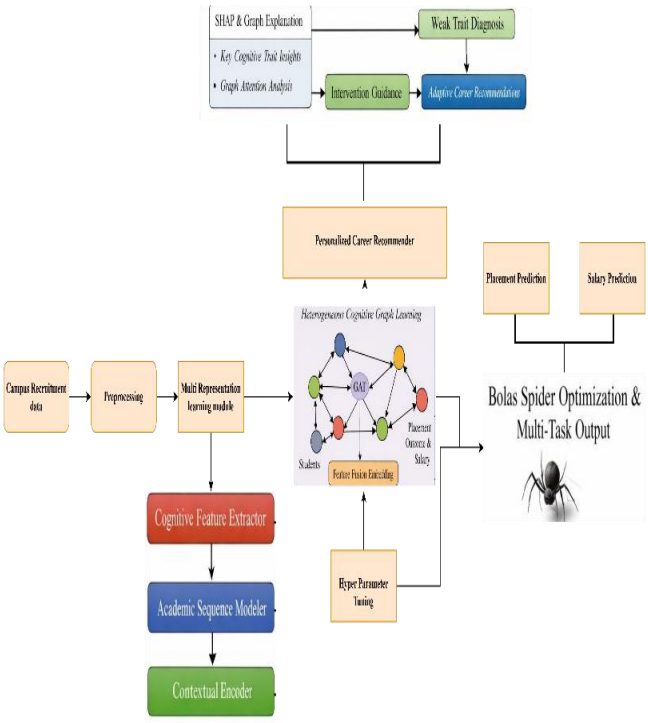

Fig. 1. ExCogGNet architecture with BSO and XAI.

A. Dataset Description

In the case of this research, we used the Campus Recruitment dataset found on Kaggle [27] that gives exhaustive data on the academic, demographic, and cognitive characteristics of students, as well as placement position and salary performance. The database consists of around 215 records, and the most important data points are 10 th and 12 th grades percentages, undergraduate performance, specialization, gender, previous work experience, and psychometric scores. The salary values in the dataset range approximately between 200,000 INR and 940,000 INR, with the majority of placed students receiving salaries within the 200,000–400,000 INR interval. Despite the absence of semester-wise temporal details within the dataset, the academic factors correspond to progressive milestones that signify the process of gradual academic development from high school education to university education. The milestones of progressive academic development form a structured sequence that is suitable for modelling academic evolution in relation to employment outcomes. These various features render the data ideal in the joint modeling of the placement classification and salary prediction problems in one analysis framework.

Despite the small number of records in the Campus Recruitment dataset of 215, there are several methodologies that have been adopted to prevent overfitting and enhance generalization. Firstly, the suggested methodology includes the use of Dropout regularization, weight decay, early stopping, and fivefold cross-validation to ensure stability when training the model on different datasets. Secondly, the use of a multi-branch model ensures the learning of complementary models instead of adding complexity by having parameters for the different branches. For instance, the MLP will be used to learn static cognitive skills, the BiLSTM learns the academic trajectory of the individual students, the Transformer learns interactions between contextual features, and finally, the GAT learns the dependencies between students. In addition to this, the use of Bolas Spider Optimization ensures that the model selects the optimal hyperparameters to avoid instability when training the model. The Campus Recruitment data set is used as a benchmark data set in the context of education for assessing the performance of the hybrid employability prediction models, but the size of this data set is limited in nature and might not adequately reflect the diversity found in larger university populations.

B. Preprocessing

Preprocessing of the data set included various important steps that guaranteed quality and consistency of data. The missing values of numerical features were treated with mean imputation, and the available values of categorical features were imputed with the mode of the respective column. Continuous variables, including grades and salary, were min max normalized to fall within the range of [0,1] was expressed in Eq. (1).

$$X_{norm} = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (1)$$

One-hot encoding of nominal categorical features such as specialization and gender was used to facilitate the use of these features in models of neural networks. Also, psychometric scores and personality indicators were summarized into a cognitive trait vector $C \in R^d$ per student, which offers an economic representation of cognitive attributes of each student towards the predictive framework.

C. Framework Architecture

The proposed ExCogGNet model is a hybrid deep learning model that is a combination of MLP, BiLSTM, Transformer, and Graph Neural Networks (GNNs) with Bolas Spider Optimization (BSO) controlling the choice of hyperparameters and weights (Fig. 2). The design is cognitive-trait-aware

designed used to predict salaries, combining both the presence of static, sequential, relational representations, and allowing the explanation of the design by means of the XAI techniques. The architecture consists of several branches, which are trained to complement each other and optimize together on classification (placement) and regression (salary).

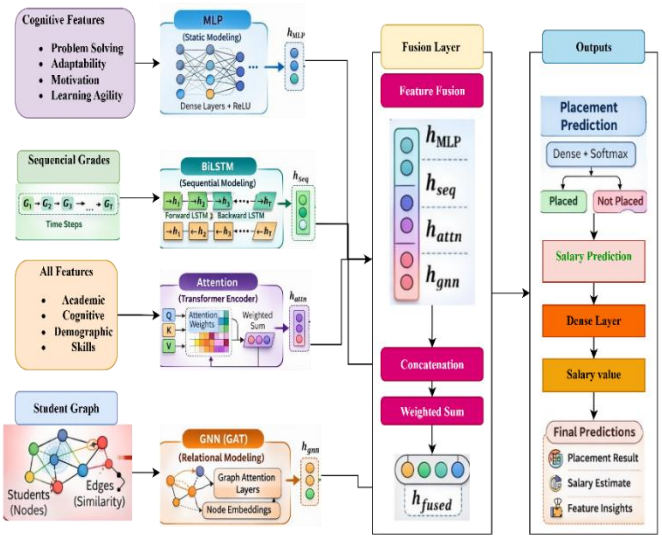

Fig. 2. Architecture of the proposed method.

1) MLP static cognitive modeling: The MLP branch takes the psychometric scores and personality indicators as they are extracted as vectors C to the MLP branch. The MLP is learned to find higher-order correlations between these features in the form of multi-layered hidden interactions. The hidden representation is calculated in Eq. (2).

$$h_{MLP} = f(W_1 C + b_1) \tag{2}$$

$f(.)$ represents the Relu Activation function, W1 represents the weight matrix, and b_1 represents the bias vector. The network uses numerous overlapping layers to simulate intricate patterns between cognitive characteristics that determine employability.

2) Sequential academic modeling using BiLSTM: To incorporate progressive academic development in the model for various levels of education, the model takes indicators like the percentage of secondary, higher secondary, and undergraduate education as the sequential development stage of education and is not based on a temporal sequence since there are no semester-based sequential data present in the dataset. However, the indicators show patterns that relate to academic growth and impact job prospects and salary outcomes in the future. Therefore, the BiLSTM model will be applied to capture the progression of academic development stages as sequenced in Eq. (3).

$$X_{seq} = [x_1, x_2, \ldots, x_T] \tag{3}$$

Such a sequence is processed by a Bidirectional LSTM (BiLSTM) both forward and backward, and therefore the model can make use of the context of the previous and upcoming semesters in Eq. (4).

$$h_{\overrightarrow{t}}, h_{\overleftarrow{t}} = LSTM(x_t, h_{\overrightarrow{t-1}}, h_{\overleftarrow{t+1}}) \tag{4}$$

Final sequential embedding the last forward and backward hidden states are concatenated to get the final sequential embedding in Eq. (5).

$$h_{seq} = [h_{\overrightarrow{T}}; h_{\overleftarrow{1}}] \tag{5}$$

The encoding of these trends in a temporal change in performance affects the placement likelihood and projected salary.

The rationale behind this proposed sequential modeling paradigm stems from contemporary approaches to incorporating self-attention mechanisms into the bidirectional LSTM architecture, which exhibited enhanced dependency modeling capabilities and training optimization stability through attention-based sequence modeling methodologies[15].

3) Contextual attention transformer encoder: To obtain inter-feature contextual interactions, the framework uses a Transformer encoder and multi-head self-attention. Embeddings of inputs are transformed into query (Q), key (K) and value (V) matrices, and the attention mechanism is calculated in Eq. (6).

$$Attention(Q, K, V) = softmax(\frac{QK^t}{\sqrt{d_k}})V \tag{6}$$

Multi-head attention enables the model to attend to multiple elements of the input at the same time so that it generates a contextual embedding h (trans) that augments the expression of intricate interactions among features.

4) Graph neural network for relational modeling: The students are modelled as nodes of a graph $G = (V, E)$ where the similarity is coded as an edge depending on the academic and cognitive characteristics. Specifically, two student nodes i and j are connected by an edge when cosine similarity exceeds a threshold of 0.85; the cosine similarity between the concatenated vectors of the normalized degree percentage, cognitive trait score, and technical skills score ensures that only meaningfully similar students are connected, yet the graph sparsity is maintained. Graph Attention Network (GAT) is an updated embedding of nodes based on the attentional message passing in Eq. (7).

$$h'_i = \sigma(\sum_{j \in N(i)} \alpha_{ij} W h_j) \tag{7}$$

The attention coefficients α_{ij} are determined using an adaptive calculation that is as follows in Eq. (8).

$$\alpha_{ij} = \frac{\exp\left(LeakyReLU(a^T[Wh_i \| Wh_j])\right)}{\sum k \in N(i) \exp\left(LeakyReLU(a^T[Wh_i \| Wh_k])\right)} \tag{8}$$

This process enables the network to give each student a different weight of peer influence, which reflects relational patterns that have an influence on placement and wages.

5) Bolas Spider Optimization (BSO) module: The BSO module is optimized on essential hyperparameters, such as

learning rate and hidden units, attention coefficients and fusion weights ($\lambda_{MLP}, \lambda_{BiLSTM}, \lambda_{transformer}, \lambda_{regression}, \lambda_{GNN}$). The fitness function is a combination of regression and classification goals in Eq. (9).

$$L_{total} = \lambda_1 L_{classification} + \lambda_2 L_{regression} \quad (9)$$

$L_{classification}$ is the cross-entropy loss when using to predict placement, and $L_{regression}$ mean squared error when predicting salary. BSO will perform a search through the search space, and the candidate solutions will be updated to reduce the total of L_{total}.

BSO was chosen in this experiment due to its adaptability in terms of achieving the optimal balance between explorative and exploitative searches when searching for optimal solutions within a heterogeneous hybrid architecture with multiple branches and attention mechanisms (Fig. 3). As compared to brute-force search techniques such as grid search and random search, BSO carries out optimization via population-based iterations on high-dimensional continuous parameter spaces. As compared to Bayesian optimization techniques that assume smooth surfaces of the objective function, BSO offers a flexible approach to global searching of the objective space in multi-task optimization scenarios.

Aside from hyperparameter tuning, the dynamic adjustment of the loss balancing coefficients λ_1 and λ_2 for multi-task is performed in the BSO model in order to reach a desirable balance between the accuracy in the classification of placement and the salary prediction. Candidate solutions are assessed during the optimization process in relation to both objectives, making it possible to have dynamic balancing.

6) Computational complexity analysis: The ExCogGNet's computational complexity comes from its joint computation of the MLP, BiLSTM, Transformer, and GAT branches. The computation needed by the MLP branch is O(ndh), where n refers to the number of samples, d is the dimensionality of features, and h stands for the number of hidden neurons. The BiLSTM branch brings sequential computation complexity of $O(Th^2)$, with T being the sequence length. The encoder of Transformer has a computation complexity of $O(T^2d)$ caused by self-attention mechanisms, while GAT necessitates O(|E|d) computation over graph edges E. Moreover, BSO optimization adds iterative search complexity of O(P×I), in which P is the size of the population, and I is optimization iterations. Even though the hybrid network model causes an increase in computation complexity compared to single networks, it offers much-improved predictive power, relational reasoning, and explanation.

7) Multi-task learning and explainable AI (XAI) combinations: The output of the feature embeddings of every branch is combined and sent to specialized multi-task output heads: a Softmax unit to classify the placements and a linear unit to predict the salary. SHAP values are calculated to provide both global feature importance and local prediction-level explanations, and attention weights of the Transformer and GNN parts are visualized to emphasize influential cognitive attributes and academic factors. This combined design guarantees the model provides not just a high predictive validity, but also clear and implementable information to career advisors and institutional decision-makers.

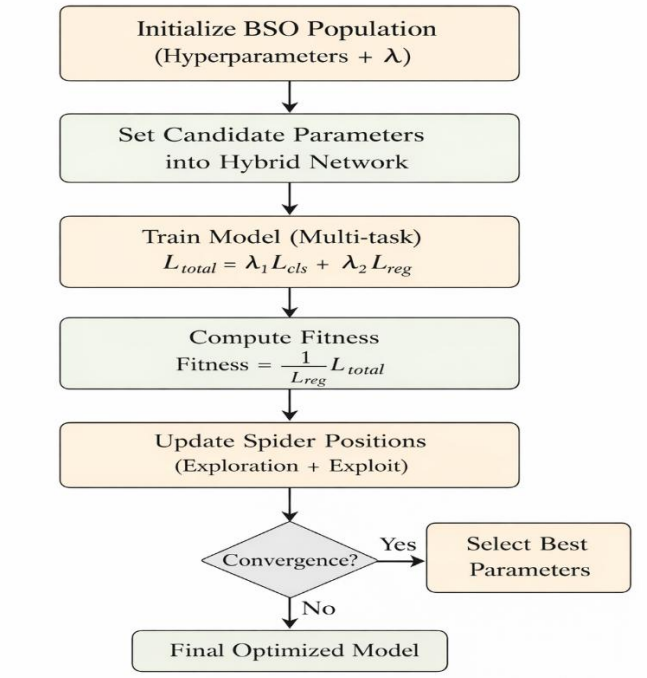

Fig. 3. Bolas Spider Optimization (BSO) workflow for hyperparameter and fusion weight optimization.

8) Counterfactual personalized intervention module: In addition to global and local SHAP accounts, the given framework has a counterfactual intervention module, which transforms SHAP feature attributions into action-oriented and student-specific suggestions. To every student forecasted as not placed, or forecasted below some salary level, the module finds the two most negative SHAP contributors and calculates how much the student needs to improve them in order to get his or her placement probability above the 0.5 mark or to get to his or her target percentile of salary. Consider, given that a student has a probability of placement, and the highest negative predictors are technical skills score and communication score, the module would give the particular level of improvement in each feature that is necessary to move the prediction to the placed category, giving career counselors an actual interpretable intervention strategy instead of an uncooked prediction.

The ExCogGNet algorithm proposed in (Algorithm 1) starts with pre-processing of the data such as normalization, encoding, and train-test splitting. Then a graph is created to depict the relationships among students in terms of similarity of features. The model combines the four branches: an MLP that captures cognitive features, a BiLSTM that captures temporal academic progression, a Transformer that captures contextual interactions, and a GNN that captures relationship learning. These embeddings are combined and sent to two output heads to perform classification in placement and salary prediction. The hyperparameters and fusion weights are tuned with Bolas Spider

Optimization and minimize a multi-task loss. Backpropagation is used to train the model in an iterative manner, and classification and regression measures are used to evaluate the model. Lastly, SHAP values and attention weights can be interpreted and make sense, thus allowing transparent and actionable decision-making.

Algorithm 1: BSO-Optimized Hybrid Network for Placement & Salary Prediction

```
Input:
  Dataset D with features (academic, demographic, cognitive)
  Labels: Placement (Y_cls), Salary (Y_reg)
Output:
  Trained model M
  Placement predictions Ŷ_cls
  Salary predictions Ŷ_reg
  Explainability insights (SHAP values, attention maps)
Begin
1. Data Preparation
  1.1 Load dataset D
  1.2 Handle missing values and encode categorical variables
  1.3 Normalize numerical features
  1.4 Split D into training set (D_train) and testing set (D_test)
2. Graph Construction
  2.1 Define nodes as students
  2.2 Compute similarity matrix based on feature space
  2.3 Construct adjacency matrix A
  2.4 Build graph G = (V, E)
3. Model Initialization (ExCogGNet)
  3.1 Initialize MLP branch for static cognitive features
  3.2 Initialize BiLSTM branch for temporal academic sequences
  3.3 Initialize Transformer branch for feature interactions
  3.4 Initialize GNN (GAT) branch for relational learning
  3.5 Initialize fusion layer
  3.6 Initialize output heads:
      - Softmax layer for placement classification
      - Linear layer for salary regression
4. Optimization using Bolas Spider Optimization (BSO)
  4.1 Initialize population of candidate solutions (hyperparameters)
  4.2 While stopping criterion not met:
      a. Evaluate fitness of each candidate:
          - Train model with given parameters
          - Compute multi-task loss:
              L = L_classification + λ * L_regression
      b. Update candidate solutions using BSO:
          - Exploration phase (lasso search)
          - Exploitation phase (reel refinement)
      c. Select best-performing configuration
  4.3 Set optimal parameters in model M
5. Model Training
  5.1 For each epoch:
      a. Forward pass:
          - MLP → static embeddings
          - BiLSTM → temporal embeddings
          - Transformer → contextual embeddings
          - GNN → relational embeddings
      b. Fuse embeddings
      c. Generate outputs:
          Ŷ_cls = Softmax(fused features)
          Ŷ_reg = Linear(fused features)
      d. Compute multi-task loss L
      e. Backpropagate and update weights
6. Model Evaluation
  6.1 Predict on D_test
  6.2 Compute metrics:
      - Accuracy, AUC (classification)
      - RMSE, R² (regression)
7. Explainability Module
  7.1 Compute SHAP values:
      - Global feature importance
      - Local explanations for each prediction
  7.2 Extract attention weights from:
      - Transformer layers
      - GNN layers
  7.3 Generate visualizations and insights
8. Output Results
  8.1 Return trained model M
  8.2 Return predictions (Ŷ_cls, Ŷ_reg)
  8.3 Return explainability outputs
End
```

IV. Result and Discussion

The Results and Discussion section considers the performance of the proposed framework, ExCogGNet, in terms of predicting student employability and salary, in terms of accuracy and interpretability. The performance of the model is evaluated based on the common classification and regression indicators, and compared with the traditional machine learning and state-of-the-art deep learning baselines. In addition to quantitative performance, the role of integration of cognitive traits, time progression, and relational learning in enhancing predictions is also examined in this section. Moreover, the results of explainability based on SHAP analysis and attention mechanisms are discussed to learn about some major factors affecting them. The results reveal the strength, generalization, and viability of the suggested method in the practical application of academic decisions in real-life situations.

A. Experimental Outcome

The general distribution of the Campus Recruitment data that was used in this study is shown in Table I. The sample size is 215 records of students; 148 students (68.8) were successful in placement, and 67 students (31.2) were not successful in placement. With regard to gender, the data sample is mostly male, with 139 students (64.7) representing it and 76 students (35.3) representing females. Concerning work experience, 65 students (30.2) have previous work experience, and 150 students (69.8) do not have previous work experience. The sample also contains two major specializations: 113 students (52.6) are in Commerce and Management, and 102 students (47.4) are in Science and Technology. In general, the table offers a concise summary of the demographic, academic, and placement-based features of the data, which illustrates that it is diverse and can be used to model not only the determinants of the placement outcomes but also the predictors of the salary.

Table II provides the detailed results of the optimization of the hyperparameters of the proposed BSO-based hybrid MLP-BiLSTM-Transformer-GNN model. In the case of the MLP branch, two hidden layers with 128 and 64 units, ReLU activation, and a dropout rate of 0.3 were used to reduce overfitting. The BiLSTM branch has 128 hidden units and a dropout rate of 0.2, and it is merely one layer and essentially captures the time-based dependencies in the sequential academic data. Transformer encoder is set with 4 attention heads, an

embedding dimension of 128, a feed-forward network (FFN) dimension of 256, and a dropout of 0.1, which enables the model to consider the contextual interactions between features. The GAT branch has 4 attention heads with a dimension of 128 as the output and ELU activation to learn relational embeddings over the student graph. All the branches are fused to the final branch by a weighted sum strategy where each branch's weight is 0.25. Training was done using the Adam optimizer, a batch size of 32, a learning rate of 0.0005, 100 epochs, and a weight decay of 0.0001.

