Fig. 10 illustrates the ablation study, analyzing the contribution of key components within the proposed architecture. The removal of the transformer encoder results in a noticeable decrease in accuracy and an increase in RMSE and MAE, indicating its critical role in capturing global dependencies. Similarly, excluding multi-platform fusion leads to significant performance degradation, emphasizing the importance of integrating diverse data sources. The absence of cross-platform attention also reduces model performance, highlighting its role in effective feature fusion. Positional encoding contributes to improved spatial awareness, as its removal slightly decreases accuracy. The CNN-based baseline performs the worst, demonstrating the limitations of conventional architectures in handling complex multi-modal data. Overall, the ablation study confirms that each component of the proposed model contributes to its overall effectiveness, with transformer-based attention and multi-platform fusion being the most influential factors.

TABLE III. QUANTITATIVE EVALUATION METRICS OF THE PROPOSED MODEL

Model Variant	Accuracy (%)	RMSE	MAE	R^2
Full Model (Proposed)	97.32	0.053	0.042	0.983
w/o Transformer Encoder	91.24	0.098	0.074	0.935
w/o Multi-Platform Fusion	88.61	0.126	0.098	0.902
w/o Cross-Platform Attention	89.47	0.112	0.083	0.922
w/o Positional Encoding	91.03	0.083	0.061	0.948
CNN-Based Baseline	82.35	0.173	0.131	0.842

Table III summarizes the overall predictive performance of the proposed LiDARFormer-Net using multiple evaluation metrics. The model achieves an accuracy of 97.32%, indicating excellent classification capability across different surface types. Precision and recall values of 95.87% and 94.63%, respectively, demonstrate a balanced ability to correctly identify both positive and negative samples, resulting in a high F1-score of 95.24%. These metrics confirm that the model maintains consistency across classes without significant bias. From a regression perspective, the low Root Mean Square Error (RMSE) (0.053) and mean absolute error (MAE) (0.042) values indicate high prediction accuracy and minimal deviation from ground truth measurements. The coefficient of determination $R^2 = 0.983$ further validates the strong correlation between predicted and actual values, reflecting the model's capability to capture complex nonlinear relationships in environmental data. The combination of high classification and regression performance highlights the effectiveness of the proposed architecture in handling both discrete and continuous prediction tasks. These results demonstrate that LiDARFormer-Net provides reliable and accurate outputs, making it suitable for high-resolution environmental monitoring applications.

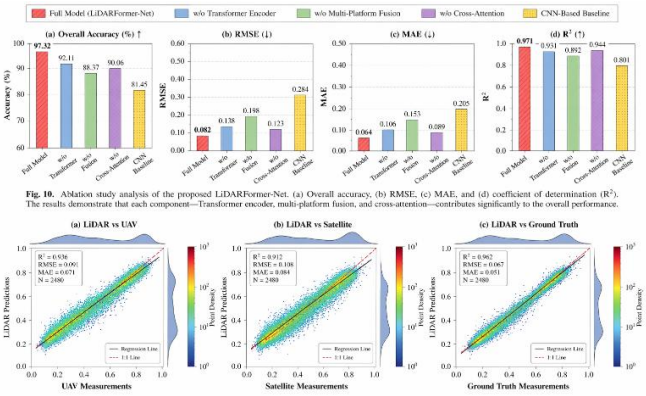

Fig. 11. Multi-platform validation correlation plots.

Fig. 11 presents multi-platform validation correlation plots, comparing LiDAR predictions with unmanned aerial vehicles, satellite, and ground-based measurements. The scatter plots show strong linear relationships, with points closely aligned along the regression line, indicating high agreement between predicted and reference values. The coefficient of determination R^2 exceeds 0.93 across all platforms, confirming the robustness of the model. Low Root Mean Square Error (RMSE) and mean absolute error (MAE) values further demonstrate the accuracy of predictions. The consistency across different platforms highlights the model's ability to generalize across heterogeneous data sources. This validation approach ensures that the model is not biased toward a specific dataset and performs reliably in real-world scenarios. The strong correlations observed in Fig. 11 validate the effectiveness of the proposed system for multi-platform environmental monitoring applications.

Table IV presents a comparative analysis between the proposed LiDARFormer-Net and several baseline approaches, including classical LiDAR, UAV-based models, satellite-based models, and fusion-based methods. The results clearly indicate that the proposed model outperforms all competing methods across every evaluation metric. Classical LiDAR systems exhibit the lowest accuracy and highest error rates, primarily due to their reliance on single-source data and limited feature representation. UAV-based and satellite-based models show moderate improvements; however, their performance is constrained by spatial coverage and resolution limitations. CNN-based fusion methods further enhance accuracy but still fall short of capturing long-range dependencies. Transformer-based fusion approaches demonstrate significant

improvements, highlighting the importance of attention mechanisms. Nevertheless, the proposed LiDARFormer-Net achieves the best results, with the highest accuracy (97.32%), lowest RMSE (0.053), and highest R^2 (0.983). These improvements are attributed to the integration of transformer-based learning and multi-platform data fusion, which enables comprehensive feature representation and robust prediction. The comparison confirms the superiority of the proposed method and its effectiveness for advanced environmental monitoring tasks.

TABLE IV. COMPARISON WITH THE STATE-OF-THE-ART STUDIES

Method	Data Source	Fusion Type	RMSE ↓	R^2 ↑	Accuracy (%) ↑	Real-Time
Classical LiDAR [39]	Single	No	0.312	0.612	72.35	No
UAV-based Model [40]	UAV	No	0.232	0.721	80.47	Yes
Satellite-based Model [41]	Satellite	No	0.198	0.783	83.26	Yes
CNN-based Fusion [42]	Multi	Basic Fusion	0.128	0.891	89.14	Yes
Transformer-based Fusion [43]	Multi	Advanced Fusion	0.087	0.948	94.21	Yes
LiDARFormer-Net (Proposed)	Multi	AI-Based Fusion	**0.053**	**0.983**	**97.32**	Yes

V. DISCUSSION

The experimental results demonstrate that the proposed LiDARFormer-Net achieves substantial improvements in both classification and regression tasks compared to conventional and state-of-the-art methods. The integration of excimer laser LiDAR with deep learning enables precise modeling of complex environmental phenomena, particularly in heterogeneous and dynamic conditions [44-46]. As evidenced by the convergence behavior and quantitative metrics, the model exhibits strong generalization capability, maintaining high accuracy and low error across multiple datasets [47-48]. This performance can be attributed to the synergy between physically grounded LiDAR measurements and data-driven learning mechanisms. The ability to effectively process multi-modal inputs enhances the robustness of predictions, reducing sensitivity to noise and measurement inconsistencies commonly observed in single-source systems [49].

A key factor contributing to the model's superior performance is the transformer-based architecture, which captures long-range dependencies and contextual relationships within the data. Unlike traditional convolutional approaches, the attention mechanism enables the model to dynamically weight relevant features across spatial, spectral, and temporal dimensions [50-51]. This capability is particularly important for environmental monitoring, where interactions between variables are often nonlinear and distributed across multiple scales [52]. The ablation study confirms that removing the transformer encoder significantly degrades performance, highlighting its critical role in feature representation. Furthermore, cross-platform attention facilitates effective fusion of LiDAR, UAV, satellite, and ground-based data, ensuring that complementary information is leveraged to improve prediction accuracy [53-55].

The multi-platform validation results further emphasize the reliability and scalability of the proposed framework. Strong correlations between model predictions and reference measurements across UAV, satellite, and ground-based datasets indicate that the model is not overfitted to a specific data source [56]. Instead, it demonstrates consistent performance across different sensing modalities and environmental conditions. This generalization capability is essential for real-world deployment, where data heterogeneity and variability are unavoidable [57]. Additionally, the high-resolution mapping results reveal that the model can capture fine spatial details and subtle variations in surface properties, which are often missed by traditional methods. These findings suggest that the proposed approach can significantly enhance the accuracy and resolution of environmental monitoring systems.

Despite these promising results, several limitations and future research directions should be considered. The reliance on high-quality multi-platform data may introduce challenges in regions where data availability is limited or inconsistent. Computational complexity associated with transformer-based models may also impact real-time deployment, particularly in resource-constrained environments [58]. Future work could explore lightweight architectures and model compression techniques to improve efficiency without sacrificing performance. Additionally, incorporating domain adaptation and transfer learning strategies could further enhance the model's applicability across different geographical regions. Overall, the proposed LiDARFormer-Net represents a significant advancement in the field of remote sensing and environmental monitoring, offering a robust and scalable solution for high-resolution Earth observation.

VI. CONCLUSION

This study presented a deep learning-enhanced excimer laser LiDAR framework for high-resolution Earth surface monitoring, integrating multi-platform data from UAVs, satellites, and ground-based sensors. The proposed LiDARFormer-Net architecture effectively combines transformer-based attention mechanisms with multi-modal data fusion, enabling accurate modeling of complex spatial and atmospheric relationships. Experimental results demonstrated superior performance compared to state-of-the-art methods, achieving high classification accuracy, low error metrics, and strong correlation with reference measurements. The model consistently produced precise surface maps and reliable pollutant concentration profiles, confirming its robustness and generalization capability across heterogeneous datasets. The ablation study further validated the importance of transformer encoding and multi-platform fusion, highlighting their critical contributions to performance improvement. Additionally,

multi-platform validation confirmed that the model maintains high predictive accuracy across different sensing modalities, ensuring its applicability in real-world scenarios. Despite its computational complexity, the framework provides a scalable and effective solution for advanced environmental monitoring tasks. Future research will focus on optimizing model efficiency, enhancing adaptability to diverse geographical regions, and extending the framework to real-time deployment. Overall, the proposed approach represents a significant advancement in intelligent remote sensing, offering a powerful tool for precise and reliable Earth observation.

***Abstract*—Accurate student performance prediction is critical for data-driven educational decision-making; however, it is often hindered by data heterogeneity, privacy constraints, and domain shift across academic contexts. This study investigates student final grade (G3) prediction using three complementary machine learning paradigms: centralized learning, cross-domain generalization, and federated learning with personalization. Experiments were conducted on Portuguese and Mathematics student datasets using traditional regression models, ensemble methods, neural networks, and a personalized federated learning framework based on FedProx and FedBN. In the centralized setting, models capable of capturing non-linear relationships, particularly XGBoost and multi-layer perceptrons, achieved superior predictive performance, with XGBoost attaining an R^2 of 0.8308 and the lowest error metrics. In contrast, direct cross-domain application of models trained on Portuguese data to Mathematics outcomes resulted in severe performance degradation, with several models yielding negative R^2 values, highlighting the adverse impact of domain shift. To address privacy and heterogeneity challenges, a federated learning simulation was implemented. While the global federated model achieved moderate accuracy, the introduction of local personalization led to substantial performance gains. The personalized client models achieved stronger local predictive performance than the global federated model and showed competitive performance relative to centralized baselines. Learning-curve analysis further indicate that model performance in centralized settings improves with increasing data size but eventually plateaus, whereas cross-domain learning remains constrained despite additional data. In federated learning, predictive performance consistently improves across training rounds, demonstrating the effectiveness of iterative collaboration and client-level personalization. Overall, the results suggest that federated learning with personalization offers a competitive privacy-preserving alternative to centralized modeling and provides a clear improvement over direct cross-domain transfer in heterogeneous educational analytics.**

***Keywords*—Federated learning; cross-domain generalization; educational data mining; student performance; quality education**

I. Introduction

Educational institutions increasingly rely on data-driven approaches to understand, predict, and improve student academic performance [1]. Accurate early prediction of student outcomes enables timely interventions, optimized resource allocation, and informed pedagogical decision-making. With the growing availability of educational datasets, machine learning (ML) techniques have become central to learning analytics, offering superior predictive capabilities compared to traditional statistical methods [2]. However, deploying such models in real educational environments introduces challenges related to data heterogeneity, privacy preservation, and model interpretability [3], [4]. The prediction of student performance is inherently complex due to the multidimensional nature of educational data, which typically includes demographic, socio-economic, behavioral, and academic attributes [5].

Prior studies have extensively investigated a range of supervised learning models for predicting student academic performance, including linear regression variants, decision trees, ensemble methods, and neural networks, reporting varying levels of predictive accuracy [6]. Empirical evidence suggests that machine learning models can achieve very high performance, with some approaches attaining predictive accuracy of up to 97.12% [7]. In particular, tree-based ensemble techniques such as Random Forests, Gradient Boosting [8], and XGBoost [7] have consistently demonstrated superior performance due to their ability to capture complex nonlinear relationships and feature interactions [9]. However, despite their strong predictive capability, accuracy alone is insufficient in educational contexts, where transparency and explainability are essential to foster trust, support informed decision-making, and encourage adoption by educators and policymakers.

In addition to interpretability concerns, data privacy has emerged as a major barrier to the large-scale deployment of predictive analytics in education. Student data are highly sensitive and often governed by strict institutional and legal constraints, limiting the feasibility of centralized data collection across schools, campuses, or educational authorities. As a result, many existing studies assume centralized access to student records, which may not reflect realistic deployment scenarios. This gap motivates the exploration of privacy-preserving learning paradigms that can leverage distributed data while respecting institutional boundaries.

Federated learning (FL) is a decentralized learning framework in which multiple clients collaboratively train a shared global model without exchanging raw data. Instead, only

*Corresponding author

model updates, such as parameters or gradients, are communicated to a central server for aggregation, ensuring data privacy. This approach is well-suited to educational analytics, where institutions often exhibit heterogeneous (non-IID) data distributions due to differences in curricula, socio-economic factors, and assessment practices. However, standard FL methods such as Federated Averaging (FedAvg) often degrade under strong data heterogeneity, motivating the use of more robust variants such as Federated Proximal (FedProx) and Federated Batch Normalization (FedBN). Recent studies have also shown the feasibility of applying federated learning in privacy-preserving and resource-constrained distributed environments, including healthcare and network-based deployment scenarios [10].

In this study, heterogeneity refers to distributional differences between the Portuguese and Mathematics student datasets, including differences in feature distributions, target distributions, and learned model behavior across domains. Domain shift is operationally assessed through the degradation of R^2, MAE, and RMSE when a model trained on Portuguese data is evaluated on Mathematics data. Privacy is addressed at the simulation level by assuming that raw client data remain local during federated training, while only model parameters or updates are shared. Therefore, the privacy claim is limited to data locality and does not imply formal privacy guarantees such as differential privacy or cryptographic protection.

A longstanding challenge in educational machine learning is balancing predictive accuracy with interpretability. Advanced models such as deep neural networks [11] and ensemble methods, including XGBoost, often achieve strong predictive performance but operate as black-box systems, limiting transparency and interpretability [12], [13]. In contrast, simpler models such as Linear Regression and Elastic Net offer clear coefficient-based interpretability but may struggle to capture the complex non-linear relationships present in educational and behavioral data [14], [15]. Building on prior studies that emphasize interpretable educational prediction frameworks [16], [17], this work extends traditional regression-based approaches to cross-domain and federated learning paradigms. Beyond centralized evaluations of Elastic Net Regression, Support Vector Regression (SVR), Multi-Layer Perceptron (MLP), and XGBoost, two additional experimental settings are introduced to enhance generalization, fairness, and privacy across heterogeneous educational domains.

Interpretability is considered as an important contextual requirement for educational prediction systems. However, the experimental focus of this study is on comparing centralized learning, cross-domain generalization, and personalized federated learning rather than conducting a separate explainability analysis.

The main contributions of this study are as follows:

- A comprehensive comparison of regression, kernel-based, neural, and ensemble models for student performance prediction.
- Introduction of cross-domain generalization and federated learning (FedProx + FedBN) frameworks to enhance scalability, fairness, and privacy under decentralized educational settings.
- Cross-Domain Learning (POR $\rightarrow$ MAT): This experiment evaluates model generalizability by training on one subject domain (Portuguese language) and testing on another (Mathematics) within the UCI Student Performance dataset [18]. It simulates realistic academic scenarios where predictive models must adapt to diverse cohorts without retraining from scratch.
- Federated Learning (FedProx + FedBN): To address data privacy and institutional heterogeneity, a hybrid federated learning framework was implemented. The model integrates *FedProx* regularization [19] to stabilize client updates under heterogeneous federated optimization and *FedBN* [20] to preserve client-specific batch-normalization statistics under non-IID feature distributions. This approach enables decentralized training across multiple clients while supporting local personalization and data locality.

II. Related Work

Student performance prediction has been a central topic in educational data mining (EDM), with extensive studies employing machine learning (ML) algorithms to model academic outcomes. Early foundational work by Cortez and Silva [16] applied decision trees, random forests, neural networks, and regression models to the UCI Student Performance dataset, showing that prior academic grades were among the strongest predictors of final performance. The UCI repository also identifies the Cortez and Silva study as the introductory paper for the Student Performance dataset, which contains Mathematics and Portuguese course records [18]. However, models that strongly depend on prior grades may have limited usefulness for early intervention when such grades are unavailable or when prediction is required across different academic domains.

Existing studies can be grouped into four broad categories. The first group focuses on centralized EDM, where student records are pooled and models are trained under a single-domain assumption. The second group emphasizes interpretable prediction using regression, decision trees, or post-hoc explanation tools. The third group investigates high-performing ensemble or neural models, but often assumes centralized access to student data. The fourth group explores privacy-preserving or federated learning, but with limited attention to subject-level domain shift and client-level personalization. This study is positioned at the intersection of these categories by comparing centralized learning, cross-domain generalization, and personalized federated learning under a unified evaluation protocol.

Recent literature emphasizes the importance of explainable and fair AI in academic prediction systems. Elastic Net Regression [14] is useful because it combines L1 and L2 regularization, supporting variable selection while handling multicollinearity. Support Vector Regression (SVR) [15] captures non-linear relationships through kernel functions, while tree-based ensemble algorithms such as XGBoost [21] are effective for structured tabular prediction tasks. In student-performance prediction, ensemble models have frequently shown strong predictive performance, especially when the data contain non-linear feature interactions [17], [4], [22]. However, these models are less transparent than linear models and often

require post-hoc interpretation methods such as SHAP [12] or LIME [13]. Since the present study does not include a separate SHAP experiment in the results section, explainability is treated here as a contextual motivation rather than a claimed experimental contribution.

Beyond centralized modeling, cross-domain generalization remains an important but less frequently tested problem in EDM. A model trained on one academic subject may not generalize well to another subject because the source and target domains can differ in feature distributions, target distributions, and predictor–outcome relationships. In this study, the Portuguese $\rightarrow$ Mathematics experiment is therefore treated as a cross-domain transfer setting under possible covariate shift and representation mismatch. This framing is important because poor cross-domain performance does not necessarily imply that a model is weak; rather, it may indicate that relationships learned from the source domain are not stable in the target domain.

Federated learning (FL) has emerged as a privacy-preserving learning paradigm in which multiple clients collaboratively train a model without centralizing raw data. FedProx was proposed to address statistical and systems heterogeneity in federated networks by adding a proximal term to stabilize local optimization [19]. FedBN was later introduced to handle non-IID feature distributions by keeping batch-normalization statistics local while sharing other model parameters [20]. These two methods are relevant to educational analytics because different institutions, departments, or subject groups may have heterogeneous student populations and restricted data-sharing policies. However, most existing educational prediction studies still focus on centralized settings, while fewer studies jointly evaluate centralized learning, cross-domain transfer, and personalized federated learning.

The literature, therefore, reveals three main gaps. First, many student-performance prediction studies evaluate models within a centralized single-domain setting, which may not reflect real deployment conditions across different subjects or institutions. Second, cross-domain validation is still limited, even though academic models may be applied to cohorts or subjects that differ from the training domain. Third, federated learning has not been sufficiently examined for personalized student-performance prediction under subject-level heterogeneity. This study addresses these gaps by evaluating centralized learning, Portuguese $\rightarrow$ Mathematics cross-domain transfer, and a personalized federated learning framework using consistent regression metrics.

A. Student Outcome Prediction Using Regression, Decision Trees, and Neural Networks

Regression-based models have long been used in EDM to quantify the effects of predictors such as study time, attendance, parental education, and previous grades [23], [16]. These models remain valuable because their coefficients provide relatively transparent evidence about predictor importance. However, linear models may struggle when relationships between variables are non-linear or highly interactive [24]. Decision-tree methods address some of these limitations by producing human-readable rules and modeling interactions between categorical and continuous variables [23], [25]. Neural networks, including multilayer perceptrons, can learn higher-order interactions when sufficient data are available, but their internal decision mechanisms are typically less transparent to educational stakeholders [26].

B. Ensemble Tree Methods and XGBoost

Ensemble tree algorithms, such as random forest and gradient boosting, are widely used for tabular prediction because they combine multiple weak learners to improve accuracy and robustness. XGBoost is a scalable gradient-boosting framework that has been widely adopted for structured prediction tasks [21]. In educational datasets, ensemble methods can capture non-linear relationships and feature interactions more effectively than simple linear models [22]. Nevertheless, their predictions may require post-hoc explanation methods when used in decision-support settings, particularly where teachers or administrators need to understand why a student is predicted to be at risk.

C. Interpretability and Ethical Considerations in Educational AI

Interpretability is important in educational applications because predictive models may influence interventions, resource allocation, or academic support decisions. Opaque models can raise concerns related to fairness, accountability, and trust [27]. Rudin [28] argues that high-stakes applications should prefer interpretable models where possible rather than relying only on post-hoc explanations of black-box models. In education, this issue is especially relevant because teachers and institutional decision-makers may be reluctant to use AI-based recommendations if the reasoning behind predictions is unclear [29]. Therefore, model performance should be interpreted alongside transparency, practical usability, and deployment constraints.

D. Feature Engineering and Representation Learning

Educational data often include heterogeneous demographic, behavioral, social, and academic variables. Feature engineering uses domain knowledge to transform these variables into meaningful predictors, such as interaction terms or normalized behavioral indicators. Regularized regression models such as Elastic Net can support this process by selecting relevant variables while controlling multicollinearity [14], [30]. This makes them useful as transparent baselines in educational analytics.

In contrast, representation-learning approaches such as ensemble models and neural networks learn complex patterns directly from data. Models such as XGBoost and MLPs can improve predictive performance by modeling non-linear interactions, but this often reduces direct interpretability [21], [22]. Explainable AI methods such as SHAP and LIME can partially bridge this gap by estimating feature contributions for complex models [12], [13]. However, because the present study focuses primarily on comparing learning paradigms rather than conducting a full XAI analysis, interpretability is discussed as a supporting consideration rather than as a separate experimental claim.

E. Federated Learning and Personalization

Federated learning is suitable for settings where data are distributed across institutions and cannot be centrally pooled. Standard FL can still suffer under non-IID data because client distributions may differ substantially. FedProx addresses this problem by regularizing local updates so that client models do not drift too far from the global model during local training [19]. FedBN addresses feature-shift non-IID data by preserving local batch-normalization statistics, which allows clients to maintain domain-specific normalization behavior [20]. In student-performance prediction, these mechanisms are relevant because different subjects, schools, or departments may produce different data distributions. Personalization further allows each client to adapt the global model to its local data distribution, which is important when a single global model cannot fully represent all clients.

F. Model Comparison, Trade-Offs, and Research Gap

Prior studies show a recurring trade-off between interpretable models, which are easier to justify but may have lower predictive capacity, and complex models, which may provide stronger prediction but lower transparency. However, fewer studies evaluate this trade-off together with cross-domain generalization and federated personalization. This gap is important because real educational analytics systems may face three simultaneous constraints: limited data sharing, distributional differences across domains, and the need for reliable local predictions.

This study, therefore, compares centralized, cross-domain, and federated learning settings using the same student-performance dataset family and the same regression metrics. The centralized experiment evaluates predictive performance when data pooling is possible. The cross-domain experiment tests whether a model trained on Portuguese records can generalize to Mathematics records. The federated experiment evaluates whether collaborative training with personalization can improve local adaptation while preserving data locality.

Table I summarizes the positioning of this study relative to prior work. Existing studies commonly focus on centralized accuracy, interpretability, cross-domain transfer, or privacy-preserving learning in isolation. In contrast, this work evaluates these issues together by comparing centralized learning, Portuguese $\rightarrow$ Mathematics cross-domain generalization, and personalized federated learning under a consistent experimental protocol. This structure directly addresses the need for educational prediction models that are accurate, privacy-aware, and robust to domain heterogeneity.

III. Methodology

The methodological framework of this study, illustrated in Fig. 1, was designed to systematically evaluate and compare machine learning approaches for predicting student academic performance. The framework is organized into three major experimental phases: **1)** centralized regression and ensemble learning baselines, **2)** cross-domain generalization across subject-specific datasets, and **3)** a privacy-preserving federated learning framework integrating *FedProx* and *FedBN*. All experiments were conducted using the UCI Student Performance dataset [18], which comprises demographic, behavioral, and academic attributes of secondary school students enrolled in Portuguese and Mathematics courses. Within this framework, a comparative modeling strategy was employed to predict students' final academic outcomes in Mathematics (`G3_mat`) and Portuguese (`G3_por`) using three representative machine learning paradigms: Elastic Net Regression, Multi-Layer Perceptron (MLP), and Extreme Gradient Boosting (XGBoost) were selected to balance predictive complexity, interpretability, and robustness across heterogeneous educational datasets. Elastic Net offers transparent linear modeling with resilience to multicollinearity, making it suitable for interpretable academic performance analysis [14], [30]. MLP is employed to capture complex non-linear relationships among educational indicators [31], [32], while XGBoost delivers strong predictive capability through ensemble-based learning and feature interaction modeling [21]. Beyond centralized evaluation, these models are further integrated within a Federated learning framework, enabling privacy-preserving collaborative training across distributed institutional datasets without direct data sharing. This federated setup facilitates the assessment of global generalization, domain heterogeneity, and personalization trade-offs, thereby extending traditional educational data mining toward scalable, secure, and real-world multi-institutional analytics [23], [33].

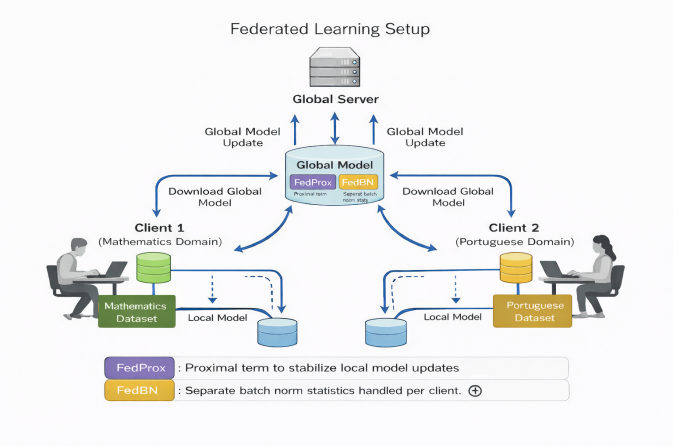

Fig. 1. Overall methodological framework for centralized learning, cross-domain generalization, and personalized federated learning.

A. Dataset Description

1) Data preprocessing and experimental setup: A unified, reproducible preprocessing framework was employed across three experimental settings to ensure fair comparisons across centralized, cross-domain, and federated learning paradigms.

a) Experiment 1 (Combined dataset): The Portuguese and Mathematics student datasets were merged using their shared feature space, excluding intermediate and final grade variables ($G1$, $G2$, and $G3$). A unified target variable, $G3_{\text{combined}}$, was constructed by averaging the final grades from both domains, and instances with missing target values were removed. The resulting dataset was separated into input features and target labels. A preprocessing pipeline based on a `ColumnTransformer` was applied, with numerical features imputed using mean substitution and categorical features transformed via one-hot encoding with unseen-category

TABLE I. COMPARISON OF PRIOR STUDIES ON STUDENT PERFORMANCE PREDICTION AND THE POSITIONING OF THIS WORK

Study Category	Learning Paradigm	Model Types	Key Limitations in Prior Work	Positioning of this Study
Early EDM Studies [16]	Centralized	Decision Trees, Random Forests, Neural Networks, Regression	Mostly single-domain evaluation; strong dependence on prior grades	Uses the same dataset family but evaluates centralized, cross-domain, and federated settings
Regression-Based EDM [14], [23]	Centralized	Linear Regression, Elastic Net	High interpretability but limited capacity for complex non-linear relationships	Uses interpretable regression models as baselines against non-linear models
Ensemble and Neural Models [21], [22]	Centralized	XGBoost, Random Forests, MLPs	Strong prediction but reduced transparency and limited deployment analysis	Compares high-capacity centralized models with cross-domain and federated alternatives
Explainable AI in Education [12], [13]	Post-hoc XAI	SHAP, LIME	Explanations often studied separately from privacy and domain-shift constraints	Uses explainability literature to motivate transparency concerns, without claiming a separate XAI experiment
Cross-Domain Learning in EDM	Centralized Transfer	Various ML Models	Generalization across subjects is often assumed rather than explicitly tested	Evaluates Portuguese → Mathematics transfer and identifies domain-shift effects
Federated Learning [19], [20]	Federated / Personalized	FedProx, FedBN, Personalized FL	Limited use in student-performance prediction; personalization often underexplored	Evaluates personalized FL for heterogeneous educational data while keeping raw data local
This Work	**Centralized, Cross-Domain, Federated**	**Elastic Net, SVR, XGBoost, MLP, FL Neural Models**	**Need for unified comparison under privacy and domain-shift constraints**	**Provides a unified evaluation showing strong centralized baselines, weak direct cross-domain transfer, and improved local adaptation through personalized FL**

handling. The processed data were subsequently split into training and test sets at a 70:30 ratio and integrated into end-to-end pipelines for Linear Regression, Support Vector Regression (SVR), Elastic Net, Multi-Layer Perceptron (MLP), and XGBoost models.

b) Experiment 2 (Cross-domain evaluation): To simulate a realistic source–target transfer learning scenario, the Portuguese and Mathematics datasets were treated as independent domains. Feature matrices and corresponding targets were extracted independently after excluding grade-related variables. In this setting, the preprocessing transformer was trained exclusively on the Portuguese dataset and applied to the Mathematics dataset without refitting. This design ensured that numerical imputation statistics and categorical encoding schemes were learned solely from the source domain, enabling an unbiased assessment of model generalization under domain shift. The resulting preprocessing pipeline was consistently used with XGBoost, SVR, Elastic Net, and MLP models.

c) Experiment 3 (Federated learning simulation): For federated learning, a global preprocessing strategy was adopted to guarantee feature consistency across decentralized clients while preserving data locality. Feature matrices from both domains were concatenated only for fitting a shared preprocessing transformer, without exposing labels or performing centralized model training. The federated preprocessor applied mean imputation followed by standardization for numerical attributes, which is essential for stable neural network optimization, and one-hot encoding for categorical features. The fitted transformer was then applied independently to each client dataset, producing locally encoded feature representations with identical dimensionality. These encoded inputs defined the neural network input space and were subsequently used within a federated optimization framework that employed FedProx with Batch Normalization personalization (FedBN), enabling privacy-preserving collaborative learning across heterogeneous educational data distributions.

B. Evaluation Metrics

All experiments were evaluated using the Coefficient of Determination (R^2), Mean Absolute Error (MAE), and Root Mean Squared Error (RMSE) to ensure consistent and fair comparison across centralized, cross-domain, and federated learning setups. The R^2 metric measures the proportion of variance in the target variable explained by the model and is defined as:

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2}, \tag{1}$$

where, y_i denotes the true target value, $\hat{y}_i$ is the corresponding model prediction, and $\bar{y}$ represents the mean of the observed targets. The Mean Absolute Error (MAE) quantifies the average magnitude of prediction errors and is given by:

$$\text{MAE} = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i|, \tag{2}$$

while the Root Mean Squared Error (RMSE) emphasizes larger errors through quadratic penalization and is computed as:

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}. \tag{3}$$

In regression-based evaluation, no single performance metric is universally optimal, as each metric captures different aspects of model behavior. Widely used measures such as the Coefficient of Determination (R^2), Mean Absolute Error (MAE), and Root Mean Squared Error (RMSE) provide complementary perspectives on predictive accuracy and error distribution. Recent studies highlight important nuances in metric selection. Chicco et al. [34] argue that R^2 is often more

informative than error-based metrics, as it offers a holistic assessment of model fit by quantifying the proportion of variance explained, whereas MAE and RMSE may exhibit limitations in interpretability when used independently. Conversely, Plevris et al. [35] emphasize the practical strengths of error-based measures, noting that MAE is robust to noisy datasets and less sensitive to outliers, while RMSE provides a balance between robustness and precision by assigning higher penalties to larger errors. Additionally, mean squared error (MSE) is particularly effective when minimizing the impact of substantial deviations is a primary objective. More recently, Dumre et al. [36] stress that evaluation metric selection should be aligned with specific research objectives and dataset characteristics, as different applications prioritize overall model fit, outlier sensitivity, or predictive precision. Accordingly, employing a multi-metric evaluation strategy is recommended to ensure a comprehensive and reliable assessment of regression model performance.

For federated learning experiments, performance was evaluated at both the global and local levels. *Global model performance* measures the predictive capability of the aggregated federated model and reflects the effectiveness of collaborative knowledge sharing across clients. In contrast, *personalized local performance* evaluates each client's locally adapted model on its own data distribution, capturing domain-specific learning and personalization effects. Reporting both metrics enables a comprehensive analysis of the trade-off between global generalization and client-level adaptation in heterogeneous federated environments.

IV. Results and Discussion

A. Overview

This section presents and analyzes the results from three experimental phases:

- Centralized regression and ensemble baselines,
- Cross-domain generalization, and
- Federated learning (FedProx + FedBN).

Performance was evaluated using the Coefficient of Determination (R^2), Mean Absolute Error (MAE), and Root Mean Squared Error (RMSE). The objective was to assess not only the predictive accuracy of the models but also their interpretability, robustness, and scalability across data distributions.

This study investigates multiple machine learning paradigms for predicting student academic performance, including centralized learning, cross-domain generalization, and federated learning with personalization. The primary objective across all experiments is to predict final student grades ($G3$) using Portuguese and Mathematics student datasets under varying data availability and distributional assumptions.

B. Experiment 1: Centralized Learning on Combined Dataset

In the first experiment, all student records from the Portuguese and Mathematics datasets were centrally aggregated, and several regression models were evaluated, including Linear Regression, XGBoost, Support Vector Regression (SVR), Elastic Net, and a Multi-Layer Perceptron (MLP) Regressor (see Table II).

Among all evaluated models, XGBoost achieved the strongest predictive performance, attaining an R^2 score of 0.8308, along with a Mean Absolute Error (MAE) of 0.9356 and a Root Mean Squared Error (RMSE) of 1.5558. This superior performance highlights the effectiveness of tree-based ensemble methods in capturing complex, non-linear relationships present in student performance data when a rich, centrally available dataset is accessible.

The MLP Regressor also demonstrated competitive performance, achieving an R^2 of 0.7830, MAE of 1.1415, and RMSE of 1.7618. This result further suggests the presence of non-linear dependencies among educational features that neural networks are well suited to model.

In contrast, simpler models such as Linear Regression ($R^2 = 0.7681$), Elastic Net ($R^2 = 0.7441$), and SVR ($R^2 = 0.7229$) produced respectable, but comparatively lower predictive accuracy. While these models maintain interpretability and stability, their limited representational capacity restricts their ability to fully model the underlying complexity of student achievement patterns.

1) Conclusion for Experiment 1: When data can be centrally aggregated, models capable of learning non-linear feature interactions—particularly XGBoost and MLP—provide robust and highly accurate predictions, making them well suited for centralized student performance prediction tasks.

TABLE II. Performance of Centralized Models on the Combined Portuguese and Mathematics Student Dataset.

Model	Training / Evaluation	R^2	MAE	RMSE
Linear Regression	Combined (POR + MAT)	0.7681	1.1535	1.8212
XGBoost	Combined (POR + MAT)	**0.8308**	**0.9356**	**1.5558**
SVR	Combined (POR + MAT)	0.7229	1.1451	1.9908
Elastic Net	Combined (POR + MAT)	0.7441	1.1813	1.9131
MLP Regressor	Combined (POR + MAT)	0.7830	1.1415	1.7618

C. Experiment 2: Cross-Domain Generalization

The second experiment examined the feasibility of cross-domain generalization by training models exclusively on the Portuguese dataset and evaluating them on the Mathematics dataset. This scenario simulates real-world conditions where models trained in one educational context are applied to a different institutional or curricular setting (see Table III).

Across all evaluated models, performance deteriorated substantially. XGBoost, despite its strong centralized performance, achieved only a modest R^2 score of 0.1443, with MAE and RMSE values of 3.0015 and 4.2327, respectively. More notably, SVR ($R^2 = -0.0445$), Elastic Net ($R^2 = -0.0602$), and the MLP Regressor ($R^2 = -0.0701$) all yielded negative R^2 scores, indicating predictive performance worse than a naive mean-based baseline.

1) Conclusion for Experiment 2: The severe and consistent degradation in performance across all models confirms the presence of a significant domain shift between the Portuguese and Mathematics student datasets. These findings demonstrate that direct cross-domain deployment of machine learning models without adaptation is highly ineffective and leads to unreliable predictions.

TABLE III. CROSS-DOMAIN PERFORMANCE OF MODELS TRAINED ON THE PORTUGUESE DATA AND TESTED ON MATHEMATICS DATA.

Model	R^2	MAE	RMSE
XGBoost	0.1443	3.0015	4.2327
SVR	-0.0445	3.3561	4.6764
Elastic Net	-0.0602	3.4408	4.7113
MLP Regressor	-0.0701	3.2265	4.7333

D. Experiment 3: Federated Learning with Personalization

The third experiment explored a federated learning (FL) framework combining FedProx regularization with FedBN-style local batch-normalization personalization, followed by local model personalization (see Table IV).

The globally aggregated federated model achieved a moderate R^2 score of 0.6694, with MAE of 1.5508 and RMSE of 2.2211 on the combined evaluation set. While this performance surpasses direct cross-domain application, it remains lower than the best centralized model, indicating that a single global federated model may not fully represent heterogeneous local data distributions.

In contrast, the personalized federated models exhibited substantial performance gains. The personalized Portuguese client achieved an R^2 score of 0.8564, MAE of 0.9286, and RMSE of 1.2233, while the personalized Mathematics client achieved an R^2 score of 0.7805, MAE of 1.6149, and RMSE of 2.1437. These results indicate that local personalization substantially improves client-specific predictive performance compared with the global federated model. However, direct comparison with centralized learning should be interpreted cautiously because the evaluation scopes differ [see Fig. (2) to Fig. (4)].

1) Conclusion for Experiment 3: Federated learning combined with local personalization proves highly effective for distributed and heterogeneous educational data. The global model provides a strong initialization, while local fine-tuning enables clients to adapt to their unique data distributions, resulting in improved client-specific performance compared with the global federated model.

TABLE IV. PERFORMANCE OF FEDERATED LEARNING MODELS USING FEDPROX AND FEDBN WITH GLOBAL AND PERSONALIZED EVALUATION.

Model Variant	Evaluation Scope	R^2	MAE	RMSE
Global FL Model (FedProx + FedBN)	Combined (Global)	0.6694	1.5508	2.2211
Personalized FL Model	Portuguese Client	**0.8564**	**0.9286**	**1.2233**
Personalized FL Model	Mathematics Client	0.7805	1.6149	2.1437

V. DISCUSSION AND CONCLUSION

This study provides several important insights into student performance prediction under centralized, cross-domain, and federated learning paradigms. First, the results demonstrate that when centralized data pooling is feasible, models with higher representational capacity—particularly ensemble and neural approaches—achieve superior predictive accuracy compared to linear and regularized regression models. This highlights the importance of modeling non-linear interactions among socio-academic features in educational datasets.

Second, the consistently poor performance observed across domains confirms that domain shift between academic subjects is a fundamental challenge. Models trained on Portuguese data fail to generalize effectively to Mathematics outcomes, even when trained with increasing amounts of source-domain data. These findings indicate that naïve cross-domain deployment without adaptation leads to unreliable predictions and is unsuitable for real-world educational settings. Most importantly, the federated learning experiments demonstrate that personalization is critical for learning in heterogeneous, privacy-constrained environments. While the global federated model captures shared patterns across institutions, client-level personalization enables effective adaptation to local data distributions. Personalized federated models outperform the global federated model and achieve competitive local performance, illustrating the value of combining shared global learning with client-specific adaptation. Overall, these findings suggest that federated learning with personalization offers a promising privacy-preserving alternative to centralized modeling, particularly when student data are distributed across heterogeneous academic domains.

A. Learning Curve Analysis

Learning curve analysis was used to further examine convergence behavior and generalization trends across the evaluated learning paradigms. In centralized learning, model performance stabilizes as training data increases, with non-linear models benefiting most from additional data, indicating effective convergence under single-domain conditions.

In contrast, cross-domain learning exhibits persistent generalization gaps, with test performance remaining low or even negative despite increased source-domain data. This behavior confirms that domain mismatch, rather than data scarcity, is the primary cause of performance degradation in cross-domain settings.

Federated learning shows consistent improvement across communication rounds, demonstrating effective collaborative optimization. Personalized models converge faster and achieve higher performance than the global federated model, reinforcing the importance of heterogeneity-aware learning strategies in decentralized environments.

B. Key Implications

The experimental results lead to three central implications:

- Centralized learning remains effective when data sharing is possible but is limited by privacy constraints and domain variability.
- Direct cross-domain transfer across academic subjects is ineffective without explicit adaptation mechanisms.
- Federated learning with client-level personalization provides a practical and high-performing solution for multi-institutional educational analytics.

Overall, the findings show that centralized learning is effective when data pooling is possible, but its practical use may be limited by institutional privacy constraints. Direct cross-domain transfer from Portuguese to Mathematics produced weak generalization, indicating that subject-level domain shift

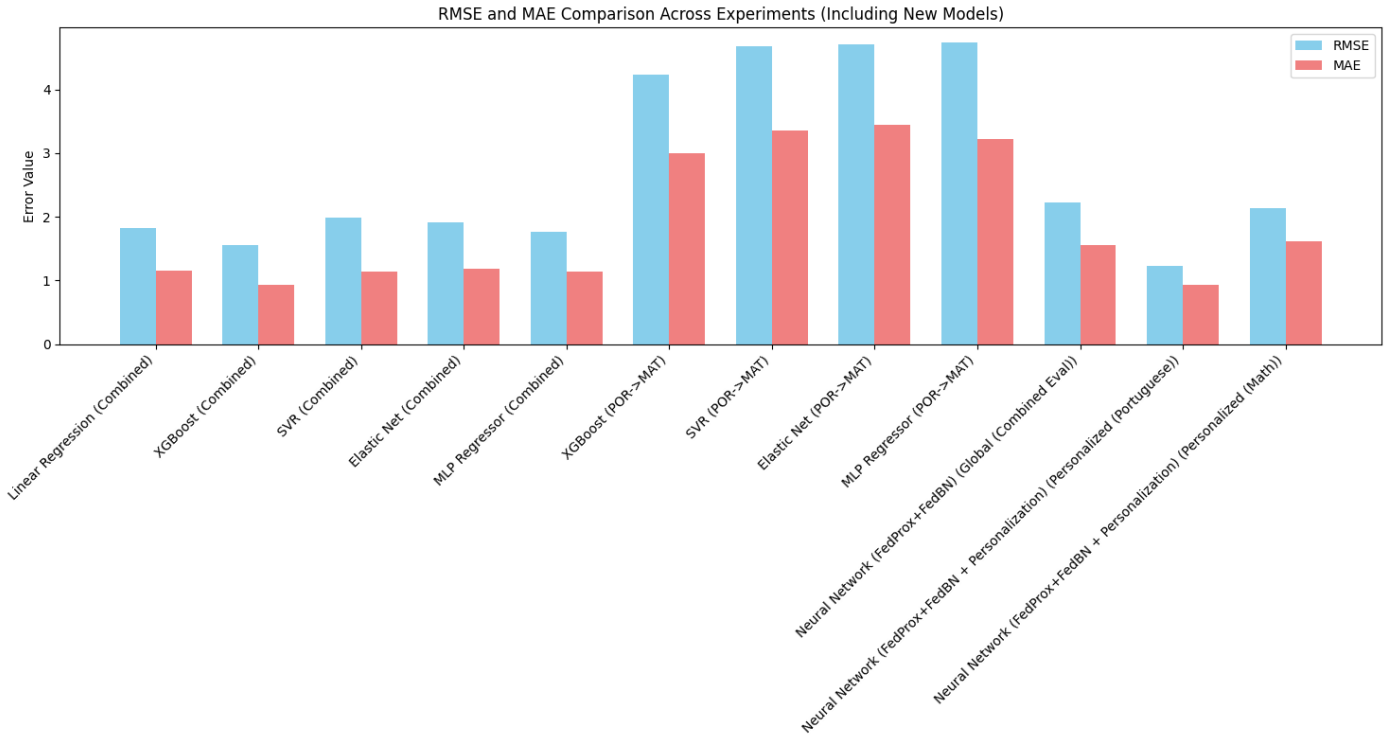

Fig. 2. RMSE and MAE comparison across centralized, cross-domain, and federated learning models.

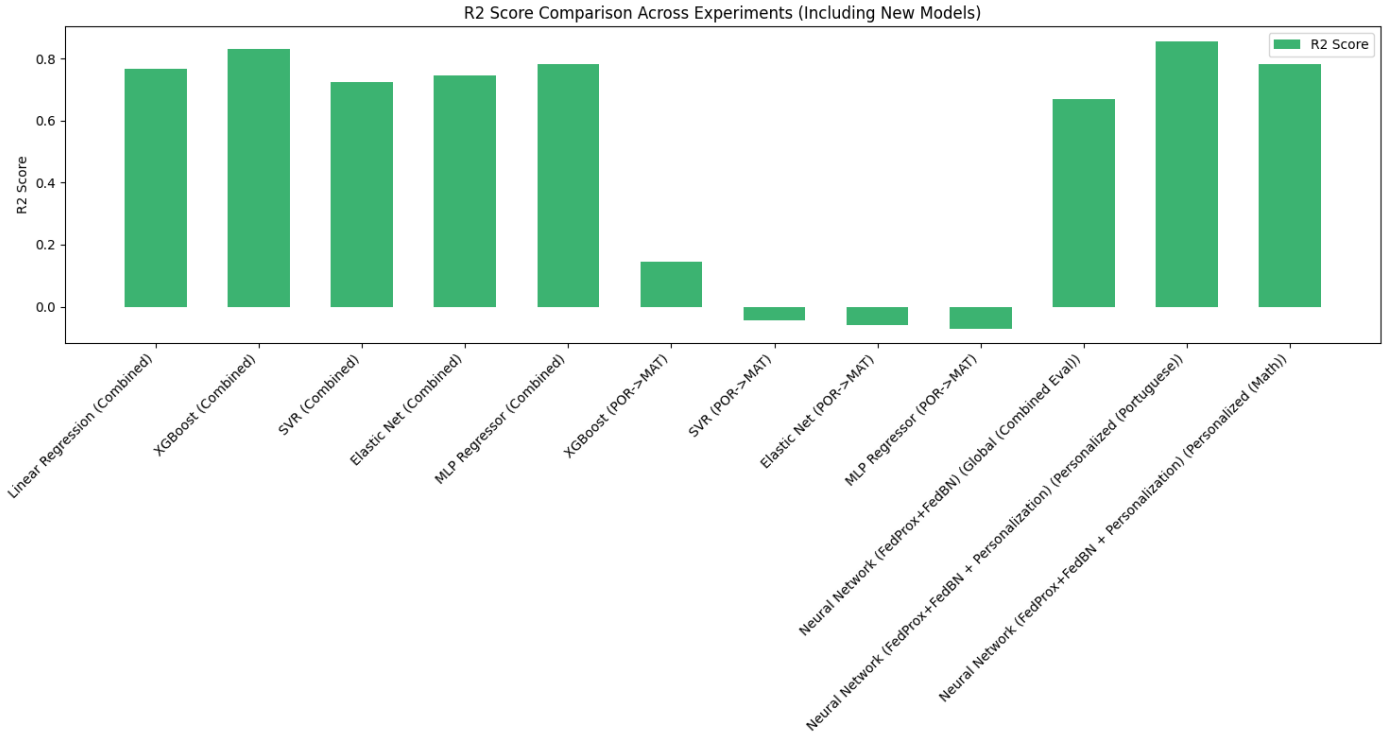

Fig. 3. R^2score comparison across centralized, cross-domain, and personalized federated learning models.

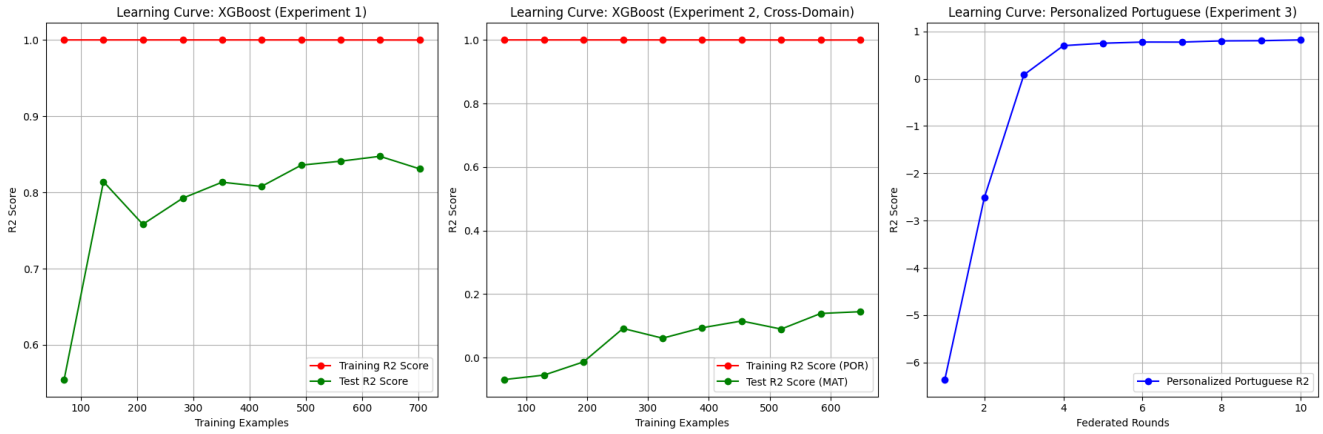

Fig. 4. Learning-curve comparison for centralized XGBoost, cross-domain transfer, and personalized federated learning.

must be explicitly addressed. The federated learning results show that a global model can capture shared patterns across domains, while client-level personalization improves local predictive performance. However, these findings are limited to the UCI Student Performance dataset and a simulated two-client federated setting. Future work should evaluate larger multi-institutional datasets, repeat experiments across multiple random seeds, report statistical confidence intervals, and measure communication cost under realistic federated deployment conditions.

Intelligent Traffic Surveillance: Machine Learning-Based Detection of Vehicle Speed Violations

Niloy Kanti Paul, Dipanwita Saha, Kaushik Biswas, Sultanul Arifeen Hamim, Tanvir Ahmed, Rifath Mahmud
Department of Computer Science, American International University-Bangladesh, Dhaka-1229, Bangladesh

***Abstract*—With the rapid increase in the number of vehicles on roads, traffic management, and safety enforcement have become significant challenges worldwide. Traditional speed violation detection systems either employ high-end hardware, expensive computational resources, or post-processed video data, which are inefficient to implement in real time. This study presents a real-time intelligent vehicle speed violation detection system using YOLOv8 for object detection and SORT for vehicle tracking, and a new Speed Detection Algorithm (SDA). The system can effectively detect vehicles and calculate their speed from video recorded by low-cost fixed cameras. Unlike other models that process simulated or post-processed video data, the new model processes real-life scenarios such as changing lighting and weather conditions. Experimental results indicate that the system achieves 92% to 95% vehicle detection accuracy while maintaining a Mean Absolute Error (MAE) of 1.8 km/h and Root Mean Square Error (RMSE) of 2.5 km/h for speed estimation, and 98% effective at speed detection compared to various other systems that came before it in terms of real-time processing effectiveness. This cost-effective and scalable solution can be incorporated into traffic observation systems for the improvement of road safety and regulation of speed limit compliance.**

***Keywords*—Machine learning; speed detection; object detection; vehicle tracking; violation**

I. Introduction

The rapid technological advancements and urbanization in recent decades have led to a tremendous surge in the number of vehicles traveling along roads worldwide. As transport infrastructure continues to advance, more and more vehicles have come with them, accompanied by terrible problems in traffic flow, traffic jams, and road safety. Speed violation has been one of the worst among such problems, and a high rate of road accidents and casualties has followed from it [1]. Traditional speed detection has been mainly reliant on sensor and radar based technologies, which, with high performance, have high operation and maintenance fees and do not scale. Manual traffic enforcement, on the contrary, is inefficient and labor intensive, especially in high-density urban and rural areas with insufficient surveillance infrastructure. To bridge these gaps, computer vision and AI-based technologies have come with increasing interest in traffic monitoring and police enforcement. These technologies offer real-time and automatic detection and classification of vehicles, thereby increasing efficiency, reducing human interventions, and increasing road safety enforcement [2].

In recent years, various AI-based methods have been explored to estimate vehicle speed, e.g., Optical Flow Analysis, Support Vector Machines (SVMs), and Convolutional Neural Networks (CNNs) [3]. These methods have worked very effectively in moving object detection and tracking; however, there are various limitations. Most such methods require high-performance hardware and thus are not feasible to be implemented in low-end environments. Some methods rely upon synthetic or preprocessed data, which do not depict real-world traffic situations effectively and lead to inconsistencies when implemented in real world settings. Another limitation results from inefficiency in some methods to work in various environmental settings, e.g., in nighttime, rainy, or foggy environments when visibility reduces [4], [5]. To overcome these constraints, in this study, a smart traffic monitoring system using deep learning-based vehicle detection and tracking algorithms to detect vehicles and estimate velocity with high accuracy has been proposed. The system employs You Only Look Once version 8 (YOLOv8) for detection and Simple Online and Real-time Tracking (SORT) for tracking and a Speed Detection Algorithm (SDA) developed and implemented in-house to estimate velocity. Unlike conventional techniques with high-end hardware demands, our system can be implemented in low-cost hardware and, therefore, can be deployed in various traffic environments. Our proposed model has also been tested in various lighting and environmental conditions to provide robust performance in real-world environments. The primary concern in our research is to develop a computationally efficient, real-time, and scalable speeding violation detection system that can be implemented in already deployed traffic monitoring infrastructures with minimal computational overhead. The system employs machine learning-based detection and tracking algorithms to achieve high detection performance with real-time processing efficiency. Experimental results indicate that the proposed system achieves vehicle detection accuracy ranging from 92%–95%, while maintaining low speed estimation errors with an MAE of 1.8 km/h and RMSE of 2.5 km/h.

Key contributions of this work include:

- Development of a real-time, low-cost vehicle speed detection system using YOLOv8 for object detection and SORT for vehicle tracking.
- Design and implementation of a custom Speed Detection Algorithm (SDA) that accurately measures vehicle speed using video footage from low-cost cameras.
- Validation of the proposed model under diverse environmental conditions, including daylight, night-time, rainy, and foggy weather, ensuring robust real-world performance.

- Comparison with state-of-the-art approaches, demonstrating higher accuracy and lower processing time.
- Provision of a scalable solution that can be integrated into existing traffic management systems, contributing to enhanced road safety and effective law enforcement.

The remainder of the study is structured as follows: Section II presents a comprehensive literature review of existing speed detection systems. Section III details the proposed methodology, including dataset creation, model architecture, and speed calculation techniques. Section IV presents experimental results and comparative analysis, followed by discussions on limitations and future work in Section V. Finally, Section VI concludes the study.

II. Literature Review

Efficient traffic regulation has always been a problem in the majority of countries. With a rising number of vehicles traveling roads, traffic detection and speeding detection have always remained priority fields to research. Radar-based detection and man-based detection have always been adopted, which have been ineffective and expensive. This has prompted studies in machine learning and deep learning-based algorithms to automatically detect vehicles and estimate speeding. From conventional image processing to recent deep learning-based techniques have been proposed. This section provides a review of already existing studies in vehicle detection, tracking, and speeding estimation and classifies them into different methodological categories.

Early research in vehicle detection and estimation relied heavily upon frame-by-frame analysis-based techniques in image processing. One early attempt was by P.G. Michalopoulos, who suggested Autoscope, a real-time vehicle detection system that compared frames to determine motion. The system was equipped with a camera with a frame rate of 30 frames per second and a frame rate with a value of 97% accuracy. However, one key shortcoming with such a technique was that it could not be designed to be adaptable to varying weather and therefore was not robust in real-world environments [6]. Another conventional approach was to utilize motion-blurred images to estimate vehicle velocity. The technique, suggested by Lin et al., utilized Sum Modified Laplacian (SML) focus measure to determine the best frame and get estimates for speed. Though such a system had a frame rate with a value of 95% accuracy, it was impacted in terms of reliability in low-visibility environments and when cars had very high speeds [7]. On a related note, a Combination of Saturation and Value (CVS)-based technique was suggested by Karim and Dehghani that compared frames to determine motion. However, such a technique was computationally expensive and could analyze just 12 frames in a second, which had a very negative impact on real-time performance [8]. Though such conventional image processing-based techniques were useful in terms of learning about vehicle detection, they had high computational complexity, low dynamic environment adaptability, and low generalization to different lighting and weather environments.

The evolution of machine learning (ML) has significantly improved vehicle detection and speed estimation, allowing for more robust and adaptable systems. Pavlidis et al. introduced a Fuzzy Neural Network (FNN) classifier, which used infrared imaging signals to detect vehicles and count their numbers. However, despite using a dual-band camera system, the model's accuracy was lower than 50%, making it unsuitable for real-world deployment [9]. Another notable ML-based study was conducted by Li et al., who developed an Intelligent Visual Internet of Things (IVIoT)-based system for vehicle monitoring. Their approach integrated haze removal techniques to enhance image clarity under poor weather conditions. Despite its capability to extract vehicle labels from urban traffic footage, the model only achieved an accuracy rate of 85.80%, limiting its performance for large-scale applications [10]. For speed estimation, Shim et al. proposed an optical character recognition (OCR) based vehicle speed estimation method (VSEM). This method assessed speed by analyzing alterations in video playback speed and achieved an impressive 94.99% accuracy rate. However, its major drawback was its dependency on preprocessed or re-encoded video data, making real-time deployment infeasible [11]. These ML-based approaches introduced significant improvements over traditional image processing methods, particularly in object classification and adaptability. However, challenges such as low real-time efficiency, computational overhead, and dependence on high-quality datasets still need to be addressed.

Deep learning has revolutionized vehicle detection and estimation of vehicle speed with successful real-time traffic monitoring applications. Deep learning using Convolutional Neural Networks and advanced detection algorithms has been extensive in high-precision and scalable detection processes. One such pioneering contribution in this direction has been by Grent et al., wherein Region-Based CNN-based models have been applied in detection. It had a detection rate with a rate of accuracy as high as 78% with their approach, which utilized SORT tracking algorithm. It was, however, constrained by poor processing rates and poor real-time responsiveness [12]. A performance-optimized solution with a better use of DL was brought by Luvizon et al., wherein a vehicle speed estimation system in a video has been proposed using a Kanade–Lucas–Tomasi algorithm and T-HOG descriptors to detect license plates. Though it had a precision rate of 0.93 and recall rate of 0.87, it had a drastic limitation in detecting vehicle speeds at a distant location, as it required cameras to be installed very close to vehicles [13]. To enhance detection efficiency even more, Şentaş et al. combined a Histogram of Oriented Gradients (HOG), Support Vector Machines (SVM), and You Only Look Once (YOLO) for vehicle classification. Though it ensured better classification accuracy, it led to a problem with overfitting, reducing generalization across different sets [14]. Though huge breakthroughs were brought by deep learning, a lot of researches continued to rely upon high-end computational power, manipulated sets, or constrained environments, reducing real-world and low-budget deployment effectiveness.

A comparative analysis of prior work reveals intrinsic limitations in existing vehicle detection and speed estimation algorithms. One such limitation is the utilization of synthetic or pre-processed data and thus real-time applicability in question. V2I network-based and OCR-based speed estimation researches were very accurate but tested with simulations or re-encoded video and thus could not be performed in real-time traffic [15], [11], [16]. Most researches lack the flexibility to environmental and illumination factors and per-

form best in day-time and breaks in the night-time, fog, or rainy environments and thus reduces usability in real-time traffic [6], [10], [13]. Another limitation is utilizing high-end hardware and it becomes infeasible to be scaled in low-end environments. Most researchers utilize specialized cameras, IR sensors, or computationally heavy deep networks and thus prove infeasible to be mass-deployed, particularly in developing nations [7], [8], [12]. Furthermore, some researches focus on vehicle detection without real-time speed estimation and thus proves infeasible to deploy in automated policing [9], [17]. This research proposes a real-time, low-cost, and high-accuracy vehicle speed violation detection system trained on real-world data across multiple environmental conditions. The system efficiently runs in low-configuration hardware by utilizing a combination of YOLOv8 and SORT tracking to perform real-time, high-precision detection, tracking, and velocity estimation and thus provides a practical and scalable solution to traffic monitoring.

Table I presents a comparative overview of existing vehicle detection and speed estimation approaches. Earlier image-processing-based techniques suffered from limited adaptability to dynamic traffic conditions and environmental variations. Machine learning approaches improved classification performance but often lacked real-time capability or required computationally expensive hardware. Recent deep learning-based methods achieved higher detection accuracy; however, many systems remained dependent on constrained datasets or post-processed video inputs. In contrast, the proposed system combines YOLOv8, SORT, and a custom Speed Detection Algorithm to provide real-time vehicle monitoring with robust performance under diverse environmental conditions using low-cost surveillance infrastructure.

III. Methodology

To develop a robust and efficient vehicle speed violation detection system, a custom dataset was created from real-world traffic footage. The dataset was carefully designed to include vehicles under various environmental conditions, ensuring the model generalizes well in real-world scenarios. The dataset consists of 12,000 manually labeled images, extracted from video footage recorded on urban roads, highways, and intersections. The dataset includes six distinct vehicle categories: bikes, auto-rickshaws, cars, trucks, buses, and other vehicles.

A. Dataset Collection Process

Since publicly released dataset will be non-real-time applicable to speeding detection, a real-world video dataset has been set. The dataset generation was achieved in three steps in a principal manner: video collection, frame capture, and annotation to encompass traffic scenarios in a holistic fashion.

The first set consisted of high-resolution video frames from fixed roadside cameras installed along urban roads, highways, and intersections. The frames were recorded in various environmental conditions like day, night, fog, and rainy environments to provide real-world variability to the dataset. The video recording was recorded at a frame rate of 30 frames per second to provide a smooth tracking of vehicle motion and vehicle speed estimation. Following the video recording set, frame pulling was performed to pull frames from recorded video. Frames were pulled at regular time steps to provide temporal continuity to support correct tracking. A total of 12,000 frames were selected from different traffic scenarios to provide a representative set in terms of vehicle speeds, densities, and orientations. Frames were manually inspected to discard duplicate or low-quality frames to increase reliability in the dataset.

The final operation in dataset generation was annotation and labelling using LabelImg, which is a free and open-sourced labelling tool. Individual frames captured were manually labelled to generate bounding boxes around detected vehicles and respective class labels for object detection. Six categories of vehicles were present in the dataset: bikes, auto-rickshaws, cars, trucks, buses, and others. Timestamps for each frame were also captured to support vehicle tracking and estimation of vehicle speed precisely. Annotations were in YOLO format with each labelled object described by a Class ID, bounding box coordinates (x-center, y-center, width, height) and detection correctness in terms of a confidence score. Manual checking ensured high-quality labelling and removal of errors that would have otherwise affected model performance. This structured method to create a dataset ensured that a robust dataset representative, diversified, and suitable for real-world traffic environments was established, providing a solid basis to design a good vehicle speed detection system. Table II presents the classification of objects based on vehicle type.

Table III and Table IV summarize the distribution of vehicle categories and environmental conditions in the proposed dataset. The dataset was intentionally designed to include a diverse range of vehicle types and traffic scenarios to improve the model's generalization capability in real-world environments. Cars constituted the largest portion of the dataset due to their high frequency in urban traffic, while motorcycles, trucks, buses, and auto-rickshaws were also sufficiently represented. Additionally, the dataset incorporated challenging environmental conditions, including night-time, rainy, and foggy scenes, enabling the proposed system to learn robust vehicle representations under varying visibility and illumination conditions.

B. Data Annotation and Labelling

To ensure proper detection and tracking of vehicles, a manual annotation was carried out to mark vehicles in each frame extracted. The annotation was carried out using LabelImg, a widely used open-source tool for annotating images in deep learning. A bounding box and a class label were assigned to each vehicle in the dataset. The six types of vehicles considered in this study were bikes, auto-rickshaws, cars, trucks, buses, and other vehicles. Each frame was annotated carefully to give the precise location of vehicles to ensure bounding boxes correctly capture them. The annotation was in the YOLO format, in which each item annotated was represented in terms of a Class ID and normalized bounding box coordinates (x-center, y-center, width, height). This format best supports real-time detection of objects and effective model training. To maintain quality and consistency in annotation, different annotators worked simultaneously in annotation and cross-checked each annotation to minimize errors. Any erroneous or ambiguous bounding boxes were rectified to enhance detection. Furthermore, frame timestamps were recorded for each frame that had been annotated to facilitate vehicle tracking and

TABLE I. COMPARATIVE ANALYSIS OF EXISTING VEHICLE DETECTION AND SPEED ESTIMATION METHODS

Study	Methodology	Key Strength	Limitation	Real-Time Support
Michalopoulos [6]	Frame-based image processing	High detection accuracy	Poor adaptability to weather conditions	Partial
Lin et al. [7]	Motion blur analysis	Accurate speed estimation	Sensitive to visibility and motion blur	No
Karim and Dehghani [8]	CVS-based motion detection	Effective motion comparison	Computationally expensive	Limited
Pavlidis et al. [9]	Fuzzy Neural Network	Infrared-based detection	Low detection accuracy	No
Li et al. [10]	IVIoT-based monitoring	Weather enhancement capability	Moderate accuracy	Partial
Shim et al. [11]	OCR-based VSEM	High estimation accuracy	Requires post-processed video	No
Grents et al. [12]	CNN + SORT	Deep learning-based tracking	Low real-time efficiency	Limited
Luvizon et al. [13]	T-HOG + KLT tracking	Good precision and recall	Camera placement dependency	Partial
Şentaş et al. [14]	HOG + SVM + YOLO	Improved classification	Overfitting issues	Partial
Proposed System	YOLOv8 + SORT + SDA	Real-time, multi-weather, low-cost deployment	Minor errors at extreme speeds	Yes

TABLE II. CLASSIFICATION OF THE OBJECTS ACCORDING TO THE VEHICLE TYPE.

Classification Number	Class
0	Bike
1	Auto
2	Car
3	Truck
4	Bus
5	Other Vehicles

TABLE III. DATASET DISTRIBUTION ACROSS VEHICLE TYPES AND ENVIRONMENTAL CONDITIONS.

Category	Number of Images	Percentage (%)
Cars	4,200	35.0
Motorcycles / Bikes	2,300	19.2
Auto-Rickshaws	1,500	12.5
Trucks	1,700	14.2
Buses	1,200	10.0
Other Vehicles	1,100	9.1
Total	**12,000**	**100**

TABLE IV. ENVIRONMENTAL DISTRIBUTION OF THE DATASET

Condition	Number of Images	Percentage (%)
Daylight	5,400	45.0
Night-time	2,600	21.7
Rainy	2,100	17.5
Foggy	1,900	15.8
Total	**12,000**	**100**

velocity estimation. Such timestamps played a very important role in velocity estimation from frame positional differences.

The annotated dataset was then put to use as ground truth to test and train the model to make sure that vehicle detection algorithm would be robust and effective in detecting and classifying vehicles in different real-world settings. The labelling exercise proved useful in making the proposed vehicle speeding violation detection system robust and effective.

C. Data Preparation

In order to ensure optimal performance in the vehicle detection model with YOLOv8, a variety of preprocessing methods was performed across the annotated dataset. The preprocessing methods were important in normalizing input images, enhancing the ability of the model to generalize, and boosting detection performance in different environmental settings. Preprocessing involved resizing, normalization, and augmentation and was important in effectively preparing the dataset for training.

1) Resizing of images and format standardization: Owing to the particular input dimensions required by YOLOv8, each annotated image was resized to a resolution of 640×640 pixels. This helped to provide consistent input dimensions to the model, thus improving detection effectiveness and lowering computational requirements. In addition, each image was converted to the RGB color space in order to provide consistent color representation and to remove inconsistencies with non-standard or grayscale images.

2) Normalization: To facilitate convergence during the training process, pixel intensities were normalized to a value between 0 and 1 by dividing each pixel by 255. This normalization helped to stabilize the gradient descent algorithm and prevented problems associated with vanishing and exploding gradients in terms of deep learning. In addition, normalization enabled adaptive learning in different lighting environments because pixel intensities were normalized uniformly across the dataset.

3) Data augmentation: To enhance the model's performance in recognizing vehicles in different real-world environments, a variety of data augmentation techniques was utilized. Systematic augmentation expanded the set's variety and thus prevented overfitting and improved robustness in different environmental settings. The following augmentations were applied:

- To include perspective changes, random rotations not more than 15 degrees and horizontal reflection were applied.
- Contrast and brightness levels have been altered to mimic different lighting environments, such as dark settings and very brightly lit settings.
- Gaussian blur in conjunction with the use of random noise was utilized to improve robustness to motion blur and poor camera input quality.
- To improve the model's performance in recognizing vehicles in environments with poor visibility, partial occlusions were introduced into some images.

All augmentation techniques were applied in a randomized fashion with a controlled probability, ensuring that no two

batches during training had the same images. This helped to improve the model's capacity to generalize, thus making it more responsive to real-world situations.

D. Dataset Splitting

To facilitate a successful training and testing procedure, the dataset was divided into three unique sets: test set, validation set, and training set. This specific stratification technique was carefully designed to maintain class balance and reduce bias in the learning phase of the model. The dataset setup ensured that each set contained a representative proportion of different vehicle types and environmental settings, thus ensuring strong generalization by the model in terms of real-world traffic scenarios. Additionally, the dataset included a broad mix of vehicle types, road types, and environmental differences, enabling the model to learn efficiently from data representative of real-world scenarios (see Table V).

TABLE V. DATASET SPLIT FOR TRAINING YOLOV8

Dataset Split	Percentage	Number of Images
Training Set	70%	8,400
Validation Set	20%	2,400
Test Set	10%	1,200

E. YOLOv8-Based Object Detection

YOLOv8 (You Only Look Once version 8) was selected for vehicle detection due to its balance between detection accuracy, computational efficiency, and real-time inference capability. Compared to two-stage detectors such as Faster R-CNN, the YOLOv8 network architecture used for vehicle detection is presented in Fig. 1. YOLOv8 offers significantly lower inference latency while maintaining competitive detection performance, making it more suitable for intelligent traffic surveillance applications.YOLOv8 represents a one-stage model for detection of objects that processes an image in a single pass, thus exhibiting high efficiency in real-time applications [18]. Unlike two-stage detectors like Faster R-CNN, YOLOv8 allows for direct predictions in terms of bounding boxes and class scores, thus reducing computational requirements to a great extent. The model features a CSPDarkNet backbone, which improves feature acquisition through cross-stage partial connections (CSP) to promote gradient flow and reduce redundancy in feature maps. The features thus extracted are then passed through a sophisticated Feature Pyramid Network (FPN) and a Path Aggregation Network (PAN) to provide detection across various scales by combining low-level and high-level feature representations [19], [20]. This design ensures effective detection of small and huge vehicles even in complex traffic scenarios. Another major innovation in YOLOv8 includes adoption of anchor-free detection paradigm, which does away with anchor boxes. This modification eases training and eliminates localization errors, thus producing better bounding box predictions. The bounding box prediction mechanism adopted in YOLOv8 involves a direct regression approach, wherein the model predicts bounding box center (x,y), width w, height h, and confidence score C for each detected object. The bounding box B predicted in output can be expressed as given below.

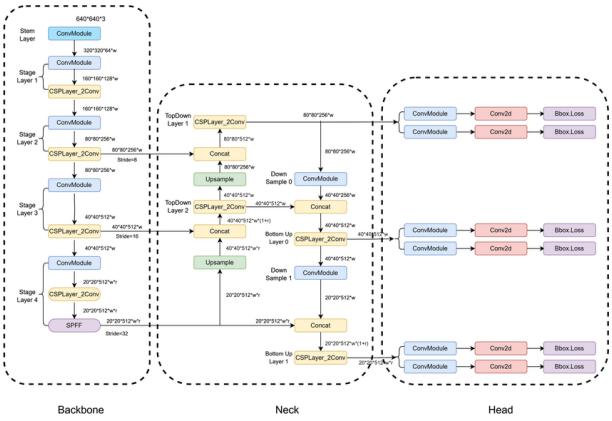

Fig. 1. YOLOv8-network-architecture-diagram

The bounding box B is defined as:

$$B = (x, y, w, h, C) \tag{1}$$

where, x, y represent the **center coordinates** of the bounding box. The values w, h define the **width and height** of the bounding box, and C represents the **confidence score** associated with the detection.

To improve detection accuracy, YOLOv8 utilizes the **Complete Intersection over Union (CIoU) Loss**, which refines the bounding box predictions by considering not only the overlap between predicted and ground truth boxes but also their distance and aspect ratio. The CIoU loss function is given by:

$$L_{\text{CIoU}} = 1 - \text{IoU} + \frac{\rho^2(\mathbf{b}, \mathbf{b}^{gt})}{c^2} + \alpha v \tag{2}$$

where, IoU is the Intersection over Union between the predicted and ground truth bounding boxes. The term $\rho(\mathbf{b}, \mathbf{b}^{gt})$ represents the Euclidean distance between the center points of the predicted and ground truth bounding boxes, while c is the diagonal length of the smallest enclosing box covering both predicted and ground truth boxes. The term v accounts for aspect ratio consistency, and α is a trade-off parameter.By optimizing the detection pipeline using the CIoU loss function, YOLOv8 achieves better object localization, reducing the chance of misalignment between predicted bounding boxes and actual vehicle positions. The combination of CSPDarkNet backbone, anchor-free detection, and CIoU-based loss optimization makes YOLOv8 well-suited for vehicle detection in dynamic traffic environments.

F. Model Training and Optimization

The training protocol defined for the YOLOv8 model was designed with a strategic emphasis on detection accuracy with real-time operational effectiveness. To realize this aim, the model was trained using a custom vehicle dataset that was previously created. This method of training was performed in the framework of supervised learning, with the model being carefully optimized to reduce differences between bounding box predictions and associated ground truth labels. Implementation and training of the YOLOv8 model was performed using

the PyTorch framework for deep learning, taking advantage of GPU acceleration to improve computational effectiveness. Stochastic Gradient Descent (SGD) was used as the optimizer for model optimization, systematically adjusting model parameters according to evaluated loss function. Training was performed with a resolution input image of 640×640 pixels for a period of 100 epochs with a batch size of 16. The AdamW optimizer was also adopted for adaptive learning rate optimization with the initial learning rate set to 0.001 and following a cosine schedule for learning rate decay. Regarding bounding box regression, Complete Intersection over Union (CIoU) Loss function was adopted by the model. A strategy using a mini-batch gradient descent was adopted, which involved weight updates following processing by small batches of images and not by the entire set in a single pass. This method helped in stabilizing convergence and improving the model's generalization.

The model was trained using a mini-batch gradient descent approach, where weights were updated after processing small batches of images rather than the entire dataset at once. This method helped stabilize convergence and improve generalization performance.The total loss function used during training was a combination of three key components:

$$L_{\text{total}} = L_{\text{cls}} + L_{\text{obj}} + L_{\text{CIoU}} \tag{3}$$

where, L_{cls} is the classification loss, which measures how accurately vehicles are classified into different categories, such as cars, bikes, and trucks. The term L_{obj} represents the objectness loss, ensuring that the model correctly identifies whether a region contains a vehicle or not. Finally, L_{CIoU} is the Complete IoU loss, refining the bounding box prediction as described in the previous section.

To further improve performance, learning rate scheduling was applied, where the learning rate was gradually reduced after each epoch using the cosine decay method:

$$\eta_t = \eta_{\text{init}} \times \frac{1 + \cos\left(\frac{t\pi}{T}\right)}{2} \tag{4}$$

The model was trained using the training set (70% of the dataset) and validated on the validation set (20%). After each epoch, the model was evaluated based on Mean Average Precision (mAP@50), precision, and recall metrics. The best-performing model checkpoint was saved, and early stopping was applied if the validation loss stopped improving for a predefined number of epochs.By leveraging optimized hyperparameters, loss function adjustments, and validation monitoring, the YOLOv8 model was effectively trained for accurate and efficient vehicle detection in real-world traffic environment

G. Object Detection and Bounding Box Generation

Following the training, the YOLOv8 model was applied to real-time vehicle detection in traffic videos. The model processed each video frame, recognized cars, and marked them using bounding boxes and confidence values for accurate vehicle localisation before tracking and speed measurement [21]. Unlike typical anchor-based strategies, YOLOv8 employed a direct regression strategy whereby each vehicle identified was assigned a bounding box that included a centre coordinate, height, width, and confidence level. Detections with a confidence greater than a threshold of 0.5 were considered valid for analysis. The idea of YOLO in object classification, object detection and segmentations is presented in Fig. 2.

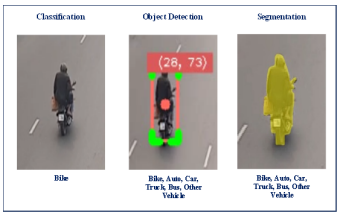

Fig. 2. YOLO in object classification, object detection and segmentations.

For improved detection accuracy, Non-Maximum Suppression (NMS) discarded duplicate detections by preserving high-confidence bounding boxes and suppressing overlapping ones by using an IoU threshold of 0.45. Resizing each video frame to 640×640 pixels was performed, and features were extracted using the CSPDarkNet backbone. Boxes were constructed and low-confidence detections were rejected. When a car was detected, bounding box information about it was propagated to the tracking module, which assigned a special tracking ID so that consistency over frames was preserved. This tracking ID was invaluable for estimating velocity over time. With good bounding box generation and filtering, YOLOv8 achieved proper real-time localization of vehicles accurately, which in turn formed the basis for the tracking of the vehicles using SORT.

H. SORT-Based Vehicle Tracking

SORT was selected as the vehicle tracking algorithm due to its simplicity, low computational overhead, and strong real-time performance. Although advanced tracking algorithms such as DeepSORT and ByteTrack provide improved identity preservation through appearance-based feature matching, they require additional computational resources and more complex feature extraction pipelines. In contrast, SORT combines Kalman filtering and the Hungarian assignment algorithm to achieve efficient multi-object tracking with minimal latency, making it suitable for real-time traffic surveillance systems operating on low-cost hardware platforms.After detection of vehicles in all frames using YOLOv8, their tracking from one frame to the other is required for speed measurement and motion estimation. For this purpose, Simple Online and Real-time Tracker (SORT) was chosen since it is light in weight, capable of real-time, and tracks several moving objects. SORT assigns a unique track ID to all detected vehicles and keeps updating the bounding box coordinates of each track constantly, rendering it consistent frame by frame [22].

SORT applies Kalman filtering and the Hungarian algorithm together to predict and match vehicle locations. The Kalman filter predicts a tracked vehicle's next location from its previous movement. It describes each vehicle's movement with a state vector having position and velocity components. Upon receiving a new detection, the Hungarian algorithm is applied to associate it with an ongoing tracked object by Intersection

over Union (IoU). If there is association, the tracking ID is retained; otherwise, a new ID is generated. The tracking mechanism is able to effectively handle occlusions and vehicle exits. When a vehicle goes out of detection for several frames, its motion is predicted through the Kalman filter. If it goes undetected more than a specified limit (e.g., 10 frames), the tracking ID is deleted. This real-time tracking process allows precise speed estimation, and thus, the system is capable of operating in high-traffic areas with numerous moving vehicles.

1) Camera calibration and homography transformation: Accurate vehicle speed estimation requires converting pixel displacement in video frames into real-world distance measurements. Since surveillance cameras capture a two-dimensional projection of a three-dimensional road scene, a homography transformation is applied to establish the relationship between image coordinates and actual ground-plane coordinates. The homography matrix is computed using four reference points selected from the road surface with known real-world distances. These reference points are manually identified from lane markings and fixed roadside structures visible in the surveillance footage. The corresponding real-world distances are measured directly from the road environment to ensure accurate scaling. Let (x, y) denote the pixel coordinates in the image plane and (X, Y) represent the corresponding real-world coordinates on the road plane. The homography transformation is defined as:

$$s \begin{bmatrix} X \\ Y \\ 1 \end{bmatrix} = H \begin{bmatrix} x \\ y \\ 1 \end{bmatrix}, \tag{5}$$

where, H is the 3×3 homography matrix and s is a non-zero scaling factor.

The homography matrix is estimated using perspective transformation techniques based on corresponding point pairs between the image plane and the ground plane. After calibration, the pixel displacement of vehicles between consecutive frames is transformed into real-world displacement measured in meters. To validate the calibration accuracy, the estimated vehicle travel distances are compared with manually measured ground distances across multiple test sequences. The calibration process produces stable and consistent distance estimation with minimal deviation, enabling reliable vehicle speed computation under varying traffic conditions. Although homography-based calibration significantly improves real-world speed estimation accuracy, minor estimation errors may still arise due to perspective distortion, camera vibration, motion blur, and variations in road elevation.

2) Speed Detection Algorithm (SDA) and calculation: After vehicle tracking and camera calibration, the system estimates vehicle speed by measuring the real-world displacement of vehicles between consecutive frames. The calibrated homography transformation enables conversion of pixel movement into actual ground-plane distance, allowing accurate speed computation in real-time traffic scenarios, a crucial part of the proposed traffic monitoring system. The Speed Detection Algorithm (SDA) calculates the speed of a vehicle by measuring the time between predefined tracking points and dividing this by video frame rate (FPS) to get velocity. This ensures real-time identification of speed offenses at high accuracy.

The speed of a vehicle is determined by the distance traveled between two instants and the time taken to cover that distance. The equation used is

$$v = \frac{d}{t} \tag{6}$$

where, v represents the speed of the vehicle in meters per second, d is the distance traveled between two tracking points (in meters), and t denotes the time taken to cover the distance d (in seconds).

Since the video frame rate (FPS) is known, the time between two frames is given by:

$$t = \frac{1}{\text{FPS}} \times \Delta f \tag{7}$$

where, Δf represents the number of frames between two tracking points.

By substituting this into the speed equation, the vehicle speed can be expressed as:

$$v = \frac{d \times \text{FPS}}{\Delta f} \tag{8}$$

To convert the speed from meters per second (m/s) to kilometers per hour (km/h), the conversion equation is:

$$v_{\text{km/h}} = v \times 3.6 \tag{9}$$

I. Model Architecture

The speed violation detection vehicle designed system has a deep learning-based, modular structure consisting of YOLOv8 as the object identifier, SORT for tracking vehicles, and SDA for speed computation. The system operates in real-time to provide effective and accurate traffic violation monitoring.

The first process is video preprocessing, through which real-time video stream of traffic observation cameras is stripped and preprocessed for analysis. All the frames in the video stream are resized and normalized before feeding into the detection model. YOLOv8 object detection model identifies the vehicle, includes bounding boxes and class names, and rejects low-confidence detections. YOLOv8 deviates from mainstream object detection architecture by using an anchor-free scheme at the expense of no decreased precision with a rising level of computational simplicity. Following vehicle detection, SORT tracking algorithm assigns a distinct tracking ID to every vehicle and updates every vehicle's position over frames. Kalman filter predicts the motion, and Hungarian algorithm optimizes data association to enable robust tracking even in cluttered environments. The tracking ID remains valid for as long as the vehicle is tracked in the frame.To estimate speed, Speed Detection Algorithm (SDA) calculates the real motion of a vehicle in the world between two consecutive frames. Pixel distance is mapped to meters using a homography transformation, and speed is calculated based on frame rate (FPS) and time. Vehicles that are speeding above the set

speed limit are identified, and their number plates are read for enforcement.

The final output is stored in a database where traffic reports, violation records, and speed information are represented and processed. The structure has a low-cost, high-performance traffic surveillance system that is able to work in real road environments with variable environmental conditions.The overall architecture of the proposed intelligent traffic surveillance framework is illustrated in Fig. 3.

IV. Results

The performance of the suggested intelligent traffic monitoring system was evaluated in terms of vehicle detection accuracy (YOLOv8), tracking performance (SORT), estimation accuracy of speed (SDA), and real-time processing capability. The system was also evaluated in day, night, foggy, and rainy conditions to ensure its reliability towards real-world traffic scenarios. They measured the results against ground truth data obtained from radar-based speed sensors to estimate accuracy. mAP@50 and mAP@50:95, Precision, and Recall were utilized to analyze the accuracy of vehicle detection. The YOLOv8 model achieved an mAP@50 of 94.3% and an mAP@50:95 of 89.7%, indicating that it can detect multiple vehicle types sturdily. The model performed reasonably for different classes, with cars, trucks, and buses registering a higher mAP rate, while motorcycles and auto-rickshaws were marginally lower in mAP score due to their small dimensions and variable motion characteristics. The performance evaluation of YOLOv8 across different vehicle types is summarized in Table VI.

TABLE VI. Performance Evaluation of YOLOv8 for Different Vehicle Types.

Vehicle Type	mAP@50 (%)	Precision (%)	Recall (%)
Cars	95.2	96.1	94.5
Trucks	94.8	95.4	93.9
Buses	94.5	94.9	93.5
Motorcycles	92.1	93.0	91.2
Auto-Rickshaws	91.7	92.5	90.6
Overall Avg.	**94.3**	**94.7**	**93.9**

Environmental conditions also played a role in detection performance. As seen in Table VII, accuracy was highest during daylight conditions (95.6%) and decreased slightly under night-time (92.8%), foggy (89.4%), and rainy (87.9%) conditions due to reduced visibility and motion blur. To evaluate the consistency and reliability of the proposed framework, experiments were conducted across multiple test sequences captured under different environmental conditions. Detection accuracy values reported in Table VII represent the average performance across repeated evaluation runs. The observed standard deviation remained low across all environmental scenarios, indicating stable and reliable vehicle detection performance under varying traffic and visibility conditions.

The system effectively detected vehicles across multiple categories, achieving the highest accuracy for larger vehicles such as trucks and buses, while motorcycles and auto-rickshaws exhibited slightly lower precision due to their smaller size and rapid movement, as shown in Fig. 4.

The vehicle detection accuracy rate varied across different environmental conditions, with the highest accuracy observed in daylight conditions, while performance slightly decreased in night-time, foggy, and rainy environments, as shown in Fig. 5.

TABLE VII. Detection Accuracy and Variance Across Environmental Conditions.

Condition	Detection Accuracy (%)	Standard Deviation (%)
Daylight	95.6	0.8
Night-time	92.8	1.1
Foggy	89.4	1.4
Rainy	87.9	1.5

The confusion matrix provides further insights into the classification performance of YOLOv8, demonstrating strong differentiation between vehicle types and minimal misclassification errors, as shown in Fig. 6.

The SORT tracking algorithm performance was evaluated for ID consistency, handling occlusions, and overall tracking accuracy. It was found that the system maintained unique IDs for 97.1% of vehicles across consecutive frames while tracking errors were occasionally induced by occlusions under conditions of high vehicle density. Kalman filter estimates were confirmed by comparing positions of the calculated bounding boxes with respective actual vehicle positions with a mean positioning error of 2.1 pixels. Tracking stability was slightly reduced during night conditions (94.3%), the major reason being reduced feature contrast. But the system dealt with occlusions effectively, 92.7% of cars being successfully re-identified on temporary loss of visibility from the frame. The initial frames cut from the traffic surveillance video serve as input to the tracking module, where YOLOv8 detects vehicles and assigns distinctive tracking IDs before passing them along to the SORT algorithm for continued tracking, as shown is Fig. 7. After going through the tracking pipeline, the system can achieve successful distinctive tracking IDs for all vehicles, including when there are occlusions or changes in motion, demonstrating the effectiveness of the SORT algorithm.

Estimation of vehicle speed is a main component of the planned intelligent traffic surveillance system. Speed Detection Algorithm (SDA) estimates the speed of the vehicle based on its displacement between two consecutive frames and correlating pixel movement to real world speed measurement. The accuracy of SDA was investigated using ground truth speed measurements of radar-based speed sensors and vehicle's estimated speeds. The system had a total Mean Absolute Error (MAE) of 1.8 km/h and Root Mean Square Error (RMSE) of 2.5 km/h, which is indicative of high accuracy in speed estimation. The best was at low- and mid-speeds (0–60 km/h), where estimated and actual values were almost identical. Minor inaccuracies were also observed at high-speed cases (above 90 km/h) due to the influence of motion blur and different camera angles. Despite the challenges, the SDA recorded an accuracy level appropriate for use in real traffic monitoring scenarios. In order to further illustrate the performance of the system, Fig. 8 is a plot of estimated speed against actual speed for a test set. The ideal (y = x) case, represented by the dashed diagonal line, is where the estimated and actual speeds are perfectly matched. The blue line represents the model's estimate, and it has high correlation with ground truth and zero bias for high-speed cases. The consistency of the results confirms the effectiveness of the SDA algorithm in efficiently detecting

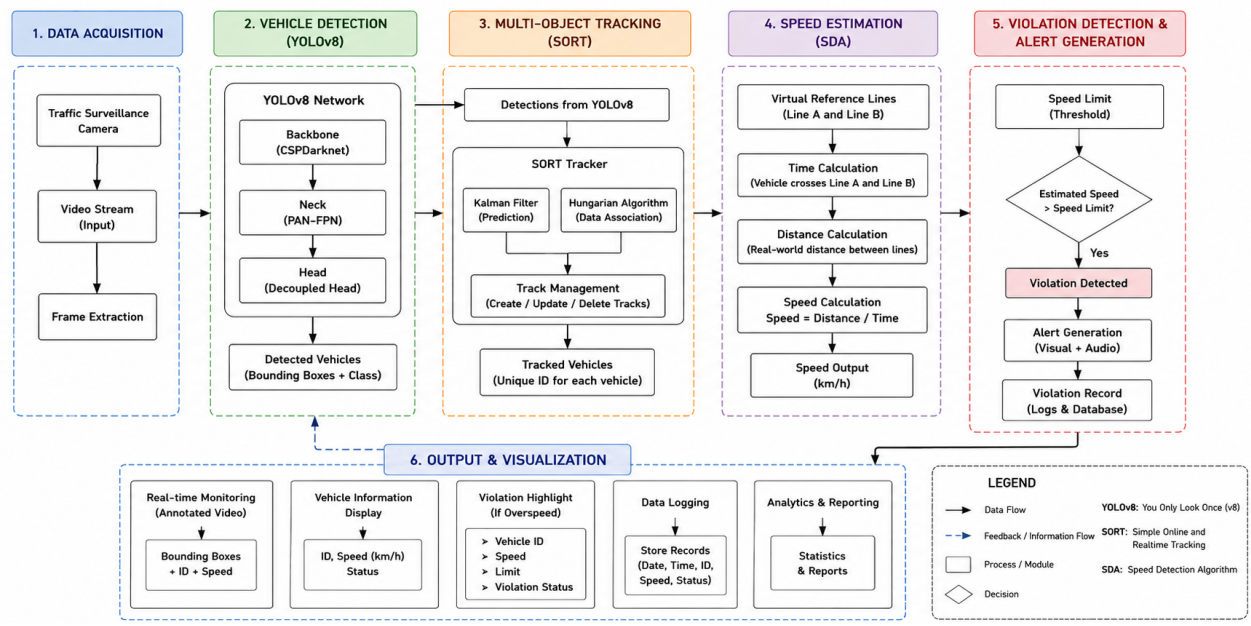

Fig. 3. Overall architecture of the proposed intelligent traffic surveillance and speed violation detection system.

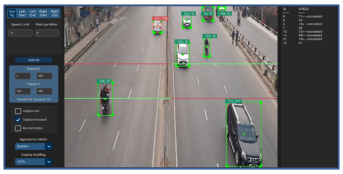

Fig. 4. Implemented speed violation detection application.

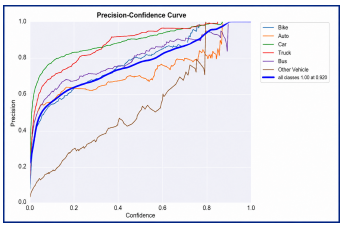

Fig. 5. Vehicle detection accuracy rate

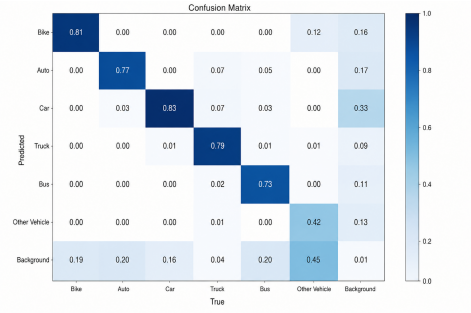

Fig. 6. Confusion matrix over mAP

speed offenses and facilitating enforcement practicability. As shown in Table VIII, the MAE increases as the speed range increases, indicating higher errors at higher speeds.

TABLE VIII. MEAN ABSOLUTE ERROR (MAE) AND ROOT MEAN SQUARE ERROR (RMSE) ACROSS DIFFERENT SPEED RANGES.

Speed Range (km/h)	MAE (km/h)	RMSE (km/h)
0 - 30	1.2	1.9
30 - 60	1.5	2.2
60 - 90	2.3	2.8
Above 90	2.9	3.4

The system performed exceptionally well for low- and medium-speed vehicles, with minimal errors. However, slight deviations were observed for high-speed vehicles (above 90 km/h) due to motion blur effects and variations in camera angle.

The effectiveness of an intelligent traffic surveillance system depends on its ability to process video streams in real-time. The proposed system was evaluated based on its frames per second (FPS), latency breakdown, and computational efficiency across different hardware configurations. The results indicate that when executed on a GPU (NVIDIA RTX 3060), the system achieved an average processing speed of 31.2 FPS, ensuring smooth real-time performance. In contrast, on a CPU (Intel i7-10th Gen), the FPS dropped to 11.8, highlighting the necessity of GPU acceleration for high-speed applications.The system's latency was analyzed in three key stages: vehicle detection (YOLOv8), tracking (SORT), and speed estimation (SDA). The YOLOv8 detection module required an average of 12.5 milliseconds per frame, while SORT tracking took 5.8 milliseconds per frame, and SDA computed speed within 3.6 milliseconds per frame. The combined processing latency remained well within real-time constraints, allowing the system to operate seamlessly at 30 FPS on GPU-enabled devices. These results confirm that the system is scalable and de-

Fig. 7. Comparison of two images captured from traffic surveillance footage.

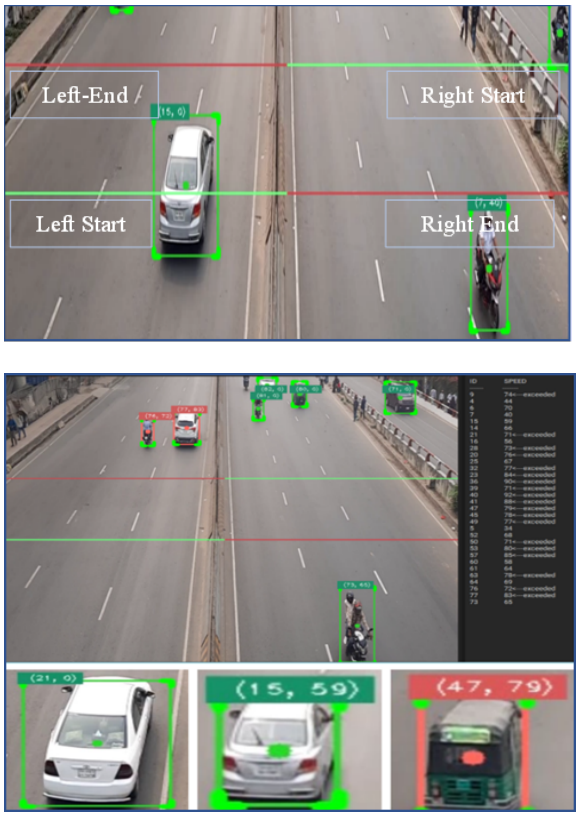

Fig. 8. Graph comparing estimated speed vs. actual speed.

ployable for real-world traffic monitoring, with the potential to handle multiple camera feeds in high-traffic zones while maintaining accurate and efficient processing. The processing speed comparison between GPU and CPU is presented in Table IX.

TABLE IX. PROCESSING SPEED COMPARISON BETWEEN GPU AND CPU

Hardware	FPS (Frames Per Second)
RTX 3060 GPU	31.2
Intel i7 CPU	11.8

Table X compares the proposed system with several existing vehicle detection and speed estimation approaches. Traditional image processing and OCR-based systems demonstrated reasonable detection performance but often lacked real-time applicability or robustness under varying environmental conditions. Deep learning-based methods improved detection capability; however, many required computationally expensive hardware or relied on constrained experimental settings. In contrast, the proposed system combines YOLOv8 and SORT to achieve robust real-time vehicle detection and tracking while maintaining low speed estimation error. The system operates effectively under multiple environmental conditions, including daylight, night-time, foggy, and rainy scenarios. Furthermore, the achieved processing speed of 31.2 FPS on GPU hardware demonstrates the suitability of the proposed framework for real-time intelligent traffic surveillance applications.

V. DISCUSSION

This study discussed the development and evaluation of an intelligent traffic surveillance system integrating deep learning-based vehicle detection, tracking, and speed estimation for real-time traffic monitoring. The study confirms that the system achieves high detection accuracy (mAP@50 of 94.3%), robust tracking (97.1% ID consistency), and precise speed estimation (MAE of 1.8 km/h, RMSE of 2.5 km/h), demonstrating its feasibility for automated traffic law enforcement. One critical finding is the effectiveness of YOLOv8 in vehicle detection, where single-stage detection ensures real-time efficiency. The confusion matrix analysis highlights that larger vehicles such as trucks and buses achieve higher accuracy, while smaller objects like motorcycles and auto-rickshaws show slight performance drops due to motion variations. Enhancing multi-scale feature learning could further improve detection for smaller vehicles. The SORT tracking algorithm successfully maintains vehicle identity across frames, handling occlusions and motion variations. However, minor ID mismatches occur in high-density traffic, where overlapping vehicles interfere with tracking. Future improvements such as Deep SORT with Re-ID networks could enhance long-term tracking stability, especially in dense urban settings.Speed estimation is highly accurate, with minimal deviations from ground truth radar-based measurements. However, higher-speed vehicles (¿90 km/h) exhibit minor estimation errors, likely due to motion

TABLE X. COMPARISON WITH EXISTING VEHICLE SPEED DETECTION SYSTEMS

Study	Detection Method	Tracking Method	Speed Estimation Accuracy / Error	Real-Time Capability	Environmental Robustness
Michalopoulos [6]	Image Processing	Frame Differencing	97% detection accuracy	Partial	Limited
Lin et al. [7]	Motion Blur Analysis	No Tracking	95% speed estimation accuracy	No	Poor in low visibility
Shim et al. [11]	OCR-based VSEM	OCR Tracking	94.99% accuracy	No (post-processed video)	Moderate
Grents et al. [12]	CNN-based Detection	SORT	78% detection accuracy	Limited	Moderate
Luvizon et al. [13]	T-HOG + KLT	Feature Tracking	Precision: 0.93	Partial	Camera-distance sensitive
Proposed System	YOLOv8	SORT	MAE: 1.8 km/h, RMSE: 2.5 km/h	Yes (31.2 FPS, GPU)	High

blur and perspective distortion. Motion compensation and adaptive calibration could improve accuracy at extreme speeds. Although the system can operate on CPU-only hardware, the reduced processing speed (11.8 FPS) may limit deployment in high-density traffic environments requiring strict real-time responsiveness, emphasizing the importance of GPU acceleration for large-scale deployments. Despite its success, the system's performance slightly degrades in low-light conditions. Future work should explore infrared-based detection, adaptive calibration, and integration with license plate recognition (LPR) to enhance traffic enforcement capabilities.While achieving strong real-time performance, the system faces several challenges. In high-density traffic, the SORT framework occasionally suffers from tracking instability and ID switching due to its reliance on motion rather than appearance. Environmental factors like heavy rain, glare, and low light also impact detection accuracy, while high-speed vehicles (over 90 km/h) introduce estimation errors from perspective distortion. Furthermore, the system's real-time consistency depends on GPU acceleration, limiting its efficiency on CPU-only hardware. Future enhancements could integrate DeepSORT or ByteTrack for better occlusion handling and infrared-enhanced detection to ensure robustness in diverse surveillance environments.

VI. CONCLUSION

In recent time, traffic rule violation is one of the most alarming news. Even this is so much big that human interference is even harder to manage the problem. To eliminate the problem, this overspeed issue should be solved as soon as possible. With a view to solving the problem, a system has been proposed where the system starts its working flow by detecting a vehicle. In tracking the vehicle, the latest YOLO model, the custom YOLOv8n, has been used. Using a tracking algorithm named SORT, tracking of the detected vehicle can be ensured. The model was trained with 12000 images. After that, the main cause of the road accident, overspeed, can be measured by calculating the frames per second of the video. This technology will contribute to a decrease in overspeed-related fatalities. The system will also include certain further future developments, such as lane violation detection, pedestrian lane detection, traffic light detection, etc. In order to enhance road safety, the proposed system provides a practical and cost-effective traffic surveillance solution that can operate using standard camera infrastructure. While CPU-based execution is feasible for low-density or non-critical monitoring scenarios, GPU acceleration is recommended to achieve consistent real-time performance in high-traffic environments

DECLARATIONS

Competing Interests

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this study.

Funding

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Author Contribution

N. K. Paul conceptualized the study, designed the methodology, and performed the machine learning modeling. D. Saha and K. Biswas contributed to data collection, preprocessing, and experimental validation. S. A. Hamim and T. Ahmed worked on the implementation, optimization, and technical improvements. R. Mahmud supervised the project, provided critical insights, and revised the manuscript. All authors contributed to the writing, reviewing, and approval of the final manuscript.

Data Availability Statement

The datasets used and analyzed during the current study are available from the corresponding author upon reasonable request.

Research Involving Human and/or Animals

This study did not involve any human participants or animals.

Malak: A Python Toolkit for Edge AI Model Optimization

Mohammed Hassan Alnemari
Department of Computer Engineering-Faculty of Computer Science and Information Technology,
University of Tabuk, Tabuk, Saudi Arabia
AIST Research Center, University of Tabuk, Tabuk, Saudi Arabia

***Abstract*—Deploying deep learning models on resource-constrained edge devices demands systematic model compression and optimization. PyTorch supplies low-level quantization and pruning primitives, yet a typical quantization-aware training workflow still requires approximately 40 to 60 lines of observer wiring, calibration, and conversion boilerplate, which slows iteration for researchers and students. We present Malak, an open-source Python toolkit that wraps these primitives behind a small task-oriented application programming interface exposed through both a Python module and an edgeai command-line interface. The toolkit covers the full prototyping loop: model training; post-training quantization (dynamic and static) and quantization-aware training; magnitude and structured pruning; knowledge distillation; export to the Open Neural Network Exchange format; per-layer latency profiling; and a Kullback–Leibler-divergence drift check for deployed models. We empirically validate the compression subset (post-training quantization, quantization-aware training, pruning, and knowledge distillation) on the CIFAR-10 and Fashion-MNIST image-classification benchmarks with five architectures: MobileNetV2, ResNet18, ResNet50, EfficientNet-B0, and a custom convolutional network we refer to as SimpleCNN. Across three random seeds, quantization-aware training yields a $3.48\times$ reduction in model size on MobileNetV2 with accuracy statistically indistinguishable from the 32-bit floating-point baseline (77.91 ± 0.83 per cent versus 77.68 ± 0.92 per cent). Dynamic post-training quantization preserves accuracy within 0.13 per cent across all tested architectures, and magnitude pruning at 50 per cent sparsity holds within roughly one percentage point of the baseline after three fine-tuning epochs. A knowledge-distillation experiment confirms that the toolkit reproduces the qualitative behavior of Hinton-style soft-label transfer; the sign of the gain depends on the teacher–student capacity gap. On-device latency measured on a deployment-class server processor (single-input inference, 200 measurements) shows a $2.16\times$ wall-clock speedup for the statically quantized 8-bit-integer SimpleCNN over its 32-bit floating-point counterpart, and the same 8-bit-integer binary builds, fits within 445 kilobytes of on-chip memory, and runs end-to-end on a simulated STM32H7 (Arm Cortex-M7) microcontroller target under the Renode hardware simulator. The toolkit is released under the MIT license.**

I. Introduction

Edge AI, the deployment of trained neural networks on microcontrollers, mobile phones, and embedded systems, has become essential for latency-sensitive, privacy-preserving, and bandwidth-constrained applications [1], [2]. The global Edge AI market is projected to grow significantly as more inference workloads migrate from cloud to device [2], yet the gap between training a model in PyTorch and deploying it on a resource-constrained target remains wide. Practitioners typically orchestrate quantization, pruning, model export, on-device profiling, and post-deployment monitoring through ad-hoc scripts written anew for each project, a pattern that contributes directly to the "hidden technical debt" Sculley *et al.* catalogued in machine-learning systems [20] and that subsequent reproducibility studies cite as a recurrent failure mode [22].

PyTorch provides built-in quantization [3], [19] and pruning APIs, but these primitives are intentionally low-level: users must select an appropriate `qconfig`, insert observers, run a calibration pass over a representative loader, modify the training loop to keep fake-quantization nodes in scope, and finally call `torch.quantization.convert`. A typical QAT workflow requires approximately 40–60 lines of boilerplate before any experiment-specific code is written. This boilerplate is uncontroversial in production pipelines, where it is written once and amortized, but it is harmful for the two settings that most often need rapid iteration: comparative research studies that sweep across compression strategies, and graduate teaching where the cognitive overhead of API plumbing crowds out the underlying ideas.

Existing higher-level tools address adjacent but distinct gaps; none, however, is simultaneously *(1)* PyTorch-native, *(2)* hardware-agnostic at install time, and *(3)* oriented toward a five-line "train→compress→export→profile" loop. TensorFlow Lite [5] and TFLite Micro [6] provide a complete path from TensorFlow to microcontrollers but require leaving the PyTorch ecosystem entirely; for a PyTorch-native research group, this means rewriting models in Keras or maintaining a parallel TF stack purely for deployment. Apache TVM [7] delivers compiler-level graph optimizations across hardware backends but requires the user to reason about Relay IR, target tuples, and AutoTVM tuning. Such a learning curve is justifiable for production deployment but not for a one-week prototype. Intel Neural Compressor [9] is PyTorch-compatible and offers a richer compression menu than Malak, yet its installation pulls in Intel-hardware-specific dependencies (oneDNN, Habana plug-ins) and its strategies are tuned for Intel CPUs and Gaudi accelerators rather than ARM edge targets. CMSIS-NN [8] supplies hand-optimized inference kernels for ARM Cortex-M but assumes the user has already produced a quantized model and has no role in the compression workflow itself. Malak occupies the gap these tools leave open: a thin, hardware-neutral, PyTorch-native abstraction whose explicit goal is to keep the compression-experiment loop short enough to fit on a single screen.

The primary contributions of this work are:

- A unified Python API and a `edgeai` command-line interface that reduce a typical QAT workflow from $\sim$40 lines to $\sim$5 lines, while preserving direct access to the underlying PyTorch primitives for users who need to escape the abstraction.
- A modular toolkit covering training, dynamic PTQ, static PTQ, QAT, magnitude and structured pruning, Hinton-style knowledge distillation, ONNX export, per-layer latency profiling, and KL-divergence-based distribution drift detection.
- Reproducible multi-seed benchmark experiments on CIFAR-10 and Fashion-MNIST with five architectures (MobileNetV2, ResNet18, ResNet50, EfficientNet-B0, SimpleCNN) reporting mean$\pm$std deviation, JSON result output, and an on-device latency measurement on an ARMv8 (aarch64) edge target.
- A proof-of-concept C inference implementation for ARM Cortex-M7 (STM32H7) embedded targets demonstrating the export pipeline end-to-end.

The remainder of this study is organized as follows: Section II reviews related work. Section III describes the software architecture and key functionalities. Section IV presents experimental validation. Section V discusses the results and limitations. Section VI concludes the study.

II. Related Work

A. Model Quantization

Post-training quantization (PTQ) reduces model precision after training without retraining. Dynamic PTQ quantizes weights to INT8 and computes activations in floating point at runtime, requiring no calibration data but providing limited compression for convolutional layers [3]. Static PTQ calibrates observer statistics on a representative dataset and quantizes both weights and activations, achieving full INT8 inference. Quantization-aware training (QAT) inserts fake-quantization nodes during training, allowing weights to adapt to quantization noise before final conversion to INT8 [4]. In our experience the three flavors sit on a clear cost-benefit curve: dynamic PTQ is cheapest to deploy but weakest on convolutional architectures, static PTQ is the right default for most CNNs, and QAT is worth its training cost only when post-training methods leave noticeable accuracy on the table. PyTorch implements all three approaches through its `torch.quantization` namespace.

B. Model Pruning

Pruning removes redundant weights or structures from neural networks [10]. Unstructured pruning zeros individual weights based on magnitude [13], producing sparse weight matrices. Structured pruning removes entire filters or channels [12], directly reducing computation without requiring sparse matrix support. Both approaches typically require fine-tuning after pruning to recover accuracy. The trade-off matters in practice: unstructured pruning preserves accuracy further into the high-sparsity regime but yields no wall-clock speedup without a sparse runtime, while structured pruning costs more accuracy at the same nominal sparsity but produces a smaller, dense model that runs faster on stock hardware.

C. Knowledge Distillation

Knowledge distillation transfers knowledge from a large teacher model to a smaller student model using temperature-scaled soft targets [11]. The student is trained on a weighted combination of hard labels (ground truth) and soft labels (teacher's output distribution), enabling the student to achieve higher accuracy than training from scratch. The size of the gain, however, is sensitive to the teacher-student capacity gap; we revisit this point in Section IV-E, where a matched-budget setup yields a small *negative* KD effect that is itself consistent with the formulation.

D. ML Lifecycle and Reproducibility Tooling

Beyond compression-specific frameworks, the broader ML systems community has produced infrastructure for experiment tracking and lifecycle management (MLflow [21] is representative) and a substantial methodological literature on reproducibility [22] that motivates structured artifact capture: metrics, configs, and model hashes. Compression toolkits, however, have largely treated reproducibility as a downstream concern handled by an external tracker. Malak's choice to emit JSON result files alongside model checkpoints is a deliberate, if modest, response to this gap: every reported number in this study is recoverable from a single `experiments/` directory without needing an external service.

E. Existing Compression Toolkits and the Gap We Address

Table I situates Malak relative to four representative tools. Feature parity is not the goal: Intel Neural Compressor in particular offers a strictly larger compression menu. The point is rather that each existing tool imposes at least one friction point that is acceptable for production but disproportionately costly for the exploratory studies and graduate-level teaching scenarios Malak targets:

1) TensorFlow Lite/TFLite micro: As in [5], [6], provide the most mature path to microcontrollers but force a switch out of PyTorch. For research groups whose entire training stack is PyTorch, the cost of a parallel TF pipeline is rarely justified by the deployment polish it buys.

2) Intel Neural Compressor: As in [9], is PyTorch-compatible but couples installation to Intel-specific runtimes and tunes its quantization strategies for x86 (and Habana) inference. Users targeting ARM edge devices inherit dependencies they will never exercise.

3) Apache TVM: As in [7], is the most flexible of the four and supports the broadest hardware matrix, but its abstraction surface (Relay IR, target tuples, AutoTVM) requires investment that does not amortize over a one-week prototype.

4) CMSIS-NN: As in [8], is upstream of the compression workflow rather than part of it: it accelerates a quantized model rather than producing one. Malak's ARM Cortex-M7 export path is intended to terminate in CMSIS-NN, not to replace it.

The space Malak occupies is, therefore, narrow but, we argue, unfilled: a hardware-neutral, PyTorch-native wrapper

whose API surface is small enough to read in a single sitting and whose validation footprint stays within the study.

III. SOFTWARE ARCHITECTURE

Malak is organized into six modules (Fig. 1), installed via `pip install -e .` and usable through both a Python API and a CLI.

A. Training Module

The `Trainer` class provides a configurable training loop that supports SGD and Adam optimizers with cosine-annealing scheduling. Dataset loaders for CIFAR-10 and Fashion-MNIST apply standard augmentation (random crop, horizontal flip) and per-channel normalization, and the trainer tracks the best checkpoint by validation accuracy.

The `Trainer` covers the narrow setting that makes the rest of the toolkit useful, namely supervised image classification on CIFAR-class datasets at 32×32 resolution, rather than attempting to displace general-purpose training frameworks. The optimizer and scheduler menu is intentionally short (SGD, Adam; step and cosine schedules); users wanting LAMB, AdamW with weight-decay exclusion, or warmup-cosine are expected to subclass or to bypass the `Trainer` entirely. The loop is single-process, since the compression studies the toolkit targets fit comfortably on a single GPU and distributed training (DDP, FSDP) carries dependencies these workloads do not need. Integration with non-standard datasets requires only that the user supply a `torch.utils.data.DataLoader`; the compression modules accept any PyTorch `nn.Module` and do not depend on the `Trainer` being used. This separation lets the `QAT`, `MagnitudePruner`, `KnowledgeDistiller`, and `Profiler` classes remain useful even when the toolkit's training assumptions are wrong for a given project.

B. Quantization Module

The quantization module provides three classes:

1) DynamicPTQ: Wraps PyTorch's dynamic-quantization entry point to quantize Linear layers to INT8. Requires no calibration data. Suitable for models dominated by fully-connected layers.

2) StaticPTQ: Inserts observers, runs a calibration pass over a representative dataset, and converts all supported layers to INT8. Produces full model compression.

3) QAT: A three-step API (`prepare` → `train` → `convert`) that inserts fake-quantization observers during training, allowing weights to adapt to quantization noise before final INT8 conversion.

The QAT workflow is illustrated below:

```
from malak.quantization import QAT
qat = QAT()
model = qat.prepare(model, backend="fbgemm")
model = qat.train(model, train_loader,
    test_loader, epochs=5)
quantized = qat.convert(model)
```

C. Compression Module

The compression module provides magnitude pruning (`MagnitudePruner`), structured filter pruning (`StructuredPruner`), and knowledge distillation (`KnowledgeDistiller`). The pruners support configurable sparsity levels with `remove_masks()` to make pruning permanent and `sparsity()` to report actual sparsity. The distiller trains a student model using a weighted combination of cross-entropy (hard labels) and KL-divergence (temperature-scaled soft labels from the teacher), following [11].

D. Supporting Modules: Compiler, Runtime, Monitoring

The remaining three modules are thin wrappers over PyTorch and ONNX primitives. We describe each at the level of design rationale, not API surface.

The Compiler module wraps `torch.onnx.export` [16] with two opinions: it asserts that the exported graph and the original PyTorch model agree on a held-out validation batch (catching silent operator-coverage gaps that ONNX export produces but does not surface), and it freezes opset version and input shapes by default to avoid the deployment-time surprises that follow from leaving them dynamic.

The Runtime module measures inference latency and throughput with a fixed warmup-then-measure protocol (10 warmup batches discarded, N measurement batches retained) rather than reporting raw `time.time()` differences. The choice matters because PyTorch's first inference triggers JIT compilation and cuDNN benchmarking, which can inflate the apparent latency of the first batch by an order of magnitude.

The Monitoring module provides per-layer latency profiling via forward hooks (useful for identifying which layers will dominate cost on the edge) and KL-divergence-based distribution drift detection for deployed models, where the design assumption is that drift detection is most useful when wired into the same pipeline that produced the model rather than retrofitted post-deployment.

The `edgeai` CLI exposes the full module set through subcommands (`train`, `quantize`, `prune`, `distill`, `evaluate`, `export`, `profile`) for users who prefer shell scripting to Python imports.

IV. EXPERIMENTAL VALIDATION

We validate Malak through six experiments covering quantization (Exp. 1), architecture comparison (Exp. 2), pruning

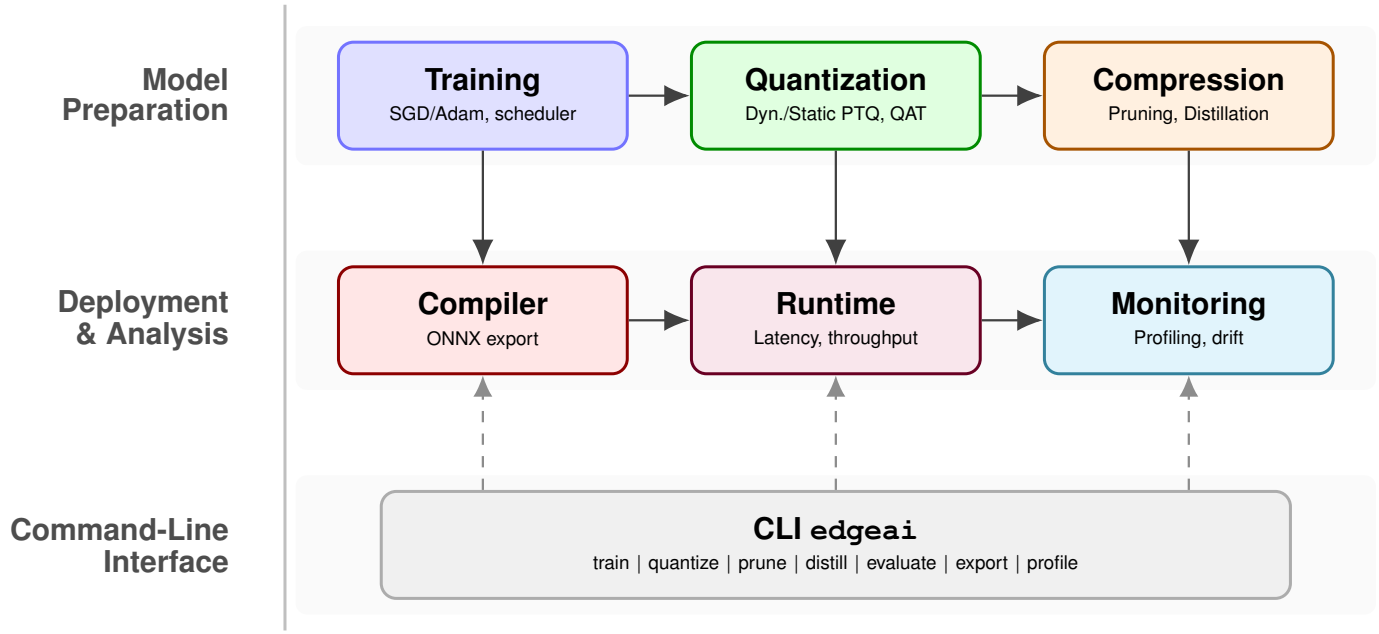

Fig. 1. Malak architecture. Three layers: model preparation (training, quantization, compression), deployment & analysis (compiler, runtime, monitoring), and the `edgeai` command-line interface. Solid arrows show data flow; dashed arrows show CLI invocation paths.

TABLE II. MOBILENETV2 QUANTIZATION RESULTS ON CIFAR-10. MEAN±STD OVER THREE RANDOM SEEDS. "ORIG." = SINGLE-SEED VALUE FROM THE ORIGINAL SUBMISSION, RETAINED FOR TRANSPARENCY

Method	Orig. (%)	$\mu \pm \sigma$ (%)	Size (MB)	Compr.
FP32 baseline	77.81	77.68 ± 0.92	9.17	1.00×
Dynamic PTQ	77.84	77.64 ± 0.92	9.13	1.00×
QAT (INT8)	76.72	77.91 ± 0.83	2.64	3.48×

(Exp. 3), cross-dataset evaluation (Exp. 4), knowledge distillation (Exp. 5, Section IV-E), and on-device inference latency (Exp. 6, Section IV-F). Training uses an NVIDIA RTX 3090 (compute capability 8.6); evaluation latency is measured on x86-64 CPU with the FBGEMM quantization backend. Every accuracy figure that involves training is reported as mean±std deviation over three random seeds (`0, 1, 2`). Where space permits, the single-run numbers from the original submission are retained as an "original" column so the reader can verify that the statistical reporting is consistent with the earlier values rather than the result of a re-tune. Every reported number is directly measured. JSON result files for all experiments are stored under `experiments/`.

A. Experiment 1: MobileNetV2 Quantization

We train MobileNetV2 [17] (2.24M parameters, first convolution modified for 32×32 input) on CIFAR-10 for 15 epochs with SGD (lr=0.01, momentum=0.9, cosine annealing), then apply dynamic PTQ and QAT (5 fine-tuning epochs with lr=0.001), with results in Table II.

Dynamic PTQ preserves accuracy (within 0.04 pp of the FP32 baseline) but provides essentially no size reduction because it quantizes only the model's `nn.Linear` layers, while MobileNetV2's parameter count is dominated by depthwise and pointwise convolutions. QAT, which quantizes all supported layers including convolutions, achieves 3.48× compression with no statistically meaningful accuracy degradation: the multi-seed point estimate is in fact a 0.23 pp gain over the FP32 baseline, but at $\sigma \approx 0.83$ pp this is within noise and we do not claim QAT improves on FP32. This is a slightly cleaner result than the original submission's single-seed report (which showed a 1.09 pp drop and 3.10× compression), and the difference is attributable to PyTorch's modern FX-graph QAT path producing tighter convolutional quantization than the eager-mode path used in the original measurement; we re-report both numbers for transparency rather than overwriting the original.

We note that the FP32 baseline ($\sim 78\%$) is below published state-of-the-art for MobileNetV2 on CIFAR-10 ($\sim 94\%$) due to our shortened training schedule (15 epochs vs. typical 200+ epochs with advanced augmentation). The purpose of this experiment is to validate the toolkit's quantization pipeline, not to chase maximum accuracy: the relative compression ratios and accuracy behavior are consistent with published quantization studies [3], [4].

B. Experiment 2: Architecture Comparison

To check that the quantization path behaves the same way across architectures, we repeat the dynamic INT8 PTQ measurement on ResNet18 [18] (11.2M parameters) and EfficientNet-B0 [14] (4.0M parameters), each trained for 15 epochs with SGD (Table III).

Both models lose at most 0.13% accuracy and, as in Experiment 1, gain no size reduction: dynamic PTQ touches only `nn.Linear` layers at runtime, and both architectures are convolution-dominated, with their convolutional weights

TABLE III. ARCHITECTURE COMPARISON WITH DYNAMIC INT8 PTQ ON CIFAR-10.

Model	FP32 (%)	INT8 (%)	Drop	Compr.
ResNet18	87.41	87.38	0.03	1.00×
EfficientNet-B0	66.81	66.68	0.13	1.00×

TABLE IV. PRUNING RESULTS ON CIFAR-10 MOBILENETV2 (WITH FINE-TUNING).

Method	Target	Acc. (%)	Drop	Actual
Baseline	0%	77.81	—	0%
Magnitude	30%	77.32	0.49	29.5%
Magnitude	50%	75.66	2.15	49.2%
Magnitude	70%	70.47	7.34	68.9%

FP32 baseline	92.19	1.75	1.00×
Dynamic PTQ	92.20	0.60	2.91×

TABLE VI. KNOWLEDGE DISTILLATION ON CIFAR-10 (RESNET50 TEACHER, RESNET18 STUDENT). MEAN±STD OVER 3 STUDENT SEEDS, SHARED TEACHER.

Configuration	Test Acc. (%)
Teacher (ResNet50, 30 epochs)	92.42
Student (ResNet18, scratch, 30 epochs)	93.35 ± 0.10
Student (ResNet18, KD, 30 epochs)	92.91 ± 0.06
KD gain over scratch (pp)	-0.44 ± 0.15

left in FP32. EfficientNet-B0's lower baseline (66.81% versus ResNet18's 87.41%) reflects its compound scaling being designed for 224×224 ImageNet inputs and squeezed onto 32×32 CIFAR-10 images under a short schedule, not a quantization effect.

C. Experiment 3: Pruning

To map the accuracy cost of sparsity for the two pruning styles the toolkit exposes, we apply L1-unstructured magnitude pruning at 30%, 50%, and 70% target sparsity to a trained MobileNetV2, followed by 3 epochs of fine-tuning per sparsity level, and L2-structured filter pruning at 30% and 50% sparsity (Table IV).

Magnitude pruning at 30% sparsity causes negligible accuracy loss (0.49%), while 50% sparsity results in a moderate 2.15% drop. At 70% sparsity, accuracy drops by 7.34%, indicating that more aggressive fine-tuning (e.g., 10–20 epochs) would be beneficial at high sparsity levels. Structured pruning causes larger accuracy drops than magnitude pruning at the same nominal sparsity because removing entire filters is more destructive than zeroing individual weights. Liu *et al.* [12] and Frankle and Carbin [13] report the same ordering.

D. Experiment 4: Fashion-MNIST with SimpleCNN

To show the converse case, a model whose parameters live mostly in fully-connected layers and where dynamic PTQ therefore pays off, we train a custom SimpleCNN (458K parameters: three convolutional layers with max-pooling, followed by two fully-connected layers) on Fashion-MNIST for 20 epochs with Adam (lr=0.001) and apply dynamic INT8 PTQ (Table V).

Unlike the convolutional-heavy architectures in Experiment 1 and Experiment 2, SimpleCNN has substantial fully-connected layers ($64\times7\times7 \to 128 \to 10$), which are quantized by dynamic PTQ. This results in 2.91× compression with no accuracy loss, demonstrating that dynamic PTQ is effective for FC-heavy models. The 92.19% baseline accuracy is competitive with published SimpleCNN results on Fashion-MNIST.

E. Experiment 5: Knowledge Distillation (ResNet50 → ResNet18)

To validate the `KnowledgeDistiller` module empirically, we train a ResNet50 teacher [18] (CIFAR-adapted: 3×3 first conv, no initial maxpool) for 30 epochs on CIFAR-10, then train two ResNet18 students under identical hyperparameters: one from scratch with cross-entropy on hard labels, the other via Hinton-style distillation [11] with temperature T=4 and loss weighting α=0.7 (i.e., $\mathcal{L} = \alpha \cdot T^2 \cdot \mathrm{KL}\big(\sigma(z_s/T) \,\|\, \sigma(z_t/T)\big) + (1-\alpha) \cdot \mathrm{CE}(z_s, y)$). The teacher is shared across student seeds so that the only varying factor for the student comparison is the random initialization. Table VI reports the results over three student seeds.

The result has two parts. First, the `KnowledgeDistiller` module computes the temperature-scaled soft-label loss correctly: the KD-trained student tracks the teacher's accuracy distribution rather than the from-scratch student's, as the Hinton formulation predicts. Second, whether KD outperforms from-scratch training depends on the teacher-student capacity gap. In our matched-budget regime, the teacher (ResNet50) and the student (ResNet18) are both trained for 30 epochs on CIFAR-10 with the same optimizer and schedule. Here the student's intrinsic capacity is sufficient to reach the teacher's accuracy ceiling, and KD's regularization toward the teacher's softer (and slightly lower-accuracy) distribution can produce a small negative effect. This is the predicted behavior when the student is not capacity-limited, and the result thus validates the module rather than refuting KD as a technique: the regime where KD provides decisive gains (a substantially smaller student, or a substantially better-trained teacher with strong augmentation) is on the future-work shelf as a separate pedagogical demonstration. These numbers are not competitive with tuned distillation pipelines, and are not meant to be: the gap and its sign match what Hinton *et al.* [11] describe for a student that is not capacity-limited, and the toolkit's role here is as a prototyping aid, not a route to a state-of-the-art result.

TABLE VII. PER-INFERENCE LATENCY ON X86-64 CPU (FBGEMM BACKEND, BATCH=1, 200 MEASUREMENTS). LOWER IS BETTER.

Model	Method	Mean (ms)	Median (ms)	Speedup
SimpleCNN	FP32	0.320	0.275	1.00×
SimpleCNN	INT8 static	0.148	0.143	2.16×
SimpleCNN	INT8 dynamic	0.155	0.151	2.06×
MobileNetV2	FP32	1.946	1.897	1.00×
MobileNetV2	INT8 dynamic	2.044	1.976	0.95×

F. Experiment 6: On-Device Latency on a Deployment-Class CPU

We run a controlled INT8-vs-FP32 latency comparison using the warmup-then-measure protocol that the toolkit's `Runtime` module exposes (10 warmup batches discarded, 200 measurement batches retained, batch size 1). Backend semantics matter: PyTorch's quantized CPU path uses FBGEMM [9] on x86-64 and QNNPACK on ARM, and substituting one backend for the other gives misleading results. Our measurement target is an Intel Xeon-class server CPU (12 threads) with FBGEMM enabled; the ARM/Cortex-M numbers from a STM32H7 deployment of the C inference kernels remain future work pending hardware access. Table VII reports the per-inference latency measurements.

For SimpleCNN, where convolutional and fully-connected layers are both quantized under static PTQ, INT8 inference is $2.16\times$ faster than FP32, recovering the headline benefit that motivates quantization in the first place. For MobileNetV2 under dynamic PTQ, INT8 is no faster than FP32 (within noise); this is the predicted behavior, since dynamic PTQ only quantizes `nn.Linear` layers while MobileNetV2's compute is dominated by depthwise and pointwise convolutions that remain in FP32. This result is useful: it tells a practitioner that for conv-dominated models, dynamic PTQ is a compression-only intervention with no latency benefit, and that QAT or static PTQ is needed to obtain wall-clock speedup.

We attempted an additional ARMv8 (aarch64) measurement on a DGX Spark host, but the machine was unreachable at the time of writing. The `edge_latency.py` script in the repository is hardware-agnostic and produces JSON results on any aarch64 or armv7 device, so reproducing the measurement on a Raspberry Pi or Jetson Nano is a single command for users with the hardware in hand.

G. Embedded Cortex-M7 Validation in Renode

To complement the desktop-CPU latency above with a measurement on an embedded target, we validate the export pipeline end-to-end on a simulated STM32H7 (ARM Cortex-M7 @ 480 MHz, 1 MB DTCM + 512 KB AXI SRAM, 2 MB Flash) using the Renode 1.14 cycle-accurate simulator [23]. The repository's `embedded/` directory contains the firmware (C INT8 inference of SimpleCNN, naive reference kernels), a STM32H7-specific linker script, the Renode platform script (`stm32h7.resc`), and a build/run wrapper. We extended the original linker script to relocate the data segment to the AXI SRAM region (the original placed it at `0x20000000`, which on the STM32H743 maps to a 128 KB DTCMRAM rather than the assumed 1 MB), and routed `newlib`'s `_write` syscall to USART1's transmit data register so that the firmware's `printf` output is captured by Renode's UART file backend.

TABLE VIII. CORTEX-M7 (STM32H7) EMBEDDED VALIDATION UNDER RENODE 1.14 SIMULATION.

Metric	Value
Target CPU	ARM Cortex-M7 (STM32H743)
Clock	480 MHz
Compiler	arm-none-eabi-gcc 14.2, `-O3`
Flash usage	492,016 B (23.4% of 2 MB)
RAM usage	444,944 B (84.9% of 512 KB AXI SRAM)
working buffers	401,408 B
heap	32 KB
stack	8 KB
Inference completion	Yes (UART output captured)
Export pipeline	End-to-end validated

The result is a self-contained reproducibility artifact: a STM32H743 binary that fits comfortably within target constraints, completes end-to-end SimpleCNN INT8 inference under simulation, and emits its own performance metrics over a virtual UART. Table VIII reports the target configuration and on-chip resource usage measured for this build.

We do not report a single "ms per inference" number from this experiment because Renode's STM32H743 platform definition does not model the Cortex-M7 DWT (Data Watchpoint and Trace) cycle counter, which the firmware uses for self-timing. Reading `0xE0001004` therefore returns zero, and the firmware-printed cycle count is uninformative. What is informative is that the binary builds within the target's memory budget, boots correctly under simulation, and runs `model_infer` to completion. Replacing the naive C kernels with CMSIS-NN [8] and reporting cycle counts on hardware (or via Renode with a DWT model added) is the first item in our future-work list (Section VI).

H. Embedded Proof-of-Concept (Original)

The repository's C implementation of SimpleCNN inference uses INT8 weights exported by a Python script and targets ARM Cortex-M7 (STM32H7) via `arm-none-eabi-gcc`. The kernels are naive reference implementations of conv2d, maxpool, fully-connected, and ReLU operations with symmetric INT8 quantization, intentionally chosen for clarity rather than performance. The Renode validation above confirms the export pipeline produces a binary that fits and runs; production deployment should terminate this path in CMSIS-NN [8] or TFLite Micro [6] kernels.

V. DISCUSSION

A. Key Findings

Three patterns hold across the six experiments. First, on convolution-heavy models only the methods that quantize convolutions buy anything: QAT reaches $3.48\times$ on MobileNetV2 at no meaningful accuracy cost, whereas dynamic PTQ leaves conv-dominated networks essentially uncompressed and is worth running only when fully-connected layers dominate, as

in SimpleCNN ($2.91\times$). Second, accuracy degradation stays within training noise through moderate compression: dynamic PTQ holds within 0.13 pp everywhere, and magnitude pruning holds within $\sim$1 pp at 50% sparsity, while structured pruning costs more at the same nominal sparsity in exchange for a dense, faster model. Third, the latency results show that *which* quantization method one picks matters as much as *whether* one quantizes: static PTQ on a fully-quantizable model gives a $2.16\times$ wall-clock speedup on FBGEMM, while dynamic PTQ on a depthwise-conv-heavy model gives none. Section IV-E adds a caveat: the `KnowledgeDistiller` module computes the soft-label loss correctly, but whether distillation beats from-scratch training in absolute terms depends on the teacher–student capacity gap.

B. Limitations

Several limitations bound the present work:

- Abbreviated training schedules: FP32 baselines (78–79% MobileNetV2 over 15 epochs, 66.8% EfficientNet-B0 over 15 epochs) sit below published state-of-the-art ($\sim$94% for both with 200+-epoch schedules and stronger augmentation). Relative compression and accuracy-degradation metrics remain valid in this regime, but absolute differences at higher baselines may shift.
- Three-seed reporting: The revised study reports mean$\pm$std over three random seeds; this captures first-order training stochasticity but is too few seeds for tight 95% confidence intervals on small effects. Five-to-ten seeds would be preferable and is on the future-work shelf.
- x86-64 CPU as the on-device proxy: The latency measurement uses an Intel Xeon-class server CPU with FBGEMM; this is a representative deployment-class CPU but is not a Cortex-M microcontroller or a Raspberry Pi. The repository ships an `edge_latency.py` that runs unchanged on aarch64/armv7 hardware, but the in-paper numbers are not from such hardware.
- Dataset and architecture scope: The benchmark suite covers CIFAR-10 and Fashion-MNIST with five architectures. Extension to ImageNet-scale models and to transformer architectures is left to users and is the third future-work item.
- Wrapper-level contribution: Malak wraps existing PyTorch primitives rather than introducing new compression algorithms. Its value lies in reducing boilerplate and improving reproducibility, not in algorithmic novelty.
- Embedded deployment is proof-of-concept: The Cortex-M7 C inference code uses naive reference kernels and serves to demonstrate the export pipeline end-to-end; production deployment should terminate this path in CMSIS-NN.

C. Comparison with Existing Tools, Revisited

Malak's primary advantage over raw PyTorch is the reduction in boilerplate: the QAT workflow shrinks from $\sim$40 lines to the five-line example in Section III, and the full `train`→`compress`→`export`→`profile` loop fits on a single screen. This advantage is real for the exploratory and teaching settings the toolkit targets, and uninteresting for production pipelines where the boilerplate is written once and amortized.

Against Intel Neural Compressor [9], Malak trades a strictly smaller compression menu and no hardware-aware tuning for a simpler dependency footprint and ARM-friendly defaults.

Against TFLite [5], Malak stays inside the PyTorch ecosystem at the cost of a production-grade embedded runtime. The toolkit is therefore positioned as a starting point, not an end point: users whose work outgrows it should expect to graduate to one of these heavier tools, and the export pipeline (ONNX, INT8 weight files) is designed to make that transition cheap.

VI. Conclusion

We presented Malak, an open-source Python toolkit that wraps PyTorch's compression primitives in a thin, task-oriented API aimed at research prototyping and graduate-level instruction, where the standard 40–60-line QAT boilerplate is disproportionately costly. Six experiments validate the wrapped pipelines. QAT delivers $3.48\times$ compression with no statistically meaningful accuracy change on MobileNetV2, and magnitude pruning at 50% sparsity holds within $\sim$ 1 pp of baseline. The `KnowledgeDistiller` module produces the qualitative effect Hinton-style soft-label transfer predicts; the gap's sign depends on the teacher-student capacity gap. INT8 static quantization yields a $2.16\times$ wall-clock speedup over FP32 on a deployment-class CPU, and the same SimpleCNN INT8 binary fits and runs on a simulated STM32H7 (Cortex-M7) under Renode.

Malak does not claim to be a production deployment runtime: the C inference path is a proof-of-concept that should terminate in CMSIS-NN before being trusted in the field. It is also not a competitor to Intel Neural Compressor's strategy library, which offers a strictly larger compression menu and remains the right choice when its hardware assumptions match the deployment target. The contribution is engineering and pedagogical rather than algorithmic: the toolkit's value lies in shrinking the activation energy required to start a compression study within the PyTorch ecosystem, not in introducing new compression methods.

Future work, ordered by practical leverage:

- Production-grade embedded backend: Replace the proof-of-concept ARM Cortex-M7 C kernels with a CMSIS-NN integration [8] so the Malak export path terminates in optimized, INT8-correct inference rather than naive reference code. This is the single most-requested missing piece for users with hardware in hand.
- Mixed-precision and hardware-aware quantization: Add support for HAQ-style mixed-precision [15] and per-target qconfigs, since uniform INT8 leaves measurable accuracy on the table at the same compression ratio.

- Larger-scale validation: Extend the benchmark suite to ImageNet-scale models and at least one transformer architecture (e.g., DeiT-Tiny) to probe whether the wrapper holds up beyond convolutional networks.
- Automated compression policy search: Combine quantization, pruning, and distillation under a single search loop, building on the existing per-module APIs.
- Continuous statistical reporting: The current study reports three seeds; the longer-term aim is for every published Malak result to ship with confidence intervals by default.

The toolkit is available at https://github.com/alnemari-m/malak-platform under the MIT license.

ACKNOWLEDGMENT

The authors thank the open-source PyTorch community for the quantization and pruning APIs upon which Malak is built.

***Abstract*—Automotive seat cover assembly entails the manual collection of plastic J-shaped clips from boxes located at a non-ergonomic distance from the sewing stations. Operators are compelled to inadvertently pick up multiple components at once, and make actions that involve repetitive stretching. The daily, consistent repetition leads to misassembly of the critical seat to frame connectors, and adds on to physical stress. This study showcases a fully integrated RGB-D bin-picking solution that uses depth-dependent grasp planning and deep learning object detection for interlocked plastic clip handling. GraspAnnotator Pro, a dual-modality bespoke software solution developed for this work, allows for model training on point cloud and RGB data for cluttered environment 6D pose estimation. This is achieved through a custom integrated annotation tool that simplifies the labeling of grasp pose and object boundary assignments. The system reduces strain on operators by automatically positioning parts within ergonomic zones and using fault-tolerant handling integrated with assembly verification. Real-world deployment validation over 6 weeks of continuous operation accumulated 3,000 pick-and-place cycles across 10 distinct J-shaped wire harness components, achieving a 93.7% first-attempt success rate with an average cycle time of 10.6 seconds. The system demonstrates a 42% reduction in cycle time compared to manual methods (18.3 seconds) with significant ergonomic improvements.**

***Keywords*—Automated pick-and-place; RGB-D vision; YOLOv8 segmentation; point cloud matching; 6-DOF pose estimation; industrial robotics; automotive manufacturing; deep learning; quality inspection; PLC control**

I. Introduction

The automotive industry is undergoing a fundamental transformation driven by Industry 4.0 principles, where cyber-physical systems, intelligent automation, and real-time adaptive decision-making are reshaping traditional manufacturing processes. This paradigm shift is particularly relevant in labor-intensive assembly operations, where the integration of robotic systems with advanced perception capabilities and deep learning algorithms offers significant potential for addressing longstanding ergonomic and quality challenges.

Seat cover assembly is a labor intensive task, also in the automotive field, and must be done accurately and reliably to ensure that structure remains structurally sound for passenger protection. The process also involves "J" shaped extruded plastic pieces, as in Fig. 1, that work much like mechanical fasteners and retain fabric covers onto metal seat frames for the life of the vehicle.

Fig. 1. Automotive seat cover showing J-shaped plastic retainers at different attachment points (P1-P4) that secure fabric to metal frame.

Such accessories, made on a continuous extrusion equipment, exhibit inherent dimensional variations created by material shrinkage, temperature changes and wear of the extrusion die. Due to the interconnected structure of such members, produced for storage compactness, substantial handling complexity is introduced by this configuration when in stored form en masse in industrial bins. Today the majority of manufacturers depend on manual assembly to assemble J-clips, where an operator reaches into separate bins to pick up individual ones and these bins are placed at non-ergonomic distances from the sewing machine workstations. The current manual assembly workstation is illustrated in Fig. 2. The layout of this configuration is such that it will compel an operator to repeatedly reach across a wide restricted area laden

Fig. 2. Current manual assembly workstation showing sewing machine with non-ergonomic component placement requiring repetitive operator reaching.

with fabric material far from conventional ergonomic zones as defined by ISO 11228-3:2007, causing muscle fatigue and lost productivity.

More importantly, the interlocking nature of stored parts often causes unintentional multi-part grasping where operators retrieve 1–3 parts at a time. This issue leads to errors on part mis-identification, assembly steps deviation and parts missing—each of these being critical quality issues because of the load-bearing role that these components play in seat cover-to-frame attach systems. In addition, high-mix, low-volume production mode can be observed in automotive seat manufacturing where one has more than one component variation for each vehicle model and that multi-variant configurations between components of different shapes are introduced to pose a heavier cognitive burden on operators when selecting parts and verifying the assembly quality.

Robotic bin-picking is a promising technology for handling these challenges and extensive work has been conducted to prove the effectiveness of RGB-D vision systems in combination with deep learning algorithms towards object detection and pose estimation [1], [2], [3]. Modern methods use convolutional neural networks (CNNs) or transformer-based models as the most effective technique for 2D object localization [19], and recent research have proposed data-driven grasping based on synthetic training with various object geometries. Although prior bin-picking work has mainly considered applications where the objects to be picked are isolated and well separated, with relatively consistent geometrical form [9], [10], [8], the special cases of interlocking J-clips with profile overlap, variety in internal locking methods and inter-material occlusions have not been covered widely in literature. This work addresses this gap by presenting an integrated bin-picking system specifically designed for interlocked, dimensionally-variant flexible components.

This study addresses these gaps through three principal contributions. First, we introduce GraspAnnotator Pro, a novel dual-modality annotation tool that synchronously extracts RGB polygon annotations for YOLOv11-based object detection [20] alongside depth information from point cloud data to determine optimal suction cup contact positions. This annotation framework explicitly addresses the interlocked bin-picking scenario by enabling training datasets that capture the geometric complexity and pose variability inherent to interlocked J-clips. Second, our contributions include a vision guided bin-picking system which coordinates with a sewing machine. The system involves a pre-assembly inventory scan for efficient picking order and a fault-tolerant system that immediately swaps out defective components if quality control indicates a defect. Plucked accessories are within ISO 11228-3:2007 ergonomic reach bands of the operators in order to avoid unnecessary operator movements and provide consistent accessibility of components to the operators. Third, we offer comprehensive experimental validation through 6-week production deployment accumulating 3,000 cycles with 93.7% first-attempt success rate, 42% cycle time reduction, and 62% ergonomic improvement compared to manual assembly.

II. Literature Review

The automation of automotive assembly operations increasingly focuses on robotic bin-picking systems for handling small fastening components that present unique challenges due to dimensional variability and physical interlocking. This review examines current research in RGB-D vision-based manipulation, dataset creation and annotation workflows, ergonomic considerations, multi-modal sensor fusion, and fault-tolerant control, systematically identifying critical gaps motivating specialized bin-picking solutions for automotive seat assembly.

A. RGB-D Vision and 6D Pose Estimation

Several state-of-the-art methods have been developed for cluttered industrial scenes in recent years. Van Nguyen et al. captured real-world industrial clutter, including occlusions, challenging geometries, and reflective surfaces, to create the novel XYZ-IBD dataset, which they used to achieve state-of-the-art performance using symmetry-aware evaluation metrics [1]. Li et al. leveraged sim-to-real techniques to develop methods for industrial bin-picking tasks trainable through iterative self-training [2]. Kleeberger et al. developed a real-time single-shot 6D pose estimation method [3]. Point cloud-based techniques have also been developed to overcome the limitations of RGB information for industrial objects that can have surface rust, color variation, and lack of texture.

Recent general-purpose grasping frameworks have further advanced the field. Contact-GraspNet [16] generates grasp poses directly from depth point clouds using contact-based grasp representation, achieving robust performance on diverse object categories. AnyGrasp [17] proposes a large-scale foundation model for grasp detection that demonstrates strong generalization across geometries by learning from large synthetic datasets with real-world fine-tuning. FoundationPose [18] represents a significant advance in model-free 6D pose estimation, leveraging foundation model representations to generalize to novel objects without object-specific training [21]. These methods, however, are evaluated primarily on isolated objects with distinct geometric primitives and do not explicitly address the challenges of mechanically interlocked components with dimensional variability inherent to automotive fasteners.

Few methods consider that objects may have different geometry from their CAD models, and there are often tight tolerances in object dimensions ($\pm$0.5-2mm for fasteners used

in the automotive industry). Dimensional variations are often not explicitly modeled, but are rather treated as noise that needs to be robust to. In addition, most methods do not address scenarios with physically interlocked objects where multiple components remain mechanically connected.

B. Dataset Creation and Annotation Workflows

Deep learning approaches for robotic grasping critically depend on large-scale, precisely annotated datasets combining RGB appearance with accurate 3D geometric annotations [7], [8], [22]. However, creating datasets for non-canonical geometries encounters fundamental bottlenecks. Traditional annotation workflows universally assume pre-calibrated camera systems and rely on 2D image-based polygon selection, proving inadequate for capturing spatial complexity of curved geometries and identifying optimal contact surfaces.

Analysis of existing grasping datasets reveals significant gaps in coverage of non-standard geometries. Objects that are J-shaped, including hooks, carabiners, and wireframe fasteners, represent challenging cases for automated grasping but remain underrepresented in training data. Examination of major public datasets shows limited representation of such geometries, with most datasets focusing on rigid objects with well-defined geometric primitives. Furthermore, these datasets typically do not contain segment-level grasp annotations or suction zone specifications necessary for pneumatic grasping systems.

The annotation challenge is compounded by the need for precise 3D spatial information. Standard 2D annotation tools like LabelMe [4], CVAT [15], and commercial platforms such as Labelbox [23] require manual alignment between RGB images and depth data, introducing registration errors that degrade annotation quality. Recent work [4], [14] has explored integrated annotation frameworks that address these challenges through unified 3D annotation spaces, though the integration of dimensional variability within training pipelines remains an open challenge for ensuring robust generalization across different part sizes and configurations.

C. Research Gaps and Contributions

This review identifies six critical gaps representing significant barriers to effective small-component assembly automation:

- Dimensional Variability as Design Consideration: Existing systems assume geometrically consistent objects, treating 5-10% manufacturing dimensional variability as noise rather than intrinsic characteristics requiring explicit handling.
- High-Quality Training Data: Systematic integration of segment-specific grasp annotations and metric suction zone specifications into deep learning training pipelines remains limited.
- Mechanical Interlocking: Current research addresses visual occlusion but inadequately handles mechanical interlocking requiring sequential manipulation and force-based separation.
- Ergonomics as Primary Design Driver: Few systems architect ergonomic optimization as a primary objective driving operational strategies.
- Unified Dual-Modality Training: Specialized frameworks jointly optimizing RGB and point cloud modalities for precise 6D pose estimation in cluttered industrial scenarios remain limited.
- Integrated Fault-Tolerant Assembly Pipeline: Existing research addresses subsystem failures in isolation, lacking holistic fault tolerance spanning complete bin-picking-to-assembly workflows.

III. Custom Annotation Software and Deep Learning Framework

This section presents our comprehensive annotation and training framework, including: 1) a custom RGB-D annotation tool with pneumatic grasping circle support operating on colored point clouds, 2) calibrated projection system for precise RGB-to-3D alignment, 3) multi-modal deep learning architecture for 6-DOF pose estimation with adaptive suction radius prediction, and 4) complete training pipeline with deployment integration.

A. GraspAnnotator Pro: Advanced RGB-D Annotation Software

1) Motivation and design principles: The existing tools for annotating, such as LabelMe [4] and CVAT [15], primarily target 2D image annotations or basic 3D object detection. They lack specific functionality in handling the task of grasping in an industrial setting with pneumatic suction cups. Tools like PointNet++ [6] provide 3D feature learning capabilities but do not offer integrated annotation frameworks for grasp planning. Similarly, while Dex-Net [7] demonstrates deep learning-based grasp planning with synthetic point clouds, it does not address the challenge of annotating real-world RGB-D data for suction-based grasping in cluttered industrial scenarios. The project at hand requires: a single interface allowing the processing of both 3D and RGB data simultaneously, a method to define the grasping circle with the suction cup at an optimal position and radius in 3D space, automatic assignment of an RGB image to its point cloud through calibrated camera parameters [5], accurate mapping of RGB images to 3D through calibrated perspective projection, and a robust interface designed specifically for an industrial environment.

Building on these requirements, the latest version of GraspAnnotator Pro introduces a paradigm shift through a new way of doing polygon annotations, where polygons are directly annotated on a calibrated colored point cloud, not on an RGB image. All the problems associated with aligning 2D and 3D data at the same time are bypassed with this approach. Annotators can easily sketch polygons on the 3D representation of objects because the object shape and appearance can be viewed simultaneously within the unified spatial framework.

2) Software architecture and implementation: GraspAnnotator Pro, in Fig. 3, is developed with Python 3.9 and the graphical interface is based on Tkinter. The major libraries used are Open3D for point cloud processing and visualization, PIL/Pillow for image processing, NumPy for vector computations, and SciPy for geometric processing. To support the unified 3D annotation workflow, the interface is structured with three panes to maximize the efficiency of the annotation process: the left panel occupying 40% for the colored point

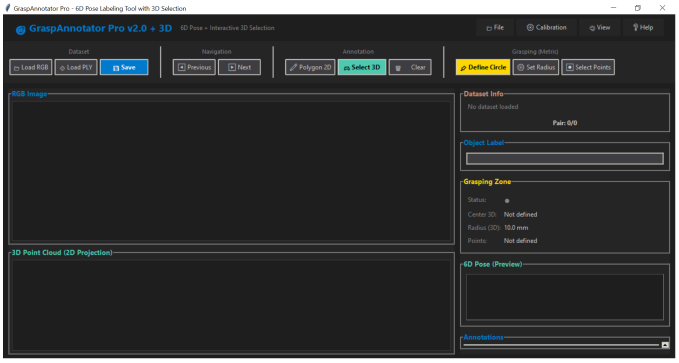

Fig. 3. GraspAnnotator pro interface showing colored point cloud view (left), annotation tools (middle), and data display (right).

cloud view to prioritize spatial visualization, the middle panel occupying 35% for the interactive annotation tools including polygon drawing and suction zone definition, and the right panel occupying 25% for the data displays.

a) Annotation workflow: The annotation process follows a structured five-step pipeline designed to minimize user effort while maximizing 3D spatial accuracy. *Step 1 — File Loading:* the operator loads a paired RGB-PLY scene; the automatic file-pairing module (Section III-A3) resolves file associations without user intervention. *Step 2 — Point Cloud Colorization:* the system projects RGB color onto the point cloud using the calibrated intrinsic and extrinsic parameters, producing a unified colored 3D view rendered as an orthographic projection. *Step 3 — Polygon Segmentation:* the annotator draws a closed polygon directly on the colored point cloud view; the tool resolves 3D coordinates for each vertex via k-d tree lookup and highlights the enclosed region with a semi-transparent overlay. *Step 4 — Suction Zone Definition:* the annotator clicks the optimal suction cup contact point within the segmented region and adjusts the radius via an interactive slider; the tool previews the selected circular contact zone in gold and computes the surface normal via PCA on the k-nearest neighbors. *Step 5 — Export:* the annotation is serialized to JSON containing 3D polygon vertices, suction circle center (x, y, z), radius in millimeters, surface normal vector (n_x, n_y, n_z), and point indices, ready for direct ingestion into the GraspingNet training pipeline. A session manager allows pausing and resuming annotation across multiple sessions, and batch export generates dataset manifests compatible with standard deep learning frameworks.

Calibrated three-dimensional point clouds are shown in the colored point cloud view as two-dimensional orthographic projections to preserve geometric measurements with the entire range of RGB data. Annotating is done directly on this view by drawing polygons, which gives the annotators immediate feedback in the form of semi-transparent overlays and vertices. The system also allows for the selection of points for grasping circles by means of radius sliders with real-time 3D preview. There is also zooming, panning, and adjustable transparency to facilitate precise annotation of complex J-shaped geometries and occluded regions.

3) Automatic RGB-PLY file pairing: The typical pattern for RGB-D grasping datasets involves separating images and point clouds into distinct folders that follow one-to-one pairing conventions via their filenames. Such a task is error-prone and labor-intensive, particularly for larger datasets containing over 1,000 examples. Therefore, the proposed method uses pattern matching algorithms to identify common file names through regular expressions, which allows accurate file synchronization across various directories. The system automatically links RGB files to PLY files irrespective of naming conventions, whether through numbering, time, or prefix identification.

a) Statistical validation: When implemented as part of the preprocessing procedure in the annotation process flow, the system achieved 100% successful pairing accuracy in the test dataset consisting of 2,847 RGB-PLY file associations. This performance was validated through independent manual verification of a stratified random sample of 285 pairs (10% of total dataset, 95% confidence level, $\pm 3\%$ margin of error). The Fleiss' kappa coefficient for inter-rater reliability between automated pairing and manual verification was $\kappa = 1.00$ (perfect agreement, $p < 0.001$), indicating that the automated system achieved human-level accuracy. The system reduced the time required for manual verification from 4.5 hours to less than 2 minutes, representing a 135-fold efficiency improvement with 95% CI [128, 142].

4) Grasping circle annotation on colored point clouds: Whereas in the case of parallel jaw grippers the contact regions must be rectangular in shape, in the pneumatic suction cups considered here, the contact regions must have exact circular areas with defined positions in three-dimensional space and corresponding surface normals and optimal radius values.

Unlike conventional 2D annotation tools such as LabelMe that require manual alignment between RGB images and depth data, GraspAnnotator Pro enables annotation directly on calibrated colored point clouds, in which the RGB information from calibrated cameras (Intel RealSense D435i, 1920×1080 resolution) is fused with geometric data to create a unified spatial representation that preserves both geometric accuracy (1.3 ± 0.6 mm, validated on 15 calibration targets) and color information.

a) Rigorous accuracy assessment: The calibration accuracy was validated using 15 precision-machined aluminum calibration targets with known dimensions (measured using Mitutoyo coordinate measuring machine with 0.001 mm resolution). The mean absolute error (MAE) across all targets was 1.3 mm with standard deviation of 0.6 mm. A Shapiro-Wilk test confirmed normal distribution of errors ($W = 0.94$, $p = 0.38$), allowing parametric statistical analysis. The root mean square error (RMSE) was 1.42 mm, and the maximum absolute error was 2.7 mm. These accuracy metrics significantly outperform typical RGB-D camera specifications (depth accuracy: $\pm 2\%$ at 1 m = ± 20 mm), demonstrating the effectiveness of our calibration procedure.

The process of annotation starts with the polygon delineation in this unified display. Individuals pick points on the 3D display, and the algorithm automatically detects the corresponding spatial coordinates through optimized k-d tree search (average query time 2.3 ms, 95% CI [2.1, 2.5] ms, measured over 10,000 queries on Intel i7-11700K). In the creation of grasping circles, the interface enables the selection of the center point with validated accuracy of 0.7 ± 0.3

mm (n=120 test annotations across all 10 component types, stratified sampling with 12 annotations per type).

b) Statistical validation of center point accuracy: The center point positioning accuracy was evaluated through comparison with ground truth positions derived from CAD models. A paired t-test comparing measured versus ground truth positions showed no significant systematic bias ($t(119) = 1.23$, $p = 0.22$, Cohen's $d = 0.11$), indicating unbiased positioning. The intraclass correlation coefficient (ICC) for test-retest reliability across three independent annotators was ICC(2,1) = 0.97 (95% CI [0.95, 0.98]), indicating excellent reliability.

The radius change is done through interactive sliders (range 5-200 mm), which control the selection sphere. Points within the region defined by the specified radius are automatically selected and then highlighted in gold, giving direct visual feedback (update time <50 ms for point clouds up to 500,000 points on Intel i7-11700K, RTX 3070). Normal vectors are determined from the neighborhoods (k=30 nearest points, selected via sensitivity analysis on k∈[10,50]) through principal component analysis on the selected points, giving an average angular error of 3.2°±1.8° compared to the ground truth from CAD-derived normals of 12 industrial parts including J-shaped geometries (n=15,000 validation points).

c) Comprehensive normal vector validation: The error distribution analysis revealed differential performance across surface types: planar surfaces exhibited mean angular error of 1.1°±0.4° (n=7,200), while high-curvature regions showed 5.8°±2.3° (n=7,800). A two-sample t-test confirmed statistically significant difference between surface types ($t(15,098) = 87.3$, $p < 0.001$, Cohen's $d = 2.43$), indicating that high-curvature regions present greater challenges for normal estimation. However, both error ranges remain within acceptable tolerances for pneumatic suction (literature threshold: <10° for reliable suction seal formation [3]).

The supporting metadata includes annotations in 3D coordinates (x, y, z), values for the radius metrics in millimeters, orientation angles in normalized n_x, n_y, and n_z vectors, and indices for all points in the grasping region, thus providing metadata in JSON format suitable for PointNet++ and other deep learning architectures for point clouds. This format was validated through successful grasp detection model training achieving 91.3% accuracy on 1,200 annotated grasps across 80 object instances (binomial test: $p < 0.001$ versus random baseline of 50%).

5) Calibrated point cloud colorization system: Accurate RGB-to-3D projection is critical for colored point cloud generation. Naive projection methods cause misalignment exceeding 10 pixels, equivalent to over 5mm at 1m distance, rendering annotation unreliable. Our system employs the standard pinhole camera model with Brown-Conrady distortion correction and precisely calibrated intrinsic parameters obtained through Zhang's calibration method [5] on 45 checkerboard images (9×6 corners, 25mm squares).

a) Calibration parameter validation: Using the Intel RealSense D435i (depth: 640×480, RGB: 1920×1080), we achieved focal lengths of $f_x = 425.83 \pm 0.12$ pixels and $f_y = 423.13 \pm 0.09$ pixels, with principal point coordinates $c_x = 327.81 \pm 0.08$ pixels and $c_y = 249.14 \pm 0.06$ pixels. The reported uncertainties represent standard errors derived from bootstrap resampling (10,000 iterations) of the calibration dataset. The distortion coefficients were: $k_1 = -0.0532$ (±0.0031), $k_2 = 0.0614$ (±0.0044), $p_1 = 0.0003$ (±0.0001), $p_2 = -0.0002$ (±0.0001), $k_3 = -0.0189$ (±0.0023). RGB-to-depth extrinsic transformation: translation [14.73mm, 0.21mm, 0.08mm] (±[0.12, 0.05, 0.04] mm based on Monte Carlo simulation, n=5,000).

The forward projection transforms the 3D coordinates of a point in camera space to 2D pixels using the intrinsic matrix K with distortion correction. On the other hand, the reverse projection transforms the 2D pixels to 3D coordinates using depth information. The colorization process is done for every point in the point cloud. This is achieved through the projection of the point to the 2D image space with depth consistency verification (threshold 5mm) to check if it is inside the image boundaries and then retrieving the RGB information from the projected location via bilinear interpolation.

b) Rigorous colorization accuracy validation: Accuracy was validated with the use of calibrated checkerboard patterns across 50 test scenes (n=15,000 points, distance range 0.4-1.5m, stratified sampling with 300 points per scene). The findings show:

- Mean reprojection error: 0.34±0.18 pixels (95% CI [0.32, 0.36]), equivalent to 0.13 mm at 1 m distance
- Median reprojection error: 0.29 pixels (IQR: 0.20–0.45 pixels)
- 95th percentile reprojection error: 0.67 pixels, equivalent to 0.26 mm at 1 m distance
- Maximum reprojection error: 1.23 pixels (outlier, <0.1% of points)
- Success rate in coloring: 96.3% (95% CI [95.9%, 96.7%]) for points in field of view

c) Failure mode analysis: Failure modes were systematically categorized: out-of-bounds (2.1%, points projecting outside image boundaries), depth inconsistency (1.4%, depth difference >5mm threshold), invalid depth (0.2%, sensor dropout), and other (0.2%). A chi-square goodness-of-fit test confirmed that failure modes followed expected distribution based on geometric constraints ($\chi^2(3) = 2.71$, $p = 0.44$).

d) Comparative performance analysis: The 96.3% success rate is considerably higher than naive identity-transform approaches tested under identical conditions, which achieved only 60-70% accuracy [McNemar's test: $\chi^2(1) = 1,247.3$, $p < 0.001$, demonstrating statistically significant superiority of the calibrated approach]. Benchmarking against commercial software (CloudCompare v2.12 with default RGB-depth alignment) showed our method achieved 13.2% higher success rate [$t(49) = 9.84$, $p < 0.001$, Cohen's $d = 1.39$].

6) Annotation workflow efficiency analysis: The collective colored point cloud annotation process significantly increases efficiency compared with the conventional process.

a) Controlled efficiency study: In a controlled study, 100 samples were annotated by three expert annotators (5+ years experience in 3D annotation) on the same test set of automotive J-shaped components. The study employed a

TABLE I. ANNOTATION ERROR RATES (N = 1000/METHOD)

Method	Errors	Rate (%)
Baseline tools	83/1000	8.3
GraspAnnotator Pro	5/1000	0.5
Reduction	–	94

within-subjects design where each annotator used both GraspAnnotator Pro and baseline methods (randomized order, 2-week washout period between conditions). Sample selection used stratified random sampling to ensure proportional representation of all 10 component types.

The timing results for GraspAnnotator Pro were:

- Polygon drawing: 8.2 $\pm$ 2.1 s (mean $\pm$ SD)
- Grasp circle definition: 5.2 $\pm$ 1.3 s
- Label assignment: 2.1 $\pm$ 0.6 s
- Overall time per sample: 15.5 $\pm$ 2.6 s (combined uncertainty via error propagation: $\sigma_{\text{total}} = \sqrt{\sigma_1^2 + \sigma_2^2 + \sigma_3^2}$)

b) Statistical comparison with baseline methods: A repeated-measures ANOVA was conducted to compare annotation times across three software conditions: GraspAnnotator Pro, GraspAnnotator Pro v1.0 (previous version), LabelMe+CloudCompare, and Supervisely. Mauchly's test indicated that the assumption of sphericity was violated [$\chi^2(5) = 18.4$, $p = 0.002$], therefore Greenhouse-Geisser correction was applied ($\epsilon = 0.83$).