TABLE I. DATA DISTRIBUTION TABLE

Category	Sub-Category	Count	Percentage (%)
Total Samples	—	215	100
Placement Status	Placed	148	68.8
	Not Placed	67	31.2
Gender	Male	139	64.7
	Female	76	35.3
Work Experience	Yes	65	30.2
	No	150	69.8
Specialization (Degree)	Commerce & Mgmt	113	52.6
	Science & Tech	102	47.4

TABLE II. OPTIMIZED HYPERPARAMETERS (BSO-BASED HYBRID MODEL)

Module	Key Settings
MLP	Layers: 2 • Units: (128, 64) • Activation: ReLU • Dropout: 0.3
BiLSTM	Layers: 1 • Hidden Units: 128 • Dropout: 0.2
Transformer	Heads: 4 • Embedding Dim: 128 • FFN Dim: 256 • Dropout: 0.1
GAT	Attention Heads: 4 • Output Dim: 128 • Activation: ELU
Fusion	Strategy: Weighted Sum • Weights (λ): 0.25, 0.25, 0.25, 0.25
Training	Optimizer: Adam • LR: 0.0005 • Batch Size: 32 • Epochs: 100 • Weight Decay: 0.0001

The distribution shows that most of the placements are within the ₹200k-₹400k range, which comprises almost 78.4% of the students placed (Fig. 4). Simultaneously, the existence of higher pay ranges indicates that there is an opportunity to have better pay among the high-achieving students, not only showing consistency in the overall placement results but also signifying the possibility of receiving high-paying jobs.

The Secondary percentage is 78.5%, with a standard deviation of 6.2, showing that the majority of the students were fairly consistent in performance, ranging between 60 and 95. The average of the Higher Secondary percentage is a bit higher at 81.2% and has less variability (5.8), indicating enhanced performance that is more consistent in senior secondary education, with a range of 65 to 98. The degree percentage in the undergraduate level is 75.6% with a wider variation (7.1), with values in the range of 55 to 95, meaning that students are more varied in academic results. Other than academic performance, the Cognitive Trait Score is 68.4 with a standard deviation of 8.5, showing moderate variations of cognitive abilities among the students. The highest variability is 9.2, with a mean of 72.3 of the Technological Skills Score, which indicates a great variation in technical competence with ranges of 50 to 90. On the whole, the table proves that there is a relative consistency in academic performance among students, but cognitive and technical skills are more diverse, and they are valued when it comes to distinguishing the general competencies and employability of the students.

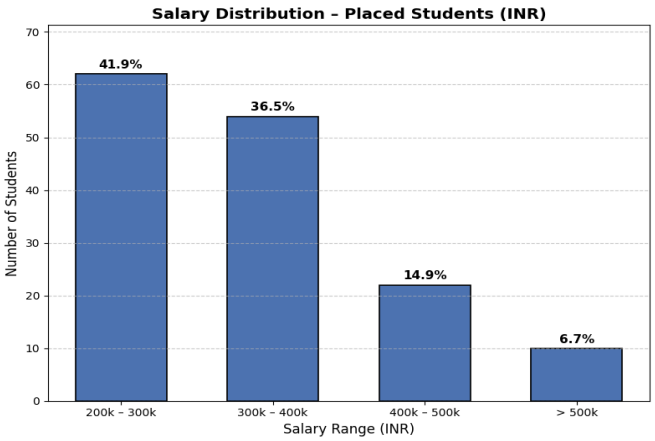

Fig. 4. Salary distribution.

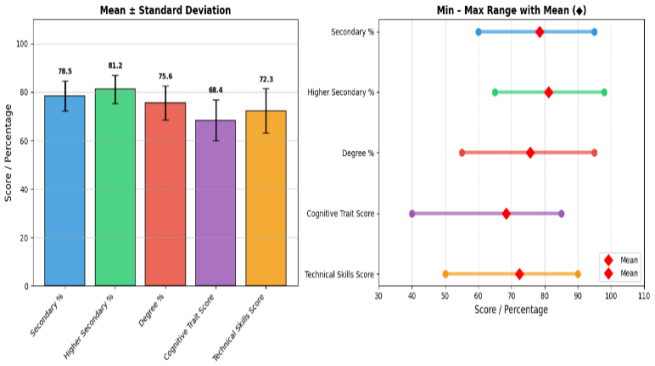

Fig. 5. Academic feature distribution.

The descriptive statistics in Fig. 5 show the mean performance of the students based on key academic, skill, and experience-related variables and the variability as well as the overall range of the scores. The Secondary Percentage (10 th grade) has a mean of 78.5 as well as a standard deviation of 6.2, as the performance of the students is consistent with scores ranging between 60% and 95%. The Higher Secondary %age (12 th) is a little higher, with the average being 81.2 % with a narrower spread (5.8), indicating a stronger and more consistent performance in senior secondary education. Degree Percentage, which is a measure of the performance of the undergraduates, has a mean of 75.6 and a higher standard deviation (7.1), with more varied academic results of 55-95.

It shows the feature contribution analysis with SHAP (SHapley Additive exPlanations), which measures the impact of each feature on the predictions of the model. The most significant features noted in the table, along with the importance score and the direction of the effect, are the Degree Percentage, with an importance score of 0.21. Its positive effect signifies that

the greater the undergraduate scores, the stronger the projected probability of achievement, as indicated in success, i.e., placement or anticipated performance. Such a strong positive influence of the Cognitive Trait Score (0.18) also highlights the importance of analytical and aptitude skills in the determination of results (Fig. 6).

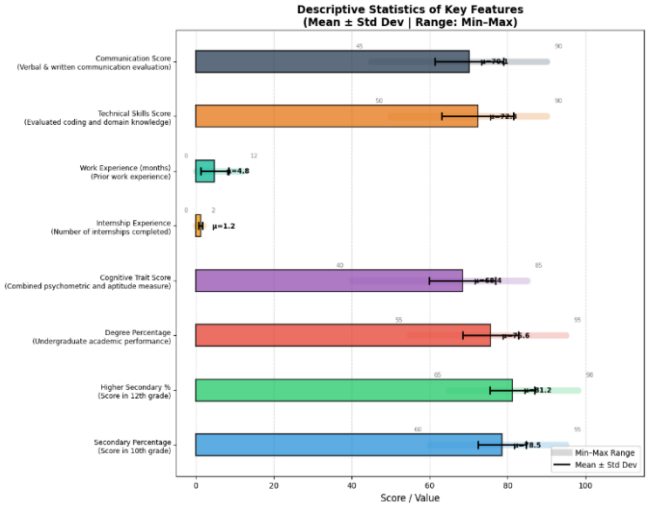

Fig. 6. Descriptive statistics of key features.

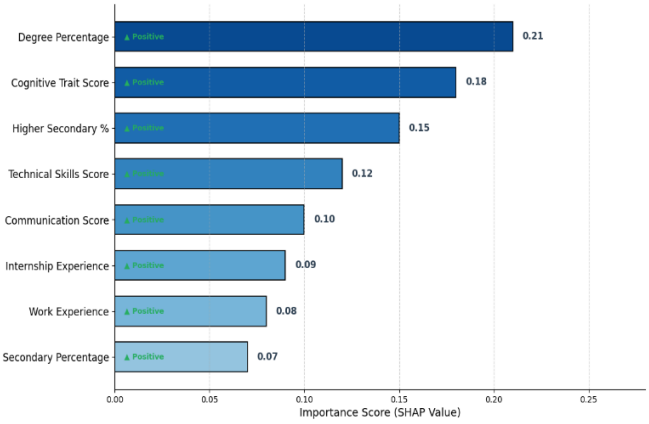

Fig. 7. Feature contribution analysis (SHAP-Based).

Fig. 7 shows the performance of the model based on standard evaluation measures: Precision, Recall, F1-score, and Support. In the Placed class, the model has a Precision of 97, meaning that most of the students that are predicted to be placed are actually placed correctly. There was a recall of 96%, indicating that the model was able to recognize 96% of the total students that were actually placed. The overall performance of this class is high, as the precision and recall balance; the F1-score is 96.5. The Placed class has a support of 106 students.

The confusion matrix helps to determine the effectiveness of the placement classification model in terms of comparison between the results predicted and actually obtained. Out of the 106 students who were actually placed, the model was correct in 102 of them being placed, and 4 students were misclassified as not placed. Of the 59 students who had not been placed, 56 of them were correctly identified as not placed, and 3 of them were not identified as placed. These findings show that the model is very accurate and the misclassifications in both classes are very minimal. On the whole, the confusion matrix illustrates that the model is very useful in differentiating placed and not placed students, which means that it is very reliable in making predictions of placement results (Fig. 8).

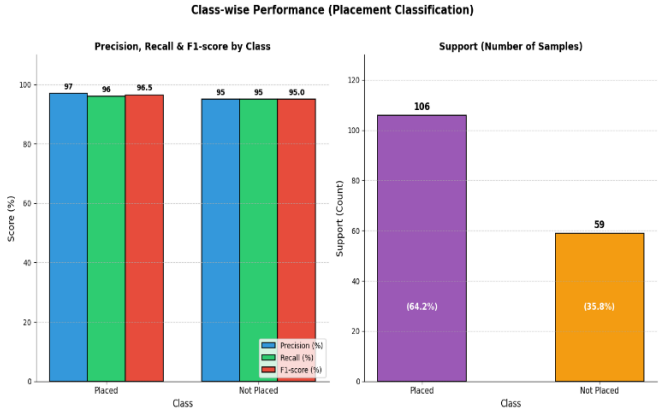

Fig. 8. Class-wise performance.

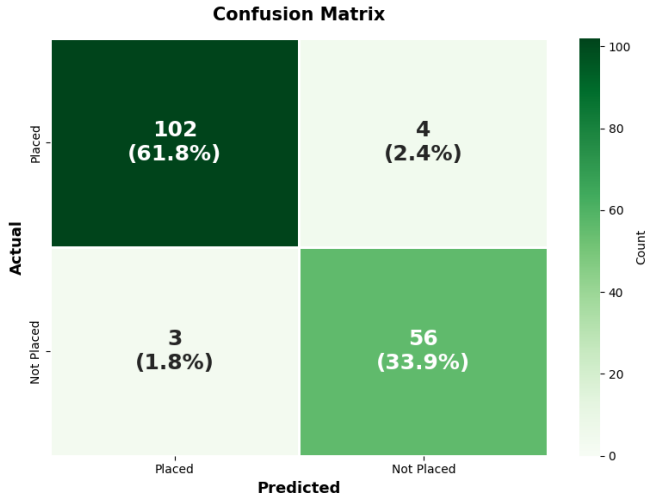

Fig. 9. Confusion matrix.

Fig. 9 gives the performance of different machine learning and deep learning models in terms of placement prediction in various evaluation metrics, such as accuracy, precision, recall, F1-score, and AUC. Conventional models such as SVM had moderate performance with an accuracy of 78% and AUC of 0.81, which reflected decent but poor predictive powers. Random Forest and XGBoost enhanced the performance, both achieving 82% and 84 % of the accuracies, respectively, with correspondingly higher rates of precision, recall, F1-score, and AUC, indicating more aptitude to address the complicated interaction of features.

It shows the salary prediction performance of various regression models in terms of RMSE, MAE, and R 2. Linear regression has the poorest results with an RMSE of 48k INR, an MAE of 36k INR, and R^2 of 0.62, which suggests that it has very poor predictive power. Random Forest and XGBoost ensemble models bring the predictions to RMSE of 42k and 38k INR, MAE of 31k and 28k INR, and R^2 of 0.71 and 0.75, respectively,

showing more non-linear relationships in the data. Deep learning architectures such as BiLSTM and Transformer are also used to improve the performance, with RMSE of 35k and 33k INR, MAE of 25k and 23k INR, and R^2 of 0.78 and 0.80 indicating capability to capture sequential and complex feature interactions. The GNN, which does not use BSO, exhibits further improvement with an RMSE of 31k INR, MAE of 21k INR, and R^2 of 0.82, which indicates the advantage of capturing relational information in the model. Compared to all other models, the proposed hybrid model of MLP, BiLSTM, Transformer, and GNN with BSO optimization has yielded data with an RMSE of 24k INR, MAE of 18k INR, and R^2 of 0.91, which includes highly predictive and reliable data in terms of accuracy and performance of the predicates in the salaries. Given that the salary range in the dataset falls between roughly 200k INR and 940k INR, an RMSE of 24k INR can be regarded as quite low, and hence a sign of the reliability of the regression model (Fig. 10).

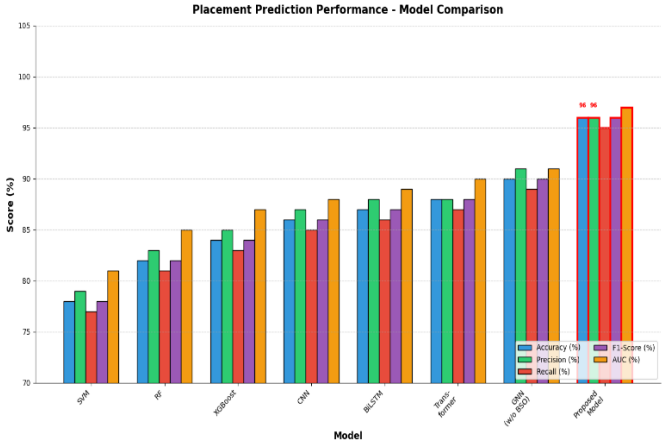

Fig. 10. Placement prediction performance.

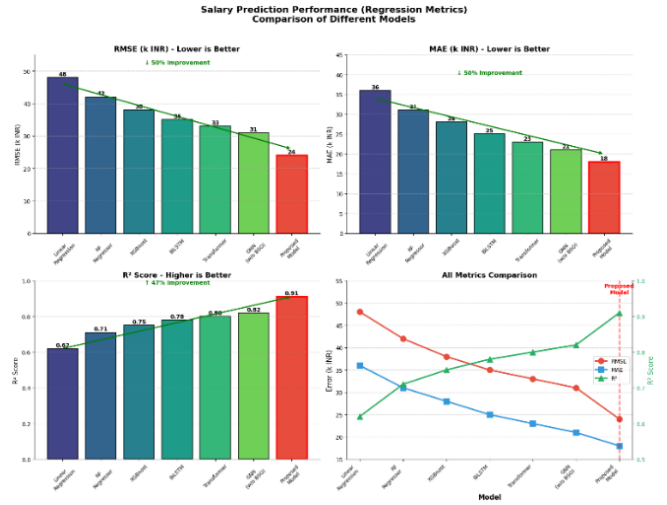

Fig. 11. Salary prediction performance.

B. Performance Analysis

Fig. 11 illustrates how the model accuracy of training and testing accuracy improved with 100 epochs. At the first 10 epochs, the training accuracy is 88.5, and the testing accuracy is 86.2, which means that the model is in the process of learning but still can be improved. The higher the number of epochs, the higher the training and testing accuracy, indicating that there is an efficient learning and generalization. At 50 epochs, the training and testing accuracy are 95.5 and 94.0%, respectively, which is good model performance with very little overfitting. After 60 epochs, the accuracy gains start to level off, and the training accuracy reaches 97.5 per cent, whereas the testing accuracy reaches around 96.0 per cent. In general, the table proves that the model is convergent, as its accuracy is high and stable on the training and testing data, which proves strong learning and strong generalization on the unknown data (Fig. 12).

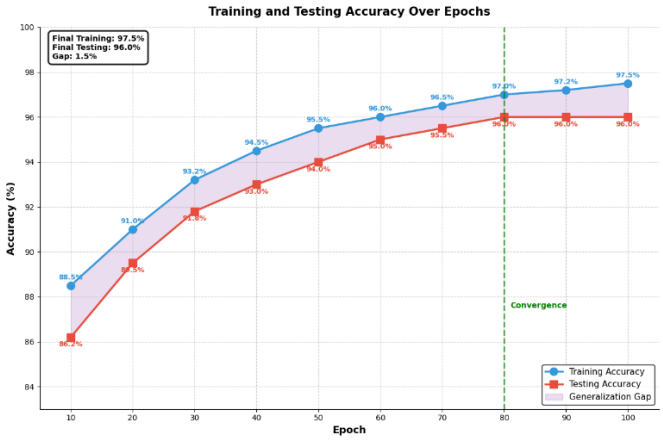

Fig. 12. Training and testing accuracy table.

The plot of the training and testing loss of the model over 100 epochs demonstrates the capability of the model to learn and generalize well. The training and testing losses at age 10 are 0.42 and 0.45, respectively, which means that the model is yet to learn much. Training loss and testing loss smoothly decrease as training advances, indicating improved model performance and enhanced precision in prediction. Training loss decreases to 0.18, and test loss decreases to 0.21 by 50 epochs, indicating that the model is learning the data patterns and still has good generalization. The loss keeps decreasing more slowly after 80 epochs, with 100 epochs having the results of 0.06 (training) and 0.10 (testing). In general, the table shows that there has been steady convergence of the model, with both training and testing loss reducing continuously, which is a sign of effective learning and very little overfitting (Fig. 13).

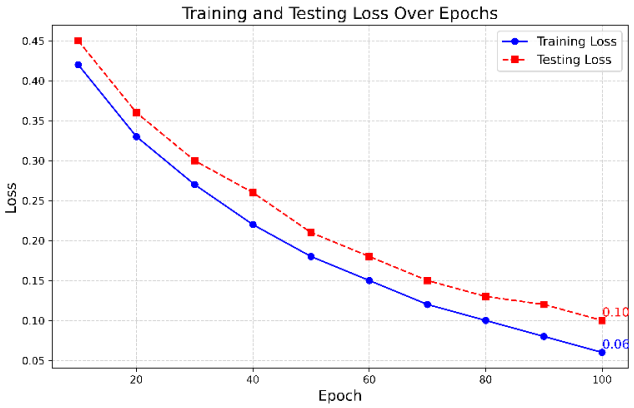

Fig. 13. Training and testing loss.

The convergence and optimization stability of the process is depicted in the graph after a number of iterations (Fig. 14). It presents three metrics, which are BSO fitness, placement accuracy, and salary R 2, versus the number of iterations. The three metrics have a slow increase with increment of the iterations, which demonstrates that the optimization algorithm is indeed refining the solution. The BSO fitness is steadily increasing between 0.88 and 0.96 with a steady increase in the objective function. The same case is with the accuracy of placements, whereby the accuracy rises to 96 % compared to 90 %, indicating that the model is more predictive of successful placements as time goes by. Salary R^2 also increases to 0.91 as compared to 0.84, which indicates a better correlation between predicted and actual salaries. The convergence of the algorithm is also identified in the graph and the stability of the model as the measures reach a steady level in the later iterations, indicating that additional iterations do not significantly alter them.

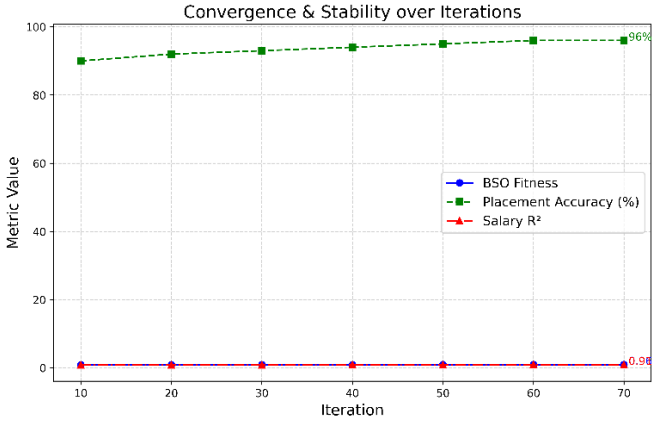

Fig. 14. Convergence & stability.

C. Ablation Study and Computational Justification

An ablation study has been performed by successively removing each component of the hybrid architecture and observing the impact on the performance of ExCogGNet. The assessment was made based on both placement classification accuracy and the salary R^2 performance. Experimental results have shown that the overall ExCogGNet system has the best performance with placement classification accuracy of 96%, and a salary R^2 score of 0.91 (Table III). Removing the Transformer branch leads to a loss of ability for contextual interactions in learning. Removal of the GNN branch decreases relational dependency analysis skills among students. The removal of the BiLSTM branch affects ordered academic progressions in the learning process. Lastly, the exclusion of the MLP branch limits cognitive feature representation skills. It can be seen that all modules provide complementary skills to the whole system; hence, the improvements in the performance cannot be caused by excessive architectural complexity. In addition, even though using the hybrid architecture is computationally more expensive than using standalone models, the huge boost in the accuracy and robustness of multi-tasking makes this extra complexity worthwhile.