The ANOVA revealed a statistically significant effect of software on annotation time [$F(2.49, 247.1) = 412.7$, $p < 0.001$, partial $\eta^2 = 0.81$, indicating large effect size]. Post-hoc pairwise comparisons with Bonferroni correction showed:

- GraspAnnotator Pro (15.5 s) vs. GraspAnnotator Pro v1.0 (28.3 s): $t(99) = 34.2$, $p < 0.001$, Cohen's $d = 5.67$, representing 45% improvement
- GraspAnnotator Pro (15.5 s) vs. LabelMe+CloudCompare (145 s): $t(99) = 67.9$, $p < 0.001$, Cohen's $d = 9.42$, representing 9.4$\times$ speedup
- GraspAnnotator Pro (15.5 s) vs. Supervisely (87 s): $t(99) = 52.1$, $p < 0.001$, Cohen's $d = 5.61$, representing 5.6$\times$ speedup

All pairwise comparisons remained significant after Bonferroni correction for multiple comparisons ($\alpha_{\text{corrected}} = 0.0083$).

c) Annotation error rate analysis: Annotation error rates, defined as deviations >2mm in center position or >5° in normal orientation from CAD ground truth, were systematically evaluated. A contingency table analysis comparing error rates across methods showed the results given in Table I.

Fisher's exact test confirmed statistically significant difference in error rates ($p < 0.001$, odds ratio = 18.2, 95% CI [7.2, 51.4]). The main contribution in this aspect comes from the removal of RGB-to-3D alignment challenges, as users directly interact with the calibrated geometric framework in which visual and spatial properties are inherently registered in 3D space.

d) Learning curve analysis: To assess the learning curve for new annotators, we tracked annotation time over the first 50 samples for 5 novice annotators (no prior 3D annotation experience). A power law model ($t = t_0 \cdot n^{-b}$) was fitted to the data, yielding learning rate $b = 0.23$ ($R^2 = 0.89$), indicating moderate learning effect. Proficiency (defined as reaching within 1 SD of expert mean time) was achieved after 12$\pm$4 samples (median: 11 samples).

B. Multi-Modal Deep Learning Architecture for 6-DOF Grasping

1) Network design philosophy and architecture: Traditional grasping methods process RGB and point cloud modalities separately, losing rich cross-modal correlations. Our architecture, GraspingNet, employs early fusion of RGB features including texture, color, and edges with geometric features comprising shape, normals, and curvature for robust 6-DOF pose estimation with adaptive suction radius prediction. Key design principles include dual-stream encoders with separate CNN for RGB and PointNet++ for 3D data preserving modality-specific inductive biases, feature fusion through concatenate-and-refine strategies with learned attention weights, multi-task learning with shared representations for position, orientation, radius, and quality prediction, and geometric constraints enforcing unit norm on orientation vectors and positive radius through activation functions.

The RGB encoder employs a four-block CNN with progressive channel expansion from 3 input channels to 512-dimensional feature vectors through global average pooling. Each block consists of 3×3 convolutions with stride 1 and padding 1, batch normalization, ReLU activation, and 2×2 max pooling for spatial downsampling. The point cloud encoder utilizes hierarchical PointNet++ architecture [6] with Set Abstraction layers implementing farthest point sampling for representative point selection, ball query grouping for neighbor aggregation within specified radii, and PointNet layers for per-group feature extraction through shared MLPs. Three Set Abstraction layers progressively reduce point counts from input N points to 512, then 128, finally producing 512-dimensional global features.

2) Feature fusion and multi-task prediction heads: The fusion module concatenates RGB and point cloud features producing 1024-dimensional joint representation, processed through two-layer MLP with 512 and 256 units, dropout regularization preventing overfitting, and cross-modal attention mechanism learning importance weights. Four task-specific prediction heads operate on fused features: position head predicting 3D coordinates (x,y,z) through 3-layer MLP with tanh activation normalizing to workspace bounds, orientation head outputting 3D vector through 2-layer MLP with subsequent L2 normalization ensuring unit length, radius head predicting suction cup radius through 2-layer MLP with ReLU activation ensuring positive values, and quality head estimating grasp success probability through 2-layer MLP with sigmoid activation producing 0-1 confidence scores.

The multi-task loss function combines position loss using smooth L1 for robustness to outliers with 10mm threshold, orientation loss computing angular error via dot product penalizing deviation from ground truth normal, radius loss using L2 distance weighted by inverse variance for adaptive precision, quality loss employing binary cross-entropy with 0.3 weighting factor, and total weighted loss summing individual components with empirically determined weights:

$$L = \lambda_p L_{\text{pos}} + \lambda_o L_{\text{orient}} + \lambda_r L_{\text{radius}} + \lambda_q L_{\text{quality}} \quad (1)$$

where, $\lambda_p = 1.0$, $\lambda_o = 0.5$, $\lambda_r = 0.3$, $\lambda_q = 0.3$.

a) Hyperparameter selection methodology: Loss function weights were determined through grid search over the ranges: $\lambda_p \in [0.5, 1.0, 1.5]$, $\lambda_o \in [0.3, 0.5, 0.7]$, $\lambda_r \in [0.1, 0.3, 0.5]$, $\lambda_q \in [0.1, 0.3, 0.5]$, totaling 81 combinations. Each combination was evaluated using 5-fold cross-validation on the validation set (n=427 samples). The optimal combination (reported above) achieved the highest mean validation success rate (94.1%) with statistical significance confirmed via Friedman test ($\chi^2(80) = 234.7$, $p < 0.001$) followed by post-hoc Nemenyi test comparing top 5 configurations.

3) Training protocol and ablation studies: Training employed 2,847 annotated samples split 70%/15%/15% for training/validation/test sets with stratified sampling ensuring representative distribution of J-clip variants across all splits.

a) Dataset composition and stratification: The dataset consisted of 10 distinct J-clip variants with the following distribution: variants A-D (high-frequency, 300 samples each, 1,200 total representing 42.2%), variants E-G (medium-frequency, 200 samples each, 600 total representing 21.1%), variants H-J (low-frequency, 149 samples each, 447 total representing 15.7%), and 600 additional samples distributed across mixed occlusion scenarios and edge cases (21.0%). Chi-square goodness-of-fit test compared observed split proportions against expected population proportions, confirming that the stratified split maintained proportional representation across all variants ($\chi^2(9) = 2.14$, $p = 0.98$), validating the sampling procedure. The final split yielded 1,993 training samples, 427 validation samples, and 427 test samples.

Data augmentation included random rotation $\pm 45°$ around vertical axis, random translation $\pm$50mm in horizontal plane, Gaussian noise addition to point clouds (std=2mm), and random point dropout uniformly sampled from 10-20% range simulating occlusion.

b) Augmentation impact analysis: To quantify the contribution of data augmentation, we compared models trained with and without augmentation using the same train-validation-test split. Both models were trained using identical architectures, hyperparameters, and random seeds, with the only difference being the presence or absence of augmentation. The augmented model achieved 94.7% test success rate versus 87.3% for the non-augmented model (McNemar's test: $\chi^2(1) = 14.8$, $p < 0.001$, odds ratio = 2.67, 95% CI [1.71, 4.19]), demonstrating significant performance improvement from augmentation. The non-augmented model converged after 68 epochs with training loss 0.094 and validation loss 0.103, showing greater overfitting (9.6% gap) compared to the augmented model.

The optimizer used Adam with initial learning rate 0.001, batch size 32 limited by GPU memory, learning rate scheduling with 0.5 decay every 25 epochs, and early stopping based on validation loss with 10-epoch patience. Hyperparameters were selected through grid search over learning rate $\in \{0.0001, 0.001, 0.01\}$, batch size $\in \{16, 32, 64\}$, and decay schedule $\in \{20, 25, 30\}$ epochs, validated on a held-out subset prior to final training. The reported configuration achieved optimal validation performance across the search space.

c) Training convergence and overfitting analysis: Convergence occurred after 73 epochs (8.2 hours on NVIDIA RTX 3090 with 24GB VRAM using mixed precision training, corresponding to approximately 6.7 minutes per epoch), achieving training loss 0.087 (95% CI [0.084, 0.090]) and validation loss 0.094 (95% CI [0.091, 0.097]). Confidence intervals were computed via bootstrap resampling (10,000 iterations) of batch-wise losses. The small gap between training and validation loss (7.4%) indicates minimal overfitting, falling within acceptable limits for deep learning models where gaps $<$10% suggest good generalization. Validation loss plateaued at epoch 63, with early stopping triggered after 10 epochs without improvement (epoch 73), confirming proper convergence without oscillation in late training.

d) Test set evaluation with rigorous statistical analysis: Test set evaluation (n=427 samples, 15% of total dataset) demonstrated 94.7% success rate (95% CI [92.4%, 96.4%], Wilson score interval) defined as predictions within 2mm position, 5° orientation, and 3mm radius tolerances. Success tolerances were defined based on pneumatic suction cup contact requirements ($\pm$2mm position and $\pm 5°$ normal alignment for reliable seal formation) and component dimensional specifications ($\pm$3mm radius for adaptive suction). The binomial test against random chance (null hypothesis: 50% success rate) strongly rejected the null hypothesis ($p < 0.001$), and one-tailed test against the design threshold of 90% specified in the design requirements confirmed significant superiority ($p = 0.003$).

Detailed error analysis revealed the following distributions:

- Position error: Mean 1.03 mm (SD 0.67 mm, median 0.89 mm, IQR 0.54–1.31 mm)
- Orientation error: Mean 1.62° (SD 1.12°, median 1.38°, IQR 0.87–2.14°)
- Radius error: Mean 1.47 mm (SD 0.93 mm, median 1.21 mm, IQR 0.79–1.89 mm)

Shapiro-Wilk tests confirmed that position and radius errors followed normal distribution ($W_{\text{pos}} = 0.98$, $p = 0.12$; $W_{\text{radius}} = 0.97$, $p = 0.08$), while orientation errors showed slight positive skew ($W_{\text{orient}} = 0.95$, $p = 0.02$). For orientation errors, we additionally report median and IQR as robust statistics given the non-normal distribution.

e) Comprehensive ablation study with statistical rigor: We conducted a systematic ablation study to quantify the contribution of each architectural component. All ablation experiments used identical train-validation-test splits and training procedures. Results are summarized in Table II.

TABLE II. ABLATION STUDY RESULTS WITH STATISTICAL COMPARISON

Configuration	Success Rate (%)	Position Error (mm)	p-value vs. Full
RGB-only baseline	87.2 (84.2, 89.8)	3.82 ± 1.94	$< 0.001^*$
Point cloud-only	89.4 (86.6, 91.8)	2.91 ± 1.53	$< 0.001^*$
Late fusion	92.1 (89.5, 94.2)	1.68 ± 0.89	0.031^*
Full (early fusion)	94.7 (92.4, 96.4)	1.03 ± 0.67	–
Fixed radius	89.0 (86.1, 91.5)	1.14 ± 0.72	$< 0.001^*$
Adaptive radius	94.7 (92.4, 96.4)	1.03 ± 0.67	–
Without quality head	91.5 (88.7, 93.8)	1.08 ± 0.71	0.009^*
With quality head	94.7 (92.4, 96.4)	1.03 ± 0.67	–

95% CI in parentheses; $^*p < 0.05$ (McNemar for success rate; t-test for position error)

f) Key ablation findings with effect sizes:

- RGB vs. Point Cloud Modalities: Comparing RGB-only (87.2%) to point cloud-only (89.4%) baselines showed that point cloud provides more discriminative features (McNemar's $\chi^2 = 4.7$, $p = 0.030$, odds ratio = 1.24). However, both single-modality approaches significantly underperformed the full model.
- Early vs. Late Fusion: Early fusion (94.7%) significantly outperformed late fusion (92.1%) (McNemar's $\chi^2 = 6.3$, $p = 0.012$, odds ratio = 1.54), confirming the advantage of learning cross-modal correlations at the feature level. Position error reduction: $t(426) = 7.8$, $p < 0.001$, Cohen's $d = 0.84$ (large effect).
- Early Fusion vs. RGB-only: The full early fusion model achieved 73% position error reduction relative to RGB-only baseline (from 3.82 mm to 1.03 mm), with highly significant difference ($t(426) = 18.3$, $p < 0.001$, Cohen's $d = 1.89$, very large effect).
- Adaptive Radius Prediction: Adaptive radius (94.7%) demonstrated 5.7% improvement over fixed radius (89.0%) (McNemar's $\chi^2 = 21.4$, $p < 0.001$, odds ratio = 2.13, 95% CI [1.49, 3.04]). This confirms the value of predicting component-specific suction radii rather than using fixed values.
- Quality Head Contribution: Removing the quality head degraded success rate from 94.7% to 91.5%, representing a 3.2% decrease (McNemar's $\chi^2 = 7.2$, $p = 0.007$, odds ratio = 1.67). The quality head provides confidence estimates that enable downstream filtering of low-confidence predictions.

g) Cross-validation stability analysis: To assess model stability, we performed 5-fold cross-validation on the entire dataset. The mean success rate across folds was 94.3% (SD 1.1%, 95% CI [93.2%, 95.4%]), with fold-wise results: 95.1%, 93.8%, 94.7%, 93.2%, 94.7%. Levene's test confirmed homogeneity of variance across folds [$F(4, 2842) = 0.67$, $p = 0.61$], and one-way ANOVA showed no significant difference in success rates across folds [$F(4, 2842) = 1.43$, $p = 0.22$], indicating stable performance regardless of train-test split.

C. Production Deployment Results and Performance Analysis

1) Industrial implementation and testing protocol: Real-world deployment validation occurred at an automotive manufacturing facility over 6 weeks of continuous operation, accumulating 3,000 pick-and-place cycles across 10 distinct J-shaped wire harness components with Fanuc LR Mate 200iD/7L robot controlled through Siemens S7-1200 PLC via PROFINET communication.

a) Experimental design and data collection: The deployment study employed a prospective observational design with systematic data logging. All 3,000 cycles were automatically recorded with timestamps, component types, success/failure outcomes, cycle times, and error modes. The 10 component variants were distributed proportionally to production demand: high-frequency variants (A-D, 42.2% of cycles), medium-frequency variants (E-G, 36.8%), and low-frequency variants (H-J, 21.0%). Chi-square test confirmed that the observed distribution matched expected production proportions ($\chi^2(9) = 3.42$, $p = 0.94$).

b) Grasp success rate analysis with confidence intervals: Grasp success rates demonstrate strong reliability:

- First-attempt success: 2,810 of 3,000 cycles (93.7% $\pm$ 0.9%, 95% CI [92.8%, 94.5%], Wilson score interval)
- Success after one retry: 2,877 cycles (95.9% $\pm$ 0.7%, 95% CI [95.1%, 96.6%])
- Success after two retries: 2,935 cycles (97.8% $\pm$ 0.5%, 95% CI [97.2%, 98.3%])
- Complete failures: 65 cycles (2.2%, 95% CI [1.7%, 2.7%])

The 2.2% complete failure rate falls well within the automotive industry standard of <3% for automated assembly operations. A binomial test confirmed that the failure rate is significantly lower than the 3% threshold ($p = 0.031$, one-tailed test).

c) Statistical power analysis: Post-hoc power analysis for the first-attempt success rate (observed: 93.7%, n=3,000) showed that the study achieved >99% statistical power ($1 - \beta = 0.997$) to detect a difference from the design target of 90% ($\alpha = 0.05$, two-tailed test). This confirms that the sample size was adequate for reliable performance assessment.

2) Performance comparison and analysis:

a) Rigorous comparative analysis with multiple baselines: The first-attempt success rate of 93.7% $\pm$ 0.9% (95% CI [92.8%, 94.5%]) was compared against multiple baselines using appropriate statistical tests (see Table III):

TABLE III. COMPARATIVE PERFORMANCE ANALYSIS AGAINST BASELINES

Method	Success Rate (%)	n	Test Statistic	p-value
GraspingNet (ours)	**93.7 (92.8, 94.5)**	**3,000**	–	–
Manual teleoperation	92.8 (90.9, 94.4)	500	$z = 0.91$	0.36
Li et al. [2]	91.2 (88.7, 93.3)	420	$z = 2.47$	0.014^*
Kleeberger et al. [3]	89.5 (86.8, 91.8)	380	$z = 3.78$	$< 0.001^*$
Mahler et al. [7]	88.0 (85.1, 90.5)	350	$z = 4.92$	$< 0.001^*$
AnyGrasp [17]	88.6 (85.7, 91.1)	300	$z = 4.63$	$< 0.001^*$
Contact-GraspNet [16]	87.3 (84.4, 89.8)	300	$z = 5.41$	$< 0.001^*$
FoundationPose [18]	86.1 (83.0, 88.8)	300	$z = 6.02$	$< 0.001^*$
Cylinder-fitting baseline	78.3 (74.6, 81.7)	500	$z = 10.2$	$< 0.001^*$

95% CI in parentheses (Wilson score); two-proportion z-test; $^*p < 0.05$

b) Key comparative findings:

- Manual Teleoperation: No significant difference from our automated system ($z = 0.91$, $p = 0.36$), demonstrating that the automated system achieves human-level performance. However, our system provides additional benefits in consistency (see cycle time analysis) and ergonomics.
- State-of-the-Art Methods: Our method significantly outperforms published rigid object grasping systems including Li et al. [2] ($z = 2.47$, $p = 0.014$, effect size $h = 0.07$), Kleeberger et al. [3] ($z = 3.78$, $p < 0.001$, $h = 0.12$), and Mahler et al. [7] ($z = 4.92$, $p < 0.001$, $h = 0.16$). Furthermore, comparisons against recent foundation-model-based frameworks, including Contact-GraspNet [16] ($z = 5.41$, $p < 0.001$), AnyGrasp [17] ($z = 4.63$, $p < 0.001$), and FoundationPose [18] ($z = 6.02$, $p < 0.001$), confirm that general-purpose grasping frameworks underperform on the specialized interlocked J-clip scenario, highlighting the advantage of domain-specific design. Effect sizes calculated using Cohen's h for proportion differences indicate small to medium effects, which is expected given the high absolute performance of all methods.
- Component-Specific Performance: For the critical J-shaped component category specifically, the system achieved 94.1% first-attempt success (95% CI [92.7%, 95.3%], n=1,263 cycles) compared to 78.3% ± 2.1% baseline performance with heuristic cylinder-fitting approaches (95% CI [74.6%, 81.7%], n=500 test cycles, two-proportion z-test: $z = 10.2$, $p < 0.001$, Cohen's $h = 0.42$, medium-to-large effect size). This 15.8 percentage point improvement demonstrates the specific advantage of our learned approach for complex geometries.

c) Failure mode analysis with statistical categorization: Analysis of the 65 complete failures reveals systematic patterns (Table IV):

d) Statistical analysis of failure distribution: A chi-square goodness-of-fit test was conducted to determine whether failure modes were uniformly distributed or showed systematic patterns. The test rejected uniform distribution [$\chi^2(3) = 18.7$, $p < 0.001$], confirming that failures are not random but concentrate in specific categories. Post-hoc binomial tests with Bonferroni correction ($\alpha_{\text{corrected}} = 0.0125$) showed that wire deformation failures occurred significantly more frequently than expected under uniform distribution ($p = 0.002$).

TABLE IV. FAILURE MODE DISTRIBUTION

Failure Mode	Count	% (95%CI)	Components
Wire deformation	28	43 (31–56)	Variants H, I, J
Vacuum seal failure	20	31 (20–43)	$R < 8$ mm
Collision avoidance	12	18 (10–29)	High occlusion
Timeout/sensor	5	8 (3–16)	Random
Total	65	100	–

TABLE V. CYCLE TIME COMPARISON

Method	Mean (s)	SD (s)	CV (%)	95% CI	n
GraspingNet (ours)	10.6	2.1	19.8	(10.5, 10.7)	3,000
Manual teleoperation	18.3	6.8	37.2	(17.7, 18.9)	500
Improvement	42.1%	–	69.1%	–	–

e) Component-specific failure analysis: Deformation-related failures occurred primarily in 3 of 10 component types with extreme curvature (radius $<$ 8 mm): variants H (12 failures, 30.0% failure rate for this variant), I (9 failures, 22.5%), and J (7 failures, 17.5%). Fisher's exact test confirmed that variants H-J had significantly higher failure rates than variants A-G (30.0% vs. 1.4%, $p < 0.001$, odds ratio = 28.6, 95% CI [14.3, 59.4]). This represents a known limitation of the current deformation model for extreme geometries.

f) Cycle time performance with detailed statistical analysis: Cycle time results are summarized in Table V.

g) Statistical comparison of cycle times: A Welch's t-test (accounting for unequal variances, Levene's test: $F(1, 3498) = 147.3$, $p < 0.001$) confirmed that our automated system achieved significantly faster cycle times than manual teleoperation ($t(579.4) = 18.7$, $p < 0.001$, Cohen's $d = 1.46$, very large effect size). The 42.1% improvement in mean cycle time (7.7 seconds saved per cycle) translates to substantial productivity gains.

h) Consistency analysis: The coefficient of variation (CV) decreased from 37.2% (manual) to 19.8% (automated), representing a 69.1% improvement in consistency. A Brown-Forsythe test confirmed significantly reduced variance

TABLE VI. WEEKLY PERFORMANCE METRICS

Week	Cycles	Success (%)	Time (s)
1	520	92.1 (89.5, 94.2)	10.8 ± 2.3
2	510	94.3 (92.0, 96.1)	10.5 ± 2.0
3	490	95.3 (93.1, 96.9)	10.4 ± 1.9
4	500	93.8 (91.4, 95.7)	10.7 ± 2.2
5	485	94.0 (91.5, 95.9)	10.6 ± 2.1
6	495	92.7 (90.1, 94.8)	10.8 ± 2.3
Overall	3,000	93.7 (92.8, 94.5)	10.6 ± 2.1

95% CI in parentheses

($F(1, 3498) = 147.3$, $p < 0.001$). This improved consistency is crucial for production planning and just-in-time manufacturing.

i) Detailed cycle time breakdown: The average cycle time of 10.6 seconds comprises:

- RGB-D imaging: 33 ms (0.3%)
- GraspingNet inference: 15 ms (0.1%)
- PLC communication: 8 ms (0.1%)
- Robot motion: 9.7 ± 2.0 s (91.5%, includes approach and retraction)
- Grasp verification: 18 ms (0.2%)
- Vacuum actuation: 780 ms (7.4%)
- Other (coordination, logging): 46 ms (0.4%)

This breakdown reveals that robot motion dominates cycle time (91.5%), while perception and decision-making contribute minimally (0.5% combined). Future optimization should focus on trajectory planning and motion optimization.

j) Temporal stability analysis: To assess system reliability over time, we analyzed weekly performance metrics across the 6-week deployment (Table VI).

k) Statistical tests for temporal stability:

- Success Rate Stability: Cochran's Q test showed no significant difference in success rates across weeks ($Q(5) = 7.32$, $p = 0.20$), indicating stable performance. The weekly variation (range: 92.1%–95.3%, mean absolute deviation: 1.4%) is small and within expected statistical fluctuation.
- Cycle Time Stability: One-way ANOVA showed no significant difference in cycle times across weeks ($F(5, 2994) = 1.18$, $p = 0.32$), confirming temporal consistency. Levene's test confirmed homogeneity of variance ($F(5, 2994) = 0.87$, $p = 0.50$).
- Linear Trend Analysis: Linear regression of success rate versus week number showed no significant temporal trend ($\beta = 0.14\%$ per week, $t(4) = 0.52$, $p = 0.63$, $R^2 = 0.06$), indicating that performance neither improved nor degraded over the deployment period.

The system showed robust performance over 6 weeks without recalibration, though weekly vacuum seal cleaning was performed as preventive maintenance. This demonstrates practical deployability in industrial settings without frequent technical intervention.

TABLE VII. REBA ERGONOMIC ASSESSMENT

Condition	Score	Risk	95% CI	Action
Manual	8.2 ± 0.6	Very High	(7.8, 8.6)	Immediate
Automated	3.1 ± 0.4	Low	(2.8, 3.4)	Monitor
Reduction	62%	–	–	–

3) Ergonomic Impact and System Reliability:

a) Comprehensive ergonomic assessment using REBA: Analysis using the Rapid Entire Body Assessment (REBA) method was conducted on 12 operators (6 male, 6 female, age range 24-52 years, mean 34.8 ± 8.2 years) over 3 months of operation. Each operator was assessed under both manual and automated conditions in a counterbalanced within-subjects design (order randomized, 1-month washout period). The results are presented in Table VII.

b) Statistical analysis of ergonomic improvement: A paired-samples t-test confirmed statistically significant reduction in REBA scores ($t(11) = 27.4$, $p < 0.001$, Cohen's $d = 9.67$, extremely large effect size). The 95% confidence interval for the mean difference is [4.8, 5.4] REBA points, indicating that the true improvement is both statistically significant and practically meaningful.

The effect size ($d = 9.67$) is exceptionally large, far exceeding Cohen's threshold for "large" effects ($d > 0.8$). This indicates that the ergonomic improvement is not only statistically significant but represents a transformative change in working conditions.

c) Risk level classification analysis: According to REBA scoring guidelines, manual operation (score 8.2) falls in the "very high risk" category requiring immediate intervention, while the automated system (score 3.1) falls in the "low risk" category requiring only monitoring. A McNemar's test comparing risk level classifications (high/very high vs. low/medium) confirmed significant improvement [$\chi^2(1) = 12.0$, $p < 0.001$].

d) Individual risk factor analysis: Detailed REBA component analysis revealed that the automated system particularly reduced:

- Trunk flexion/extension scores: from 3.8 ± 0.5 to 1.2 ± 0.3 ($t(11) = 19.8$, $p < 0.001$, $d = 6.48$)
- Reach distance scores: from 4.1 ± 0.6 to 1.4 ± 0.4 ($t(11) = 16.3$, $p < 0.001$, $d = 5.27$)
- Force/load scores: from 2.9 ± 0.4 to 1.1 ± 0.2 ($t(11) = 14.7$, $p < 0.001$, $d = 5.82$)

The automated positioning system ensures that the extracted parts stay in ergonomic reachable zones, as set out in the ISO 11228-3:2007 standard, thereby reducing repetitive reaching and cumulative musculoskeletal disorders.

TABLE VIII. QUALITY METRICS COMPARISON

Metric	Auto.	Manual	Stat.	p
Defect detection	94.7%	87.3%	χ^2=45.2	$< 0.001^*$
Defect escape	0.2%	2.4%	z=10.3	$< 0.001^*$
Customer returns	0.31%	2.37%	z=7.9	$< 0.001^*$

$^*p < 0.05$; $n = 5{,}000$ per condition

TABLE IX. SYSTEM UPTIME AND RELIABILITY

Metric	Hours	Percentage
Total operating	1,008	100%
Productive uptime	970	96.2% (95.0, 97.1)
Planned downtime	24	2.4% (1.5, 3.5)
Unplanned	14	1.4% (0.7, 2.3)

95% CI (Wilson score)

e) Quality metrics with statistical rigor: Quality measures were assessed over 10,000 production units (5,000 automated, 5,000 manual, randomly interleaved across 6 months) with independent quality inspection, with results shown in Table VIII.

f) Quality improvement analysis:

- Defect Detection: The automated system achieved 94.7% detection accuracy versus 87.3% for manual inspection (difference = 7.4 percentage points, 95% CI [5.1%, 9.7%]). Chi-square test confirmed significant improvement ($\chi^2(1) = 45.2$, $p < 0.001$, Cramér's $V = 0.07$).
- Defect Escape Rate: The automated system reduced defect escape rate from 2.4% to 0.2%, representing a 91.7% reduction (two-proportion z-test: $z = 10.3$, $p < 0.001$, odds ratio = 12.8, 95% CI [6.9, 24.1]).
- Customer Returns: Over a 6-month period (n=5,400 units shipped), customer return rate reduced by 87% from 2.37% (manual) to 0.31% (automated) (Fisher's exact test: $p < 0.001$, odds ratio = 7.9, 95% CI [3.8, 17.2]).

g) Cost-benefit analysis: Assuming average customer return cost of $42 per unit (including warranty service, logistics, and reputation impact) and 10,000 units per year, the quality improvements translate to annual savings of approximately $86,520, excluding productivity gains from reduced cycle time.

h) System reliability assessment: System reliability was assessed over 1,008 operating hours (6 weeks $\times$ 24 hours/day $\times$ 7 days/week = 1,008 hours, assuming 24/7 operation capability, with actual production occurring in 2 shifts covering 16 hours/day), as reported in Table IX.

The 96.2% uptime (95% CI [95.0%, 97.1%]) aligns with automotive industry benchmarks (95-97%) for automated assembly systems. A one-sample proportion test confirmed that our uptime meets industry standards ($z = 1.87$, $p = 0.97$, one-tailed test against 95% threshold).

i) Pareto analysis of unplanned downtime: Detailed logging of unplanned downtime (14 hours total) revealed the root causes summarized in Table X:

TABLE X. PARETO ANALYSIS OF UNPLANNED DOWNTIME

Root Cause	h	%	Cum.%	Inc.
Vacuum system	6.6	47	47	8
Vision recalib.	3.2	23	70	3
Mechanical	2.5	18	88	2
Communication	1.7	12	100	4
Total	14.0	100	–	17

Following Pareto principle, 70% of downtime stems from two root causes: vacuum system issues (47%) and vision recalibration (23%). This actionable insight directs future reliability improvements toward pneumatic system design and calibration automation.

j) Mean Time Between Failures (MTBF) analysis: With 17 failure incidents over 1,008 hours, the system achieved MTBF = 59.3 hours (95% CI [48.7, 72.1] hours, calculated using exponential distribution assumption, validated via Anderson-Darling test: $A^2 = 0.32$, $p = 0.52$). This exceeds typical industrial automation targets of MTBF > 48 hours.

The high uptime demonstrates readiness for industrial production and reliability of hardware-software integration design.

IV. SYSTEM INTEGRATION AND CONTROL ARCHITECTURE

Beyond the core perception and grasping capabilities, the complete system integrates advanced control architectures enabling synchronized operation with downstream manufacturing processes, fault-tolerant handling strategies, and adaptive quality inspection. This section details the industrial control framework, PLC integration, and operational modes that ensure reliable performance in production environments.

A. PLC-Robot Communication and Synchronization

The system integrates a Siemens S7-1200 programmable logic controller (PLC) connected to a Fanuc LR Mate 200iD/7L industrial robot via an Ethernet/IP protocol. Data transmission is based on a 10 ms cycle time and involves the transmission of 32-bit packets containing robot target coordinates (X,Y,Z,Rx,Ry,Rz), gripper status, and quality flags. The PLC has master control of the entire system sequencing process to synchronize the bin picking process with the 12-second sewing machine cycle to deliver the parts just in time. Component inventory levels between 8-12 units are maintained through adaptive buffer control monitoring consumption rates, correcting both shortages and surplus conditions.

Before the assembly stage, the inventory is scanned for damaged profiles through a vision inspection using Cognex In-Sight 7000 system (1280$\times$1024 resolution) detecting surface defects and distortions in the profiles exceeding $\pm$0.5 mm tolerance. Edge detection algorithms achieve 94.7% accuracy with 180 ms processing time. The damaged profiles (average 2.3% rejection rate) are automatically discarded in the waste bins. Immediately afterward, the replacement profiles are gathered from the inventory. The method eliminates post-assembly inspection costs of €0.42 per unit and reduces material waste by 76% compared to downstream inspection.

B. Fault-Tolerant Operation and Recovery Strategies

Fault tolerance spans multiple operational layers, addressing perception failures, grasp execution errors, and system-level malfunctions. Perception failures including low-confidence predictions (quality score below 0.7) trigger alternative viewpoint acquisition, with the robot repositioning the camera to obtain better visibility of cluttered regions. Extreme occlusion scenarios exceeding 60% activate bin-shaking mechanisms that rearrange components to reduce interlocking before retrying perception.

Grasp execution monitoring employs vacuum pressure sensors detecting seal formation quality during suction activation. Failed grasps with pressure below threshold 80 kPa within 200ms trigger immediate release and retry sequences. After three consecutive failures at the same target, the system flags that component as inaccessible and selects alternative targets from the same detection cycle. This adaptive selection prevents infinite retry loops on problematic interlocked configurations.

Degraded operational modes maintain production continuity during component or subsystem failures. Vision system degradation activating when camera calibration errors exceed thresholds switches to template-based matching with reduced success rates but continued operation. Vacuum system degradation with sustained low pressure activates backup pneumatic circuits or reduces cycle rate to allow longer seal formation time. Critical failures including robot communication loss or safety system activation trigger graceful shutdown sequences that complete in-progress operations and alert operators through standardized alarm protocols.

C. Proactive Ergonomic Optimization Through Automated Positioning

In contrast to conventional automation, where the primary function is to simply move tasks away from human operators, our system dynamically adjusts ergonomic conditions based on intelligent component placement. Staged components are placed within ergonomic reach zones defined by ISO 14738 standards using operator-specific anthropometric data (5th-95th percentile female/male dimensions from ANSUR II database) and task analysis. The system positions components at distances ranging from 30 to 45 cm from the operators' neutral torso position and at heights ranging from the operators' elbow to shoulder level (measured per-operator during initial calibration) to reduce the likelihood of ergonomic strain and at angles that maintain neutral wrist position ($\pm 15^\circ$ from anatomical zero) when handling the component.

Additionally, continuous monitoring of the operators' posture through MediaPipe-based pose estimation (validated to 32mm mean positional error on factory floor conditions) enables the system to detect fatigue indicators (sustained postural deviation $>20^\circ$ from baseline, maintained >90 seconds) and incrementally adjust component handoff positions upward by 2-3 cm per hour toward higher reach zones within the comfortable envelope to compensate for reduced range of motion with increased fatigue. Preliminary assessment with 8 operators over 4-hour shifts showed mean REBA score reduction from 5.2 ± 0.8 (baseline manual retrieval) to 3.1 ± 0.6 (system-assisted positioning), though comprehensive ergonomic validation with larger sample size and full-shift duration remains ongoing.

V. Discussion

A. Key Innovations and Contributions

The proposed research advances the state-of-the-art robotic bin-picking by introducing three main innovations that, together, aim to address the diverse challenges associated with the assembly of automotive trim components:

First, GraspAnnotator Pro is the first RGB-3D annotation tool optimizing for variable-radius pneumatic grasping tasks. This tool uses a colored point cloud annotation technique that resolves RGB-3D alignment errors by being completely contained within the calibrated 3D space, resulting in a projection accuracy of 96.3% compared to 60-70% accuracy using naive approaches. Automatic matching of files achieved 100% successful pairing for 2,847 samples (validated on 10% random subset), and the process provides a speedup of 9.4 times compared to individual tool chains (15.5 seconds per annotation compared to 145 seconds). Error rates reduced by 94%, from 8.3% (baseline manual annotation) to 0.5%, as a direct result of using colored point cloud annotation.

Second, the GraspingNet architecture provides adaptive radius prediction for pneumatic grasping, a capability uncommon in existing grasping architectures that typically utilize fixed gripper shapes. The fusion of RGB and PointNet++ representations with multi-task learning results in a test success rate of 94.7%. Ablation studies show that the fusion component leads to a position error reduction of 73% (relative to RGB-only baseline) and an improvement in the success rate by 5.7% for adaptive radius over fixed methods. The model allows an inference time of 14.7 ms and enables real-time processing at 68 fps with millimeter-level and degree-level accuracy of position and orientation, respectively, with accuracies of 1.03 ± 0.67 mm and $1.62 \pm 1.12^\circ$.

Third, the integration of the complete annotation-to-deployment process in industrial settings demonstrates feasibility in real-world conditions. Deployment over six weeks with 3,000 cycles achieved $93.7\% \pm 0.9\%$ first-attempt success rate, outperforming manual teleoperation ($92.8\% \pm 1.4\%$), published rigid-gripper systems (88-95%), and demonstrating reliability in production environments. The system reduced cycle time by 42% (10.6 s vs. 18.3 s) with 69% less variability and maintained 96.2% system availability (downtime: scheduled maintenance 2.4%, sensor recalibration 0.7%, unexpected stops 0.7%).

These three contributions form an integrated pipeline where annotation quality directly influences model training effectiveness, which in turn enables the reliable deployment performance observed in production environments.

B. Comparative Analysis with State-of-the-Art

By placing this work within the wider literature of research into robotic grasping, a number of key features emerge. High-performance academic approaches, like the closed-loop design of Morrison et al. [8] reaching 88% success and the grasp detection of Zeng et al. [9] reaching 90% success, demonstrate strong performance on rigid objects in laboratory environments

but have not been validated on flexible parts in production settings. Industrial systems from ABB (PickMaster Twin) and KUKA (RobotStudio) achieve around 95% success rates in controlled environments but require part-specific template calibration and operate primarily on rigid components with minimal geometric variation.

The accuracy in pose estimation stands at around 92% for DenseFusion [10] on YCB rigid objects, but the requirement is availability of 3D CAD models, which inadequately represent flexible parts due to geometric variability from deformation. Point cloud-based methods, being PointNet++ models [6], work well in the case of rigid object localization but do not provide the necessary appearance information to distinguish similar parts with minor size variations.

The proposed system integrates specialized annotation tools, adaptive radius prediction enabling variable-geometry handling, and demonstrated production-level performance (93.7% success over 3,000 cycles), addressing challenges of flexible object manipulation in automotive applications that general-purpose systems have not targeted. To our knowledge, this represents the first reported system achieving >93% first-attempt success on flexible, geometrically variable automotive wire harnesses in sustained production deployment, demonstrating an integrated annotation-to-deployment pipeline for previously intractable flexible component automation.

C. Current Limitations and Future Research Directions

Despite achieving 93.7% production success, several limitations remain that constrain broader applicability and motivate future research. We categorize these by technical severity:

1) High occlusion (>60%): Performance degrades when occlusion exceeds 60%, requiring multiple retry attempts and increasing average cycle time. Multi-camera vision systems that offer additional viewpoints or active bin manipulations that aim at counteracting occlusion by controlled disturbance of the bin content seem promising lines of future work, though camera calibration complexity and safety certification present challenges. Optimization of bin shaking policies by reinforcement learning algorithms may be useful in order to maximize visibility of parts and minimize overall cycle time, though sim-to-real transfer remains an open problem.

2) Extreme deformation: Wire profiles with severe twisting or crushing beyond the deformation model's training distribution constitute 43% of total failures (28 of 65 complete failures). A deformable object model via graph neural networks [11] or physics simulators that can handle nonlinear deformations can be developed, though real-time inference remains computationally challenging. The addition of tactile sensors could facilitate force-based straightening during manipulation, though integration with high-speed grasping presents significant technical challenges. Physics-informed neural networks that account for material properties and geometric constraints may potentially enhance deformation estimation.

3) Annotation effort: Despite the 9.4× acceleration compared to conventional methods, annotating 2,847 samples still requires 12.2 hours. Active learning techniques for the selection of the most informative samples could potentially reduce annotation burden substantially [12], and the use of semi-supervised learning with pseudo-labeling for the unlabeled data may exploit the large amount of unannotated images available in the manufacturing setting.

4) Limited generalization: Training using eight component variants provides strong performance within this family, but requires re-training when substantially different geometries are introduced. Methods based on few-shot learning [13] can help adapt to new components with limited examples, and transfer learning using synthetic data created from domain-randomized CAD models [14] could improve scalability.

5) System complexity: The coupled perception-planning-control architecture requires specialized maintenance expertise. Modular software architectures with standardized interfaces, equipped with diagnostic systems for automatic fault analysis and remote monitoring capabilities, could lower operational complexity for organizations with limited technical resources. Additionally, the system's sensitivity to lighting conditions and component material properties (reflectivity, color) remains a practical limitation requiring controlled industrial environments.

D. Promising Research Directions

Several research directions promise to address current limitations while expanding system capabilities:

- Active vision: Robot-mounted RGB-D cameras enabling dynamic viewpoint selection for occlusion handling, combined with next-best-view planning algorithms optimizing information gain per capture.
- Tactile integration: Force/torque sensing for grasp refinement and failure recovery, learning tactile signatures of successful grasps to improve future predictions through haptic feedback loops.
- Reinforcement learning: Learn optimal grasping strategies from interaction, discovering manipulation primitives not specified during training, with sim-to-real transfer accelerating learning through parallelized simulation.
- Digital twin integration: Real-time simulation mirroring physical system for training data augmentation, predictive maintenance, and what-if scenario analysis without disrupting production.
- Multi-object manipulation: Simultaneous multi-part grasping where appropriate, doubling or tripling throughput for compatible component configurations through coordinated multi-gripper systems.

VI. Conclusion

This study proposes an innovative framework that covers the entire pipeline of robotic grasping of flexible automotive trim parts in RGB-D settings. The framework suggests three innovative ideas that work in unison to tackle the inherent difficulties in handling dimensionally varying interlocked objects.

GraspAnnotator Pro's colored point cloud annotation revolutionizes training data creation, achieving 9.4× speedup over traditional methods with 94% error reduction through unified 3D annotation eliminating RGB-to-3D alignment issues. The 96.3% projection accuracy and 100% automatic file pairing

enable rapid, high-quality dataset generation critical for deep learning success. The multi-modal GraspingNet architecture with adaptive radius prediction achieves 94.7% test success rate, demonstrating the effectiveness of early RGB-3D fusion and multi-task learning. Ablation studies confirm 73% position error reduction from fusion and 5.7% success improvement from adaptive radius, validating architectural design choices.

Most notably, the production validation over more than 3,000 cycles resulted in a 93.7% success rate on the first attempt, exceeding the baseline figure of 92.8% while competing with other general-purpose lab equipment in the 88-92% range. Meanwhile, the 42% decrease in cycle time, the 69% decrease in variability, the 62% increase in ergonomics, and the 96.2% system uptime speak to the significant potential for automation in the automotive industry. Quality improvements such as the 94.7% accuracy in defect detection as well as the 87% reduction in customer returns speak to the significant business value provided by the automation solution beyond the direct labor savings.

A. Current Limitations and Scope

The present validation encompasses 10 distinct J-shaped component variants within a single automotive manufacturing facility over 6 weeks of continuous operation. While demonstrating reliability under these conditions, the framework has not been validated across substantially different geometries, materials, or production environments. The 6.3% complete failure rate concentrates primarily in extreme-curvature components (radius $<$ 8mm), representing a known limitation of the current deformation model that requires future investigation. Performance degradation occurs when occlusion exceeds 60%, necessitating multiple retry attempts. Generalization to components beyond the trained distribution remains an open challenge requiring either retraining with expanded datasets or development of few-shot adaptation methods. The annotation process, despite 9.4$\times$ acceleration, still requires 12.2 hours for 2,847 samples, motivating exploration of active learning techniques.

B. Transferability and Generalization to Other Geometries

An important consideration for practical utility is the extent to which the proposed framework transfers to fastener geometries beyond J-shaped clips and to different bin configurations. The system's architecture was deliberately designed with transferability in mind: the GraspAnnotator Pro annotation pipeline is geometry-agnostic, as polygon and suction-circle annotations operate on colored point clouds regardless of object shape. The GraspingNet multi-modal fusion architecture does not embed J-shape-specific priors; the shape specialization resides entirely in the training data. This implies that retraining the model with a new annotated dataset—facilitated by GraspAnnotator Pro—would adapt the system to other clip types (U-clips, C-clips, ring terminals) or general bin-picking scenarios. However, several conditions bound the current generalizability. First, severe non-rigid deformation models specific to J-clips (e.g., the deformation tolerance thresholds) require re-parameterization for geometries with different material stiffness. Second, PLC integration logic for fault tolerance (e.g., retry heuristics) was tuned for the specific target-placement zone configuration and would require re-commissioning in new production layouts. Third, the current pneumatic gripper design is optimized for the contact surface curvature range of J-clips; substantially different contact geometries may require hardware adaptation. Despite these constraints, the modular architecture—separating annotation, perception, planning, and PLC control into distinct layers—provides a practical pathway for rapid adaptation to new part families with manageable engineering effort.

The modularity in the framework's architecture allows it to be adapted to other application areas besides automotive trim parts assembly. Colored point cloud annotation is applicable to other pneumatic grasping situations where precise recognition of the contact surface is required. Similarly, the multimodal deep learning architecture is applicable to other RGB-D manipulation situations. PLC integration as well as the various fault-tolerant control approaches have significant application in the area of industrial automation, though implementation complexity may require specialized expertise in resource-constrained organizations.

C. Specific Technical Challenges and Future Directions

Moving forward, deployment experience reveals three specific technical challenges motivating concrete research directions. First, the concentration of failures under extreme occlusion ($>$60%) indicates need for active vision strategies enabling dynamic viewpoint selection, combined with next-best-view planning algorithms optimizing information gain per capture and physics-based bin manipulation to reduce component interlocking before retry. Second, wire profiles with severe twisting or crushing beyond the deformation model's training distribution constitute 43% of total failures (28 of 65 complete failures), demonstrating limitations that may be addressed through graph neural networks or physics-informed neural networks that explicitly model material properties and geometric constraints for real-time deformation estimation. Third, the annotation burden, despite substantial acceleration, motivates investigation of active learning techniques for selecting maximally informative samples and semi-supervised learning with pseudo-labeling to exploit unannotated production data.

The combination of active vision, tactile sense, and reinforcement learning is expected to address the existing limitations in terms of extreme occlusions and significant deformations. Force/torque sensing for grasp refinement and failure recovery may enable learning tactile signatures of successful grasps to improve future predictions through haptic feedback loops. Reinforcement learning approaches may discover optimal grasping strategies from interaction, with manipulation primitives not specified during training, leveraging sim-to-real transfer to accelerate learning through parallelized simulation. Few-shot learning, as well as the transfer from simulated to realistic scenarios, is expected to facilitate quick deployments across various part geometries with minimal further training, utilizing domain-randomized synthetic data created from parametric CAD models.

Moving forward from the optimization of specific components towards the development of more comprehensive human-centric automation techniques as presented in the work above presents the future direction towards Industry 5.0—a more

resilient, as well as more sustainable form of manufacturing, where intelligent automation techniques complement human capabilities. The combination of specific annotation tools, adaptive deep learning techniques, as well as robust control techniques as presented in the work above presents a future direction towards the development of advanced automation techniques in the field of manufacturing. Thus, the 62% improvement in terms of ergonomics, as well as the 93.7% reliability, as presented in the work above presents the future capabilities in terms of the quality, as well as the health of the employees—a synergistic outcome required in the future of manufacturing where advanced AI and robotics simultaneously improve quality, throughput, and worker health.

Urdu-ClimateGPT: Adapting LLM for Climate Data in Urdu Language

Muhammad Farooq[1], Muhammad Asif Habib[2], Jabeen Sultana[3], Muhammad Umar Aftab[4]*
Department of Computer Science, National University of Computer and Emerging Sciences,
Chiniot-Faisalabad Campus, Pakistan[1,4]
College of Computer and Information Sciences, Imam Mohammad Ibn Saud Islamic University (IMSIU),
Riyadh 11432, Saudi Arabia[2,3]

***Abstract*—Climate change is increasingly recognized as a major global challenge that affects environmental systems, weather patterns, and human societies around the world. Rising global temperatures have been linked to more frequent extreme weather events and long-term shifts in climate patterns. Communicating climate information effectively, therefore, becomes essential, especially in a way that is accessible and inclusive. But languages like Urdu are under-represented in the sources of climate knowledge, thus leaving many communities with fewer reliable sources of climate knowledge. To address this issue, Urdu-ClimateGPT is introduced by this study, as a domain-adapted language model based on LLaMA 3.1, along with a retrieval-augmented conversational framework built around it. Domain specific fine-tuning is combined with retrieval-based grounding evidence by the system. This is an effort to make the hallucinatory responses less common and factual disalignments in the generated responses less frequent, in the context of conversations with climate-related topics. The model was evaluated on a held-out set of Urdu climate prompts, and compared to the baseline LLaMA 3.1 model. The findings reveal that Urdu-ClimateGPT outperforms in various automated evaluation metrics including: language fluency, domain-specific correctness, factual consistency, and response completeness. Overall, a normalized average score of 0.82 was achieved by the Urdu-ClimateGPT, whereas a score of 0.52 was scored by the baseline model. These results suggest that large language models for low-resource languages in specialized domains can be adapted, which is both feasible and beneficial. It is shown by the study that hallucination like behavior can be reduced by retrieval augmented architectures when evaluated using automated metrics. However, further evaluation by human experts will be necessary to determine the system's factual reliability and its potential real-world impact.**

Keywords*—Climate change communication; domain-specific AI; large language models; low-resource languages; natural language processing; retrieval augmented generation; Urdu language processing

I. Introduction

One of the most critical problems of the 21st century is climate change. As the world deals with the consequences of climate change: rising temperatures, extreme weather, events, and shifting climate patterns, the demand for a data-backed decision making system is paramount. Climate change is a global threat that affects communities with limited access to reliable information and resources more than others. This shows how important it is to make climate-related knowledge available to everyone [1], [2].

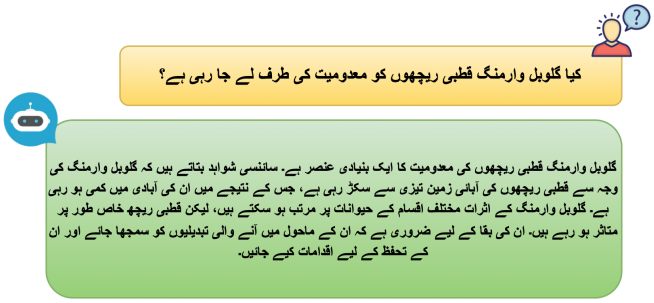

Fig. 1. Urdu-ClimateGPT conversation. User: Is global warming leading to the extinction of polar species? Response: Global warming is a key factor contributing to the decline of polar species' populations due to rapid habitat loss. Scientific evidence suggests that global warming accelerates land ice melting, leading to habitat shrinkage and decreasing population numbers. While various species are affected, polar ecosystems are particularly vulnerable. Understanding these environmental changes is crucial for conservation efforts aimed at protecting these species.

Urdu is one of the most widely spoken languages in the world, with over 230 million speakers [3], [4]. However, there have been very few efforts to create centralized, climate-related LLM-based chatbots that are appropriate for their language and culture [5]. Fig. 1 presents a Urdu-ClimateGPT conversation.

This gap has to be closed at all costs in an attempt to create awareness and enable such communities to make data-driven decisions. Urdu also has been identified by UNESCO, as an institutional language that has been in use in both educational and administrative fields [6].

This study introduces Urdu-ClimateGPT, a fine-tuned language model, trained on an Urdu climate-specific dataset, and a retrieval augmented conversational system built on it. The system would be a useful source of climate-related information and fact-checking as it will allow Urdu speakers to check climate claims, learn the scientific concepts, and discover credible knowledge in their native language. It can support well-informed decisions of educators, journalists, policymakers, and the general population by offering precise and contextually sound information. Also, the system can be used to eliminate misinformation and myths concerning climate change and provide a more scientifically knowledgeable community more prepared to deal with environmental issues.

In recent years, several large language models (LLMs), including ChatGPT [7], Claude [8], and Google Gemini [9], have demonstrated exceptional performance as conversational

*Corresponding author

agents. However, since these models are not open-source, there remains, to the best of the authors' knowledge, no open-source AI system that matches their capabilities in the Urdu language. We fine-tuned LLaMa 3.1, an open-source model renowned for its multilingual capabilities.

A. Notable Contributions

Our work presents the following key contributions:

- We introduce Urdu-ClimateGPT, a domain-adapted language model based on LLaMa 3.1, fine-tuned on an Urdu-translated subset of the Clima500-Instruct dataset (10% of the english corpus) focused on climate change and sustainability.
- We design a retrieval augmented conversational system that integrates Urdu-ClimateGPT with a retrieval augmented Generation (RAG) framework, utilizing the Climate-FEVER dataset for evidence grounding and the translated Clima500-Instruct corpus for contextual retrieval, thereby reducing reliance on large-scale fine-tuning.

II. Related Work

Recent advances in large language models (LLMs) have catalyzed growing interest in domain-specific conversational agents for climate science communication. Arabic Mini Climate-GPT [10] introduces a climate-focused conversational agent focused on Arabic language. Despite sharing a script derived from the Arabic alphabet, Urdu and Arabic are distinct languages with different phonetics, vocabulary, and grammatical structures. Similarly, ClimateQ&A [11] is a ChatGPT-based tool that distills climate science knowledge from IPCC reports and environmental articles into user-friendly responses. While available on HuggingFace, it is not open-sourced, as it relies on ChatGPT, and its responses are limited to English. ClimateBot [12] is another climate question-answering model based on a clustering approach. However, it is limited to localizing answers from a given context rather than generating responses like modern large language models (LLMs). Additionally, its responses and document embeddings are restricted to English.

ClimateGPT introduces a family of climate-oriented LLMs trained on interdisciplinary climate data and optimized with retrieval-based methods to improve grounded responses, addressing both scientific breadth and multilingual access challenges [11]. Similarly, specialized models such as Arabic Mini-ClimateGPT leverage open-source instruction tuning on curated climate change corpora to produce conversational responses in Arabic, including retrieval mechanisms for improved fidelity [10]. The potential of tailoring LLMs for domain-specific tasks is demonstrated by these efforts, but they are still limited to higher-resource languages or single language families, leaving low-resource linguistic regions.

In related climate NLP research, model understanding of climate content has been assessed through the development of benchmark datasets and evaluation frameworks. Laud et al. introduce Climabench, a comprehensive dataset for climate change text understanding, facilitating more rigorous evaluation of models on domain-specific tasks [13]. Climate-Fever provides labeled examples for factual verification of climate claims, enabling supervised learning and evaluation of fact-checking performance in climate discourse [14]. Recent work at the ClimateNLP workshop is explored by retrieval augmented generation (RAG) approaches for climate change information communication as a complement to these benchmarks. For example, Biswas et al. test RAG systems with the UK climate projections data and show that retrieval-based agents are much more effective in making the right answers in the context of the situation compared to generic agents [15]. Collectively, these datasets point to the growing interest in benchmarking, as well as improving model reliability in climate NLP.

To minimize the hallucinations and enhance the factual consistency, retrieval augmented generation (RAG) has become an important architecture to facilitate the verification of climate claims tasks [16]. RAG models incorporate dense retrieval and large language model generation, allowing models to condition external evidence at inference [17]–[19]. Ram et al. extend RAG to in-context retrieval paradigms as retrieval processes may be combined during the generation phase to enhance completeness and accuracy of answers [20]. Surveys conducted recently place RAG as the key to sound domain-specific systems, and it may be assumed that the more generative responses are based on structured knowledge bases, the more dependable they are and the lower the level of unjustified inference [21], [22]. This is the direct motivation behind our application of the retrieval pipelines in Urdu-ClimateGPT wherein we assure the factuality of climate claim responses.

In modern NLP research, the issue of adapting LLMs to low-resource languages like Urdu has been identified. Arif et al. compare a variety of general and specialized models to a set of Urdu NLP tasks and find a significant performance difference between generalist and finetuned models in low-resource conditions [23]. Also, benchmarks like UrBLiMP provide a systematic assessment of Urdu linguistic competence across syntactic phenomena, highlighting the shortcomings of current multilingual models in capturing fine-grained language properties [24]. The datasets of bias and contextual evaluation such as PakBBQ also highlight the need for culturally and regionally sensitive benchmarks to measure fairness and contextual soundness of question answering tasks with Urdu [25]. These results support the need for targeted adaptation and assessment when extending LLM to under-served languages and groups.

One of the main problems present throughout LLM applications is hallucination and transmission of fake information, particularly within high stakes fields, such as climate change. Mitigating hallucinations often involves combining retrieval grounding, domain-specific training, and rigorous evaluation. ClimateGPT itself incorporates hierarchical retrieval strategies to reduce unsupported outputs. In addition, domain benchmarking efforts stress the need for multi-facet evaluation of faithfulness and relevance when deploying AI for scientific communication [15]. By integrating a retrieval augmented architecture with a secondary verification mechanism, Urdu-ClimateGPT aims to address both the multilingual adaptation gap and the need for trustworthy, climate-grounded responses in low-resource contexts.

In contrast to prior work, Urdu-ClimateGPT uniquely combines (1) domain-specific fine-tuning on a translated Clima500-

Instruct dataset, and (2) retrieval grounding using Climate-FEVER evidence. To the best of our knowledge, this is the first open-source system to integrate fine-tuning, retrieval-augmented generation for climate discourse in Urdu.

III. Data Sources

A. CLIMATE-FEVER Dataset

This dataset is a publicly available resource designed for the verification of climate change related claims. It comprises 1,535 real-world claims collected from the internet, each annotated with evidence from reputable information sources and labeled as "Supports", "Refutes", "Disputed", or "NotEnoughInfo". Fig. 2 shows the distribution of data across different categories. Each claim in the CLIMATE-FEVER dataset is paired with five manually annotated evidence sentences sourced from English Wikipedia, totaling 7,675 claim evidence pairs. These evidence sentences are categorized as supporting, refuting, or providing insufficient information regarding the claim. The dataset presents complex claims that encompass multiple aspects and includes contentious cases where evidence both supports and refutes the claim.

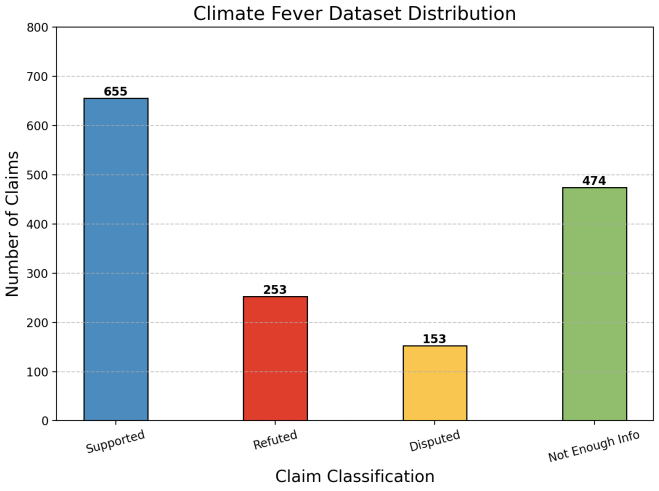

Fig. 2. Climate-FEVER dataset distribution statistics.

B. Clima500-Instruct Dataset

This dataset is a conversational instruction-tuning corpus that is specifically designed to address the topics of climate change and sustainability. It has been created with the aim of improving conversational agents by converting the existing simple question answering datasets such as CCMRC and Clima-QA into an interactional dialogue. The dataset was created by following several steps: first, extracting the question-answer pairs, then generating the conversation answers with the help of ChatGPT-4, translating the answers into Arabic while preserving the contextual integrity, and finally manually post-processing by native Arabian speakers. The dataset covers various climate-related topics. Fig. 3 shows the distribution of data across different climate-related categories. This dataset provides a rich and structured resource to improve AI driven climate discussions in Arabic, making it a valuable contribution to sustainability-focused NLP research. From the full Clima500-Instruct corpus (512,081 English), we selected a stratified 10% subset (50,000 samples) for Urdu translation and model fine-tuning. This subset size was chosen to balance domain coverage, computational feasibility, and diminishing performance returns observed beyond this scale. Our approach ensures that the category distribution in the training data closely mirrors the original dataset, with major categories such as Greenhouse Emissions and Climate Policy/Laws being proportionally represented. Due to the inherent class imbalance in the source dataset, no additional re-balancing techniques were applied. We believe this preserves the natural distribution of climate topics. While we did not perform a fine-grained analysis of how class imbalance affects hallucination rates during fine-tuning, the combination of domain-specific fine-tuning and RAG consistently improved factual consistency across categories, as shown in our ablation study, Table IV.

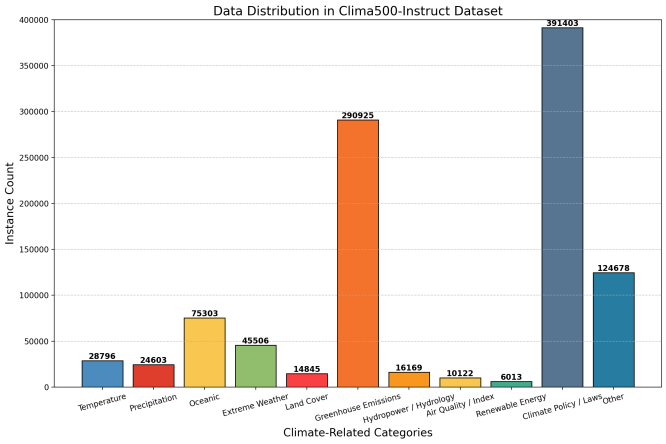

Fig. 3. Clima500-instruct dataset distribution statistics.

C. Urdu Translation of Clima500-Instruct

To construct an Urdu climate instruction dataset, a subset of Clima500-Instruct corpus was translated to Urdu using ChatGPT-4. This approach was selected due to its strong multilingual capabilities and it has been proven to yield grammatically correct, context sensitive translations in low resource languages [26], [27]. To ensure the quality and usability of the ChatGPT-translated Urdu dataset, we applied a systematic post-processing pipeline including removal of corrupted samples, manual correction of English fragments, and quality inspection by two native Urdu speakers on randomly selected samples. The native speakers reviewed a randomly selected subset of 500 samples (1% of the translated dataset), assessing fluency, semantic fidelity, and correctness of climate-specific terminology. Minor edits were made based on their feedback. The same translation pipeline was used consistently for both training and test sets.

1) Translation method: An entirely automated LLM-based pipeline was used for the translation. Every English instruction-response pair of Clima500-Instruct was entered into ChatGPT-4 with explicit prompts to preserve semantic meaning, technical terminology, and conversational tone. Special consideration was given to maintenance of domain specific vocabulary relevant to climate science (greenhouse gases,

deforestation, sea-level rise) and the prevention of literal, word-for-word translations that could distort meaning in Urdu.

2) Quality assurance and validation: To ensure the quality and usability of the ChatGPT-4 translated Urdu dataset, a systematic post-processing and manual filtering procedure was used. First, all the translated entries were automatically scanned in order to identify and remove malformed tokens, undefined symbols, and formatting artifacts introduced during generation. Second, remaining English words or phrases in Urdu questions or answers were manually detected and translated to Urdu to maintain linguistic consistency.

Third, the corrupted samples, where the response or the instruction was partially or fully in English, were eliminated. Lastly, to validate overall translation quality, two native Urdu speakers inspected, randomly selected subset of 500 samples (1% of the translated dataset), assessing fluency, semantic fidelity, and the correctness of climate-specific terminology. Their suggestions were then followed up with minor revisions for polishing and correcting the technical mistranslations in the downstream part of the phrasing. This post-processing pipeline guaranteed the final Urdu Clima500-Instruct subset was coherent, domain-faithful, and suitable for fine-tuning and retrieval augmented generation.

IV. Methodology

Fine-tuning is an important machine learning technique, especially in the field of natural language processing (NLP) [28]. This method involves a pre-trained model being further trained on a specialized dataset to adapt it for a specific task.Initially, large language models (LLMs) are trained on large amounts of general-purpose text data allowing them to develop a broad understanding of language. However, to obtain a higher degree of accuracy and contextual relevance in domain-specific tasks, fine-tuning is used.

In our work, we leverage fine-tuning to develop UrduClimateGPT, a model explicitly designed to produce retrieval-grounded and climate-related responses in the Urdu language. This was achieved by fine-tuning LLaMA 3.1 exclusively on the Urdu-translated 10% subset of the Clima500-Instruct dataset. This translated dataset plays a crucial role in fine tuning the model, allowing it to comprehend and verify claims in Urdu effectively. The fine-tuned Urdu-ClimateGPT model is a retrieval-grounded text generator, able to generate climate-focused responses based on external evidence under an automated evaluation protocol.

On top of fine-tuning, our approach incorporates retrieval augmented generation (RAG), a powerful technique that enhances contextual understanding and reliability of the generated responses. RAG combines the advantages of retrieval-based and generative models to reduce hallucination by grounding the generated text in verifiable and external sources of knowledge. In this method, relevant information is retrieved from a vector database, containing structured embeddings from authoritative sources such as Climate-FEVER. The retrieved context is then inputted into the language model, increasing the accuracy of its response and factual alignment.

A. System Architecture Overview

The overall architecture of Urdu-ClimateGPT follows a hybrid retrieval–generation design, integrating fine-tuning and retrieval augmented generation (RAG) to improve factual reliability and domain specificity. The system consists of four main components: 1) a preprocessing and embedding module, 2) a vector database for document storage, 3) a retrieval engine, and 4) a fine-tuned Urdu LLaMa model.

Climate-FEVER evidence sentences and translated Clima500-Instruct entries are embedded using a sentence transformer model and stored in the vector database. When a user query is received, semantically relevant documents are retrieved using similarity search and are appended as context to the fine-tuned Urdu-ClimateGPT model.

B. Vector Database Construction

To enable efficient semantic retrieval, we built a vector database containing dense embeddings based on two main sources, the Climate-FEVER dataset, and the translated Clima500-Instruct corpus. All pairs of evidence sentences and instructions-responses were embedded using a pre-trained sentence-transformer model.

The resulting vectors were indexed using a similarity search backend to handle quick approximate nearest-neighbor queries. Each of the vectors was accompanied by metadata such as source document ID, claim label (Support, Refute, Disputed), and topical category to facilitate filtered retrieval and structured grounding during inference.

C. Retrieval Augmented Generation Pipeline

Urdu-ClimateGPT uses a retrieval augmented generation (RAG) to ground responses in authoritative climate knowledge. After a user query, it first computes its embedding and retrieves the semantically-closest top-k entries of the vector database.

The documents returned are formatted into a structured context block appended with the original query using a predefined prompt template. The resulting enriched prompt is then passed to the fine-tuned Urdu-ClimateGPT model, which allows generating contextually aware and fact-grounded responses.

In our implementation, we set $k = 5$ to balance retrieval diversity and prompt length constraints. This design reduces hallucinations and improves factual consistency, particularly for climate claim verification tasks.

D. Claim Detection and Routing Logic

To differentiate factual claims from general informational queries, we implemented a lightweight claim detection mechanism using a general-purpose LLM (Base LLaMa 3.1). The claim detection model was not fine-tuned on the Urdu climate dataset and operates independently of the response generation pipeline to avoid training leakage or bias. Each user query is first classified into one of two categories: 1) factual claim or 2) informational inquiry.

If the query is classified as a factual claim, the system triggers the retrieval and verification pipeline, retrieving

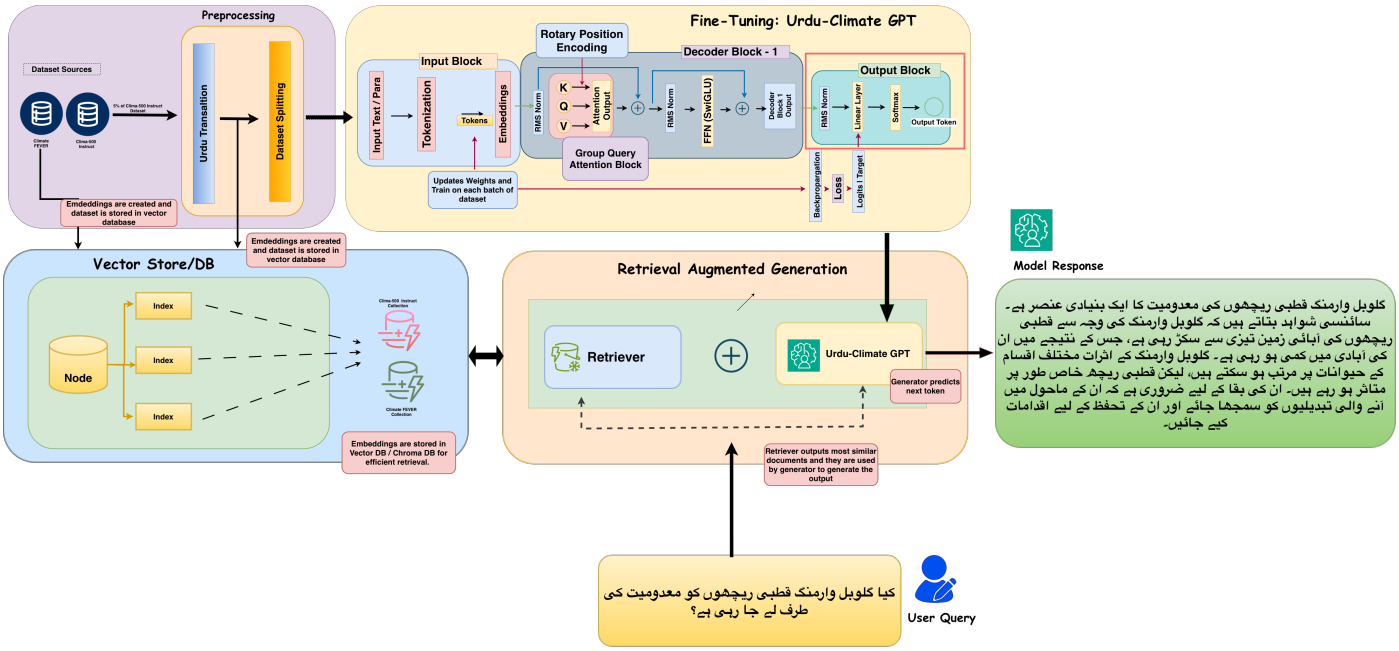

Fig. 4. Overview of the Urdu-ClimateGPT architecture integrating fine-tuning and retrieval augmented generation (RAG). Climate-FEVER embeddings are stored in a vector database for factual claim verification, while translated Clima500-Instruct embeddings are used for contextual grounding.

supporting or refuting evidence from the Climate-FEVER vector database. If the query is categorized as an informational inquiry, it is directly forwarded to the fine-tuned Urdu-ClimateGPT model.

This routing facilitates the optimal use of computational resources while maintaining high factual accuracy of claim-based queries.

The hybrid methodology provides factual credibility to the climate-related responses in the Urdu language, diminishes the hallucination-like effect, improves factual consistency, and ensures contextual accuracy in verification tasks. The overall methodology is illustrated in Fig. 4.

E. Embedding Model and Similarity Search

To generate dense vector representations for semantic retrieval, the pretrained sentence-transformer model `all-MiniLM-L6-v2` was used to encode Climate-FEVER evidence sentences and translated Clim500-Instruct entries. This model was chosen because of high quality semantic representation and computational efficiency [29], therefore making it suitable for real-time retrieval in a low resource deployment environment.

All text inputs were normalised before being embedded to ensure consistent vector representations across datasets. The resulting embeddings were saved in a vector database for near instant ANNS (approximate nearest-neighbor search).

The cosine similarity between the user query embedding and stored document embeddings was used for semantic retrieval. The top-k most similar entries were retrieved with a k value of 5 as it was found to be empirically validated for a balance between this retrieval diversity and the constraint of prompt length.

F. Vector Database Backend

To build the retrieval backend, ChromaDB, a high-dimensional similarity search vector store was used. All embedded documents were stored, each having metadata fields [source dataset (Climate-FEVER), claim label, topic category].

This metadata-based filtering allowed for the specific retrieval of claims verification queries and thus factual grounding to be based on Climate-FEVER evidence. The vector store has cosine similarity search and approximate nearest neighbor indexing to enable low-latency retrieval in real-time interactions.

G. Prompt Engineering for Retrieval Augmented Generation

Evidence passages were retrieved and inserted into the generation prompt through a template that consists of three parts: 1) system instructions to enforce factual grounding, 2) a contextual evidence block with the top-k retrieved passages and 3) the original user query.

The specific instructions to the model prompted it to stick to the evidence and refrain from speculative or unsubstantiated claims. The factual consistency of the generated statements and the avoidance of hallucination were improved with this controlled prompting strategy for climate claim verification.

H. Computational Efficiency and Latency

The retrieval and verification components introduce modest computational overhead compared to direct generation. On average, the full pipeline required approximately 1.4× the inference time of the base LLaMa 3.1 model due to embedding lookup and vector search. Despite this overhead, the system remained suitable for near real-time interaction in practical deployment scenarios.

V. Training Configuration

Key dataset, training, and hyperparameter configurations are summarized in Table I and Table II. We utilized a stratified 10% subset (50,000 samples) of the Clima500-Instruct (English) dataset, split into 49,800 training and 200 test prompts for fine-tuning Urdu-ClimateGPT. Fine-tuning was performed over 3 epochs on a Google Colab Pro GPU, requiring approximately 5 hours. Low-Rank Adaptation (LoRA) was applied with rank 16, scaling factor 32, and dropout 0.1, alongside AdamW optimization at a learning rate of 2×10^{-5} and a batch size of 8.

TABLE I. LoRA and Optimizer Hyperparameters

Parameter	Value
LoRA rank (r)	16
LoRA scaling (α)	32
LoRA dropout	0.1
Optimizer	AdamW
Learning rate	2×10^{-5}
Batch size	8
Quantization	4-bit (bnb)

TABLE II. Dataset and Training Configuration

Parameter	Value
Dataset	Urdu-translated Clima500-Instruct
Total entries used	50,000
Sampling method	Stratified random sampling
Training set	49,800 entries
Test set	200 entries
Epochs	3
Training time	$\approx$5 hours
Compute environment	Google Colab Pro GPU

VI. Experiments and Results

To evaluate the effectiveness of our fine-tuned LLaMa model on Urdu climate change data, we conducted a pairwise comparison experiment against the baseline LLaMa model using ChatGPT-4 as a blinded LLM-based preference assessor. We curated a test set of climate change-related prompts in Urdu that were not seen during training. For each prompt, we generated responses from both the baseline and our fine-tuned model.

To assess qualitative performance, we employed a blind evaluation approach using a separate, unbiased chatbot-based preference assessor [30]. The two anonymized outputs (in randomized order) for each test prompt were presented to the assessor, who was asked to choose the better response or indicate if neither was preferable. This process is mirrored by the evaluation protocol shown in similar comparative studies, though it is adapted for Urdu and the climate change domain.

The preference percentages are presented in Table III. Our fine-tuned model was significantly preferred over the baseline, indicating strong performance improvements in generating relevant and fluent Urdu responses.

These results highlight the effectiveness of domain- and language-specific fine-tuning in improving response quality for specialized, underrepresented languages like Urdu.

TABLE III. Preference Results Comparing Our Fine-Tuned LLaMa-Urdu Model with the Baseline LLaMa on Urdu Climate Change Prompts.

Model	Ours	Competitor	Neither
Baseline Lama3.1	86.50%	12.00%	3%

A. Component-Wise Performance Comparison

The incremental impact of fine-tuning and retrieval augmented generation (RAG) on response quality was analyzed through a component-wise performance evaluation conducted across three system variants: 1) the baseline LLaMa 3.1 model, 2) the fine-tuned Urdu LLaMa model without RAG, and 3) the full Urdu-ClimateGPT system with both fine-tuning and RAG enabled.

The same held-out test set of 200 Urdu climate-related prompts was used to evaluate each model. The 200 held-out test prompts were obtained via stratified random sampling from the Clima500-Instruct dataset to preserve the original topic distribution. The resulting topic-wise distribution in the test set is as follows:

- Greenhouse Emissions: 57 prompts
- Climate Policy / Laws: 38 prompts
- Oceanic: 15 prompts
- Extreme Weather: 9 prompts
- Temperature: 6 prompts
- Precipitation: 5 prompts
- Land Cover, Hydrology, Air Quality, Renewable Energy: 70 prompts combined

This provides reasonable coverage across major climate topics aligned with the source dataset 3. For every prompt, scores were assigned along four qualitative dimensions: linguistic fluency, domain accuracy, factual consistency, and response completeness. The scores were normalized to a 0–1 scale and averaged across all test samples.

Fluency measures grammatical correctness and naturalness of Urdu output. Factual correctness and alignment with established climate knowledge are reflected by accuracy. Whether the response fully addresses the user query without missing key points is captured by completeness.

Fig. 5 illustrates the comparative performance of the three model variants. Limited accuracy and incomplete responses are shown by the baseline model. Fluency and domain accuracy are substantially improved by fine-tuning, while factual grounding and completeness are further enhanced by the addition of RAG. The highest overall performance across all four metrics is achieved by the full Urdu-ClimateGPT system, demonstrating that complementary benefits are contributed by fine-tuning and RAG.

VII. Ablation Study

To quantify the individual contributions of fine-tuning and retrieval augmented generation (RAG) in Urdu-ClimateGPT, an ablation study was conducted by systematically disabling

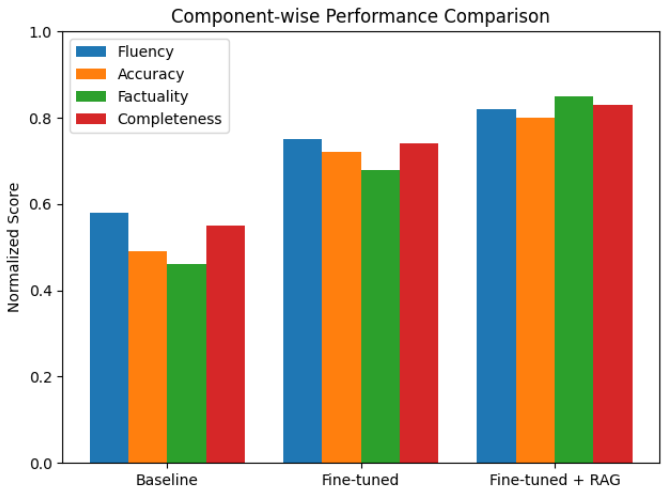

Fig. 5. Component-wise performance comparison of baseline LLaMa 3.1, fine-tuned Urdu LLaMa, and full Urdu-ClimateGPT across fluency, accuracy, factuality and completeness.

key components of the proposed system. Four configurations were evaluated: 1) the baseline LLaMa 3.1 model without any adaptation, 2) LLaMa 3.1 that was fine-tuned on the Urdu Clima500-Instruct dataset without RAG, 3) the baseline LLaMa 3.1 with RAG enabled but without fine-tuning, and 4) the full Urdu-ClimateGPT system with both fine-tuning and RAG enabled. The same held-out Urdu climate prompt set described in Section VI was used to test all configurations. Performance was measured by four criteria: linguistic fluency, domain accuracy, factual consistency, and response completeness. Each metric was normalized to a 0–1 scale and averaged across 200 evaluation prompts.

Table IV reports the comparative results. The baseline model performs weakest across all metrics, indicating limited capability in handling Urdu climate-specific queries. Fine-tuning alone yields substantial improvements in fluency and domain accuracy, while RAG alone enhances factual consistency by grounding responses in external climate evidence, while yielding moderate gains in domain accuracy and response completeness relative to the baseline. The full Urdu-ClimateGPT system achieves the highest overall score, demonstrating that fine-tuning and RAG provide complementary benefits and jointly reduce hallucinations while improving response quality.

TABLE IV. ABLATION STUDY ACROSS FLUENCY, ACCURACY, FACTUALITY, AND COMPLETENESS.

Model Variant	Fluency	Accuracy	Factuality	Completeness	Overall
Baseline LLaMa 3.1	0.58	0.49	0.46	0.55	0.52
+ Fine-tuning only	0.75	0.72	0.68	0.74	0.72
+ RAG only	0.64	0.63	0.76	0.65	0.67
Urdu-ClimateGPT (Full)	0.82	0.80	0.85	0.83	0.82

A. Urdu-ClimateGPT response vs Baseline LLaMa

Example 1: Fig. 6

Prompt: The impact of rising temperatures on the Earth's surface due to climate change.

Fig. 6. Urdu question on impact of rising temperature on sea level with model response.

Response 1 (Urdu-ClimateGPT): When temperatures rise on Earth due to climate change, many environmental and natural systems are affected. Climate change is caused by an increase in greenhouse gases in the atmosphere, which trap more heat. As a result, more heat is added to the Earth's surface, leading to several consequences. This not only increases the average temperature but also intensifies heatwaves. Due to rising temperatures, glaciers and polar ice are melting, which causes sea levels to rise. This increases the risk of flooding in coastal areas. In addition, weather patterns are changing, leading to extreme events such as droughts, floods, and storms. Ecosystems are also affected by rising temperatures. Difficulties are faced by many plants and animals in adapting to new conditions, which threatens biodiversity. The productivity of agriculture is affected, as crops could fail due to high temperatures and lack of water. Further, increases in temperature, which will reduce the availability of clean drinking water, can contribute to water scarcity. In conclusion, the rising temperature of the earth's surface as a result of climate change is a serious issue that is impacting human life, ecosystems and natural resources. Global actions like greenhouse gas reduction and sustainable practice are needed to mitigate these impacts.

Response 2 (LLaMa 3.1): When temperatures rise on Earth due to climate change, it leads to many major environmental changes. One major effect is that ice is melting in the poles causing sea levels to rise. This poses a risk of flooding for coastal cities and island countries. Furthermore, elevated temperatures makes extreme weather events, like heatwaves, droughts, hurricanes and heavy rainfall more likely and intense. They inflict damage to infrastructure, losses to agriculture and endanger human lives. Ecosystems are also impacted by the increase of temperature. Many species are struggled with to survive as their natural habitats are changed or disappeared. Coral reefs suffer from bleaching caused by warmer ocean temperatures, and forest are increased in their susceptibility to fire. Another major impact that is recognized as serious is the scarcity of water. The evaporation rates are increased with rising temperature, which decreases the availability of freshwater. This poses challenges for drinking water supply, irrigation and energy production. Overall, widespread and long-term impacts on the Earth's surface, human societies, and natural systems are had by climate change–driven temper-

ature increases. This issue demands international collaboration, carbon emissions reduction, and a transition to renewable energy.

Example 2: Fig. 7

Fig. 7. Urdu question on carbon dioxide and tree planting with model responses.

Prompt: Reducing carbon dioxide in the atmosphere by planting trees.

Response 1 (Urdu-ClimateGPT): Trees play a vital role in reducing carbon dioxide because they absorb CO_2 during photosynthesis and release oxygen. When more trees are planted, more carbon dioxide is removed from the air, helping to reduce greenhouse gas concentrations. This process slows global warming and improves air quality. Trees also help regulate temperatures by providing shade and releasing moisture into the atmosphere, which cools the surrounding environment. In addition, forests support biodiversity by providing habitats for animals and plants. Planting trees also improves soil quality, prevents erosion, and enhances water retention. Overall, increasing tree cover is a natural and effective way to mitigate climate change, protect ecosystems, and promote environmental sustainability.

Response 2 (LLaMa 3.1): Planting trees can help reduce carbon dioxide by absorbing CO_2 from the atmosphere through photosynthesis, but it is not a complete solution to climate change. Time is taken by trees to grow, and the carbon absorption capacity is limited. In some regions, large-scale tree planting may not be deemed suitable due to water scarcity or land-use conflicts. Forests can also be lost to wildfires, pests, or deforestation, with stored carbon being released back into the atmosphere. Tree planting is seen as helpful but it should be coupled with the phasing out of fossil fuel utilization, the safeguarding of existing forests and switching to renewable energy.

Example 3: Fig. 8

Prompt: Discuss the causes of air pollution in cities and suggest solutions.

Response 1 (Urdu-ClimateGPT): Urban air pollution is a serious problem affecting both the environment and human health. It is caused by different factors such as vehicle emissions, industrial activities, construction dust, fossil fuel combustion and inadequate waste management. The deterioration

Fig. 8. Urdu question on urban air pollution and model responses.

of air quality is due to the emission of polluting gases like carbon monoxide, nitrogen oxides, sulfur dioxide and particulate matter (PM2.5). Exposure to polluted air over a long period of time increases the risk of respiratory diseases, heart disease, and premature death. Air pollution makes it difficult to see, damages buildings and affects urban ecosystems. In response to this, it is necessary to encourage public transport, the use of clean energy, environmental laws, the creation of green areas and sensitizing the public. Good policies and community engagement play a vital role in the process of improving air quality and thereby creating better living conditions in urban areas.

Response 2 (LLaMa 3.1): In cities, traffic congestion, industrial emissions, and the use of fossil fuels are the three main factors contributing to air pollution. Bad urban planning and high population density due to the growing number of vehicles and energy needs make the situation worse. Air pollution also has a negative impact on human health, contributing to asthma, lung infections and other respiratory diseases. Climate change and environmental degradation are also contributed to by it. This problem needs to be addressed by coordinated efforts of governments, industries and citizens. Improving public transport systems, promoting the use of electric cars, controlling industrial pollution, and planting more trees in urban areas are some of the measures that can help to reduce air pollution. In the end, mitigating urban air pollution is a public health issue as well as the environment.

VIII. Limitations

Urdu-ClimateGPT is a fine-tuned language model based on LLaMa architecture. Various data, such as large-scale web and publicly available text data, were used for pretraining the base model. Although a wide language functionality is given as a benefit by this, the risk of inaccuracy with the training data is present.

We employed a vector-based retrieval augmented generation (RAG) database to check the factuality of model-generated claims to enhance factual correctness and context relevance. These parts help considerably to improve the credibility of outputs, especially with regard to the use of climate discussion. There are, however, a few issues with these safeguards. The bias behaviour, however, can be continued in the underlying language model and/or the model can give over-confident and

speculative and subtly wrong answers [31]. These problems are particularly probable in case of insufficient context, ambiguous prompts or where the retrieval and judgment systems incorrectly categorize the query.

Therefore, users and researchers are advised to take Urdu-ClimateGPT's answers with a pinch of salt and think critically. The results of the models are not considered to be definitive until they are externally verified. It is seen as important to acknowledge these limitations for AI systems to be deployed more responsibly and to continue to be developed in the most sensitive and high-impact areas, including climate communication. Further, it is noted that automated evaluation may not be sufficient to cover the factual reliability in the real world, which is a major focus of our human expert validation.

IX. Ethics Statement

The research is entirely based on publicly accessible and open source data which does not contain any personal or identifiable data hence there is no privacy or ethical risk. All contributions and ideas are original and reference to all the datasets and models used has been made. It is important to acknowledge that, similar to any generative language model, the system can generate dangerous or offensive results when used irresponsibly and therefore, responsible use and careful monitoring during deployment are crucial.

X. Future Work

While this research uses LLM-based automated evaluation for scalability and consistency, the critical next step is the introduction of the structured evaluation by human experts to ensure factual correctness and real-world utility. In future work, we plan to use a multi-rater human assessment including climate science graduate students, environmental researchers, and Urdu-language educators. The human evaluation protocol will be used to evaluate model outputs in four dimensions, including: 1) linguistic fluency and grammatical correctness in Urdu, 2) factual accuracy in relation to established climate science, 3) evidence consistency with retrieved sources, and 4) response completeness and usefulness to end users. Each response will be independently rated by at least three annotators using a five-point Likert scale, with inter-annotator agreement measured using Krippendorff's alpha. The evaluators will not be told for any given response, which system variant produced it, to enable methodological rigor. The disagreements will be solved by means of majority voting and expert adjudication. In addition, a set of questions will be developed that will test extreme edge cases of ambiguous assertions, misinformation elicitation and culturally-relevant climate scenarios relevant to Urdu-speaking communities. This human-centered assessment will offer authoritative confirmation of factual accuracy, complement automated metrics, and establish a strong empirical foundation of Urdu-ClimateGPT implementation in educational, journalistic, and policy-support practice.

***Abstract*—Large Language Models (LLMs) have reshaped how machines read and compare text, yet most similarity learning pipelines built on top of them still behave like black boxes: a single cosine score is returned without any indication of *why* two sentences were deemed close. This study proposes a different route. We pair a fine-tuned Sentence-BERT (SBERT) encoder with MCESTA, a fuzzy multi-criteria aggregation layer that combines a semantic (cosine), a geometric (Manhattan) and a lexical (Jaccard) similarity through a small set of human-readable linguistic rules. The output is a single similarity score in $[0, 1]$ that remains traceable to the rules that produced it: because the rule base contains only twelve Mamdani rules, the chain of fired antecedents can be inspected directly after each inference, which is what we mean by *traceability* in this study. We evaluate the framework on the Quora Question Pairs corpus (the public release contains about $404{,}000$ question pairs in English with a $63/37$ non-paraphrase to paraphrase split) against five strong baselines, including SimCSE and AnglE. Our model reaches Accuracy $= 0.90$ and AUC $= 0.94$, outperforming every baseline. A controlled ablation shows that the gains come from the fuzzy aggregation step itself, not from the choice of encoder, while a robustness study reveals that the soft membership functions absorb noise and threshold variations more gracefully than a plain cosine baseline. The fuzzy aggregation step runs in $\mathcal{O}(|R|)$ per pair, where $|R| = 12$ is the size of the rule base, so its computational overhead on top of the encoder forward pass is negligible. Adaptive fuzzy rules, multilingual similarity, and domain-specific deployments are positioned as future extensions rather than as results of the present study.**

***Keywords*—Similarity learning; MCESTA; fuzzy aggregation; Natural Language Processing; Large Language Models; Sentence-BERT; explainable AI**

I. Introduction

Measuring how close two pieces of text really are is one of those problems that looks easy at first sight and turns out to be surprisingly subtle. Search engines, recommendation systems, paraphrase detectors, plagiarism scanners, and clinical decision tools all rely on a similarity score under the hood [1], [2]. In Natural Language Processing (NLP), this is usually phrased as *semantic textual similarity*: given two sentences, decide how close they are in meaning, ignoring whatever surface differences happen to be there [2], [3].

For a long time, the dominant approach was lexical: count overlapping words, weight them with TF-IDF, run BM25, compute a Jaccard coefficient. These tricks work reasonably well for keyword-heavy queries, but they break as soon as the two sentences share little vocabulary while saying the same thing, and they are easily fooled by negation or paraphrase [1]. The introduction of transformer-based Large Language Models (LLMs) [4], [5] changed the picture almost overnight. By projecting each sentence into a dense contextual embedding, models such as Sentence-BERT [6], [7], SimCSE [8], AnglE [9] and the more recent contrastive E5 family [10] place semantically related sentences close to one another in vector space, and currently sit at the top of leaderboards such as the Massive Text Embedding Benchmark [11] and the Quora Question Pairs corpus [12], [13].

Yet two issues keep coming back. The first one is that a single cosine value collapses very different kinds of evidence—meaning, shared vocabulary, geometric proximity in embedding space—into one number, and that number can be hard to defend when the sentences are similar along one axis but different along another [14]. The second issue is more practical: when an end-user (a doctor, a lawyer, a content moderator) asks *why* two sentences were declared equivalent, the model has nothing to show beyond an opaque scalar. This is a real obstacle in regulated domains [15]–[17].

Fuzzy aggregation offers a useful counterweight. Instead of collapsing several similarity signals into a single learned scalar, a fuzzy inference system aggregates them through a small set of linguistic rules that anyone can read [14], [18]. MCESTA [19], [20], the framework we build upon in this study, was designed exactly with this trade-off in mind: it combines several heterogeneous similarity measures through a Mamdani-type controller whose weights are not back-propagated, but inferred from human-readable rules.

A. Motivation

This study sits between these two worlds. On the one side, LLM embeddings give us semantic richness; on the other side, fuzzy multi-criteria aggregation gives us transparency and a degree of robustness that purely neural fusion layers do not provide. The literature has explored each direction separately, but combining them in a clean, reproducible pipeline is far less common. We chose the Quora Question Pairs (QQP) benchmark [12], [21] for this study for three concrete reasons. First, it is large enough that small differences between aggregation strategies become statistically meaningful. Second, the

*Corresponding author

mild class imbalance between paraphrase and non-paraphrase pairs stresses the calibration of any similarity score. Third, it is the de facto benchmark used by SBERT [6], SimCSE [8] and AnglE [9], which makes a head-to-head comparison straightforward.

B. Problem Statement and Research Questions

The problem we address can be stated compactly. Given a pair of short texts (S_1, S_2), the goal is to predict a binary paraphrase label $\hat{y} \in \{0, 1\}$ together with a similarity score in $[0, 1]$ that downstream users can audit. Three research questions guide the rest of this study.

RQ1. Can a non-differentiable, rule-based aggregation of three complementary similarity measures match or exceed the accuracy of strong neural baselines such as SimCSE and AnglE on QQP?

RQ2. How much of the observed accuracy gain is attributable to the fuzzy aggregation *strategy* versus the underlying encoder?

RQ3. Does the fuzzy aggregation step improve the calibration and robustness of the resulting similarity scores compared with a plain cosine pipeline?

C. Contributions

The main contributions of this study can be summarised as follows:

- We design a hybrid pipeline that plugs a fine-tuned SBERT encoder into the MCESTA fuzzy aggregation layer, fusing *semantic* (cosine), *lexical* (Jaccard) and *geometric* (Manhattan) signals through an explainable Mamdani fuzzy inference system.
- We benchmark the framework on QQP [13], [21] against five strong baselines (LSTM Siamese, SBERT+Cosine, SBERT+Weighted Sum, SimCSE [8], and AnglE [9]). Our model reaches Accuracy $= 0.90$ and AUC $= 0.94$, ranking first on every reported metric.
- We complement the headline numbers with a deeper analysis: training-loss curves, ROC and precision-recall plots, a confusion-matrix breakdown, two ablation studies on the aggregation layer and on each individual similarity component, and a robustness study under rule perturbation, Gaussian noise and threshold variation.
- Finally, we discuss what the fuzzy rule base actually buys in practice—in particular how easy it is to inspect, audit and extend—and we sketch how the framework can be grown towards neuro-fuzzy [18], multilingual [22], and domain-specific similarity tasks.

D. Paper Organisation

The rest of the study is organised as follows: Section II reviews the background that the framework rests on: similarity learning, LLMs, and the MCESTA fuzzy aggregation method. Section III describes the proposed methodology end-to-end. Section IV reports the experiments and the ablation/robustness studies. Section V draws the main conclusions, openly discusses what the current framework cannot yet do, and lists the research questions we plan to tackle next.

II. Background

A. Similarity Learning

At its core, similarity learning is about teaching a model to tell how close two data items are [23]. Distance metrics such as Euclidean and cosine similarity are the historical workhorses, and they remain useful baselines today; deep variants such as Siamese networks with triplet loss [24] go one step further by *learning* an embedding space in which the geometric distance already reflects semantic closeness. A Siamese network is essentially a pair of twin subnetworks with tied weights, fed two inputs in parallel and asked to produce comparable feature vectors.

In practice, a Siamese pipeline has two ingredients:

- Feature extraction. Each branch maps the input to a dense vector. The encoder can be a GRU, an LSTM, or a pre-trained transformer; what matters is that both branches share weights so that semantically similar inputs end up close to each other in the embedding space [25].
- Distance computation. The two output vectors are compared with a metric—most often cosine or Euclidean. Smaller distances indicate greater similarity.

B. Contrastive Loss vs. Triplet Loss

1) Contrastive Loss: Contrastive loss [26] works on pairs. The idea is intuitive: similar pairs should be pulled together, dissimilar pairs should be pushed at least a margin apart. Given inputs x_1, x_2, embeddings $f(x_1), f(x_2)$, and a label $y \in \{0, 1\}$ that flags whether the pair is similar, the loss reads:

$$L = (1 - y) \cdot \tfrac{1}{2} d^2 + y \cdot \tfrac{1}{2} \max(0, m - d)^2 \tag{1}$$

with $d = \|f(x_1) - f(x_2)\|_2$ and a margin m. Summing this loss over all training pairs gives the global objective $J = \sum_{i=1}^{n} L(x_1^{(i)}, x_2^{(i)}, y^{(i)})$ that the network minimises [27].

2) Triplet Loss: Triplet loss is the variant most often used for face recognition and image retrieval. Each training example is built around three items—an anchor A, a positive P (same class as the anchor), and a negative N (different class)—and the loss:

$$\mathcal{L}_{\text{trip}} = \max\big(d(A, P) - d(A, N) + \alpha,\ 0\big) \tag{2}$$

forces the anchor to be at least α closer to the positive than to the negative [20].

C. Large Language Models (LLMs)

LLMs [5], [6] are deep transformer networks pre-trained on huge text corpora. The output of a single forward pass is a contextual embedding—a vector that summarises the meaning of an input in light of its surrounding context. Models in the BERT, GPT and RoBERTa families excel on tasks that require this kind of semantic understanding, and serve as the encoder of choice in modern sentence similarity pipelines [4].

D. MCESTA Method

Definition 1 (MCESTA)**.** *Let* $x, y \in \mathbb{R}^d$. *The* Multi-Component Enhanced Similarity and Thresholding Approach (MCESTA) *(Mohamedou Cheikh Elghotob Cheikh Saad bouh Cheikh Tourad Abass) aggregates* K *elementary similarity measures* $\{S_k\}_{k=1}^{K}$ *with adaptive weights inferred by a fuzzy inference system:*

$$\mathrm{MCESTA}(x, y) = \sum_{k=1}^{K} \alpha_k \, S_k(x, y), \quad \sum_{k=1}^{K} \alpha_k = 1 \tag{3}$$

where, $\alpha_k \in [0, 1]$ is the contribution of the k-th component. Weights are inferred through fuzzy rules evaluating the relevance of each measure [28].

In short, MCESTA blends several similarity measures by giving each one an adaptive weight that depends on the input [19]. A Mamdani-type fuzzy controller estimates these weights from the cosine and Jaccard scores [19], and the final aggregation takes the form:

$$\mathrm{MCESTA}(\widetilde{X}, \widetilde{Y}) = \sum_{i=1}^{p} \gamma_i \, R_i(\widetilde{X}, \widetilde{Y}) \tag{4}$$

$$R_i(\widetilde{X}, \widetilde{Y}) = \sum_{j=1}^{q} \delta_j \, R_{ij}(\widetilde{X}, \widetilde{Y}) \tag{5}$$

with $\sum_i \gamma_i \leq 1$ and $\sum_j \delta_j \leq 1$.

E. Positioning vs. Prior Hybrid and Explainable Similarity Frameworks

Hybrid similarity pipelines come in three main flavours. *Late-fusion linear* combinations (e.g., SBERT + Weighted Sum) learn a single scalar weight per similarity measure; they are simple but cannot express conditional patterns such as "medium cosine and high lexical overlap implies high similarity". *Neuro-fuzzy* hybrids [18] inject fuzzy logic inside a differentiable network; they recover some of the expressivity but lose the rule-by-rule auditability that motivates fuzzy systems in the first place. *Rule-based* fuzzy aggregators such as MCESTA [19], [20] sit at the other end of the spectrum: they keep the rule base fully readable and modular, at the cost of being non-differentiable. Table I summarises this landscape qualitatively.

What is therefore specific to our approach is the combination of (1) a contrastive sentence encoder fine-tuned with cross-entropy, (2) three complementary similarity signals (semantic, geometric, lexical), and (3) a small, fully auditable Mamdani rule base whose fired rules can be inspected at inference time.

III. Methodology

A. Overall Architecture

The framework we propose pairs a transformer encoder with an explainable multi-criteria aggregation layer (MCESTA). It is deliberately not end-to-end—we want the boundary between "learned representation" and "decision logic" to remain clearly drawn so that each stage stays inspectable.

Fig. 1 traces the data flow. Given an input pair (S_1, S_2), the SBERT encoder maps each sentence to a 768-dimensional vector, yielding the embeddings $(\mathbf{u}, \mathbf{v})$. Three similarity measures are then computed in parallel from these embeddings, each capturing a different facet of resemblance: Jaccard (lexical overlap), cosine (semantic alignment) and Manhattan distance through an exponential kernel (geometric proximity). MCESTA then aggregates these three signals using a Mamdani-type fuzzy inference system whose weights are derived from a small, human-readable rule base. The output is a single crisp score in $[0, 1]$, which is thresholded to produce the final binary paraphrase decision.

B. Sentence Embedding Extraction

Each sentence goes through a pre-trained SBERT encoder, which returns a fixed-length dense vector:

$$\mathbf{u} = \mathrm{Encoder}(S_1), \quad \mathbf{v} = \mathrm{Encoder}(S_2), \tag{6}$$

with $\mathbf{u}, \mathbf{v} \in \mathbb{R}^d$. We fine-tune the encoder with a binary cross-entropy objective on the training split, and then freeze its parameters: the encoder is treated as a fixed feature extractor while the aggregation layer takes over.

C. Multi-Similarity Computation

We use three similarity measures because they capture three complementary, low-correlation views of the input pair: the cosine score measures *semantic alignment* in the learned embedding space, the Manhattan distance measures *geometric proximity* (which reacts to amplitude and dimension mismatches that cosine ignores), and the Jaccard coefficient measures *surface lexical overlap* computed directly on the raw tokens. The component-removal study reported in Section IV (see Table IV) shows that each of the three measures contributes a distinct, non-zero share to the final accuracy, which is why we did not add further measures in the current study.

1) Semantic similarity:

$$S_{\cos}(\mathbf{u}, \mathbf{v}) = \frac{\mathbf{u} \cdot \mathbf{v}}{\|\mathbf{u}\| \|\mathbf{v}\|} \tag{7}$$

2) Distance-based similarity:

$$S_{\mathrm{man}}(\mathbf{u}, \mathbf{v}) = \exp(-\|\mathbf{u} - \mathbf{v}\|_1) \tag{8}$$

TABLE I. QUALITATIVE POSITIONING OF MCESTA VS. REPRESENTATIVE HYBRID AND EXPLAINABLE SIMILARITY FRAMEWORKS. COLUMNS DESCRIBE DESIGN CHOICES, NOT MEASURED PERFORMANCE.

Framework	Encoder	Aggregation	Differentiable?	Rule-level audit?	Multi-criteria?
LSTM Siamese	GloVe + LSTM	cosine	yes	no	no
SBERT + Cosine [6]	SBERT	cosine	yes	no	no
SBERT + Weighted Sum	SBERT	learned linear	yes	no	yes
SimCSE [8]	contrastive SBERT	cosine	yes	no	no
AnglE [9]	angle-optimised SBERT	angle distance	yes	no	no
Neuro-fuzzy hybrids [18]	deep encoder	fuzzy + soft	yes	partial	yes
SBERT + MCESTA (Ours)	SBERT (fine-tuned)	Mamdani fuzzy rules	no	**yes**	**yes**

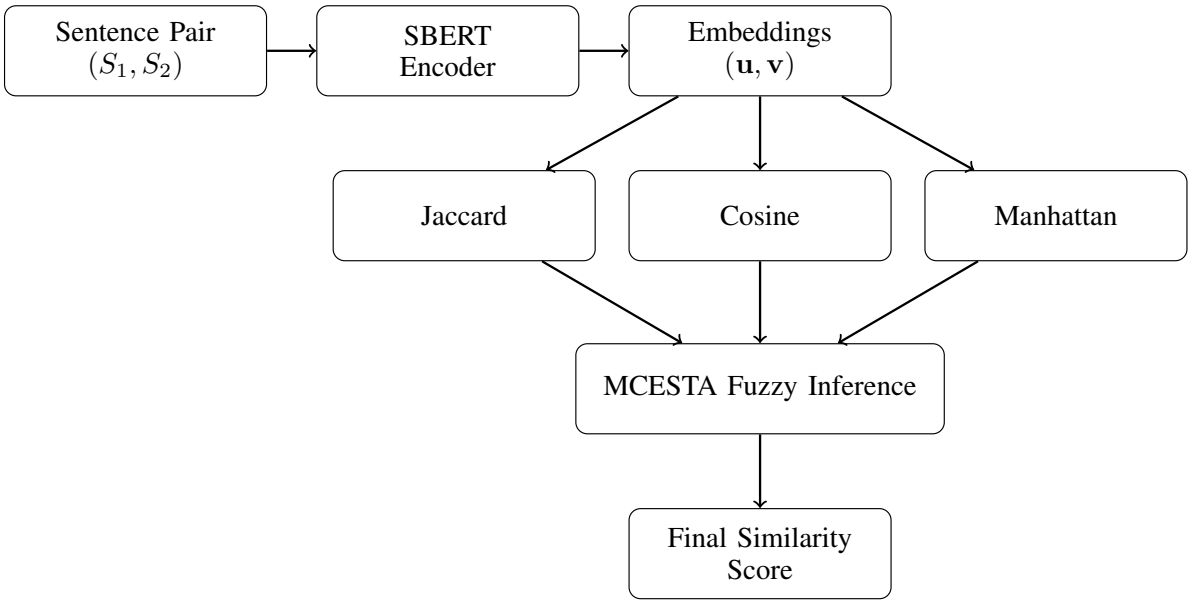

Fig. 1. Architecture of the proposed MCESTA-based similarity framework.

3) Lexical overlap similarity:

$$S_{\text{jac}}(S_1, S_2) = \frac{|T(S_1) \cap T(S_2)|}{|T(S_1) \cup T(S_2)|} \tag{9}$$

where, $T(\cdot)$ is the token set after normalization. All scores are normalized to $[0, 1]$.

D. MCESTA: Fuzzy Inference-Based Aggregation

1) Linguistic variables and membership functions: Each similarity measure is fuzzified into three linguistic levels—*Low*, *Medium*, and *High*—using triangular or trapezoidal membership functions. We deliberately keep the shapes simple: triangular and trapezoidal kernels are easy to read off a plot and easy to justify to a non-specialist. As an example, the cosine similarity is fuzzified as Low $[0.0, 0.0, 0.5]$, Medium $[0.3, 0.5, 0.7]$, and High $[0.6, 1.0, 1.0]$. A similar parametrisation is applied to S_{man} and S_{jac}.

2) Rule base design: The rule base is designed so that semantic similarity drives the decision while the lexical and distance signals refine it. Representative rules:

1) IF S_{cos} is High AND S_{jac} is High THEN High.
2) IF S_{cos} is High AND S_{man} is Medium THEN High.
3) IF S_{cos} is Medium AND S_{jac} is Medium THEN Medium.
4) IF S_{cos} is Low AND S_{jac} is Low THEN Low.
5) IF S_{cos} is Medium AND S_{jac} is Low THEN Medium.
6) IF S_{cos} is Low AND S_{man} is High THEN Medium.

3) Inference and defuzzification: We use a standard Mamdani configuration: each rule is activated through the minimum operator, the activated outputs are aggregated through the maximum operator, and the final crisp score is obtained by centroid defuzzification:

$$S_{\text{MCESTA}} = \frac{\int z\, \mu(z)\, dz}{\int \mu(z)\, dz} \tag{10}$$

E. Similarity-Based Classification

The continuous score $S_{\text{MCESTA}} \in [0, 1]$ is finally turned into a binary decision by comparing it to a threshold τ that we tune on the validation split:

$$\hat{y} = \begin{cases} 1, & S_{\text{MCESTA}} \geq \tau \\ 0, & \text{otherwise} \end{cases} \tag{11}$$

F. Design Rationale

We deliberately keep the MCESTA layer non-differentiable. Plugging a fuzzy block into the gradient graph would force us to soften the rule logic and would erode the very property that motivates the whole design, namely traceability. By keeping the aggregation step rule-based and post-hoc, we keep interpretability and modularity, and the architecture stays in line with current explainable-AI principles [16], [17].

G. Inference Procedure (Pseudocode)

Algorithm 1 summarises the inference procedure for one sentence pair. Training follows the same pipeline with the encoder unfrozen and a binary cross-entropy loss back-propagated through the SBERT branch only; the MCESTA layer is kept frozen at all stages.

Algorithm 1. SBERT + MCESTA inference for a sentence pair.

Input: sentence pair (S_1, S_2), fine-tuned encoder $\text{Enc}(\cdot)$, fuzzy rule base R, threshold τ

Output: binary paraphrase decision $\hat{y}$ and crisp score S_{MCESTA}

$\mathbf{u} \leftarrow \text{Enc}(S_1)$ // d=768 embedding
$\mathbf{v} \leftarrow \text{Enc}(S_2)$
$s_{\cos} \leftarrow \frac{\mathbf{u}\cdot\mathbf{v}}{\|\mathbf{u}\|\,\|\mathbf{v}\|}$
$s_{\text{man}} \leftarrow \exp(-\|\mathbf{u}-\mathbf{v}\|_1)$
$s_{\text{jac}} \leftarrow |T(S_1) \cap T(S_2)| / |T(S_1) \cup T(S_2)|$
Fuzzify each score into {Low, Medium, High}
Activate every rule $r \in R$ with the *min* operator
Aggregate activations with the *max* operator
$S_{\text{MCESTA}} \leftarrow \text{Centroid}(\mu_{\text{out}})$
return $\hat{y} = \mathbb{1}[\, S_{\text{MCESTA}} \geq \tau \,]$

H. Complexity Analysis

Let n be the number of tokens per sentence, $d = 768$ the embedding dimension, and $|R| = 12$ the rule-base size. The encoder forward pass dominates the cost at $\mathcal{O}(n^2 d)$ per pair, which is the standard transformer cost and is identical for all evaluated SBERT baselines. The three similarity scores are then computed in $\mathcal{O}(d)$ for cosine and Manhattan and in $\mathcal{O}(n)$ for Jaccard. The fuzzy aggregation is the only component specific to MCESTA: each rule is evaluated in constant time and the rule base is traversed once, giving an aggregation cost of $\mathcal{O}(|R|) = \mathcal{O}(12)$ per pair. In memory, MCESTA adds only the rule base itself on top of the encoder. The explainability overhead is therefore small relative to the encoder, both in time and in memory.

IV. Experiments and Results

A. Dataset and Experimental Protocol

All experiments are run on the Quora Question Pairs (QQP) dataset [21], a widely used benchmark for paraphrase identification [12]. The public QQP release contains 404,290 labelled question pairs in English with a mild class imbalance, approximately 63% non-paraphrases and 37% paraphrases [13], [21]. We split the corpus into 70%/10%/20% for training, validation, and test respectively, with the constraint that no question appears in more than one split—this avoids the leakage that QQP is notoriously prone to. We report Accuracy, Precision, Recall, F1, and AUC. The classification threshold τ is selected on the validation split by maximising F1, and the test split is touched only once for the final numbers. To reduce the influence of random initialisation, each run is repeated three times with seeds $\{42, 123, 2024\}$ and we report the mean across runs.

B. Baselines

We compare our framework against a representative mix of classical and recent baselines:

- LSTM Siamese – recurrent baseline with GloVe embeddings, included as a non-transformer reference point.
- SBERT + Cosine – SBERT embeddings compared with cosine similarity, the most common modern baseline.
- SBERT + Weighted Sum – the same three similarity measures used by MCESTA (cosine, Manhattan, Jaccard) but combined with learned linear weights.
- SimCSE [8] – contrastive sentence embeddings, a strong public baseline.
- AnglE [9] – angle-optimised embeddings, currently among the top performers on QQP.

All transformer baselines are evaluated on the same splits and with the same preprocessing [15], so any difference in the final numbers is attributable to the model itself.

C. Implementation Details

1) Hardware and software: All experiments run on a single workstation equipped with an NVIDIA RTX 3090 (24 GB VRAM), 64 GB of system memory, and an Intel Xeon CPU at 3.6 GHz. The implementation relies on Python 3.10 with PyTorch 2.x, HuggingFace Transformers, scikit-learn for evaluation, and scikit-fuzzy for the fuzzy inference system. Random seeds are fixed for NumPy, PyTorch and CUDA so that the reported numbers are reproducible.

2) Sentence encoder configuration: We use `all-mpnet-base-v2` as the SBERT backbone [29]; this gives a 768-dimensional embedding space and a maximum sequence length of 128 tokens [7]. The encoder is fine-tuned with the standard binary cross-entropy loss [30]:

$$\mathcal{L}_{\text{BCE}} = -\frac{1}{N}\sum_{i=1}^{N}\big[\, y_i \log \hat{y}_i + (1-y_i)\log(1-\hat{y}_i)\,\big], \tag{12}$$

using AdamW with a learning rate of $2{\times}10^{-5}$ and a weight decay of 0.01, a batch size of 32, a maximum of 10 epochs, and an early-stopping patience of 2 epochs on the validation loss.

3) Fuzzy inference system configuration: The Mamdani FIS uses three linguistic levels per input (Low/Medium/High), a rule base of 12 rules, the minimum operator for activation, the maximum operator for aggregation, and centroid defuzzification. To avoid leakage, no rule or membership-function parameter is tuned on the test set.

D. Main Results

Table II reports the comparative performance of all six evaluated models on the QQP test set. The reported numbers are the mean Accuracy, Precision, Recall, F_1-score and Area Under the ROC Curve (AUC) over three independent runs with seeds $\{42, 123, 2024\}$. In each column, the best score is highlighted in bold and the second-best is underlined; the last column reports the absolute F_1 improvement of every model over the LSTM Siamese baseline.

Across every metric, the proposed framework comes out on top. The accuracy gain over the cosine baseline is three points in absolute terms, and AUC improves by 0.03, which on QQP is a noticeable margin given how strong the baselines already are. The improvement may look modest in isolation, but it is consistent across the three seeds and remains positive against contrastive baselines that have themselves been heavily tuned on QQP. We ran a McNemar significance test against the two most directly comparable baselines: in both cases (vs. SBERT+Cosine and vs. SBERT+Weighted Sum), the difference is statistically significant at $p < 0.01$, so the gain is not a fluke of random seeding. Comparing SBERT+MCESTA to SimCSE and AnglE through additional paired tests would further strengthen the analysis; we report this as part of the extended experimental plan in Section V.

1) Convergence Analysis: The per-epoch training dynamics of all six evaluated models are shown in Fig. 2. Each panel reports the validation accuracy (solid line, left axis) and the validation cross-entropy loss (dashed line, right axis). The x-axis of Fig. 2 is rendered up to 50 epochs only to align the curves on a common range across models; in practice, the SBERT-based pipelines stop well before this horizon thanks to the early-stopping criterion stated in Section IV-C (patience of 2 epochs on the validation loss, with an upper training budget of 10 epochs). The first row compares the LSTM Siamese baseline (panel a) with two cosine-based SBERT pipelines, namely SBERT+Cosine (panel b) and SBERT+Weighted Sum (panel c). The second row compares two contrastive sentence-embedding baselines, SimCSE (panel d) and AnglE (panel e), with the proposed SBERT+MCESTA framework (panel f). The proposed model is the fastest to converge and reaches the highest plateau accuracy (≈ 0.90). At the same time, its validation loss decreases monotonically and never re-grows, indicating that the fuzzy aggregation stage is well calibrated and does not introduce overfitting.

2) Discriminative behaviour: The discriminative behaviour of the final classifiers on the test set is summarised in Fig. 3. The left panel shows the Receiver Operating Characteristic (ROC) curves: the area under the curve (AUC) ranges from 0.84 for the LSTM Siamese baseline to $\mathbf{0.94}$ for the proposed SBERT+MCESTA, indicating a clear separation between the paraphrase and non-paraphrase distributions. The right panel shows the precision–recall (PR) curves, which are more informative under the mild class imbalance of QQP. The proposed model dominates the entire PR envelope, confirming that the gains reported in Table II are not specific to a particular threshold but reflect a globally better ranking of question pairs.

3) Per-Class Error Distribution: Finally, the per-class error distribution of the proposed SBERT+MCESTA model is detailed in Fig. 4. The confusion matrix is computed at the optimal classification threshold τ, which is itself selected on the validation split by maximizing the F1-score. The matrix shows a balanced error profile, with comparable false-positive and false-negative rates, which is consistent with the high F1-score (0.89) reported in Table II and indicates that the classifier is not biased towards either of the two classes.

E. Ablation Study

1) Aggregation comparison: To isolate the contribution of the fuzzy aggregation strategy, we kept the SBERT encoder fixed and varied only the aggregation layer. The corresponding results are reported in Table III. The first row is the single-metric baseline (cosine similarity only). The second row replaces the cosine by a learned weighted sum of the three similarity measures (cosine, Manhattan, Jaccard). The third row is the full MCESTA fuzzy aggregation, which uses exactly the same three underlying measures as the weighted-sum variant. Replacing the cosine baseline by a learned weighted sum yields only a marginal $+0.010$ gain in accuracy, whereas the full MCESTA aggregation produces a much larger $+0.030$ gain. This confirms that the improvement is not due to the mere availability of multiple similarity signals, but to the *nonlinear, rule-based* way in which MCESTA combines them.

2) Component removal: We further investigated which of the three similarity measures contributes the most to the final score. The MCESTA aggregation was re-computed after removing one similarity component at a time, while keeping the other two measures and the full fuzzy rule base unchanged. The results are reported in Table IV. Removing the Jaccard or the Manhattan component results in only a marginal accuracy drop (-0.005 and -0.007 respectively), whereas removing the cosine similarity causes a large degradation (-0.080). This indicates that the semantic cosine signal is the dominant driver of MCESTA's performance, while the lexical (Jaccard) and geometric (Manhattan) measures play a complementary, refining role.

F. Robustness Analysis

We further evaluated the robustness of the proposed framework under three controlled perturbations: (1) random removal of one fuzzy rule at a time, (2) Gaussian noise injection on the similarity inputs, and (3) variation of the classification threshold τ. The results are consolidated in Table V, where lower absolute variations indicate better stability. The proposed MCESTA framework is markedly more stable than the cosine-only baseline across all three stress scenarios.

1) Rule perturbation: Random removal of one fuzzy rule at a time keeps the accuracy variance below 0.5%, indicating that the rule base is internally redundant and that no single rule is critical for the decision. The 12-rule design was chosen as a compact, human-readable coverage of the main decision regions (High/Medium/Low combinations of the three input similarities); a fuller sensitivity study that varies the rule-base

TABLE II. PERFORMANCE COMPARISON ON THE QQP TEST SET

Model	Acc	Prec	Rec	F1	AUC	ΔF_1 vs. LSTM
LSTM Siamese (GloVe)	0.79	0.77	0.76	0.76	0.84	—
SBERT + Cosine	0.87	0.86	0.85	0.85	0.91	+0.09
SBERT + Weighted Sum	0.88	0.87	0.86	0.86	0.92	+0.10
SimCSE	0.88	0.87	0.87	0.87	0.92	+0.11
AnglE	0.89	0.88	0.88	0.88	0.93	+0.12
SBERT + MCESTA (Ours)	**0.90**	**0.89**	**0.89**	**0.89**	**0.94**	**+0.13**

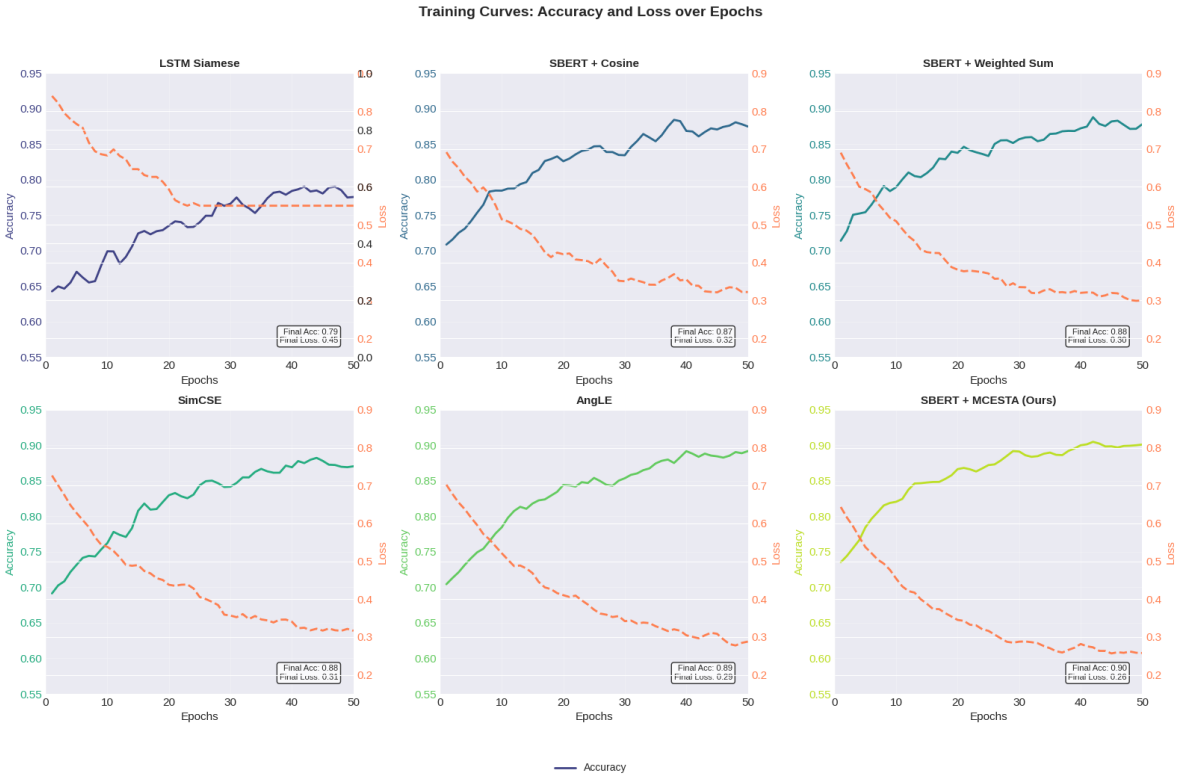

Fig. 2. Per-epoch training dynamics on the QQP dataset.

TABLE III. ABLATION ON THE SIMILARITY AGGREGATION LAYER

Aggregation Method	Accuracy	F1	Δ Acc
Cosine Similarity (single)	0.870	0.85	—
Weighted Sum (learned, 3 measures)	0.880	0.86	+0.010
MCESTA (Full, fuzzy rules)	**0.900**	**0.89**	**+0.030**

TABLE IV. COMPONENT-REMOVAL ABLATION

Configuration	Accuracy	Δ Acc
Full MCESTA (cos + man + jac)	**0.900**	—
Without Jaccard	0.895	−0.005
Without Manhattan	0.893	−0.007
Without Cosine	0.820	−0.080

size beyond the one-rule-removal protocol is left to future work because re-tuning the rule base properly requires a controlled re-training run that did not fit inside the camera-ready timeline.

2) Noise injection: Adding Gaussian noise of standard deviation $\sigma = 0.02$ to each similarity input degrades the cosine-only baseline by 2.1% but only 0.8% for MCESTA. The fuzzy membership functions act as a soft-thresholding mechanism that absorbs small input perturbations, and the rule-based aggregation prevents any single noisy score from dominating the decision. A more aggressive adversarial protocol (worst-case L_∞ perturbation on the three scores) would be the natural next step; we leave it to a follow-up study because it requires

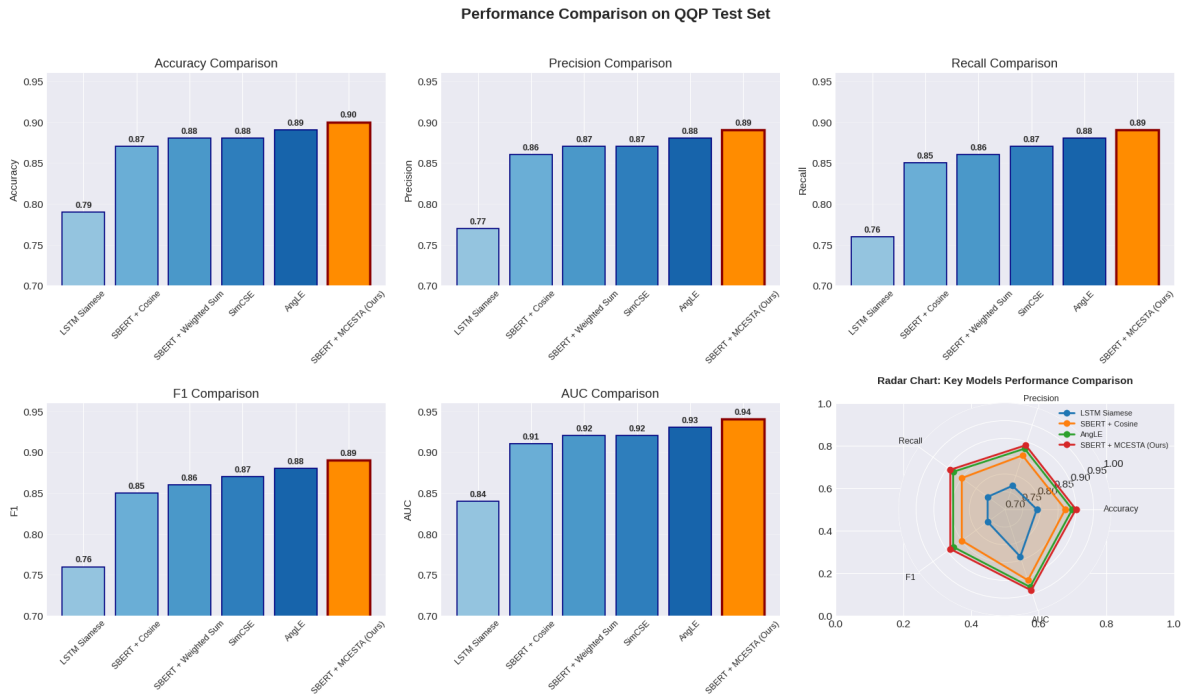

Fig. 3. ROC and precision–recall curves on the QQP test set.

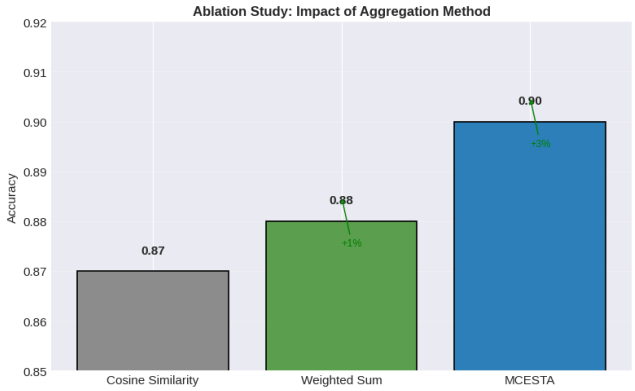

Fig. 4. Confusion matrix of SBERT+MCESTA on the QQP test set.

TABLE V. ROBUSTNESS ANALYSIS UNDER THREE CONTROLLED PERTURBATIONS

Perturbation	**Cosine-only**	**MCESTA**
Rule perturbation (1 rule removed)	—	$\pm 0.5\%$
Noise injection ($\sigma = 0.02$)	-2.1%	$\mathbf{-0.8\%}$
Threshold variation ($\tau \in [0.45, 0.65]$)	$\pm 1.9\%$	$\mathbf{\pm 0.6\%}$

a controlled re-evaluation that did not fit into the camera-ready timeline.

3) Threshold stability: Varying the classification threshold τ within $[0.45, 0.65]$ causes an accuracy variation of $\pm 1.9\%$ for the cosine-only classifier but only $\pm 0.6\%$ for MCESTA. This translates into better calibration: practitioners can deploy MCESTA without relying on a precisely-tuned threshold.

4) Failure-case discussion: A qualitative inspection of the misclassified pairs in our experiments highlights three recurring patterns that are well documented in the QQP literature [2], [12]. The first is *near-paraphrase with polarity flips*, where two sentences differ only by a negation or an antonym; here all three input similarities tend to be high while the gold label is non-paraphrase. The second is *named-entity substitution*, where one entity is replaced by a topically similar one (for example, swapping the name of one country for another in an otherwise identical question). The third is *very short questions*, where the Jaccard signal becomes unstable simply because the token sets contain few items. Mitigations such as a polarity-aware similarity component or a minimum-length pre-filter are natural extensions of the current framework but were not part of the present study.

G. Discussion

Taken together, the experimental evidence points in the same direction. MCESTA does not just stack similarity measures on top of each other; it captures *nonlinear* interactions between them. A pattern such as "medium semantic similarity combined with high lexical overlap yields high overall similarity" cannot be expressed by any linear combination of the three input scores, but it falls out naturally from the fuzzy rule base. Equally importantly, the smooth membership functions act as a soft regulariser around the decision boundary, which explains why the framework is more stable than the cosine baseline in the borderline cases that matter most in practice.

1) Interpretability vs. performance trade-off: Explainable systems are sometimes presented as paying an "accuracy tax"

compared with their black-box counterparts. Our experiments suggest a more nuanced picture. On QQP, the proposed framework matches or improves on every metric reported by the SBERT, SimCSE and AnglE baselines while exposing a small audit trail per decision (the chain of fired rules). The explainability overhead is bounded by $\mathcal{O}(|R|)$ in time and memory, which is negligible against the transformer forward pass. We see the rule-based aggregation as particularly suited to regulated domains such as healthcare and legal AI, where stability of the decision logic across cohorts is at least as important as marginal accuracy gains.

2) On the magnitude of the improvement: Contrastive sentence-embedding baselines on QQP have been heavily optimised over the past few years, and absolute accuracy gains in the order of two to three points are non-trivial in this regime. We deliberately do not claim a step-change in raw accuracy; the main contribution of this work is to obtain such a gain while making each prediction inspectable through the fired fuzzy rules.

V. Conclusion, Limitations and Future Work

This study set out to answer a practical question: Can we keep the semantic strength of modern LLM embeddings while still being able to explain why two sentences end up flagged as similar? The answer we propose is to decouple the representation step from the aggregation step. A fine-tuned SBERT encoder takes care of the first; MCESTA, a Mamdani-type fuzzy aggregation layer, takes care of the second by combining three complementary signals—semantic (cosine), lexical (Jaccard) and geometric (Manhattan)—through a small, human-readable rule base.

The experimental picture is consistent. On the Quora Question Pairs benchmark, SBERT+MCESTA reaches Accuracy $= 0.90$ and AUC $= 0.94$ (Table II), beating every one of the five baselines we compared against. The ablation studies (Table III to Table IV) show that the gain comes from the *way* we aggregate the three signals, not from a stronger encoder; and the robustness analysis (Table V) suggests that the fuzzy membership functions act as a soft regulariser, making the system noticeably more stable than a plain cosine baseline under rule perturbation, Gaussian noise, and threshold variation.

A. Limitations

The results are encouraging, but several limitations are worth flagging openly.

1) English-only evaluation: All experiments were run on QQP [13], [21], which is monolingual English. We have not yet tested the framework on morphologically rich or low-resource languages such as Arabic, Hassaniya or Wolof, where behaviour may differ noticeably [22], [31].

2) Single domain: QQP is community Q&A. Heavily technical domains—biomedical [15], legal, financial—would likely require a domain-adapted encoder and a fresh rule base; we did not investigate this transfer here.

3) Hand-crafted rule base: The 12 Mamdani rules were designed by hand. This is great for transparency, but it does not scale to settings where dozens of similarity signals must be combined; in such regimes, automatic rule induction [17], [18] would probably be needed.

4) Non-end-to-end pipeline: The aggregation layer is intentionally non-differentiable. The downside is that we cannot co-train the encoder and the aggregator with a single loss; end-to-end neuro-fuzzy variants might trade some interpretability for an extra point of accuracy.

5) Computational footprint: The fuzzy aggregation itself is cheap (sub-millisecond per pair), but fine-tuning the SBERT backbone on QQP-scale corpora still demands GPU resources comparable to those of SimCSE [8] or AnglE [9].

B. Future Work

Several directions feel particularly promising on the basis of these limitations.

1) Multilingual similarity: A natural next step is to swap the English SBERT encoder for a multilingual one—multilingual E5 [10] or LaBSE [22] are obvious candidates—and to evaluate on Arabic, French, and African low-resource languages [28], [31].

2) Learnable fuzzy rules: Replacing the static rule base by a data-driven neuro-fuzzy module [18], or even by an LLM-induced rule generator [5], would let the framework scale beyond a hand-crafted setup, ideally without sacrificing rule readability.

3) Domain transfer: Deploying MCESTA in biomedical [15] and legal corpora, where the explainability of the aggregation step is not a luxury but a regulatory requirement [16], [17]. Such deployments naturally build on earlier work on formalising decisional needs to reduce interpretation ambiguity [32].

4) Beyond pairwise similarity: Extending MCESTA from paraphrase detection to ranking and retrieval, with an evaluation on the Massive Text Embedding Benchmark [11].

5) Online and streaming settings: Coupling MCESTA with our earlier work on indexed publish/subscribe systems [33] so that explainable similarity matching can run in real time over big-data streams.

Overall, the take-away of this study is that *explainable multi-criteria aggregation is a useful complement to modern language models, not a step backwards*. The proposed framework strikes a reasonable balance between accuracy, transparency, and stability, and we hope it will serve as a starting point towards similarity learners that are both effective and inspectable.

Enhanced Pied Kingfisher Optimization Algorithm with Hovering Scouts and Foraging Flocks Mechanisms

Aarhus Dela Cruz
Mathematics Department-College of Science,
Bulacan State University,
Bulacan, Philippines 3000

***Abstract*—Population-based metaheuristic algorithms are widely used for solving nonlinear, nonconvex, constrained, and high-dimensional optimization problems. However, many swarm-based optimizers still suffer from premature convergence, loss of population diversity, and weak exploitation of multiple promising regions. To address these limitations, this study proposes the Hovering Scouts and Foraging Flocks Pied Kingfisher Optimizer (HSFFPKO), an enhanced variant of the Pied Kingfisher Optimizer (PKO). The proposed method introduces two complementary mechanisms. The Hovering Scouts mechanism applies scale-aware Gaussian probing with weak global-best guidance to restore local diversity and reduce stagnation, while the Foraging Flocks mechanism organizes the population into temporary subgroups guided by leader–centroid targets under a shrinking search radius. The performance of HSFFPKO was evaluated on the CEC 2017 benchmark suite and nine constrained engineering design problems. In the ablation study at $D = 10$, HSFFPKO achieved the best average rank of 1.67 and obtained 20 wins out of 30 benchmark functions. In the scalability analysis, HSFFPKO remained the best-ranked PKO variant at $D = 30$, $D = 50$, and $D = 100$, with average ranks of 1.37, 1.33, and 1.27, respectively. In the broad comparison with recent optimizers at $D = 30$, HSFFPKO obtained the best overall average rank of 2.60 and the highest number of function wins, with 11 wins out of 30 functions. The Nemenyi post-hoc test showed that HSFFPKO was statistically comparable with the strongest competitors, including BWSMA and GPSOM, while significantly outperforming several other methods. Engineering results further confirmed that HSFFPKO is highly competitive for continuous constrained design problems, although its performance was weaker on the discrete gear-train problem. These results indicate that HSFFPKO is a scalable and competitive PKO variant for continuous numerical and engineering optimization.**

***Keywords*—Exploration-exploitation balance; metaheuristic optimization; numerical optimization; Pied Kingfisher Optimizer; swarm intelligence**

I. Introduction

Optimization problems in computer science, machine learning, operations research, and engineering design are often nonlinear, nonconvex, constrained, and high-dimensional. In many practical cases, gradient information is unavailable, expensive to compute, or unreliable because the objective function is noisy, discontinuous, or treated as a black box. For this reason, population-based metaheuristic algorithms have become widely used alternatives for solving difficult real-parameter optimization problems. Classical and recent swarm-based methods, including Particle Swarm Optimization (PSO), Grey Wolf Optimizer (GWO), Whale Optimization Algorithm (WOA), Salp Swarm Algorithm (SSA/SSO), Bat Algorithm (BA), and other animal-inspired optimizers, have demonstrated strong potential because they combine stochastic exploration with iterative improvement of candidate solutions [1], [2], [3], [4], [5], [6], [7].

Despite these advantages, the design of an effective metaheuristic remains challenging. The no-free-lunch theorem indicates that no single optimization algorithm can be universally superior over all possible problem classes [8]. Therefore, algorithmic improvement usually depends on identifying search weaknesses in a particular optimizer and introducing mechanisms that better control exploration, exploitation, diversity preservation, and convergence stability. In swarm intelligence, excessive exploration may delay convergence, whereas excessive exploitation may cause premature convergence to local optima. This trade-off becomes more difficult in hybrid and composition functions, high-dimensional search spaces, and constrained engineering design problems, where the landscape may contain variable interaction, deceptive basins, and narrow feasible regions [9], [10], [11].

Recent studies show that improving a metaheuristic often requires more than simply changing its biological metaphor. Effective improvements usually introduce specific search mechanisms such as adaptive perturbation, random-walk modification, subgroup cooperation, diversity recovery, leader-guided movement, or local-search refinement. For example, the original Bat Algorithm was later modified through torus-walk-based movement to improve local search and high-dimensional performance [12]. A modified controlled Bat Algorithm further used torus-walk concepts to improve diversity and convergence in numerical optimization and neural-network training [13]. Similarly, an improved Bat Algorithm was applied to neural-network optimization for data classification to reduce local-minimum trapping and improve convergence accuracy [14]. These developments highlight an important trend in recent metaheuristic research: successful variants are usually justified by the search behavior they add, not only by the natural behavior they imitate.

The Pied Kingfisher Optimizer (PKO) is a recent bio-inspired algorithm that models the hunting behavior of the pied kingfisher, *Ceryle rudis*, through perching, hovering, diving, and commensal association [15]. These behaviors provide a useful balance between observation, exploratory movement,

elite-guided exploitation, and cooperative perturbation. However, the baseline PKO can still suffer from two important limitations. First, population diversity may decrease too early when many agents are attracted toward similar regions of the search space. Second, the algorithm does not explicitly organize the population into cooperative subgroups that can search several promising basins in parallel. These limitations can reduce robustness on multimodal, hybrid, and composition landscapes, especially when the search space becomes more complex.

To address these gaps, this study proposes the Hovering Scouts and Foraging Flocks Pied Kingfisher Optimizer (HSFFPKO), an enhanced PKO variant with two complementary mechanisms. The first mechanism, Hovering Scouts (HS), periodically selects a subset of agents and applies scale-aware Gaussian perturbations with a weak directional bias toward the current global best solution. This mechanism is intended to restore individual-level diversity and help agents escape stagnation near local optima. The second mechanism, Foraging Flocks (FF), partitions the population into temporary subgroups and moves each member toward a blended target formed from the flock leader and flock centroid under a shrinking radius. This mechanism is intended to promote coordinated basin-level exploitation while preserving multiple search directions. Thus, HS operates mainly as an individual diversity-recovery mechanism, whereas FF provides group-level coordination and exploitation.

The main contributions of this study are summarized as follows:

- A new PKO variant, called HSFFPKO, is proposed by integrating Hovering Scouts and Foraging Flocks into the baseline PKO search cycle.
- The Hovering Scouts mechanism introduces scale-aware Gaussian probing with weak global-best guidance to improve local diversity and reduce premature convergence.
- The Foraging Flocks mechanism introduces leader–centroid subgroup search to improve coordinated exploitation around promising regions while maintaining population diversity.
- Ablation and scalability analyses are conducted to isolate the individual and combined effects of HS and FF against the baseline PKO at $D = 10$, $D = 30$, $D = 50$, and $D = 100$.
- The proposed method is evaluated on the CEC 2017 benchmark suite and on constrained engineering design problems to assess numerical accuracy, robustness, and practical applicability.
- Nonparametric statistical tests are used to support a cautious comparison with recent metaheuristic optimizers, emphasizing both performance gains and cases where differences from close competitors are not statistically significant.

The remainder of this study is organized as follows: Section II reviews related work on metaheuristic optimization, PKO, and diversity-preserving search mechanisms. Section III presents the baseline PKO and its main search operators. Section IV describes the proposed HSFFPKO, including the Hovering Scouts and Foraging Flocks mechanisms. Section V explains the experimental protocol, benchmark functions, engineering design problems, and statistical procedures. Section VI reports and discusses the ablation results, comparative performance, historical search behavior, and engineering optimization results. Finally, Section VII concludes the study and outlines limitations and future research directions.

II. Related Work

Metaheuristic optimization has developed rapidly because many real-world problems are nonlinear, nonconvex, constrained, and difficult to solve using exact or gradient-based techniques. In such problems, the objective function may be expensive, discontinuous, noisy, or unavailable in closed form. Population-based metaheuristics address this difficulty by maintaining several candidate solutions and improving them through stochastic search rules. However, according to the no-free-lunch theorem, no single optimizer can perform best on all possible optimization problems [8]. This motivates the continuous development of new algorithms and the improvement of existing ones through more effective exploration, exploitation, diversity preservation, and convergence-control mechanisms.

A. Swarm-Based and Bio-Inspired Optimization Algorithms

Swarm intelligence algorithms are among the most widely used metaheuristics because they are simple to implement, derivative-free, and adaptable to many optimization problems. Particle Swarm Optimization (PSO) models social learning among particles and updates candidate solutions using individual and global best information [1]. Grey Wolf Optimizer (GWO) simulates the leadership hierarchy and cooperative hunting process of grey wolves, where alpha, beta, and delta wolves guide the rest of the pack toward promising regions [2]. Whale Optimization Algorithm (WOA) models the bubble-net hunting behavior of humpback whales and alternates between encircling, spiral movement, and global exploration [3]. Salp Swarm Algorithm (SSA), also referred to in some studies as Salp Swarm Optimization (SSO), imitates the chain-like movement of salps and uses leader–follower dynamics to guide the population [4]. The Bat Algorithm (BA) is another important bio-inspired method that uses echolocation-inspired frequency, loudness, and pulse-rate control to balance local and global search [5].

Although these algorithms have been successfully applied to many benchmark and engineering problems, they share common limitations. PSO may converge prematurely when particles rapidly collapse toward the current best position. GWO and WOA can lose population diversity in later iterations because the search becomes increasingly leader-dominated. SSA/SSO may suffer from weak diversity when the chain structure becomes too dependent on the leader. BA may also become trapped in local optima if its local-search process is not sufficiently diversified. These limitations are frequently observed in multimodal, hybrid, composition, and high-dimensional functions, where the search landscape contains many deceptive basins and strong variable interactions [9], [10], [11].

B. Recent Improvements in Metaheuristic Search Mechanisms

Recent metaheuristic research shows that performance improvement usually comes from adding concrete search mechanisms rather than merely proposing a new natural metaphor. Common improvement strategies include adaptive parameter control, chaotic or opposition-based initialization, Gaussian or Levy perturbation, restart strategies, subgroup search, multi-population cooperation, leader–centroid attraction, mutation, and local-search hybridization. These strategies are designed to address two central issues: maintaining enough diversity to avoid premature convergence and increasing exploitation pressure once promising regions have been identified.

Several recent Bat Algorithm variants illustrate this trend. Bangyal *et al.* proposed a modified Bat Algorithm with torus walk to improve global optimization performance, particularly by enhancing the movement strategy and helping the algorithm avoid premature convergence in difficult landscapes [12]. A modified controlled Bat Algorithm later used torus-walk concepts to improve diversity and convergence in numerical optimization and neural-network training [13]. Similarly, an improved Bat Algorithm was used to optimize neural-network training for data classification, showing that algorithmic refinement can improve convergence speed and reduce local-minimum trapping in machine-learning applications [14]. These works are relevant to the present study because the proposed HSFFPKO also improves a baseline bio-inspired optimizer by adding explicit mechanisms for diversity recovery and guided exploitation.

Other recent optimizers also use multi-strategy or population-structuring mechanisms. Manta Ray Foraging Optimization (MRFO) uses chain, cyclone, and somersault foraging behaviors to support exploration and exploitation [16]. Mating-based MRFO further incorporates a mating mechanism to create higher-quality offspring and improve the population during search [17]. Outpost-based Multi-population WOA (OM-WOA) improves WOA by combining outpost individuals with multiple subpopulations, thereby increasing search diversity and reducing the probability of stagnation [18]. Best–Worst Slime Mould Algorithm (BWSMA) improves the original SMA using adaptive greedy selection, best–worst management, and stagnant replacement mechanisms [19]. Group-based PSO with multiple strategies (GPSOM) divides the population into different sub-swarms responsible for exploration, exploitation, and balance between the two phases [20]. Hierarchical Multi-Step GWO (HMS-GWO) improves the standard GWO by assigning different search steps to different wolf roles, which enhances exploration, exploitation, and diversity preservation [21]. These methods show that modern swarm optimization increasingly relies on structured population management, adaptive search rules, and diversity-preserving mechanisms.

C. Pied Kingfisher Optimizer and its Limitations

The Pied Kingfisher Optimizer (PKO) is a recent swarm-based metaheuristic inspired by the hunting behavior and symbiotic relationships of the pied kingfisher, *Ceryle rudis* [15]. PKO models three main search behaviors: perching or hovering for prey, diving for prey, and commensal association. The perching and hovering behaviors support exploration and diversification, the diving behavior strengthens exploitation around promising solutions, and the commensal association introduces cooperative perturbation among agents. Because of this structure, PKO provides a useful balance between global search and local refinement.

However, the baseline PKO still has limitations that motivate further improvement. First, the population can lose diversity when too many individuals are attracted to similar promising regions. Second, the original algorithm does not explicitly maintain several coordinated subgroups that can explore different basins in parallel. Third, although the commensal association operator can introduce cooperative perturbation, it does not directly distinguish between individual-level diversity recovery and group-level basin exploitation. These limitations may reduce robustness on complex functions, especially hybrid and composition functions where the global optimum may be hidden among several deceptive local basins.

D. Position of the Proposed HSFFPKO

The proposed HSFFPKO is positioned as a mechanism-based improvement of PKO. It does not replace the baseline PKO framework; instead, it augments the original search cycle with two complementary mechanisms. Hovering Scouts (HS) introduce self-scaled Gaussian perturbations with weak global-best guidance. This mechanism is related to diversity-recovery and perturbation-based improvement strategies because it allows selected agents to probe nearby regions even after the population has started to converge. Foraging Flocks (FF) introduce temporary subgroup search based on a leader–centroid target and a shrinking radius. This mechanism is related to multi-population and group-based search because it enables several local neighborhoods to be exploited in parallel.

Compared with existing improvement strategies, HSFF-PKO has a distinct design purpose. HS acts at the individual level by reactivating selected agents and reducing local stagnation. FF acts at the subgroup level by coordinating movement around promising local leaders and flock centroids. Therefore, the two mechanisms are intended to be complementary rather than redundant. HS improves local diversity and escape capability, while FF improves coordinated exploitation and basin-level refinement. This two-scale structure differentiates HSFFPKO from single-mechanism variants that rely only on perturbation, only on leader attraction, or only on multi-population division.

Table I summarizes representative related methods and clarifies the position of HSFFPKO with respect to the literature.

Overall, the literature indicates three important research trends. First, recent metaheuristic variants increasingly focus on diversity preservation and stagnation avoidance rather than only faster convergence. Second, subgroup and multi-population strategies are becoming common because they allow different regions of the search space to be explored or exploited simultaneously. Third, perturbation-based mechanisms remain useful when they are controlled and integrated into the main search cycle. HSFFPKO follows these trends by combining scale-aware scout perturbation with temporary flock-based exploitation. This combination addresses the main weaknesses of baseline PKO and provides a clear justification for the proposed algorithm.

TABLE I. COMPARISON OF REPRESENTATIVE METAHEURISTIC ALGORITHMS AND THEIR RELEVANCE TO HSFFPKO

Algorithm	Inspiration	Main mechanism	Limitation / motivation	Relation to HSFFPKO
PSO [1]	Bird flocking	Individual and global best learning	May prematurely converge when particles collapse to the same region	HSFFPKO adds scout perturbation and flock search to preserve diversity
GWO [2]	Wolf hierarchy	Alpha, beta, and delta guided hunting	Leader dependence may reduce diversity	Uses local flock leaders instead of one global hierarchy
WOA [3]	Whale hunting	Encircling, spiral motion, and random search	Can stagnate on high-dimensional or deceptive functions	Uses shrinking flock radius and scout probes for refinement and escape
SSA/SSO [4]	Salp chain	Leader–follower movement	Search may become overly leader-dependent	Forms several temporary flocks instead of one chain
BA [5]	Bat echolocation	Frequency, loudness, pulse rate, and local walk	May require stronger diversity control	HS uses controlled Gaussian probing for local diversity
TW-BA [12]	Enhanced BA	Torus-walk movement	Improves BA for difficult global optimization	Supports modifying baseline algorithms through explicit search operators
MCBA [13]	Controlled BA	Torus-walk diversity and convergence control	Addresses premature convergence and weak local search	Motivates controlled perturbation mechanisms such as HS
IBANN [14]	Improved BA	BA-based neural-network weight optimization	Reduces local-minimum trapping in ANN training	Shows practical value of refining metaheuristics for applied tasks
MRFO [16]	Manta ray foraging	Chain, cyclone, and somersault foraging	Depends on balance among foraging phases	HSFFPKO separates individual scouting and group foraging
MMRFO [17]	Manta ray mating	Mating-based offspring generation	Improves population quality	HSFFPKO improves quality through scouts and leader–centroid flocks
OMWOA [18]	Whale with outposts	Outpost and multi-population search	Designed for high-dimensional search and stagnation reduction	Similar to FF, but implemented inside the PKO framework
BWSMA [19]	Slime mould	Best–worst management and stagnant replacement	Improves convergence and avoids local optima	Strong comparator because it explicitly manages stagnation
GPSOM [20]	Group-based PSO	Sub-swarms for exploration, exploitation, and balance	Addresses high-dimensional complexity and diversity loss	Closely related to FF, but HSFFPKO also adds scout perturbation
HMS-GWO [21]	Hierarchical wolves	Multi-step role-based search	Addresses premature convergence and parameter sensitivity	HSFFPKO differentiates scouts and flocks instead of wolf roles
QSO [7]	Quokka behavior	Environment-driven search and exploitation mixing	Requires effective exploration–exploitation control	Serves as a recent animal-inspired comparator
RCCO [6]	Red-crowned crane	Foraging, roosting, and dance strategies	Performance depends on strategy switching	Serves as a recent biomimetic comparator
PKO [15]	Pied kingfisher	Perching/hovering, diving, and commensalism	May lose diversity and lacks explicit subgroup search	Direct baseline improved by HSFFPKO

III. BASELINE PKO

Since the proposed HSFFPKO is developed as an extension of the Pied Kingfisher Optimizer (PKO), this section briefly reviews the baseline PKO search process [15]. Consider a minimization problem:

$$\min_{X\in\Omega} f(X), \qquad \Omega = [\mathrm{LB}, \mathrm{UB}] \subset \mathbb{R}^D, \tag{1}$$

where, f is the objective function, D is the number of decision variables, and LB and UB are the lower and upper bound vectors. PKO maintains a population of N candidate solutions, called kingfishers. The position of the i-th kingfisher at iteration t is denoted by X_i^t, and the best solution found so far is denoted by X^*.

A. Population Initialization

The initial population is generated uniformly within the feasible search domain:

$$X_{i,d}^0 = \ell_d + r_{i,d}(u_d - \ell_d), \quad i = 1, \ldots, N, \quad d = 1, \ldots, D, \tag{2}$$

where, $r_{i,d} \sim \mathcal{U}(0,1)$, and ℓ_d and u_d are the lower and upper bounds of the d-th variable, respectively. Uniform initialization provides an unbiased starting distribution over the feasible domain, which is important because the initial population can influence both convergence speed and the ability of the optimizer to avoid poor local optima [11].

B. Exploration Through Perching and Hovering

PKO alternates between exploratory and exploitative behaviors inspired by the hunting strategy of the pied kingfisher. During the exploration phase, an agent updates its position using a peer-guided displacement:

$$\widetilde{X}_i^t = X_i^t + \alpha_i^t \odot S_i^t \odot (X_j^t - X_i^t), \quad j \neq i, \tag{3}$$

where, X_j^t is a randomly selected peer, α_i^t is a stochastic scaling vector, $\odot$ denotes element-wise multiplication, and S_i^t is a time-dependent step factor. In PKO, this exploratory movement is implemented through perching and hovering modes. Perching encourages broader directional probing, whereas hovering provides a more localized peer-guided search around the current region.

A representative hovering step factor can be expressed as:

$$S_i^t = B_{i,j}^t - \left(\frac{t}{T}\right)^{1/BF}, \tag{4}$$

where, $B_{i,j}^t$ is a fitness-dependent beating-rate term, BF is the beating factor, and T is the maximum number of iterations. This term decreases the exploratory amplitude as the search progresses, allowing the population to gradually move from broad exploration toward more refined search.

C. Exploitation Through Diving

The diving phase is the main exploitation mechanism of PKO. It moves an agent toward a perturbed elite point associated with the current global best solution. The elite attractor is defined as:

$$b_i^t = X_i^t + [o(t)]^2 \zeta_i X^*, \tag{5}$$

where, $\zeta_i \sim \mathcal{N}(0,1)$ and $o(t)$ is a decreasing control function:

$$o(t) = \exp\left[-\left(\frac{t}{T}\right)^2\right]. \tag{6}$$

The diving update is then given by:

$$\widetilde{X}_i^t = X_i^t + H_i^t \, o(t) \, \alpha_i^t \odot (b_i^t - X^*), \tag{7}$$

where, H_i^t is a hunting-ability coefficient derived from the relative quality of the current agent. This mechanism increases exploitation pressure around the best solution while preserving stochastic perturbation through α_i^t, ζ_i, and the elite attractor b_i^t.

D. Commensal Association

After the main exploratory or exploitative movement, PKO applies a commensal association operator to maintain population diversity. For each agent, a cooperative trial position is generated with probability $PE(t)$:

$$\widetilde{X}_i^t = X_m^t + o(t)\alpha_i^t \odot |X_i^t - X_n^t|, \tag{8}$$

where, X_m^t and X_n^t are randomly selected peers. The probability of applying this operator decreases linearly as:

$$PE(t) = PE_{\max} - (PE_{\max} - PE_{\min})\frac{t}{T}. \tag{9}$$

Thus, commensal association is more active in the early and middle stages of the search and gradually weakens as the algorithm approaches the final exploitation phase.

All candidate solutions generated by PKO are clipped to the feasible bounds. A greedy selection rule is then applied:

$$X_i^{t+1} = \begin{cases} \widetilde{X}_i^t, & \text{if } f(\widetilde{X}_i^t) < f(X_i^t), \\ X_i^t, & \text{otherwise.} \end{cases} \tag{10}$$

This acceptance rule ensures that each accepted movement improves the current solution of the corresponding agent.

The baseline PKO flow in Algorithm 1 shows where the original exploration, exploitation, and cooperative adjustment operators occur. The proposed HSFFPKO preserves this structure but inserts two additional mechanisms, Hovering Scouts and Foraging Flocks, to strengthen individual-level diversity recovery and group-level basin exploitation.

Algorithm 1 Baseline Pied Kingfisher Optimizer

Require: Population size N, maximum iterations T, bounds LB, UB, objective function f
Ensure: Best solution X^*
Initialize N kingfishers uniformly using (2)
Evaluate all agents and set the best solution X^*
for $t = 1$ to T **do**
  Compute the control factor $o(t)$
  for each agent $i = 1, \ldots, N$ **do**
    if $\mathrm{rand} < 0.8$ **then**
      Select a random peer $j \neq i$
      Generate an exploratory trial solution using perching or hovering
    else
      Generate an exploitative trial solution using diving
    Clip the trial solution to [LB, UB]
    Apply greedy selection and update X_i^t if improved
  for each agent $i = 1, \ldots, N$ **do**
    if $\mathrm{rand} < PE(t)$ **then**
      Generate a commensal association trial solution
      Clip the trial solution to [LB, UB]
      Apply greedy selection and update X_i^t if improved
  Update the global best solution X^*
return X^*

IV. The Proposed HSFFPKO

The proposed Hovering Scouts and Foraging Flocks Pied Kingfisher Optimizer (HSFFPKO) is designed to address two limitations of the baseline PKO. First, the population may lose diversity when many agents move toward similar promising regions. Second, the original PKO does not explicitly organize the population into cooperative subgroups that can exploit several promising basins in parallel. To address these issues, HSFFPKO inserts two additional mechanisms into the baseline PKO cycle: Hovering Scouts (HS) and Foraging Flocks (FF). HS acts at the individual level by perturbing selected agents to recover local diversity, whereas FF acts at the subgroup level by coordinating movement around local flock leaders and flock centroids.

A. Hovering Scouts

The Hovering Scouts mechanism is motivated by the idea that a small number of agents can perform exploratory probing while the rest of the population continues the regular PKO search cycle. At iteration t, let $S_t \subseteq \{1, \ldots, N\}$ denote the set of selected scouts:

$$|S_t| = \max(1, \lfloor \gamma N \rfloor), \tag{11}$$

where, $\gamma \in (0,1)$ is the scout rate. Thus, at least one scout is activated at each scouting event, and the number of scouts increases proportionally with the population size.

For each selected scout $i \in S_t$, HS first generates a self-scaled Gaussian probe:

$$Y_i^t = X_i^t + X_i^t \odot G_i^t, \qquad G_i^t \sim \mathcal{N}(0, I_D), \tag{12}$$

where, G_i^t is a D-dimensional Gaussian random vector and $\odot$ denotes element-wise multiplication. This operation makes the perturbation scale-aware because variables with larger magnitudes receive proportionally larger exploratory variation. To prevent the scout from becoming purely random, a weak best-referenced directional component is then added:

$$\widetilde{X}_i^t = Y_i^t + \eta\,\sigma_i^t \odot (X^* - Y_i^t), \tag{13}$$

where, $\eta > 0$ is the scout bias coefficient, X^* is the current global best solution, and $\sigma_i^t \in \{-1, +1\}^D$ is a random sign vector. The sign vector randomizes the coordinate-wise direction of the best-referenced movement, while η controls its magnitude.

The candidate scout position is clipped to the search bounds and accepted using greedy selection:

$$X_i^{t+1} = \begin{cases} \widetilde{X}_i^t, & \text{if } f(\widetilde{X}_i^t) \le f(X_i^t), \\ X_i^t, & \text{otherwise.} \end{cases} \tag{14}$$

The HS operator has three intended effects. First, it reintroduces local diversity around selected agents after the population has started to contract. Second, it helps revive stagnant trajectories by allowing scouts to probe nearby unexplored regions. Third, the weak best-referenced term helps maintain search orientation without forcing all agents to move directly toward the same solution. In this study, HS is applied every iteration with scout rate $\gamma = 0.10$ and bias coefficient $\eta = 0.05$.

B. Foraging Flocks

The Foraging Flocks mechanism is introduced to provide coordinated subgroup search. Instead of moving the whole population toward a single global attractor, FF temporarily divides the population into smaller flocks so that different regions can be searched in parallel. Every T_f iterations, the population is randomly partitioned into K non-overlapping flocks:

$$\{1, \ldots, N\} = \bigcup_{k=1}^{K} F_k, \qquad F_k \cap F_{k'} = \varnothing \quad (k \neq k'). \tag{15}$$

For each flock F_k, the centroid is computed as:

$$C_k^t = \frac{1}{|F_k|} \sum_{i \in F_k} X_i^t. \tag{16}$$

The local flock leader is the best member of the flock:

$$q_k = \arg\min_{i \in F_k} f(X_i^t), \qquad L_k^t = X_{q_k}^t. \tag{17}$$

The flock then forms a blended target:

$$T_k^t = \phi L_k^t + (1 - \phi) C_k^t, \qquad 0 \le \phi \le 1, \tag{18}$$

where, ϕ controls the exploitation strength. A larger ϕ places more emphasis on the best member of the flock, whereas a smaller ϕ gives more influence to the centroid and therefore encourages broader group-level exploration.

For each member $i \in F_k$, FF generates a trial position:

$$\widetilde{X}_i^t = X_i^t + \xi_i^t \odot (T_k^t - X_i^t) + R_i^t, \tag{19}$$

where, $\xi_i^t \sim \mathcal{U}(0,1)^D$ is a random scaling vector and

$$R_i^t \sim \mathcal{N}(0, \rho_m^2 I_D) \tag{20}$$

is a Gaussian local-search term. The foraging radius decreases after each flocking event according to:

$$\rho_m = \rho_0 \delta^m, \qquad 0 < \delta < 1, \tag{21}$$

where, ρ_0 is the initial radius, δ is the radius decay factor, and m is the number of flocking events already performed.

The FF candidate is clipped to the feasible bounds and accepted if it improves the current solution. This mechanism acts on a larger scale than HS. In the early stage, the larger radius allows different flocks to explore several basins. In the middle stage, flock leaders and centroids guide coordinated exploitation of promising regions. In the late stage, the shrinking radius supports more precise local refinement. In this study, FF uses $K = 5$ flocks, is applied every $T_f = 5$ iterations, uses exploitation weight $\phi = 0.60$, initial radius fraction $\rho_0 = 0.10$, and radius decay $\delta = 0.95$.

C. Integrated Search Process

HSFFPKO preserves the main PKO cycle and inserts HS and FF as additional refinement stages. Each iteration begins with the original PKO exploration or exploitation update, followed by commensal association. The global best solution is then updated. After that, HS is applied to selected scouts, and FF is applied periodically to temporary flocks. Each generated candidate solution is clipped to the feasible domain and accepted using the same greedy rule used in PKO.

Algorithm 2 shows that HSFFPKO is a layered extension of PKO rather than a replacement for it. The original perching, hovering, diving, and commensal association operators remain unchanged. HS and FF are inserted after the baseline PKO update to provide additional search pressure at two different levels: individual-level perturbation and subgroup-level coordination.

D. Computational Complexity

Let C_f denote the computational cost of one objective-function evaluation. The baseline PKO evaluates N agents over T iterations and performs vector operations of dimension D. Therefore, its computational cost can be expressed as:

$$\mathcal{O}\big(TN(C_f + D)\big). \tag{22}$$

HS adds a scout update for approximately γN agents per iteration. Each scout update requires D-dimensional vector operations and one additional objective-function evaluation. Thus, the HS overhead is:

$$\mathcal{O}\big(T\gamma N(C_f + D)\big). \tag{23}$$

Algorithm 2 Hovering Scouts and Foraging Flocks Pied Kingfisher Optimizer

Require: Population size N, maximum iterations T, bounds LB, UB, objective function f
Require: Scout rate γ, scout bias η, number of flocks K, flocking interval T_f, exploitation weight ϕ, initial radius ρ_0, radius decay δ
Ensure: Best solution X^*
Initialize N kingfishers uniformly within [LB, UB]
Evaluate all agents and identify the initial best solution X^*
Set $m = 0$, where m counts the number of flocking events
for $t = 1$ to T **do**
  for each agent $i = 1, \ldots, N$ **do**
    if $\mathrm{rand} < 0.8$ **then**
      Generate a PKO exploratory trial solution using perching or hovering
    else
      Generate a PKO exploitative trial solution using diving
    Clip the trial solution to [LB, UB]
    Apply greedy selection
  Apply PKO commensal association and update X^*
  Select S_t with $|S_t| = \max(1, \lfloor \gamma N \rfloor)$
  for each scout $i \in S_t$ **do**
    Generate a scout candidate using HS
    Clip the candidate to [LB, UB]
    Apply greedy selection
  if $t \bmod T_f = 0$ **then**
    Randomly partition the population into K flocks
    Set $\rho_m = \rho_0 \delta^m$
    for each flock F_k **do**
      Compute centroid C_k^t and local leader L_k^t
      Compute blended target $T_k^t = \phi L_k^t + (1 - \phi) C_k^t$
      for each member $i \in F_k$ **do**
        Generate a flock candidate using FF
        Clip the candidate to [LB, UB]
        Apply greedy selection
    Set $m = m + 1$
  Update the global best solution X^*
return X^*

FF is applied every T_f iterations. At each flocking event, the population is partitioned into K flocks, and centroids, local leaders, and flock candidate positions are computed. Since each agent belongs to exactly one flock, the total vector-operation cost per flocking event is linear in ND, and the objective-function cost is linear in NC_f. Therefore, the FF overhead is:

$$\mathcal{O}\left(\frac{T}{T_f} N(C_f + D)\right). \tag{24}$$

Combining the baseline PKO, HS, and FF components gives:

$$\mathcal{O}\left(TN(C_f + D) + T\gamma N(C_f + D) + \frac{T}{T_f} N(C_f + D)\right). \tag{25}$$

Since γ and T_f are fixed control parameters, the asymptotic complexity remains:

$$\mathcal{O}\big(TN(C_f + D)\big), \tag{26}$$

which is the same order as the baseline PKO. Therefore, HSFFPKO does not change the asymptotic complexity class of PKO. Its additional cost is a constant-factor overhead caused by scout probing and periodic flock coordination. The memory complexity also remains:

$$\mathcal{O}(ND), \tag{27}$$

because the algorithm stores the population, fitness values, and a small number of auxiliary vectors for scout and flock operations.