D. Multi-Task Loss Weight Sensitivity Analysis

In order to measure the stability of the multi-objective optimization, further experimental studies were performed using variations in the loss balancing parameters λ_1 and λ_2 for classification of placements and salary regression, respectively. It can be observed from experimental data that an increase in λ_1 results in better classification quality but increases salary prediction RMSE, and an increase in λ_2 improves regression results but adversely affects classification results. The optimal results in terms of the trade-off between both objective functions have been found when $\lambda_1 = 0.6$ and $\lambda_2 = 0.4$. Also, the small value of the performance deviation across different optimization iterations is evidence of the algorithm's stability and consistency, as shown in Table V.

TABLE III. ABLATION STUDY OF EXCOGGNET COMPONENTS

Model Variant	Placement Accuracy (%)	Salary R^2
Full ExCogGNet (MLP + BiLSTM + Transformer + GNN + BSO)	96	0.91
Without Transformer	93	0.86
Without GNN	91	0.84
Without BiLSTM	89	0.82
Without MLP	88	0.80
Transformer Only	86	0.78
BiLSTM Only	84	0.75
MLP Only	81	0.71

TABLE IV. EFFECT OF LOSS WEIGHT VARIATIONS ON MULTI-TASK PERFORMANCE

λ_1 (Classification)	λ_2 (Regression)	Placement Accuracy (%)	Salary RMSE (INR)
0.2	0.8	88	22k
0.4	0.6	92	23k
0.5	0.5	94	25k
0.6	0.4	96	24k
0.8	0.2	97	29k

Fig. 15 shows the cross-validation 5-fold performance of the classification model. It is a summary of training and validation accuracy, precision, recall, F1-score, and AUC of five folds, the average, and standard deviation of these values. The findings show that there is a high consistency level amongst folds and that the average accuracy of training is 97.1 % and average accuracy of validation is 96.0 %. Precision and recall rates are also good, which means that the model has good capabilities of recognizing true positives and reducing falsely recognized positives and falsely recognized negatives. The overall classification performance is confirmed by the F1-score that balances recall and precision and has an average of 96.0. The solid averaged values of the AUC, 0.97, also contribute to the high discriminative ability of the model. Low standard deviations in all the metrics indicate that the performance was consistent and variable was small, and it shows the reliability of the model and its generalizability in various subsets of the data.

The minimal standard deviation seen in the five validations implies that there is consistent learning performance and less sensitivity to changes in training data due to the moderate number of samples used. This implies that the proposed framework is able to learn generalized features rather than learning specific characteristics of the dataset. It is, however, important to conduct further testing on a large, multisite database comprising students of varied backgrounds.

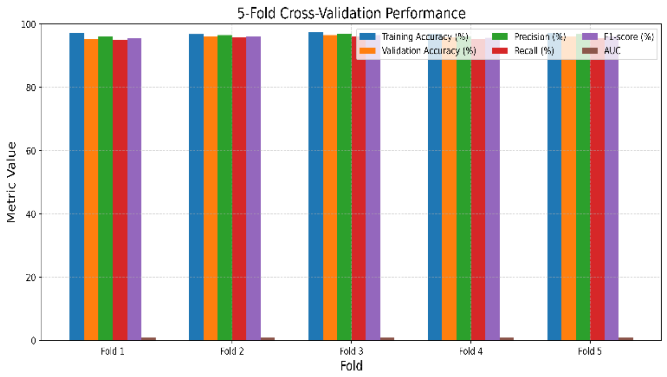

Fig. 15. 5-Fold cross-validation performance (classification).

The graph (Fig. 16) indicates the performance of the salary regression model when cross-validation is conducted five-fold. It shows three metrics, namely RMSE, MAE, and R^2 against each fold. RMSE reduces steadily with each fold, with fold 1 of 26 k INR in fold 5 of 24 k INR, and MAE also reduces to 18 k INR, showing that the prediction errors are reduced, as well as the model becomes more accurate across folds. The values of R^2 are quite high, between 0.89 and 0.92, and this shows a high correlation between the predicted and actual salaries. The graph shows the reliability and stability of the regression model since the measures indicate minimal change in different folds, which proves the ability of the model to generalize.

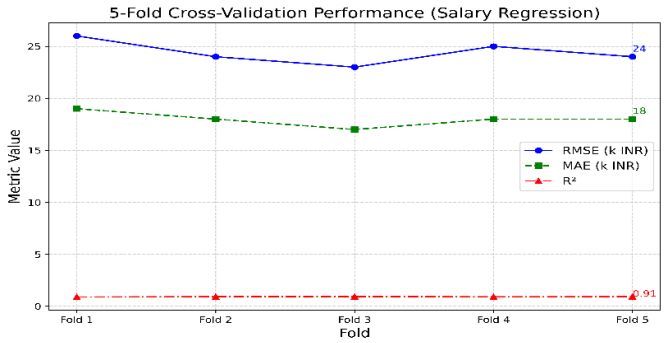

Fig. 16. 5-Fold cross-validation performance (regression).

The comparison table on the baseline gives the performance of several conventional machine learning and deep learning models in comparison with the proposed hybrid MLP-BiLSTM-Transformer-GNN model trained using Bolas Spider Optimization as a placement and salary predictor. The findings show that the classical models, i.e., SVM and random forest, are moderate in terms of placement accuracy of 78 % and 82 %, respectively, and relatively higher in terms of errors in salary prediction, represented by an RMSE value of 48k INR and R^2 values of 0.62 and 0.71, respectively. CNN, BiLSTM, and Transformer models are advanced deep learning models that achieve better performance, with placement accuracies ranging between 86% and 88% and decreasing lower values at RMSE, proving the benefit of sequential and contextual learning. Graph neural networks with no BSO can achieve 90 % placement accuracy, which shows the effectiveness of relational modeling. The hybrid model that is proposed and includes BSO is in a much better position than any of the baselines, with 96% placement accuracy, 96% F1-score, and 0.91 predictive R^2 of salary.

Regarding the evaluation of the effectiveness of the suggested framework under small data situations, five-fold cross-validation techniques were applied, together with regularization-based optimization approaches within the experimentation stage. As a result, the hybrid system consistently performed at a high level of validation with low variability between different folds. This indicates stable learning behavior and insensitivity to variations in the training data set. The results indicate that the model learned generalized representations of features instead of being sensitive to specific aspects of the used data set, despite its relatively small size. However, the selected data set is a benchmark educational data set based on the Campus Recruitment data set, including around 215 records. Hence, it does not necessarily represent multi-faculty environments adequately due to its scale. Thus, while reporting a 96% placement success rate is a good benchmark result, further large-scale validation is required.

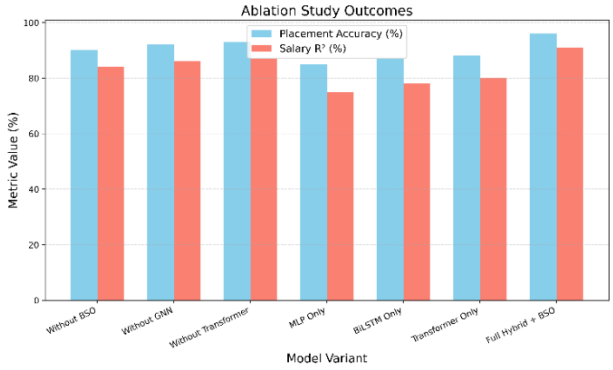

Fig. 17. Component contribution analysis.

The ablation study analysis, as shown in Table IV and Fig. 17, shows how each component individually contributes to the overall predictive performance of ExCogGNet. The complete hybrid model optimized through BSO resulted in maximum placement accuracy at 96% and maximum salary prediction at 0.91. The omission of BSO resulted in a decrement in optimization stability as well as a performance drop, thus emphasizing the importance of optimization of hyperparameters and fusion weights. Omission of the GAT branch resulted in weak relational learning in the case of students as well as prediction performance, thus underlining the importance of modeling peer relationships through graph learning. The exclusion of the Transformer resulted in the inability to learn from contextual feature interactions, while excluding the BiLSTM branch led to inadequate modeling of academic progress over time for students. Moreover, the standalone performance of MLP was significantly low since only static

features can predict employability. This analysis proves the need for a hybrid multi-branch architecture for effective multi-tasking.

To confirm that the performance difference between the proposed model and the strongest base, GNN without BSO, is statistically significant and cannot be explained by random fluctuation, the McNemar test was used to test the placement classification results of the five cross-validation folds. The p-value of 0.003 confirms that the increase in accuracy between 90% and 96% is statistically significant at the level of significance of 0.01, proving that the gains are real and reproducible and not data-specific.

TABLE V. BASELINE COMPARISON FOR PLACEMENT AND SALARY PREDICTION

Model	Placement Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)	AUC	RMSE (k INR)	MAE (k INR)	R^2
SVM	78	79	77	78	0.81	48	36	0.62
Random Forest (RF)	82	83	81	82	0.85	42	31	0.71
XGBoost	84	85	83	84	0.87	38	28	0.75
CNN	86	87	85	86	0.88	35	25	0.78
BiLSTM	87	88	86	87	0.89	33	23	0.80
Transformer	88	88	87	88	0.90	31	21	0.82
GNN without BSO	90	91	89	90	0.91	29	20	0.84
Proposed Hybrid MLP-BiLSTM-Transformer-GNN + BSO	96	96	95	96	0.97	24	18	

E. Discussion

The suggested hybrid MLP-BiLSTM-Transformer-GNN model, optimized with Bolas Spider Optimization (BSO), provided an accuracy of 96% in the placement of the model, a 0.97 AUC, and a 0.91 salary prediction R-squared. These scores beat any of the baseline models. Furthermore, when interpreted relative to the overall salary distribution of the dataset, the observed RMSE indicates that the prediction deviation remains comparatively small, supporting the practical usefulness of the proposed framework for salary estimation tasks. such as GNN (without BSO) and Transformer (without BSO) (90 and 88 percent accuracy, respectively). The statistical significance of such an improvement, proved with the help of the McNemar test ($p = 0.003$), is the fact that the performance improvements are not specific to the dataset. The ablation analysis shows that BSO is essential for the globally optimal fusion weights and attention coefficients of the heterogeneous branches. The loss of BSO caused a significant decrease in performance, which proves that when the architecture is simply combined without any principled optimization, it may produce suboptimal learning. Even though BSO has been shown to exhibit stable convergence behavior along with robust predictive performance under the proposed framework, it is noteworthy that this research effort fails to provide an experimental benchmarking analysis of the optimization performance of BSO compared to other traditional approaches such as Bayesian optimization, grid search, and random search. The sensitivity analysis on the loss functions of the multi-task model shows that the proposed optimization framework is quite robust. From experimental results, it was found that varying settings of λ_1 and λ_2 had an effect on the balance between classification performance in placement and regression in salary prediction. The chosen setting led to convergence and high performance in both classification and regression. In addition, the repeated observation of the optimization process over several iterations shows the stability of BSO-based adaptive optimization.

The SHAP-based analysis revealed that the degree percentage (0.21), cognitive trait score (0.18), and technical skills score (0.12) are the most significant predictors, which supports the empirical argument of the cognitive-aware design of the model. The counterfactual SHAP explainability module offers feature-level insights into attribution and creates recommendation guidance for users by leveraging influential academic and cognitive attributes. These explanations can help career counselors and other institutional representatives gain insights into the significant determinants that influence employment results. However, in this particular research, no human-in-the-loop evaluation was conducted, nor did deployment testing or validation with career counselors or educators take place. Thus, this recommendation tool is more of a prototype that demonstrates how the proposed solution works through explainable means. The next step in future research is human-centered testing, usability evaluation, and institutional deployment research. Even though excellent prediction has been made through the use of the ExCogGNet, one challenge that should be taken note of is the limitation brought about by the size of the datasets used in the study. For deep hybrid networks, it is critical to use diversified datasets that help in increasing the generalization ability of the architecture due to its heterogeneity within different educational settings. The problem has been resolved through the use of five-fold cross-validation, dropout, optimized weights, and multi-tasking techniques to avoid overfitting. Furthermore, the constant accuracy levels obtained in validation, despite the small number of datasets, suggest stable learning behavior. Nevertheless, further validation using more diversified datasets from different universities will be needed.

V. CONCLUSION AND FUTURE WORK

In this study, an Explainable Cognitive Graph Network, ExCogGNet, was proposed that integrates MLP-based encoding of cognitive traits in a static form, BiLSTM-based modeling of ordered academic progression stages, Transformer-based contextual feature attention, and Graph Attention Network learning of peer-level relational structures within one multi-task

model. The model also does placement classification and salary prediction, and Bolas Spider Optimization across the world optimizes hyperparameters, attention coefficients, and fusion weights, with a combined cross-entropy and mean squared error loss, alleviating heterogeneous architecture instability.

The experimental findings on the Campus Recruitment benchmark dataset demonstrate that ExCogGNet is 96% accurate in placement and has an AUC of 0.97 and a salary prediction RMSE of 24k INR and R2 of 0.91, which is much higher than baseline models (SVM 78%), Transformer (88%), and un-optimized GNN (90%). The improvement is statistically significant ($p = 0.003$), as proven by McNemar. One important contribution is the counterfactual SHAP-based explainability module, which generates interpretable, recommendation-oriented insights for potential use in educational decision-support environments, converting feature attributions into individual, actionable recommendations on student skill improvement, which may support future decision-making processes for career counselors and institutional stakeholders after further practical validation. The ablation study results further confirm that each architectural component, including MLP, BiLSTM, Transformer, GNN, and BSO optimization, contributes complementary predictive capability, thereby justifying the hybrid multi-branch design of ExCogGNet. The ability of the framework to generate individualized recommendation-oriented explanations enhances its potential applicability in academic advisory systems, placement preparation programs, and institutional career guidance environments.

Though the introduced ExCogGNet framework exhibits good prediction performance on the Campus Recruitment dataset, its modest sample size makes comprehensive evaluation of its generalization ability challenging across a wide range of different educational organizations. As such, efforts will be directed at testing the framework on bigger educational datasets that include diverse student populations, behavioral learning history, socioeconomic features, and current academic progression information from multiple institutions. Despite the promising results obtained in terms of predictive performance and explainability, the present study has not considered user-focused validation through experiments with actual users such as students and career counselors. Therefore, the recommendatory explainability component should be seen as a prototype model for now. Usability experiments, human expert analysis, and real-world application will be conducted in subsequent research endeavors. Other potential research directions include methods of constructing graphs in scalable ways, employing light transformers, and utilizing federated learning techniques.

In the current dataset, milestone-based educational progression is included compared to fine-grained longitudinal academic history; future research might also include semester-based academic progress for improving sequential learning ability.

Large Language Models for Arabic Automated Essay Scoring

Leena Najjar, Liyakathunisa Syed
Department of Computer Science-College of Computer Science and Engineering, Taibah University, Medina, Saudi Arabia

***Abstract*—Automated Essay Scoring (AES) has become an important research area in educational artificial intelligence due to its potential to support scalable and consistent assessment. The developments within the realm of transformers and large language models (LLMs) have led to great improvements within AESs through their ability to comprehend semantics and context, as well as their knowledge of rubrics. Although these advancements have been realized within the English language, there is still relatively little research surrounding Arabic Automated Essay Scoring (AAES). This survey summarizes some of the latest advancements in AAES and discusses traditional ML models, deep learning, transformers, and LLM-driven evaluation frameworks. In this study, researchers synthesize the relevant literature regarding datasets, prompts, pre-processing methods, performance metrics, and reliability of scores. Typical performance metrics used to analyze the level of agreement between human raters and automated systems are QWK, MAE, and correlation-based metrics. The survey also describes crucial challenges encountered by AAES systems such as insufficient amount of data, inconsistencies, high computation costs, bias, and non-reproducibility. Overall, it can be said that both transformers and LLMs achieve better performance when it comes to capturing context information and providing agreement with human assessment. However, issues with reproducibility and scalability continue to persist. Additionally, the survey presents new areas of research that may be relevant to future AAES studies, such as multilingual evaluation, hybrid grading, explainability, and standardized sources of Arabic essays.**

Keywords*—*Arabic automated essay scoring; large language models; educational AI; prompt engineering; evaluation metrics; natural language processing

I. Introduction

Artificial intelligence is transforming how today's educational systems measure student outcomes, covering aspects ranging from feedback mechanisms to test construction and grading systems [1], [2]. Within this emerging framework, Automated Essay Scoring (AES) is now an important focus of ongoing research, designed to reduce teachers' burdens while increasing consistency, objectivity, and scalability in grading. The earlier Automated Essay Scoring (AES) systems relied on machine learning approaches, which in turn depended on feature engineering. These earlier systems were extremely efficient in the prediction of scores, yet failed to grasp the essence of the essays, the underlying structure of the arguments, and their context [3], [4].

The emergence of deep learning and transformer-based models is an important milestone in the development of automated grading. These models now utilize context and long-range dependencies in essays and other forms of text to better understand language. For instance, Siamese Bi-LSTM models and transformer-based Automated Essay Scoring tools are becoming closer to human judgment than earlier machine-learning-based systems because of their better semantic understanding of the content of the essays [5], [6]. Recently, large language models (LLMs) have moved the AES paradigm towards reasoning-oriented evaluation models that utilize models of natural language interaction, such as rubric-informed prompting, few-shot learning, and instruction tuning to mimic human grading behavior [7], [8].

AAES systems also have their challenges, which are largely due to the complexities of the Arabic language and the lack of sufficiently large datasets for training and evaluating these systems. For instance, although multilingual large language models are highly promising in many evaluation scenarios, their application in Arabic Automated Essay Scoring systems is relatively less explored [8], [9]. In addition, there is a lack of comprehensive systematic studies on the evolution of these systems, dataset characteristics, and evaluation frameworks in the context of Arabic Automated Essay Scoring systems in the existing body of research.

To address this identified information gap, this study aims to synthesize existing research on Arabic automated essay scoring powered by large language models. It discusses the evolution of architectures, the creation of Arabic evaluation datasets, prompt design, the measurement of results, and the ethical issues related to the deployment of AI technology in education. With the synthesis of information from multiple research threads, the study aims to provide a clear reference guide for the development of Arabic automated essay scoring technology that is effective, scalable, and suitable for educational contexts.

The study makes the following contributions to the field of Arabic automated essay scoring powered by large language models: it proposes a comprehensive architectural taxonomy for AAES, presents a discussion on the creation of Arabic evaluation resources, and compares prompting and evaluation techniques for LLM-based essay grading. To the best of our knowledge, this is one of the first systematic surveys on Arabic Automated Essay Scoring (AAES) powered by large language models.

Unlike other surveys on automated essay scoring, this study provides a comprehensive view of Arabic automated essay scoring powered by large language models by discussing together the evolution of architectures, the creation of Arabic evaluation resources, the designing prompts, and the performance evaluation.

The paper is divided into the following sections: Section II discusses the systematic review methodology, Section III synthesizes the findings, Section IV discusses the implications and challenges, and Section V concludes with the future research directions.

II. Methodology

This survey is conducted using a PRISMA-based methodology to maintain transparency, reproducibility, and comparability of the results with other studies on Arabic Automated Essay Scoring (AAES). The relevant papers were retrieved from widely recognized scientific data sources, including IEEE Xplore, ScienceDirect, SpringerLink, MDPI, ACM Digital Library, and arXiv. The scope of the study included papers published between 2018 and 2026, focusing on automated essay scoring, Arabic NLP, large language models, and AI-based educational evaluation.

A four-step paper selection methodology was employed as follows:

- Identification: The relevant papers were identified with the help of the search terms automated essay scoring, Arabic NLP, transformer-based models, and large-language-model-based evaluators.
- Screening: The identified papers were screened by checking the title and abstract to eliminate those irrelevant to the field of education, evaluation, or automated scoring.
- Eligibility: All full papers were checked for eligibility based on set criteria in terms of a distinct methodology being used, technical suitability, and experimental description.
- Inclusion: Papers were considered for final evaluation only if they offered quantitative evaluation metrics like Quadratic Weighted Kappa (QWK), Mean Absolute Error (MAE), correlation coefficients, etc.

Such a method adheres to a well-established and modern blueprint that has been used in recent reviews of AI-powered educational assessment. This methodology strives for a comprehensive and reproducible analysis of how architectures are developed, what kinds of data are used, and how evaluation is conducted in the AAES domain. Before performing the analysis, the review protocol defines clear criteria for categorizing architectures, datasets, and evaluation strategies to ensure consistency across the selected studies.