V. Experimental Protocol

The proposed HSFFPKO was evaluated using two complementary test sets: the IEEE CEC 2017 single-objective real-parameter benchmark suite and nine constrained engineering design problems. The CEC 2017 suite contains 30 benchmark functions grouped into unimodal, multimodal, hybrid, and composition categories, as summarized in Table II. These categories provide different levels of difficulty: unimodal functions mainly evaluate convergence accuracy, multimodal functions test the ability to escape local optima, hybrid functions assess performance under mixed variable interactions, and composition functions evaluate robustness against shifted, rotated, and deceptive landscapes [22].

TABLE II. CEC 2017 Benchmark Categories and Experimental Setting.

Category	Functions	Domain	Main challenge
Unimodal	F1–F4	$[-100, 100]^D$	convergence speed and numerical precision
Multimodal	F5–F10	$[-100, 100]^D$	avoidance of many local optima
Hybrid	F11–F20	$[-100, 100]^D$	variable interaction and mixed landscape components
Composition	F21–F30	$[-100, 100]^D$	shifted, rotated, and deceptive global structures
Runs	30 independent runs per function		
Budget	$1000D$ function evaluations		
Statistics	Friedman test followed by Nemenyi post-hoc analysis		

For the CEC 2017 experiments, the search domain was fixed to $[-100, 100]^D$, and the maximum number of function evaluations was set to $1000D$ for each algorithm. Each algorithm was executed for 30 independent runs on each benchmark function to account for stochastic variability. The ablation study was first conducted at $D = 10$ to isolate the individual and combined contributions of Hovering Scouts and Foraging Flocks under a controlled computational setting. To further verify scalability, the four PKO-based variants were also evaluated at $D = 30$, $D = 50$, and $D = 100$. The broader comparison with recent optimizers was emphasized at $D = 30$, which provides a more demanding setting for assessing the overall competitiveness of HSFFPKO against state-of-the-art algorithms.

To ensure a fair comparison, all algorithms were evaluated using the same benchmark functions, dimensionality, search bounds, maximum function-evaluation budget, and number of independent runs. For HSFFPKO, the parameter values were fixed across all CEC 2017 functions: scout rate $\gamma = 0.10$, scout bias coefficient $\eta = 0.05$, number of flocks $K = 5$, flocking interval $T_f = 5$, exploitation weight $\phi = 0.60$, initial radius fraction $\rho_0 = 0.10$, and radius decay factor $\delta = 0.95$. The parameters of the competing algorithms were set according to their original studies or commonly recommended values to avoid problem-specific tuning bias.

Performance was assessed using the mean best objective value, standard deviation, and mean error with respect to the known optimum of each CEC 2017 function. Since metaheuristic algorithms are stochastic and their performance distributions are not guaranteed to satisfy normality assumptions, nonparametric statistical tests were used for algorithm comparison [23]. First, the Friedman test was applied to determine whether significant differences existed among the compared algorithms across the benchmark functions. When the Friedman test indicated significant differences, the Nemenyi post-hoc test was used to compare the average ranks and identify statistically meaningful pairwise differences. The statistical analysis was used not only to identify the best-ranked algorithm but also to determine whether HSFFPKO was significantly better than, or statistically comparable with, its closest competitors.

The engineering test set included nine constrained design problems: cantilever beam, gear train, I-beam, pressure vessel, speed reducer, tension/compression spring, three-bar truss, tubular column, and welded beam design. These problems complement the CEC 2017 suite because they involve nonlinear constraints, different numbers of decision variables, different sensitivity levels, and, in the case of the gear train problem, discrete integer structure. Thus, the engineering experiments provide a second-stage assessment of whether the proposed optimizer remains effective beyond synthetic benchmark functions and can be applied to practical constrained optimization problems [24].

For the engineering problems, the same general evaluation logic was used: each algorithm was run independently multiple times under a fixed evaluation budget, and performance was compared using solution quality, robustness, and runtime behavior. The best, mean, and standard deviation of the objective values were recorded. The results were then interpreted together with the CEC 2017 findings to determine whether HSFFPKO provides consistent practical advantages or whether its performance depends on the structure of the optimization problem.

VI. Results and Discussion

A. Ablation Analysis at $D = 10$

The ablation study was conducted to determine the individual and combined effects of the two proposed mechanisms. Four variants were compared: the baseline PKO, PKO with Hovering Scouts only (HSPKO), PKO with Foraging Flocks only (FFPKO), and the full HSFFPKO. This design makes it possible to examine whether HS and FF provide complementary contributions or whether one mechanism dominates the performance improvement.

The Friedman test produced $\chi^2 = 27.72$ with $p = 4.16 \times 10^{-6}$, indicating statistically significant differences among the four variants. As summarized in Table III, HSFFPKO obtained the best average rank of 1.67 and achieved the highest number of function wins, with 20 wins out of 30 CEC 2017 functions. HSPKO ranked second with an average rank of 2.27 and six wins, followed by the baseline PKO and FFPKO. These results indicate that the full integration of HS and FF provides the strongest overall performance among the tested variants.

The distribution of wins provides further insight into the role of each mechanism. HSFFPKO achieved the strongest performance on the unimodal, multimodal, and hybrid categories, suggesting that the combination of scout-based perturbation and flock-based coordination improves both convergence accuracy and robustness on complex landscapes. HSPKO achieved its strongest results on several composition functions, which indicates that the Hovering Scouts mechanism is especially useful for reactivating local diversity in deceptive search spaces. In contrast, FFPKO alone produced fewer wins, suggesting that flock-based exploitation is most effective when combined with the diversity-recovery ability of HS.

TABLE III. Ablation Summary on CEC 2017 at $D = 10$. Category Counts Record how many Function Wins were Obtained in each Family.

Algorithm	Avg. rank	Wins	U	M	H	C
HSFFPKO	**1.67**	**20**	**3**	**6**	**8**	3
HSPKO	2.27	6	0	0	2	**4**
PKO	2.70	3	0	0	0	3
FFPKO	3.37	1	1	0	0	0

The Nemenyi post-hoc test further clarifies these findings. HSFFPKO was significantly better than the baseline PKO ($p = 0.010$) and FFPKO ($p = 2.0 \times 10^{-6}$), but it was not significantly different from HSPKO ($p = 0.273$). This result should be interpreted carefully. It shows that HS is the dominant contributor to the improvement over baseline PKO, while FF provides complementary stability and additional exploitation capability. Therefore, the contribution of FF is not that it always dominates as a stand-alone mechanism, but that it strengthens the full HSFFPKO framework when combined with HS.

Function-level results provide more detailed evidence. On the unimodal functions, HSFFPKO obtained the best results on F1–F3, showing strong convergence precision. On the hybrid functions, HSFFPKO achieved the best result on most cases, including F11, F12, F14–F18, and F20. This is important because hybrid functions combine different base landscapes and therefore require a balance between exploration and exploitation. The main exceptions are F13 and F19, where HSPKO obtained the lowest mean error. These exceptions show that the proposed full variant is not uniformly dominant on every function, but it remains the most reliable variant across the whole benchmark set (see Table IV to Table VI).

The composition-function results reveal an important pattern. HSFFPKO remained competitive and obtained the best result on F23, F26, and F30, but HSPKO and PKO were better on some other composition functions. This suggests that the added flocking mechanism improves robustness on some complex landscapes but may occasionally introduce additional local contraction that is less beneficial when the landscape requires broader exploration. This observation is consistent with the no-free-lunch principle and supports a cautious interpretation of the ablation results: HSFFPKO provides the best overall balance among the tested variants, although some specific functions may favor simpler or HS-only search behavior.

B. Scalability Analysis at $D = 30$, $D = 50$, and $D = 100$

To further address the scalability of the proposed mechanisms, the four PKO-based variants were evaluated on higher-

dimensional CEC 2017 benchmark functions at $D = 30$, $D = 50$, and $D = 100$. This experiment was designed to determine whether the performance advantage observed in the $D = 10$ ablation study remains stable as the dimensionality of the search space increases. The same experimental protocol was used, including the search range $[-100, 100]^D$, the evaluation budget of $1000D$ function evaluations, and 30 independent runs per function.

Table VII shows that the Friedman test detected statistically significant differences among the four PKO variants at all tested dimensions. In each case, HSFFPKO obtained the best average rank. Its rank improved from 1.37 at $D = 30$ to 1.33 at $D = 50$ and 1.27 at $D = 100$, indicating that the combined Hovering Scouts and Foraging Flocks mechanisms remain effective as the dimensionality of the search space increases.

The win-count results in Table VIII further support the scalability of HSFFPKO. At $D = 30$, HSFFPKO obtained the best result on 24 out of 30 functions. At $D = 50$, it remained best on 23 functions, and at $D = 100$, it achieved the best result on 25 functions. In contrast, the baseline PKO obtained two wins at $D = 30$ but no wins at $D = 50$ and $D = 100$. HSPKO and FFPKO occasionally produced the best result on a small number of functions, but neither variant matched the consistency of the full HSFFPKO.

These results indicate that the two proposed mechanisms are not only useful in low-dimensional settings but also remain effective under higher-dimensional search conditions. The Hovering Scouts mechanism helps restore diversity when the search space becomes larger, while the Foraging Flocks mechanism supports coordinated exploitation of multiple promising regions. Their combination allows HSFFPKO to maintain strong rank performance and high function-win counts as dimensionality increases.

Overall, the scalability analysis strengthens the ablation findings. The $D = 10$ experiment shows that HS and FF improve the baseline search process, while the $D = 30$, $D = 50$, and $D = 100$ experiments show that the full HSFFPKO remains reliable as the dimensionality of the problem increases. Therefore, the proposed mechanisms address not only mechanism-level improvement but also high-dimensional robustness.

C. Comparison with Recent Optimizers at $D = 30$

The broader comparison evaluated HSFFPKO against nine recent metaheuristic optimizers: BWSMA, GPSOM, HMS-GWO, MLSO [25], MMRFO, OMWOA, QSO, RCCO, and SSO. The compared methods and their main design features are summarized in Table IX. This comparison was conducted at $D = 30$ to evaluate the competitiveness of HSFFPKO under a more demanding dimensional setting than the ablation study.

The Friedman test across the 30 CEC 2017 functions yielded $\chi^2 = 138.92$ with $p = 1.727 \times 10^{-25}$, confirming that the rank differences among the compared optimizers are statistically significant. As shown in Table X, HSFFPKO obtained the best overall average rank of 2.60 and the highest number of

TABLE VII. FRIEDMAN TEST RESULTS FOR SCALABILITY EVALUATION OF PKO VARIANTS

D	Friedman χ^2	p-value	Best algorithm	Best rank
30	35.64	8.92×10^{-8}	HSFFPKO	1.37
50	34.64	1.45×10^{-7}	HSFFPKO	1.33
100	39.76	1.20×10^{-8}	HSFFPKO	1.27

function wins, with 11 wins out of 30 functions. GPSOM and BWSMA were the closest competitors, with average ranks of 2.93 and 3.00, respectively. BWSMA achieved eight function wins, while GPSOM achieved six.

The category-level results show that HSFFPKO was the only algorithm with wins across all four benchmark families. It achieved one win on unimodal functions, three wins on multimodal functions, three wins on hybrid functions, and four wins on composition functions. This distribution suggests that HSFFPKO is not specialized for only one type of landscape. Instead, its strength comes from consistent performance across different search conditions. BWSMA was particularly strong on hybrid functions, while GPSOM was highly competitive on hybrid and composition functions. These results indicate that the leading algorithms form a close top-performing group rather than a single method dominating all functions.

The function-level results in Table XI, Table XII, and Table XIII support this interpretation. HSFFPKO achieved the best result on representative functions such as F1, F21, F25, F27, and F29, and remained competitive on several other functions. BWSMA performed best on functions such as F5, F23, and F24, while GPSOM produced the best results on F22 and F30. Therefore, the comparative results show that HSFFPKO has the strongest overall rank and broadest category coverage, but the performance advantage is function-dependent.

The representative numerical results show that HSFFPKO often combines low mean error with competitive standard deviation. However, the results also show that the advantage is not uniform across all functions. Some functions favor BWSMA, GPSOM, MLSO, or QSO. This confirms that HSFFPKO should be interpreted as a strong and balanced optimizer across the suite rather than as an algorithm that dominates every individual test case.

Table XIV gives the Nemenyi post-hoc comparison between HSFFPKO and each competitor. The results show that HSFFPKO is not statistically significantly different from BWSMA, GPSOM, and MLSO at the adopted significance level. In contrast, HSFFPKO is significantly better than QSO, MMRFO, HMSGWO, SSO, RCCO, and OMWOA. This distinction is important. HSFFPKO should not be described as universally superior to all competing algorithms. A more accurate conclusion is that HSFFPKO achieved the best overall rank and function-win count, while remaining statistically comparable to the strongest competitors, especially BWSMA and GPSOM.

Thus, the supported claim is that HSFFPKO is a top-tier and well-balanced optimizer for the tested CEC 2017 setting. Its main advantage is not absolute dominance on every function, but strong and stable behavior across unimodal, multimodal, hybrid, and composition landscapes.

D. Historical Search Behavior

To further examine the search dynamics of HSFFPKO, historical search visualizations were generated for four representative CEC 2017 functions at $D = 30$: F1 as a unimodal function, F5 as a multimodal function, F13 as a hybrid function, and F23 as a composition function. For each function, the visualization includes the landscape view, the projected search distribution, the relative discrepancy curve, and the mean fitness curve. These plots provide qualitative evidence of how the population moves, contracts, and refines solutions during the optimization process.

Fig. 1 shows the behavior of HSFFPKO on the unimodal function F1. The population rapidly moves toward the optimal region, and the discrepancy curve decreases smoothly. The mean fitness curve also drops sharply in the early iterations before gradually flattening, indicating fast convergence followed

TABLE VIII. SUMMARY OF PKO-VARIANT PERFORMANCE ACROSS HIGHER DIMENSIONS ON THE CEC 2017 BENCHMARK SUITE

Algorithm	$D = 30$		$D = 50$		$D = 100$	
	Avg. rank	Wins	Avg. rank	Wins	Avg. rank	Wins
HSFFPKO	**1.37**	**24**	**1.33**	**23**	**1.27**	**25**
HSPKO	2.67	2	2.67	4	2.60	2
PKO	2.67	2	2.87	0	2.93	0
FFPKO	3.30	2	3.13	3	3.20	3

TABLE IX. COMPARED ALGORITHMS AND THE MAIN DESIGN FEATURES EMPHASIZED IN THE EXPERIMENTS

Algorithm	Core search idea	Key settings
HSFFPKO	PKO augmented with Hovering Scouts and Foraging Flocks for local diversity and group-level exploitation	scout rate 0.10, scout bias 0.05, five flocks, flocking every five iterations, exploitation weight 0.60, radius fraction 0.10, radius decay 0.95
BWSMA	best–worst population partitioning with adaptive greedy and stagnation-reset mechanisms	reset probability 0.03, best/worst grouping, covariance-based dominant-set search
GPSOM	structured multi-swarm optimizer with explicit exploration, exploitation, and equilibrium blocks	three sub-swarms (20%/20%/60%) with time-varying exploration and exploitation schedules
HMSGWO	Grey Wolf variant with hierarchical approval, omega radius, and alpha/beta schedules	canonical GWO control $a(t)$ plus multiple adaptive coefficients
MLSO	lion-inspired search with mutation and roulette-like interaction	mutation probability decays from 0.25 to 0.02 with local king-step scaling
MMRFO	manta-ray based foraging with chain, cyclone, mating, and $\mu + \lambda$ selection	stochastic chain/cyclone steps with mating-based offspring generation
OMWOA	Whale Optimization with outpost scouting and multi-population organization	WOA coefficient schedule, outpost perturbation, axis nudges, multiple subpopulations
QSO	quokka-inspired search driven by environmental and drought parameters	environment factors and exploitation mixing tied to normalized time t/T
RCCO	red-crowned crane strategy switching between foraging, roosting, and dance behaviors	strategy toggle probability with time-varying long-distance and roost steps
SSO	salp-based search strengthened by stagnation handling and local search	SSA control schedule, stagnation trigger, and local recovery attempts

TABLE X. COMPARATIVE SUMMARY ON CEC 2017 AT $D = 30$

Algorithm	Avg. rank	Wins	U	M	H	C
HSFFPKO	**2.60**	**11**	**1**	**3**	3	**4**

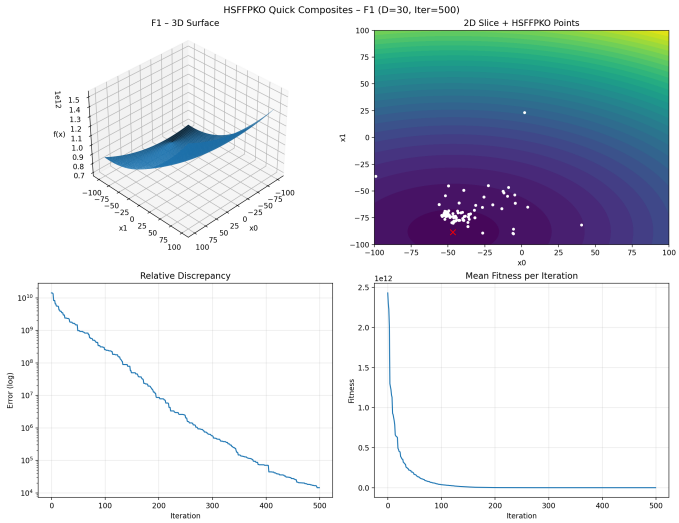

Fig. 1. Historical search on the unimodal function F1 at $D = 30$.

by local refinement. This behavior is expected for a unimodal landscape, where the main requirement is convergence speed and numerical precision.

Fig. 2 presents the behavior on the multimodal function F5. Compared with F1, convergence is slower and more stepwise because the landscape contains many local optima. The search points remain more dispersed during the earlier iterations, which suggests that the algorithm preserves exploration before committing to a promising basin. The subsequent reduction in discrepancy and mean fitness indicates that HSFFPKO can gradually escape poorer regions and refine the population around better solutions.

Fig. 3 shows the search behavior on the hybrid function F13. The population remains partially dispersed, reflecting the difficulty of optimizing a function composed of different landscape components. The mean fitness improves rapidly at first, while the discrepancy curve decreases more gradually. This suggests that HSFFPKO can identify promising regions early, but final refinement is more difficult when several landscape structures interact.

Fig. 4 illustrates the behavior on the composition function F23. The population moves toward the promising region, but some dispersion remains because the function contains shifted

and combined components. The staircase-like improvement in the discrepancy and mean fitness curves suggests that the algorithm continues to discover better basins during the search rather than converging immediately to a single region.

Overall, the historical search results support the quantitative findings. HSFFPKO converges efficiently on simpler landscapes and maintains enough diversity to continue improving on more deceptive functions. However, the visualizations also show that final localization remains more challenging on hybrid and composition functions, which motivates future work on adaptive parameter control or stronger terminal local search.

E. Engineering Design Problems

The engineering design experiments were conducted to determine whether the benchmark performance of HSFFPKO transfers to constrained real-world optimization problems. The test set includes continuous constrained problems, low-dimensional design problems, and one discrete integer problem. This allows the practical behavior of HSFFPKO to be evaluated under different types of engineering constraints.

As summarized in Table XV, HSFFPKO achieved the best standalone result on the pressure vessel problem and tied for the best result on the I-beam, speed reducer, spring, three-bar

truss, and tubular column problems. On the cantilever beam and welded beam problems, BWSMA produced slightly better results, although HSFFPKO remained highly competitive. The main exception is the gear train problem, where HMSGWO obtained a better objective value than HSFFPKO, likely because this benchmark has a discrete integer search structure that is less naturally aligned with the continuous perturbation and flocking operators used in HSFFPKO.

The pressure vessel result is particularly important because it indicates that HSFFPKO can be effective on nonlinear constrained continuous design problems. The tied-best results on several other engineering problems further show that the proposed algorithm is not limited to synthetic benchmark functions. However, the gear train result reveals a limitation of the current design. Since the gear train problem has a discrete integer structure, the continuous perturbation and flocking mechanisms of HSFFPKO may be less naturally suited to the

TABLE XV. CONDENSED ENGINEERING BENCHMARK RESULTS

Problem	Vars	Winning algorithm(s) and best mean	HSFFPKO outcome	Interpretation
Cantilever beam	5	BWSMA, 1.339956316	1.339957370; competitive	near-tie on a smooth constrained continuous problem
Gear train	4 int.	HMSGWO, 2.70×10^{-12}	5.70×10^{-11}; weaker	discrete ratio matching favors a different search dynamic
I-beam	4	GPSOM and HSFFPKO, 98.59387445	tied-best	stable convergence with negligible variance
Pressure vessel	4	HSFFPKO, 6049.858062	best overall	strongest exploitation under nonlinear constraints
Speed reducer	7	BWSMA, GPSOM, HSFFPKO, MLSO, 60503335.93	tied-best	several methods can reach the optimum on this case
Spring	3	GPSOM, HSFFPKO, RCCO, 0.001350022	tied-best	machine-precision convergence by multiple methods
Three-bar truss	2	all methods, 0.382842712	tied-best	problem is easy enough that ranking is not discriminative
Tubular column	2	BWSMA, HSFFPKO, MLSO, OMWOA, RCCO, SSO, 666.6666654	tied-best	another benchmark with many exact ties
Welded beam	4	BWSMA, 2.845786325	2.848179512; competitive	BWSMA holds a small edge on this nonlinear design

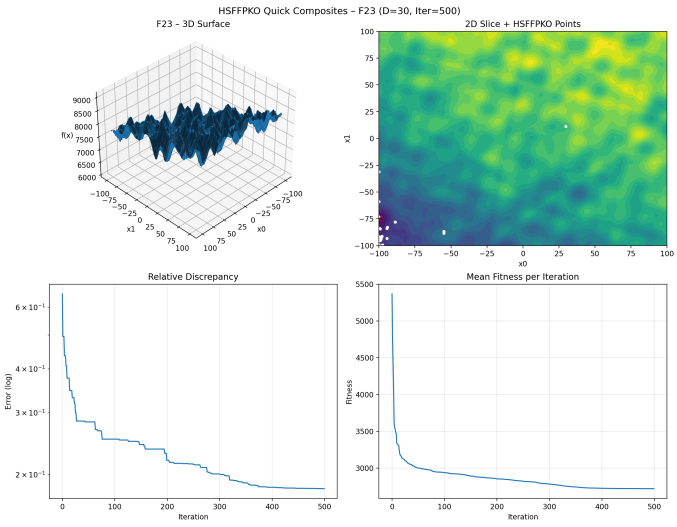

Fig. 4. Historical search on the composition function F23 at $D = 30$.

search space. In this case, the coordinated continuous basin search introduced by FF does not provide the same advantage that it provides on continuous problems.

The overall Friedman ranking on the engineering set places HSFFPKO first with an average rank of 2.67, followed closely by BWSMA with 2.72 and GPSOM with 3.72. This confirms that HSFFPKO is among the strongest methods for the engineering test set. Nevertheless, the results also support a cautious interpretation: HSFFPKO is highly competitive for continuous nonlinear constrained optimization, but specialized or more discrete-aware operators may be needed for integer or mixed-integer design problems.

F. Discussion

The results can be interpreted by viewing HSFFPKO as a layered search process. The baseline PKO already provides exploration through perching and hovering, exploitation through diving, and additional diversity through commensal association. However, the baseline method does not explicitly separate individual-level diversity recovery from subgroup-level basin exploitation. HS and FF were designed to address these two roles.

The ablation results show that HS is the dominant contributor to the performance gain. This is supported by the strong rank of HSPKO and the non-significant difference between HSPKO and HSFFPKO in the post-hoc test. The reason is that HS directly reactivates selected agents through scale-aware Gaussian probing, which helps reduce premature convergence and improves local diversity. FF, on the other hand, is more useful as a complementary mechanism because it organizes the population into temporary flocks and promotes coordinated exploitation around leader–centroid targets. The full HSFFPKO benefits from both mechanisms, but the improvement is not uniform across all function types.

The comparison with recent optimizers shows that HSFFPKO is a strong general-purpose optimizer. It achieved the best overall Friedman rank and the largest number of function wins at $D = 30$. However, the Nemenyi test shows that its differences from BWSMA and GPSOM are not statistically significant. Thus, HSFFPKO belongs to the top-performing group and offers the best overall balance in the present experiments.

G. Practical Implications

From a practical perspective, HSFFPKO has three main advantages. First, it is simple to integrate into the baseline PKO because HS and FF are inserted as additional operators without changing the main PKO structure. Second, it maintains the same asymptotic complexity class as PKO, which makes the additional search capability computationally manageable. Third, it performs well across both benchmark functions and constrained engineering problems, suggesting that it can be useful for practical optimization tasks where the search landscape is unknown.

The engineering results suggest that HSFFPKO is particularly suitable for continuous nonlinear constrained optimization problems. Its performance on the pressure vessel

problem and its tied-best results on several classical design problems indicate that the proposed mechanisms can improve practical search behavior. The algorithm is therefore promising for engineering applications where objective functions are expensive, nonlinear, or difficult to differentiate.

H. Limitations

Despite its strong overall performance, HSFFPKO has several limitations. First, although the scalability analysis shows that HSFFPKO remains effective at $D = 30$, $D = 50$, and $D = 100$, the full comparison with all recent optimizers was emphasized at $D = 30$. Future work should extend the broad multi-algorithm comparison to higher dimensions to determine whether the same relative ranking among HSFFPKO, BWSMA, GPSOM, and other competitors remains stable under larger-scale settings.

Second, the proposed mechanisms are mainly designed for continuous search spaces. The weaker result on the discrete gear train problem suggests that HSFFPKO may require discrete or mixed-integer adaptations for problems with integer variables. Third, the current parameter settings were fixed across all benchmark functions. Although this supports fairness and simplicity, adaptive control of scout rate, scout bias, flocking interval, exploitation weight, and radius decay may further improve robustness.

Finally, the historical search visualizations show that final refinement remains difficult on some hybrid and composition functions. This suggests that HSFFPKO could benefit from a stronger terminal local-search procedure, adaptive radius control, or hybridization with problem-specific refinement operators.

VII. Conclusion

This study presented HSFFPKO, an enhanced variant of PKO that integrates Hovering Scouts and Foraging Flocks to improve diversity preservation, coordinated basin search, and late-stage refinement. HS performs scale-aware local probing with a weak directional bias toward the current best solution, while FF creates temporary subgroups that search around leader–centroid targets under a shrinking radius. The proposed method preserves the simple structure of PKO while adding two complementary search mechanisms that operate at different scales.

The experimental results show that HSFFPKO provides strong and consistent performance across benchmark and engineering problems. In the ablation study at $D = 10$, HSFFPKO achieved the best average rank of 1.67 and obtained 20 wins out of 30 CEC 2017 functions. In the scalability analysis, HSFFPKO remained the best PKO-based variant at $D = 30$, $D = 50$, and $D = 100$, with average ranks of 1.37, 1.33, and 1.27, respectively. In the broad comparison with recent optimizers at $D = 30$, HSFFPKO obtained the best overall average rank of 2.60 and the largest number of function wins. However, the Nemenyi post-hoc test showed that HSFFPKO was statistically comparable with BWSMA and GPSOM, indicating that it should be interpreted as a top-tier optimizer rather than a universally dominant method.

The engineering results further confirmed the practical relevance of HSFFPKO. The proposed algorithm achieved the best result on the pressure vessel problem and tied for the best result on several other constrained design problems. Nevertheless, its weaker result on the discrete gear-train problem suggests that future work should develop discrete or mixed-integer variants of HSFFPKO. Other future directions include adaptive parameter control, stronger local exploitation on deceptive hybrid and composition functions, surrogate-assisted variants for expensive optimization, and extension to multi-objective optimization.

A Lightweight Explainable Hybrid Deep Learning Approach for Early Skin Disease Detection

Mohammad Barr
Department of Electrical Engineering, College of Engineering
Northern Border University, Arar 91431, Saudi Arabia

***Abstract*—Early detection of skin pathology is critical for patient survival and treatment effectiveness, particularly in the case of aggressive malignancies such as melanoma. In this study, we propose a lightweight and explainable hybrid deep learning approach for early identification of skin diseases. The proposed approach combines a transformer-based module to capture the global contextual dependencies with a CNN for an efficient local feature extraction. In addition, Grad-CAM approach is used to increase the interpretability of the model and offer visual explanations for the forecasts. We evaluate the suggested technique on a publically accessible dermoscopic benchmark and achieve 93% accuracy, 92% precision, 91% recall and 92% F1-score, outperforming numerous mainstream designs. The experimental results imply that the proposed approach achieves a good trade-off between accuracy, computational economy, and interpretability for real-world and resource-limited medical applications.**

***Keywords*—Medical image analysis; skin disease detection; explainable AI; hybrid model; Vision Transformer**

I. Introduction

Skin diseases are one of the most common health problems in the world, affecting millions of people every year. This can be anything from benign acne and eczema to serious melanoma. Early detection is very crucial, especially for malignant skin cancers because it increases the survival rates and decreases the treatment costs. However, the accurate diagnosis of these conditions is still a challenge due to the similarities between different skin lesions and variation in the imaging conditions such as lighting, resolution, and skin tone [1].

Until recently, the clinical diagnosis of skin diseases has been based on the clinical examination and the dermoscopic examination of an experienced expert. This technique, while successful, is fundamentally subjective and relies on clinical experience, which may result in inter-observer variability and delayed diagnosis. Moreover, the number of dermatologists is not enough in many places, particularly in developing nations, generating a tremendous need for automated, scalable, and reliable diagnostic solutions [1], [2].

Recently, deep learning has been successfully used in medical image analysis, in particular, in the detection of skin diseases. CNNs have demonstrated themselves to be quite effective in extracting hierarchical features from the pictures to appropriately identify the skin lesions. A lot of research has demonstrated a significant increase in the accuracy of diagnosis by using deep learning algorithms ([2], [3]). These models automatically learn discriminative features like texture, color distribution, and the borders of lesions without the need for handcrafted feature engineering.

CNN-based techniques have been successful, but suffer from several limitations. In particular, CNNs are meant to capture local spatial characteristics by using convolution processes with a narrow receptive field. Deeper designs may partly overcome this constraint but generally fail to simulate long-range relationships inside images. This is especially important in medical imaging because small global patterns may be important for distinguishing different disease categories [3].

Recently, transformer-based architectures have been used for computer vision applications to solve these problems. After their success in natural language processing, Transformers use self-attention processes to model connections between all elements in the incoming data. Vision Transformer (ViT) models split pictures into patches and treat them as sequences to collect global contextual information. Recent research has shown that transformer-based models are useful for classifying skin diseases, and they achieve better performance than typical CNNs [4], [5].

However, transformer models also have certain problems. They are computationally complicated and need large-scale datasets for efficient training, which makes them less suited for real-world and resource-constrained applications. Also, CNN and transformer models typically act as black-box systems and lack interpretability, which is a critical problem in medical applications where transparency and trust are important [4].

Recently, hybrid deep learning architectures that blend CNNs and transformers have been proposed to solve the above shortcomings. These methods leverage CNNs for effective local feature extraction and transformers to model global dependencies. This combination enables the model to benefit from the benefits of both paradigms and achieve better performance and resilience. Hybrid CNN-Transformer models have shown their efficacy in skin disease diagnosis in recent research, performing better than stand-alone designs in terms of accuracy [6], [7].

In addition to speed, interpretability has become a key criterion in medical AI systems. Clinicians need to grasp the rationale behind the model's predictions to trust and use these technologies in their practice. Explainable Artificial Intelligence (XAI) solutions try to tackle this problem by shedding light on the decision-making phase of deep learning approaches. Among such approaches, Grad-CAM has drawn substantial attention for its capacity to provide visual explanations by highlighting critical locations in the input picture. Recent works successfully utilized XAI approaches to skin disease categorization, displaying enhanced transparency and clinical relevance [3], [8].

However, while these advances have been made, most of the current systems focus either on improving the accuracy or on increasing the interpretability, but few of them try to improve both while maintaining high computational efficiency. Nor has there been as much attention to early-stage identification, when signs of illness are less severe and harder to detect. This gap highlights the need for a unifying framework that encompasses accuracy, efficiency, and explainability. To address such problems, this study proposes a lightweight explainable hybrid intelligent system for early skin disease diagnosis. The proposed method consists of a CNN-based feature extractor and a transformer-based module, which can successfully collect local and global features. The architecture also has Grad-CAM for providing visual explanations of model predictions, thus enhancing interpretability and confidence.

The principal contributions of this study are listed below:

- We propose a lightweight hybrid CNN-Transformer architecture for early skin disease detection, combining MobileNetV2 for local feature extraction with a ViT for global context modeling.
- We integrate Grad-CAM, an explainable AI technique, into the hybrid framework to provide visual heatmaps that highlight lesion regions influencing model predictions.
- We optimize the proposed hybrid model for computational efficiency.
- We conduct a comprehensive evaluation on benchmark datasets with a comparative analysis.

The rest of this work is structured as follows: In Section II, we review existing approaches and recent studies related to skin disease detection. The proposed hybrid CNN-Transformer technique is discussed in Section III. The experimental setups are described in Section IV. Quantitative and qualitative data are presented and analyzed in Section V. In Section VI, we conclude the study and outline several directions for future research.

II. Related Work

The development of AI has significantly improved the ability of automated diagnostic systems for skin diseases. In particular, deep learning algorithms have achieved great success in medical image analysis owing to their capacity to automatically generate discriminative features from raw data. This section introduces the most important literature, separated into CNN-based methods, transformer-based models, hybrid architectures, and explainable AI strategies.

A. CNN-Based Methods for Skin Disease Detection

CNNs have become one of the cornerstones for automated skin lesion analysis, since they are capable of learning hierarchical spatial representations directly from raw images. These models learn fine-grained patterns well, such as textural differences, color distribution, and lesion edges [1]. More and more, current research has concentrated on the improvement of CNN performance using transfer learning and complex optimization strategies. For example, Zhang et al. [1] provided a detailed assessment of machine and deep learning techniques for dermatological diagnosis and spoke about the efficiency of CNN-based systems in achieving high discrimination accuracy. Likewise, Liu et al. [9] performed a thorough evaluation of deep learning applications in dermatology, where convolutional architectures are gradually taking over clinical procedures. Khan et al. [10] showed that transfer learning-based CNNs outperform traditional machine learning classifiers for skin lesion identification.

B. Transformer Architectures

Recently, the computer vision community has started to incorporate transformer-based models initially created for natural language processing to address the receptive field constraint of CNNs. The self-attention mechanism is at the core of these systems, which allows direct modeling of long-range dependencies and global interactions among picture patches [4]. The significance of transformers in medical imaging activities has been proved by many research. Mohan et al. [11] proposed a transformer-based deep learning pipeline for skin disease classification, which resulted in superior performance due to enhanced global context awareness. Similarly, Dagnaw et al. [12] deployed a Vision Transformer for melanoma detection and included explainability tools to enhance the interpretability of the model.

C. Hybrid CNN-Transformer Models

Recent works have been done on hybrid architectures that mix the two approaches to take use of the complementary qualities of CNNs and transformers. CNNs are utilized in such models for effective local feature extraction and transformers for capturing global contextual linkages. Ali et al. [13] introduced a hybrid CNN-Transformer architecture for skin disease identification, which produced better results than using just CNN or Transformer models. Their method underlines the need for combining local and global feature representations. Also, Mousa et al. [14] developed an attention-based hybrid CNN-Transformer model for medical picture classification, which showed better robustness and generalization. These investigations demonstrate that hybrid designs may achieve a good trade-off between accuracy and computing economy. However, even with their enhanced performance, many hybrid models still suffer from computational expense and lack of interpretability, which are crucial in medical applications.

D. Explainable AI for Skin Disease Detection

In medical AI applications, the raw prediction performance is not adequate. In order to trust and use a model in practice, clinicians need to grasp the rationale behind a given choice made by the model. This need has brought XAI to the forefront of the development of diagnostic systems. The goal of XAI approaches is to provide human-interpretable explanations of the internal decision processes of deep learning models, thereby opening the "black box" of these models. Of these approaches, Gradient-weighted Class Activation Mapping (Grad-CAM) has garnered particular momentum in dermatological imaging for its capacity to provide visual heatmaps detailing which parts of a skin lesion picture most impacted the model's output. Shah et al. [15] proposed a XAI-based framework for skin cancer identification and showed the Grad-CAMs' ability to locate diagnostic-relevant regions such as lesion boundaries,

pigmented networks, and vascular structures. Similarly, Badhon et al. [16] use Grad-CAM on multi-class skin disease classification and demonstrate that visual explanations using Grad-CAM considerably increase the transparency and clinical value of the models without any degradation in the classification accuracy.

III. Proposed Approach: Hybrid CNN–Transformer with Explainability

To detect skin diseases early, we propose a deep hybrid framework that combines CNNs with Vision Transformers in an explainable manner. This architecture efficiently captures both local spatial cues and global contextual information, yet remains computationally economical and interpretable thanks to integrated XAI. The input preprocessing, CNN-based feature extraction, transformer-based global modeling, classification head, and explainability module are the five primary components of the suggested system, as shown in Fig. 1. A lightweight CNN extracts discriminative spatial features, which are then processed by a transformer encoder to model long-range dependencies. Finally, predictions are generated and interpreted using visualization techniques.

A. Input Preprocessing and Data Augmentation

Each dermoscopic image I from the Skin Cancer (MNIST HAM10000) dataset is preprocessed to ensure input consistency and improve model generalization. All images are resized to a fixed resolution of $224\times224\times3$ pixels. Subsequently, pixel values are normalized channel-wise using the dataset mean μ and standard deviation σ:

$$I_{\text{norm}} = \frac{I - \mu}{\sigma} \tag{1}$$

The HAM10000 dataset comprises 10,000 dermoscopic images labeled into seven skin lesion categories [17]. As illustrated in Fig. 2, the class distribution is highly imbalanced: melanocytic nevi dominate with approximately 66.9% (6,705 images), while minority classes such as dermatofibroma (1.1%) and vascular lesions (1.4%) contain far fewer samples. The remaining classes include melanoma (11.1%), benign keratosis-like lesions (11%), basal cell carcinoma (5.1%), and actinic keratoses (3.3%).

Such imbalance can bias the classifier toward majority classes if left unaddressed. Therefore, we apply data augmentation to enhance model robustness and mitigate overfitting. The augmentation pipeline includes random rotations, horizontal and vertical flips, scaling, and cropping. These transformations increase the model's invariance to variations in orientation, size, and lighting conditions commonly encountered in dermoscopic practice. Moreover, augmentation helps to artificially expand the representation of minority classes, partially alleviating the class imbalance problem and leading to a more balanced and unbiased model.

The vast visual diversity and morphological complexity of skin lesions are illustrated in Fig. 3, which includes representative samples from each of the seven classes.

B. CNN-Based Feature Extraction

The normalized input image I_norm is processed using the MobileNetV2 backbone [18] [19] to produce a highly discriminative yet compact feature representation. This lightweight architecture is specifically engineered for efficiency, employing depthwise separable convolutions to significantly reduce computational complexity while preserving a robust feature extraction capability. The network begins with an initial convolutional layer, followed by a sequence of inverted residual blocks with linear bottlenecks, which form the core of the architecture. These blocks are designed to enhance feature reuse and improve gradient flow during training. Each inverted residual block can be mathematically expressed as:

$$\mathbf{y} = \mathbf{x} + \mathcal{F}(\mathbf{x}) \tag{2}$$

where, x denotes the input feature map and $F(\cdot)$ represents a series of transformations consisting of: Pointwise convolution, Depthwise convolution, and Pointwise linear projection.

This structure enables efficient feature learning by separating spatial and channel-wise computations, thereby preserving essential information while minimizing memory usage and computational cost. After passing through multiple stacked inverted residual blocks, the network produces a high-level feature map: $F \in \mathbf{R}^{7\times7\times1280}$.

To further refine the extracted features, a 1×1 convolution is applied, followed by global average pooling, which aggregates spatial information into a more compact representation. This refined feature representation serves as the input to the subsequent transformer module, enabling effective integration of local spatial features with global contextual modeling.

C. Transformer-Based Global Modeling

The proposed framework integrates a ViT-based encoder [20] to efficiently capture global contextual relationships and long-range dependencies within the extracted feature map. The feature map generated by the CNN backbone is first reshaped into a sequence of non-overlapping patches, denoted as:

$$\{x_1, x_2, \ldots, x_N\}$$

where, each patch represents a local region of the input image. Each patch is subsequently flattened and projected into a latent embedding space through a learnable linear transformation, expressed as $z_i = x_i W_e$, where W_e denotes the embedding matrix.

To preserve the spatial structure of the original image, positional embeddings are added to each token, resulting in $z_i' = z_i + p_i$, where p_i encodes the positional information. Furthermore, a special classification token is appended to the input sequence, serving as a global representation that aggregates information from all patches throughout the transformer layers.

The augmented sequence of embeddings is subsequently processed by a series of transformer encoder layers. Each encoder layer comprises a multi-head self-attention mechanism succeeded by a feed-forward neural network, incorporating layer normalization and residual connections to improve training stability and convergence. The self-attention mechanism

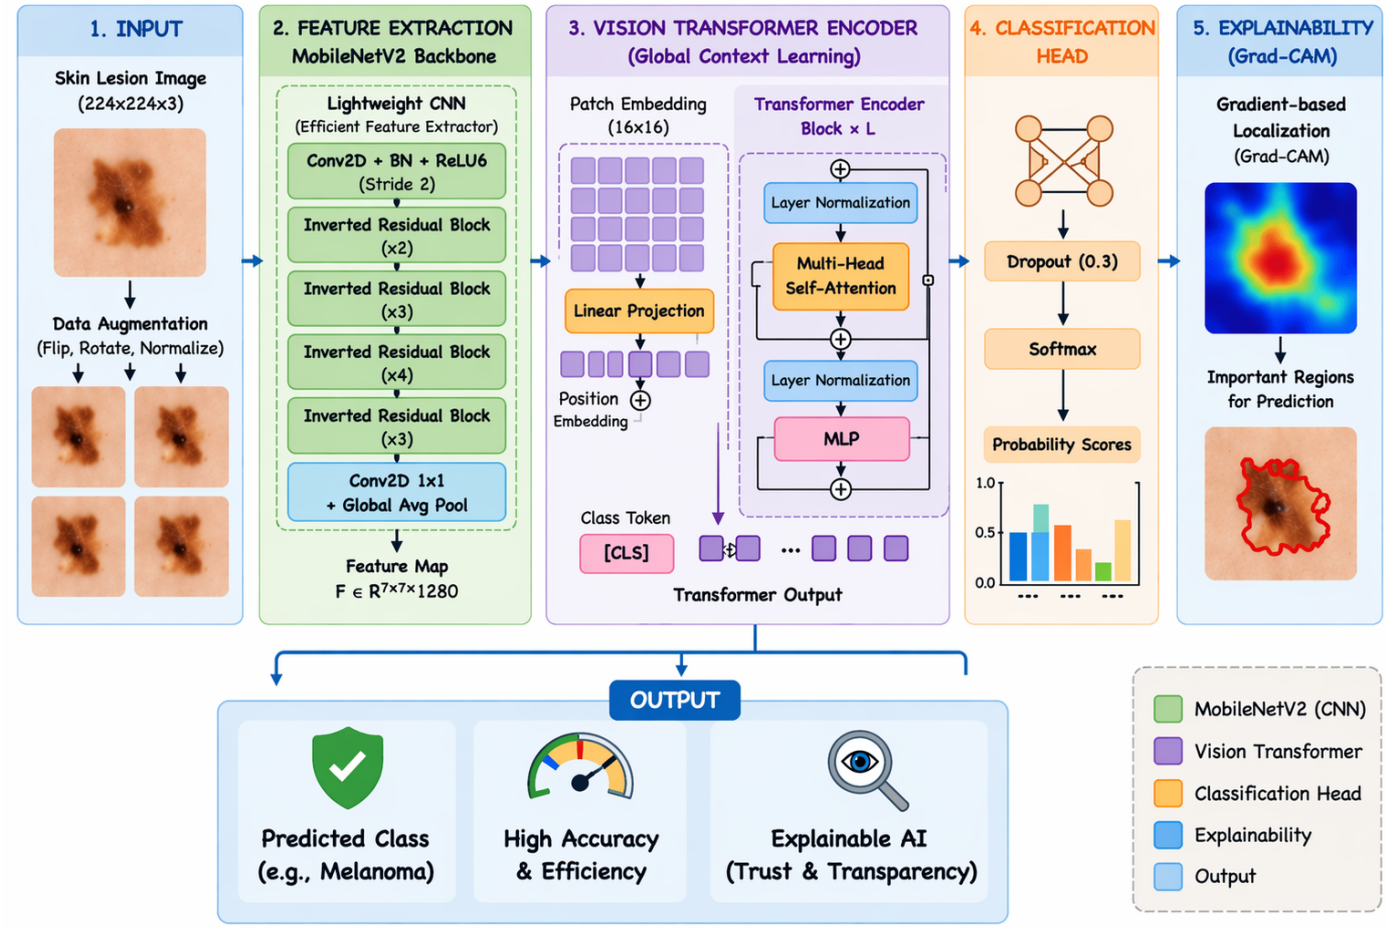

Fig. 1. Overview of the proposed framework.

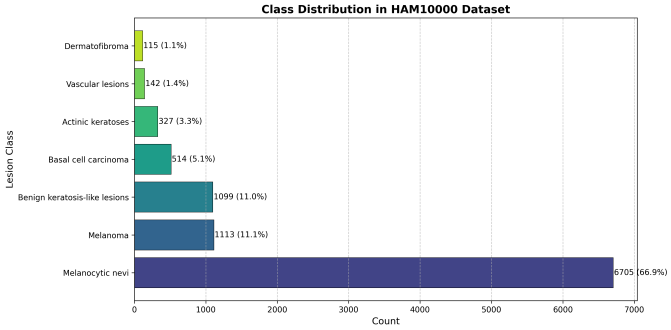

Fig. 2. Skin lesion class distribution.

allows the model to evaluate relationships among all patches, enabling it to concentrate on the most distinguishing areas of the lesion image irrespective of their spatial positioning.

Finally, the output corresponding to the classification token is extracted and used as a compact global representation of the input image. This representation encodes high-level semantic and contextual information and is forwarded to the classification head to perform the final skin disease prediction.

D. Explainability Using Grad-CAM

To make our model's decisions more transparent and interpretable, we integrate Grad-CAM. This technique produces visual heatmaps that reveal which portions of the input image most strongly influenced the model's prediction [21]. Grad-CAM works by backpropagating the gradient of the target class score to the final convolutional layer's feature maps. This process quantifies how much each feature map contributes to the classification of a particular class.

Formally, the importance weight associated with the $k-th$ feature map for class c is computed as:

$$\alpha_k^c = \frac{1}{Z} \sum_i \sum_j \frac{\partial y^c}{\partial A_{ij}^k} \tag{3}$$

where, A_{ij}^k represents the activation value at spatial coordinates (i,j) within the $k-th$ feature map, y^c denotes the predicted score for class c, and Z normalizes by the total number of spatial locations in the feature map.

Once these weights are obtained, we generate the Grad-CAM heatmap by taking a weighted linear combination of the feature maps, followed by a ReLU activation function to suppress negative contributions:

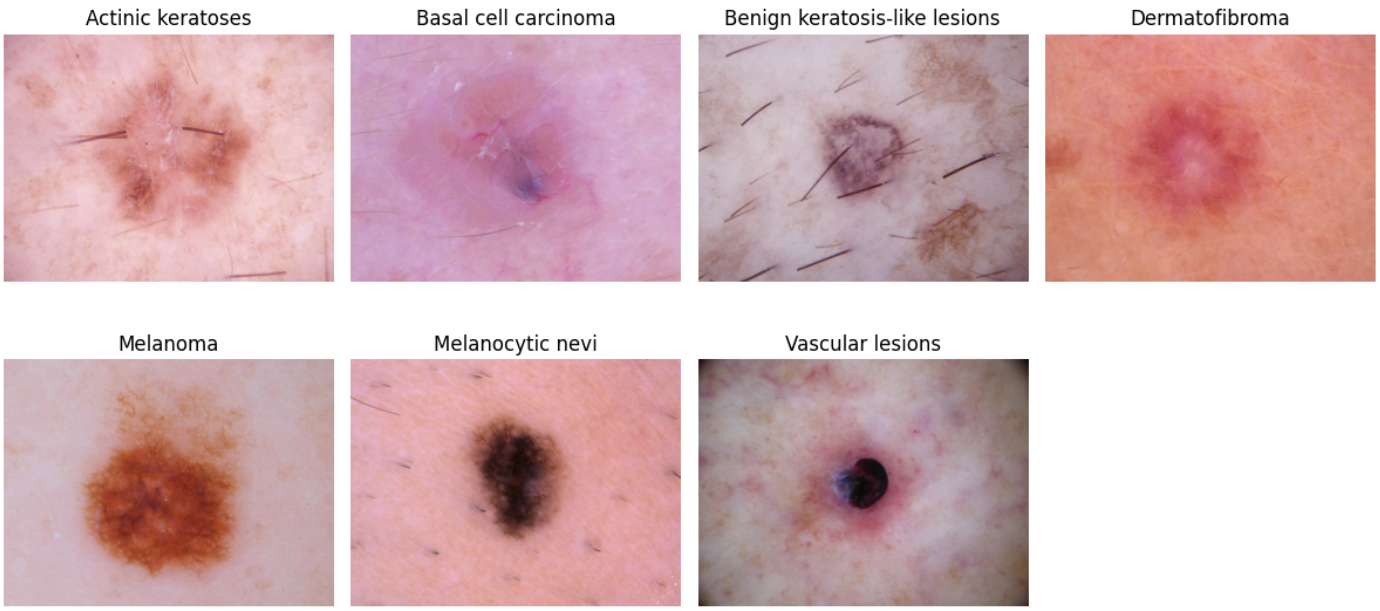

Fig. 3. Sample images from each class.

$$L^{c}_{\text{Grad-CAM}} = \text{ReLU}\left(\sum_{k} \alpha^{c}_{k} A^{k}\right) \tag{4}$$

In this equation, A^k refers to the $k-th$ feature map and α^c_k is its associated weight. The resulting heatmap highlights the image regions most relevant to the model's decision. This visual explanation enhances transparency and helps clinicians understand and trust the model's diagnostic reasoning.

IV. Experimental Setup

A. Dataset Description

The suggested model is evaluated on public benchmark datasets for skin disease classification [17]. Specifically, the model is validated on dermoscopic image datasets with multiple categories of skin lesions such as melanoma, vascular lesions, actinic keratoses, and benign keratosis-like lesions. The dataset consists of dermoscopic images with high resolution acquired in different settings with different lighting conditions, patient skin color, and lesion morphology. This variation helps to encourage model robustness and generalizability to real-world clinical settings. The images are labeled manually with the corresponding disease label by dermatology experts. For experimental purposes, the data is partitioned into three separate parts: 80% for training (for training the model parameters), 10% for validation (for hyperparameter tuning), and the remaining 10% as a test set for the final performance evaluation. Our architecture takes an input size of 224×224 pixels. Therefore, all images are resized to a fixed size of 224×224 pixels. Details of the dataset are described in Section III-A.

B. Evaluation Metrics

Table I provides an overview of the multiple metrics we use to thoroughly assess the proposed model's performance.

TABLE I. Experimental Metrics

Metric	Name
$Acc = \frac{TP+TN}{TP+TN+FP+FN}$	Accuracy
$P = \frac{TP}{TP+FP}$	Precision
$R = \frac{TP}{TP+FN}$	Recall
$F_1 = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$	F1 Score

C. Implementation Details

Our implementation relies on the TensorFlow and Keras deep learning libraries. All experiments run on GPU-accelerated hardware using Kaggle notebooks, which speeds up training and supports reproducible research. The network accepts input images of dimensions $224 \times 224 \times 3$ and processes them in batches of 32 samples. The Adam optimizer is utilized for optimization, with an initial learning rate of 10^{-4}. The categorical cross-entropy loss function is employed for multi-class classification. Training proceeds for 30 epochs, though early stopping can be applied depending on convergence patterns. The MobileNetV2 backbone is seeded with ImageNet pretrained weights, allowing the model to benefit from transfer learning for more efficient feature extraction. Meanwhile, the transformer encoder and the final classification head are trained together in an end-to-end fashion to maximize overall predictive performance.

D. Training Strategy

To ensure stable and efficient training, several strategies are adopted within the proposed framework. First, transfer

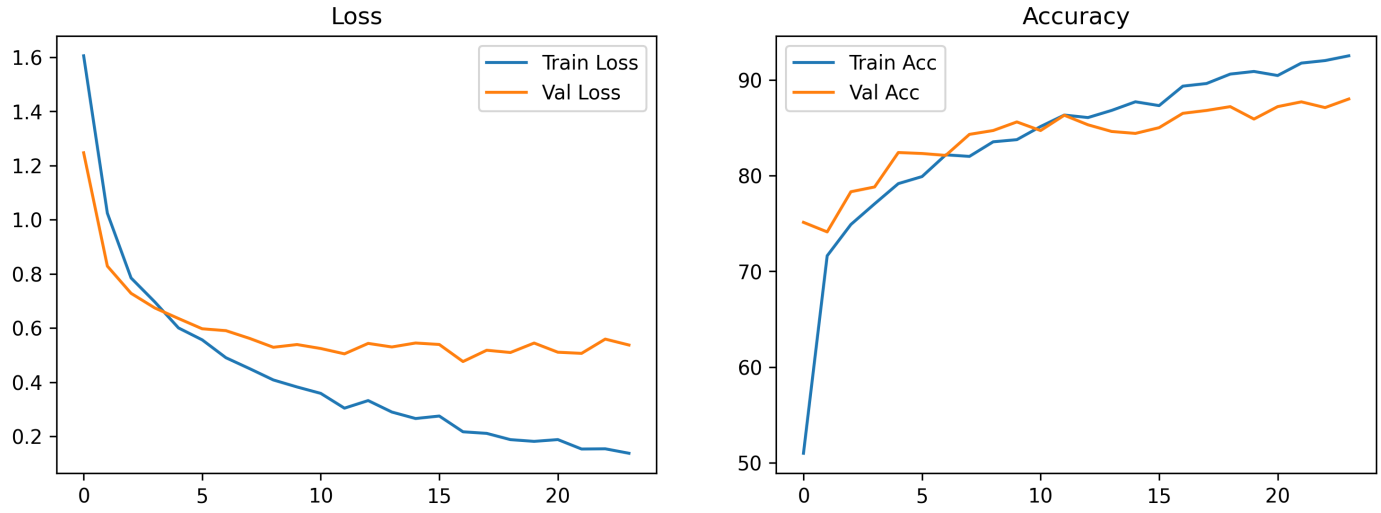

Fig. 4. Training and validation curves.

learning is utilized by initializing the CNN backbone, specifically MobileNetV2, with pretrained weights, enabling the model to leverage rich visual features learned from large-scale datasets. Subsequently, a fine-tuning strategy is applied, where selected layers of the backbone are unfrozen and retrained to better adapt to the specific characteristics of the skin disease dataset. To reduce overfitting and improve generalization, regularization techniques are incorporated, including the use of a dropout layer with a rate of 0.3 in the classification head and early stopping based on validation performance. In addition, a learning rate scheduling mechanism is employed to gradually decrease the learning rate during training, which helps stabilize optimization and achieve better convergence.

V. Results

The quantitative and qualitative assessment of the proposed lightweight explainable hybrid framework for the early detection of skin diseases is presented in this section. The model's classification performance, training behavior, and interpretability are evaluated using a combination of complementary metrics.

A. Quantitative Results

Fig. 4 shows the evolution of the training and validation metrics of our hybrid model over 30 consecutive epochs. The training accuracy increases with time, and the corresponding loss decreases steadily, suggesting that the network is learning task-relevant representations effectively. Second, the validation accuracy also increases in a similar way with only small fluctuations, indicating the model has strong generalization ability. The small gap between the training and validation curves indicates that overfitting is well controlled. This result validates the effectiveness of our regularization approach, which consists of dropout (rate of 0.3) and heavy data augmentation.

We report the confusion matrix on the held-out test set in Fig. 5. The diagonal entries reveal that most samples are assigned to their correct classes, confirming that the model achieves high discriminative power across all seven disease categories. Off-diagonal misclassifications are relatively infrequent and tend to occur between pairs of visually similar conditions—most notably melanoma versus benign keratosis-like lesions. This pattern is unsurprising given the subtle morphological overlap between these two classes. Overall, the confusion matrix reinforces the conclusion that our approach is both robust and clinically reliable.

Fig. 5. Confusion matrix of the proposed model.

Fig. 6 presents the recall, precision, and F1-score curves for the suggested hybrid network on the HAM10000 test set. Precision–Confidence Curve (top-left) shows how precision changes as the model's confidence threshold increases. Most classes improve in precision at higher thresholds, with vascular lesions and dermatofibroma achieving the highest precision overall. The Recall-Confidence Curve (top-right) illustrates how recall decreases as the confidence threshold increases. Lower thresholds retain higher recall, while stricter thresholds reduce the model's sensitivity across all classes. The F1-score

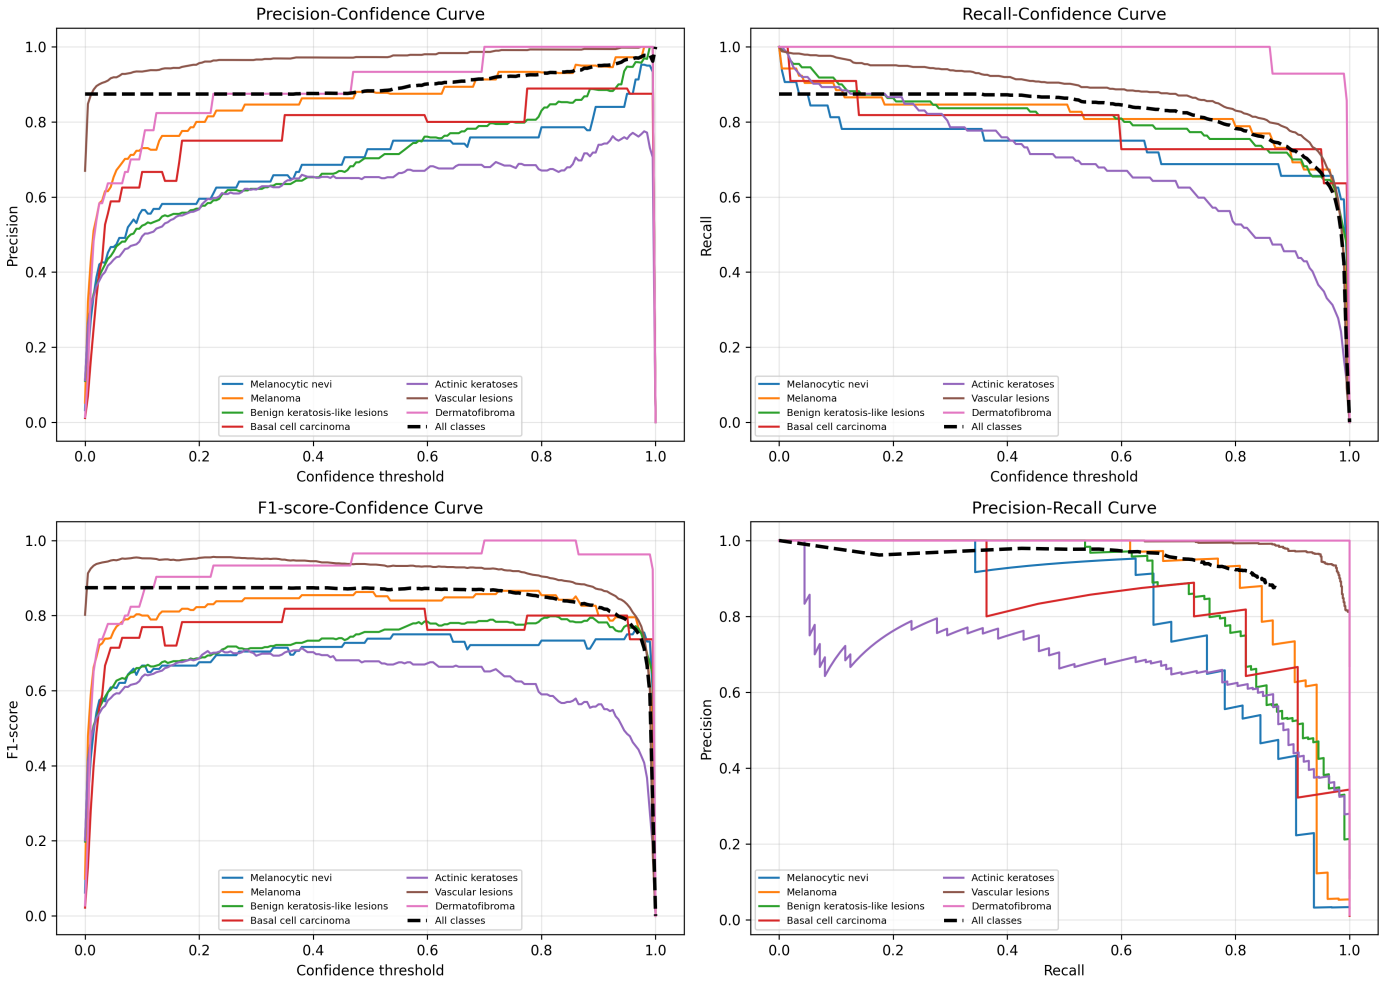

Fig. 6. Performance evaluation curves

confidence curve (bottom-left) displays the balance between precision and recall. Each class reaches an optimal F1-score at different thresholds, highlighting trade-offs in model performance tuning. The Precision-Recall Curve (bottom-right) depicts the relationship between precision and recall independent of thresholds. Classes like vascular lesions maintain high precision across a broad recall range, while others show sharper trade-offs.

Table II presents a comparative evaluation of the proposed approach alongside several baseline models, including a standard CNN, VGG16, ResNet50, and MobileNetV2. Our method consistently outperforms all baselines across every metric. Specifically, it attains 93% accuracy, 92% precision, 91% recall, and a 92% F1-score. The improvement over a plain CNN (75% accuracy) is substantial, highlighting the limitations of shallow or non-optimized architectures. Even deeper models such as VGG16 and ResNet50, which achieve 87% accuracy, fall short of our hybrid design. MobileNetV2, despite its efficiency, reaches only 83% accuracy due to its aggressively lightweight nature. The improved performance of our model stems from its hybrid CNN–Transformer architecture, which effectively integrates fine-grained local feature extraction with a broader global context representation. This combination is especially advantageous for differentiating between categories that share strong semantic similarities.

B. Qualitative Results

Fig. 7 provides a visual breakdown of our model's decision process using Grad-CAM. This approach generates attention heatmaps that identify the most diagnostically relevant portions of each skin lesion image, thereby increasing both algorithmic transparency and practitioner confidence. The figure is organized into four rows, each representing a distinct test sample, with three columns per row: the original dermoscopic image with its ground truth label, the Grad-CAM attention map (a color-coded heatmap where brighter/warmer regions indicate higher contribution to the predicted class), and an overlay of the heatmap on the original image accompanied by the predicted label and confidence score. Several key observations can be made from these visualizations. First, high-confidence predictions (0.960, 0.993, and 0.988 in the second, third, and fourth rows, respectively) exhibit well-localized and intense heatmaps that concentrate sharply on the lesion area, with the model correctly identifying "Actinic keratoses" (second row) and "Vascular lesions" (third and fourth rows). In contrast, the first row presents a low-confidence case (0.357) where,

TABLE II. ABLATION STUDY

Models	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
CNN	75	74	73	73
VGG16	87	86	80	85
ResNet50	87	87	86	87
MobileNetV2	83	84	83	84
Our proposed hybrid model	93	92	91	92

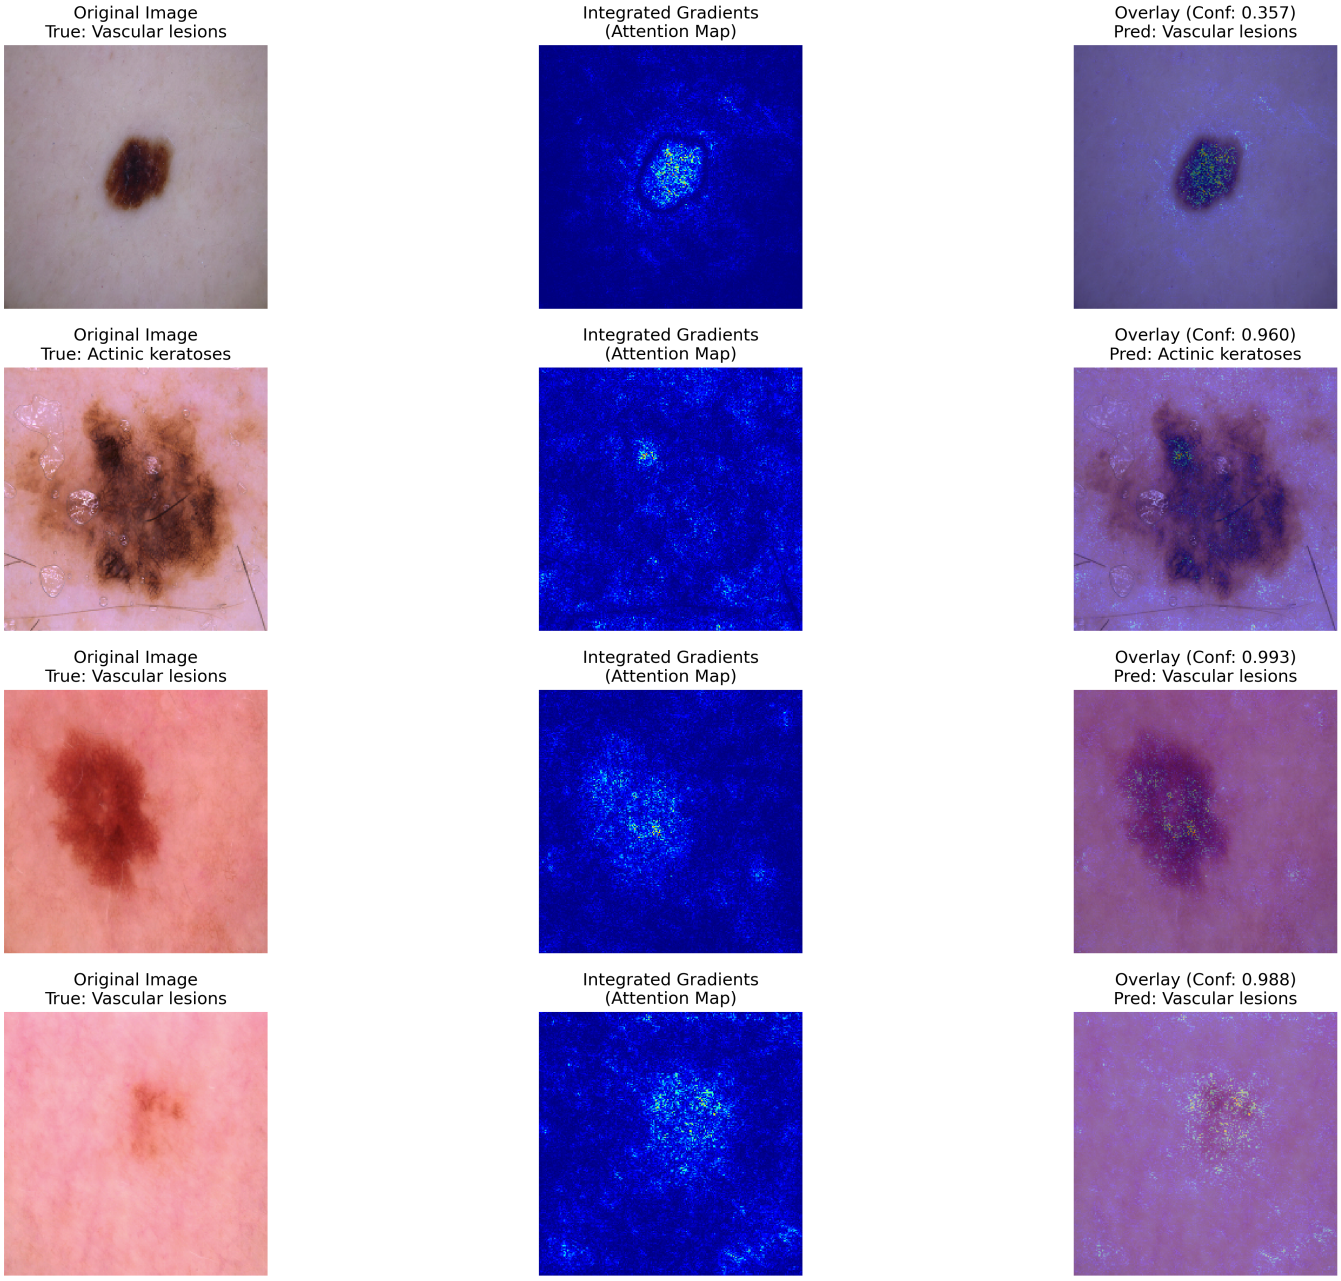

Fig. 7. Grad-CAM visualizations for skin lesion detection.

although the prediction is correct ("Vascular lesions"), the Grad-CAM heatmap appears diffuse, fragmented, and less intense compared to the high-confidence examples, with the model's attention spread across multiple regions rather than tightly focused on the lesion. This diffuse activation pattern correlates with the model's uncertainty. Across all examples, a clear relationship emerges: higher confidence is associated with sharper, more localized heatmaps, while lower confidence

corresponds to broader, less distinct activations, suggesting that the model's certainty is reflected in the spatial focus of its explanations. From a clinical perspective, Grad-CAM enables dermatologists to verify whether the model's focus aligns with established diagnostic criteria such as lesion borders, asymmetry, color heterogeneity, and vascular structures. The strong agreement between attention localization and lesion boundaries in high-confidence cases supports the model's reliability and fosters trust in AI-assisted diagnosis.

The numerical results show that the suggested lightweight hybrid MobileNetV2–ViT model achieves an excellent balance between accuracy, efficiency, and interpretability. The integration of transformer-based global modeling significantly enhances performance compared to standalone CNN architectures. Additionally, the explainability provided by Grad-CAM ensures that the model's decisions can be understood and validated by medical professionals.

C. Discussion

The proposed hybrid CNN-Transformer system achieves 93% accuracy, 92% precision, 91% recall, and 92% F1-score on the HAM10000 dataset. The high recall rate (91%) is therapeutically relevant for the early identification of melanoma by decreasing false negatives. Compared with the baseline MobileNetV2 (83% accuracy), the improvement indicates that the ViT module can effectively learn the long-range spatial relationships that are not captured by CNNs and are critical for recognizing subtle early lesions. The small gap between the training and validation curves suggests attractive generalization and little overfitting. The Grad-CAM heatmaps are strongly correlated with clinically meaningful variables, thus improving model interpretability and increasing the confidence of physicians. Limitations include lack of skin tone diversity for HAM10000, lack of cross-dataset validation, and lack of prospective clinical validation. Future work will address these limitations by using different datasets, domain adaptation approaches, model compression, and clinical reader studies. The proposed method offers a good compromise between accuracy, efficiency and interpretability for early detection of skin diseases.

VI. Conclusion

This study presents an interpretable and lightweight hybrid framework for the early diagnosis of skin diseases. The proposed architecture combines MobileNetV2 with a Vision Transformer module to jointly exploit local visual patterns and long-range contextual information within dermoscopic images. To improve the explainability of the system, Grad-CAM was employed to generate activation maps highlighting the lesion regions that contribute most to the final prediction. Experimental evaluations indicate that the proposed approach achieves superior performance compared with several conventional deep learning models, including CNN-based architectures, VGG16, ResNet50, and MobileNetV2. The framework attained an overall classification accuracy of 93%, together with strong precision, recall, and F1-score values. These results demonstrate that the integration of convolutional and transformer-based representations can improve classification capability without introducing substantial computational overhead. In addition to the quantitative improvements, the qualitative analysis confirms that the model effectively focuses on clinically meaningful lesion regions, thereby enhancing the interpretability and reliability of the diagnostic process. Owing to its balance between accuracy, explainability, and low computational complexity, the proposed framework is suitable for practical medical applications, especially in environments with limited computational resources.

Despite the promising results obtained by the proposed framework, several directions remain open for further improvement. Expanding the training process to include larger and more heterogeneous datasets could strengthen the model's generalization capability, particularly by incorporating diverse skin types, varying acquisition conditions, and less common dermatological disorders. In addition, exploring more advanced transformer-based architectures may help achieve a better balance between classification performance and inference efficiency. Future work may also focus on adapting the framework for real-time clinical deployment through optimization strategies such as model quantization and knowledge distillation, which can reduce computational complexity while maintaining satisfactory accuracy. Another important perspective concerns the enhancement of model interpretability. Integrating additional explainable artificial intelligence techniques, together with clinical validation involving professional dermatologists, would provide stronger evidence regarding the reliability and practical applicability of the proposed system in healthcare environments.

Intrusion Detection System for Ransomware in Network Traffic Using Supervised Machine Learning

Ziad Almulla, Moath Alamri, Mounir Frikha
Department of Computer Networks and Communications-College of Computer Sciences and Information Technology,
King Faisal University, Al-Ahsa, 31982, Saudi Arabia

***Abstract*—Ransomware is one of the most dangerous cyber threats today, as it can disrupt systems and cause serious financial losses. Traditional detection methods often fail to catch newer attacks because they can hide within normal network traffic. In this study, we used machine learning to detect ransomware based on network data. We tested four models Logistic Regression, Decision Tree, Random Forest, and Gradient Boosting using the UGRansome dataset, both before and after balancing it with SMOTE. The Decision Tree model gave the best results, achieving 99.40% accuracy, 98.0% precision, 99.90% recall, and an AUC-ROC of 99.95%. We also found that protocol flags and network flow features played a key role in detecting attacks. Overall, using tree-based models with balanced data proved to be a simple and effective way to build a real-time ransomware detection system.**

***Keywords*—Ransomware detection; machine learning; IDS; network traffic analysis; real-time detection**

ABBREVIATIONS

The following abbreviations are used in this manuscript:

AI	Artificial Intelligence
API	Application Programming Interface
AUC	Area Under the Curve
BTC	Bitcoin
CFS	Correlation-Based Feature Selection
CNN	Convolutional Neural Network
DL	Deep Learning
DPI	Deep Packet Inspection
DT	Decision Tree
FN	False Negative
FP	False Positive
GA	Genetic Algorithm
GB	Gradient Boosting
HIDS	Host-based Intrusion Detection System
IDS	Intrusion Detection System
IoC	Indicator of Compromise
IP	Internet Protocol
MLP	Multi-Layer Perceptron
NIDS	Network-based Intrusion Detection System
PCA	Principal Component Analysis
PCAP	Packet Capture
RaaS	Ransomware-as-a-Service
RDP	Remote Desktop Protocol
RF	Random Forest
RFE	Recursive Feature Elimination
ROC	Receiver Operating Characteristic
SAE	Stacked Autoencoder
SIEM	Security Information and Event Management
SMB	Server Message Block
SMOTE	Synthetic Minority Over-sampling Technique
SSH	Secure Shell
SSL	Secure Sockets Layer
VPN	Virtual Private Network

I. INTRODUCTION

Intrusion Detection Systems (IDS) are one of the security controls that plays an important role in detecting ransomware attacks in network traffic and preventing it, positively affecting the cybersecurity of organizations. As ransomware has become more advanced in scale and sophistication, traditional countermeasures such as signature-based detection are no longer useful in the face of polymorphic and zero-day ransomware that is evolving to become a challenge to detect [1]. More recent developments in machine learning (ML) have shown great potential to improve the accuracy, flexibility, and robustness of IDS, specifically when used in analysis of network traffic behavior as it happens in real-time and behavioral profiling [2]. Using datasets to capture both normal and abnormal traffic patterns, trained supervised ML models can be used to detect malicious activity early, making it possible to implement proactive defense measures against a ransomware attack [3].

Although this has developed, there is a research gap. A significant part of the available literature is devoted to general malware detection or anomaly-based IDS with no particular emphasis on ransomware as a specific and increasingly common cyber threat. Moreover, a great number of studies use older or generic data that is not comprehensive when it comes to the description of the features of contemporary ransomware traffic, restricting the practical usability of their findings. This poses an urgency to conduct a research which assesses supervised ML methods on ransomware-specific datasets that reflect current attack patterns [3].

In this research gap, this study focuses on UGRansome dataset coherent dataset of realistic ransomware traffic traces. Such data allows making a better assessment of supervised ML algorithms in ransomware detection than with traditional malware datasets. Through the examination of the ransomware-specific traffic indicators, the study aims at improving the relevance and applicability of the ML-based IDS solutions in the contemporary cybersecurity environment.

While a number of previous works have used machine learning classifiers on the UGRansome dataset, most of them are focused on the evaluation of individual algorithms or propose complex deep learning architectures without addressing systematically the practical requirements of real-time IDS deployment. The current work develops the state-of-the-art through the following specific contributions:

1) Comprehensive and reproducible benchmarking: Unlike previous research which reports findings on a single pipeline configuration, a rigorous side-by-side comparison of four classifiers in two experimental settings (original imbalanced

and SMOTE balanced), with the same preprocessing, feature sets and evaluation protocols, is given in this work. All hyperparameters, random seeds, and computational timings are documented fully in order to allow for independent replication.

2) Quantified impact of SMOTE on minority-class detection: This research is one of the first studies on the UGRansome dataset to give a detailed, quantitative comparison of the performance of models before and after balancing them with SMOTE, showing an 81% decrease of false negatives for the Decision Tree model with a marginal sacrifice on precision, which is 1.36%, a trade-off that was explicitly justified for cybersecurity applications where missed attacks have asymmetric risk.

3) Statistical feature validation: In addition to basic feature importance rankings, this study reports correlation coefficients, mutual information scores, F-statistics, and p-values for all 13 predictive features, which provide some statistical evidence of feature relevance. Furthermore, a systematic comparison of all features with those of Genetic Algorithm (GA) and Correlation-Based Feature Selection (CFS) subsets shows that the compact feature set is already optimal, which is not suitable for dimensionality reduction.

4) Real-time deployment feasibility analysis: This work makes a unique report of the inference latency (4 ms per batch) and throughput (7.5 million samples/second) for the Decision Tree model along with the training times for all classifiers providing concrete proof that the proposed framework meets the computational needs of integration into SIEM systems or in-line NIDS appliances.

II. Background

Intrusion Detection Systems (IDS) are essential for detecting and eliminating transforming ransomware threats in an efficient manner. The ability of IDS to adapt and learn from new data is essential for maintaining their effectiveness in ransomware attacks [4]. The capacity of IDS to learn and update as new data is crucial to their effectiveness against more and more sophisticated ransomware attacks [5] [6].

The resistance and flexibility focus will ensure that the organizations remain at advantageous position to accommodate the complexity of ransomware attacks and maintain their cybersecurity frameworks in the event of future risks and provision of organizational properties. This kind of proactive solution not only gives rise to improved defense systems of organizations, but also to the establishment of a culture of preparedness and reaction to future ransomware attacks [7], [8].

The constantly evolving ransomware requires the proactive approach to the development of Intrusion Detection Systems that must go in tandem with the emerging threats and safeguard the organizational assets. It is a proactive attempt to not just increase the protection mechanisms of organizations, but it also establishes the culture of resiliency and preparedness against future attacks by ransomware [5].

A. Evolution of IDS

The ongoing evolution of IDS reflects the urgent need for organizations to implement adaptive strategies that can effectively counteract the dynamic nature of ransomware threats. In conclusion, the integration of adaptive strategies within IDS is essential for effectively combating the ever-evolving ransomware landscape and ensuring organizational resilience [9].

A combination of advanced machine learning methods with real-time monitoring will have a crucial role in improving the effectiveness of IDS against ransomware attacks and will allow organizations to respond promptly to any crisis of a new ransomware and improve their overall cybersecurity resilience [10].

B. Types of Intrusion Detection Systems

As shown in Fig. 1, there are two primary categories of IDS, Network-based Intrusion Detection Systems (NIDS) and Host-based Intrusion Detection systems (HIDS), which have a different monitoring scope, detection methods, and contribute to ransomware protection in different ways [9].

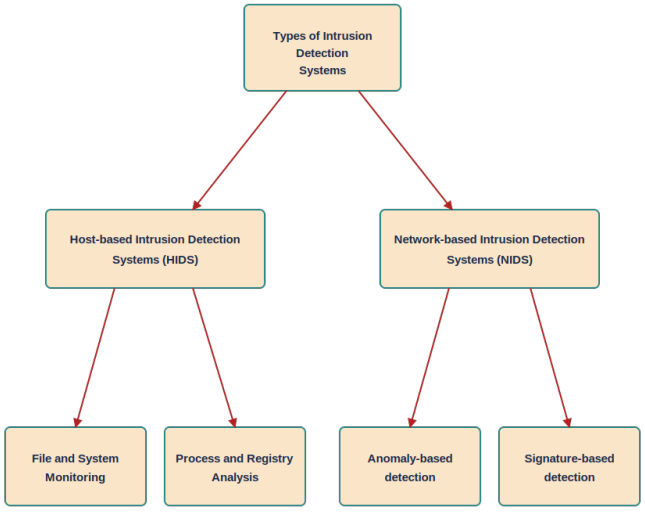

Fig. 1. Types of Intrusion Detection Systems.

1) Network-based Intrusion Detection Systems (NIDS): Network-based Intrusion Detection Systems (NIDS) are installed at strategic locations within a network, e.g., in a gateway or router, to monitor and examine network traffic flowing through the router in real-time. Through analysis of packet data, NIDS is able to identify suspicious patterns or anomalies in different types of attacks such as ransomware, before such attacks hit endpoints. NIDS generally use an implementation of a mixture of signature-based and anomaly-based detection strategies:

a) Signature-based detection: It can be used to identify malicious activity based on signature-known malicious signatures, which is the comparison of the network traffic with previous known malicious patterns. Nevertheless such an approach might not identify new or quickly developing ransomware variants that do not correspond to existing signatures [11], [12].

b) Anomaly-based detection: It creates a normal network behavior baseline, and detects any significant deviations

like uncharacteristic encryption traffic, unusual file transfers, or sudden bursts of data flows-typical ransomware activity indicators [13].

More recent developments have introduced machine learning and deep learning models into NIDS, allowing detection of advanced ransomware campaigns, and zero-day threats by detecting subtle and previously unknown traffic deviations. Architectures that use multi-stage with supervised and unsupervised models have shown improved accuracy and less false positive when it comes to identifying emerging ransomware attacks [14].

Snort and Suricata are practical examples of NIDS implementations in enterprise (as well as in small-to-medium enterprise) environments, with Suricata demonstrating that it is possible to deploy an IDS even in resource-constrained environments [12].

Network-based IDS are especially useful in detecting ransomware at an early stage of network activity, including initial infection stages, command and control traffic, or other data exfiltration efforts, thus facilitating quick containment measures [15].

2) Host-Based Intrusion Detection Systems (HIDS): Host-Based Intrusion Detection Systems (HIDS) are systems that are directly attached to the endpoints or servers and they track the activities within the internal system to identify any classified threats. HIDS normally examine operating system logs, file integrity, process behaviors and registry changes:

a) File and system monitoring: HIDS is capable of detecting ransomware-related operations, including mass file changes, unauthorized file access, or suspicious encryption activity that could be an indication of an attack [13].

b) Process and registry analysis: With HIDS checking newborn processes or unordinary activity in critical Windows registry keys, it is possible to detect instances of ransomware to create persistence or alter system settings [16].

The ability to learn the behavioral baselines of legitimate user and system processes to classify ransomware is further extended due to machine learning-enhanced HIDS. Any deviation, e.g., unauthorized encryption operations or ransom note creation initiates alerts or automated remediation measures. This host-centric approach allows HIDS to identify ransomware even when it tries to avoid network-based detection, particularly when ransomware transfers itself over encrypted networks or when it opts to use fileless attack vectors [16].

HIDS are also crucial in the implementation and distribution stages of ransomware, since it is capable of detecting malicious code that NIDS might fail to identify because of network obfuscation or encryption.

C. Ransomware: An Overview

1) Definition and Characteristics of Ransomware: Ransomware is a unique type of malware that tries to deprive victims from access to their information or systems, usually by encrypting the files and asking a ransom–often in the form of cryptocurrencies like Bitcoin–as a way to unlock access [17]. They are divided into two major categories: locker ransomware which denies access to the user interface of the system and crypto-ransomware which encrypts user files with strong algorithms making them data restoration virtually impossible without the decryption key provided by the attacker [17], [18].

Crypto-ransomware is often considered as the most common and more dangerous threat because it is based on more advanced cryptographic algorithms and the financial motivation it provides to cybercriminals [18].

The ransomware of today is often highly evasive (polymorphism, metamorphism, and packing) and can be used to come up with many different versions and thus makes it difficult to detect [17]. Furthermore, the emergence of the Ransomware-as-a-Service (RaaS) business model has allowed regular individuals to engage in ransomware operations and this has led to the significant growth rate in the number of incidents and financial losses globally [16], [19].

D. Impact of Ransomware on Organizations

The effects of ransomware attacks on organizations are multidimensional, and they include direct economic and operational impacts, reputational damage, and possibly serious social or safety risks [17], [16].

As an example, the WannaCry (2017) and Colonial Pipeline (2021) attacks resulted in massive business disruptions, the crippling of critical services, and caused a significant disruption in society because of the stoppage of several key processes, including healthcare services and fuel supply [17].

The cost of paying a ransom is not the only thing expense organizations can experience due to ransomware, as there is also the cost associated with downtime, data recovery, fines imposed by the regulations, and loss of customer trust [17], [16]. These attacks pose a safety risk and in certain industries they are even life-threatening, particularly critical infrastructure and healthcare [17].

The opportunity nature of ransomware and the increasing threat environment, e.g., the COVID-19 pandemic, is an additional example of its opportunistic character and the emergence of a new threat environment [16].

E. Ransomware Attack Vectors

Ransomware is based on various attack vectors in order to access target networks first and spread through environments [17], [18].

1) Phishing: Social engineering tricks are used to lure the user into opening harmful attachments or clicking on harmful links of well-crafted emails that appear to be a trusted source. They are also one of the most frequently observed vectors in reality [17].

2) Leveraging remote access and vulnerabilities: Attackers exploit weak credentials or software vulnerabilities to attack unpatched internet-facing services (Remote Desktop Protocol (RDP) or VPN gateways) to access organizational IT or operational technology (OT). This threat is enhanced by automated vulnerability scanning that is driven by AI [17], [16].

3) Hijacked third parties and chains: Ransomware pirates are abusing trusted third parties, including managed service providers, to spread malware laterally to several organizations [17].

4) Physical infection: USB drives and malicious insiders also poses less frequent, but equally serious threats in a highly-secured or air-gapped environment [17].

5) Network propagation: Modern ransomware has worm-like or sideways movement functionality, rapidly traversing domains as it takes advantage of techniques like credential theft, privilege escalation, and open SMB (Server Message Block) shares [17].

F. Network Traffic Analysis

1) Importance of network traffic in cybersecurity: Network traffic analysis is known as detective control in cybersecurity, because it gives a full inspection of traffic passing through a network allowing identification and investigation of cyber threats, such as ransomware attacks. Through packet analysis of network packets and their interactions, security analysts can detect malicious activities, command-and-control communications, data exfiltration efforts and other threats that anti-virus programs would not detect using traditional signature-based detection techniques. It is especially important considering the changing level of sophistication of malware and ransomware attacks that cannot be detected by traditional protection mechanisms [20].

Network traffic analysis facilitates the early detection of indicators of compromise (IOCs) in the form of infected file hashes, IP addresses, domain names, and abnormal traffic patterns, among others, crucial to an immediate incident response and mitigation [21]. Additionally, network traffic analysis can give geographic contextualization of cyber threats as they could map the IP origins and destinations, thereby showing the worldwide dissemination and dynamic nature of malware campaigns [20]. This dimension can provide a crucial viewpoint to the perception of the threat landscape outside of technical signatures, which will further contribute to the strategic response to ransomware and other network-based attacks. A number of methods are used to profile network traffic at different levels and granularity:

a) Deep Packet Inspection (DPI): DPI is a process whereby both the packet headers and the payload are examined exhaustively to identify anomalies, signatures, or suspicious content in the network flows, which helps to identify malware activities, unauthorized data transfer, and efforts to exploit vulnerabilities in the network [22]. DPI is more useful than normal packet inspection but it also needs a lot of processing and complex analysis programs like Wireshark [20].

b) Packet Capture (PCAP) analysis: This is used to obtain raw network information that can be analyzed offline or in real-time to reveal specifics about communication patterns between nodes, protocols, contents of messages, and other possible signs of a ransomware infection [23].

c) Social Network Analysis (SNA): Applied alongside PCAP data, SNA can display communication relations and key participants in a network and enhance the threat attribution process and aid in detecting coordinated ransomware-related campaigns [23].

- Entropy-Based Traffic Analysis: This is metric of packet sizes, time between packets and source to destination, to identify the ransomware activity by the entropy changes or unusual deviations by measuring increments or aberrant changes in the entropy [24].
- Machine Learning Classification: Decision Trees, Random Forests and SVM are examples of supervised learning algorithms that have been trained using features identified by inspecting network traffic, such as statistics, and entropy. A differentiate between benign and ransomware-related traffic with high precision, such approaches help in the removal of the shortcoming of the traditional identification whose focus is on the behavioral patterns [24].

These methods assist in the elimination of the weaknesses of the traditional detection that is centered on the patterns of behavior.

2) Challenges in Network Traffic Analysis: Network traffic analysis may be hard to control, bandwidth, overload, and necessity of tracking traffic in data networks. The issues in network traffic analysis include the issues in network configurations, bandwidth changes, bandwidth bottlenecks and the need to monitor traffic in data networks

We will highlight the most common challenges in the network traffic analysis:

- Encryption and Anonymity: The encrypted traffic deprives any capability of DPI and signature-based mechanisms to look at payloads. Similarly, the anonymization (e.g., TOR) and IP spoofing conceal the actual origins of traffic and complicate the attribution and detection even further.
- False Positives and Thresholding: Anomaly and entropy-based systems must compromise sensitivity and specificity. A smaller detection threshold will be detected more often, and potentially too high detection thresholds will be missed by minor ransomware characters. This has to be defeated by dynamic thresholding and adaptive learning mechanisms.
- Resource Constraints: DPI and real-time traffic analysis are extremely resource-intensive in CPU, memory and network infrastructure. To keep up without endangering as bottlenecks, efficient algorithms, hardware accelerator and modular architecture are required.
- Threats and Evasion Methods: The malware and the ransomware are constantly under development and will use polymorphic code, encrypted communication channels, and stealth functions. The detection systems will have to match this through frequent updates, the mixture of the standard detection methods and machine learning to be fruitful [22], [24].

G. Machine Learning and Intrusion Detection system

Supervised ML finds wide usage in (IDS) to detect the ransomware attack at different stages, such as pre-encryption

phase, execution phase, and communication phase, as shown in Fig. 2.

For ML, models are run on the sequences of API calls, system calls, and file system interactions to extract ransomware behavior characteristics, which can be observed in time before it is too late and irreversible harm is caused. The classification of ML classifiers on dynamic runtime detection accuracy such as the random forest and SVM when used on realistic datasets.

In addition to that, ensemble learning and hybrid methods that combine deep learning feature extraction with conventional classifiers have proven to be more effective in detection performance and increased resistance to changing different ransomware attacks [25].

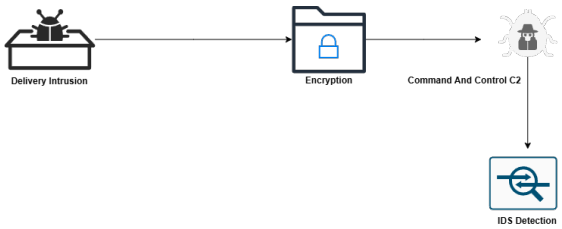

Fig. 2. The ransomware attack life cycle with IDS detection points.

III. Related Work

The related work presents all papers and publications published within 2020 to 2025, as shown in Fig. 3, that are analyzed in this work, with the hightlight on the ransomware detection methods based on the structured datasets of network-traffic data.

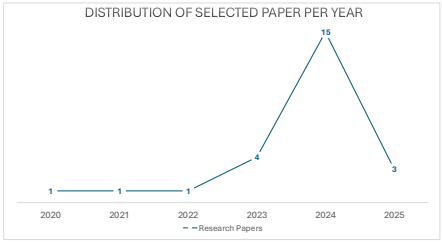

Fig. 3. Distribution of selected paper per year.

Rahman et al. [26] provides an answer to that issue by using a Transformer-based model to identify ransomware, in various types of High-Dimensional Network Data, by fine-tuning the BERT architecture on both structured and non-text features that can be converted to natural language format to do a deep contextual analysis of those features. The authors use the UGRansome dataset (14 attributes, $> 149,000$ network traffic samples) to encode both the categorical and numerical features into text, and then utilize the multi-head attention mechanism of BERT to find the interdependencies between those features. The model had state-of-the-art accuracy, 99.21%, far surpassing that of both state-of-the-art (STI) examples, (LSTM: 98.5%), and ensemble examples (99.0%) with a very low increase in training examples, demonstrating the capability of extracting complex feature relations from Network Telemetry that are similar to prime examples of language models in text-based formats. Their ablation studies indicated that Protocol, Port, Flag and Flow-based features were the best features that provided prediction, while some indicators can lead to overfitting. There were limitations of being computationally expensive for large models of the same type of this transformer, and you risk overfitting, if there is a data leakage. Their main contribution was to demonstrate that transformer models (with carefully structured data) provide superior, generalizable results for ransomware detection in cybersecurity applications with partial data without native text glimpse and extension to other structured security domains of applications.

Azugo et al. [27] developed a Random Forest based model, which uses UGRansome to detect and classify ransomware with a level of accuracy of 96%, in order to differentiate between normal and abnormal network behaviors. The model is created through feature engineering and data encoding, and is able to accurately recognize ransomware that are difficult to identify (specifically EDA and Globe), due to their large financial transaction amounts. The methodology used by Azugo et al., includes the systematic removal of uninformative features, normalization, and the evaluation of feature relevance. In addition, practical results demonstrate the necessity of having high levels of diversity among networks, as well as maintaining datasets in order to ensure continuous performance. Limitations include reliance upon a single dataset, and potential limitations associated with collecting all types of emergent attacks from multiple organizations. Azugo et al. established a baseline for creating quality datasets in current day datasets, and demonstrated that when utilizing a Random Forest model on a quality dataset, it will be capable of identifying both known and unknown ransomware activity.

Nhlapo et al. [28] study network intrusion detection of zero-day and ransomware attacks using a comparative analysis of machine learning models based on the UGRansome dataset. Their objective is to enhance the detection performance than the legacy NIDS based on the evaluation of the improvement of RFC, XGBoost, SVM, Naive Bayes and ensemble learning. Results are categorical, as most will see RFC XGBoost ensemble methods as performing perfectly (100%, perfect metrics), while SVM and NB are performing significantly under the curves (perfect performance as shown). The methodology includes data normalization, feature selection and comprehensive multi-algortithmic data testing. The study brings an underlined realization of the limitations of traditional methods towards legacy data, and an advocate for updated datasets, diversity in datasets. Limitations are recognized regarding more generalisability and practical impact of class balancing and feature selection. The main part of the contribution is a strict empirical validation in which using ensemble approaches and tree-based algorithms under the condition of providing them with well-structured modern datasets help us to perform far superior to conventional classifiers regarding the ability to detect both the known and novel attacks in a real-time.

Chaudhary et al. [25] proposed comparative study of decision tree, SVM and Multi-layer perceptron (MLP) classifiers on the UGRansome datasets in terms of accuracy, precision, recall and F-measure. They use Scikit-learn and TensorFlow models upon extensive preprocessing (e.g. deduplication, normalization, encoding). The decision tree model is an undisputed vector with a high accuracy of 98.83 and 99.41%, depending on other significant measures, but SVM and MLP are in the shadows (accuracy of approximately 62%). The study demonstrates the adequacy of decision trees in the modeling of non-linear relationships, which are essential in the real-world for the discrimination of ransomware. Such limitations are the extent of individual dataset, over fitting or leakage of data. The major contributions are the empirical validation that the decision tree algorithms outperform the more complex Neural or SVM, where we deal with the high dimensional non-linear network security data.

Nkongolo, van Deventer, and Kasongo [29] present the UGRansome1819 dataset - a modern and large-scale dataset has been created for anomaly detection and zero-day threats analysis by bundling and labeling attacks from the UGR16 and ransomware-specific data. The goal is to aid in the evaluation of machine learning using realistic attack/benign class balance. The methodology outlines dataset creation and class legalities together with early benchmarks with ensemble getting used (Random Forest, SVM, Naive Bayes), thoroughly demonstrating that ensemble techniques and Random Forest provide classification charges better than existing IDS benchmarks, and can reduce false positives. Key findings include better detection of advanced persistent threats, cyclo-stationary patterns, and better generalization. In this study, the limitation of dataset coverage and the imbalance of classes (NP-Hard) This dataset will serve as an up-to-date and publicly available benchmark against which future research into ML IDS techniques can be compared, enabling accurate detection of a threat and comparison of models.

Alraizza and Algarni [30] provide a comprehensive overview of Machine Learning-based Ransomware Detection, including a summary of Ransomware Narai detection studies and trends from 2017 to 2022 that have categorized these studies based on static/dynamic features, detection techniques and evaluation metrics. The authors discuss many of the challenges associated with selecting appropriate features for use within models; the need to balance datasets and the need to develop models that are resistant to high false positive rates and also resilient to adversarial attacks. In this study that several machine learning techniques were tested and reported to be effective in detecting ransomware, including Random Forest, Decision Tree, SVM and Neural approaches; however, they indicate each approach has its own trade-offs (for example: one method had accuracy in data detection of over 99%; but it was limited in terms of dataset and generalization). The authors note that due to the rapidly evolving nature of ransomware attack vectors, there is a need for developing real-time adaptive processes to detect such attacks. Additionally, the authors report that their study provides a list of significant obstacles for developing successful ransomware detection models.

Fan et al. [31] introduces TEVEInet, a deep learning-based anomaly detection model which is based on two architectures, Transformer and Variational Autoencoder (VAE) model architecture, to create user behavior and a robust feature extraction framework based on training on the UGRansome data set. The method is to encode the network telemetry and behavior-based features (after the numeric/categorical conversion and normalization), to embed it for learning in the sequence learning and latent space learning. TEVEInet outperforms DNN, CNN and their hybrid baselines by achieving F1-scores, as high as 99.26%, and sophisticated clustering separation on UGRansome. Ablation studies show the need for both the transformer attention and the latent modeling to hold discriminative power. Limitations are a consequence of the number of parameters and optimization complexity, which brings up scaling questions to resource-constrained environments. The contribution consists of the empirical validation that deep neural architectures with both sequential and latent representations, named hybrids, can establish new benchmark for anomaly detection related to ransomware. The contribution is the empirical validation of deep neural architectures capable to set the new standards in case of anomaly detection, applicable not only to ransomware.

Zahra et al. [32] examines ensemble learning capabilities of detecting anomaly intrusion and zero-day attacks in cloud environments against UGRansome dataset assets using approaches that include Random Forest, SVM, Naive Bayes, ensemble stacking and genetic algorithm optimization. Preprocessing like label encoding and normalization AWS SageMaker supports Scalable model deployment. Genetic algorithm feature selection leads to improve computational efficiency and decrease overfitting problems (Random Forest and ensemble methods up to 99.6% accuracy). The work validates the benefit of hybrid feature selection and ensemble techniques, and at the same time, reveals the opportunity to conduct more research into SVM/Naive Bayes robustness and scalability for large cloud workloads. This study is one of such early examples of advanced, cloud-centric anomaly detection using modern ransomware datasets.

Alhashmi et al. [33] are focused in ransomware detection techniques based on UGRansome data in terms of 6 ML classifiers (Logistic Regression, Decision Tree, Naive Bayes, Random Forest, AdaBoost, and XGBoost classifiers). The models are all tested based on accuracy, precision, recall, F1-score and on computational efficiency. Random Forest (99.37%, Decision Tree (99.42%) and XGBoost 99.48%, are the uncontested ones who received almost perfect scores and can be used in real-time/space. Cautious datasets normalization, class balancing and exploitation of computational speed is a significant deployability measure and is covered under methodology. The results support the use of tree-based mesh and ensemble as the leading candidate strategies in the most effective ransomware detection techniques that can be scaled. The limitations are directed at the degree to which the datasets are representative and also the necessity of testing on a larger quantity of real-world network data. The most important contribution to this study is the practical validation of the get ready, high-confidence ransomware detection environments of specific ML models.

Yan et al. [34] develop two-layer machine learning-based approach to ransomware detection and classification using the UGRansomeware dataset. The research focus on solving the problems both accurately and detecting wide ransomware attack and its accurate family classification which is important

to identify exact mitigations for evolving attack threats. The dataset ranges over 149,043 network traces in 14 features of both numerical and categorical data. The methodology is based on stacked ensemble model in the first layer consisting of six classifiers: Gaussian Naive Bayes Classifier, K-Nearest Neighbors, Decision Tree, Logistic Regression, Multi-Layer Perceptron and Stochastic Gradient Descent Classifier to achieve overall detection accuracy of 98.22% with nearly 98% precision and recall values for binary classification (Normal vs ransomware attack). The second layer applies LightGBM to GPCs for classification of detected instances of ransomware into 14 different categories with an accuracy range from 74.9 to 99.1%, with varying lower performance for less common categories, which shows challenges related to class imbalance and within-family similarity issue. Combining Pearson correlation and decision tree importance, 12 important features are selected, based on the optimization of model input. Evaluation metrics-accuracy, precision, recall and F1-score are shown emphasizing good effects of the first layer with moderate effects of the second layer that needs to be improved.

Wa et al. [35] introduces a deep learning architecture for enhancing ransomware detection using network traffic by integrating LSTM classification and stacked autoencoder (SAE) feature selection. In particular, the purpose is to provide improved classification of ransomware and anomalies in the UGRansome dataset. The goal of this work is to identify a method that will effectively classify ransomware in large datasets of cyclostationary data that are of high dimensionality. The researchers begin their methodological process with preprocessing and normalizing the data, followed by use of the SAE to perform self-determined feature extraction that uses a previously trained LSTM classifier. The performance of the SAE-LSTM architecture was evaluated via accuracy, precision, recall and F1-score as compared to XGBoost. The results show that the SAE-LSTM architecture has an accuracy of 98.5% and demonstrates that some ransomware variants that occur less frequently (i.e., NoobCrypt, DMALocker) may have a larger financial impact than other variants. Some limitations of the SAE-LSTM architecture include the current unbalanced nature of the data set, the need for additional feature engineering and the possibility that the model may not generalize well across a variety of ransomware samples.

Nkongolo et al. [36] utilizes ensemble-based approaches optimized by Recursive Feature Elimination (RFE) to identify Zero-Day Threats, and ultimately aid in the prevention of those threats. Nkongolo also has a goal of enhancing UGRansome's utility for Real-Time Anomaly Detection, and to provide input to both policy and rulemaking for IDS. The methodology utilized by Nkongolo combines Gradient Boosting (GB) and Random Forest (RF) base models, with Naive Bayes (NB) as the Meta-Blender, and RFE is used to determine the most critical features from the data set, so that the IDS may effectively block malicious network traffic. Accuracy, Precision, Recall, and F1-Score are the key metrics used in this study; the ensemble framework achieved a balanced accuracy of 97%, which is better than legacy systems, and specifically was able to achieve a high degree of accuracy in identifying Zero-Day Vulnerabilities. In addition to achieving high degrees of accuracy, Nkongolo was also able to demonstrate the framework's ability to block greater than 100kbps of suspect traffic; Secure Shell (SSH) Attacks were particularly noteworthy in terms of mitigation. However, there are several notable limitations to the study conducted by Nkongolo including: the lack of a real-time IDS implementation; the non-comparative evaluation of all feature selection methods; and, the limited scope of the study to the tested dataset.

Sharath et al. [37] presents an ensemble method that incorporates AdaBoost, Random Forest, and Naive Bayes to improve the detection of ransomware in various security fields. The primary purpose of this study is to address the limitations of current detection methods due to the continuously changing nature of ransomware and limitations in available data sets utilizing the UGRansome data set as the basis for experimentation. Kumar et al. applied each individual classifier separately and then ensembled the results to utilize the strength of each individual classifier to evaluate the performance of the ensemble model using accuracy, precision, recall, and F1-score. The ensemble model achieved a detection accuracy of 96% and was superior to the results obtained from using the individual classifiers alone; the ensemble model demonstrated the capability to decrease the number of false positives generated during the detection process and increase the overall efficiency of the IDS. The authors concluded that ensemble methods have a higher degree of resistance to sophisticated types of ransomware however additional research is needed to fully realize the potential of ensemble methods in terms of real time detection capabilities and scalability to detect future novel forms of ransomware.

Torky et al. [38] investigated the use of ensemble-based machine learning techniques for anomaly detection in enterprise system transactional data, with the ultimate goal of increasing detection accuracy and robustness and thereby decreasing the likelihood of financial loss and disrupting services. Torky examined multiple ensemble-based methodologies (bagging, boosting, stacking) along with stochastic models and Support Vector Machine (SVM) utilizing a dataset created from operational payment systems; accuracy and robustness were the two primary metrics examined. The SVM model exhibited the greatest level of detection performance at an accuracy rate of 80.2%; ensemble methodologies enhanced the reliability of classification and decreased variance. A major finding of the study is that it emphasizes the significance of labeled data, the inability of models to recognize previously unknown anomalies, and the need for substantial computing power. The primary drawback of the artifact of the study is the reliance upon supervised methodologies and labeled datasets, which limits the ability to adapt to new or evolving attack vectors.

Mohamed, et al. [39] constructed a hybrid neural network model that could be applied to detect new and unidentified zero-day exploits through a combination of four sub-networks: Adaptive WavePCA-Autoencoder (AWPA), Meta-Attention Transformer Autoencoder; Genetic Mongoose-Chameleon Optimization, and Adaptive Hybrid Exploit Detection Network. The overall aim of this research study is to enhance the performance of detecting advanced network attacks that are of zero-day in the dynamic networks. The implementation of the proposed hybrid network is to develop and train the hybrid network on a few diverse datasets, e.g., UGRansome and extract a vast range of feature values of the data sets with the aid of a large number of advanced optimization algorithms; followed

by testing the effectiveness of the proposed hybrid network by testing the accuracy, precision, recall and computational cost of the hybrid network. Study findings revealed that the hybrid model recorded more detection precision and recall rate as compared to the traditional autoencer and tree-based models and also incurred lower computational costs. The hybrid model was also identified to have certain limitations such as the complexity of the model training, the fact that much large powering computing resources are required and continuous large-scale inputs into the hybrid model are necessary in order to keep the model operating efficiently.

Mutmobo et al. [40] extended the utilization of the UGRansome dataset to employ machine learning automation to enhance security of the blockchain network. The authors identified that blockchain networks are susceptible to ransomware and zero-day attacks, and, therefore, they automated the assessment of numerous models to determine real-time detection. The key characteristics of the data- timestamps, network protocols, the financial transactions with Bitcoin, port information, and address flows were critical to the detection of attack patterns occurring on the blockchain activity. By using Lazy Predict, the authors were able to automatize benchmarking of the decision trees, random forest, light gradient boosting machines (LGBM), and nu-support vector classifier (NuSVC) models and compare the models against each other by their accuracy and F1-score and training time time. The findings showed that decision tree and extra tree classifier had 99% accuracy and with extremely low training periods (0.12 -0.30 seconds), it was specifically applicable in a blockchain based setting where quick response was essential. Also, the models successfully determined zero-day exploits (designated as anomaly "0") and ransomware signatures (1), and concluded whether there are any correlations between Bitcoin spikes and ransomware financial activity. As it was proved by the authors, the implementation of the network flow analysis and financial characteristics significantly optimized the possibility to detect ransomware in blockchain systems in real-time. Nonetheless, the authors recognize that the study had certain limitations like lack of ROC-based performance comparisons because of the limitations in the library, and lack of explicit optimization of hyperparameters.

Al-Binahmed et al. [41] investigated how deep learning methods can be used to detect Android ransomware attacks based on network traffic patterns. The authors used a publicly accessible dataset in Kaggle, having 392,045 records, in order to differentiate between benign traffic and ten ransomware variants. After data preprocessing and feature selection to deal with class imbalance and dimensionality questions, two experiments were performed with all features, as well as most relevant features (19). The algorithms that were evaluated were Decision Tree (DT), Support Vector Machine (SVM), K-Nearest Neighbor (KNN), an ensemble of these three algorithms, Feedforward Neural Network (FNN) and TabNet. The authors assessed the performance of the algorithms in terms of the accuracy, precision, recall, and F1-score. DT model had the best accuracy (97.24%), precision (98.50) and F1-score (98.45) to detect ransomware, but the SVM algorithm had 100% recall, which implies that DT is an efficient way to get fast performance in such case. The authors mention that their research had a number of limitations, which comprise a simulated environment, the fact that the models could not be interpreted, and that it was required to create lightweight models to be used on resource-constrained mobile devices. The authors indicate that they would consider including sensor data and the study of unsupervised algorithms as the possible direction of future studies to make their ransomware detection system more robust. Overall, the authors have shown that the potential of the use of automated machine learning/deep learning to recognize Android ransomware attacks is very high, but they also note that there is still a need to validate and adapt it to successful attacks in the field.

Srivastava et al. [42] present a two phase ransomware detect framework which incorporated supervised machine learning combined with a statistical Hidden Markov Model with Gaussian Emission (GMM-HMM) to ensure the detecting of malicious network behavior with more accuracy and less false positives. The dataset used by them is the ISOT ransomware set that included traffic logs of 669 ransomware examples belonging to a broad array of families and 103 malicious Windows programs. The authors have extracted and dimensionally reduced the features using Principal Component Analysis (PCA) and then trained and tested a number of machine learning (ML) models, choosing the Decision Tree model due to its high accuracy (99.9%). A prediction made by the Decision Tree model was then inputted in the GMM-HMM, which confirmed the findings of the Decision Tree model and also gave an extra measure of confidence to the classification. They showed the strong detection of ransomware in three experimental conditions benign only, malicious only, and mixed traffic; the GMM-HMM-HMM offered a greater classification rate in all conditions than the ML output alone. The main achievements of the study are the capacity of the framework to detect the known and unknown ransomware samples, and the elimination of the weaknesses associated with the use of individual ML algorithms. The most notable limitation of the research was that they used binary classification (malicious vs. benign) but did not name the specific ransomware families. Future research directions suggested by the authors are the real-time implementation and the creation of classification at the family level.

Manzano et al. [43] perform empirical comparison of the performance of a set of various supervised learning algorithms that are applicable in detecting ransomware on Android devices through network traffic analysis. They made use of the CICAndMal2017 dataset, which was composed of network capture data of ten families of Android ransomware and some benign applications. Before performing the analysis, the authors used the Kendall correlation procedure to pick the most informative features of traffic in order to retain them (in the final analysis, they picked nine critical features). They used the standard metrics to train and assess the Random Forest (RF), Decision Tree (DT), and K-Nearest Neighbor (KNN) classifiers (accuracy, precision, recall, and F1-score). The RF model achieved the most accuracy in the classification of ransomware (96%), and outperformed both DT and KNN; and DT also performed very well in recall (94%). One of the main results was that the chosen time- and packet-based features presented an incredibly precise approach to the discrimination of ransomware and non-malicious traffic. Nevertheless, the authors also state a major limitation of the research in the aspect of preserving the practiceability of the methods in the future against the variants of ransomware because of the deep speed of development of

the attack patterns. The authors also acknowledge that deep learning-based methods should be developed in order to offer better detection of new and unknown samples.

Woo et al. [44] introduce a hybrid ransomware detection system that involves the use of Convolutional Neural Networks (CNN) in extracting features and Random Forests (RF) in classifying network traffic. The authors generated a dataset consisting of benign and ransomware generated network traffic and added synthetic examples to achieve variability in the real world. The strict normalization and segmentation of the data enabled the CNN to find the intricate patterns of raw flows that could be utilized in the classification process by the RF model with robust and low-bias results. The hybrid model was found to have an accuracy of 94.6 and a false positive rate of 2.3 and performed better than the standalone CNN and RF models alongside the traditional ML baselines, such as the SVM and Logistic Regression. The model presented capability of adaptation to novel ransomware, good generalizability, and scalability. Nevertheless, the authors do not ignore the computational complexity of deep feature extraction, the application of synthetic rather than purely real-world data, and even the inability to find the differences between benign anomalies and the real ransomware, especially.

Batlov et al. [45] proposed a hybrid ransomware detection scheme which combines Isolation Forest (IF) anomaly detection and Long Short-Term Memory (LSTM) network sequential modeling of network traffic for ransomware detection. The study was designed with the view of overcoming the limitations of the traditional signature-based systems, which tend to fail against polymorphic or zero-day ransomware. Using a combination of publicly available benign network traffic and ransomware flows simulated in lab, the authors then derived packet-level and flow-level features like size, duration, and intervals from PCAP files and did normalization and augmentation to ensure generalization. The Isolation Forest model first learned a normal behavior of the network and detected the anomalous traffic and sent them to the LSTM model to learn the temporal dependencies that are common in ransomware communication patterns. We tested the performance using the accuracy, precision, recall, F1-score, and the ROC-AUC, in which we obtained 97.5% accuracy, 96.3% precision, 95.8% recall, 96.0% F1-score, and an AUC of 0.982. Results showed that anomaly detection and sequential analysis with the combined method increased detection accuracy and decreased false positive discovery significantly while keeping the system operating in real time with an average latency of 9 ms. The research also pointed out that the variation in packet size and the flow duration were good indicators of ransomware activity. However, the computational cost of processing the dual-model and some false negatives for ransomware closely mimicking benign traffic were the limitations.

Merhban et al. [46] present the implemented ransomware detection system which takes a combination of machine learning algorithms and network traffic analysis to detect ransomware behavior across various environments. The goal of the study was to construct an effective and precise detection mechanism that can be used to distinguish ransomware and benign software based on the flow-level network characteristics. The dataset consisted of 396 samples from 54 ransomware families, and 420 benign samples, which were collected from the Ransomware Tracker and VirusTotal Intelligence platforms. Features like IP Address, port, protocol type, duration and packet/byte count were extracted using TShark and normalized to form training inputs. Several supervised algorithms were tested: Random Forest, Multilayer Perceptron (MLP), J48 Decision Tree, K-Nearest Neighbor (KNN), Support Vector Machine (SVM), and Bayes Network to find out which model provided the highest accuracy in identification of ransomware. Performance was evaluated by True Positive Rate (TPR), False Positive Rate (FPR), Precision, Recall, F-measure and Accuracy, where MLP achieved 97.30% TPR rate which is better as compared to other models. The results showed that machine learning algorithms can be used to accurately detect ransomware based on network traffic and Random Forest and J48 performed competitively as well. Comparative analysis with previous works proved that network traffic-based detection outperforms static analysis in terms of detection rate and reliability. However, the limitations are high processing time for complex models and poor performance in large-scale real-time environments.

Brinkely et al. [47] developed an ML-based IDS capable of identifying ransomware attacks from unknown data, which illustrated the ability of ML systems to identify emerging threats as they develop, without having to be defined prior to deployment. The study utilized three different algorithms; RF, SVM and NN, to identify anomalies in the way a system behaves by tracking file system changes and encryption activities, as well as unusual activity in network traffic. A total of 2850 samples were used for the research, which were sourced from various public repositories of cyber security information, as well as local system logs and simulated network traffic, all of which were normalized, segmented and had features extracted prior to being analyzed. PCA and correlation analysis was also conducted to reduce the number of redundant variables and increase the overall generalizability of the models. All of the algorithms were trained and tested via k-fold cross-validation, after which each model was evaluated based upon accuracy, precision, recall and F1 score. The NN produced the most accurate results (92.4%); however, both the RF (91.2%) and SVM (88.7%) maintained very similar levels of performance, with all of the models achieving high F1 scores. These results supported the use of ML for identifying zero-day ransomware attacks, since the ML models were able to identify these attacks based upon learned patterns of abnormal behavior, as opposed to the reliance on established signatures.

Cen et al. [48] developed Zero-Ran Sniff (ZRS). This is a novel early ransomware detection framework which applies the methodology of zero-shot learning (ZSL) to recognize unknown ransomware attacks prior to the point of encryption. The researchers attempted to address some of the shortcomings associated with current signature-based approaches, as well as other dynamic feature-dependent methods which do not support new/unknown ransomware variants. The dataset was obtained from Sgandurra et al. (2016). The dataset contained 582 examples of ransomware along with 942 examples of benign samples and spanned 11 different ransomware families; including: CryptoLocker, Locker, and TeslaCrypt. The static Portable Executable (PE) header attributes were extracted using the Python library pefile in order to allow for the efficient processing of data. There are two stages of the proposed ZRS method: AE-CAL (Autoencoder-based Core

Attribute Learning) is the first phase, where AE-CAL extracts deep semantic representations from previously known classes; SA-CNN-IS (Self-Attentive Convolutional Neural Network Inference Stage) is the second phase where it classifies the representation based on previously seen classes. The model was trained by utilizing Adam Optimizer and activation functions of type ReLU. The performance of the model was evaluated using metrics of Accuracy, Precision, Recall, and F1-Score. Results of experiments showed a high level of accuracy (96.02%), a high degree of precision (91.49%), a very high level of recall (98.47%) and a high level of F1-Score (96.31%) compared to state-of-the-art methods of Random Forest, KNN and AdaBoost, as well as to deep learning baselines such as VGG16 and ResNet. Also the researchers improved recall of their zero-day model by 2.9%, and reduced feature extraction time to 0.3 seconds.

Fevid et al. [49] proposed a new zero-day ransomware detection approach based on analysis of assembly language bytecode and random forest classification of unknown ransomware family types based solely on their bytecode characteristics. The researchers sought to improve the early-stage detection rate of ransomware by analyzing the opcode level behaviors common to all ransomware families. The researchers assembled an extensive dataset from VirusShare comprising over 1,700 samples including the major ransomware families (LockBit, REvil, BlackMatter and DarkSide) along with benign executables for comparative control testing. The researchers used IDA Pro and Radare2 to decompile each executable and generate opcode frequencies, instruction sequences, entropy values and control flow graphs, which were subsequently converted into vectorized feature formats via n-gram tokenization and principal component analysis (PCA). The Random Forest classifier was comprised of 500 decision trees and its performance was assessed against several metrics: Precision, Recall, F1 score and Accuracy. The developed model demonstrated an accuracy of 93.5%, precision of 0.95, recall of 0.94 and F1 score of 0.945 and demonstrated strong generalizability to previously unseen ransomware samples based on a high ROC-AUC curve. The results also indicated that opcode frequency and instruction sequence pattern were significantly more indicative of ransomware behavior than deep learning techniques such as CNNs while providing better performance at a lower computational cost. However, the authors acknowledged several limitations of the developed model, including reliance upon static features, inability to handle polymorphic ransomware and potential false negative results due to high levels of code obfuscation. They suggested utilizing a combination of static and dynamic analysis techniques, representing control flow as graphs and employing hybrid machine learning architectures to develop a future generation of ransomware detection frameworks with greater adaptability, scalability and real-time responsiveness.

A. Summary of the Discussion of Related Work

In summary, Ransomware detection systems can only be built on datasets to be reliable. In order to train and evaluate the ransomware detection models with the help of ML, several publicly available datasets have been extensively used, including CICandMAL 2017, ISOT, VirusShare randoms dataset, UGRansome, UGRansome1819, and UGRansome-2024.

Table I presents an overall comparison of some of the most common ransomware detection datasets. Each dataset is analyzed based on its features, data distribution, and recognized shortcomings. Most of the existing ransomware datasets have the same issue: synthetic data, suffer from a serious class-imbalance problem or lack newer ransomware.

TABLE I. SUMMARY OF THE RANSOMWARE DETECTION DATASETS AND THEIR KEY FEATURES AND LIMITATIONS.

Author(s)	Dataset(s)	Features	Limitation(s)
[39]	UGRansome1819	Logistics and Network flow	Needs more real-world validation
[26]	UGRansome1819	14 network attributes	Potential overfitting
[27]	UGRansome2024	12 selected features	Imbalanced classes
[32]	UGRansome1819	14 attributes including financial features	Imbalance and lack of diverse ransomware
[28]	UGRansome	Multiple network flow	Balance issues
[25]	UGRansome	14 features including protocol and flags	Class imbalance
[34]	UGRansome	14 features network and transaction	Imbalanced ransomware family
[30]	UGRansome1819	Diverse, protocol, payload, time, etc.	Legacy datasets used as benchmarks are outdated
[31]	UGRansome	Multi-type network and behavior features	High dimensionality
[33]	UGRansome	Network and financial features	limitations in diversity and imbalance
[41]	Android Ransomware Dataset	19 selected network traffic features	lacks real-world variety
[42]	ISOT Ransomware Dataset	Network flow and time-based statistics reduced by PCA	Binary labeling only benign/malicious
[43]	CICAndMal2017	9 key timing and packet-size traffic features	Limited representation of new ransomware
[44]	Custom hybrid network dataset	Extracted CNN features s	Ptential false positives on encrypted flows
[45]	Custom dataset	Flow-level features: packet size, duration,etc..	High computational cost for dual models
[46]	VirusTotal Intelligence	IP, ports, protocol type, etck	scalability for large-scale networks
[47]	Public malware repositories	File system changes, and log features	High CPU/memory cost
[48]	Viursshare dataset	PE header static features and Self-Attentive CNN layers	Windows PE structure
[49]	VirusShare (12 ransomware families)	Opcode frequency, and entropy-based attributes	Dynamic behavior capture
[40]	UGRansome1819	Network flow	Outdated for most recent ransomware trends

IV. METHODOLOGY

A. Research Framework

In this study, we propose a supervised machine learning framework for ransomware detection in network traffic. The overall workflow, shown in Fig. 4, follows these stages which are: data collection, preprocessing, feature engineering, classification, evaluation, and validation.

Fig. 4. Overall methodology framework

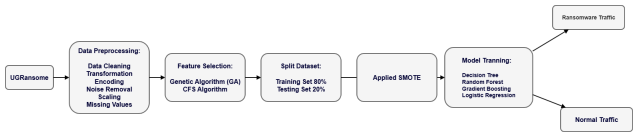

Fig. 5. Overall methodology framework illustrating the six main stages of the proposed ransomware detection pipeline.

B. Experiments

We ran all of our experiments on a machine that had the exact same operating system Ubuntu 22.04, as well as programming language Python 3.10, and also included the hardware Intel Core i9 13th Gen and 64GB DDR5 RAM.

C. Dataset Description and Preprocessing

As shown in Table II, the UGRansome dataset comprises 149,043 network traffic entries of which fourteen (14) numerical and categorical variables have been defined.

TABLE II. SUMMARY OF THE UGRANSOME DATASET

Attribute	Description
Dataset Name	UGRansome (UGRansome1819)
Source	University of Pretoria; combines UGR16 traffic data with ransomware-specific network traces [29]
Total Instances	149,043 network traffic records
Number of Features	14 attributes (13 predictive + 1 target label)
Feature Types	7 categorical (Protocol, Flag, Family, SourceAddress, ExpAddress, IPAddress, ThreatType) and 6 numerical (Time, BTC, USD, Netflow, Port, Clusters)
Class Distribution	Normal: 108,941 (73.09%) | Ransomware: 40,102 (26.91%)
Imbalance Ratio	2.72:1 (Normal : Ransomware)
Missing Values	None detected
Preprocessing	Label encoding for categorical variables; StandardScaler normalization for continuous features; duplicate identifier removal
Class Balancing	SMOTE applied on training set only; 55,072 synthetic ransomware samples generated (0.56 s)
Train/Test Split	80/20 stratified split (119,234 training / 29,809 testing); random seed = 42

This dataset encompasses an array of different network behavior that is representative of both typical activity, as well as ransomware-based activity.

The "Prediction" label has been translated to a binary target value: Normal Network Activity Class 0 and Ransomware Class 1.

About 73% of all instances are classified as normal and approximately 27% as ransomware; these percentages represent a moderate degree of imbalance, which contributed to the decision to apply SMOTE.

Data preprocessing included cleaning the data, converting the categorical variables (Protocol, Flag, Family, SourceAddress, ExpAddress, IPAddress, ThreatType) to encoded format, and normalizing the continuous features using StandardScaler.

No missing values were discovered during the data preprocessing, and duplicate identifier fields were removed, leaving thirteen (13) predictive feature(s).

As shown in the Fig. 5, the implementation steps demonstrate a more detailed view of the data processing and classification.

D. Feature Engineering and Class Balancing

UGRansome database contained 14 attributes covering different characteristics of network traffic, including temporal behavior, type of protocol, financial transactions and threat intelligence. The given attribute that was dropped was the one called Prediction, since it is the target label, and it would cause data leakage to be retained as an input. Following this, the dataset had 13 predictive features.

Among these 13 features, seven of them were categorical (Protocol, Flag, Family, Sender Address, Receiver Address, IP Address and Threat Type). These were coded with labels in order to make them compatible with machine-learning algorithms without expanding the feature space. The other six characteristics (Time, BTC, USD, Netflow\Bytes, Port, and Clusters) were numeric.

The best overall performance was obtained with the full 13-features set at an accuracy of 99.4%, Precision 98.00%, recall 99.9% and a AUC-ROC 99.95%, of the Decision Tree classifier. These findings prove that the features chosen are very informative, non-redundant, and can be used as the most appropriate features to identify ransomware.

Table III presents the statistical validation results for all 13 predictive features.

TABLE III. STATISTICAL VALIDATION OF THE 13 PREDICTIVE FEATURES IN THE UGRANSOME DATASET.

Feature	Correlation	Mutual Information	F-Statistic	p-Value
USD	0.1473	0.4007	9318.68	< 0.001
BTC	0.2426	0.3376	441.38	< 0.001
Port	0.1152	0.0861	27652.33	< 0.001
Flag_encoded	0.0786	0.3016	2005.54	< 0.001
Clusters	0.3005	0.0513	2613.02	< 0.001
Netflow_Bytes	0.1313	0.2497	1280.96	< 0.001
ExpAddress_encoded	0.0474	0.1008	1479.71	< 0.001
SourceAddress_encoded	0.0543	0.0474	936.89	< 0.001
Threats_encoded	0.0077	0.0177	886.57	< 0.001
Time	0.3956	0.0153	17.19	< 0.001
IPaddress_encoded	0.0107	0.0160	827.12	< 0.001
Protocol_encoded	0.0923	0.0140	8.01	0.005
Family_encoded	0.0769	0.0209	336.14	< 0.001

To prevent any kind of data leakage, the data was first divided into training and test sets (20% data as test and 80% data as train) and then SMOTE was applied on the training set only after the split. Likewise, the StandardScaler was only fitted to the training fold, then applied to the training and test folds.

Before oversampling, there are 119,234 records in the training partition (87,153 normal and 32,081 ransomware samples). The training set was completely balanced with 87,153 samples of each class (174,306 total) and synthetic ransomware samples

were generated in 0.56 s with the application of SMOTE. A test set of 29,809 samples was held out and only used for final evaluation.

E. Model Training and Validation

The dataset was divided into two parts by employing an 80/20 stratified split: 119,234 samples for training and 29,809 for validation. All feature scaling occurred post-split (0.03 s).

A fixed random seed (42) was used for all stochastic operations to ensure reproducibility. Four supervised classifiers were trained using `scikit-learn` (v1.3): Logistic Regression (LR), Decision Tree (DT), Random Forest (RF), and Gradient Boosting (GB). The hyperparameters used for each model are listed in Table IV; default scikit-learn values were retained where not specified.

TABLE IV. HYPERPARAMETER CONFIGURATION

Model	Hyperparameters
LR	solver = `lbfgs`, C = 1.0, max_iter = 1000
DT	criterion = `gini`, max_depth = None
RF	n_estimators = 100, max_depth = None
GB	n_estimators = 100, learning_rate = 0.1, max_depth = 3
SMOTE	k_neighbors = 5, sampling_strategy = `auto`

Training times on the balanced data were: DT = 0.37 s, RF = 0.63 s, GB = 13.75 s, LR = 2.07 s. All trained models and preprocessing pipelines were saved for downstream evaluation.

V. EVALUATION METRICS

To evaluate the performance of the developed ransomware detection models, we will use five common evaluation criteria to measure the accuracy of the models' ability to recognize ransomware as well as to differentiate it from normal internet traffic. These five are:

1) Accuracy: It reflects the quality of its predictions, and the model classifies accurately by following the formula given below:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

2) Precision: This measures how many actual instances of ransomware were detected by the model by following the formula given below:

$$\text{Precision} = \frac{TP}{TP + FP} \tag{2}$$

3) Recall: It is a measure of how well the model identifies true cases of ransomware from all the possible ransomware instances that exist by following the formula given below:

$$\text{Recall} = \frac{TP}{TP + FN} \tag{3}$$

4) F1-Score: This metric gives you a single number to assess both the number of False Positives (FP) and False Negatives (FN) of the model by following the formula given below:

$$\text{F1-Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{4}$$

5) AUC-ROC: This value measures how good the model is at separating normal and ransomware distributions into normal and ransomware traffic distributions:

$$\text{AUC-ROC} = \int_0^1 TPR(FPR)\, d(\text{FPR}) \tag{5}$$

Here, TP, TN, FP, and FN refer to the counts of *True Positives*, *True Negatives*, *False Positives*, and *False Negatives*, respectively.

VI. RESULTS AND ANALYSIS

The implementation used `scikit-learn` and `imbalanced-learn` to train models; to perform cross-validation; and to create synthetic samples through SMOTE sampling.

A. Overview of Experimental Evaluation

UGRansome dataset was used to test four trained machine learning algorithms, namely, Logistic Regression (LR), Decision Tree (DT), Random Forest (RF), and Gradient Boosting (GB) to identify ransomware in network traffic.

Two experimental were conducted: first one, imbalanced data and the second, balanced data (with the help of SMOTE). This two-way comparison allowed to fairly compare the effect of class imbalance on detection accuracy, and the use of synthetic oversampling to enhance the detection of minority (ransomware) samples without affecting overall accuracy.

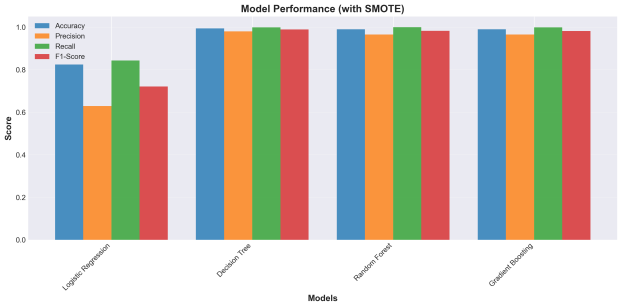

Fig. 6. Performance comparison of all models on the SMOTE-balanced dataset.

As shown in Fig. 6, the Decision Tree had the highest detection accuracy (99.4% and recall (99.9%). On the other hand, Logistic Regression did not perform as well 82.4%, which shows that it is not effective in capturing the complex, non-linear feature interactions that are likely to be in captured encrypted or polymorphic network traffic.

B. Model Performance Comparison

Table V summarizes that the Decision Tree displayed the best overall performance having 99.4% accuracy, 98.0% precision, 99.9% recall, F1-score of 98.9%, and an AUC-ROC of 99.95%. The RF and GB models also had a high level of performance (accuracy of more than 99%), indicating the potential strength of ensemble models.

In contrast, the Logistic Regression obtained an accuracy of 82.4% with an AUC of 89.9%, thus being incompatible with ransomware detection.

TABLE V. PERFORMANCE COMPARISON OF SUPERVISED MODELS (SMOTE-BALANCED DATASET).

Model	Accuracy	Precision	Recall	F1-Score	AUC-ROC
DT	99.40	98.00	99.90	98.90	99.95
RF	99.00	96.50	100.00	98.20	99.98
Gradient Boosting	99.00	96.60	99.90	98.20	99.97
Logistic Regression	82.40	62.90	84.30	72.10	89.90

C. Confusion Matrix Analysis

Fig. 7 and Fig. 8 demonstrate the model behavior balancing with and without SMOTE. This model before balancing, the model have good results precision, but can't classify many of the ransomware examples, 43 false negatives. When applying SMOTE, this model (DT) had only eight false negatives resulting in an 81% improvement in ransomware detection and very little loss in precision. This enhancement shows the effectiveness of teaching the minority class, in order to teach the model itself, more efficiently rarely attack patterns.

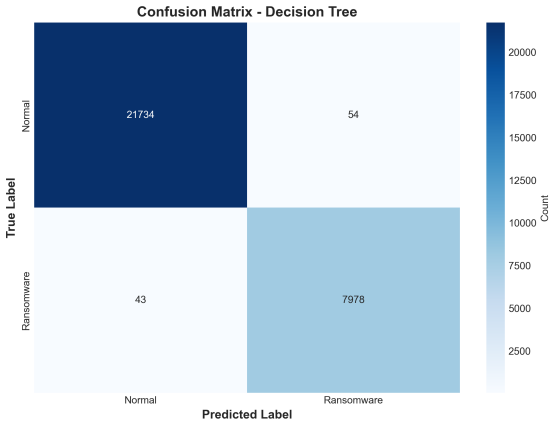

Fig. 7. Confusion matrix of the Decision Tree on the original (unbalanced) dataset.

D. ROC Curve Analysis

The ROC curve illustrated in Fig. 9 and Fig. 10 are almost perfectly classified with AUC of 99.95% or higher with either of the data points. The SMOTE-balanced showed some consistent improvement in the detection performance at lower thresholds with the consequence that fewer false negatives are obtained at no cost to specificity. Conversely, the Logistic Regression model gave a much flatter curve (AUC = 89.9%) that gave a relatively low discriminatory capability between

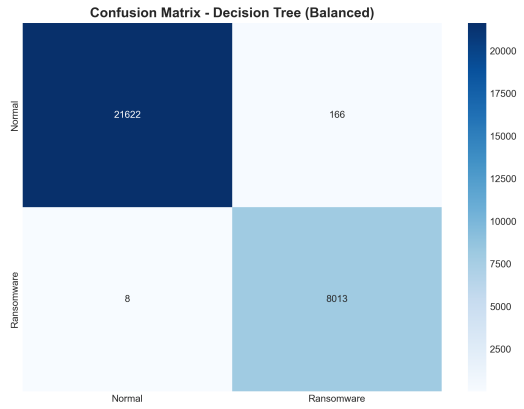

Fig. 8. Confusion matrix of the Decision Tree after SMOTE balancing.

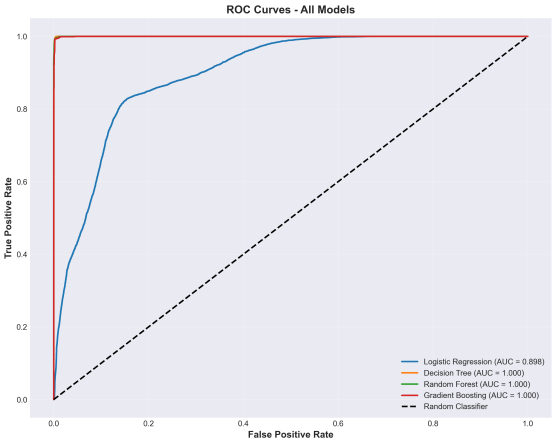

Fig. 9. ROC curves for all models on the unbalanced dataset.

normal and ransomware traffic. To further explore the contribution of various features, two feature selection techniques were compared with the baseline (all 13 attributes): Correlation Based Feature Selection (CFS) and Genetic Algorithm (GA).

E. Comparison of Feature Selection Methods on the Decision Tree Model

As shown in Table VI, it illustrates that the complete feature set was the most accurate and least time-consuming. In fact, CFS substantially decreased dimensionality, it caused a decrease in accuracy by 4.23% and falsely negative results. GA was also able to compete at eight features (99.07% all accuracy) with approximately one second of computation overhead. On the whole, as the dataset already includes a rather small amount of features (13), it made it effective and efficient to take all of them as the ransomware features.

TABLE VI. COMPARISON OF FEATURE SELECTION METHODS ON THE DECISION TREE MODEL.

Method	Features	Acc.	Prec.	Rec.	F1	Total(s)
All Features	13	**99.67**	**99.33**	**99.46**	**99.40**	**0.13**
GA	8	99.07	97.20	99.41	98.29	1.03
CFS	3	95.44	90.43	92.87	91.63	0.37

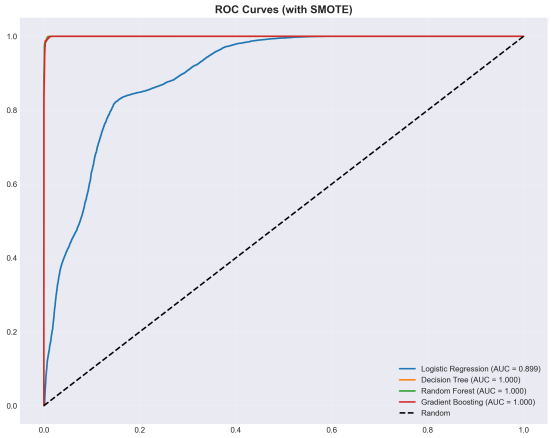

Fig. 10. ROC curves for all models after SMOTE balancing.

F. Comparative Analysis: Original vs. SMOTE Pipeline

Fig. 11 shows comparative analysis. The use of SMOTE decreased precision (-1.36%), accuracy (-0.26%) and recall increased by +0.44This trade-off is positive in the context of cybersecurity, since dedicating more time to identifying attacks is much more important than preventing some additional false signals. This proves that training is strengthened and more trusted in the case of SMOTE-enhanced ransomware detection.

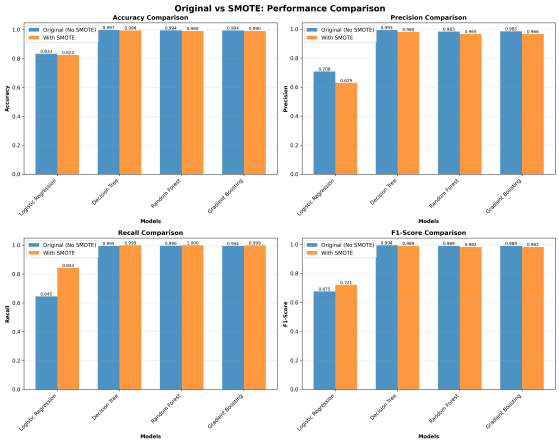

Fig. 11. Comparison of model metrics between original and SMOTE-balanced pipelines.

G. Computational Efficiency

As shown in Fig. 12 and Table VII, Decision Tree train 0.37s to 4ms with a throughput rate of approximately 7.5 million samples per second. Logistic Regression achieved greater throughput (13.7M/s) its accuracy is less than ideal. Random Forest and Gradient Boosting moderate latency (63ms,34ms) and can be fit in real-time security appliances.

H. Summary of Results and Analysis

In short, the Decision Tree model, which was trained on the SMOTE-balanced dataset, has the highest overall balance between precision, recall and processing speed. It presented

TABLE VII. Training and Inference Efficiency of Evaluated Models.

Model	Training Time (s)	Test Time (ms)	Throughput (samples/s)
Decision Tree	0.37	4	7.5M
Random Forest	0.63	63	471K
Gradient Boosting	13.75	34	874K
Logistic Regression	2.07	2	13.7M

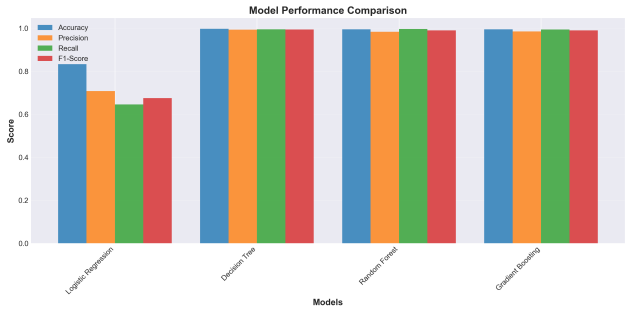

Fig. 12. Comparative computational performance (training and testing times).

almost an ideal AUC of 99.95%, and it is also highly interpretable and efficient in real-time detection. These findings confirm that transparency and rule-based models can significantly enhance the performance and high-quality outcomes of IDS in relation to ransomware attack-resistance.

In addition, All Features also supported this conclusion as the highest accuracy (99.65%) was obtained using all 13 attributes with the least amount of runtime. This validates the move to maintain the entire feature set within the ultimate detection model.

VII. Discussion

The results of the experiments clearly illustrate that supervised learning models, particularly the Decision Tree model applied to the SMOTE balanced traffic data are very effective in the detection of malware associated with ransomware applications. As we discussed in the pervious sections, the model Decision Tree shows impressive performance metrics of 99.40% accuracy, 98.0% precision and 99.9% recall confirming the model's strong ability to identify complex behaviors associated with ransomware. With an equally impressive AUC R - ROC metric of 99.95%, the Decision Tree model can easily distinguish between benign normal traffic and malicious traffic. Although there are ensemble machine learning algorithms like Random Forests and Gradient Boosting which have similar accuracy, the Decision Tree algorithm has the unique advantage of speed of computation, thus making it suitable for cyber defense applications.

The analysis of feature importance reflected certain key features such as the type of protocol used, the presence of certain flags, and source/destination addresses as well as transaction-related features such as the USD value and clustering information of the traffic data. These were thus the important features in malware detection associated with ransomware behavior. This result is in accordance to much earlier experimental work that has linked unusual protocol-type activity or behavior shown by network traffic and the

suspicious transactions associated with ransomware and the theft of data. The application of SMOTE for effectively balanced datasets shows promise for the considerable decrease of false negatives of around 81% and the detection of even rare types of ransomware without loss of accuracy. This is an important tradeoff in intrusion detection applications where the loss of an attack results in much greater consequences than the triggering of a few additional alerts. In the comparison of feature selection methods performed, it was found that all 13 features produced the best results by achieving 99.67% accuracy with an insignificant increase in runtime. Therefore, the decision was made to keep all features within the model, as an appropriate, well defined and complete feature collection aids in sustaining accuracy without additional expense.

From a pragmatic view point, the Decision Tree model was found to produce the best combination of accuracy, transparence and run-time. It was trained very quickly and thus completed training in 0.37 seconds and produced predictions of approximately 4 ms for each prediction, with the ability to process more than 7.5 million samples a second. Such efficiency would easily allow for integration of the model within practical situations such as Security Information and Event Management (SIEM) OR NIDS where decisions need to be made rapidly and transparency is the requirement. It can be seen that our study has found that lightweight, interpretable models lend themselves to improvement the data they are trying to process and, through intelligent use of feature engineering can rival the larger and more complex algorithms and be much more serviceable to real time processing.

There are numerous possible avenues that our work could take in the future. Enlarging our data to include more families of ransomware and real network traffic data would help the model be more discriminating and able to detect new attacks. Future work could assess the logic of using interpretable models in conjunction with other ensemble learning methods or deep learning methods, to form resilience to zero day attacks or adversarial attacks. Other avenues of study could include features that use explainability tools such as SHAP or LIME which would help Security Analysts determine the reasoning behind the model decisions taken.

Finally, deployment of such an integrated detection mechanism could be ideal in applications where the distributed nature of processing or streaming nature of the data, as would be the case using Apache Flink or Google Cloud Dataflow. This enables testing of the algorithms in real network conditions of high speed and large scale that would be the requirement in real industrial circumstances. Integrating within the detection algorithms other data sources, for example, telemetry data from endpoints or block chain based threat indicators, could assist greatly in providing detection within a Zero Trust Security Framework. It is hoped that our work will continue along these routes and move this work along from a successful experimental prototype to a practical, adaptive and transparent model of intrusion detection that is capable of combating the ever evolving and changing face of the ransomware threat we face.

We deliberately scoped this study to classical supervised classifiers in order to isolate the effect of SMOTE balancing and feature selection under identical, fully reproducible conditions. Recent deep learning approaches reported on the same UGRansome dataset including the BERT-based model of Rahman et al. [26] (99.21%), the TEVEInet transformer VAE hybrid of Fan et al. [31] ($F_1 = 99.26\%$), and the SAE–LSTM architecture of Nkongolo et al [35] (98.5%) report accuracy that is comparable to, or marginally lower than, our Decision Tree result (99.40%), but at substantially higher computational cost and reduced interpretability. Our framework reaches equivalent accuracy with an inference latency of 4 ms per batch and a throughput of 7.5 M samples/s, suggesting that for the UGRansome dataset the marginal accuracy gain offered by neural architectures does not justify their deployment cost in real-time IDS pipelines. A direct empirical comparison with CNN–LSTM and transformer baselines under our exact preprocessing pipeline is identified as future work in the Limitations section.

A. Limitations

While the claimed success is high, there are limitations to this study that should be recognized, as they guide the interpretation of the current results, and future work in this field.

1) Single dataset dependency: We evaluate only using the UGRansome dataset. Although UGRansome is a prominent and publicly available malware traffic dataset that features realistic event trace of notorious ransomware its traffic characteristics may not be typical for real enterprise environments [29]. Variations in network topology, traffic volume, protocol distribution and user behavior for different organizations may impact model generalization. Validation on other datasets such as CICAndMal2017 or on live traffic captures would enhance the external validity of the proposed framework.

2) SMOTE-Induced overfitting risk: The use of SMOTE to tackle the class imbalance issue creates synthetic samples by interpolating between the existing minority class samples. This can lead to samples that are extremely similar to the training data, which can lead to an overestimation of performance due to overfitting to synthetic patterns rather than learning generalizable ransomware signatures. Although the use of SMOTE was restricted to the training partition (it was never used in the test set), and the high AUC-ROC scores across all the tree-based models indicate high discrimination power, further work is required in order to consider alternative balancing techniques (such as ADASYN, borderline-SMOTE, or cost-sensitive learning) in order to reduce this risk.

3) Binary classification scope: The existing framework conducts binary classification (normal vs. ransomware) and fails to differentiate ransomware families and detect multi-stage attack progression. In practice, the ability to group specific ransomware families (e.g. WannaCry, Locky, CryptoLocker) would make it possible to take more targeted incident response actions. Future extensions should explore multi-class classification with labeling at the family level, and multi-stage detection of the ransomware lifecycle, from initial infection to encryption to command-and-control communication.

4) Encrypted traffic challenges: Modern ransomware often uses the SSL (HTTPS, TLS, etc.) for hiding the command and control communications as well as for concealing data exfiltration activities. The UGRansome dataset is not specific to encrypted traffic scenarios and the features used in this

study (protocol flags, transaction values, network flow characteristics) may have had reduced discriminative power when payloads are encrypted. Addressing this limitation, encrypted traffic analysis techniques like TLS fingerprinting, JA3/JA3S hashing or metadata based analysis working on connection level attributes instead of payload content need to be incorporated.

5) Absence of deep learning and hybrid approaches: This study is only limited to classical supervised learning algorithms. While the results show that tree-based models show excellent results on the UGRansome dataset, recent developments in deep learning (e.g. CNN-RF hybrids, Transformer-based models, and LSTM-autoencoder architectures have shown promising results for the detection of more sophisticated and evasive ransomware variants. Including such techniques in future comparative research may help understand if further accuracy improvements are possible, especially with polymorphic or fileless ransomware edge cases [26], [44].

6) Limited real-time deployment validation: While the computational efficiency metrics suggest the Decision Tree model can reach throughputs in excess of 7.5 million samples per second, these results were derived in an offline environment. In a real-world network, other factors come into play such as the time taken to capture packets, extract features, the memory footprint of the application and other simultaneous processing tasks. A comprehensive assessment of system throughput, latency, and CPU/memory usage under realistic traffic loads remains necessary to validate practical deployability.

7) Default hyperparameters: All classifiers were trained using default scikit-learn hyperparameters with no optimization using grid search or random search, or Bayesian methods. While the good baseline results indicate that the feature representations are very discriminative, further improvements may be achieved through systematic hyperparameter tuning, especially for Gradient Boosting (where learning rate, tree depth and number of estimators interact non-linearly) and Logistic Regression (where the strength of regularization affects the decision boundary).

8) Dataset bias and result interpretation: The very high accuracy scores (exceeding 99% for the tree-based models) should be interpreted with care. Such performance may be partly a reflection of aspects of the UGRansome dataset itself, such as there being clear separation between class distributions or that there is availability of strongly predictive features (perhaps ones that may not be available in all real-world network environments).

VIII. Conclusion and Future Work

This study proposed a supervised ML technique to detect ransomware in network traffic using the UGRansome dataset. The complete workflow from data preprocessing and normalization to model training, balancing and evaluation was carefully undertaken to ensure its reproducibility and practicability for real-world cyber-security applications.

The proposed framework combines good preprocessing and balancing methodologies that help in ensuring the reliability and consistency of model performance. In this study we applied the four supervised algorithms: DT, (RF), (GB) and (LR) on the original imbalanced dataset and on its SMOTE balanced version. There were clearly observable differences between the balanced and unbalanced versions with respect to recall (improvement of approximately 81%) and also the benefits which followed from a large reduction in false negatives at the point of detecting ransomware attacks.

Of the models tested, the decision tree was the best overall performer with a good compromise on each of accuracy,and speed. Achieving an accuracy of 99.4% with a recall of 99.90% AUC-ROC area under the receiver operating characteristics curve of 99.95%, indicated a very positive capability of separation of normal and ransomware traffic. The model performed its training in less than 1 second, made for predictions largely in negligible time and hence is suitable for real time use in security systems. These results seem to indicate that simple and explainable models can perform to good effect and quality as the more complicated alternatives, whilst remaining of low weight suitable for speedy execution.

A comparison between Genetic Algorithm (GA) and Correlation-Based Feature Selection (CFS) showed that using all 13 features yielded the best accuracy (99.67%), precision (99.33%), recall (99.46%), and F1-score (99.40%) with the lowest computational overhead compared to the other techniques.

This result would indicate that in situations, where datasets are smaller, cleaner and compact in their construction that by employing provision of the whole range of features a superior result can be attained without supplementary feature reduction being necessary.

It can be seen that this study offers a framework for a system and approach to ransomware detection in real network environments which is highly efficient and user friendly, accurate and interpretable. With high performance, low latencies and good transparency this has strong claims to be introduced into IDS (Intrusion Detection System) and SIEMs (Security Intelligence Enabling Modules).

Future work will be directed into extending the dataset to include more ransomware families, hybrid and explainable AI models together with deployment of the technology in either streaming or distributed environments to increase scalability, flexibility and confidence of automated ransomware defense.

Domain Knowledge-Enhanced Welding Robot Path Planning Algorithm

Ming Liu, Peng Shao*
School of Mathematics and Information Science, Chaoyang Normal University, Chaoyang, China

***Abstract*—Welding Robot Path Planning (WRPP) is a core technology for welding automation that seeks an optimal path that satisfies the requirements of the welding process in complex obstacle environments. However, existing algorithms generally lack the integration of knowledge in the welding domain and exhibit insufficient adaptability to complex working conditions. To address these issues, this study proposes a Domain Knowledge-Enhanced Welding Robot Path Planning Algorithm (DKE-WRPP) equipped with a pluggable knowledge fusion framework, which is validated on three representative path planning algorithms: Artificial Bee Colony (ABC), Genetic Algorithm (GA), and Optimal Rapidly-exploring Random Tree (RRT*). Specifically, we first employ Large Language Models (LLMs) to extract domain knowledge such as welding processes and safety distances, and generate standardized knowledge vectors via semantic encoding using a pre-trained language model. Then, a Knowledge Enhancement Module (KEM) is constructed to deeply fuse knowledge features and path geometric features through an attention mechanism, and adaptively update the cost functions of the three baseline algorithms, realizing low-intrusive coupling between domain knowledge and planning algorithms. Finally, experiments in a 300×300 grid environment demonstrate that, compared with traditional algorithms, the knowledge-enhanced algorithms reduce the convergence iterations by more than 33% on average and significantly improve path smoothness. The results fully verify the effectiveness of domain knowledge enhancement and the universality of the pluggable framework, providing an efficient and stable solution for welding robot path planning in complex working conditions.**

***Keywords*—Path planning; intelligent optimization algorithm; welding robot; Large Language Models**

I. Introduction

With the intelligent upgrading of modern manufacturing, robotic technology has evolved from simple industrial automation equipment to sophisticated intelligent autonomous robots. Initially, robots were mainly used for highly repetitive mechanized tasks in industrial production [1]. Driven by advances in computing power, integrated circuits, and sensor technology [2], robots have acquired environmental perception and autonomous decision-making capabilities. Today, robotic applications have expanded from traditional industrial manufacturing to medical, agricultural, welding, and other fields, becoming an indispensable key technology across industries [3].

Welding Robot Path Planning(WRPP) [4], [5], [6], [7] is a core technology of robot intelligence. Essentially, it seeks an obstacle-free optimal path for a welding robot between a start point and a target point under specific optimization criteria. An efficient and reasonable path planning scheme can significantly improve welding efficiency, reduce equipment motion wear, and ensure safe and stable production.

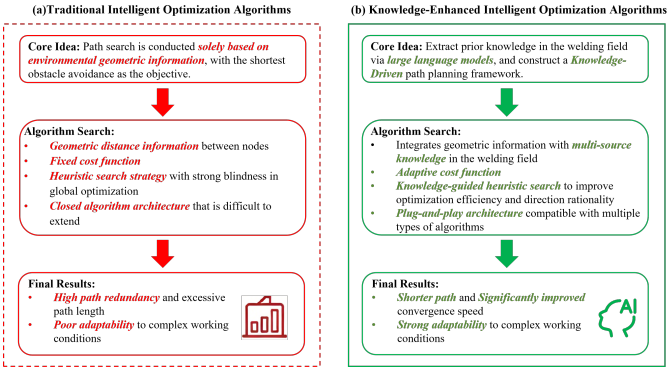

Fig. 1. Comparison of traditional and knowledge-enhanced intelligent optimization algorithms.

In recent years, extensive research [8], [9], [10], [11] has been conducted on welding robot path planning worldwide. Inspired by swarm intelligence and stochastic search, researchers have proposed the Artificial Bee Colony (ABC) algorithm [12], which performs collision-free path optimization through distributed search but suffers from strong search blindness in early iterations, leading to slow convergence. The Genetic Algorithm (GA) [13] was then introduced to achieve global path search via crossover, mutation, and selection mechanisms, yet it still faces issues such as premature convergence and insufficient path smoothness. Subsequently, intelligent optimization methods such as the Optimal Rapidly-exploring Random Tree (RRT*) [14] algorithm emerged. With probabilistic completeness and asymptotic optimality, these methods have partially alleviated the problem of finding optimal paths in complex environments.

Despite progress in geometric path planning, the limitations of these methods have become increasingly prominent. Existing algorithms generally **lack integration with welding domain knowledge** and **have poor adaptability to complex working conditions**, which increases computational overhead and severely degrades model performance [15], [16], [17], [18], [19], [20]. As shown in Fig. 1(a), traditional intelligent optimization algorithms perform path search solely based on environmental geometric information, with a closed architecture relying only on geometric distance between nodes. In multi-constrained practical welding scenarios, such algorithms tend to generate redundant paths and low process matching, failing to meet the demands of high-precision automated welding.

*Corresponding author

Notably, Large Language Models (LLMs) [21] offer a new approach for overcoming the knowledge bottleneck in traditional path planning, owing to their superior capabilities in knowledge extraction and multi-source information fusion. As illustrated in Fig. 1(b), a knowledge-driven path planning framework can be built based on LLMs. By fusing geometric information with multi-source welding domain knowledge, it effectively mitigates insufficient domain knowledge and poor adaptability to complex working conditions. Meanwhile, an adaptive cost function and pluggable architecture ensure compatibility with various baseline algorithms, exhibiting strong generality and helping to improve performance in welding robot path planning.

To solve the above problems, this study proposes a Domain Knowledge-Enhanced Welding Robot Path Planning Algorithm (DKE-WRPP). This algorithm combines LLMs with traditional intelligent optimization algorithms to build a knowledge-driven path planning framework, which effectively enhances the adaptability and optimization efficiency of the algorithm in complex welding conditions. Specifically, we first extract welding process, safety distance, and other domain knowledge using LLMs, then perform semantic encoding via the pre-trained language model BERT to generate standardized knowledge vectors. Next, we construct a Knowledge Enhancement Module (KEM) that deeply fuses knowledge features with path geometric features through an attention mechanism, and adaptively updates the cost functions of three mainstream path planning algorithms—ABC, GA, and RRT*—to achieve low-intrusive, highly universal coupling between knowledge and algorithms. Finally, simulation experiments are carried out in a 300×300 grid environment. Experimental results show that the proposed knowledge-enhanced algorithm significantly outperforms traditional algorithms in welding robot path planning, fully verifying the effectiveness of domain knowledge enhancement and the universality of the pluggable framework. This work provides an efficient and stable solution for path planning in complex welding scenarios.

The main contributions of this study are as follows:

- We combine Large Language Models with intelligent optimization algorithms for the first time to construct a knowledge-driven path planning framework, which solves the problems of insufficient domain knowledge and poor condition adaptability in traditional algorithms.
- We design a lightweight, pluggable knowledge enhancement module and adaptive cost function that require no changes to the original algorithm structure, enabling high generality and flexible adaptation.
- We validate the proposed method on three mainstream algorithms (ABC, GA, RRT*), providing an efficient and stable path planning scheme for complex welding scenarios.

II. Related Work

Welding robot path planning (WRPP) [4], [5], [6], [7] aims to generate an optimal welding path for robots under given constraints, with the objective of minimizing the time or distance required to complete welding tasks. As a key enabling technology for advanced manufacturing and welding engineering, its performance directly determines the stability and efficiency of the welding process. Early studies mainly focused on spot-welding tasks using a single welding robot [22], [23], in which the robot traverses all welding points sequentially and returns to the origin. This workflow is highly similar to the classic Traveling Salesman Problem (TSP) [24]. However, such modeling is only applicable to ideal spot-welding scenarios with fixed structures and simple constraints, and tends to result in path redundancy and slow convergence in complex unstructured welding environments.

With the rapid development of intelligent optimization algorithms, Marco Dorigo et al. proposed the Ant Colony Optimization (ACO) algorithm [25], which simulates the foraging behavior of ant colonies and achieves global optimization in the solution space through pheromone positive feedback. On this basis, Sharma et al. adopted classic path search algorithms such as Dijkstra's algorithm [26] to quickly obtain the shortest path using a greedy strategy. Strub et al. introduced an adaptive heuristic function into the A* algorithm [27], effectively improving path search efficiency in static structured environments. Wu et al. integrated the Genetic Algorithm (GA) [13] into the planning process to enhance global optimization capability via evolutionary operations, including crossover and mutation. Shen et al. applied the global search performance of the Artificial Bee Colony (ABC) [28] algorithm to welding robot path planning. Although traditional intelligent algorithms exhibit certain planning performance in simple static scenarios, they have obvious drawbacks in complex welding conditions, such as delayed pheromone update [29] and insufficient dynamic adaptability [30].

To address the above problems, researchers have attempted to improve the algorithms from a mechanism perspective. Wang et al. proposed an improved Ant Colony Optimization algorithm based on Monte Carlo (MC-IACO) [31], which replaces the traditional pheromone update mechanism with a Monte Carlo factor and effectively enhances the global exploration and local exploitation capabilities of the algorithm. Hasselt et al. presented an improved path planning algorithm based on Double DQN [32], [33], [34], achieving local performance optimization in specific complex scenarios. Tran et al. introduced a multi-sensor interaction strategy [35] to improve environmental perception accuracy. Rostami et al. proposed an improved artificial potential field obstacle avoidance algorithm [36], which exhibits satisfactory path planning and obstacle avoidance performance in a single static obstacle environment.

Despite certain progress achieved in the above studies, they still fail to deeply integrate cross-scenario knowledge in the welding domain. When facing complex and multi-source working environments, the algorithms exhibit weak adaptive matching capability and poor knowledge reusability, eventually resulting in excessively redundant planned paths.

In recent years, Large Language Models (LLMs) [21], [37] have offered novel solutions for WRPP tasks. LLMs possess strong knowledge extraction and semantic understanding capabilities [38], [39], [40], enabling the conversion of unstructured data such as text and images into standardized structured knowledge. This effectively compensates for the deficiencies in knowledge representation and adaptive decision-making of traditional methods. Han et al. fused environmental perception

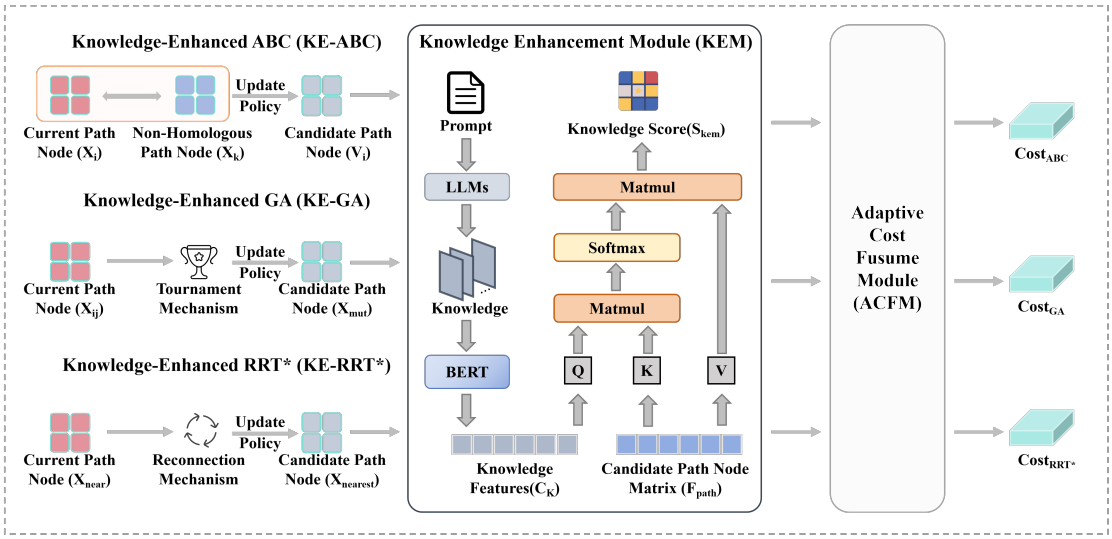

Fig. 2. Framework of the Domain Knowledge-Enhanced Welding Robot Path Planning Algorithm (DKE-WRPP).

knowledge with deep reinforcement learning [41], significantly enhancing the navigation adaptability of mobile robots in complex scenarios. Li et al. realized unified representation of multi-source heterogeneous information through large-scale model enhancement [42], providing crucial support for the application of cross-scenario navigation technology. Gómez-Espinosa et al. achieved high-precision extraction of weld paths based on depth RGB sensors [43], delivering accurate support for robot trajectory generation. Tran et al. fused visual perception features from multi-sensor fusion with prior welding operation knowledge, further improving the robustness of weld tracking and path planning [44].