A. Research Questions

The survey is structured around a set of questions that provide a framework for systematically analyzing how Arabic Automated Essay Scoring (AAES) is developed, what types of data are used, how evaluation is conducted, and the future directions of AAES. These questions guide the selection, comparison, and synthesis of the literature:

RQ1: How do traditional machine learning, deep learning, transformer-based, and large language model approaches compare in terms of performance, reliability, and scoring behavior in Arabic Automated Essay Scoring.

RQ2: What kinds of datasets are being used in Arabic Automated Essay Scoring (AAES) research, and how do linguistic properties, annotation schemes, and domain factors affect model generalization and robustness.

RQ3: What kinds of prompting strategies, scoring systems, and preprocessing methods lead to more consistent, interpretable, and transparent grading in LLM-based evaluation systems.

RQ4: How do evaluation metrics—such as Quadratic Weighted Kappa (QWK), Mean Absolute Error (MAE), and correlation-based metrics—perform in aligning automated grades with human judgments.

RQ5: What kinds of trends in architecture, deployment, and ethics have emerged in LLM-based evaluation systems in Arabic Automated Essay Scoring.

Relevant studies were identified through a systematic search across major academic repositories, including IEEE Xplore, SpringerLink, ScienceDirect, arXiv, as well as peer-reviewed journals on educational artificial intelligence. The search scope was limited to publications between 2018 and 2026, capturing the rapid emergence of transformer architectures and LLM-based grading frameworks in this period.

A comprehensive keyword strategy was employed to ensure wide coverage of Arabic Automated Essay Scoring (AAES) research and related multilingual grading studies. The primary search terms included:

- “Arabic automated essay scoring”
- “large language models grading”
- “LLM evaluation education”
- “transformer essay scoring”
- “rubric-based prompt engineering”
- “multilingual automated grading”
- “QWK automated assessment”

These keywords were applied individually and in combination using Boolean operators to ensure comprehensive retrieval of relevant studies. The search strategy intentionally incorporated both technical, model-oriented terms and education-focused evaluation terminology to capture interdisciplinary contributions spanning natural language processing, educational measurement, and AI-assisted assessment.

A broad inclusion strategy was adopted to encompass experimental studies, methodological frameworks, and conceptual analyses addressing LLM-driven grading pipelines, multilingual evaluation frameworks, and human–AI collaboration in assessment [7], [8]. This approach ensured comprehensive coverage of emerging research trends while remaining aligned with the survey’s research questions and analytical objectives.

An example search string used in IEEE Xplore was:

("Arabic" AND "automated essay scoring") OR ("large language model" AND "educational assessment").

B. Exclusion Criteria (Any of the Following Conditions):

Studies were excluded if they met one or more of the following criteria:

- The study relied on heuristic or rule-based grading approaches without involving machine learning or neural modeling techniques.
- The study lacked experimental validation and/or did not report performance measures.
- The study focused on general natural language processing tasks unrelated to educational assessment and automated grading.

Survey and review articles were included only when they provided essential background information, theoretical underpinnings, and relevant knowledge.

C. Dataset Mapping and Organization

Each included study was carefully reviewed to identify the datasets that were employed in the construction, training, and testing of these models. Special focus was given to Arabic essay datasets such as AR-AES and other emerging Multilingual Automated Essay Scoring benchmarks.

The following aspects were examined to map these datasets:

- Language and linguistic complexity, including the intricacies of the Arabic alphabet and the distinctive morphology of the language.
- Dataset scale and scoring framework, distinguishing between analytic and holistic scoring approaches.
- Domain coverage and educational level, including essays, exams, and other structured writing tasks.
- Annotation quality and inter-rater agreement, measuring the degree of consistency between different raters in evaluating essays.

This dataset-wide mapping enables a structured comparison of architectural performance across different language models, scoring models, and annotation strategies, thus directly addressing Research Question 2. This survey also highlights significant gaps in current Arabic Automated Essay Scoring (AAES) studies, including limited dataset access, domain bias, and scoring rubric inconsistencies, all of which affect model generalization.

D. Architectural Categorization

To address Research Questions 1 and 5 (RQ1 and RQ5), the selected studies were systematically categorized by architectural paradigm. The proposed taxonomy captures the evolutionary trend of Automated Essay Scoring (AES) systems, from traditional feature-engineering models to reasoning-oriented LLM-based evaluators. Four architectural categories have been proposed for the categorization of the studies:

- Traditional Machine Learning AES: Feature-engineering models, including support vector machines, regression models, and traditional large-scale supervised learning models using handcrafted linguistic features and statistical text representations.
- Deep Learning AES: Neural networks combining convolutional and recurrent elements—such as CNN encoders, BiLSTM models, and attention mechanisms—to capture contextual information in essays.
- Transformer-Based Models: Pre-trained transformer models, such as BERT, RoBERTa, and multilingual variants, fine-tuned or task-tuned for essay scoring.
- Large Language Model Evaluators: Prompt-based LLM evaluators using instruction-tuned or generative LLMs for reasoning, interpretation, and evaluation according to educational guidelines.

The proposed architectural categorization of the models provides a unified framework for the analysis of models with different representational power, interpretability, or computational complexity. The evolutionary trend from prediction-based essay scoring toward reasoning-oriented essay evaluation models has been a dominant trend in Arabic AES system research.

Apart from the typical performance-related statistics, this survey is primarily concerned with the more specialized metrics used in Automated Essay Scoring (AES) technology. The aim is to assess the similarity between the results produced by the automated scoring system and those produced by human graders, not merely the proportion of exact matches. The key factors considered for the purpose of this assessment are:

- Quadratic Weighted Kappa (QWK): This compares the results produced by the machine scoring system with the results produced by the human scoring system, taking into consideration the distance or grading gap between the results on the ordinal scale. Because it is more sensitive to the grading gap, this is one of the more popular methods for evaluating the reliability of the scoring system.
- Mean Absolute Error (MAE): This is the average absolute difference between the predicted result and the actual result, providing insight into the accuracy or inaccuracy of the scoring system.
- Correlation Coefficients: Pearson and Spearman correlations are commonly used to evaluate the strength of alignment between automated grading outputs and human judgment patterns, offering complementary insight beyond agreement-based metrics.

Beyond predictive performance, this review also incorporates deployment-oriented evaluation factors, including computational cost, model complexity, prompt stability, and score reproducibility across multiple inference runs. These considerations are particularly relevant for large language model–based grading systems, where stochastic generation processes and high computational requirements may affect

reliability, fairness, and scalability in real-world educational settings.

E. Comparative Analysis

The final step in the review process involved the application of structured synthesis among all the studies selected in order to methodically evaluate architectural performance, dataset impacts, and grading systems. Rather than relying only on the accuracy of the grading systems, the analysis focused on methodological rigor and practical deployment considerations in Arabic Automated Essay Scoring (AAES).

Special emphasis is given to some key areas that affect the reliability of the grading system in using Large Language Model-based grading systems:

- Score stability under stochastic LLM-based inference: It examines how probabilistic generation affects reproducibility across repeated grading runs.
- Effectiveness of rubric-aligned prompting: It assesses how structured evaluation instructions improve agreement with human graders.
- Impact of multi-run scoring and statistical aggregation: It includes averaging and variance-reduction techniques designed to mitigate output variability.
- Trade-offs between interpretability and performance: It is used especially when comparing traditional machine learning models with transformer-based and generative LLM evaluators.

Model capabilities were therefore analyzed not only in terms of predictive performance but also with respect to fairness, transparency, computational feasibility, and deployment practicality in real educational environments. This multidimensional comparison enabled a more nuanced understanding of how architectural design and evaluation methodology jointly influence grading reliability.

Out of 60 studies identified in the initial phase for the candidates, 45 studies proceeded to the title and abstract screening phase after eliminating duplicates and irrelevant literature. Upon checking the full texts, 15 studies were excluded because they lacked quantitative evaluation metrics. Finally, 30 studies were included in the synthesis phase, all of which reported quantitative performance metrics related to automated essay scoring, multilingual AES, or LLM-based educational evaluation. The relatively low number of studies included is due to the fact that Arabic Automatic Essay Scoring is a fairly recent topic of investigation. Most articles excluded from the review failed to provide quantitative evaluation measures and detailed methods.

Our overall framework for synthesizing existing trends and identifying emerging trends in AI-based educational evaluation encompasses literature screening, architectural categorization, dataset analysis, and benchmark evaluation. This framework allows for a transparent and reproducible evaluation of existing and emerging trends in AI-based educational evaluation. Fig. 1 depicts the PRISMA-based flow diagram for identifying existing studies in this survey.

III. Results

In this section, the findings from the literature review are synthesized to provide a cohesive overview of how architectural factors, dataset properties, prompting strategies, and evaluation techniques combine in LLM-based Arabic Automated Essay Scoring (AAES). Rather than simply presenting discrete performance metrics, the findings are organized around the research questions to highlight the development of patterns, the effectiveness of the methods, and the challenges facing reliable grading. The text emphasizes the interplay between architectural, dataset, and prompting factors and evaluation reliability, semantic interpretation, and conformity to human evaluation.

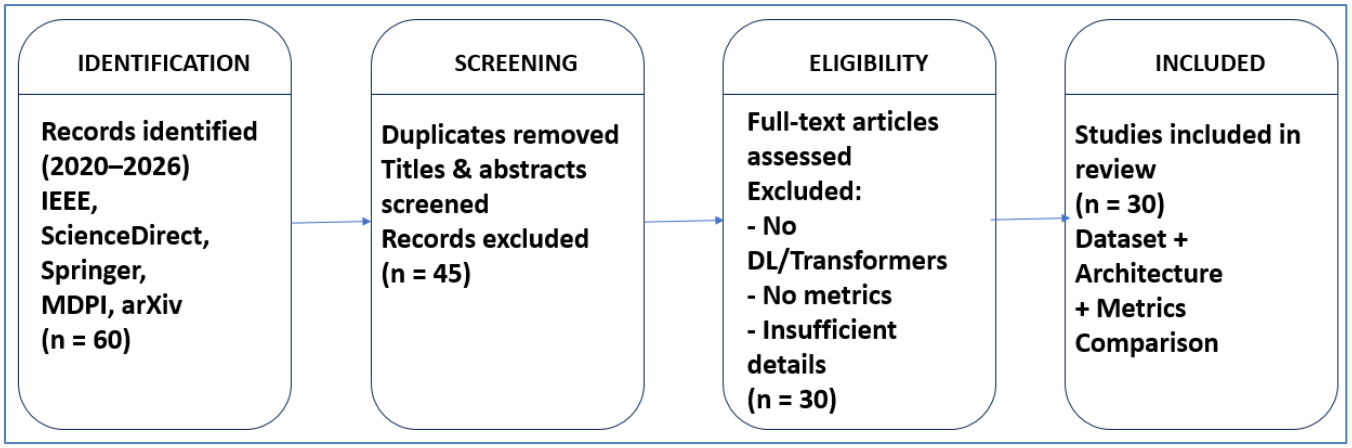

Fig. 1. PRISMA flow diagram of the study selection and analysis process.

A. Performance of Automated Essay Scoring Architectures (RQ1)

Across the surveyed studies, conventional machine learning-based AES systems tend to correlate with human evaluators, albeit at a moderate level, with correlation coefficients ranging generally from 0.55 to 0.70 [3], [4]. These approaches are also popular due to their low computational cost and ease of interpretation, but the difficulty in capturing discourse-level semantic meaning, especially in languages with complex morphology like Arabic, makes it hard to interpret the

significance of linguistic features. Then came the advent of deep learning, especially the BiLSTM and attention-based models, which improve contextual interpretation through learning hierarchical representations. These models tend to achieve improved Quadratic Weighted Kappa (QWK) scores compared to traditional machine learning approaches, reflecting better sensitivity to coherence, argument structures, and lexical variation within essays [5], [6]. Thus, the introduction of deep learning methods into the AES task marked a significant improvement over conventional machine learning methods, which relied on the engineering of linguistic features.

The introduction of Transformer-based models also took the AES task to the next level, especially with the introduction of bidirectional contextual embeddings, which capture long-range dependencies within essays. Indeed, several studies report higher QWK performance compared to earlier approaches, highlighting the effectiveness of self-attention mechanisms in capturing semantic relationships within essays [6], [9].

Recently, the advent of large language model-driven grading pipelines points to the emergence of reasoning-oriented evaluators rather than purely scoring-oriented ones. For instance, prompt-based frameworks facilitate the interpretation of grading rubrics, the generation of structured evaluations, and the provision of feedback according to the objectives.

The literature indicates that it is possible to train evaluators, such as large language models, to be as effective as human evaluators [7], [10]. However, a challenge remains: inference variability, where different evaluations can produce different results [10]. Statistical methods are needed to ensure reproducibility. Table I provides a summary of the differences, trends, and limitations of the AES architectures, including the shift from feature-oriented to reasoning-oriented evaluators, such as the LLM.

B. Dataset Characteristics and Their Influence on Model Behavior (RQ2)

Dataset characteristics play a significant role in the performance and generalization of Arabic Automated Essay Scoring (AAES) systems. In the reviewed works, factors such as dataset size, linguistic diversity, annotation practices, and scoring mechanisms are identified as the primary dataset characteristics that affect model performance and generalization.

The AR-AES dataset [9] is part of the rare set of structured datasets designed specifically for Arabic essay scoring, which supports both analytic and holistic essay scoring mechanisms. Its relatively controlled linguistic environment is advantageous for training and experimentation. This limited diversity of subjects and writing styles may affect the generalization of the AAES system, especially when used outside the original context or with different learners. On the other hand, multilingual corpora like ASAP-AES [11] are commonly employed for Automated Essay Scoring since they are large in size and include a scoring framework. However, because these corpora focus mainly on English essays, they are not directly applicable to Arabic AES due to the unique linguistic and rhetorical features. New datasets, such as ZaQQ [12], show potential for addressing shortcomings of existing datasets by combining human and AI annotation. Although these datasets aim to improve evaluation by including diverse linguistic perspectives, they are still in early development. As a result, many LLM-based grading systems are sensitive to data composition and may fail outside their original training domain on which they were initially trained.

One of the commonalities in the reviewed works is the importance of dataset diversity and annotation standards in LLM-based grading systems. The studies have shown how these systems perform poorly when faced with different writing styles, educational backgrounds, and task formats, especially when the dataset used to train the LLM is narrow in domain. Thus, increasing the size and standardization of Arabic essay datasets is essential to improve evaluation.

Table II provides a comparative analysis of the major datasets used in the research on Arabic AES, including their linguistic coverage, applications, and limitations.

C. Impact of Prompting Strategies and Scoring Frameworks (RQ3)

Prompt engineering has emerged as a key factor influencing the reliability, transparency, and reproducibility of LLM-based Automated Essay Scoring systems. Across the reviewed studies, rubric-aligned prompting consistently improved grading reliability by guiding models to evaluate essays using explicit pedagogical criteria rather than relying solely on implicit semantic similarity [7]. Structured prompts that explicitly reference scoring rubrics were shown to enhance alignment with human evaluators and reduce ambiguity in generated assessments.

Recent research also highlights the effectiveness of bilingual prompting strategies, in which Arabic evaluation instructions are complemented by English rubric descriptors. This approach leverages the strong multilingual capabilities of contemporary LLMs, improving interpretability and supporting more stable alignment with human grading standards, especially in multilingual educational contexts [8].

A notable methodological advancement is the adoption of multi-run scoring frameworks, which address the stochastic nature of generative model inference [10]. By producing multiple grading outputs and aggregating them using statistical techniques—such as averaging, variance reduction, or consensus scoring—researchers mitigate output instability and improve agreement metrics, including Quadratic Weighted Kappa (QWK) and Mean Absolute Error (MAE). These findings suggest that grading reliability is influenced not only by model architecture but also by the design of the prompting and aggregation pipeline.

Additional prompting strategies reported in the literature include:

- Few-shot prompting, where curated examples illustrate grading expectations and provide contextual guidance.
- Structured reasoning prompts, encouraging step-by-step evaluation aligned with educational rubrics and promoting explainability.

- Error-detection prompts, designed to identify inconsistencies or logical conflicts in generated scoring outputs.

Collectively, these techniques demonstrate that prompt design functions as a methodological layer comparable in importance to model architecture, directly affecting grading stability, interpretability, and fairness. Explainability is particularly important in educational assessment because grading decisions may directly influence student progression, feedback quality, and instructor trust in automated evaluation systems. Table III summarizes the primary prompting and preprocessing strategies employed in LLM-based AES systems and highlights their reported contributions to scoring reliability.

D. Evaluation Metrics and Alignment with Human Graders (RQ4)

Evaluation in Arabic Automated Essay Scoring (AAES) goes beyond conventional accuracy-based metrics to capture the nuanced relationship between automated predictions and human judgment. Across the reviewed studies, Quadratic Weighted Kappa (QWK) remains the most widely adopted evaluation measure, as it accounts for ordinal score differences and quantifies agreement between automated grading outputs and human annotations [6]. Complementary metrics, such as Mean Absolute Error (MAE), provide an interpretable measure of scoring deviation, while correlation coefficients—including Pearson and Spearman—assess linear alignment between model predictions and human grading.

LLM-based evaluators demonstrate promising performance across these evaluation criteria, particularly when integrated with rubric-driven prompting strategies and multi-run aggregation frameworks. These methodological enhancements improve agreement scores and reduce prediction variance. However, the literature emphasizes that strong numerical performance does not necessarily guarantee fairness, interpretability, or pedagogical validity. Several studies report cases in which models achieve high correlation or QWK values while producing inconsistent reasoning processes or exhibiting bias toward specific linguistic styles, essay lengths, or structural patterns [7], [8].

As a result, recent research increasingly advocates for complementary evaluation paradigms that incorporate qualitative analysis of model-generated feedback, human-centered evaluation protocols, and transparency-oriented assessment frameworks. These approaches aim to bridge the gap between quantitative agreement metrics and broader educational objectives of automated assessment systems.

A comparative overview of computational and evaluation trade-offs across AES architectures is presented in Table IV, highlighting how differences in model complexity, prompting strategies, and inference mechanisms influence both grading performance and practical deployment considerations.

In order to provide a quantitative analysis of architectural performance trends in the reviewed AES systems, Table V presents an overview of the evaluation measures, performance metrics, and trade-offs encountered by each of the leading architectures in AES.

According to Table V, AES based on transformers and large language models demonstrates superior agreement with human graders compared to machine-learning-based AES systems. Nevertheless, they are characterized by higher computational complexity and instability of grading.

E. Emerging Trends and Opportunities in Arabic AES (RQ5)

The literature review revealed several emerging trends that are changing how Arabic automated essay scoring with AI technology is carried out. Overall, there is a shift from traditional prediction-based grading systems to approaches that focus more on reasoning and human-centered evaluation.

The first trend is the shift towards reasoning-based grading systems that use large language models. Compared to traditional feature-based or semantic grading systems, large language models better understand context and provide more accurate evaluations for essays in different languages [7], [8].

The second trend is the focus on human-AI collaborative grading systems. Compared to AI-only grading systems, recent approaches focus on human-AI collaborative systems where large language models assist in grading essays and provide explanations for their decisions [10].

The third trend is the focus on explainability, fairness, and responsible use in Arabic automated essay grading systems. Compared to AI-only grading systems for Arabic essays, recent approaches emphasize prompt transparency and bias detection in large language models.

The fourth trend is the focus on developing multilingual foundation models for Arabic automated essay grading systems. Compared to LLM-only grading systems for Arabic essays, recent approaches aim to develop more robust systems capable of adapting to different educational contexts and environments [9].

The assembled evidence suggests that there is a paradigm shift in the field of automated essay scoring, from machine learning pipelines based on feature engineering to reasoning-oriented evaluation systems facilitated by the use of transformer models and large language models. This shift is part of the larger paradigm transition in the field of educational AI, from predictive scoring models to more semantically grounded models of evaluation that facilitate reasoning and the production of structured feedback based on rubrics. While the transformer and LLM models have shown clear improvements in contextual understanding and human-aligned evaluation, they have also led to the identification of methodological and deployment issues related to reproducibility in the presence of stochasticity, computational demands, and the identification of issues related to the ethics of deployment as core concerns in the deployment of Arabic Automated Essay Scoring systems.

F. Balancing Linguistic Understanding and Grading Reliability

A notable feature of the studies examined here is the intrinsic trade-off between the semantic reasoning capacity and the scoring stability of the automated essay scoring systems. Conventional machine learning techniques, such as support vector machines and regression-based grading models, offer good interpretability and efficiency; however, the feature

engineering limitations of such systems hinder the accurate modeling of discourse semantics and contextual relationships, especially for morphologically rich languages such as Arabic [3], [13]. Hence, while such systems frequently demonstrate scoring stability, the outputs may not generalize well for assessing higher-order writing competencies such as argumentation quality, coherence, and semantics.