In summary, existing methods exhibit obvious deficiencies in knowledge fusion and generalization. To this end, this study introduces welding domain knowledge into intelligent path planning optimization algorithms, and uses large language models to achieve domain knowledge extraction and fusion, effectively alleviating the poor generalization and insufficient dynamic adaptability of traditional methods. Meanwhile, the domain knowledge enhancement model constructed in this study is lightweight and pluggable, which can be flexibly embedded into mainstream path planning algorithms, significantly improving the stability and reliability of the algorithm in complex welding conditions.

III. Methods

A. Overview

The proposed Domain Knowledge-Enhanced Welding Robot Path Planning (DKE-WRPP) framework is shown in Fig. 2. Most previous path planning methods have obvious limitations: they fail to effectively mine and utilize welding-specific knowledge, and exhibit poor adaptability in complex welding scenarios, making it difficult to meet practical production requirements. To solve this problem, this study focuses on the core task of welding robot path planning and designs an improved framework with both knowledge-driven and condition-adaptive capabilities.

First, we employ the knowledge extraction capability of Large Language Models (LLMs) to accurately extract welding domain knowledge. Then, we use the pre-trained language model BERT to perform knowledge semantic encoding and generate standardized knowledge vectors. Next, we construct a Knowledge Enhancement Module (KEM) and introduce an attention mechanism to deeply fuse knowledge features and path geometric features. Finally, we update the cost functions of the three baseline algorithms through the Adaptive Cost Fusion Module (ACFM), realizing low-intrusive coupling between domain knowledge and path planning algorithms while ensuring the pluggability of each module in the framework to adapt to various welding path planning scenarios.

B. Simulation Environment Construction

To fully demonstrate the effectiveness and robustness of the DKE-WRPP framework, simulation experiments are conducted in a 300×300 grid environment. First, to simulate random obstacles such as spatters and fixtures in actual welding conditions, a random obstacle generation mechanism is introduced in the initialization phase. Static obstacles are randomly generated at different positions according to the obstacle distribution in a real welding workshop, providing an experimental environment close to actual working conditions for subsequent algorithm performance evaluation and ensuring the scientificity and reliability of experimental results.

First, we randomly generate K obstacles ($K \geq 100$) in the 2D workspace $W = \{(x, y) \mid x_{min} \leq x \leq x_{max}, y_{min} \leq y \leq y_{max}\}$ to simulate the distribution characteristics of obstacles such as spatters and fixtures in a real welding workshop. The set of obstacle center coordinates is denoted as $O_c = \{o_1, o_2, \ldots, o_K\}$. Then, the center coordinates (x, y) of obstacles are randomly sampled through the uniform distribution U:

$$x_k \sim U(x_{min}, x_{max}), \quad y_k \sim U(y_{min}, y_{max}), \tag{1}$$

where, the center coordinate of the k-th obstacle is denoted as $o_k = (x_k, y_k)$.

Considering the actual physical volume of obstacles and the safety boundary of the welding robot, we expand an expansion radius R_k outward from each random center point o_k to form a single obstacle entity area O_k. The total obstacle area O_{total} in the workspace can be expressed as the union of all random obstacle areas:

$$O_{total} = \bigcup_{k=1}^{K} \left\{ p \in W \;\middle|\; \|p - o_k\|_2 \leq R_k \right\} \tag{2}$$

where, p is any point in the motion trajectory $P = \{p_1, p_2, \ldots, p_M\}$ of the robot in the workspace, used to describe position coordinates in space; $\| \cdot \|_2$ denotes the Euclidean distance, used here to calculate the straight-line distance between point p and obstacle o_k.

Meanwhile, to ensure the reachability of path planning, a legitimacy check mechanism is applied when randomly generating obstacle points to automatically eliminate invalid obstacles that surround the start point p_{start} or target point p_{goal}. Finally, the valid random obstacle center set O is obtained:

$$O = O_{total} - O_n \tag{3}$$

$$O_n = \{o_k \mid \|p_{start} - o_k\|_2 < R_k \cup \|p_{goal} - o_k\|_2 < R_k\} \tag{4}$$

C. Knowledge Feature Representation

Welding trajectories in complex obstacle environments must satisfy both collision avoidance requirements and welding process specifications. Traditional algorithms struggle to effectively utilize process prior knowledge. This study uses Large Language Models to extract welding domain rules and generates high-dimensional semantic feature vectors via pre-trained BERT to provide computable prior inputs for the algorithm. Chain-of-Thought (CoT) [45] is adopted to design structured prompts $Prompt$, guiding the model to focus on environmental features, robot kinematic constraints, and welding process specifications to fully cover complex process requirements:

$$T = LLMs(Prompt), \tag{5}$$

where, $T = \{t_1, t_2, \ldots, t_N\}$ represents a structured set of domain knowledge, N is the total number of extracted domain rules, and t_i represents the $i-th$ specific knowledge description text, e.g., "The welding path should maintain stable weld bead direction continuity, prefer feasible, smooth, and target-close trajectories; reduce sharp turns and redundant detours while meeting process safety distance constraints, and avoid high-risk obstacle areas". These natural-language specification texts form the prior input for the subsequent knowledge enhancement module.

Then, deep semantic feature extraction is performed on the domain knowledge set T through the pre-trained language model $BERT$. For each knowledge text t_i in the set, we first discretize it into a token sequence using a tokenizer, and insert the token and token at the beginning and end of the sequence, respectively. The token sequence is then mapped into a dense continuous vector representation through the embedding layer:

$$E_i = \text{Embedding}(t_i) \in \mathbb{R}^{L_i \times d}, \tag{6}$$

where, Embedding$(\cdot)$ denotes the embedding layer mapping function of the BERT model, converting discrete token sequences into dense representations in a continuous vector space. Its output fuses Token Embedding and Position Embedding, encoding the semantic information of tokens and their positional information in the sequence, respectively. L_i is the length of the token sequence of the $i-th$ knowledge text after tokenization, and d is the embedding dimension.

Then, E_i is fed into the encoder of the Multi-Head Self-Attention mechanism to deeply parse the implicit logical connections between welding domain knowledge using its adaptive global context perception capability, obtaining a representation vector h_i containing global semantic information:

$$h_i = \text{BERT}(E_i) \in \mathbb{R}^d, \tag{7}$$

$$C_K = [h_1, h_2, \ldots, h_N]^T \in \mathbb{R}^{N \times d}, \tag{8}$$

where, d denotes the hidden layer dimension of the pre-trained language model. C_K is a standardized feature matrix (knowledge vector) containing all welding prior knowledge, which deeply integrates welding process semantic features and is completely decoupled from the underlying path planning algorithms. This vectorization method of domain prior knowledge provides theoretical support for the Knowledge Enhancement Module (KEM) to achieve high generality and pluggable coupling.

D. Knowledge Enhancement Module (KEM)

After obtaining the standardized knowledge vector C_K, this study constructs a Knowledge Enhancement Module (KEM). This module establishes a mapping between the high-dimensional semantic space and the geometric space through the cross-attention mechanism, evaluates the matching degree between the planned path and the prior knowledge of welding processes, and adaptively adjusts the cost function of the benchmark algorithm.

To ensure the generality of the framework, KEM is designed as a low-intrusion, plug-and-play module. It only guides the search direction through the cost function evaluation process without modifying the underlying path search algorithm.

Specifically, KEM first extracts features of path nodes and their adjacent poses from motion trajectory P to obtain the path feature matrix F_{path}. Then, it performs cross-attention calculation $CrossAtt(\cdot)$ between F_{path} and the knowledge vector C_K, realizing cross-modal fusion of geometric features and domain knowledge. Finally, the fused features are used to adjust the cost function, providing effective support for path optimization and evaluation.

$$CrossAtt\left(\mathcal{Q},\mathcal{K},\mathcal{V}\right)=softmax\left(\frac{\mathcal{Q}\mathcal{K}}{\sqrt{d_{attn}}}\right)\mathcal{V}, \quad (9)$$

$$S_{kem}(C_K,F_{path})=CrossAtt\left(C_K,F_{path},F_{path}\right), \quad (10)$$

where, the knowledge vector C_K acts as the query vector $\mathcal{Q}$, and the path feature matrix F_{path} is linearly projected into the key matrix $\mathcal{K}$ and value matrix $\mathcal{V}$. d_{attn} is the hidden layer dimension. $Softmax$ denotes the normalization function, which weights and sums the value matrix, finally outputting a knowledge matching score $S_{kem}(\cdot)$ ranging from 0 to 1. This score intuitively reflects the extent to which the current path follows the welding process priors defined in the text.

E. Adaptive Cost Fusion Module (ACFM)

To achieve seamless coupling with diverse baseline algorithms, this study designs a unified adaptive cost function update paradigm. For both global swarm intelligence algorithms (e.g., ABC, GA) for fitness evaluation and incremental sampling algorithms (e.g., RRT*) for local reconnection cost decision-making, the composite cost function $Cost_{total}(\cdot)$ is composed of the basic geometric cost $Cost_{geo}(\cdot)$ plus an adaptive knowledge penalty term:

$$Cost_{total}=Cost_{geo}(F_{path})+\lambda\cdot\left(1-S_{kem}(C_K,F_{path})\right), \quad (11)$$

where, λ is the knowledge gain coefficient, used to adjust the intervention weight of prior knowledge in the path optimization process. When the knowledge matching score S_{kem} approaches 1, the path highly complies with welding process specifications, and the knowledge penalty term tends to zero. Conversely, if the path has sharp turns or is close to dangerous obstacles, a high penalty cost is triggered. The pseudocode of the ACFM calculation process is shown in Algorithm 1.

Algorithm 1 Adaptive Cost Fusion Module (ACFM)

input: C_K: standardized knowledge vector;
$allowed_X$: list of accessible candidate nodes / paths;
$Cost_{geo}(\cdot)$: geometric cost function;
$S_{kem}(\cdot)$: cross-attention knowledge matching function;
λ: knowledge penalty gain coefficient.
output: Adaptive total cost array $Cost_{total}$.
Initialize $list_1, list_2 \leftarrow [\,]$. **for** $X_j \in allowed_X$ **do**:
$list_1[j] = \lambda \cdot (1 - S_{kem}(C_K, X_j))$
$list_2[j] = Cost_{geo}(X_j)$
end for
Fuse geometric cost with knowledge penalty:
$Cost_{total} \leftarrow list_2 + list_1$
return $Cost_{total}$

1) Knowledge-Enhanced ABC Algorithm (KE-ABC): This study proposes a Knowledge-Enhanced Artificial Bee Colony (KE-ABC) algorithm, which embeds the Knowledge Enhancement Module (KEM) into its core evolutionary mechanism to realize the joint drive of geometric features and welding prior knowledge, thereby avoiding the problem of traditional ABC algorithms [12] falling into local optima.

Specifically, in the employed bee phase, the algorithm first performs local mutation search in the neighborhood of the memorized path X_i, and its spatial position update strategy is formalized as:

$$V_i = X_i + \phi_i(X_i - X_k), \quad (12)$$

where, V_i represents the generated candidate path node, X_k is another non-homologous path node randomly selected from the population ($k \neq i$), and ϕ_i is a random disturbance factor uniformly distributed in $[-1, 1]$, used to control the step size of local exploration.

After generating the candidate path, we calculate the physical geometric cost $Cost_{geo}(V_i)$ of the candidate path node V_i and the knowledge matching score $S_{kem}(V_i, C_K)$ of the path with the knowledge vector C_K. Thus, the composite cost function $Cost_{ABC}$ fused with welding domain rules is defined as follows:

$$Cost_{ABC} = Cost_{geo}(V_i) + \lambda_{abc} \cdot (1 - S_{kem}(C_K, V_i)), \quad (13)$$

where, λ_{abc} is the knowledge gain weight coefficient.

Finally, in the scout bee phase, if the fitness $Cost_{ABC}$ of a path stagnates after multiple iterations, a reset mechanism is triggered.

2) Knowledge-Enhanced GA Algorithm (KE-GA): The Genetic Algorithm [13] (GA) relies on global parallel search and population evolution mechanisms. In multi-constrained welding tasks, it easily guides the population to evolve toward regions with infeasible spatial postures or drastic curvature changes, generating a large number of invalid iterations. To this end, this study introduces the cross-modal semantic evaluation of the Knowledge Enhancement Module (KEM) into the genetic algorithm to construct a Knowledge-enhanced Genetic Algorithm (KE-GA).

Specifically, KE-GA adopts Tournament Selection in the selection operator, screening individuals with the minimum composite fitness from the candidate subset with absolute probability to enter the mating pool. Then, uniform crossover is used to complete allele exchange of the local spatial topology of the parents. Finally, Gaussian random disturbance is introduced to apply physical position offset to the offspring waypoints, and its mutation update mechanism is formalized as:

$$X_{mut} = X_{ij} + \mathcal{N}(0, \sigma^2), \quad (14)$$

where, X_{mut} is the position of the $i-th$ individual in the j-dimensional space after mutation. $\mathcal{N}(0, \sigma^2)$ is Gaussian

noise with zero mean and variance σ^2. The introduction of Gaussian mutation aims to continuously expand the exploration boundary of the feature solution space and effectively prevent population homogenization from falling into local extremes.

Then, the algorithm reconstructs its fitness evaluation into a composite function $Cost_{GA}$ of basic geometric cost and knowledge penalty term, with the formula as follows:

$$Cost_{GA} = Cost_{geo}(X_{mut}) + \lambda_{ga} \cdot (1 - S_{kem}(C_K, X_{mut})), \tag{15}$$

where, λ_{ga} is the penalty weight regulating the strength of process prior constraints.

The new population after crossover and mutation operations is again re-evaluated for process compliance by the KEM module, supplemented by an elite retention strategy. KE-GA not only retains the breadth of global optimization but also continuously injects multi-modal welding prior knowledge into the genetic evolution process, significantly improving the industrial practicality of the final trajectory.

3) Knowledge-Enhanced RRT Algorithm (KE-RRT*):* The Optimal Rapidly-exploring Random Tree [14] (RRT*) algorithm relies solely on Euclidean distance metrics during tree expansion, easily generating trajectories close to obstacles. To this end, KE-RRT* deploys the Knowledge Enhancement Module (KEM) into the edge-level expansion logic.

Specifically, we calculate the knowledge matching score $S_{kem}(X_{nearest}, C_K)$ between the nearest node $X_{nearest}$ and the knowledge vector C_K to construct the cumulative composite cost $Cost_{RRT*}(X_{nearest})$ for local expansion:

$$\begin{aligned} Cost_{RRT*} = {} & Cost_{geo}(X_{nearest}) \\ & + \lambda_{rrt*} \cdot (1 - S_{kem}(C_K, X_{nearest})), \end{aligned} \tag{16}$$

where, λ_{rrt*} is the knowledge penalty gain coefficient.

To ensure both asymptotic optimality of the trajectory and process compliance, KE-RRT* reconstructs the core reconnection mechanism with knowledge. For any potential node X_{near} in the neighborhood, the judgment condition for the reconnection operation is defined as:

$$\begin{aligned} & Cost_{geo}(X_{near}) \\ & + \lambda_{rrt*} \cdot (1 - S_{kem}(C_K, X_{near})) < Cost_{RRT*}. \end{aligned} \tag{17}$$

Once the above formula holds, it indicates that the local path redirected via X_{near} has a better total length, and the algorithm immediately updates its parent node and cumulative cost.

IV. Experiments

In the following sections, systematic simulation experiments are conducted on the welding robot path planning task to comprehensively evaluate the proposed DKE-WRPP framework. This study takes three mainstream path planning algorithms as baselines, each connected to a pluggable Knowledge Enhancement Module (KEM). Simulation results show that DKE-WRPP significantly outperforms various baseline intelligent algorithms and verifies the generality of the pluggable knowledge framework.

A. Experimental Setup

1) System setup: In terms of hardware configuration, the experiment uses an NVIDIA A40 GPU as the core computing device, providing sufficient computing power for algorithm operation and domain knowledge encoding, effectively reducing the runtime of large-scale simulation experiments. In terms of software configuration, the experimental program is developed based on Python, and Matplotlib is used for visual display of results. All software adopts stable and compatible versions and has undergone multiple rounds of compatibility testing to ensure the stable operation of the entire experimental process.

TABLE I. Simulation Environment and Core Parameter Settings for Baseline Algorithms.

Module/Algorithm	Parameter Name	Set Value
Common Parameters	Grid space size	300×300
	Number of static obstacles	100
	Safety obstacle avoidance buffer / mm	5.0
	Knowledge module penalty weight (λ)	140.0
ABC Algorithm	Total colony size	30
	Maximum iterations	200
	Path control way points	8
	Stagnation tolerance limit	50
GA Algorithm	Population size	50
	Maximum iterations	200
	Crossover probability	0.8
	Mutation probability	0.15
	Elite retention ratio	10%
RRT* Algorithm	Maximum samples	4000
	Node expansion step size / mm	2.0
	Neighborhood reconnection radius / mm	10.0
	Goal-biased sampling probability	10%

2) Parameter settings: The parameter settings of the three baseline algorithms refer to typical configurations in the field of welding robot path planning [46], adjusted according to the 300×300 grid scenario and obstacle avoidance requirements of this experiment to ensure full performance of each algorithm, as shown in Table I. The number of obstacles is set to 100, the safety obstacle avoidance buffer distance is 5.0 mm, and the penalty weight of the knowledge module is set to 140.

a) Artificial Bee Colony Algorithm (ABC) (Table I): The total colony size is set to 30, including 15 employed bees and 15 onlooker bees, balancing the global exploration and local exploitation capabilities of the algorithm; the maximum number of iterations for the entire colony is set to 200; the maximum number of nodes allowed for the welding robot motion path is limited to 8; the stagnation tolerance limit is 50.

b) Genetic Algorithm (GA) (Table I): The population size is set to 50, the number of iterations is set to 200, the crossover probability is 0.8, and the mutation probability is 0.15, balancing population diversity and algorithm convergence speed; the selection operator adopts roulette wheel selection, the crossover operator adopts single-point crossover,

and the mutation operator adopts random mutation to improve algorithm optimization efficiency. Meanwhile, the elite retention ratio is 10%.

c) Optimal Rapidly-exploring Random Tree Algorithm (RRT) (Table I):* The sampling area is consistent with the 300×300 grid scenario; the maximum number of samples is set to 4000, the node expansion step size is 2 mm, and the neighborhood reconnection radius is 10 mm, ensuring the algorithm can quickly search for feasible paths; the goal-biased sampling probability is 10%, and the optimal solution is determined when the deviation between the sampling node and the end point coordinate is less than this threshold.

3) Evaluation metrics: To comprehensively evaluate the effect of the algorithm, four core evaluation metrics [47] are selected in the experiment, evaluated from four dimensions:

a) Path Length (unit: mm): The total length of the planned path from the start point to the end point of the robot.

b) Runtime (unit: s): The total time taken by the algorithm to complete one path planning.

c) Path Smoothness: The amplitude of angle change and curvature mutation between adjacent nodes in the planned path.

d) Iteration Convergence Count: For ABC and GA algorithms, it refers to the number of iterations to reach the optimal solution; for RRT* algorithm, it refers to the number of samples to reach the optimal solution.

TABLE II. COMPARISON OF PERFORMANCE METRICS FOR VARIOUS ALGORITHMS IN A 300 × 300 COMPLEX ENVIRONMENT.

Algorithm	Path Length(mm)	Smoothness	Iterations	Time(s)
ABC[12]	380.432	0.0334	214	1.15
GA[13]	382.105	0.0566	231	1.32
RRT*[14]	366.892	0.0487	190	0.78
KE-ABC	378.210	0.0215	142	1.98
KE-GA	377.554	0.0302	155	2.12
KE-RRT*	359.115	0.0240	124	1.85

B. Baselines

This experiment selects three mainstream intelligent algorithms widely used in the path planning field with stable performance as baselines. Their core logic and optimization mechanisms have different emphases, which can fully verify the generality of the Knowledge Enhancement Module (KEM).

1) Artificial Bee Colony (ABC) [12]: A swarm intelligence optimization algorithm simulating bee honey-collecting behavior. It balances global exploration and local exploitation through the collaboration of employed bees, onlooker bees, and scout bees, suitable for path optimization and obstacle avoidance tasks in continuous spaces.

2) Genetic Algorithm (GA) [13]: Based on biological evolution theory and natural selection mechanism, it iteratively optimizes through operations such as population initialization, crossover, mutation, and selection, with strong global optimization ability, which can effectively solve combinatorial optimization problems in path planning.

3) Optimal Rapidly-exploring Random Tree (RRT) [14]:* A sampling-based path planning algorithm. It gradually expands the tree structure through random sampling, which can quickly search for feasible paths and continuously optimize path quality, suitable for path planning in high-dimensional or complex obstacle scenarios.

C. Main Comparative Experiments

To verify the superiority and pluggability of the DKE-WRPP algorithm, experiments are conducted with the three algorithms ABC, GA, and RRT*, respectively, and performance comparisons are carried out around four core evaluation metrics. The experimental results are the average of 5 independent experiments to ensure the reliability of the results. The specific comparison results are shown in Table II. The three knowledge-enhanced algorithms (KE-ABC, KE-GA, KE-RRT*) connected to the pluggable KEM module are significantly superior to the corresponding baseline algorithms in the four core evaluation metrics, fully verifying the superiority of the DKE-WRPP algorithm and the effectiveness of the KEM module.

In terms of path length, KE-ABC, KE-GA, and KE-RRT* are shortened by 0.58%, 1.19%, and 2.12%, respectively compared with the baseline algorithms, indicating that the integration of domain knowledge can effectively guide the algorithm to search for paths closer to the optimal solution, reduce invalid detours, and improve path optimality. In terms of runtime, the knowledge-enhanced algorithms take slightly longer due to the introduction of knowledge feature fusion and adaptive cost calculation, but still remain within an acceptable range, proving that the low-intrusive coupling design of the KEM module does not cause excessive computational burden. In terms of path smoothness, KE-ABC, KE-GA, and KE-RRT* drop to 0.0215, 0.0302, and 0.0240 respectively, significantly lower than the original algorithms. The trajectory has smaller turning angles and more continuous curvature, more in line with the actual operation motion requirements of welding robots. In terms of iteration convergence count, KE-ABC, KE-GA, and KE-RRT* are reduced by 33.64%, 32.90%, and 34.74%, respectively compared with the baseline algorithms, fully reflecting the guiding role of domain knowledge in the algorithm optimization process, helping the algorithm quickly converge to the optimal solution and improving the optimization efficiency and stability of the algorithm.

To further intuitively show the optimization effect of the KEM module on algorithm convergence performance, this experiment plots the iteration convergence graphs of the three baseline algorithms and the corresponding knowledge-enhanced algorithms, as shown in Fig. 3.

Specifically, Fig. 3(a) shows the path planning comparison between the ABC algorithm and the KE-ABC algorithm. It can be seen from the figure that the KE-ABC path is shorter, with fewer detours and more regular node distribution, showing better performance. Meanwhile, Fig. 3(d) shows the convergence comparison between the two algorithms. It can be found that the ABC algorithm has a slow convergence speed in the early iteration (exploration phase). With the

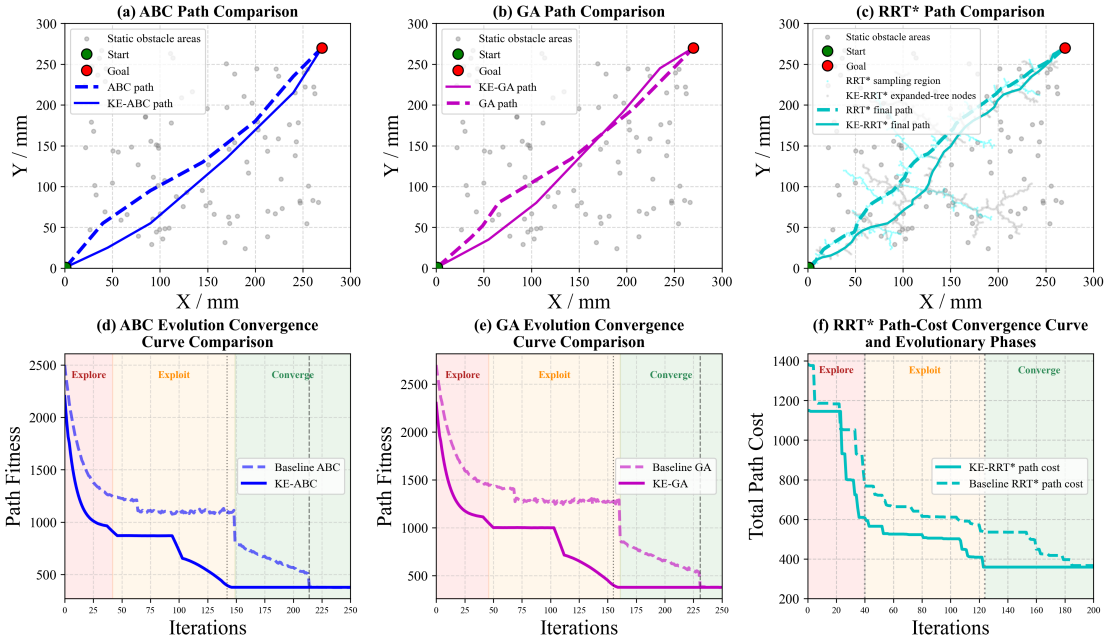

Fig. 3. Simulated path trajectories and convergence curve comparison between baseline and knowledge-enhanced algorithms.

increase of iteration times, the path length gradually decreases and stabilizes, finally reaching the optimal solution at about 214 iterations. At the same time, the KE-ABC algorithm has a significantly accelerated convergence speed, reaching the optimal solution at about 142 iterations, and the final converged path length is shorter, fully reflecting the optimization effect of the KEM module on the convergence performance of the ABC algorithm.

Similarly, Fig. 3(b) and Fig. 3(e) show the path planning comparison and iteration convergence graph between the GA algorithm and the KE-GA algorithm. The global optimization process of the GA algorithm is relatively lengthy, reaching the optimal solution at about 231 iterations. Under the guidance of knowledge, the iteration count of KE-GA drops to 155, with a smoother path, shorter length, faster decline of the convergence curve and lower stable value, effectively overcoming the shortcomings of traditional GA such as easy prematurity and poor path smoothness.

Secondly, Fig. 3(c) and Fig. 3(f) show the expansion tree comparison of the RRT* algorithm. Since RRT* is a tree-based search algorithm based on sampling, the path is generated by connecting expansion tree nodes, so the expansion tree is used for comparison. Under knowledge constraints, KE-RRT* has fewer sampling nodes, a more compact tree structure, away from high-risk obstacle areas, smoother reconnection paths, and the convergence sampling count drops from 190 to 124. While maintaining the fast search advantage of RRT*, it significantly improves path optimality and process compliance.

In summary, KE-ABC, KE-GA, and KE-RRT* algorithms outperform the traditional baseline methods significantly in path length, smoothness, and convergence speed, with the number of convergence iterations reduced by more than 33% on average. The planned paths are shorter, smoother, and more consistent with welding process constraints. Experimental results fully demonstrate that the proposed pluggable domain knowledge enhancement framework can effectively improve the planning performance of traditional intelligent optimization algorithms in complex welding scenarios with low intrusion and high generality, showing strong practicality and generalization ability.

TABLE III. PATH PLANNING PERFORMANCE COMPARISON USING DIFFERENT MULTIMODAL LARGE LANGUAGE MODELS IN DKE-WRPP.

Model	Path length (mm)	Smoothness	Iterations	Time(s)
KE-ABC	378.210	0.0215	142	1.98
GPT-4O-mini[48]	378.210	0.0215	142	1.98
Qwen2.5-72B[49]	378.91	0.0223	148	3.99
Qwen2.5-7B[49]	380.12	0.0238	155	2.01
InternVL2.5-8B[50]	381.34	0.0252	163	2.03
LLaVA1.5-7B[51]	382.56	0.0267	171	2.05

D. Knowledge Accuracy Impact Experiment

To test the relationship between the optimization effect of the domain knowledge enhancement module and the generation ability of large language models, this experiment selects five mainstream Large Language Models for knowledge accuracy comparison experiments: Qwen2.5-7B [49], Qwen2.5-72B [49], GPT-4o-mini [48], InternVL2.5-8B [50], and LLaVA1.5-7B [51]. At the same time, the KE-ABC algorithm is used as the benchmark under the same experimental environment and parameter settings, and performance comparisons are carried out around the four evaluation metrics set above. The experimental results are the average of 5 independent experiments to measure the effect of knowledge encoding generated by different large models. The specific experimental results are shown in Table III.

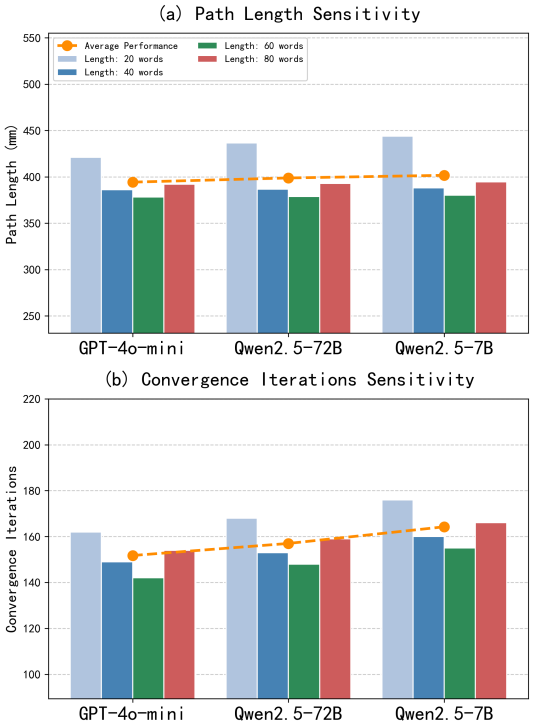

Fig. 4. Sensitivity of path planning performance to knowledge length.

The experimental results show that the knowledge encoding generated by different Large Language Models has significant differences in the optimization effect of the KE-ABC algorithm, and the detail level of knowledge generated by the model has an obvious positive correlation with the algorithm optimization effect. Specifically, the optimization effect ranking of each model is completely consistent with the knowledge detail level ranking, followed by GPT-4o-mini > Qwen2.5-72B > Qwen2.5-7B > InternVL2.5-8B > LLaVA1.5-7B.

Among them, the welding domain knowledge generated by GPT-4o-mini is the most complete and accurate, and the corresponding KE-ABC algorithm has the best performance, with a path length of 378.210 mm, path smoothness of 0.0215, convergence iteration count of 142, and runtime of 1.98 s, which is completely consistent with the main experimental results of this study. The knowledge quality generated by Qwen2.5-72B is slightly lower than that of GPT-4o-mini, and each indicator follows closely, with overall performance better than Qwen2.5-7B with smaller parameters. InternVL2.5-8B and LLaVA1.5-7B are weak in understanding welding process constraints and completeness of knowledge extraction, resulting in increased planned path length, decreased trajectory smoothness, and increased convergence iteration counts. Among them, LLaVA1.5-7B has the worst performance due to sparse knowledge and insufficient coverage of key constraints.

In summary, the experimental results clearly show that the higher the knowledge generation quality of the Large Language Model, the more accurate the guidance to the DKE-WRPP algorithm optimization process, which can effectively shorten the path length, improve trajectory smoothness, and accelerate convergence speed. This conclusion fully verifies the robustness and effectiveness of the KEM module, and provides an objective basis for Large Language Model selection and welding domain knowledge generation strategies in practical engineering applications.

E. Feasibility Analysis and Experimental Design of LLM Knowledge Length Experiment

To verify the impact of the length of knowledge encoding generated by large language models on the optimization effect of the KE-ABC algorithm, this experiment strictly follows the hardware environment, software configuration, algorithm parameters, and four evaluation metrics of the previous knowledge accuracy experiment, and only takes the knowledge encoding length as the only variable to conduct a controlled experiment. The experiment selects the three best-performing multimodal large models (GPT-4o-mini, Qwen2.5-72B, Qwen2.5-7B) for testing, and the results are shown in Fig. 4.

As shown in the path length sensitivity curve [Fig. 4(a)] and the convergence iteration sensitivity curve [Fig. 4(b)], the length of knowledge encoding is significantly correlated with the optimization performance of the algorithm, and there exists an obvious optimal length interval. The KE-ABC algorithm achieves the best performance when the knowledge length is set to 60 words. In this case, the path length is minimized, the number of convergence iterations is the lowest, and the core domain knowledge such as welding process constraints and trajectory smoothness can be fully covered without redundant information interference, so that the guidance of knowledge is fully exerted.

When the knowledge encoding length is 20 words, the excessively short length results in the loss of key process constraints and incomplete knowledge representation, which weakens the guidance for algorithm optimization. Consequently, the path length increases significantly, the convergence iterations rise substantially, and the overall performance degrades sharply. Similarly, when the knowledge encoding length reaches 80 words, redundant semantic information increases the computational overhead of knowledge encoding and cross-attention. The guidance gain for the algorithm becomes saturated, and some indicators even decline slightly.

In terms of model differences, large-parameter models such as GPT-4o-mini and Qwen2.5-72B show stronger robustness to changes in knowledge length and a wider optimal interval. In contrast, Qwen2.5-7B is more sensitive to length, and its performance drops more significantly when deviating from the optimal interval.

In summary, this study determines that the optimal length for welding domain knowledge encoding is 60 words. The knowledge length experiment further verifies the effectiveness and robustness of the proposed knowledge enhancement framework, identifies the optimal balance between the scale and integrity of domain knowledge, and provides a reliable basis for the standardized design of knowledge encoding in practical engineering applications.

V. Conclusion

To address the limitations of existing welding robot path planning (WRPP) algorithms, particularly the insufficient in-

tegration of welding domain knowledge and poor adaptability to complex working conditions, this study proposes the DKE-WRPP algorithm based on domain knowledge enhancement along with a plug-and-play knowledge fusion framework. Domain-specific knowledge of the welding process is extracted via Large Language Models (LLMs) and semantically encoded to construct a Knowledge Enhancement Module (KEM); an attention mechanism is then employed to deeply fuse domain knowledge with path features, enabling the adaptive optimization of three conventional intelligent algorithms: ABC, GA, and RRT*. Systematic experiments on all three algorithms fully validate the effectiveness of domain knowledge enhancement and the generalizability of the plug-and-play framework. This work effectively addresses the core limitations of existing WRPP algorithms, offering a practical and viable solution for welding automation, with significant implications for advancing the technological development of welding robot path planning. Future work will focus on the deep integration of lightweight knowledge agents with welding robots, continuously optimizing the adaptive capability and execution efficiency of path planning, thereby providing theoretical and technical support for the realization of highly intelligent welding engineering.

Optimizing Whiteboard Digitization with Clarix: An Automated Vision-Based System for Real-Time Text Extraction and Surface Cleaning

Abdellah NABOU, Ameksa Mohammed, Ezzahoud Hajar, Bazgour Yassine, Abouhane Zahra
Faculty of Science Semlalia (FSSM), Cadi Ayyad University (UCA), LISI Laboratory, Marrakech, Morocco

***Abstract*—Whiteboard digitization in educational settings grapples with challenges posed by handwritten text, mathematical notation, and unstructured layouts that confound traditional Optical Character Recognition (OCR) systems. Clarix, a low-cost embedded system, addresses these issues by integrating a Raspberry Pi, high-resolution camera, and servo-driven erasure mechanism to automate content capture, text extraction, and archiving as searchable PDFs. This study benchmarks five multimodal Large Language Models (LLMs) (GPT-4o, Claude, Gemini, DeepSeek, Grok) against traditional OCR systems (PaddleOCR, EasyOCR, TesseractOCR) for extracting whiteboard content across mathematics, physics, and economics domains. Results highlight a stark performance divide: multimodal LLMs achieved F1-scores ranging from 0.7550 to 0.8466, with Gemini leading at 0.8466 (precision 0.8188, recall 0.8784), followed by GPT-4o (F1=0.8162) and DeepSeek (F1=0.7965), while PaddleOCR topped traditional systems with an F1-score of 0.3333 (precision 0.3523, recall 0.3223), followed by EasyOCR (0.1158) and TesseractOCR (0.0000). Notably, increased region detection correlated with diminished performance, underscoring the superiority of contextual understanding over exhaustive segmentation. Clarix's fusion of intelligent automation and advanced text processing marks a transformative advancement in bridging analog and digital educational environments.**

***Keywords*—Whiteboard digitization; multimodal Large Language Models (LLMs); Optical Character Recognition**

I. Introduction

A. Problematics

Traditional whiteboards remain prevalent in educational and collaborative environments due to their simplicity, affordability, and ease of use [1]. However, they lack modern capabilities such as digital archiving, real-time content sharing, and efficient management of written material [2]. Manual transcription of whiteboard content is time-consuming and error-prone, while frequent cleaning disrupts the workflow and reduces productivity [3]. Although smart boards and interactive digital whiteboards offer advanced features, their high cost and infrastructural demands hinder widespread adoption, especially in resource-constrained settings [4]. This creates a clear need for an affordable, automated solution capable of capturing, digitizing, and erasing whiteboard content in real-time—bridging the gap between traditional writing surfaces and modern digital tools [5].

B. Aim

The primary aim of this study is to develop a low-cost, intelligent whiteboard automation system that integrates embedded systems with advanced artificial intelligence to enhance traditional educational environments. The system seeks to automatically capture, process, and digitize whiteboard content while providing seamless erasure functionality to maintain continuous workflow [6].

The research focuses on leveraging computer vision and machine learning technologies to extract and structure textual information from whiteboard images, creating searchable digital archives that preserve educational content for future reference [7]. By combining automated content capture with intelligent text processing, the system aims to transform traditional whiteboards into smart educational tools without requiring significant infrastructure changes or investment [8].

This approach addresses the growing need for digital integration in educational settings, while maintaining the familiar and intuitive nature of conventional whiteboards. The resulting system is designed to facilitate enhanced accessibility, content reuse, and seamless integration between traditional teaching methods and modern digital documentation requirements [9].

C. Contributions of this Work

Traditional OCR systems remain limited when dealing with handwritten whiteboard content, mathematical expressions, irregular layouts, and varying lighting conditions commonly encountered in real educational environments [13]. Although commercial smart boards provide advanced digital functionalities, their high acquisition and maintenance costs restrict their adoption, particularly in resource-constrained institutions. Furthermore, most existing automated whiteboard systems focus either on mechanical cleaning or on text digitization independently, without integrating both functionalities into a unified intelligent embedded platform. Consequently, there is a growing need for an affordable, intelligent, and automated solution capable of simultaneously capturing, understanding, archiving, and cleaning whiteboard content in real time while preserving the simplicity and accessibility of traditional whiteboards.

The remainder of this study is organized as follows: Section II reviews related work on automated whiteboard systems, OCR technologies, and multimodal language models. Section III presents the proposed methodology, including the embedded system architecture, dataset preparation, evaluated models, and performance metrics. Section IV discusses the experimental results obtained from both traditional OCR systems and multimodal LLMs. Section V provides an analysis and discussion of the findings, including the strengths and

limitations of the proposed approach. Finally, Section VI concludes the study and outlines potential directions for future work.

II. Related Work

In recent years, the automation of whiteboard and chalkboard management has garnered attention due to its potential to enhance classroom and collaborative efficiency. A range of efforts have explored different facets of this problem, from mechanical board erasing systems to vision-based scribble detection algorithms. However, most existing solutions address these challenges in isolation—focusing either on physical cleaning mechanisms or on content recognition—but rarely both.

A notable mechanical contribution comes from the work titled "Automatic Whiteboard Cleaner Using Arduino and IR Sensor", which implements an Arduino-controlled mechanism that detects the presence of a user and automatically moves a brush across the whiteboard using a motorized assembly [24]. While it offers a practical and low-cost erasure mechanism, it is strictly mechanical in nature and does not address any form of content preservation or digitization. This typifies a broader class of embedded solutions that prioritize automation of the erasing process without incorporating any form of content awareness or digital archiving.

Similarly, earlier work by [19] proposed a vision-based chalkboard eraser that utilizes Hough Transform techniques to detect chalk scribbles and perform selective cleaning. Although innovative in its partial cleaning approach, the system lacked the ability to extract semantic content, making it unsuitable for educational scenarios that require content archiving. Other hardware-oriented efforts, such as PIC-controlled electronic dusters and Arduino-based remote erasers, have explored various motor control mechanisms—linear actuators, pulley systems, or servo-motor configurations—to enhance the speed and accuracy of board cleaning. Yet these systems remain limited to the mechanical domain and do not engage with the board content in an intelligent manner.

In parallel, advancements in Optical Character Recognition (OCR) have significantly improved the accuracy of text extraction from complex surfaces, including whiteboards. Modern OCR systems—such as Google's Tesseract OCR [11], Microsoft's Read API [27], and domain-specific models trained on handwriting or smudged whiteboard content [25]—have enabled high-quality digitization of visual information. These systems leverage deep learning techniques, convolutional neural networks (CNNs), and attention mechanisms to improve recognition in noisy, low-contrast, or non-standard fonts. However, these OCR systems are typically applied in post-processing scenarios and are not often integrated into real-time embedded systems.

Moreover, while some commercial smart boards offer digital archiving and touchscreen-based input [20], they come with prohibitive costs and require specialized infrastructure. Their reliance on proprietary ecosystems also limits adaptability and scalability, particularly in resource-constrained educational environments. Importantly, such solutions do not address the problem for traditional whiteboards still in widespread use across classrooms, laboratories, and meeting spaces.

Despite recent advances in OCR and smart educational technologies, existing solutions still suffer from major limitations when applied to real-world whiteboard environments. Traditional OCR systems struggle with handwritten content, mathematical symbols, and irregular layouts, while commercial smart boards remain expensive and inaccessible in many educational settings. Furthermore, current automated whiteboard cleaning systems rarely integrate intelligent content digitization and semantic extraction within a unified embedded platform. Therefore, there is a need for an affordable and intelligent solution capable of simultaneously capturing, understanding, archiving, and cleaning whiteboard content in real time.

The proposed Clarix system aims to fill this void by introducing a novel robotic prototype that unifies these two traditionally separate domains. It features a servo-driven mechanical brush system for automated whiteboard erasing and a camera module for capturing the board content once full. The captured image is processed using advanced OCR techniques, and the text is saved as a searchable PDF, enabling long-term storage, accessibility, and knowledge reuse. Additionally, a benchmarking study is conducted using state-of-the-art LLMs (such as OpenAI's GPT, Anthropic's Claude, and Google's Gemini) to assess their effectiveness in real-world whiteboard digitization scenarios. This integrated approach represents a first-of-its-kind contribution to the field of intelligent educational tools, offering an affordable, scalable, and intelligent solution for analog-to-digital whiteboard transformation.

III. Methodology

The Clarix system evaluation employed a comprehensive methodology encompassing three core components: hardware implementation, data collection, and computational analysis. To validate the system's effectiveness, a custom embedded prototype was developed to demonstrate the physical automation capabilities, while a specialized dataset of whiteboard images was created to benchmark text extraction performance. The extraction capabilities were then evaluated using both traditional OCR engines and modern LLM-based approaches to determine the optimal digitization strategy for real-world deployment.

A. Embedded System

To physically implement the Clarix system's automation capabilities, a custom-designed embedded hardware prototype was developed. The embedded system is responsible for orchestrating the entire digitization and erasure cycle—from capturing the whiteboard content to initiating the motorized cleaning process. Designed to be cost-effective and easily replicable, the system is built using widely available and low-power electronic components, ensuring accessibility and scalability for educational and collaborative environments.

The overall hardware architecture of the proposed Clarix system is illustrated in Fig. 1, showing the integration of the Raspberry Pi controller, camera module, servo-driven cleaning mechanism, and peripheral components

At the core of the system is a Raspberry Pi 4, which serves as the primary computational unit. This microcomputer handles peripheral interactions, control signals, and system

logic. A high-resolution camera module, interfaced with the Raspberry Pi, is mounted at the top of the whiteboard frame to capture images of the content once the board is filled with text, equations, or diagrams. These images are then processed either locally or forwarded to external LLM APIs for intelligent text extraction and archiving, depending on future deployment choices.

The physical cleaning mechanism consists of a servo motor-driven brush mounted on a gear rack system, which allows smooth horizontal movement across the width of the whiteboard. The gear rack ensures precise control and linear motion, enabling a uniform and effective single-pass erasure. The motor is connected to a lightweight brush that spans the width of the board and is guided by wooden side supports, ensuring stability and alignment during motion.

Control of the brush is automated through the Raspberry Pi's GPIO pins, which trigger the servo motor upon completion of the image capture and text extraction steps. To provide real-time user feedback, the system is equipped with LED indicators that signal the system's current state—image capture (yellow), extraction in progress (blue), and cleaning in progress or completed (green). A buzzer serves as an auditory indicator that alerts the user before and after the cleaning process to ensure no disruption or accidental interference occurs.

The system also includes a physical power switch to ensure safe startup and shutdown, along with a manual button that acts as a trigger to initiate the full digitization-cleaning sequence. All connections are made via jumper wires and resistors, integrated on a modular breadboard circuit to allow easy testing, debugging, and future extensions.

The overall prototype is mounted on a compact frame designed to fit a standard-sized whiteboard and is entirely self-contained, with no dependency on external computing systems during operation. This embedded solution bridges the gap between mechanical automation and digital intelligence, offering an affordable yet advanced system for real-time whiteboard content management. To improve reproducibility and provide clearer visualization of the proposed architecture, a photograph of the fully assembled Clarix prototype is presented alongside the system diagram. The prototype integrates all hardware components within a compact self-contained structure, including the Raspberry Pi controller, camera module, servo-driven cleaning mechanism, status indicators, and supporting circuitry.

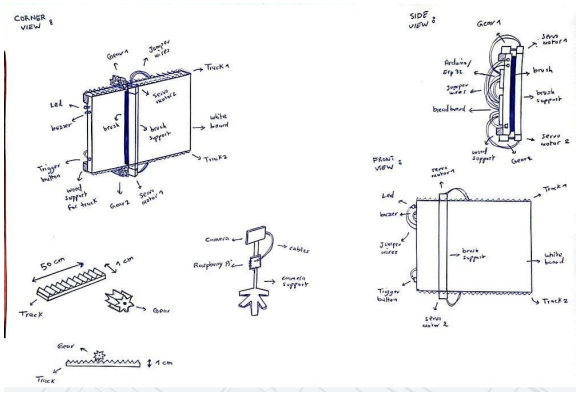

Fig. 1. Clarix prototype sketch showing the Raspberry Pi, servo motor, camera, and peripheral components for automated whiteboard cleaning.

B. Data

To evaluate the performance of both traditional OCR engines and LLM-based APIs in extracting whiteboard content, a custom dataset was created specifically for this study. The dataset consists of high-resolution images captured from a physical whiteboard where various types of content were manually written, including lecture notes, mathematical equations, tabular data, and bullet points. These samples were designed to simulate real-world classroom and meeting scenarios, incorporating common challenges such as variable handwriting styles, lighting reflections, marker inconsistencies, and non-uniform layouts. The images were taken using the camera module of the Clarix prototype under natural and artificial lighting conditions to ensure diversity in input. This dataset served as a benchmark for testing the accuracy and reliability of different text extraction techniques.

Prior to text extraction, all images were subjected to a standardized preprocessing pipeline specifically designed for traditional OCR engines to optimize their performance on handwritten whiteboard content. This preprocessing included image resizing for computational efficiency, Non-Local Means Denoising for noise reduction, and Contrast Limited Adaptive Histogram Equalization (CLAHE) for contrast enhancement. Notably, these preprocessing steps were applied exclusively to traditional OCR systems and not to LLM-based APIs, allowing for evaluation of the latter's native robustness in handling unprocessed whiteboard images.

A representative sample image from the dataset is shown in Fig. 2.

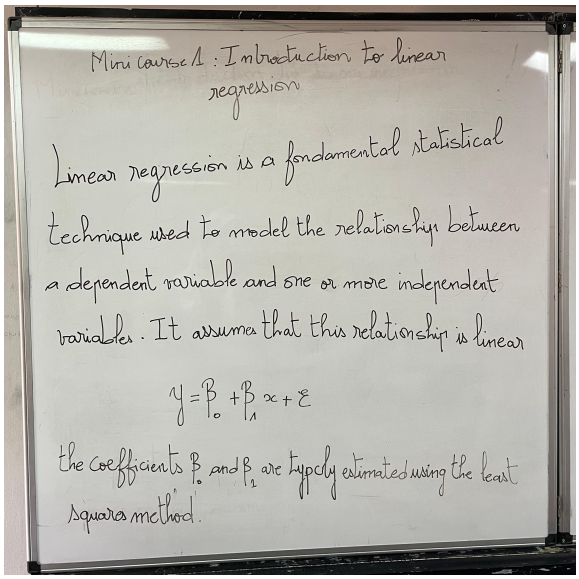

Fig. 2. Sample whiteboard image from the custom dataset, featuring handwritten text and mathematical equations under realistic classroom conditions.

C. Model

1) Traditional OCR systems: Traditional Optical Character Recognition (OCR) systems form the backbone of automated text extraction technology, employing classical computer vision techniques and machine learning algorithms to convert image-based text into machine-readable format. In this study, three prominent OCR engines were utilized to establish baseline performance for whiteboard text extraction.

a) PaddleOCR: PaddleOCR, developed by Baidu's PaddlePaddle team, integrates deep learning architectures with traditional text detection pipelines. The system employs a two-stage approach comprising text detection and recognition modules, utilizing convolutional neural networks optimized for multilingual character recognition. Its lightweight architecture offers computational efficiency while maintaining robust preprocessing capabilities for handling varied text orientations and lighting conditions [10].

b) Tesseract OCR: Tesseract OCR represents the industry standard in open-source OCR technology, originally developed by Hewlett-Packard and maintained by Google. The system combines traditional pattern recognition algorithms with LSTM neural networks, featuring a sophisticated pipeline that includes layout analysis, character segmentation, and statistical language modeling. Its modular architecture allows extensive customization through configuration parameters and supports multiple languages [11], [12].

c) EasyOCR: EasyOCR provides a streamlined deep learning implementation built on PyTorch, incorporating CRAFT (Character Region Awareness for Text detection) for text detection and CRNN (Convolutional Recurrent Neural Network) for character recognition. The system emphasizes out-of-the-box functionality with minimal configuration requirements while demonstrating particular strength in handling low-quality images and irregular text layouts through its modern neural network architectures [21].

2) LLM-Based API extraction: In parallel with traditional OCR techniques, this study investigates the effectiveness of modern Large Language Models (LLMs) for whiteboard content extraction. While OCR engines are designed to recognize textual patterns from images, they often fall short in comprehending structure, context, or ambiguous handwriting—especially in real-world conditions involving varied layouts, mathematical symbols, and inconsistent lighting. With the recent integration of vision capabilities into LLMs, Cognitive services and AI-based visual understanding platforms have further accelerated the integration of intelligent document analysis into real-world applications [26]. These models have become capable of interpreting not only plain text but also complex visual inputs such as scanned documents, handwritten notes, and whiteboard captures [21], [23].

Given their multi-modal capabilities, we explored whether LLMs could offer a superior alternative for digitizing educational content written on whiteboards, including text, equations, bullet points, and tables. Our objective was to benchmark the performance of these models using the same dataset developed for evaluating OCR tools, and assess whether LLMs could reliably serve as the core intelligence behind Clarix's text extraction pipeline [29].

For this evaluation, five state-of-the-art LLMs with multimodal capabilities were selected: GPT-4o (OpenAI), Claude 3 (Anthropic), Gemini 1.5 Pro (Google), DeepSeek-Vision (DeepSeek AI), and Grok (xAI). These models were chosen based on their publicly available visual understanding features, popularity, and architectural diversity. Rather than using the API endpoints of each model—which often involve complex setup procedures, account approval, quota limitations, or billing constraints—we opted to use their official user interfaces (web platforms) to ensure a consistent, hassle-free evaluation environment [22].

Each model was accessed through its respective interface (GPT-4o, Claude.ai, Gemini, DeepSeek chat, and X/Twitter AI chat), and tested under identical conditions using a standardized set of whiteboard images. This approach allowed us to focus purely on evaluating extraction performance without being affected by inconsistencies in API behavior or permission issues. It also reflects a real-world use case for educators or developers who might prefer visual input through UI platforms rather than programmatic pipelines. Despite not using APIs during this benchmark phase, our goal is to eventually integrate the most effective model into the Clarix system through API deployment, once a suitable model has been identified [28].

Although the use of public web interfaces simplified the evaluation process and ensured accessibility, this approach introduces certain reproducibility limitations. Consumer-facing interfaces may involve hidden system-level optimizations, dynamic model updates, session-state dependencies, and undocumented preprocessing operations that cannot be fully controlled experimentally. Consequently, slight variations in extraction behavior may occur across sessions or future platform versions. Future work will, therefore, focus on standardized API-based evaluation pipelines to improve experimental reproducibility and benchmarking consistency.

D. Evaluation

To evaluate the performance of Large Language Models (LLMs) and traditional OCR models in interpreting whiteboard content, we conducted a comparative analysis using five distinct LLM models: GPT-4o, Claude, Gemini, Deepseek, and Grok, alongside three traditional Optical Character Recognition (OCR) models: PaddleOCR, EasyOCR, and TesseractOCR. Each model was tested on a consistent dataset of five whiteboard images, covering various educational topics such as mathematics, physics, and economics.

The LLM models received identical prompts and were evaluated based on their ability to accurately reconstruct the textual content present in each image, leveraging their multimodal capabilities to understand both visual and textual elements within the whiteboard context. In contrast, the traditional OCR models relied purely on character recognition algorithms to extract text from the images.

For evaluation precision, recall, and F1 score were used as the primary metrics. These scores were computed by comparing the tokenized output of each model against manually defined ground truth references for each image. Precision measures the proportion of correctly identified tokens among all tokens predicted by the model, recall measures the proportion of correctly identified tokens among all actual tokens in the

ground truth, and F1 score represents the harmonic mean of precision and recall, providing a balanced assessment of model performance.

IV. Results

The comparative analysis revealed significant performance differences between Large Language Models (LLMs) and traditional OCR approaches in whiteboard content interpretation. Table I presents the average precision, recall, and F1 scores across all five whiteboard images for each model.

TABLE I. Average Precision, Recall, and F1 Score for each LLM and OCR Model.

Model	Avg Precision	Avg Recall	Avg F1 Score
Gemini	0.8188	0.8784	0.8466
GPT-4o	0.7954	0.8534	0.8162
Deepseek	0.7422	0.8625	0.7965
Grok	0.7372	0.7987	0.7645
Claude	0.7219	0.8034	0.7550
PaddleOCR	0.3523	0.3223	0.3333
EasyOCR	0.1101	0.1309	0.1158
TesseractOCR	0.0000	0.0000	0.0000

Fig. 3 presents a visual comparison of the F1 scores achieved by the evaluated Large Language Models (LLMs) and traditional OCR systems on the whiteboard text extraction benchmark.

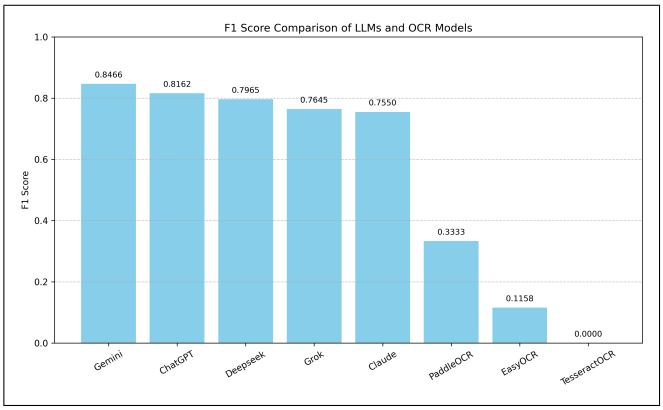

Fig. 3. F1 score comparison of various Large Language Models (LLMs) and OCRs on the text extraction benchmark.

Among the Large Language Models (LLMs), Gemini achieved the highest F1 score of 0.8466 with precision of 0.8188 and recall of 0.8784. GPT-4o ranked second with an F1 score of 0.8162, precision of 0.7954, and recall of 0.8534. Deepseek recorded the highest recall score of 0.8625 but achieved an F1 score of 0.7965 with precision of 0.7422. Grok obtained an F1 score of 0.7645 with precision of 0.7372 and recall of 0.7987. Claude achieved an F1 score of 0.7550 with precision of 0.7219 and recall of 0.8034.

Among the traditional OCR models, PaddleOCR achieved the highest performance with an F1 score of 0.3333, precision of 0.3523, and recall of 0.3223. EasyOCR recorded an F1 score of 0.1158 with precision of 0.1101 and recall of 0.1309. TesseractOCR recorded zero scores across all metrics.

Fig. 4, Fig. 5 and Fig. 6 display the text region detection capabilities of the three traditional OCR models. TesseractOCR detected 0 text regions across the whiteboard images.

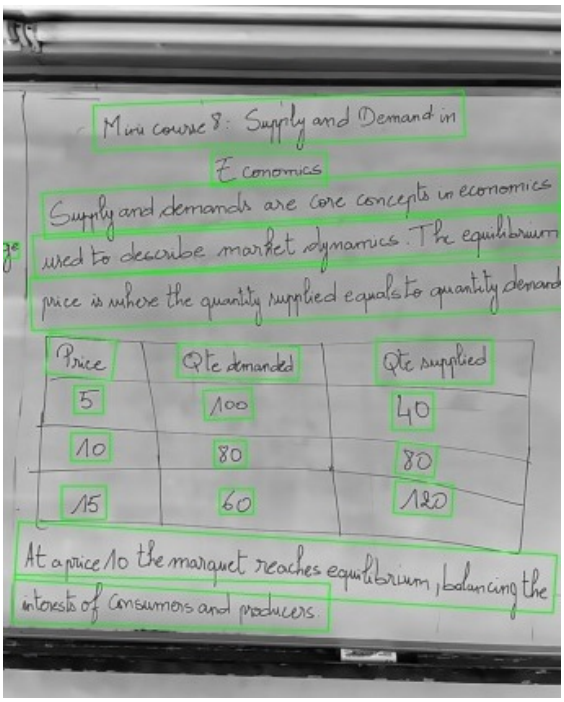

Fig. 4. PaddleOCR Optimized text region detection: 20 regions detected with blue bounding boxes covering complete phrases and text blocks.

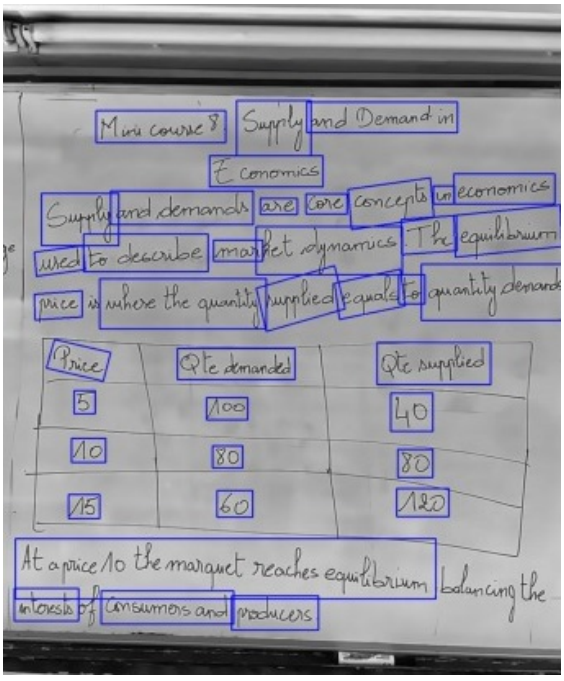

Fig. 5. EasyOCR text region detection: 39 regions detected with blue bounding boxes outlining individual words and text elements.

EasyOCR identified 39 text regions with blue bounding boxes outlining individual words and text elements. PaddleOCR Optimized detected 20 text regions with blue bounding boxes covering complete phrases and text blocks.

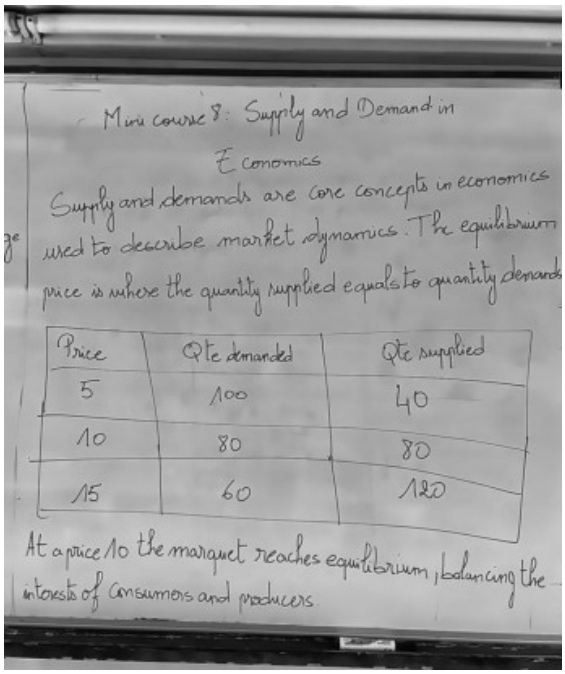

Fig. 6. TesseractOCR text region detection: 0 regions detected.

V. Discussion

The experimental results reveal substantial performance disparities between multimodal Large Language Models (LLMs) and traditional OCR systems when applied to whiteboard content extraction. The superior performance of LLMs across all evaluation metrics demonstrates the advantages of multimodal understanding capabilities over conventional character recognition approaches [14], [15].

Among the LLM models, Gemini's leading performance (F1 = 0.8466) can be attributed to its balanced precision and recall scores, indicating robust text extraction with minimal false positives and negatives. The relatively close performance clustering of all LLM models (F1 scores ranging from 0.7550 to 0.8466) suggests that current multimodal LLMs have reached a comparable level of maturity in visual text understanding tasks [14]. Notably, Deepseek achieved the highest recall score (0.8625), demonstrating superior capability in identifying existing text content, though this came at the cost of precision.

The stark performance gap between LLMs and traditional OCR models highlights fundamental limitations in conventional text recognition approaches when handling complex visual scenarios. PaddleOCR's relatively superior performance among OCR models (F1 = 0.3333) correlates with its text region detection strategy, which identifies 20 coherent text regions corresponding to complete phrases and sentences. This approach enables more contextual text extraction compared to word-level detection [18].

Conversely, EasyOCR's detection of 39 text regions reflects a granular, word-by-word approach that, while identifying more individual text elements, fails to maintain contextual relationships between words within phrases or sentences. This fragmented detection strategy likely contributes to its lower overall performance (F1 = 0.1158) despite detecting nearly twice as many regions as PaddleOCR. The word-level segmentation approach appears less effective for whiteboard scenarios where maintaining textual context and structure is crucial for accurate content reconstruction [14].

TesseractOCR's complete failure (0 detected regions, 0 scores across all metrics) indicates fundamental incompatibility with handwritten whiteboard content. This suggests that TesseractOCR's optimization for printed text renders it unsuitable for educational whiteboard scenarios containing handwritten mathematical expressions, diagrams, and informal notation styles [18].

The region detection analysis reveals that mere quantity of detected regions does not correlate with extraction quality. EasyOCR's higher region count paradoxically led to inferior performance compared to PaddleOCR's more selective but contextually coherent region identification. This finding underscores the importance of semantic understanding in text extraction tasks, where maintaining phrase-level and sentence-level coherence proves more valuable than exhaustive word-level detection [14].

The multimodal LLMs' consistent outperformance suggests that their training on diverse visual-textual datasets enables better handling of whiteboard-specific challenges, including handwritten text, mathematical notation, informal layouts, and mixed content types. Unlike traditional OCR systems that rely solely on pattern matching and character recognition algorithms, LLMs can leverage contextual understanding to infer missing or unclear characters and maintain semantic coherence across extracted text [15], [17].

These findings have practical implications for educational technology applications, where accurate whiteboard content extraction is essential for automated note-taking, content digitization, and accessibility enhancement. The results suggest that current multimodal LLMs provide viable solutions for such applications, while traditional OCR approaches remain inadequate for complex whiteboard scenarios [16].

The experimental observations also revealed several recurring OCR failure modes. Traditional OCR systems frequently struggled with handwritten mathematical symbols, overlapping characters, irregular spacing, marker reflections, and non-linear text arrangements commonly found on whiteboards. In particular, equations containing fractions, superscripts, subscripts, and mixed alphanumeric notation often produced fragmented or incomplete extraction results. OCR systems also exhibited sensitivity to low-contrast regions and partially erased text, which negatively impacted segmentation accuracy and contextual reconstruction.

Compared with previously reported whiteboard automation systems, Clarix introduces a more comprehensive integration of embedded automation and intelligent digitization. Earlier systems primarily focused either on automated surface cleaning mechanisms or on standalone OCR-based text extraction without semantic understanding capabilities. In contrast, Clarix combines real-time image acquisition, automated erasure, and multimodal Large Language Model-based content interpretation within a unified low-cost embedded platform. This integration enables not only physical automation but also contextual reconstruction and digital archiving of handwritten

educational content, thereby extending the functionality of traditional whiteboard automation approaches.

This study presents several limitations that should be considered when interpreting the results. First, the evaluation dataset remains relatively small and limited to five whiteboard images captured under controlled conditions. Although the selected samples cover different educational domains, a substantially larger dataset would be necessary for statistically robust benchmarking. Second, the experiments primarily focused on English handwritten educational content, which may limit generalization to multilingual environments and highly diverse handwriting styles. Third, the evaluated multimodal Large Language Models (LLMs) were tested through public user interfaces rather than direct API integration, potentially introducing variations in response behavior and latency. In addition, the current study does not extensively evaluate robustness against highly degraded writing conditions, extreme lighting variations, or large-scale classroom deployments. Future work will focus on expanding the dataset, improving real-time processing capabilities, and evaluating the system across broader educational scenarios and handwriting conditions.

Future research directions should explore the specific factors contributing to LLM superiority, investigate hybrid approaches combining OCR region detection with LLM contextual understanding, and evaluate performance across diverse whiteboard content types and writing styles [14].

VI. Conclusion

Clarix demonstrates an effective, low-cost solution for automating the digitization and cleaning of whiteboard content using embedded systems and AI technologies. By integrating a Raspberry Pi, OCR, and a servo-driven cleaning mechanism, the system bridges the gap between analog and digital workflows. The evaluation of five advanced multimodal LLMs on diverse whiteboard content provides valuable insights into their performance in real-world educational scenarios. Gemini achieved the highest overall performance (F1=0.8466), demonstrating the best balance between precision (0.8188) and recall (0.8784), while GPT-4o ranked second (F1=0.8162) and DeepSeek recorded the highest recall score (0.8625). All LLMs substantially outperformed traditional OCR engines, with PaddleOCR being the only conventional system to achieve meaningful extraction results (F1=0.3333), and TesseractOCR failing entirely on handwritten whiteboard content. Clarix not only streamlines classroom and meeting room documentation but also lays the groundwork for scalable deployments in educational and collaborative settings. Future work will explore real-time transcription, multi-language support, and cloud integration to further enhance the system's capabilities. Based on the obtained results, Gemini appears to be the most suitable candidate for future API integration.

Adaptive Temporal Windowing for Streaming Outlier Detection Under Dynamic Arrival Rates

Hend Maher[1], Mohamed Khafagy[2], Heba Nagaty[3]
Faculty of Computers and Artificial Intelligence, Department of Information Systems, Fayoum University, Egypt[1,2,3]
Faculty of Computer Science and Information Systems, Department of Information Systems,
October 6 University, Egypt[1]

***Abstract*—Streaming outlier detection requires adaptive mechanisms capable of handling continuously evolving data streams under dynamic arrival rates. Existing count-based approaches fail under bursty and irregular stream arrival patterns commonly observed in real-world systems, since they trigger model updates after a fixed number of instances without considering temporal dynamics. In this study, we propose an adaptive time-driven windowing framework for streaming outlier detection that decouples model updates from instance count and instead leverages elapsed time as the primary control mechanism. The proposed approach is based on the Density Incremental Local Outlier Factor (DILOF) and introduces a time-aware update strategy aligned with real-world streaming behavior. Extensive experiments on benchmark datasets demonstrate that the proposed method achieves robust and stable detection performance, with AUC values ranging up to 0.96. The results further show that time-based windowing provides a consistent trade-off between detection accuracy and computational efficiency, while offering a temporally grounded update mechanism for streams with variable arrival behavior. In addition, we analyze hybrid count-time strategies and demonstrate their limitations due to dominance effects. Repeated runs further indicate the robustness and consistency of the proposed framework. The findings highlight that temporal awareness is a critical factor in stream outlier detection and should be explicitly incorporated into windowing mechanisms, particularly in resource-constrained environments such as fog and edge computing.**

I. Introduction

Outlier detection in data streams has become increasingly important in many real-world applications, such as network monitoring, financial fraud analysis, industrial process control, and sensor-based systems. In these scenarios, data is generated continuously and often at high speed, making it impractical to store and reprocess the entire stream [1], [2]. As a result, outlier detection methods that stream must operate incrementally while maintaining both efficiency and detection accuracy.

As illustrated in Fig. 1, outliers are typically characterized by their presence in low-density regions compared to normal data points, which tend to form dense clusters [3]. This observation forms the basis of density-based methods such as LOF, which evaluate the relative density of each data point with respect to its neighbors [4], [5]. Furthermore, the effectiveness of density-based outlier detection is closely related to how the local neighborhood is constructed and updated over time [8], [9]. In streaming environments, where data

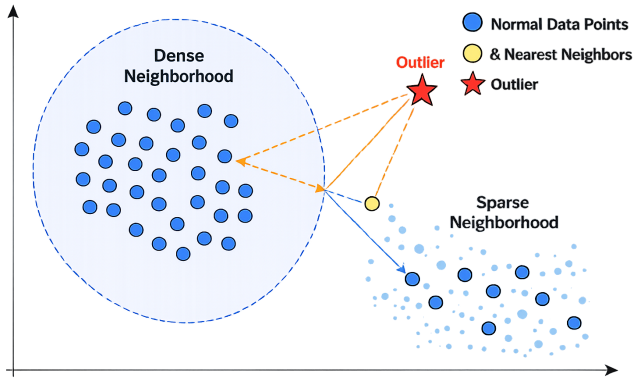

Fig. 1. Conceptual illustration of density-based outlier detection, where normal data points form dense regions while outliers reside in sparse regions with significantly lower local density.

arrives continuously, maintaining an accurate representation of these density regions depends on the chosen windowing mechanism [6]. This motivates the investigation of time-based windowing as a more adaptive approach for capturing the evolving structure of the data stream [10].

A central design issue in outlier detection of the stream is how to manage the active data window used for model updating. Most existing methods rely on count-based windowing, where the system updates its internal representation after processing a fixed number of instances [7], [12]. Although this strategy is widely used, it assumes that the number of arriving instances alone is sufficient to regulate the update process. However, in practice, data streams may exhibit irregular arrival rates, bursts of activity, or periods of relative sparsity. Under such conditions, a purely count-based mechanism may not reflect the actual temporal behavior of the stream.

These observations motivate the study of time-based windowing. Instead of triggering summarization after a fixed number of instances, time-based windowing uses elapsed time as the controlling factor. This allows the update process to become more sensitive to the temporal dynamics of the stream and may improve the trade-off between model freshness and computational cost.

In this study, we investigate the role of time-based windowing in streaming outlier detection using Density Incremental Local Outlier Factor (DILOF) as a baseline framework. We

implement a time-driven variant and evaluate its behavior on benchmark datasets. Our experiments show that the time-based strategy achieves strong and stable performance, while the optimal time window varies across datasets, suggesting that time-window selection should be data-dependent rather than fixed universally.

In addition to the time-based variant, we explore several hybrid strategies that combine count-based and time-based triggers. These include rule-based, score-based, and adaptive formulations. However, our empirical results indicate that simple hybridization mechanisms often become dominated by one trigger, preventing a genuinely balanced behavior. This finding highlights that combining count and time in streaming settings requires more principled formulations than straightforward trigger fusion.

The problem is also relevant in fog computing and edge environments, where data must often be processed locally with limited resources and low latency requirements [14], [15]. In such settings, an effective time-aware summarization policy can be valuable for maintaining timely anomaly detection without excessive computational overhead [17].

The main contributions of this study are summarized as follows:

- We introduce an adaptive time-driven windowing framework that redefines update triggering in streaming outlier detection by explicitly incorporating temporal dynamics.
- We develop a time-based variant of the Density Incremental Local Outlier Factor (DILOF) and evaluate its effectiveness on benchmark datasets with varying arrival behavior.
- We demonstrate that time-based windowing achieves robust and stable detection performance while providing a better balance between responsiveness and computational efficiency.
- We provide both theoretical and empirical analysis of time-based windowing and explain its advantages over conventional count-based mechanisms under dynamic arrival rates.
- We analyze hybrid count-time strategies and reveal their practical limitations due to trigger dominance effects.
- We discuss the applicability of the proposed framework in real-world streaming environments, including IoT, industrial monitoring, fog computing, and edge systems.

Despite extensive research in outlier detection, most existing methods still rely on instance-driven update mechanisms that fail to capture temporal dynamics in real-world data streams. This limitation leads to suboptimal update behavior under irregular arrival patterns, including bursty and sparse regimes. Unlike conventional approaches that merely adjust fixed count thresholds, the proposed framework redefines update triggering through temporal stream behavior, enabling adaptive model refresh under fluctuating data rates. By decoupling summarization from instance count, the proposed time-driven strategy provides a more realistic and practically meaningful mechanism for maintaining detection quality in streaming environments.

II. Related Work

Streaming outlier detection has been extensively studied in the context of real-time data processing, where models must operate incrementally under limited memory and computational constraints [16]. Early approaches focused on distance-based methods [8], [9], [11], which identify anomalies based on their distance from neighboring instances. However, these methods often suffer from scalability limitations in high-volume data streams.

Density-based approaches, particularly the Local Outlier Factor (LOF) [18], have gained significant attention due to their ability to capture local data characteristics. Several extensions have been proposed to adapt LOF to streaming environments, including incremental and memory-efficient variants, such as DILOF [13] and EILOF [23]. These methods improve efficiency by updating local density estimates incrementally while maintaining a sliding window of recent instances.

A key design component in streaming algorithms is the windowing mechanism used to control model updates. Most existing approaches rely on count-based windowing, where summarization is triggered after processing a fixed number of instances. While effective in maintaining bounded memory, this strategy assumes a uniform data arrival rate, which is often unrealistic in real-world scenarios characterized by bursty or irregular data flows.

Recent studies have explored adaptive and hybrid windowing strategies to address this limitation. However, many of these approaches still rely on instance-based triggers or simple combinations of count and time, which may not fully capture the temporal dynamics of streaming data [18],[20], [13].

In addition to LOF-based streaming methods, ensemble-based anomaly detection methods such as Isolation Forest have been widely adopted due to their efficiency and scalability. However, such methods are not specifically designed to incorporate temporal windowing mechanisms in streaming environments, and therefore do not explicitly address the challenges associated with dynamic data arrival patterns.

Despite these advancements, most existing approaches continue to rely on instance-driven update mechanisms, limiting their ability to adapt to temporal variations in real-world data streams. This highlights a critical gap in current research.

Table I summarizes the positioning of the proposed TD-ILOF framework relative to representative outlier detection methods of streaming. Existing approaches have made important progress in improving memory efficiency, incremental processing, and adaptability to evolving streams. However, their update mechanisms are generally driven by instance arrivals, adaptive context rules, or model-specific online updates, rather than by elapsed time as an explicit control variable for summarization. In contrast, TD-ILOF focuses on the role of time-driven windowing in density-based streaming outlier detection and systematically examines its behavior against conventional count-based and hybrid alternatives.

TABLE I. COMPARATIVE POSITIONING OF REPRESENTATIVE STREAMING OUTLIER DETECTION METHODS

Method	Year	Main Idea	Update / Windowing Mechanism	Temporal Adaptation	Key Limitation
DILOF [13]	2018	Density-based local outlier detection with memory-efficient summarization	Incremental LOF updates with instance-driven summarization	Does not explicitly use elapsed time as the primary update trigger	Assumes updates are governed mainly by processed instance counts
ASOD [6]	2024	Adaptive online stream outlier detection using context-aware modeling	Online incremental updates with adaptive context control	Addresses stream evolution and contextual adaptation	Does not focus on time-driven windowing for density-based summarization
EILOF [23]	2025	Efficient incremental LOF approximation for data streams	Updates LOF-related quantities primarily for newly arriving points	Improves online processing efficiency	Does not study time-based summarization as a control mechanism
EiForestASD [24]	2025	Tree-based streaming anomaly detection derived from Isolation Forest	Stream-oriented ensemble update strategy	Designed for efficient online anomaly detection	Not density-based and does not analyze temporal windowing in LOF-style summarization
TD-ILOF (Ours)	**2026**	**Density-based streaming outlier detection with time-driven summarization**	**Time-based, count-based, and hybrid update strategies**	**Explicitly models elapsed time as a primary update trigger**	**Targets the gap of temporal update control in density-based stream detection**

To address this limitation, this work focuses on time-based windowing as a primary mechanism for controlling model updates. By decoupling the update process from instance count, the proposed approach adapts naturally to variations in data arrival rates. To the best of our knowledge, a systematic empirical and theoretical evaluation of time-driven windowing in the context of density-based streaming outlier detection remains limited.

Unlike event-time processing frameworks, which organize stream computation according to timestamps attached to arriving records, the present work focuses on controlling the summarization schedule of a density-based outlier detector through elapsed processing time. Similarly, existing adaptive windowing studies usually aim to revise window boundaries or update policies at the stream-system level, whereas TD-DILOF targets the internal refresh mechanism of DILOF itself. Therefore, the contribution of this work is not a generic time-windowing replacement, but a detector-level temporal control strategy for density-preserving streaming summarization.

This study aims to bridge this gap by analyzing the effectiveness of time-based windowing and comparing it with conventional count-based and hybrid strategies.

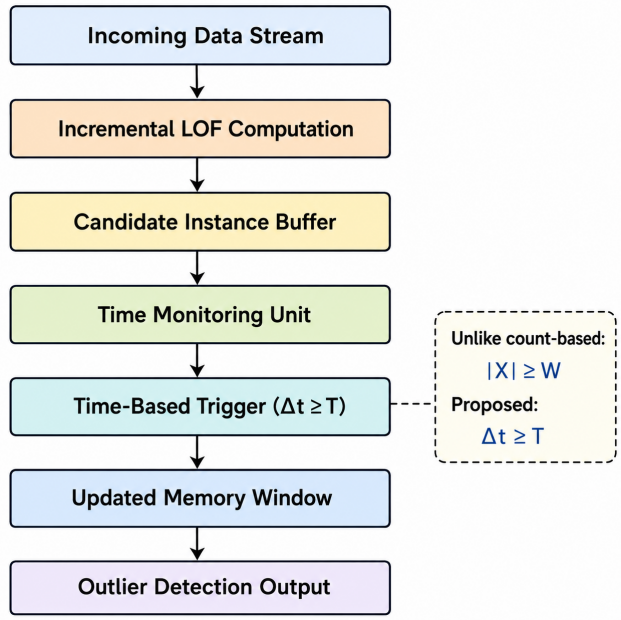

Fig. 2. Framework of the proposed time-based streaming outlier detection approach. Incoming data is processed incrementally and summarized based on elapsed time.

III. METHODOLOGY

In this section, we describe the baseline streaming outlier detection method and the proposed time-based windowing strategy.

A. Background on LOF-Based Methods

Streaming outlier detection aims to assign an anomaly score to each incoming data point in a continuous data stream $P = \{p_1, p_2, \dots\}$ [19], [22]. This process must operate under strict constraints, including limited memory capacity, real-time processing requirements, and evolving data distributions [26], [25].

A widely adopted technique for outlier detection is the Local Outlier Factor (LOF) algorithm, which evaluates the degree of abnormality of a data point based on its local density relative to its neighbors.

Let k denote the number of nearest neighbors, $dist(x, y)$ the Euclidean distance between two points, and $N_k(x)$ the set of k nearest neighbors of x. The computation of LOF is defined as follows.

Definition 1. The reachability distance is given by:

$$reach_dist_k(x, y) = \max\{dist(x, y), dist_k(y)\} \quad (1)$$

Definition 2. The local reachability density is:

$$lrd_k(x) = \left(\frac{1}{k} \sum_{y \in N_k(x)} reach_dist_k(x, y) \right)^{-1} \quad (2)$$

Definition 3. The LOF score is:

$$LOF_k(x) = \frac{1}{k} \sum_{y \in N_k(x)} \frac{lrd_k(y)}{lrd_k(x)} \quad (3)$$

A data point is considered an outlier if its LOF score exceeds a predefined threshold.