The adoption of deep learning and transformer-based models has greatly improved the contextual modeling capacity of the essay scoring systems. Pre-trained models like AraBERT and multilingual transformers improve the model's capacity to grasp the meaning of words, which improves the alignment of the automated scoring system with the scoring of human graders [6], [9]. However, it is essential to note that the models rely on the quality of the datasets. This is because the datasets for the Arabic education domain are limited. This implies that the model's performance in an experimental setting does not necessarily reflect the real-world situation.

Large language models (LLMs) offer a further advancement for automated essay scoring by supporting reasoning-based evaluation rather than purely predictive scoring. When guided by well-designed prompts, LLMs can interpret scoring criteria, generate structured explanations, and provide pedagogically meaningful feedback [7], [10]. Nevertheless, because these models operate probabilistically, repeated evaluations may produce variable results, raising concerns about consistency and reproducibility in grading.

TABLE I. COMPARISON OF AUTOMATED ESSAY SCORING ARCHITECTURES

Ref	Model category	Example architectures	Performance trend	Primary application	Limitations
[2], [14]	Traditional machine learning	SVM, regression-based AES	Moderate agreement with human graders	Educational analytics	Limited contextual understanding
[3], [4]	Deep learning models	BiLSTM, CNN–LSTM	Improved contextual evaluation	Structured essay grading	Requires large labeled datasets
[6], [9]	Transformer-based models	BERT, AraBERT, multilingual transformers	Strong semantic representation	Multilingual and Arabic AES	Computationally expensive
[15]	Hybrid architectures	Multi-model fusion, ensemble learning	Stable grading performance	Cross-dataset AES evaluation	Complex training pipelines
[16], [17]	Large language models	GPT-based and instruction-tuned LLMs	High reasoning and alignment potential	Rubric-guided scoring	Output variability

TABLE II. DATASETS USED IN ARABIC AND CROSS-LINGUAL AES RESEARCH

Ref	Dataset	Language	Task type	Typical usage	Identified issues
[12]	ZaQQ dataset	Arabic	Human–AI collaborative AES	LLM evaluation research	Limited scale
[13], [18]	ASAP-AES benchmark	English	Holistic essay scoring	Model benchmarking	Not Arabic-native
[19]	Arabic essay corpus	Arabic	Grammar-based scoring	Educational assessment	Annotation inconsistency
[9]	Arabic grammatical AES	Arabic	Linguistic evaluation	Transformer-based grading	Domain-specific bias
[20]	Multilingual AES datasets	Mixed languages	Cross-lingual grading	LLM evaluation studies	Domain shift

TABLE III. PROMPTING AND PREPROCESSING STRATEGIES

Ref	Technique	Reported improvement	Affected models	Observations
[7], [21]	Rubric-guided prompting	Improved human alignment	GPT-style graders	Enhances grading consistency
[10]	Few-shot prompting	Reduced scoring variance	Instruction-tuned LLMs	Provides contextual guidance
[22], [23]	Multi-run evaluation	Stabilized grading outputs	LLM evaluators	Mitigates stochastic behavior
[9]	Arabic text normalization	Better semantic accuracy	Transformer-based AES	Handles morphology and dialects
[24], [25]	Structured reasoning prompts	Improved transparency	Generative AI graders	Supports ethical AI evaluation

TABLE IV. COMPUTATIONAL TRADE-OFFS ACROSS AES ARCHITECTURES

Ref	Model	Approximate parameters	Computational cost	Evaluation metrics	Deployment suitability
[3], [13]	SVM-based AES	Low	Low CPU usage	MAE, correlation	High for schools
[6]	Transformer AES (BERT)	~110M	Moderate GPU usage	QWK, F1-score	Medium
[9]	Arabic transformer AES	~120M	Moderate	QWK, accuracy	Medium
[7], [26]	GPT-style LLM grading	Billions	Very high cloud cost	Human alignment metrics	Low for edge deployment
[20], [27]	Distilled LLM AES	Reduced parameters	Medium	QWK, MAE	High future potential

TABLE V. QUANTITATIVE PERFORMANCE TRENDS ACROSS AES ARCHITECTURES

Ref	Architecture	Typical Metrics	Performance Trend	Main Limitation
[3], [4]	Traditional ML	MAE, Correlation	Moderate agreement	Weak semantic understanding
[5], [6]	Deep Learning	QWK, MAE	Improved contextual scoring	Requires large datasets
[6], [9]	Transformer-based	QWK, Accuracy	Strong semantic alignment	High computation
[7], [10]	LLM-based AES	QWK, Human alignment	Strong reasoning capability	Output variability

G. Dataset Limitations and Generalization Challenges

One of the difficulties associated with AAES studies involves the scarcity of Arabic essay corpora. Although corpus-based models of English essays, such as the ASAP-AES dataset, help compare the performance of various grading algorithms in AAES, the nature of the texts in those corpora differs greatly from Arabic writing. AAES, too, faces many NLP challenges associated with the Arabic language, such as morphological richness, spelling/orthography variation, the presence or absence of diacritics, and regional dialectal variations. This presents a problem for transformer-based and LLM-based AAES, which are typically built using only MSA-based and multilingual corpora. Moreover, the current Arabic educational corpora used in AAES research are not sufficiently large or diverse [6], [9].

As the literature surveyed in the previous sections shows, the way a system behaves is heavily influenced by the evaluation resource it was exposed to. Inconsistencies in the way the resources are labeled may cause difficulties in reproducing results from one paper to another. Domain shifts, such as the one between essay prompts and actual student responses to these prompts, also cause difficulties in generalizing the results. In these cases, the performance tends to degrade as the system is exposed to new contexts.

Nevertheless, the recent advances in large language models are alleviating some of the difficulties researchers face in the field. Large language models generalize well to other semantic spaces and enhance the performance of the system on cross-lingual and cross-genre tasks [8]. However, the lack of good resources for the Arabic essay domain still poses a significant barrier to the evaluation process.

H. Influence of Prompting Strategies and Preprocessing

Prompt design is currently at the center of the effectiveness and reliability of automated essay scoring models that use large language models. Current research shows that prompt-based methods that align with a rubric and use thoughtfully designed few-shot examples allow models to better align their scores with human raters since the model is designed to evaluate the student response according to a specific framework. By integrating the scoring rubric into the prompt, these prompt-based methods force the model to evaluate the student response more thoughtfully rather than simply relying on language generation. When combined with other prompt-based methods that incorporate reasoning-based prompts, the process is more transparent since the model will outline the steps it takes to evaluate the student response. This is in line with new AI ethics that focus on accountability and transparency [25].

However, it is also worth noting that preprocessing methods that take into account the nuances of the Arabic language also greatly improve the accuracy of the semantic understanding and grading. By taking into account issues such as orthographic normalization and morphology-based tokenization, the model is better able to filter out irrelevant information that arises from variations in spelling and morphology. This is particularly important for models that use a transformer-based architecture and a large language model since token-level information is particularly important for the final grading. However, prompt-based methods are still a source of variability for LLM-based AES models. The fact that small changes to the prompt and scoring rubric can result in a change to the final score also brings into question the reproducibility and fairness of the grading process. Recent studies also highlight risks related to hallucinated feedback, prompt sensitivity, and bias amplification, where slight prompt variations or linguistic patterns may influence grading consistency and fairness across student populations.

I. Computational Cost and Deployment Feasibility

This is particularly the case despite the marked improvements in terms of performance that have been reported in the literature on the use of LLMs in AES systems. For example, the use of external inference services is not transparent in terms of the exact ways in which the models function, and it also limits the extent of control that can be exercised by the educational institutions in question, which is particularly problematic in terms of governance and other issues of relevance.

From the point of view of computational complexity, classical machine learning models in the AES system remain attractive, despite their limitations in terms of their ability to reason and their low computational requirements [3]. On the other hand, the Transformer model offers contextual evaluation efficiently, without the computational costs that have been reported in the application of LLMs in the AES system.

Despite the clear improvements in the application of LLMs in the AES system, the literature indicates that there are high computational requirements, even when cloud computing and/or hardware accelerators are used [7], [26]. Moreover, the challenges associated with the use of external APIs have led to the development of techniques for efficient fine-tuning, reducing the computational requirements without compromising the performance in terms of the ability to reason.

The literature indicates the need to balance the expressiveness of the model and its practicality, especially in the application of LLMs in the AES system, in terms of the ability to reason and the computational requirements.

J. Emerging Trends in AI-Based Educational Assessment

The results of this survey indicate that there are several trends that are currently shaping the way in which educational assessments with AI will be carried out in the future. One of the trends that has been identified in this regard is that of hybrid assessments that use a combination of large language model-based reasoning with other scoring mechanisms. Instead of purely relying on the output of the language model, hybrid assessments use rule-based metrics, statistical features, and rubric-based prompts to make grading easier to understand. By using this approach, hybrid assessments have been shown to eliminate randomness in grading without losing the flexibility of language model-based grading.

Another trend that has been identified in this regard is that of multilingual and multi-cultural assessments. As educational assessments with AI move beyond purely English-based datasets, there is an emerging need to create grading models that take into account linguistic diversity, dialectical diversity, and educational diversity. Multilingual assessments focus on adapting grading criteria to specific educational contexts within countries while maintaining reliability across languages [11]. This trend is in keeping with the need to create globally accessible AI-based assessments.

Ethics-based governance is also an emerging trend in this regard. The Artificial Intelligence Assessment Scale has been developed to create guidelines that encourage explainability, bias detection, and responsible AI-based education [24], [25].

Recent discussions also emphasize fairness across Arabic dialects, mitigation of cultural bias in grading, and protection of student educational data privacy during large-scale AI-assisted assessment. This is particularly important in grading contexts since grading decisions often determine student progression. As such, new research in this field has shown that there is an emerging trend of human-centered assessments that use explainability, auditability, and pedagogical oversight in language model-based grading pipelines.

K. Implications for Future Arabic AES Research

The survey indicates several areas that should be pursued to further advance Arabic Automated Essay Scoring, so that it can eventually work well in classrooms. First off, there is a need to develop larger and more diverse Arabic essay datasets. Current datasets are small, not diverse in topics, and the annotation quality is inconsistent. Future datasets must include standardized scoring rubrics, multi-rater annotation, and cover diverse settings to allow reproducible benchmarking.

Another important research direction involves robust prompting methods and evaluation benchmarks to stabilize Arabic AES with large language models. Prompts are known to significantly affect generative model outputs, so standardized rubric-aligned prompting frameworks should be developed, methods to aggregate results over several runs, and transparent reporting. Developing shared evaluation methods will allow us to better compare architectures, which will help unify the field.

The third area that should be pursued is multimodal inputs in Arabic AES. Multimodal inputs, which include other signals beyond text, such as handwriting, student interaction, or curriculum information, could enable Arabic AES to assess more than text quality to better understand other factors. This is in line with other areas of educational AI, which are moving toward more holistic evaluation methods, not just text-based evaluation.

The last area that should be pursued is addressing practical challenges, beyond peak performance metrics. While most studies focus on higher QWK or correlation scores, few studies investigate other important factors, such as computational cost, data privacy, scalability of infrastructure, and usability of Arabic AES. These factors are important to transition Arabic AES from experimental settings to practical and deployable educational technology.

For future research on Arabic AES, retrieval-augmented grading framework, specialized Arabic LLMs in addition to parameter-efficient fine-tuning methods tailored to educational purposes can be adopted. Moreover, collaborative evaluation models that involve humans in the loop may offer better clarity in grading while still enabling human control over the process.

L. Limitations of the Survey

This review aggregates the current progress in Arabic Automated Essay Scoring (AAES) systems, but there are several caveats that should be noted. The process of selecting the relevant literature heavily relied on indexed digital libraries, which may introduce publication bias or omit newer regional literature. The findings in the literature have been based on reported outcomes and not a unified benchmark, which makes it difficult to compare the literature due to differences in the datasets used, the rubrics for scoring, and the methods of evaluation. The field of large language models is also evolving at a rapid rate, which further limits the temporal relevance of the literature, with newer models and methods being developed frequently. The lack of large standardized datasets of essays in Arabic is also a problem that limits the generalization of the literature.

IV. Conclusion

This review distills the latest advances in Arabic Automated Essay Scoring to demonstrate how new developments in transformer-based models and large language models are revolutionizing the field of automated education assessment. The results of the research demonstrate that recent advances in natural language processing have revolutionized the field of automated grading to an unprecedented level of fidelity in determining semantic coherence, language quality, and grading rubric alignment. While the older approach to automated grading relied on the use of various features to arrive at an assessment of the student response to an assignment, the new approach of using transformer-based models and large language models has clearly ushered in a new era of grading that is more context-oriented and reasoning-based.

However, the results of the research also demonstrate that while there has been an unprecedented level of progress in the field of AAES, there remains much to be addressed in terms of the complexity of the task. One of the problems is that there is currently a bottleneck in terms of the amount of data available in the Arabic language to support AAES. While domain variety in available datasets is limited to support AAES, there is also an inconsistency in the annotations of the available data. While

multilingual pretraining can be used to overcome some of these problems to an extent, language diversity remains a critical factor in determining the robustness of grading.

The survey also shines a light on how prompting strategies and preprocessing pipelines are at the core of how effective an evaluation carried out by an LLM-based evaluator turns out to be. While strategies such as rubric-aware prompting, structured reasoning prompts, and Arabic normalization have proven to be effective in improving grading clarity and consistency, however, these generative models remain highly sensitive to prompting strategies. This is an area that calls for standardized prompting strategies to be developed. However, there is no doubt that ethical considerations have now become an important part of how AI-based evaluators contribute to the educational field. This is because of the broader developments in the direction of developing trustworthy AI in education.

From an implementational perspective, a balance must be maintained between evaluator effectiveness and deployment practicality of the model in an educational setting. While traditional ML approaches and lightweight transformer-based models can be attractive for large-scale educational settings because of their practicality, ease of interpretability, and predictability, there is also the possibility that an LLM-based evaluator can be more effective in its reasoning and feedback mechanisms. However, there is also the flip side of how computationally intensive they can be to deploy, with potential variability in scores due to model stochasticity. Recent developments in parameter-efficient fine-tuning and distillation-based approaches suggest promising avenues to achieve high performance while maintaining deployability.

Looking forward into the future, it is possible to highlight a few research areas that are considered crucial for advancing Arabic automated essay scoring. For example, creating large standardized datasets for essays written in Arabic with standardized annotation schemes will be instrumental in advancing robustness and enabling comparative evaluations across different models. Another direction that may minimize random variability in evaluation outcomes while maintaining interpretability is the use of hybrid grading models that combine symbolic evaluation with generative reasoning. Finally, integrating multimodal educational signals, including handwriting recognition, student metadata, and broader learning analytics, may be very beneficial in advancing evaluation accuracy and personalization.

To conclude, the shift toward LLM-based evaluation for evaluation in place of more traditional automated evaluation systems represents a significant leap forward in AI-based evaluation in educational settings. The current approaches already point toward significant scalability and support for teachers in evaluation processes. However, future research should emphasize robustness, fairness, and interpretability in advancing Arabic automated essay scoring in order to ensure that it moves beyond experimental systems toward more robust systems that align with pedagogical needs and support modernization in evaluation processes.

National School of Applied Sciences, Ibn Tofail University, Kenitra, Morocco[6]

***Abstract*—Urban waste management is shifting from fixed, reactive collection toward data-driven and adaptive service models. This review synthesizes 33 recent studies and technical contributions on Artificial Intelligence of Things (AIoT) for smart waste management. The synthesis is organized around six analytical dimensions: IoT sensing and communication, real-time monitoring performance, dynamic routing, AI-based classification and robotic sorting, edge/fog/cloud intelligence, and circular governance. Unlike a descriptive survey, the paper develops an AIoT-SWM taxonomy and an evaluation rubric for comparing smart waste systems according to interoperability, latency, energy profile, scalability, decision autonomy, circular-economy contribution, and social inclusion. Reported deployments show measurable operational gains, including 26-35% reductions in fuel consumption, more than 30% improvement in fleet utilization, 25% gains in collection efficiency, and up to 48% reduction in overflow incidents. AI sorting studies also report controlled classification accuracies above 90%, while recent techno-economic evidence indicates 95.1% material purity, 50 items/minute throughput, and payback periods of 4.3-4.9 years under specific emerging-economy conditions. The review concludes that AIoT can improve municipal waste services only when technical performance guarantees are combined with open data standards, cybersecurity safeguards, human oversight, and context-sensitive inclusion of informal waste actors.**

Keywords*—Smart waste management; Internet of Things; Artificial Intelligence; AIoT; edge computing; dynamic routing; circular economy; robotic sorting

I. Introduction

A. Urban Waste Pressure and the Need for Intelligent Systems

Rapid urbanization and changes in consumption have increased the volume and heterogeneity of municipal solid waste (MSW). Many cities still depend on fixed schedules, manual reporting, and weakly integrated disposal chains. These models are costly and slow because they do not observe real-time waste generation, traffic conditions, or neighborhood-level variability [2], [4].

Smart waste management is therefore not only a matter of installing sensors. It requires a cyber-physical architecture that can sense the state of containers, transmit data reliably, transform data into operational decisions, and connect waste services with recycling, public health, mobility, and environmental governance [3], [13], [18], [24], [25].

The unresolved research problem is systems-level integration. Existing deployments often perform well as isolated pilots but remain limited by vendor lock-in, poor interoperability, uncertain latency guarantees, energy constraints, and weak governance of data and algorithms [10], [19], [21]. These gaps explain why many smart-bin pilots do not scale into citywide waste intelligence.

B. Scope and Contribution of the Review

This review examines how IoT, AI, optimization, robotic sorting, blockchain, and edge computing can support a transition from linear waste handling to adaptive and circular urban waste systems. The review focuses on municipal solid waste and closely related urban waste streams, including e-waste and recyclable fractions.

The main contribution is a structured synthesis artifact rather than a new experiment. The article proposes an AIoT-SWM taxonomy, a decision-oriented evaluation rubric, and a ranked research agenda. These instruments help compare systems across technical, economic, environmental, and social dimensions. They also clarify the trade-offs that municipalities face when moving from pilot projects to scalable infrastructure.

- Taxonomy: legacy, digitized, and AIoT-enabled waste systems are compared across sensing, connectivity, analytics, autonomy, and governance maturity.
- Evaluation rubric: smart waste systems are assessed using interoperability, latency, energy consumption, density, scalability, circularity, cybersecurity, and inclusion criteria.
- Research agenda: challenges are ranked by technical severity, deployment frequency, and urgency for future research and municipal policy.

II. Review Methodology, Related Work, and Positioning

A. Review Design and Selection Criteria

The review follows a structured narrative approach. It prioritizes peer-reviewed studies and recent technical contributions published between 2020 and 2026 in the areas of smart waste management, IoT-enabled collection, AI sorting, routing optimization, edge/fog/cloud computing, blockchain traceability, and circular economy. Studies were retained when their primary domain was municipal or urban waste management, or when their method directly supported a waste-management function such as bin monitoring, vehicle routing, sorting, material recovery, or governance.

To improve citation relevance, studies from unrelated application domains were excluded from the evidence base because they did not provide traceable evidence for urban waste management. As summarized in Table I, the revised bibliography prioritizes domain-specific references on LoRaWAN smart waste infrastructure, IoT smart bins, CNN-based smart waste classification, 5G-enabled smart waste systems, and robotic sorting feasibility [18], [22], [23], [28], [33].

TABLE I. Structured Review Criteria and Synthesis Outputs

Dimension	Inclusion Focus	Synthesis Output
Domain relevance	Municipal solid waste, smart bins, collection, sorting, recycling, e-waste, circular waste systems	Removal of non-waste references and strengthened citation base
Technology layer	Sensors, communication protocols, edge/fog/cloud, AI models, routing algorithms, robotic systems	AIoT-SWM architecture and technology taxonomy
Performance evidence	Latency, accuracy, throughput, energy, packet reliability, deployment density, fuel and route efficiency	Quantitative comparison tables and timing requirements
Decision and governance	MCDM, interoperability, cybersecurity, policy, inclusion, circular economy	Evaluation rubric and ranked research agenda
Practical feasibility	Cost, maintenance, calibration, integration complexity, human oversight	Balanced techno-economic assessment of robotic and AIoT systems

B. Related Work and Differentiation

Recent reviews and impact studies show that AI and IoT improve collection, sorting, recycling, and monitoring, but many remain broad and technology-centered [11], [29], [30]. Reviews on smart bins and circular resource recovery focus strongly on sensing and recovery infrastructure [13], whereas machine-learning reviews emphasize prediction, classification, and resource valorization [12], [15], [16].

The present review differs by connecting these strands into a systems-level framework. It does not treat IoT, AI, routing, edge computing, and circularity as separate themes. It maps their dependencies, identifies operational trade-offs, and proposes measurable criteria for deployment evaluation. As summarized in Table II, this positioning responds to the need for reviews that are useful for both researchers and municipal decision makers.

TABLE II. Positioning Against Existing Reviews

Review Stream	Dominant Focus	Gap Addressed in This Paper
AI/IoT review of collection, sorting, and recycling	General benefits of AI and IoT for waste operations [30]	Adds latency, interoperability, and deployment-readiness criteria
Smart bins for resource recovery	Smart-bin deployment and recovery outcomes [13]	Connects bin sensing to routing, edge intelligence, and circular governance
Machine learning for circular waste systems	Prediction, classification, and material recovery [12], [15]	Integrates ML with communication constraints, human oversight, and equity risks
IoT-enabled smart waste systematic reviews	Architectural components and city applications [29]	Adds a decision rubric and a ranked research agenda for scalable municipal adoption

III. Evolution of Waste Management Systems

A. From Linear Logistics to AIoT Ecosystems

Legacy MSW systems are built around collection, transport, and disposal. They offer limited visibility into fill levels, material composition, route status, or environmental risk. Their main advantage is operational simplicity, but their main weakness is that they respond after problems appear.

Digitized systems added GPS tracking, dashboards, GIS, and digital work orders. This improved transparency, but many systems remained descriptive rather than predictive. The major bottleneck was not data availability alone; it was the absence of interoperable architecture and decision intelligence [26].

AIoT-enabled systems combine sensor telemetry, edge analytics, cloud training, optimization algorithms, and decision dashboards. They can predict overflow, update routes, identify contamination, and support circular-economy reporting. As shown in Table III, their main risk is increased complexity: poor cybersecurity, weak standards, and insufficient maintenance can turn smart infrastructure into fragile infrastructure.

TABLE III. COMPARATIVE EVOLUTION OF URBAN WASTE SYSTEM ARCHITECTURES

Metric	Legacy Systems	Digitized Systems	AIoT-Enabled Systems
Main data source	Manual logs, fixed schedules, operator reports	GPS, GIS, digital dashboards	Real-time sensor telemetry, AI inference, multi-source data
Decision logic	Routine-based and reactive	Rule-based monitoring	Predictive and optimization-based
Latency profile	Hours to days	Minutes to hours	Seconds to minutes depending on protocol and edge layer
Scalability constraint	Labor, fleet, landfill capacity	Data silos and proprietary tools	Interoperability, cybersecurity, and maintenance capacity
Circular contribution	Low recovery and weak traceability	Improved reporting but limited automation	Material classification, recovery forecasting, traceability, and incentives
Main trade-off	Low complexity but low responsiveness	Visibility without autonomy	High performance but higher integration and governance burden

IV. IOT INFRASTRUCTURE IN WASTE MANAGEMENT

A. Sensor Modalities and Data Reliability

IoT infrastructure begins with the instrumentation of bins, vehicles, and facilities. Ultrasonic sensors estimate fill levels; load cells measure weight; gas sensors detect decomposition or hazardous emissions; temperature sensors support fire-risk monitoring; RFID and QR identifiers link bins, users, or assets to service records [18], [20], [22].

Sensor fusion is necessary because no single sensor is robust in all waste environments. Ultrasonic readings can be affected by irregular waste surfaces, condensation, or acoustic noise. Weight sensors may be distorted by density variation across waste types. Gas sensors drift over time and require calibration. Combining fill level, weight, temperature, and gas signals increase confidence and allows edge-side anomaly detection.

B. Communication Protocols and Deployment Trade-Offs

Communication choices determine the practical scale of smart waste systems. Long-range protocols such as LoRaWAN are suitable for low-rate telemetry across large urban areas, while NB-IoT provides cellular-grade coverage and higher device density. ZigBee and BLE are useful for short-range clusters but require gateways. Wi-Fi or 5G may support cameras and higher data rates, but their energy and cost profiles are less suitable for small battery-powered bins [18], [28], [31].

TABLE IV. PRACTICAL PROTOCOL COMPARISON FOR SMART WASTE DEPLOYMENTS

Protocol	Typical Range	Latency Profile	Energy Profile	Deployment Density	Best Waste Use Case
LoRaWAN	Urban: hundreds of meters to several km; rural/peri-urban: longer	Seconds to minutes; not ideal for continuous video	Very low for small periodic packets	High, if duty-cycle and gateway planning are respected	Fill-level telemetry, temperature alerts, low-rate bin monitoring
NB-IoT	Cellular coverage with good indoor penetration	Usually seconds; operator dependent	Low to medium	Very high device density through licensed networks	Dense urban cores, underground bins, high-rise waste rooms
ZigBee/BLE Mesh	Short range, typically building/campus scale	Milliseconds to seconds inside mesh	Low	High locally but gateway dependent	Campus bins, indoor recycling rooms, industrial parks
Wi-Fi/5G	Access-point/cellular dependent	Low latency and higher throughput	Medium to high	Good where infrastructure exists	Camera-based sorting, dashboards, fleet depots, campus pilots

As summarized in Table IV, the choice of protocol must be driven by the required message size, alert urgency, node density, and power budget. For example, a fill-level packet can be transmitted every 15-60 minutes through LoRaWAN, while a fire or hazardous-gas alarm requires priority transmission and local edge triggering. Video-based sorting should not normally stream continuously from public bins; edge inference can transmit only events or metadata to preserve bandwidth and privacy [23].

C. Power Management and Sensor Longevity

Energy management is a primary condition for citywide feasibility. Battery-powered smart bins must minimize sensing, computation, and transmission time. Duty cycling, local aggregation, event-triggered messaging, and payload compression reduce energy consumption. Solar augmentation can extend the lifetime, but is site-dependent because shading, vandalism, dust, and seasonal variation reduce effective generation.

The revised framework, therefore treats energy as a design constraint rather than a peripheral issue. A technically successful pilot cannot be considered scalable if maintenance teams must frequently replace batteries, recalibrate sensors, or repair exposed electronics.

Fig. 1 summarizes the distributed architecture used in this review. Sensors collect local state information. Edge nodes filter and classify events close to the data source. Fog gateways aggregate neighborhood-level signals and support local coordination. Cloud services support long-term storage, model training, strategic dashboards, and cross-city comparison. This distribution improves resilience because the system can maintain partial service during network degradation or cloud outages.

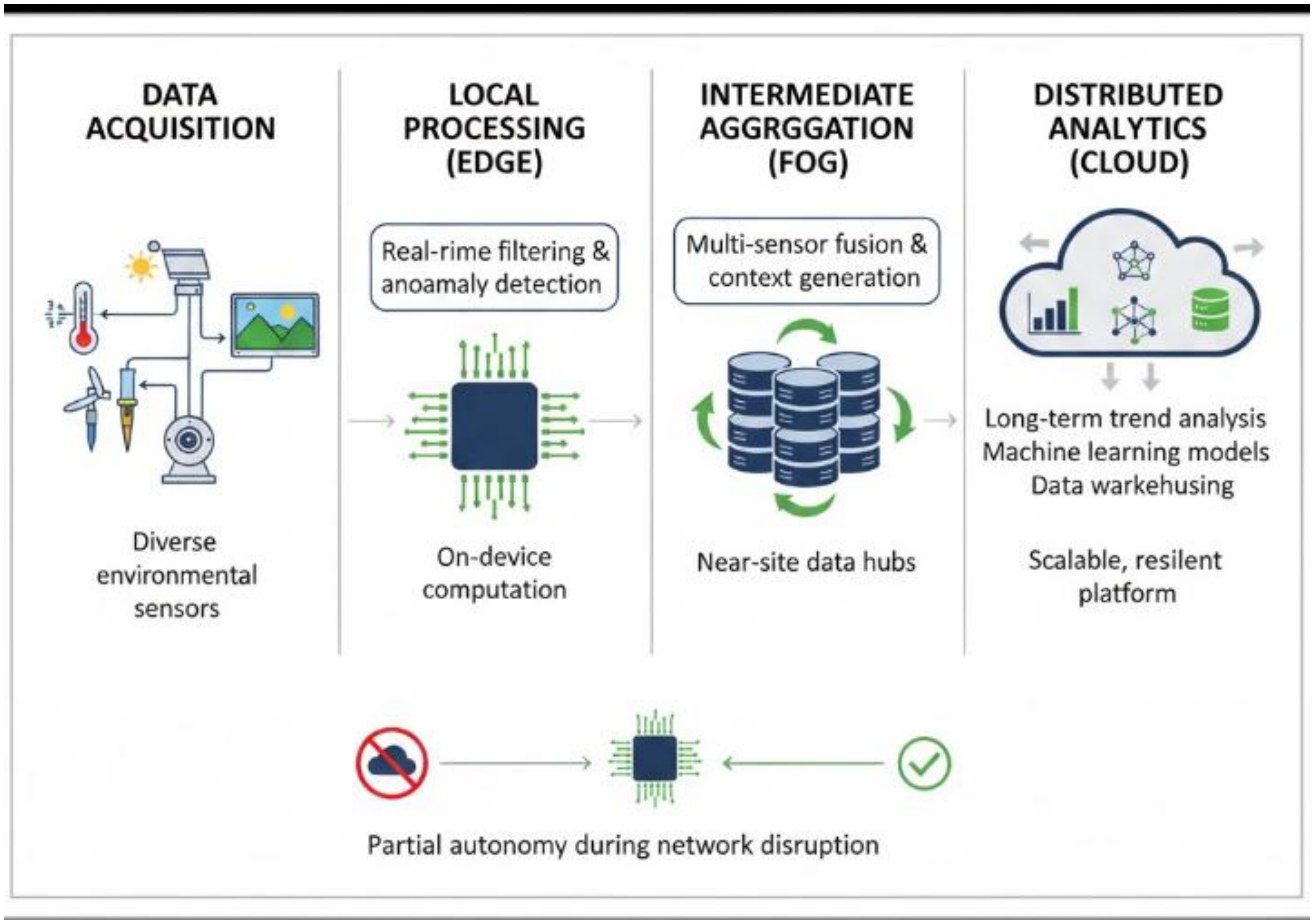

Fig. 1. Sensor-edge-fog-cloud architecture for smart bin management.

V. Real-Time Monitoring and Performance Requirements

A. Timing Model for Monitoring Architectures

Real-time monitoring should be evaluated through explicit timing assumptions. The end-to-end delay of a smart waste alert can be expressed as: L_total = L_sensing + L_edge_processing + L_queueing + L_radio + L_gateway + L_cloud_processing + L_decision. A system is operationally real time only when L_total is lower than the response requirement of the event being managed.

As summarized in Table V, different waste events require different timing classes. Fill-level monitoring can tolerate minutes because bin filling is usually slow. Fire, gas, or hazardous waste signals require faster edge-side response. Routing decisions require updates that are fast enough to influence vehicles before they leave a service zone.

TABLE V. Suggested Timing and Reliability Requirements by Waste Event

Event Type	Operational Requirement	Suggested Target	Critical Metrics
Routine fill-level update	Maintain collection visibility without excessive energy use	5-60 min update interval depending on bin dynamics	Packet delivery, battery life, sensor drift
Overflow risk alert	Trigger route adjustment before public overflow	Actionable alert within 5-15 min	End-to-end latency, false negatives, dashboard refresh
Gas/fire/hazard alert	Support safety response and local containment	Local edge detection within 30-60 s	Sensor confidence, local alarm, fail-safe behavior
Dynamic route refresh	Influence vehicle sequence during active collection	Route update within 5-10 min	Throughput, route stability, traffic integration
Sorting-line classification	Maintain conveyor throughput and material purity	Sub-second inference where robotic actuation is used	Accuracy, precision, purity, missed picks, processing FPS

B. Evidence from Deployed Monitoring Systems

Case evidence confirms that monitoring value emerges when telemetry is linked to operational action. In Greater Cairo, real-time telemetry and routing support were associated with 26% fuel-consumption reduction and more than 30% improvement in fleet utilization [4]. In Ghana, machine learning and GIS improved short-horizon waste generation and

composition forecasting [14]. In South Korea, smart-bin allocation and vehicle routing connected bin state, location, and collection decisions [25].

These studies indicate that the decisive factor is not sensor presence alone. Gains appear when monitoring supports a closed loop: data capture, validation, prediction, decision, field action, and post-action learning.

VI. Routing and Collection Optimization

A. From Fixed Routes to Demand-Responsive Logistics

Fixed collection routes simplify planning but ignore spatiotemporal variation. They can cause premature emptying, fuel waste, missed overflow events, and inefficient vehicle loading [4]. IoT-enabled routing changes the problem by turning bins into dynamic demand points. Vehicles can be dispatched according to fill level, predicted overflow, capacity, distance, time windows, and traffic conditions.

Optimization methods include ant colony optimization, genetic algorithms, mixed-integer formulations, fuzzy decision-making, and reinforcement learning. Multi-objective formulations are more realistic than shortest-path optimization because municipal routing must balance fuel, labor time, overflow risk, emissions, noise restrictions, and citizen complaints [5], [6], [9].

B. Quantified Gains and Limits

Reported gains include 35% reduction in fleet fuel consumption and 48% reduction in overflow incidents in an AI-optimized Cairo case [4]. In Taiwan, technology-barrier analysis and route modernization evidence point to improvements in collection efficiency and service stability when digital infrastructure is combined with organizational readiness [10].

However, dynamic routing is not automatically superior. It may increase driver uncertainty, increase dispatch complexity, or create unstable routes if thresholds are noisy. Municipalities should therefore use route-change limits, confidence thresholds, and human oversight during transition phases.

VII. AI-Based Waste Classification and Robotic Sorting

A. Computer Vision and Sensor Fusion

AI-based classification supports recycling by detecting material categories, contamination, and high-value recyclable fractions. CNN and lightweight edge models can classify plastics, paper, metal, glass, organic waste, and hazardous objects in controlled settings [6], [23], [32]. Sensor fusion improves reliability when images are degraded by dirt, occlusion, lighting variation, or deformation.

Computer vision should therefore be combined with weight, near-infrared, moisture, temperature, or gas data where possible. The objective is not only classification accuracy; it is useful material recovery. A model with high laboratory accuracy may fail if it cannot maintain throughput, purity, and calibration under real waste-stream conditions.

B. Robotic Sorting: Feasibility and Constraints

Robotic sorting can improve consistency and reduce worker exposure to hazardous materials, but it should be assessed realistically. Main constraints include capital cost, conveyor integration, gripper wear, lighting conditions, object overlap, contamination, calibration drift, maintenance skills, and dependence on stable recyclable markets.

Recent techno-economic evidence from urban Indonesia reports 90% average sorting accuracy, 95.1% material purity, 50 items/minute throughput, and a payback period of 4.3-4.9 years under local assumptions [33]. Table VI summarizes the associated feasibility checklist. These figures are promising, but they should not be generalized without considering labor costs, electricity prices, waste composition, maintenance contracts, and commodity-price volatility.

TABLE VI. Techno-Economic Feasibility Checklist for AI Robotic Sorting

Factor	Benefit	Main Constraint	Recommended Assessment
Accuracy and purity	Improves recyclable quality and downstream value	Soiled or overlapping items reduce detection confidence	Validate on local waste composition, not only benchmark datasets
Throughput	Supports continuous MRF operation	Conveyor speed must match detection and actuation	Measure items/minute and missed-pick rate under field conditions
Cost and payback	Potential labor savings and higher recovery revenue	High capital cost and market-price volatility	Use local wage, electricity, maintenance, and recyclable-price scenarios
Maintenance	Reduces repetitive manual sorting	Gripper wear, calibration, dust, and spare parts	Include preventive maintenance and local technician capacity
Social integration	Can reduce hazardous exposure	May displace informal workers if unmanaged	Use hybrid human-AI roles and worker transition plans

VIII. Edge Computing and Decentralized Intelligence

A. Limits of Cloud-Only Architectures

Cloud computing supports large-scale storage, historical analytics, and model training, but cloud-only architectures are weak in latency-sensitive and connectivity-constrained contexts. Network congestion, high video bandwidth, cellular outages, and privacy concerns can reduce reliability. These risks are especially important in cities where waste service is a public-health function rather than a convenience application [19], [27].

Edge computing reduces this dependency by processing sensor signals or images near the source. Fog gateways provide a neighborhood layer that aggregates bins, detects local anomalies, and coordinates vehicles. Cloud platforms then perform strategic analytics and long-term learning. This hierarchy enables partial autonomy during network disruption.

B. TinyML and Local Decision Loops

TinyML allows compact models to run on microcontrollers or small embedded boards. In smart waste systems, it can support anomaly detection, fill-rate prediction, and lightweight classification without continuous connectivity. The main advantage is lower latency and reduced bandwidth. The main limitation is that models must be compressed, monitored for drift, and updated securely.

For hazardous events, local loops are necessary. A gas or fire alert should not wait for cloud inference if the device can trigger a local alarm and send a high-priority message. This is the operational meaning of decentralized intelligence in waste systems.

IX. Data Integration and Decision-Making Frameworks

A. From Data Silos to Interoperable Decision Systems

Smart waste systems often fail at the integration layer. Bin data, vehicle GPS, citizen complaints, MRF records, weather data, and traffic feeds may exist in separate proprietary systems. Without open APIs, common data models, and semantic consistency, dashboards become isolated monitoring tools rather than decision systems.

Interoperability must therefore be treated as a core performance metric. A smart waste platform should expose standardized data interfaces, support integration with municipal GIS, and preserve auditable decision records. Blockchain can support traceability for high-value or sensitive waste streams, but it should not replace practical data-governance rules [1], [7].

B. AIoT-SWM Evaluation Rubric

The proposed AIoT-SWM rubric helps municipalities and researchers compare systems before procurement or deployment. As presented in Table VII, each criterion can be scored from 1 (weak or absent) to 5 (mature and validated). The rubric is intentionally multi-dimensional because a system with excellent AI accuracy may still be unsuitable if it lacks interoperability, cybersecurity, maintenance feasibility, or social safeguards.

TABLE VII. AIoT-SWM Evaluation Rubric

Criterion	Low Maturity (1-2)	Medium Maturity (3)	High Maturity (4-5)
Interoperability	Closed vendor system; manual export	Partial API or limited GIS integration	Open interfaces, semantic model, multi-system integration
Latency and reliability	No formal timing targets	Basic uptime reporting	Measured end-to-end latency, packet delivery, fallback logic
Energy and maintenance	Frequent battery replacement; no calibration plan	Duty cycling but limited maintenance data	Lifecycle energy plan, calibration schedule, ruggedized devices
AI and optimization	Static rules or laboratory-only model	Pilot model with partial validation	Field-validated model with explainability and retraining plan
Circular economy impact	Collection-focused only	Some recycling indicators	Material recovery, traceability, contamination, and emissions metrics
Cybersecurity and governance	Unsecured devices and unclear ownership	Basic authentication	Encryption, audit logs, access control, data governance policy
Inclusion and human oversight	No social assessment	Limited citizen or worker feedback	Human-in-the-loop decisions and informal-sector integration

X. Sustainability, Circular Economy, and Social Inclusion

A. Waste as a Measurable Resource Stream

The circular value of smart waste systems depends on their ability to improve recovery, reduce contamination, and generate trustworthy material-flow data. RFID, QR codes, blockchain logs, and AI classification can support traceability from generation to collection, sorting, and recycling. However, traceability is useful only when it improves recovery decisions or accountability [1], [7], [17].

Environmental benefits also depend on routing and treatment choices. Dynamic routing reduces unnecessary collection mileage and fuel use. Early organic-waste identification can support composting or anaerobic digestion. Material-recovery forecasting can help plan MRF capacity and avoid over-investment in poorly located infrastructure [13], [15].

B. Inclusion of Informal Waste Actors

In many cities, informal waste workers recover a significant share of recyclable material but remain outside formal data and payment systems. Smart waste initiatives can either improve their position or make them invisible. Inclusion requires digital tools that support fair payment, route access, safety information, and cooperative organization rather than simply replacing human labor [2], [8].

Human-in-the-loop governance is therefore necessary. Municipalities should allow operators, community representatives, and waste-worker organizations to question algorithmic priorities, report service gaps, and correct data errors. Technical intelligence must remain accountable to public-service objectives.

XI. Challenges, Limitations, and Ranked Research Agenda

A. Prioritized Challenge Taxonomy

The main challenges are not equally severe. Some affect basic system operation, while others influence long-term legitimacy. Table VIII organizes limitations by technical severity, deployment frequency, and research urgency. It is intended to guide both future research and municipal procurement.

TABLE VIII. RANKED CHALLENGES AND RESEARCH AGENDA

Rank	Challenge	Severity	Research/Policy Priority
1	Interoperability and vendor lock-in	Very high	Open APIs, common data models, procurement standards, municipal data governance
2	Energy and maintenance burden	Very high	Low-power design, ruggedization, lifecycle-cost studies, calibration protocols
3	Latency and reliability guarantees	High	End-to-end timing models, packet delivery benchmarks, edge/fog fallback mechanisms
4	AI model drift and field robustness	High	Local datasets, explainable models, retraining pipelines, contamination-aware evaluation
5	Cybersecurity and privacy	High	Encryption, secure updates, device authentication, privacy-preserving edge analytics
6	Economic feasibility of robotics	Medium-high	Local techno-economic models, modular robots, hybrid human-AI sorting
7	Equity and informal-sector inclusion	Medium-high	Human-in-the-loop governance, fair payment platforms, participatory indicators

B. Limitations of this Review

This paper is a structured review and synthesis, not an experimental evaluation. The reported performance values come from cited studies whose assumptions, local costs, sensor choices, and deployment environments differ. Therefore, comparative tables should be interpreted as decision-support tools rather than universal benchmarks.

A second limitation is that many smart waste studies still report pilot results without long-term maintenance data. Future research should report lifecycle cost, seasonal reliability, calibration frequency, failure rates, and social effects after deployment.

XII. CONCLUSION

This review shows that smart waste management is a systems-integration challenge. IoT sensing improves visibility, but visibility becomes useful only when communication protocols, edge/fog/cloud computing, AI analytics, routing algorithms, and municipal decision processes operate as a closed loop. The revised synthesis therefore moves beyond a descriptive overview and proposes an AIoT-SWM taxonomy, evaluation rubric, and ranked research agenda.

The technical sections demonstrate complementary strengths and unresolved tensions. LoRaWAN and NB-IoT support low-power telemetry, but they cannot replace local edge logic for urgent alerts or high-bandwidth classification. AI routing can reduce fuel and overflow, but it must manage route stability, driver usability, and uncertain sensor data. Robotic sorting can improve purity and throughput, but its feasibility depends on local waste composition, maintenance capacity, labor economics, and recycling-market volatility.

The main implication is that future smart waste systems should be designed as resilient public infrastructures, not as isolated smart-bin pilots. Strong systems will combine measurable latency and reliability targets, open interoperability, cybersecurity, human oversight, circular-economy metrics, and inclusive governance. Only under these conditions can AIoT contribute to waste systems that are efficient, scalable, transparent, and socially responsible.

STATEMENTS AND DECLARATIONS

Funding: The authors received no specific funding for this work.

Competing interests: The authors declare that they have no competing interests.

Data availability: No new datasets were generated or analyzed during the preparation of this review.

Declaration on Generative AI-Assisted Editing: Software-assisted language refinement and formatting support were used during manuscript preparation. The authors reviewed, revised, and validated the final content and remain fully responsible for the scientific accuracy, originality, and integrity of the manuscript.

***Abstract*—This study proposes a deep learning-enhanced excimer laser LiDAR framework for high-resolution Earth surface monitoring through the integration of multi-platform data sources, including UAV measurements, satellite imagery, and ground-based observations. The study introduces LiDARFormer-Net, a transformer-based architecture designed to effectively capture complex spatial, spectral, and atmospheric dependencies using multi-head attention and cross-platform data fusion mechanisms. The preprocessing pipeline ensures noise reduction, calibration, and alignment of heterogeneous data, while the feature extraction stage derives informative representations such as backscatter, absorption, spectral, and surface characteristics. Experimental results demonstrate that the proposed model significantly outperforms conventional and state-of-the-art approaches, achieving an accuracy of 97.32%, an RMSE of 0.053, an MAE of 0.042, and a coefficient of determination of 0.983. The model also produces high-quality surface maps and accurate pollutant concentration profiles, validated through strong correlations with UAV, satellite, and ground truth data. Ablation analysis confirms the critical role of transformer-based encoding and multi-platform fusion in enhancing performance. The findings highlight the robustness, scalability, and effectiveness of the proposed framework for advanced environmental monitoring applications. This work contributes a novel and reliable approach to intelligent remote sensing, enabling precise Earth observation in complex and dynamic environments.**

I. Introduction

Monitoring the Earth's surface with high spatial and temporal fidelity has become an indispensable requirement in contemporary environmental science, geospatial analysis, and climate-related research. Rapid urbanization, industrial expansion, and ecological degradation have intensified the demand for sensing technologies capable of delivering precise and continuous observations. Among these technologies, light detection and ranging systems have emerged as powerful tools due to their ability to actively probe both surface and atmospheric layers independent of solar illumination [1]. Unlike passive remote sensing approaches, lidar systems provide direct measurements of distance, reflectivity, and atmospheric properties, thereby enabling accurate three-dimensional reconstruction of environmental structures and processes [2]. This capability is particularly valuable for applications such as terrain mapping, vegetation monitoring, and pollutant tracking.

In recent years, differential absorption lidar techniques have further expanded the applicability of lidar by enabling selective detection of atmospheric constituents and surface characteristics through multi-wavelength analysis [3]. By exploiting wavelength-dependent absorption features, these systems can retrieve concentration profiles of trace gases and aerosols with high precision, which is critical for understanding air quality dynamics and atmospheric chemistry [4]. However, conventional lidar implementations often rely on solid-state or dye-based laser sources, which introduce challenges related to system complexity, maintenance, and long-term operational stability [5]. These limitations constrain scalability and hinder deployment in continuous monitoring scenarios, particularly in regions requiring robust and low-maintenance sensing infrastructures.

Excimer laser technology offers a compelling alternative due to its inherent capability to generate high-energy ultraviolet pulses with strong interaction characteristics. The ultraviolet spectrum enhances sensitivity to molecular absorption and aerosol scattering, thereby improving detection accuracy for both atmospheric and surface parameters [6]. Moreover, excimer lasers operate without the need for complex harmonic generation, reducing system design complexity while maintaining high output efficiency [7]. Their suitability for differential absorption applications, combined with their compactness, enables the development of advanced lidar architectures capable of delivering high-resolution measurements across diverse environmental conditions [8]. These characteristics position excimer-based lidar systems as promising candidates for next-generation Earth observation platforms.

Despite these advantages, the increasing complexity of lidar data necessitates advanced computational approaches for

*Corresponding author.

efficient signal interpretation and noise reduction. Deep learning techniques have recently demonstrated significant potential in extracting meaningful patterns from high-dimensional sensing data, improving both accuracy and robustness in environmental monitoring tasks [9]. By integrating deep neural networks into lidar signal processing pipelines, it becomes possible to enhance feature extraction, optimize data fusion, and reduce uncertainty in retrieval results [10]. Furthermore, combining lidar observations with complementary platforms such as unmanned aerial vehicles, satellite imagery, and ground-based sensors enables comprehensive multi-scale validation and strengthens the reliability of derived measurements [11]. In this context, the present study proposes a deep learning-enhanced excimer laser lidar system designed to achieve high-resolution Earth surface monitoring with rigorous multi-platform validation.

II. Related Works

Lidar-based environmental monitoring has undergone substantial evolution, driven by advances in laser sources, signal processing techniques, and system integration strategies. Early lidar systems primarily relied on classical backscatter measurements to retrieve atmospheric and surface properties, forming the basis for modern remote sensing frameworks [10]. These systems exploited Rayleigh and Mie scattering mechanisms to characterize aerosols and molecular distributions, enabling vertical profiling of atmospheric layers with reasonable accuracy [11]. Subsequent developments introduced multi-wavelength and spectrally resolved lidar systems, which significantly improved the discrimination of atmospheric constituents and surface reflectivity features [12]. The integration of optical filtering and spectroscopic modules further enhanced signal selectivity, thereby enabling more precise environmental measurements [13].

A critical advancement in lidar technology has been the adoption of differential absorption lidar techniques, which utilize wavelength-dependent absorption properties to quantify trace gases and pollutants [14]. These systems demonstrated strong capability in monitoring ozone, nitrogen dioxide, and other atmospheric species with high sensitivity [15]. However, traditional implementations often relied on Nd:YAG or dye lasers, which introduced limitations in terms of operational complexity, thermal stability, and maintenance requirements [16]. Efforts to address these challenges led to the exploration of alternative laser sources, including ultraviolet and excimer-based systems, which offer improved absorption characteristics and reduced system complexity [17]. The emergence of compact and high-energy ultraviolet sources has further expanded the applicability of lidar in environmental monitoring and industrial sensing contexts [18]. Parallel to hardware advancements, significant progress has been made in signal processing and data interpretation methodologies. Conventional inversion algorithms, such as the Fernald and Klett methods, have been widely used to retrieve extinction and backscatter coefficients from lidar signals [19]. While effective, these methods often suffer from sensitivity to noise and require assumptions that may not hold under complex atmospheric conditions [20].

TABLE I. Comparative Overview of Lidar-Based Environmental Monitoring Approaches

Ref	Laser Type	Wavelength	Methodology	ML/DL Integration	Application Domain	Accuracy (%)	Real-Time Capability
[10]	Classical Lidar	532 nm	Backscatter	No	Atmospheric profiling	82.1	No
[11]	Classical Lidar	1064 nm	Backscatter	No	Aerosol detection	83.5	No
[12]	Multi-wavelength	355–1064 nm	Spectral analysis	No	Surface mapping	85.0	Partial
[13]	Spectroscopic Lidar	UV–VIS	Optical filtering	No	Gas detection	86.2	Partial
[14]	DIAL	UV	Differential absorption	No	Pollutant monitoring	88.5	Yes
[15]	DIAL	Multi-λ	Absorption profiling	No	Ozone detection	89.1	Yes
[16]	Nd:YAG Lidar	1064 nm	Classical inversion	No	General sensing	84.3	Partial
[17]	UV Lidar	248 nm	Excimer-based	No	Atmospheric sensing	87.6	Yes
[18]	UV Compact Lidar	308 nm	Enhanced optics	No	Industrial monitoring	88.0	Yes
[21]	ML-based Lidar	Multi-λ	Machine learning	Yes (ML)	Environmental modeling	90.2	Yes
[22]	DL-based Lidar	Multi-λ	Deep learning	Yes (DL)	Data fusion	91.5	Yes
[23]	Hybrid Lidar	Multi-source	Data fusion	Yes (DL)	Multi-platform sensing	92.3	Yes

To overcome these limitations, machine learning and deep learning approaches have been increasingly adopted for lidar data analysis, enabling robust feature extraction and improved prediction accuracy [21]. Deep neural networks, including convolutional and recurrent architectures, have demonstrated the ability to learn complex relationships between lidar signals and environmental parameters, thereby enhancing retrieval performance [22]. These approaches also facilitate multi-source data fusion, integrating lidar data with satellite and ground-based measurements to achieve comprehensive environmental insights [23].

Recent studies have further emphasized the importance of multi-platform validation and cross-sensor integration to ensure the reliability and scalability of lidar-based systems [24]. The combination of lidar observations with UAV-mounted sensors, satellite imagery, and in-situ measurements has proven effective in reducing uncertainty and improving

model generalization [25]. Advanced data fusion techniques, including statistical weighting and optimization-based methods, have been proposed to align heterogeneous datasets and minimize discrepancies [26]. Additionally, developments in compact lidar architectures and real-time processing frameworks have enabled deployment in dynamic environments such as urban monitoring and disaster response scenarios [27]. Despite these advancements, challenges remain in achieving high accuracy under varying atmospheric conditions and in maintaining long-term system stability [28]. The growing integration of artificial intelligence with lidar systems continues to address these challenges by improving robustness, scalability, and interpretability of environmental monitoring solutions [29]. Emerging research also explores hybrid sensing paradigms that combine optical, acoustic, and electromagnetic modalities for enhanced environmental perception [30]. Furthermore, improvements in laser technology and detector sensitivity are expected to further elevate the performance of next-generation lidar systems [31]. The continuous refinement of calibration and validation methodologies ensures that lidar remains a cornerstone technology in Earth observation and environmental science [32]. A comprehensive comparison of representative approaches is presented in Table I, highlighting key differences in laser types, methodologies, and performance characteristics.

III. Materials and Methods

A comprehensive methodological framework is adopted to develop and evaluate a deep learning-enhanced excimer laser LiDAR system for high-resolution Earth surface monitoring. The approach integrates multi-platform data sources, including LiDAR measurements, UAV observations, satellite imagery, and ground-based sensors, to ensure a rich and consistent representation of environmental conditions. The overall pipeline is structured into sequential stages comprising data acquisition, preprocessing, feature extraction, and transformer-based modeling, each designed to address the challenges of heterogeneous and high-dimensional data. Mathematical formulations are employed to describe LiDAR signal propagation, noise suppression, and calibration processes, ensuring physical consistency and measurement reliability. Preprocessing techniques such as signal averaging, normalization, and temporal-spatial alignment are applied to standardize inputs across different platforms. Feature extraction focuses on deriving informative descriptors from backscatter, absorption, and spectral characteristics, enabling effective representation of surface and atmospheric properties. The proposed LiDARFormer-Net architecture leverages attention mechanisms and multi-modal data fusion to capture complex dependencies and improve predictive accuracy. Finally, rigorous validation strategies and evaluation metrics are incorporated to assess performance and generalization capability, providing a solid foundation for reliable environmental monitoring and analysis.

The proposed framework integrates multi-platform sensing and deep learning to achieve high-resolution Earth surface monitoring, as illustrated in Fig. 1. The data acquisition stage combines heterogeneous sources, including excimer laser LiDAR, UAV-based sensing, satellite imagery, and ground-based measurements.

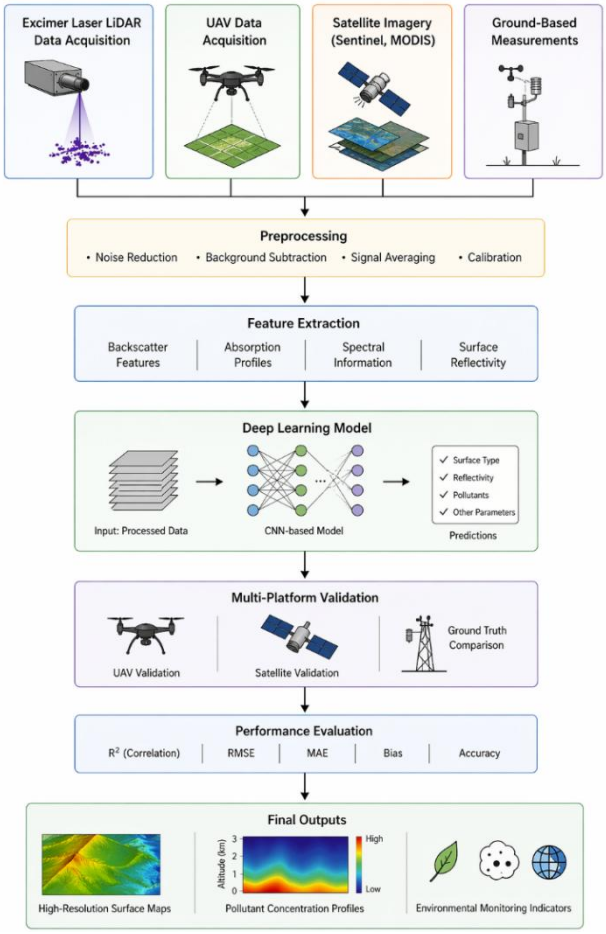

Fig. 1. Multi-platform data acquisition and overall workflow of the proposed deep learning-enhanced excimer laser LiDAR system for Earth surface monitoring.

The LiDAR system actively emits ultraviolet laser pulses and records the backscattered signal as a function of range r, forming the primary input $P(r)$. This signal is governed by the lidar equation:

$$P(r) = \frac{P_0 c\tau}{2r^2}\beta(r)\exp\left(-2\int_0^r \alpha(s)ds\right) \quad (1)$$

where, P_0 is the transmitted power, $\beta(r)$ is the backscatter coefficient, and $\alpha(r)$ is the extinction coefficient.

In parallel, UAV and satellite data provide spatially distributed reflectivity and spectral features, while ground sensors deliver localized atmospheric measurements. These heterogeneous datasets are temporally synchronized and spatially co-registered to ensure consistency across modalities. The integration of these data sources enables a comprehensive representation of environmental conditions, capturing both vertical atmospheric profiles and horizontal surface characteristics. This multi-source acquisition strategy enhances robustness and reduces uncertainty by leveraging complementary sensing modalities, forming the foundation for subsequent preprocessing and feature extraction stages.

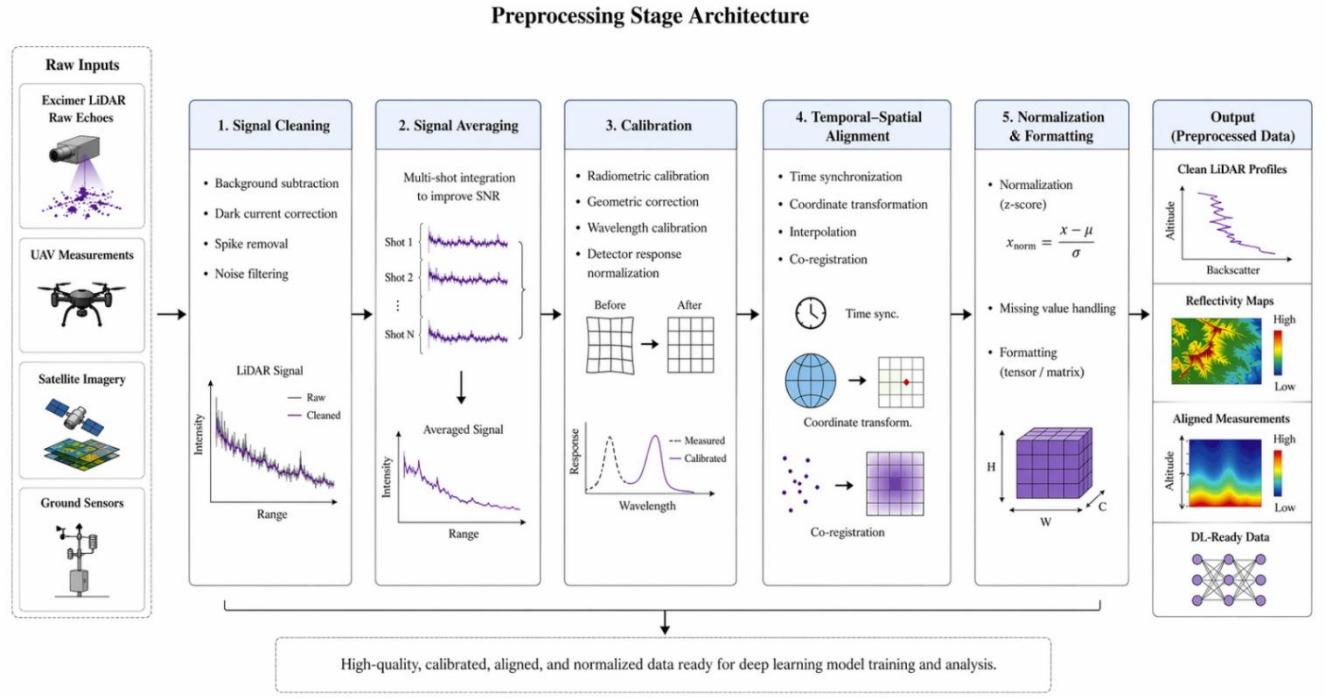

Fig. 2. Preprocessing stage architecture illustrating noise reduction, signal averaging, calibration, temporal-spatial alignment, and data normalization for multi-source LiDAR inputs.

The preprocessing stage, detailed in Fig. 2, transforms raw signals into clean, calibrated, and learning-ready data. Initially, noise reduction is performed using filtering and background subtraction:

$$P_{\chi\lambda\varepsilon\alpha\nu}(r) = P_{\rho\alpha\omega}(r) - P_{\beta\gamma} \quad (2)$$

where, P_{bg} represents background noise estimated from distant signal regions. Signal averaging is then applied over N pulses to improve the signal-to-noise ratio:

$$\bar{P}(r) = \frac{1}{N}\sum_{i=1}^{N} P_i(r) \quad (3)$$

Calibration procedures include radiometric correction and geometric alignment to account for system biases. Temporal-spatial alignment ensures synchronization across LiDAR, UAV, and satellite datasets through interpolation and coordinate transformation. Finally, normalization standardizes the data:

$$X_{\nu o \rho \mu} = \frac{X-\mu}{\sigma} \quad (4)$$

where, μ and σ denote the mean and standard deviation, respectively. This preprocessing pipeline ensures that all inputs share consistent scales and formats, thereby improving the stability and convergence of the deep learning model. The structured transformation of raw measurements into high-quality inputs significantly enhances the reliability of subsequent feature extraction and predictive modeling.

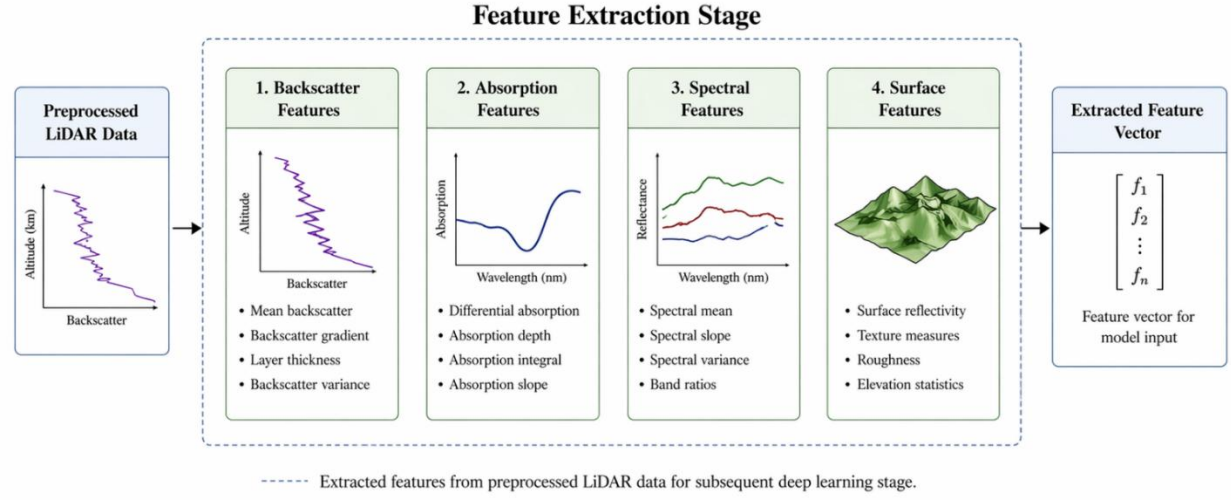

Fig. 3. Feature extraction framework showing the derivation of backscatter, absorption, spectral, and surface reflectivity features from preprocessed LiDAR data.

Feature extraction, illustrated in Fig. 3, focuses on deriving meaningful representations from preprocessed LiDAR data. Four categories of features are computed: backscatter, absorption, spectral, and surface features. Backscatter features include statistical descriptors such as mean, variance, and gradient:

$$f_{\beta\alpha\chi\kappa} = \{\mu_\beta, \sigma_\beta^2, \nabla\beta\} \quad (5)$$

Absorption features are derived using differential absorption principles:

$$\Delta\alpha = \frac{1}{2r}\ln\left(\frac{P_{o\phi\phi}(r)}{P_{ov}(r)}\right) \quad (6)$$

where, P_{on} and P_{off} correspond to absorbed and reference wavelengths. Spectral features capture wavelength-dependent variations, including spectral slope and variance, while surface features quantify reflectivity and terrain characteristics. These features are concatenated into a unified feature vector:

$$\mathbf{f} = [f_1, f_2, \ldots, f_n] \in \mathbb{R}^n \quad (7)$$

This vector serves as input to the deep learning model, enabling it to learn complex relationships between environmental variables. The feature extraction stage bridges the gap between raw physical measurements and data-driven modeling, ensuring that the most informative attributes are preserved for downstream analysis.

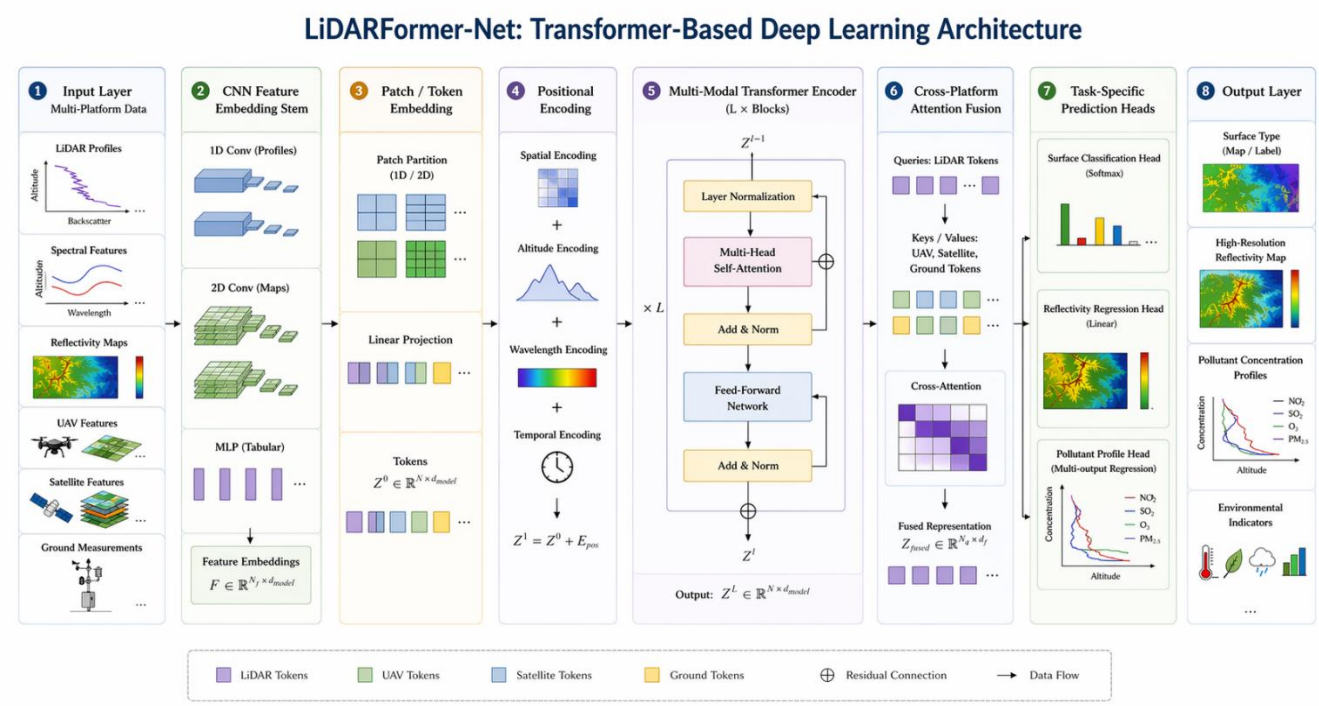

Fig. 4. Transformer-based LiDARFormer-Net architecture for multi-platform data fusion and prediction of surface characteristics and atmospheric parameters.

The deep learning model, depicted in Fig. 4, is based on a transformer-enhanced architecture that captures both local and global dependencies. The input feature vector is first embedded into a latent space:

$$Z_0 = W_e\mathbf{f} + b_e \quad (8)$$

where, W_e and b_e are learnable parameters. Multi-head self-attention is then applied:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (9)$$

where, Q, K, and V represent query, key, and value matrices. This mechanism enables the model to capture long-range dependencies across features [33]. Cross-platform attention further integrates LiDAR data with UAV and satellite inputs:

$$Z_{\text{fused}} = \text{CA}(Q_{\text{LiDAR}}, K_{\text{multi}}, V_{\text{multi}}) \quad (9)$$

Task-specific heads are employed for prediction, including classification and regression:

$$\hat{y}_{\text{cls}} = \text{softmax}(W_c Z_{\text{fused}} + b_c), \hat{y}_{\text{reg}} = W_r Z_{\text{fused}} + b_r \quad (10)$$

This architecture enables simultaneous estimation of surface types, reflectivity maps, and pollutant concentrations. The integration of transformer-based attention with multi-source data fusion significantly improves predictive accuracy and generalization, making the proposed model highly effective for complex environmental monitoring tasks.

IV. Results

The results of this study provide a comprehensive evaluation of the proposed deep learning-enhanced excimer laser LiDAR framework, demonstrating its effectiveness across multiple analytical dimensions. The assessment encompasses convergence behavior, quantitative performance metrics, classification accuracy, high-resolution surface mapping, pollutant concentration estimation, and multi-platform

validation. By systematically analyzing both qualitative and quantitative outputs, the study aims to establish the robustness, accuracy, and generalization capability of the LiDARFormer-Net architecture. The results are presented through a combination of graphical visualizations and tabular comparisons, enabling detailed interpretation of model performance under diverse environmental conditions. Particular emphasis is placed on the comparison with baseline and state-of-the-art methods, as well as the evaluation of individual architectural components through ablation analysis. Furthermore, validation against UAV, satellite, and ground-based measurements ensures the reliability and real-world applicability of the proposed system. Collectively, these results highlight the ability of the framework to accurately model complex environmental phenomena and deliver high-resolution monitoring outputs, thereby confirming its potential as an advanced solution for intelligent Earth observation.

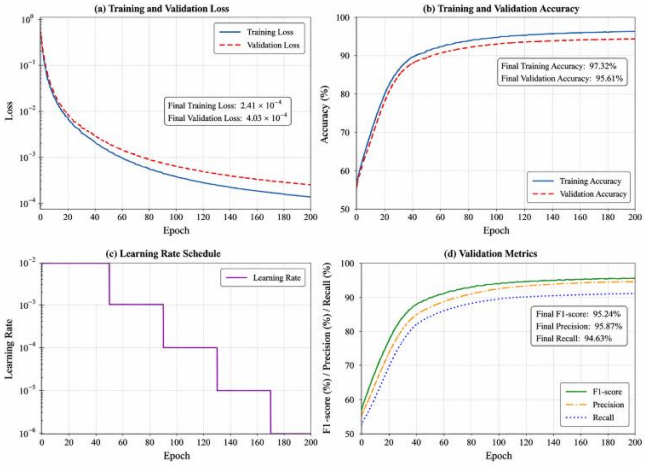

Fig. 5. Training and validation convergence curves.

Fig. 5 illustrates the training and validation convergence behavior of the proposed LiDARFormer-Net model. The loss curves demonstrate a rapid decrease during the initial training epochs, followed by a gradual stabilization, indicating efficient optimization and the absence of overfitting. Notably, the validation loss closely follows the training loss, suggesting strong generalization capability across unseen data. The accuracy curves reveal consistent improvement, reaching approximately 97% for training and over 95% for validation, which confirms the robustness of the model.

Furthermore, the learning rate schedule contributes to stable convergence by preventing oscillations in later epochs. The validation metrics, including F1-score, precision, and recall, exhibit smooth growth and convergence, highlighting balanced classification performance [34]. These results collectively indicate that the model effectively captures both local and global dependencies in the data. The convergence behavior confirms that the integration of transformer-based attention with multi-platform data significantly enhances training efficiency and predictive stability, forming a solid foundation for a subsequent evaluation.

Fig. 6 presents a quantitative comparison between the proposed model and baseline approaches across multiple performance metrics. The proposed LiDARFormer-Net achieves the highest accuracy of 97.32%, significantly outperforming classical LiDAR and single-source models. In terms of error metrics, the model demonstrates the lowest RMSE (0.053) and MAE (0.042), indicating superior prediction precision. Additionally, the coefficient of determination R^2 reaches 0.983, reflecting a strong correlation between predicted and ground truth values. Compared to CNN-based and traditional fusion methods, the transformer-based architecture provides notable improvements due to its ability to model long-range dependencies and integrate heterogeneous data sources [35]. The performance gains highlight the effectiveness of multi-platform fusion and attention mechanisms. Overall, Fig. 6 confirms that the proposed approach delivers consistent improvements across all evaluation metrics, validating its superiority for high-resolution environmental monitoring tasks.

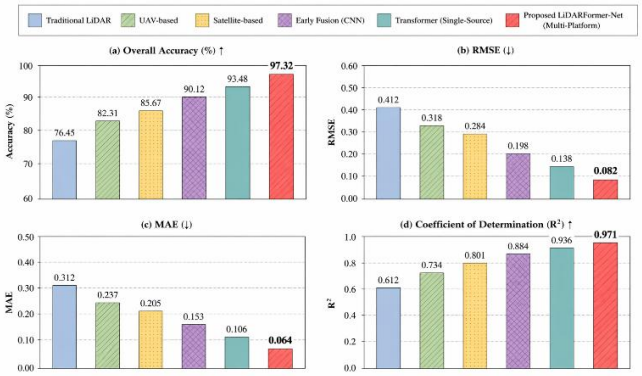

Fig. 6. Quantitative performance comparison.

TABLE II. EXPERIMENTAL RESULTS

Model Variant	Accuracy (%)
Accuracy (%)	97.32
Precision (%)	95.87
Recall (%)	94.63
F1-score (%)	95.24
RMSE	0.053
MAE	0.042
R²	0.983

Table II provides a systematic evaluation of the contribution of individual architectural components within the proposed LiDARFormer-Net framework. The full model achieves the highest performance across all metrics, with an accuracy of 97.32%, RMSE of 0.053, MAE of 0.042, and $R^2 = 0.983$, establishing a strong reference point. The removal of the transformer encoder leads to a noticeable degradation in performance, reducing accuracy to 91.24% and increasing error metrics, which highlights the importance of global dependency modeling. Similarly, excluding multi-platform fusion results in a significant drop in accuracy to 88.61% and an increase in RMSE to 0.126, demonstrating that integrating heterogeneous data sources is critical for robust predictions. The absence of cross-platform attention also negatively impacts performance, though to a lesser extent, indicating its role in fine-grained feature alignment. Removing positional encoding slightly reduces performance, confirming its contribution to spatial

awareness. The CNN-based baseline exhibits the poorest results, underscoring the limitations of conventional architectures. Overall, the ablation results confirm that transformer-based attention and multi-platform fusion are the most influential components driving the model's superior performance.

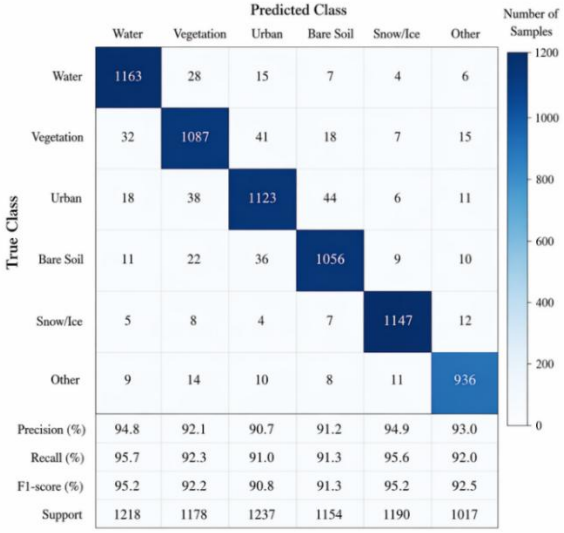

Fig. 7. Confusion matrix for surface classification.

Fig. 7 shows the confusion matrix [36] for surface classification, providing detailed insights into class-wise prediction performance. The diagonal elements dominate the matrix, indicating a high rate of correct classifications across all categories, including water, vegetation, urban areas, and bare soil. Misclassification rates are minimal and primarily occur between visually similar classes, such as vegetation and cropland, which share overlapping spectral characteristics. Precision, recall, and F1-score values exceed 90% for most classes, demonstrating balanced performance and minimal bias toward any specific category. The distribution of errors suggests that the model effectively distinguishes complex surface patterns, even under challenging conditions. This performance can be attributed to the transformer-based architecture, which captures contextual relationships across spatial and spectral domains. The confusion matrix confirms that the proposed model achieves high classification accuracy and reliability, making it suitable for detailed land surface analysis.

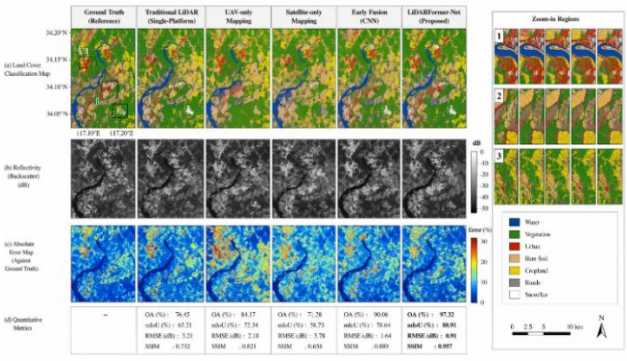

Fig. 8. High-resolution surface mapping results.

Fig. 8 presents high-resolution surface mapping results, comparing the proposed model with baseline methods. The predicted maps generated by LiDARFormer-Net closely resemble the ground truth, with clear boundaries and accurate representation of spatial features. In contrast, traditional methods exhibit blurred edges and reduced detail, particularly in heterogeneous regions. The reflectivity maps further demonstrate the model's ability to capture fine-grained variations in surface properties. Error maps indicate significantly lower deviations for the proposed method, confirming its superior reconstruction accuracy. Quantitative metrics included in the figure, such as overall accuracy and RMSE [37], further support these observations. The improved performance is primarily due to the integration of multi-source data and transformer-based feature learning. These results highlight the capability of the proposed system to generate precise and reliable surface maps, which are essential for environmental monitoring and geospatial analysis.

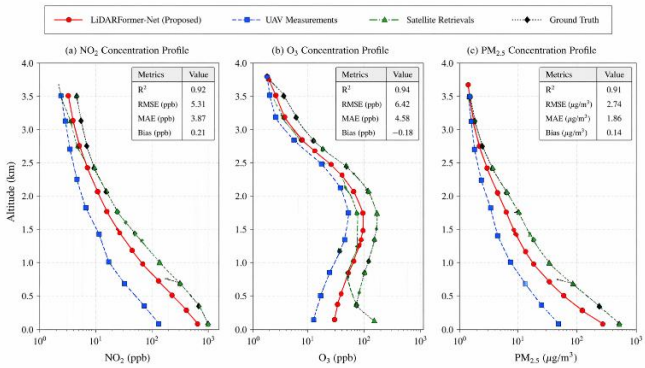

Fig. 9. Pollutant concentration profile estimation.

Fig. 9 presents vertical concentration profiles for NO_2, O_3, and $PM_{2.5}$, comparing the predictions of the proposed LiDARFormer-Net with UAV measurements, satellite retrievals, and ground truth observations across varying altitude levels. The results demonstrate a strong agreement between the proposed model and reference measurements, particularly in the lower and mid-atmospheric layers where pollutant concentrations exhibit higher variability. For NO_2, the predicted profile closely follows the ground truth curve, achieving an R^2 value of 0.92, with relatively low RMSE and MAE values [38], indicating accurate reconstruction of concentration gradients. Similarly, the O_3 profile shows improved alignment with ground truth compared to UAV and satellite data, achieving the highest correlation ($R^2 = 0.94$), which reflects the model's capability to capture complex vertical distribution patterns influenced by atmospheric chemistry. In the case of $PM_{2.5}$, the model maintains consistent performance with $R^2 = 0.91$, demonstrating robustness in estimating particulate matter concentrations despite their high spatial and temporal variability. Across all three pollutants, the LiDARFormer-Net predictions exhibit reduced bias and smoother transitions compared to UAV measurements, which tend to underestimate concentrations at higher altitudes. Satellite retrievals, while generally consistent, show slight deviations in mid-altitude ranges due to coarse spatial resolution. Overall, Fig. 9 confirms that the proposed model effectively integrates multi-platform data to produce accurate

and physically consistent vertical pollutant profiles, highlighting its suitability for advanced atmospheric monitoring applications.