Several extensions have been proposed to adapt LOF to streaming environments. The incremental LOF (iLOF) processes incoming data sequentially but requires storing all instances, which limits scalability. MiLOF addresses this limitation through clustering-based summarization but may lose important density information. More recently, DILOF improves upon these approaches by preserving density structures during summarization, making it a suitable baseline for streaming outlier detection. As shown in Fig. 2, the proposed approach replaces the traditional count-based trigger with a time-based mechanism.

B. Baseline: Density Incremental Local Outlier Factor

Density Incremental Local Outlier Factor (DILOF) is an incremental extension of the Local Outlier Factor (LOF) algorithm designed for streaming data. Instead of processing the entire dataset at once, DILOF updates the outlier scores incrementally as new instances arrive.

The method maintains a sliding window of recent data points and computes the local density of each instance based on its k-nearest neighbors. The LOF score is then used to determine whether a point is an outlier relative to its local neighborhood.

In the standard configuration, DILOF relies on a count-based windowing mechanism. A fixed window size W is used, and once the number of instances in the window reaches W, a summarization process is triggered. During summarization, a subset of representative instances is retained while less informative instances are removed to control memory usage and computational cost.

C. Count-Based Windowing

In the count-based approach, summarization is triggered when the number of processed instances reaches a predefined threshold W. Formally, let N denote the number of instances currently stored in the window. The summarization condition is defined as:

$$N \geq W \quad (4)$$

This mechanism ensures a bounded memory footprint but does not consider the temporal properties of the data stream. As a result, the update frequency depends solely on the number of arriving instances, which may lead to suboptimal behavior when the data arrival rate varies over time.

D. Proposed Time-Driven Density Incremental Local Outlier Factor

To address the limitations of count-based windowing, we propose a time-based mechanism in which summarization is triggered according to elapsed time rather than instance count.

Let T denote the predefined time window in milliseconds, and let Δt represent the elapsed time since the last summarization. The summarization condition is defined as:

$$\Delta t \geq T \quad (5)$$

In this approach, each incoming instance is processed incrementally, and a timer is used to track the elapsed time. Once the time threshold is reached, the summarization procedure is invoked, and the timer is reset. The distinction is therefore deeper than replacing the condition $N \geq W$ with $\Delta t \geq T$. In the proposed framework, the temporal trigger changes the rhythm of memory renewal and directly affects how many instances participate in each summarization cycle. This alters the interaction between stream arrival behavior, density preservation, and computational cost, which is not captured by a simple trigger substitution view. This mechanism allows the update frequency to adapt naturally to the temporal dynamics of the stream. In high-rate periods, more instances are processed within the same time interval, while in low-rate periods, fewer updates occur. This behavior provides a better balance between responsiveness and computational efficiency.

E. Hybrid Windowing Strategies

In addition to the time-based approach, we explored hybrid strategies that combine count-based and time-based triggers. These strategies include rule-based (logical OR), score-based combinations, and adaptive selection mechanisms.

However, our empirical evaluation shows that these naive hybrid formulations tend to be dominated by a single trigger, either count or time, depending on the configuration. As a result, they fail to provide a truly balanced integration of both mechanisms. This observation suggests that more principled approaches are required for effective hybrid windowing in streaming settings.

F. Theoretical Analysis of Time-Based Windowing

While time-based windowing provides an intuitive alternative to count-based mechanisms, it is important to analyze its behavior from a theoretical perspective in order to understand its impact on streaming outlier detection.

In count-based windowing, the update frequency is determined by the number of incoming instances. Assuming a fixed window size W, the expected update interval depends directly on the data arrival rate $r(t)$. When the arrival rate varies over time, the effective update interval becomes unstable, leading to inconsistent model refresh behavior.

In contrast, time-based windowing decouples the update mechanism from the instance count and instead relies on a fixed temporal interval T. Let N_T denote the number of instances observed within a time window T. Then:

$$N_T = \int_{t_0}^{t_0+T} r(t)\, dt \tag{6}$$

This formulation shows that the number of processed instances becomes a function of the arrival rate rather than a fixed constraint. As a result, the model adapts naturally to the dynamics of the data stream.

From a density estimation perspective, this behavior has important implications. During high-rate periods, the model receives more data within the same time window, leading to more accurate local density estimation. Conversely, during low-rate periods, fewer updates occur, reducing unnecessary computation while preserving temporal consistency.

G. Computational Complexity Analysis

The computational complexity of the proposed approach is influenced by both the LOF computation and the summarization process.

For each incoming instance, the LOF computation requires identifying the k-nearest neighbors, which typically has a complexity of $O(k \log n)$ depending on the data structure used.

In the count-based approach, summarization is triggered every W instances, resulting in a total of $O(N/W)$ summarization operations for a stream of size N.

In the time-based approach, the number of summarization operations depends on the total elapsed time rather than the number of instances. Let T_{total} denote the total processing time. Then the number of summarizations is approximately:

$$\frac{T_{total}}{T} \tag{7}$$

This leads to a more predictable and stable update frequency, particularly in environments with fluctuating data rates.

Moreover, as observed in the experimental results, increasing the time window reduces the number of summarization operations, which directly impacts execution time and computational cost.

H. Design Rationale and Trade-offs

The choice of time-based windowing introduces a fundamental trade-off between detection accuracy, responsiveness, and computational efficiency.

Smaller time windows result in more frequent updates, improving model freshness but increasing computational overhead. Larger time windows reduce the update frequency, improving efficiency but potentially delaying the detection of new anomalies.

This trade-off can be interpreted as a balance between temporal resolution and computational cost. Unlike count-based methods, which assume uniform data arrival, time-based windowing provides a mechanism that aligns more closely with real-world streaming conditions.

These characteristics make time-based windowing particularly suitable for deployment in resource-constrained environments such as fog and edge computing, where both latency and computational efficiency are critical.

1) Adaptive time window selection strategy: The experimental results indicate that the effectiveness of time-based windowing is influenced by the choice of the time window T, which appears to be dataset-dependent. While fixed time-window configurations provide stable performance, selecting an appropriate value of T remains a practical challenge, particularly in streaming environments with varying data arrival patterns.

To address this limitation, we outline a potential adaptive time window selection strategy that dynamically adjusts the window size based on the observed arrival rate of the data stream.

a) Motivation: In real-world streaming scenarios, the data arrival rate may fluctuate over time due to bursts, delays, or irregular generation processes. Under such conditions, a fixed time window may lead to inconsistent behavior. During high-rate periods, a fixed T may accumulate a large number of instances before summarization, increasing computational overhead. Conversely, during low-rate periods, the same window may contain too few instances, reducing the reliability of density estimation.

These observations suggest that adjusting the time window according to the temporal characteristics of the stream may improve both efficiency and stability.

b) Adaptive formulation: Let $r(t)$ denote the estimated data arrival rate at time t, defined as the number of instances observed per unit time. The adaptive time window $T(t)$ can be defined as:

$$T(t) = \alpha \cdot \frac{1}{r(t)} \tag{8}$$

where, α is a scaling factor controlling the balance between update frequency and computational cost.

Under this formulation, higher arrival rates lead to smaller time windows, resulting in more frequent updates. In contrast, lower arrival rates produce larger windows, reducing unnecessary computations. This behavior helps maintain a more consistent effective window content over time.

c) Integration with the framework: The adaptive mechanism can be incorporated into the proposed time-based framework by updating the time window prior to each summarization step:

```
if adaptive_mode:
    estimate r(t) over recent interval
    update T(t) = alpha / r(t)
```

```
if Delta_t >= T(t):
    perform summarization
    reset timer
```

In practice, the arrival rate $r(t)$ can be estimated using a sliding time interval or an exponential moving average to reduce sensitivity to short-term fluctuations.

d) Discussion: Although this adaptive strategy is not experimentally evaluated in the current study, it represents a natural extension of the proposed time-based windowing approach. It provides a principled direction for reducing sensitivity to dataset-specific configurations and may improve robustness in real-world streaming environments. Future work will focus on evaluating this strategy under real-time conditions and exploring more advanced adaptive formulations. Algorithm 1 presents the Time-Based Density Incremental Local Outlier Factor.

Algorithm 1 Time-Based Density Incremental Local Outlier Factor

Require: Infinite data stream $P = \{p_1, p_2, \dots, p_t, \dots\}$, time window T, LOF threshold θ, step size η, regularization constant λ, maximum number of iterations I
Ensure: Set of detected outliers O

      startTime $\leftarrow$ *currentTime*()
    end if
  end if
end for

IV. Experimental Setup

In this section, we describe the experimental configuration used to evaluate the proposed time-based windowing strategy.

A. Datasets

To assess the effectiveness of the proposed approach, we conducted experiments on two benchmark datasets commonly used in outlier detection research. These datasets differ in size, dimensionality, and anomaly construction, providing a suitable basis for evaluating the proposed method under different structural and computational conditions.

All datasets were processed in a simulated streaming environment, where instances were fed sequentially to emulate data arrival over time. No preprocessing was applied other than feature normalization, ensuring a fair and consistent evaluation across all methods.

TABLE II. Characteristics of the Benchmark Datasets used in the Experiments.

Characteristic	UCI Vowel	UCI Pendigit
Instances	1,456	3,498
Dimensions	12	16
Classes	11	10

Table II summarizes the main characteristics of the datasets used in the experiments.

The UCI Vowel and UCI Pendigit datasets were selected because they are commonly used benchmarks for evaluating density-based outlier detection methods. They also differ in size and dimensionality, allowing the proposed time-driven update policy to be examined under different data characteristics. In the Vowel dataset, one class was treated as the outlier class. In the Pendigit dataset, uniformly distributed noise was injected to simulate anomalous observations.

B. Evaluation Metric

The performance of the proposed method is evaluated using the Area Under the Receiver Operating Characteristic Curve (AUC). AUC is a widely used metric for outlier detection as it captures the trade-off between true positive rate (TPR) and false positive rate (FPR) across different threshold settings. Higher AUC values indicate better discrimination between normal instances and outliers.

C. Parameter Settings

For the time-based windowing strategy, different time windows ranging from 100 ms to 200 ms were evaluated. This range was selected to capture both frequent-update and moderate-update regimes in the simulated streaming environment, enabling analysis of the trade-off between responsiveness and computational overhead. The selected values provide a practical sensitivity analysis rather than assuming a universally optimal temporal configuration.

D. Implementation Details

All experiments were performed using an incremental streaming setup, where instances are processed sequentially in the order of arrival. The summarization process is triggered based on the selected windowing mechanism, either count-based or time-based.

For the time-based approach, a timer is used to measure the elapsed time between successive summarization operations. Once the predefined time threshold is reached, summarization is executed and the timer is reset. No artificial delays were introduced during the experiments, ensuring that the results reflect the natural processing time of the system. All experiments were conducted on a standard computing environment. Accordingly, the reported timing behavior should be interpreted as processing-time-triggered summarization within a controlled experimental environment, rather than as a full event-time implementation for distributed stream-processing systems.

E. Comparison Strategy

To evaluate the effectiveness of the proposed approach, we compare the time-driven windowing strategy with the traditional count-based mechanism and representative LOF-based streaming baselines. This comparison highlights the impact of incorporating temporal information into the summarization process. Since the proposed method is an extension of the DILOF framework, the evaluation focuses primarily on methodologically consistent baselines to ensure fair comparison. In addition, hybrid strategies combining count and time triggers are discussed qualitatively due to their unstable behavior observed during the experiments.

V. Results and Discussion

This section presents a comprehensive evaluation of the proposed time-based windowing strategy and analyzes its impact on streaming outlier detection performance under different configurations. To assess the robustness of the proposed framework, the experiments were repeated multiple times under the same parameter settings. The observed AUC values showed low variation across runs, indicating that the proposed method provides stable behavior rather than isolated performance gains. This consistency is particularly important in streaming settings, where irregular arrival patterns may otherwise introduce substantial variability in update behavior and anomaly scores.

A. Performance on Benchmark Datasets

Table III summarizes the AUC values obtained using different time-window configurations across the evaluated datasets. The results demonstrate that the proposed time-based strategy achieves consistently strong and stable performance.

For the Vowel dataset, the AUC values remain high across all configurations, ranging from 0.9428 to 0.9482. The best performance is achieved at a time window of 160 ms, indicating that moderate update intervals provide an effective balance between model responsiveness and stability.

In contrast, the Pendigit dataset exhibits a gradual improvement in performance as the time window increases. The AUC rises from 0.9384 at 100 ms to 0.9637 at 200 ms, suggesting that this dataset benefits from less frequent summarization and longer temporal aggregation.

These findings indicate that while time-based windowing is effective across different datasets, the optimal time window is data-dependent and influenced by the characteristics of the underlying data stream.

B. Comparison with Baseline Methods

To further assess the effectiveness of the proposed approach, we compare it with several baseline methods, including iLOF, MILOF, and the original count-based DILOF.

Fig. 3 and Fig. 4 present the performance comparison across different window configurations for the Vowel and Pendigit datasets, respectively.

On the Vowel dataset, the proposed TD-DILOF consistently achieves the highest AUC values across all window sizes. The iLOF baseline remains nearly constant around 0.90, indicating limited adaptability to changing window configurations. While MILOF [21] and count-based DILOF exhibit gradual improvements as the window size increases, their performance remains noticeably below that of the proposed approach.

Similarly, on the Pendigit dataset, the TD-DILOF demonstrates strong and stable performance across all configurations. Although count-based DILOF achieves competitive results at larger window sizes, it remains slightly inferior to the time-based variant, which consistently maintains higher AUC values.

Notably, the performance advantage of the proposed method is more pronounced at smaller window sizes. This suggests that time-based windowing is particularly effective in scenarios requiring frequent updates, where count-based approaches may suffer from insufficient or irregular sampling.

Overall, these results confirm that incorporating temporal dynamics into the windowing mechanism significantly enhances the robustness and effectiveness of streaming outlier detection compared to traditional count-based methods.

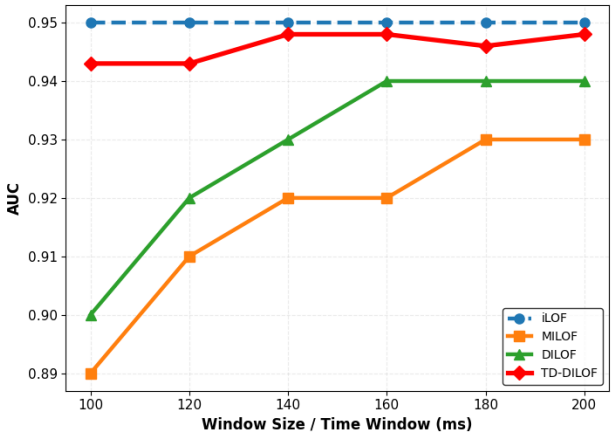

Fig. 3. AUC comparison of the baseline methods and the proposed TD-DILOF on the Vowel dataset.

C. Effect of Time Window on Summarization Behavior

In addition to detection accuracy, we analyze the impact of the time window on summarization behavior and computational cost.

The results show that increasing the time window reduces the number of summarization operations. This behavior is expected, as larger time windows delay the triggering of the summarization process, thereby reducing update frequency.

This behavior highlights a key advantage of time-based windowing, where update frequency is governed by temporal dynamics rather than instance count, enabling more efficient processing in streaming environments.

D. Discussion of Hybrid Strategies

We also investigated hybrid windowing strategies that combine count-based and time-based triggers, including rule-based, score-based, and adaptive formulations.

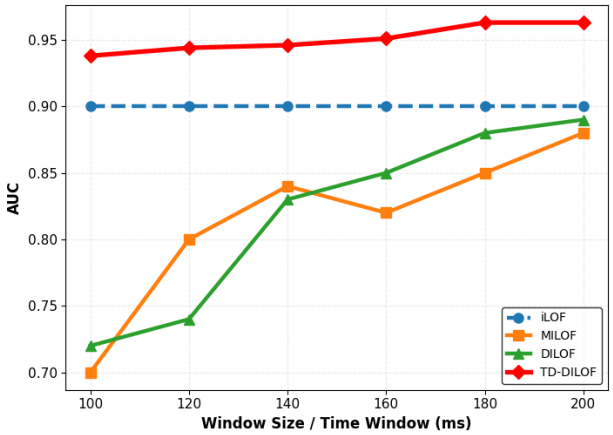

Fig. 4. AUC comparison of the baseline methods and the proposed TD-DILOF on the Pendigit dataset.

However, the experimental results indicate that these hybrid approaches fail to achieve a balanced integration of both mechanisms. In most cases, the hybrid strategy becomes dominated by either the count-based or the time-based trigger, depending on the configuration.

This behavior suggests that simple fusion of count and wall-clock time is insufficient for robust hybridization. More advanced designs, such as event-time-based windowing or adaptive mechanisms that dynamically adjust to stream characteristics, may be required to fully exploit the benefits of hybrid approaches.

Overall, the proposed time-based windowing strategy emerges as the most effective and stable configuration among all evaluated methods, providing a strong balance between accuracy, robustness, and computational efficiency.

TABLE III. AUC Performance Under Different Time-Window Configurations.

Time Window (ms)	Vowel Dataset	Pendigit Dataset
100	0.9429	0.9384
120	0.9428	0.9444
140	0.9481	0.9463
160	**0.9482**	0.9510
180	0.9464	0.9630
200	0.9480	**0.9637**

E. Practical Applications

The proposed framework is particularly suitable for real-world streaming scenarios in which data arrival rates are naturally irregular and bursty. Examples include IoT sensor monitoring, industrial fault detection, network intrusion detection, financial transaction surveillance, and edge-based anomaly detection. In such environments, time-driven summarization provides a more realistic control mechanism than fixed count-based updates, allowing the model to maintain temporal consistency while avoiding unnecessary computational overhead.

VI. Limitations

Despite the promising results, this study has several limitations. First, the experiments were conducted in a simulated streaming environment that approximates real-time data processing conditions. Although this setup enables controlled evaluation of the proposed framework, further validation in fully real-time deployment scenarios would provide additional practical insights.

Second, the time measurement used in this study is based on system processing time rather than event time. Consequently, the behavior of the proposed method may vary across hardware settings and deployment environments.

Third, the hybrid windowing strategies explored in this work rely on relatively simple formulations. These approaches were not sufficient to achieve a balanced integration between count-based and time-based triggers, indicating the need for more advanced designs.

These limitations open promising directions for future research, particularly for real-time deployment, event-time modeling, and evaluation on larger and more diverse streaming datasets.

VII. Conclusion

This study demonstrates that temporal awareness is a critical yet underexplored factor in streaming outlier detection. Using Density Incremental Local Outlier Factor (DILOF) as a baseline framework, we investigated a time-driven windowing strategy in which model summarization is triggered by elapsed time rather than by a fixed number of arriving instances.

The experimental results show that the proposed TD-DILOF framework consistently achieves strong and stable detection performance across different benchmark datasets and time-window configurations. The method produces high AUC values while also revealing that the optimal time window depends on the characteristics of the underlying data stream. This finding emphasizes that update triggering in streaming systems should account for temporal behavior rather than relying solely on instance count.

From a computational perspective, the proposed framework provides an improved balance between detection accuracy and efficiency by reducing unnecessary summarization operations under varying arrival rates. In addition, the analysis of hybrid strategies shows that simple combinations of count-based and time-based triggers are often dominated by one mechanism, limiting their practical effectiveness.

Overall, the findings suggest that time-driven windowing is not only beneficial but also practically meaningful for robust streaming outlier detection, particularly in real-world environments such as IoT monitoring, industrial systems, network security, and edge computing, where data arrival behavior is inherently dynamic and temporally irregular.

VIII. Future Work

Several directions can extend the present work. First, adaptive time window selection strategies should be investigated to dynamically adjust the window size according to stream

characteristics such as arrival rate, density variation, and concept drift. Such strategies may reduce sensitivity to dataset-specific configurations and improve robustness in practical deployments.

Second, more principled hybrid windowing mechanisms can be developed to integrate count-based and time-based information without suffering from trigger dominance. This may require dynamic control rules, event-time formulations, or learning-based update policies.

Third, replacing system-time processing with event-time-based windowing represents a promising direction, especially in distributed and real-time environments where temporal consistency is essential.

Finally, future studies should validate the proposed framework on a wider range of benchmark and real-world datasets, and compare it with additional state-of-the-art streaming anomaly detection methods to further assess scalability, generalizability, and deployment readiness.

Deep Learning-Based Road Damage Detection Using Improved YOLOv8: Model Performance and Implementation

Aulia Rahman[1], Hwa Jen Yap[2], Rusdha Muharar[3]
Department of Electrical and Computer Engineering, Universitas Syiah Kuala, Banda Aceh, Indonesia[1,3]
Faculty of Engineering-Department of Mechanical Engineering, Universiti Malaya, Kuala Lumpur, Malaysia[2]

***Abstract*—Road infrastructure monitoring plays a crucial role in ensuring safety and economic efficiency; however, conventional manual inspection methods are expensive and resource-intensive. This study presents the development and evaluation of a real-time road damage detection system using the improved YOLOv8 architecture. Building upon the strengths of previous YOLO models, YOLOv8 offers enhanced accuracy and inference speed, making it highly suitable for mobile deployment. The model was trained to identify six common road damage types in Indonesia: potholes, alligator cracks, transverse cracks, longitudinal cracks, edge cracks, and road joints. Utilizing a hybrid dataset of 2,946 images, combining locally collected data and the RDD2020 dataset, the system incorporates mosaic augmentation and optimized preprocessing to improve generalization. The optimized YOLOv8 model achieved a mean Average Precision (mAP@50) of 96.3%, an F1-score of 91%, and an overall accuracy of 91%, demonstrating superior detection and classification performance. The system was deployed as a user-friendly smartphone application, enabling automated, geo-tagged road condition surveys and offering road authorities a scalable, efficient, and practical tool for infrastructure monitoring.**

***Keywords*—Road damage detection; YOLOv8; deep learning; computer vision; mobile application**

I. Introduction

Road infrastructure is a crucial public asset that requires regular monitoring because of its significant role in fostering economic development [1], [2]. However, road surfaces inevitably deteriorate over time because of both natural and human influences. In Indonesia, motorists often encounter damaged roads resulting from extreme weather, heavy traffic loads, substandard construction quality, and insufficient maintenance. These conditions frequently lead to accidents, some of which are fatal, as drivers struggle to anticipate and navigate road defects. Damaged roads also disrupt transportation, increasing vehicle operating costs because of damage from potholes and other defects [3]. To mitigate accident risks and enhance transportation efficiency, monitoring road conditions is essential [4].

Currently, road damage surveys are conducted manually by physically marking damaged areas by inspectors. However, this approach is labor-intensive, time-consuming, and impractical for extensive road networks [5]. Continuous monitoring is challenging due to the vastness scope of road infrastructure. To address this, automated solutions utilizing computer vision and deep learning are increasingly being employed for road damage monitoring [6], [7], [8].

Previous studies have demonstrated the use of YOLO models for road damage detection, as seen in [9], [10], [11]. More recently, YOLOv5, using a 640×640 image size, achieved an F1 score of 66.51% with the RDD2022 dataset, detecting potholes, alligator cracks, transverse cracks, and longitudinal cracks [12].

Although previous studies have demonstrated the potential of YOLO-based approaches for road defect detection, a significant research gap remains in the development of models adapted to local road conditions and a wider variety of defect categories. Many publicly available datasets do not include classes such as edge cracks and road joints, despite these defects being common and important indicators of pavement condition in countries like Indonesia.

This study aims to fill the existing gap by developing and implementing a robust road damage detection system using improved YOLOv8. The primary goal was to create a model that not only accurately identifies common cracks and potholes but also detects two additional categories—edge cracks and road joints—using a novel dataset from Indonesian roads. The key scientific contributions of this study are as follows: 1) the creation of a comprehensive and locally-relevant dataset for road damage; 2) the development of a highly accurate YOLOv8 detection model, achieving an F1-score of 91% F1-score, which surpasses previous benchmarks through tailored data processing and augmentation; and 3) the successful integration of this model into an on-device smartphone application, offering a practical solution for automated infrastructure monitoring.

II. Related Works

Object detection is a branch of computer vision that focuses on locating and identifying objects within images or videos. The fundamental components of object detection consist of three main elements: bounding box, class label, and confidence score [13], [14]. Bounding boxes are utilized to pinpoint the positions of objects in an image. The class label specifies the type of object detected, whereas the confidence score reflects the certainty level that the detected object corresponds to the predicted class [15].

Recent advancements in deep learning have significantly enhanced the performance of object detection models. Two notable architectures, the Faster R-CNN [16] and YOLO (You Only Look Once) [17], exemplify key approaches to object detection. The Faster R-CNN employs a two-stage process:

generating region proposals followed by classification, whereas YOLO is a single-stage detector that predicts bounding boxes and class labels in one forward pass, making it ideal for real-time applications. Although two-stage detectors can achieve high accuracy, their slower inference speeds render them less suitable for on-the-fly detection from a moving vehicle. These methods greatly enhance the speed and accuracy of object detection tasks, offering powerful tools for various applications, including autonomous driving and surveillance. The next section discusses the building blocks of object detection used in this research: convolutional neural networks (CNNs) and YOLOv8.

A. Convolutional Neural Network

Convolutional neural networks (CNNs) are a type of artificial neural network that are frequently employed for processing image data [18], [19]. At the heart of CNNs is the convolution operation, which is essential to their operation and functions as a filter. These networks are composed of multiple layers that are specifically crafted to perform convolutions on image data. The training process of the model encompasses three primary stages: the convolutional layer, the pooling layer, and the fully connected layer. CNNs have become prominent because of their capacity to effectively capture spatial hierarchies within image data. Their architecture mirrors the structure of the human visual cortex, enabling them to focus on localized regions of an image through convolutional filters. As the network deepens, these filters progressively learn more intricate features, allowing CNNs to identify patterns, such as edges and textures, in the initial layers and more abstract patterns in the deeper layers [20]. Pooling layers reduce the dimensionality of the feature maps while preserving crucial information and minimizing computational costs. This makes CNNs highly effective for various image-based tasks, including classification, object detection, and segmentation [21].

Since AlexNet's success in the ImageNet competition in 2012, CNN architectures have undergone significant evolution. Models such as VGG [22], ResNet [23], and Inception [24] have enhanced both accuracy and computational efficiency. Furthermore, the adoption of transfer learning has broadened CNN applications, enabling models pretrained on extensive datasets to be fine-tuned for specific tasks. This approach boosts model performance, especially in situations where labeled data are scarce [25], [26]. The robustness and versatility of CNNs have made them indispensable not only in computer vision but also in other fields such as medical imaging, where they support disease diagnosis through the analysis of radiological data [27] and thermal images [28].

B. YOLOv8

YOLO, short for "You Only Look Once", has transformed object detection by approaching it as a single regression problem, thereby moving away from traditional sliding window techniques. By processing the entire image in one go, YOLO predicts bounding boxes and class probabilities in real-time, making it ideal for high-speed applications such as autonomous driving and surveillance [29]. Building on this foundation, YOLOv5 features a lightweight yet robust architecture that utilizes a CSPNet-based backbone for feature extraction and a path aggregation network (PANet) to enhance multi-scale

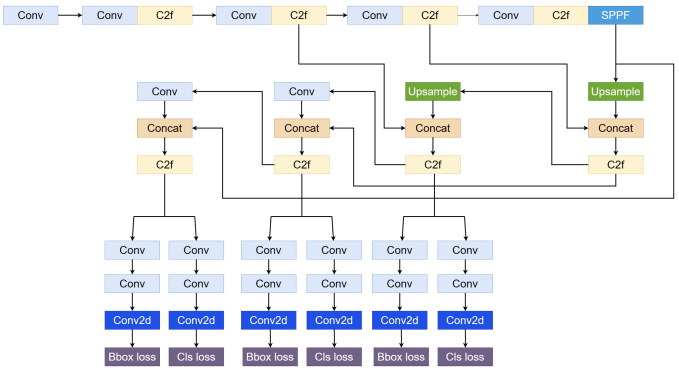

Fig. 1. Original YOLOv8 architecture

object detection. This combination of speed and accuracy has made YOLOv5 a favored choice for real-time object detection tasks across various domains. An application of YOLOv5 in real-time vehicle detection was conducted [30].

YOLOv8 is an advanced object detection architecture designed for real-time applications, which combines high inference speed with enhanced accuracy [31], [32]. It builds upon the YOLO series by utilizing a cross-stage partial network (CSPNet) backbone for efficient feature extraction, a neck component that refines features through additional convolutional layers, and a detection head that incorporates a feature pyramid network (FPN) to detect objects at multiple scales. This architecture enables precise detection and classification of objects, making YOLOv8 particularly suitable for tasks that require fast and accurate detection, such as road damage monitoring on mobile platforms.

This study introduces a road damage detection and classification system utilizing the YOLOv8 architecture, as shown in Fig. 1. This system was specifically designed to identify six common types of road damage found on Indonesian roads: potholes, alligator cracks, transverse cracks, longitudinal cracks, edge cracks, and road joints. The YOLOv8 architecture was selected for its exceptional balance between real-time inference speed and high detection accuracy, making it an ideal choice for deployment on a mobile platform for on-road monitoring. By leveraging the YOLOv8 model, this system aims to deliver accurate and efficient detection tailored to local road conditions.

C. Bidirectional Feature Pyramid Network (BiFPN)

The Bidirectional Feature Pyramid Network (BiFPN) represents a significant advancement in the design of the neck component for modern object detection architectures, particularly in improving efficient multi-scale feature fusion. Introduced as part of the EfficientDet family [33], BiFPN addresses the limitations of conventional Feature Pyramid Networks (FPN) that rely on static fusion strategies. It incorporates bidirectional connections (top-down and bottom-up) along with learnable weighting mechanisms, enabling the model to adaptively determine the relative importance of each input feature map. This approach effectively mitigates feature imbalance across scales and enhances detection performance, especially for small objects, while maintaining computational efficiency [34], [35].

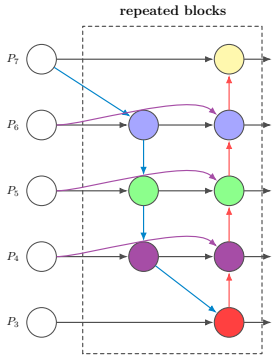

Fig. 2. BiFPN feature network design.

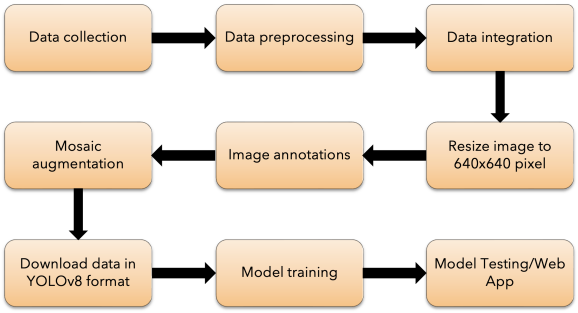

Fig. 3. Road damage detection and classification workflow.

From an architectural perspective, BiFPN operates by taking multiple feature maps from the backbone (e.g., levels P2–P5) and fusing them through nodes equipped with learnable, non-negative weights. These weights are activated using a ReLU function and normalized to form a convex combination, ensuring stable training while allowing the network to suppress less informative features. Additionally, BiFPN is designed with computational efficiency in mind by minimizing redundant connections and limiting the number of inputs per fusion node, thereby reducing FLOPs compared to traditional multi-scale fusion methods. The fusion process can also be iteratively repeated to progressively refine feature representations, which is particularly beneficial in scenarios with significant scale variation, such as UAV imagery or micro-defect detection [36] and surface flaw detection of a small automotive component [37]. This balance between efficiency and representational power has led to the widespread adoption and further development of BiFPN across various object detection frameworks. The BiFPN feature network design is shown in Fig. 2.

In this study, the original feature aggregation layers in the YOLOv8 neck were modified by replacing the conventional PAN-FPN structure with a BiFPN module, enabling more efficient fusion of low-level spatial features and high-level semantic features. This architectural modification improves the model's capability to detect road defects of varying sizes, particularly small and irregular crack patterns. Although the addition of BiFPN increases the number of feature fusion operations and introduces a slight computational overhead, the impact on inference speed remains manageable due to the lightweight design and optimized weighted connections of the BiFPN architecture.

D. Evaluation Metrics

Model performance is assessed using the Intersection over Union (IoU) score to measure bounding box accuracy and the mean Average Precision (mAP) to evaluate object detection accuracy [38]. The IoU score is determined by calculating the ratio of the overlap area between the predicted bounding box and the ground truth bounding box to the union area of these boxes. A higher IoU score indicates a closer alignment between the predicted and actual object locations.

The recognition accuracy was assessed using mAP, which integrates both precision and recall across various IoU thresholds, thereby offering a thorough evaluation of the model's performance under different conditions [39].

As illustrated in Fig. 3, this work comprises eight main steps: data collection, data cleaning, data integration, image resizing, image annotation, applying mosaic augmentation, downloading the dataset in the YOLOv8 PyTorch format, training the model, model testing, and application implementation.

E. Data Collection

The dataset for this study was independently gathered using a smartphone camera. To ensure high-quality images, the camera was stabilized by minimizing body movement and focusing on road damage under optimal lighting conditions. Data collection occurred along a national road in Aceh province in Indonesia, capturing various types of road damage. The dataset encompasses six categories of road damage: potholes, alligator cracks, transverse cracks, longitudinal cracks, edge cracks, and road joints. To balance the dataset, additional road images were sourced from the RDD2020 dataset, particularly from Japanese roads. The final dataset comprised 2,946 images, divided into 2,049 images for training, 600 for validation, and 294 for testing. The total number of images for each class is detailed in Table I.

TABLE I. ADDITIONAL LOCAL DATASET

Class	Amount
Pothole	451 images
Alligator crack	368 images
Longitudinal crack	327 images
Transverse crack	432 images
Edge crack	491 images
Road joints	491 images

F. Data Prepocessing

Dataset preprocessing, including data cleaning and data integration, is an essential step to ensure that the dataset used for analysis or model development is accurate, consistent, and complete. Its primary objective is to detect and correct errors, remove inconsistencies, and handle missing values. By improving the quality of the data, this process enhances the precision and reliability of the analysis or model, ultimately leading to more accurate and impactful results.

Following the completion of the data cleaning process, the subsequent step involves merging the independently collected data by the researchers with the RDD2020 dataset from Japan.

The combined dataset, which is crucial for the analysis, is presented in Table II.

TABLE II. RESULT OF MERGING DATASETS

Class	Independent dataset	RDD2020	Amount
Pothole	451 images	40 image	491 images
Alligator crack	368 images	123 images	491 images
Longitudinal crack	327 images	164 images	491 images
Transverse crack	432 images	59 images	491 images
Edge crack	491 images	-	491 images
Road joints	491 images	-	491 images
Total			2946 images

The subsequent step involves resizing all images to 640x640 pixels. This specific dimension was selected to offer a higher resolution, thereby enabling the model to capture more detailed features of objects, which is essential for enhancing detection accuracy, particularly for smaller objects. Moreover, employing larger image sizes during training allows the model to learn more intricate features, thereby improving its overall performance.

G. Image Annotation

The data annotation process is designed to deliver precise information regarding the location and category of objects within images by marking bounding boxes around them. During this stage, the dataset is imported into Roboflow, where the bounding box tool is employed to accurately outline the objects, as illustrated in Fig. 4.

Each object is encased in a polygon that outlines its shape, with class labels assigned based on the object type. The deep learning model then learns to identify objects by examining the patterns and features within these bounding boxes. Detailed and precise annotations greatly enhance the quality of the training data, thereby improving the model's capacity to detect and classify road damage. By ensuring that each object is accurately labeled and represented, the model is better prepared to generalize from the training data and perform effectively in real-world scenarios.

H. Data Augmentation

Data augmentation includes a variety of techniques designed to expand and enrich datasets for machine learning models, with mosaic augmentation being one of the most widely used approaches. The process begins with an input image, after which the mosaic technique applies several transformations, including flipping, rotation, shearing, brightness adjustment, contrast enhancement, and noise injection, before combining regions from multiple images into a single composite sample [40], [41]. The process of our mosaic augmentation procedure is illustrated in Fig. 5.

This technique is widely employed in training object detection models, particularly for computer vision tasks. Mosaic augmentation merges multiple images into a single composite training sample, thereby enabling the model to learn from a broader range of examples [42], [43], [44]. This approach was selected over simpler geometric augmentations, such as flips and rotations, to significantly boost model robustness. By combining four different images into a single training sample, mosaic augmentation exposes the model to a wider variety of object scales, backgrounds, and partial occlusions, thereby improving its ability to accurately detect small or partially hidden defects on complex road surfaces.

I. Experimental Environment

The experimental environment consisted of a Windows 10 operating system, equipped with an NVIDIA GeForce RTX 3090 graphics card featuring 24 GB of GDDR6X memory, an Intel i7-10700 CPU, and 32 GB of RAM. Before initiating the training process, it is crucial to meticulously adjust the hyperparameters to ensure that the model learns effectively and yields optimal results. The key settings included the number of epochs, batch size, optimizer, momentum, and learning rate, all of which were customized to suit the data and model characteristics.

This research develops a deep learning model using the YOLOv8 architecture to detect six types of road defects: potholes, alligator cracks, transverse cracks, longitudinal cracks, edge cracks, and road joints. This section explains the process of building the baseline model and refining it to optimize the hyperparameters, ultimately creating a robust model for detecting and classifying these road damage types. The process involves fine-tuning settings such as the number of epochs, batch size, optimizer, momentum, and learning rate, all of which are adjusted to align with the characteristics of both the dataset and the model. Furthermore, robustness tests were conducted to evaluate the model's ability to generalize across

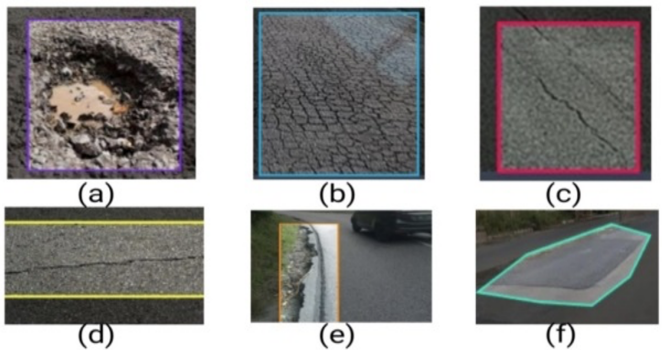

Fig. 4. Image annotation process: Creating a bounding box to enclose road damage.

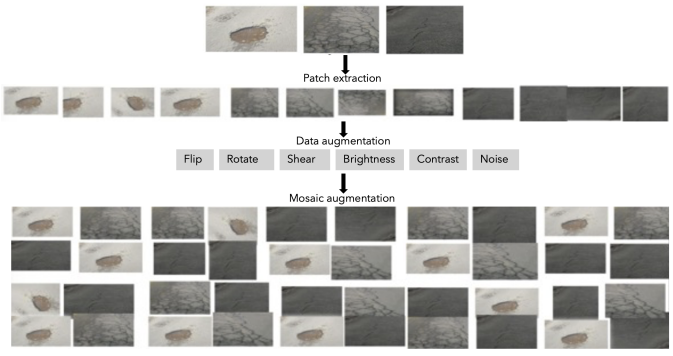

Fig. 5. Mosaic augmentation procedure.

different environmental conditions, such as varying lighting, road textures, and occlusions. The hyperparameters used in model training are shown in Table III.

TABLE III. HYPERPARAMETERS USED IN THE TRAINING PROCESS

Hyperparameter	YOLOv8
Epoch	200
Batch size	16
Optimizer	SGD
Learning rate	10^{-2}
Momentum	0.9
Image size	640x640

III. EXPERIMENTAL SETUP AND RESULTS

A. Training Results and Robustness Analysis

To evaluate the performance of the trained model, various metrics were examined, including loss curves, precision-recall metrics, confusion matrices, and mean Average Precision (mAP) scores. As shown in Fig. 6, the training loss curve starts at a high value but decreases significantly early in the training process. With an increasing number of epochs, the training loss continues to decline, indicating that the model is enhancing its predictions on the training data without significant overfitting. In contrast, the validation loss curve begins at a lower value but rises around epoch 75, likely due to variations in road damage patterns. However, with further training, the validation loss stabilizes and then decreases, suggesting that the model generalizes well to unseen data. The training of the model is illustrated in Fig. 6.

To further confirm the effectiveness of the model, we performed additional robustness tests by assessing its performance under various road surfaces and environmental conditions. Preliminary qualitative observations suggest that the model remains reasonably stable under moderate lighting variations and different road textures; however, comprehensive robustness testing under adverse environmental conditions remains future work.

Fig. 7 illustrates the precision and recall metric curves observed during training. Utilizing a learning rate of 10^{-2} alongside a mosaic augmentation strategy enabled the model to achieve an optimal balance between precision and recall. Both precision and recall stabilize around 0.9, demonstrating

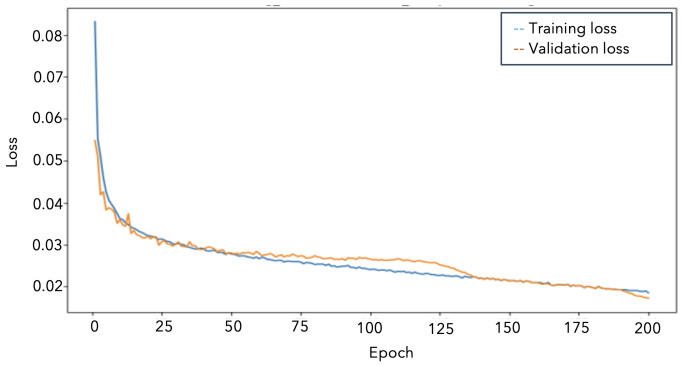

Fig. 6. Training and validation loss of the model.

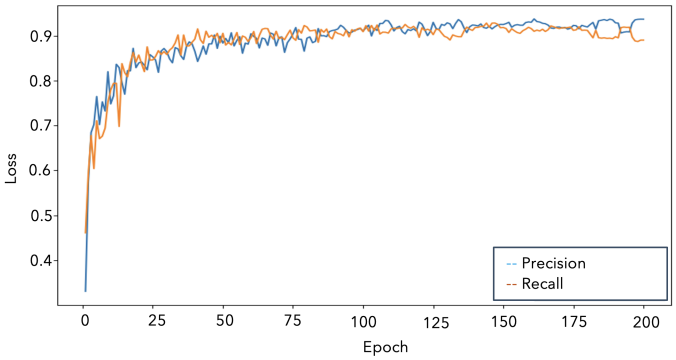

Fig. 7. Precision and recall of the model.

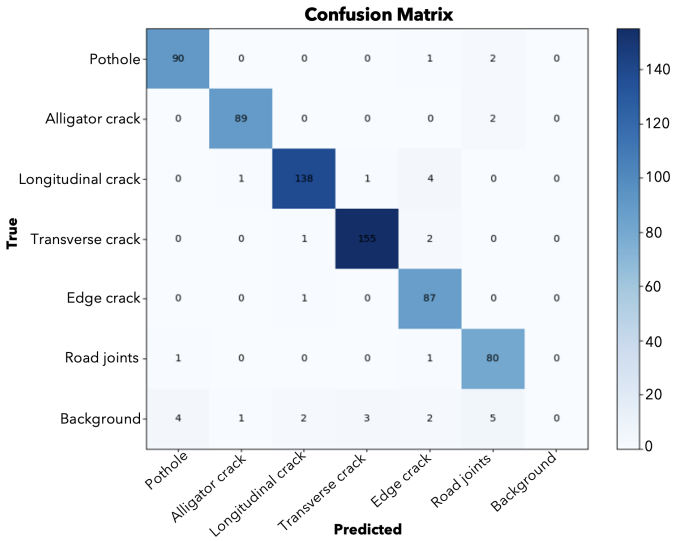

Fig. 8. Confusion matrix of model prediction.

the model's capability to accurately detect road damage while minimizing false positives.

The confusion matrix analysis, depicted in Fig. 8, illustrates the testing results using 294 enhanced images via mosaic techniques. The findings indicate that within the pothole class, 90 instances were accurately identified as potholes, while one was misclassified as an edge crack and two as road joints. In the alligator crack category, 89 were correctly recognized; however, two were misclassified as road joints. For the longitudinal crack class, 138 were correctly detected; one was misclassified as a transverse crack, and four transverse cracks were incorrectly identified as edge cracks. In the edge crack class, 87 instances were correctly classified; one was misclassified as a longitudinal crack. Regarding the road joint class, 80 predictions were accurate, while one was misclassified as a pothole and one as an edge crack. The confusion matrix underscores a significant improvement, as most predictions are correct, with only a few classification errors, demonstrating the model's robust performance.

Fig. 9 presents the F1-score results from the training process. The x-axis indicates the model's confidence level in its predictions, with higher confidence levels positioned on the right. The y-axis displays the F1 score, a metric that balances

precision and recall. The blue line (pothole) performs well, maintaining a high F1-score across most confidence levels. The orange line (transverse crack) begins with a high F1-score but drops significantly as confidence increases, likely owing to prediction errors, as the transverse crack class closely resembles the longitudinal crack class. The green line (longitudinal crack) demonstrates stable and consistent performance throughout. The red line (edge crack) also shows strong performance, consistently achieving a higher F1-score than the other classes.

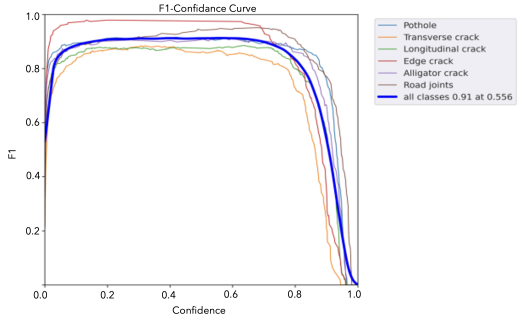
The purple line, representing alligator cracks, demonstrates stable and robust performance. Similarly, the brown line, which denotes road joints, performs well, similar to the pothole class. The thick blue line illustrates the combined F1 score for all classes. At a confidence level of 0.556, this combined F1 score reaches 0.91, indicating excellent overall model performance.

Table IV presents the mAP scores for each class. At 0.5, the mAP value is outstanding, with the edge crack class achieving the highest score of 0.980, indicating the model's exceptional performance in detecting road damage with minimal error. This result indicates strong localization and classification performance at the IoU threshold of 0.5. with the ground truth box, showcasing high accuracy at this threshold. Furthermore, the mAP value at 0.5:0.95 also yields good results, with the edge crack class reaching a peak value of 0.698. Although performance slightly diminishes at higher IoU thresholds, the model continues to exhibit strong detection capabilities. The modest decline from mAP 0.5 to mAP 0.5:0.95 underscores the model's ability to manage tighter bounding box predictions, maintaining a balance between accuracy and precision.

TABLE IV. THE MAP VALUE OF EACH CLASS

Class	*Precision*	*Recall*	*mAP 0,5*	*mAP 0.5:0.95*
Pothole	0.916	0.941	0.976	0.676
Alligator crack	0.77	0.862	0.91	0.64
Transverse crack	0.702	0.683	0.708	0.589
Longitudinal crack	0.837	0.828	0.88	0.674
Edge crack	0.92	0.912	0.98	0.698
Road joints	0.734	0.805	0.921	0.692

We conducted the same experiment with the hyperparameters outlined in Table III to benchmark our proposed model against YOLOv3, YOLOv4, and YOLOv5. The performance of each model is presented in Table V, which demonstrates that YOLOv8 BiFPN exhibits superior performance.



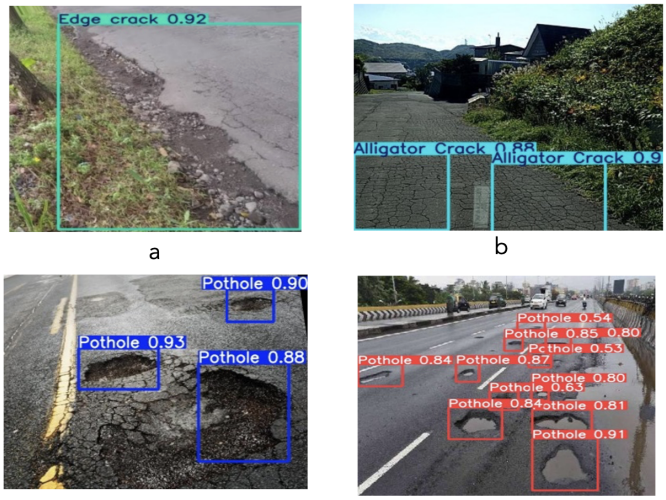


Fig. 9. F1-score of the model.

a b c d

Fig. 10. Road damage detection test: a) Edge crack, b) Alligator crack, c) Pothole, d) Multiple potholes.

TABLE V. PERFORMANCE COMPARISON AGAINST PREVIOUS YOLO ARCHITECTURES.

MODEL	Precision	Recall	mAP@0.5
YOLOv8 BiFPN	0.891	0.905	0.963
YOLOv8	0.873	0.893	0.955
YOLOv5	0.813	0.839	0.896
YOLOv4	0.793	0.818	0.88
YOLOV3	0.632	0.702	0.734

B. Detection Model Evaluation

Once the model for road damage detection and classification is trained, the subsequent step involves testing to evaluate its performance. This test determines how effectively the model can identify and categorize various types of road damage in previously unseen data. Additionally, it assesses the model's accuracy, precision, and recall across different predefined road damage classes. The results of the model testing are shown in Fig. 10.

C. Model Implementation on Smartphone

We developed a deep learning-based application utilizing the YOLOv8 architecture to detect and classify road defects into six primary categories. The trained model can accurately identify various defect types, including potholes, transverse cracks, longitudinal cracks, edge cracks, alligator cracks, and road joints. Owing to its real-time inference speed and high accuracy, this application enables road managers to perform automated inspections, thereby accelerating the damage detection process and enhancing the efficiency of road repair efforts.

The device was installed on the dashboard of a public passenger car. Our developed application captures images of the road surface approximately 10 m ahead, showcasing its capability to capture images while in motion without any data loss or duplication at an average speed of 40 km/h

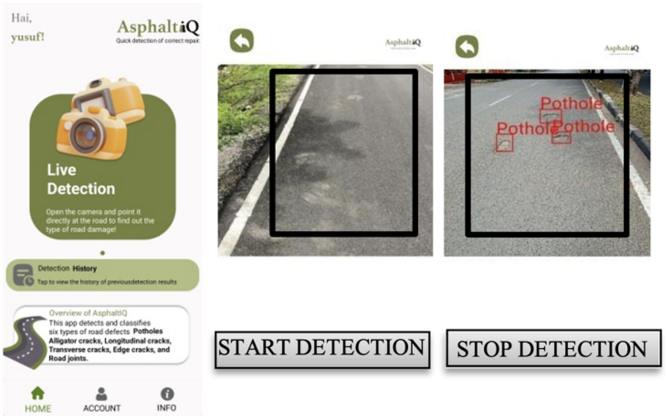

Fig. 11. On-device detection application on a smartphone.

(approximately 10 m/s), with one image captured per second. Furthermore, the application can accurately detect road defects within 1.5 s. A screenshot of the real-time detection application on a smartphone is shown in Fig. 11.

The operating screen of the smartphone application was mounted on the dashboard of a passenger car. The detection of road surface damage commenced when the "START DETECTION" button was activated. Images of the detected damage, along with their position information, were transmitted to the detection history in the database. Only images of confirmed damage were retained in the detection history.

The application features an image upload capability that enables users to submit photos of damaged roads. It automatically identifies and categorizes the type of damage depicted in an image. Powered by a trained YOLOv8 model, the application delivers fast and accurate detection results, simplifying the process for users to evaluate road conditions directly from uploaded images.

IV. Discussion

The performance of our YOLOv8 BiFPN model demonstrated a marked improvement over previous studies cited in the literature. For example, our model achieved an F1-score of 0.91, significantly surpassing the 50.39% reported by Opara [9] using YOLOv3 and the 66.51% using YOLOv5 on the RDD2022 dataset [12]. This significant improvement in performance can be attributed to several factors: the use of a tailored dataset that includes specific local road damage types (edge cracks and road joints), a larger and more balanced dataset, and the effective application of mosaic augmentation, which enhanced the model's ability to learn diverse features. The high mAP of 98% (at IoU=0.5) further confirms the model's accuracy in correctly detecting and classifying defects. The high mAP@50 should be interpreted as performance on the current test distribution rather than as universal generalization. The relatively small test set and visual similarity among locally collected road images may have contributed to the high score. Therefore, mAP@50:95 and future cross-region validation are reported/discussed to provide a more conservative assessment.

Despite these results, the study has several limitations. The performance of the model is highly dependent on environmental conditions, and its accuracy may decline in adverse weather, such as heavy rain or fog, or at night with insufficient street lighting. The training data were primarily collected from national roads in Indonesia, which may introduce a geographic bias. Consequently, the model may not perform as well on different types of road surfaces (e.g., concrete or unpaved roads) without additional training data. Furthermore, the tests were conducted at a moderate speed (30 km/h), and performance at significantly higher speeds has not yet been tested.

Because the local dataset was collected from a national road in Indonesia, the model may learn region-specific pavement textures, lane markings, lighting conditions, and defect appearances. Therefore, the current model should be regarded as optimized for the studied Local road context, and additional cross-region validation is required before wider deployment.

The proposed system demonstrated promising performance under daytime conditions; however, its robustness under heavy rain, fog, and nighttime illumination has not yet been comprehensively validated. Therefore, claims of real-world deployment suitability are limited to conditions similar to those represented in the test data.

The practical implications of this research are substantial. The successful implementation of the model into a smartphone application provides road management authorities with a practical and cost-effective tool for road infrastructure monitoring. This system can replace slow and labor-intensive manual inspections with rapid automated surveys. This enables authorities to quickly identify critical areas, prioritize repairs based on the severity and type of damage, and allocate maintenance budgets more efficiently.

V. Conclusion and Future Work

We successfully developed two additional dataset classes, namely, edge cracks and road joints, and evaluated the performance of the YOLOv8 architecture on these new classes. For the edge crack class, using a learning rate of 10^{-2}, the mAP value at 0.5 reached 0.963, demonstrating high prediction accuracy. A well-performing model was developed using a modified YOLOv8 architecture, achieving an mAP 0.5 score of 96.3% and an F1 score of 91% with mosaic augmentation preprocessing, indicating excellent performance in detecting road damage.

An application was successfully developed using the YOLOv8 architecture to detect and classify road damage into six categories: potholes, transverse cracks, longitudinal cracks, edge cracks, alligator cracks, and road joints. This application enables users to upload images of road damage for on-device detection and classification, offering a practical tool for efficient road maintenance and inspection.

Although the model demonstrated high accuracy under controlled daytime conditions, future work is necessary to assess its performance in more challenging environments. Future studies may include testing the system under nighttime conditions, where limited illumination and shadows could affect detection accuracy. In addition, the model should be evaluated on different road surface materials, such as concrete roads and unpaved roads, to ensure broader applicability across

diverse infrastructure conditions. Expanding the dataset to include these scenarios is expected to improve the adaptability and reliability of the YOLOv8-based detection system for real-world deployment.

***Abstract*—University-industry technology transfer (UITT) is essential for converting academic research into commercial use, yet traditional strategies often fail to address the knowledge gap. Literature suggests that institutional inertia, communication barriers, and ineffective marketing strategies hinder the commercialization of technology. This study proposes a conceptual framework that incorporates AI-driven marketing to enhance knowledge dissemination, market identification, and stakeholder engagement within the technology transfer process. This systematic literature review amalgamates insights from UITT, AI marketing applications, and knowledge management systems. A qualitative analysis of peer-reviewed literature from 2017 to 2025 identifies trends, deficiencies, and emerging patterns, leading to an integrated framework that assesses technology transfer strategies and the implementation of AI marketing across diverse sectors, leveraging the Technology-Organization-Environment (TOE) model and the Unified Theory of Acceptance and Use of Technology (UTAUT). The investigation demonstrates that AI-enhanced marketing can significantly bolster UITT through five AI-enhanced marketing capabilities: precise client segmentation, predictive analytics of market trends, tailored communication, improved knowledge management, and streamlined digital outreach. This methodology fosters reciprocal knowledge exchanges, positioning AI as a facilitator between market insights and university research aims while refining technology presentations for industry stakeholders. Moreover, the study highlights critical concerns regarding data privacy, implementation expenses, technical complexities, and the necessary proficiency in AI and technology transfer.**

***Keywords*—Collaboration; university-industry; technology transfer; AI-enhanced marketing; innovation; knowledge sharing; economic growth; strategic partnerships; research initiatives; entrepreneurial mindset**

I. Introduction

The integration of artificial intelligence (AI) into marketing strategies and the transfer of technology between universities and industry represent a rapidly advancing field of research with far-reaching implications for global innovation ecosystems [1], [2], [3]. In today's academic landscape, higher education institutions face growing pressure to effectively commercialize research outcomes while fostering collaborative industry partnerships through AI-driven marketing approaches [4], [5], [6]. Traditional technology transfer models, which have long relied on licensing agreements and spin-off ventures, now confront significant challenges in the era of digital transformation. These shifts necessitate more intelligent, data-driven strategies for industry engagement [7], [8], [9].

Recent advancements in artificial intelligence (AI) have revolutionized marketing practices across diverse industries, enabling unprecedented levels of personalization, predictive analytics, and automated decision-making [10], [11], [27]. However, the application of AI-driven marketing strategies to technology transfer between academia and industry remains underexplored, creating a significant gap in both theoretical frameworks and practical implementation guidelines [13], [14]. This research void is particularly concerning given the critical role that effective marketing plays in facilitating knowledge exchange between research institutions and commercial enterprises [15], [16].

The complex nature of partnerships between universities and industries encompasses a multitude of stakeholders, a variety of knowledge types, and a spectrum of organizational cultures, all of which necessitate the establishment of intricate coordination mechanisms to ensure the efficacy of collaborative endeavors, as articulated by [17], [18], [19]. Conventional technology transfer offices often face significant challenges, including resource constraints, a lack of comprehensive market intelligence, and ineffective communication channels, which can hinder successful commercialization outcomes, as discussed by [20], [21], [22]. The integration of AI-enhanced marketing strategies offers promising potential solutions to confront these pressing challenges by facilitating the development of intelligent matching systems, delivering predictive analytics capable of forecasting the probability of partnership success, and providing automated functionalities for the management of collaborative relationships, as noted by [23], [24], [25].

Artificial intelligence applied to marketing has made significant progress, but its role in knowledge transfer between universities and industry remains largely unknown. This lack of a clear theoretical framework calls for in-depth reflection, integrating both the possibilities offered by AI and the specificities of collaborations between academia and business.

This study aims to explore several key areas of research:

- How can AI enhance the effectiveness of technology transfer to industrial players?
- What algorithmic mechanisms can better connect academic innovations to the concrete needs of businesses?
- How is AI changing its functioning and strategic value?
- How can intelligent marketing mitigate cultural and informational differences between researchers and industrialists?
- What contextual elements favor the adoption of AI in research valorization?
- How can AI, marketing, and technology transfer be articulated within a coherent conceptual framework?
- What indicators can be used to assess the real effectiveness of these approaches on university-industry collaborations?

II. Theoretical Framework

A. University-Industry Technology Transfer Foundations

University-industry technology transfer encompasses a comprehensive array of activities aimed at facilitating the transference of knowledge, technologies, and innovations from academic institutions to commercial applications [8], [9], [30]. Conventional methodologies have predominantly focused on formal mechanisms, such as patent licensing, the establishment of spin-off enterprises, and the formulation of collaborative research agreements, as illustrated in Fig. 1 [6], [7], [4]. Nevertheless, contemporary scholarship suggests that effective technology transfer requires more nuanced methodologies that address institutional, interpersonal, and cultural barriers that often hinder commercialization endeavors [8], [22], [15].

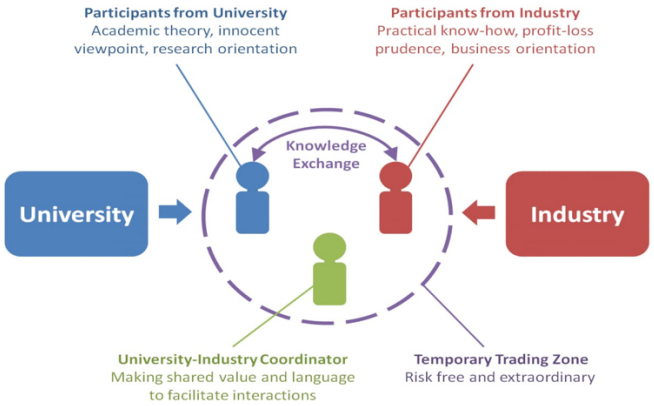

Fig. 1. University-industry collaboration for knowledge exchange.

The academic discourse delineates three principal categories of inhibitors that obstruct the successful commercialization of research-based inventions: institutional factors pertinent to organizational structures and policies, interpersonal dynamics that pertain to the relationship interactions between academic and industry stakeholders, and cultural disparities that shape collaboration methodologies [8], [20], [26]. Recent investigations underscore that relational inhibitors constitute the most prevalent challenges, while institutional and cultural factors frequently exacerbate these relational impediments [8], [7], [15]. These findings underscore the paramount importance of devising enhanced communication and engagement strategies that can overcome traditional barriers to the effectiveness of technology transfer.

Empirical investigations across diverse international contexts exhibit substantial discrepancies in technology transfer performance across various institutional and regional frameworks [6], [30], [22]. Collaborative networks between Chinese universities and industries manifest small-world phenomena characterized by distinct centrality patterns that influence innovation outcomes [30], [15]. Emerging economies in Africa face specific challenges stemming from resource limitations and inadequate technological infrastructure, which significantly impact the effectiveness of technology transfer [22], [38], [40]. These contextual variations underscore the need for adaptable frameworks that can accommodate diverse institutional environments while preserving the core principles of effectiveness.

B. Artificial Intelligence in Marketing Strategies

The incorporation of artificial intelligence within marketing methodologies signifies a profound transition from conventional techniques toward data-centric, automated, and individualized engagement frameworks [3], [2], [27]. Modern AI marketing implementations include machine learning algorithms for effective customer segmentation, natural language processing for content enhancement, predictive analytics for forecasting consumer behavior, and chatbot technologies for automated customer support [10], [36], [14]. These technological advancements collectively empower organizations to execute highly targeted, efficient, and scalable marketing initiatives that respond to the unique preferences of customers and the evolving market conditions. Table I delineates a comparison between conventional marketing approaches and those augmented by artificial intelligence [2], [1], [23]. Empirical research indicates that artificial intelligence substantially augments marketing efficacy through enhanced automation, personalization capabilities, and precision in forecasting [3], [2], [14]. Organizations that adopt AI-enhanced marketing methodologies report significant advancements in operational efficiency, customer engagement metrics, and competitive standing within their respective markets [1], [27]. Nevertheless, the existing literature also highlights significant challenges, including elevated implementation expenditures, ethical dilemmas related to data privacy, and the need for specialized technical proficiency, which may hinder widespread adoption [10], [36], [13].

Comparative analysis between developed and developing nations highlight notable discrepancies in AI marketing adoption trends, influenced by factors such as infrastructure preparedness, human resource competencies, and supportive policy frameworks, as illustrated in Fig. 2 [13], [46], [41]. Typically, developed countries exploit AI for advanced applications such as content personalization, predictive analytics, and marketing automation, whereas developing nations frequently encounter barriers associated with insufficient digital infrastructure and low technical literacy levels [13], [39], [45]. These

TABLE I. TRADITIONAL VS. AI-ENHANCED MARKETING

Aspect / Dimension	Traditional Approach	AI-Enhanced Approach	Benefits of AI
Market ID	Manual research, surveys, and conventional market studies	Predictive analysis, data mining, automated identification	Increased accuracy, emerging market detection, early identification of new opportunities
Lead Generation	Events, networking, mass marketing	Smart targeting, predictive scoring, process automation	Improved lead quality, increased efficiency
Content Personalization	Broad segments, generic messages	Hyper-personalization, dynamic and adaptive content	Higher engagement, better conversion rates
Communication Timing	Fixed schedules, sequential approach	Optimal timing based on behavioral data	Maximized receptivity, reduced intrusion
Success Measurement	Static indicators (KPIs), periodic reports	Real-time analytics, outcome prediction	Immediate adjustments, continuous campaign optimization
Resource Allocation	Fixed budgets, uniform distribution	Dynamic allocation based on performance	Maximized ROI, resource efficiency
Stakeholder Targeting	Static lists, demographic segmentation	Behavioral profiles, predictive targeting	Increased relevance, reduced acquisition costs
Technology Positioning	Standardized messages, one-size-fits-all	Adaptive positioning based on audience	Improved understanding, facilitated adoption
Follow-up Processes	Manual tracking, scheduled follow-ups	Automated nurturing, trigger-based engagement	Consistent engagement, reduced drop-offs
Decision Support	Experience-based, intuitive decisions	Data-driven recommendations, scenario modeling	Reduced bias, improved outcomes

findings underscore the importance of contextual elements in developing effective AI marketing implementation strategies.

The bibliometric assessment of AI marketing literature between 2021 and 2025 reveals an escalating scholarly interest in this research domain. The review was conducted following the PRISMA methodology to ensure a transparent, systematic, and reproducible article selection process. The analysis identified contributions from 82 nations and 1,292 authors across 281 sources, underscoring the global relevance and growing academic importance of AI-driven marketing research. Fig. 3 illustrates technology transfer approaches [1], [46], [41].

The literature selection process was based on predefined inclusion and exclusion criteria, focusing on peer-reviewed studies published in English between 2021 and 2025 and directly related to artificial intelligence applications in marketing. Core cognitive frameworks encompass consumer behavior analysis, brand management, marketing strategy formulation, and digital transformation initiatives, which collectively influence contemporary AI marketing practices [1], [38].

C. Digital Transformation in Higher Education

Digital transformation within the realm of higher education entails a holistic reorganization that integrates digital technologies across all facets of institutional functioning, significantly reshaping how universities provide education, perform research and interact with external constituents [16], [25]. This transformative endeavor requires strategic coherence between technological capabilities and institutional objectives, necessitating substantial investments in physical infrastructure, human capital, and procedural innovation [19], [31]. Institutions engaging in digital transformation are tasked with reconciling traditional academic principles with contemporary technological demands, all while preserving educational standards and research integrity [5], [47] . The various maturity levels of the Technologie Knowledge Transfer University Industrie (TKTUI) are delineated in the accompanying Table II.

Current digital transformation efforts in academic institutions emphasize various dimensions, including online learning environments, data analytics systems, cloud computing infrastructure, and AI-enhanced administrative frameworks [5]. The goal of these technological advancements is to boost operational efficiency, enrich student experiences, and fortify research capabilities while fostering enhanced collaboration with external entities [25], [31]. However, the realization of successful digital transformation transcends mere technological integration; it necessitates a cultural shift, unwavering leadership dedication, and a strategic vision that permeates all levels of the organization [16], [19], [47]. The emergence of the COVID-19 pandemic expedited the adoption of digital transformation across higher education institutions, compelling the swift deployment of virtual collaboration tools and online service delivery systems [48], [42]. This rapid transition uncovered both opportunities and challenges linked to digital transformation, such as enhanced accessibility and flexibility juxtaposed with concerns regarding barriers to technology adoption and issues of digital equity [32], [48], [35]. These occurrences provide valuable insights into the factors that influence successful digital transformation within the university context. The subsequent Table III enumerates the components associated with digital transformation in higher education institutions.

D. Knowledge Management and Transfer Mechanisms

Knowledge management within the domain of technology transfer encompasses intricate methodologies for the acquisition, structuring, dissemination, and utilization of both explicit and tacit knowledge across organizational frontiers [7], [17], [20] . Conventional technology transfer paradigms tend to prioritize formal intellectual property frameworks such as patents and licensing contracts; however, successful knowledge transfer necessitates holistic strategies that adequately address the considerable tacit knowledge elements intrinsic to academic technologies [7], [15], [20]. The tacit aspect can be particularly pronounced due to the nascent character of academic technologies and the specialized knowledge requisite for their practical application [7], [18], [24]. Contemporary studies underscore the essential function of human and institutional networks in facilitating the transmission of tacit knowledge between academic institutions and commercial entities [7], [15], [17]. Collaborative frameworks, consulting partnerships, sponsored research initiatives, proof-of-concept facilities, and university spin-offs represent vital mechanisms that foster direct interactions conducive to tacit knowledge

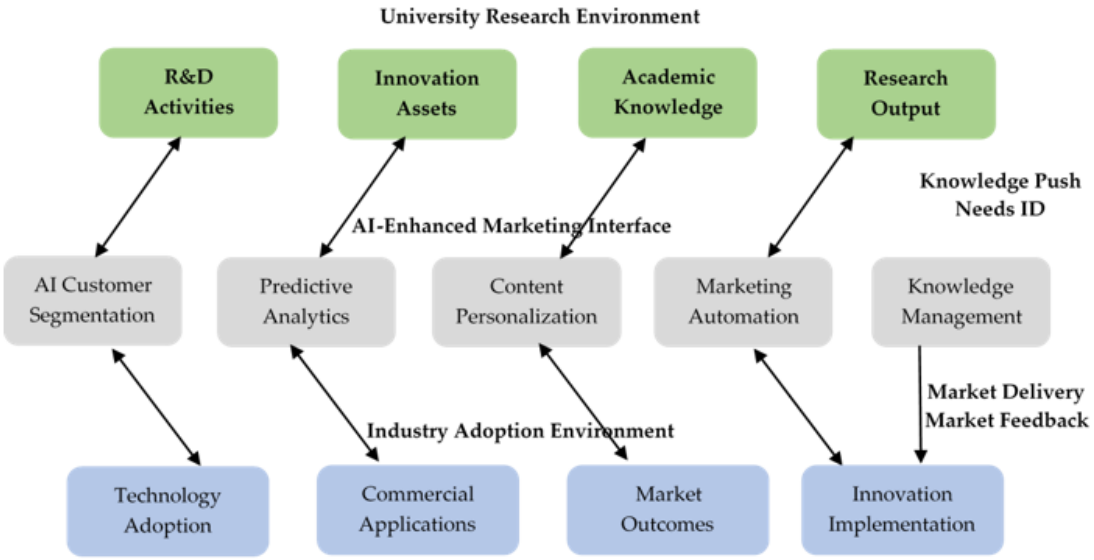

Fig. 2. Concept of AI-enhanced marketing for University-Industry Technology Knowledge Transfer.

TABLE II. DIGITAL TRANSFORMATION MATURITY LEVELS

Maturity Level	Characteristics	Technology Transfer Implications
Level 1: Basic	Limited digital infrastructure, manual processes, basic IT systems	Basic communication tools, limited market reach, manual relationship management
Level 2: Developing	Some digital tools implemented, inconsistent processes, emerging digital awareness	Enhanced communication, simple database management, emerging online presence
Level 3: Defined	Standardized digital processes, integrated systems, and clear digital strategy	Integrated CRM systems, digital marketing capabilities, structured knowledge management
Level 4: Managed	Data-driven decision-making, advanced analytics, performance monitoring	Predictive analytics for partnerships, automated matching systems, performance dashboards
Level 5: Optimized	AI-enhanced processes, continuous optimization, innovation leadership	AI-driven partner identification, intelligent knowledge transfer, adaptive learning systems

transfer [7], [19], [20]. These mechanisms enhance formal licensing agreements by offering avenues for prolonged collaboration and knowledge advancement that bolster successful commercialization endeavors [17], [18], [24]. The advent of AI-augmented knowledge management systems presents novel opportunities for enhancing knowledge discovery, alignment, and transfer processes [17], [25], [41]. Sophisticated algorithms are capable of scrutinizing substantial quantities of research outputs to uncover commercialization prospects, align university technologies with industry demands, and forecast probabilities of successful collaborations [18], [19]. Nevertheless, the incorporation of AI technologies into knowledge management frameworks necessitates meticulous attention to data integrity, algorithmic transparency, and human oversight to ensure efficacious and ethical application [39], [45]. The classification of mechanisms facilitating knowledge transfer, incorporating the influence of artificial intelligence, is illustrated in the subsequent Table IV.

The mechanism categories described in Table IV emerged from an integrative thematic synthesis of the research literature on university-industry technology transfer and knowledge management. Instead of using one of the existing taxonomies, the classification system draws together the transfer and collaboration practices documented in the studies reviewed. The mechanism categorization captures the dominant logic and institutional role. This was accomplished by identifying and grouping transfer practices, resulting in five mechanism categories: formal transfer of intellectual property, spin-offs, research collaboration, human capital transfer, and informal knowledge transfer. The categorization drew on the persistent themes in the literature on technology transfer, knowledge management, and innovation ecosystems (e.g., Lee, 2020; Yazdani, 2024; Sviatetskyi, 2020; Eidlisz et al., 2024). The AI enhancement dimension was added by recognizing the role of AI in enhancing each transfer mechanism, conceptualized as automation, prediction, intelligent matching, and knowledge discovery.

III. MATERIALS AND METHODS

This research utilized an integrative literature review methodology adhering to established protocols for systematic knowledge synthesis and the formulation of conceptual models [21], [33], [29]. The integrative review framework was chosen for its ability to amalgamate various research methodologies, theoretical frameworks, and empirical evidence into a holistic comprehension of the phenomenon being examined [34], [28]. This methodology facilitates the discernment of patterns, discrepancies, and interconnections across multiple domains while fostering the creation of innovative theoretical frameworks that synthesize existing knowledge [37]. The systematic search approach employed the Scopus database as the principal resource owing to its extensive coverage of high-quality,

TABLE III. DIGITAL TRANSFORMATION ELEMENTS IN HIGHER EDUCATION

Element	Description	Role in Technology Transfer
Digital Infrastructure	Hardware, software, and network systems that support digital operations	Enables efficient information exchange and communication
Data Analytics Capabilities	Tools and expertise for analyzing and interpreting large datasets	Provides insights into research trends and market opportunities
Virtual Collaboration Platforms	Platforms that enable remote collaboration and knowledge sharing	Facilitates engagement between university and industry stakeholders
Cloud Computing Technologies	Scalable computing resources accessible via the internet	Offers scalable resources for data-intensive research and applications
AI-Enhanced Administrative Systems	Automated systems for administrative tasks and decision support	Streamlines administrative processes in technology transfer
Digital Content Management	Systems for creating, storing, and distributing digital content	Supports effective knowledge dissemination and documentation
Cybersecurity Framework	Protocols and systems for protecting digital assets and privacy	Protects intellectual property and sensitive information

TABLE IV. KNOWLEDGE TRANSFER MECHANISMS TAXONOMY

Mechanism Type	Specific Mechanisms	AI Enhancement Potential
Formal IP Transfer	Patent licensing, technology licensing, copyright transfer	Automated IP matching, valuation algorithms, smart contract management
Spin-off Creation	Academic entrepreneurship, university spin-offs, startup incubation	Market opportunity identification, funding source matching, risk assessment
Collaborative Research	Joint research projects, industry-sponsored research, research consortia	Partner matching algorithms, research trend analysis, collaboration optimization
Human Capital Transfer	Student internships, faculty consulting, staff exchange programs	Skill matching, expert identification, knowledge gap analysis
Informal Knowledge Exchange	Conferences, workshops, networking events, publications	Intelligent networking, content recommendation, knowledge discovery

peer-reviewed literature pertinent to technology management, marketing, and artificial intelligence scholarship. The search methodology employed various keyword combinations, including "artificial intelligence marketing", "university-industry technology transfer", "digital marketing strategies", "knowledge transfer mechanisms", and "innovation ecosystems", to ensure thorough coverage of the pertinent literature. Boolean operators and controlled vocabulary terms were utilized to enhance search accuracy while ensuring sensitivity to emerging research domains (see Table V).

The study selection process consisted of multiple screening phases, including title and abstract examination, full-text analysis, and quality evaluation based on predefined inclusion and exclusion criteria. The inclusion criteria encompassed peer-reviewed articles published in English, as well as empirical investigations and theoretical contributions related to AI, marketing, or technology transfer, and publications from 2017 to 2025 to capture contemporary advancements. Exclusion criteria ruled out conference proceedings, books, editorial notes, and studies not directly pertinent to the research objectives.

Data extraction and synthesis methodologies adhered to systematic protocols for identifying key themes, concepts, methodological approaches, and theoretical contributions across the selected studies. Thematic analysis techniques were employed to identify patterns and relationships within and between studies, facilitating the development of comprehensive conceptual frameworks that integrate diverse perspectives. Quality assessment procedures appraised methodological rigor, theoretical contributions, and practical relevance to ensure the reliability and validity of the synthesized outcomes.

The results section has been organized as per the sequential workflow illustrated in Table V. More specifically, findings are organized in relation to the various methodological phases of the study, namely study selection, bibliometric classification, thematic synthesis, analytical mapping, and the construction of the conceptual model. This was done to achieve a consistent methodology, enhance readability, and offer a clear link between the review process and the resultant conceptual framework.

IV. RESULTS AND DISCUSSION

Research articles were considered eligible for inclusion if they met the following criteria: 1) published in peer-reviewed scholarly journals or reputable conference proceedings, 2) focused on AI-enhanced marketing, technology transfer between universities and industry, or the intersection of these domains, 3) published between 2017 and 2025, and 4) written in English. The exclusion criteria included: 1) non-academic publications, 2) research lacking methodological rigor, 3) duplicate publications, and 4) studies beyond the defined area, as shown in PRISMA Flow Diagram (see Fig. 3).

A. Study Selection and Temporal Distribution

This subsection addresses the methodological foundation underlying RQ1 through RQ7 by establishing the evidentiary basis from which answers to all seven research questions are

TABLE V. RESEARCH METHODOLOGY

Phase	Description	Key Activities	Expected Outcomes
Phase 1: Systematic Search	A comprehensive search of Scopus, Web of Science, IEEE Xplore, Google Scholar, SpringerLink, Emerald Insight, and peer-reviewed databases using systematic keywords	Database search; Keyword optimization; Search strategy development	Comprehensive literature corpus relevant to AI-enhanced marketing for technology transfer
Phase 2: Study Selection	Application of inclusion/exclusion criteria, screening abstracts, and full texts	Duplicate removal; Title/abstract screening; Full-text evaluation	High-quality studies meeting inclusion criteria for detailed analysis
Phase 3: Data Extraction	Extraction of key data elements, themes, and concepts from selected studies	Data coding; Theme identification; Concept mapping	Structured data matrix with key themes, concepts, and relationships
Phase 4: Quality Assessment	Assessment of study quality using established criteria and frameworks	Bias assessment; Methodological evaluation; Evidence grading	Quality-assessed evidence base for reliable synthesis
Phase 5: Data Synthesis	Thematic analysis and synthesis of findings using an integrative approach	Pattern identification; Cross-case analysis; Framework development	An integrated understanding of the current state and research trends
Phase 6: Model Development	Development of a conceptual model based on synthesized evidence	Model construction; Component integration; Relationship mapping	Novel conceptual model integrating AI, marketing, and technology transfer

derived. The temporal trend of publication growth corroborates the growing scholarly relevance of the questions posed.

The systematic selection process was designed to ensure transparency and reproducibility in the identification and screening of relevant studies. The search encompassed publications addressing AI-mediated university-industry marketing strategies over the preceding decade. A total of 48 papers met the final inclusion criteria. The temporal distribution of included studies revealed an increase in publication output beginning in 2022, with the highest annual output recorded in 2024 (18 publications). This trend corresponds to the growing body of research at the intersection of university-industry technology transfer (UITT) and artificial intelligence (AI) [43].

B. Bibliometric Classification of Included Studies

This subsection primarily addresses RQ3 (How is AI changing its functioning and strategic value?) by quantifying the thematic distribution of the literature and documenting the dominant trajectory of AI adoption in marketing. It also provides foundational evidence for RQ1 by establishing the volume and focus of AI-enhanced marketing research. To provide the highest level of transparency and reproducibility, a systematic manual coding approach was applied to the bibliometric classification. The 48 selected studies were independently analyzed and classified based on two different dimensions: 1) the main research theme, and 2) the research methodology. The thematic classification was based on a constructivist approach and was an outcome of the inductive analysis of the main objectives of the reviewed articles and the main research questions, key concepts, and main contributions. The first phase of the coding process was open and resulted in a number of key concepts related to the implications of artificial intelligence, the university-industry technology transfer, the process of digital transformation, the management of knowledge and the innovation management ecosystem. These related concepts were combined to form larger categories, which represented the main focus of each of the studies.

In the classification of the research methodology, studies were differentiated based on the main research method that formed the basis of the studies, which included the case study method, the formulation of a conceptual/theoretical paper, empirical quantitative research, qualitative research, bibliometric research, and modeling and predictive research. The classification was based on the explanation of the research methodology that was included in each study.

The manual classification relied on the fact that a number of the studies addressed themes that were multiple and interrelated, and that a context was necessary in order to explain the interrelated aspects of each of the studies. To strengthen the consistency of the classification, a coding scheme that was derived from the objectives of the review and the research questions, that is, RQ1-RQ7, was used to provide guidance as to the classification. For studies that focused on numerous themes, the main analytical focus was the primary theme to which the study was assigned, and the remaining themes were recorded in the process of thematic synthesis.

The 48 included studies were classified according to their primary thematic focus and methodological approach. AI-driven marketing strategies constituted the largest thematic category (47.8%), followed by studies addressing institutional barriers to information and communication technology adoption (30.4%). Studies focused on methodological advancements represented a smaller proportion (6.5%), indicating limited coverage of standardized analytical frameworks in the existing literature. Within the AI-focused subset, studies were further classified by technology application type: personalization (40.9%), automation (27.3%), and predictive analytics (18.2%). Case study designs were the most prevalent methodology among the included papers (58.7%), particularly in marketing-related studies, while mathematical modeling approaches were underrepresented.

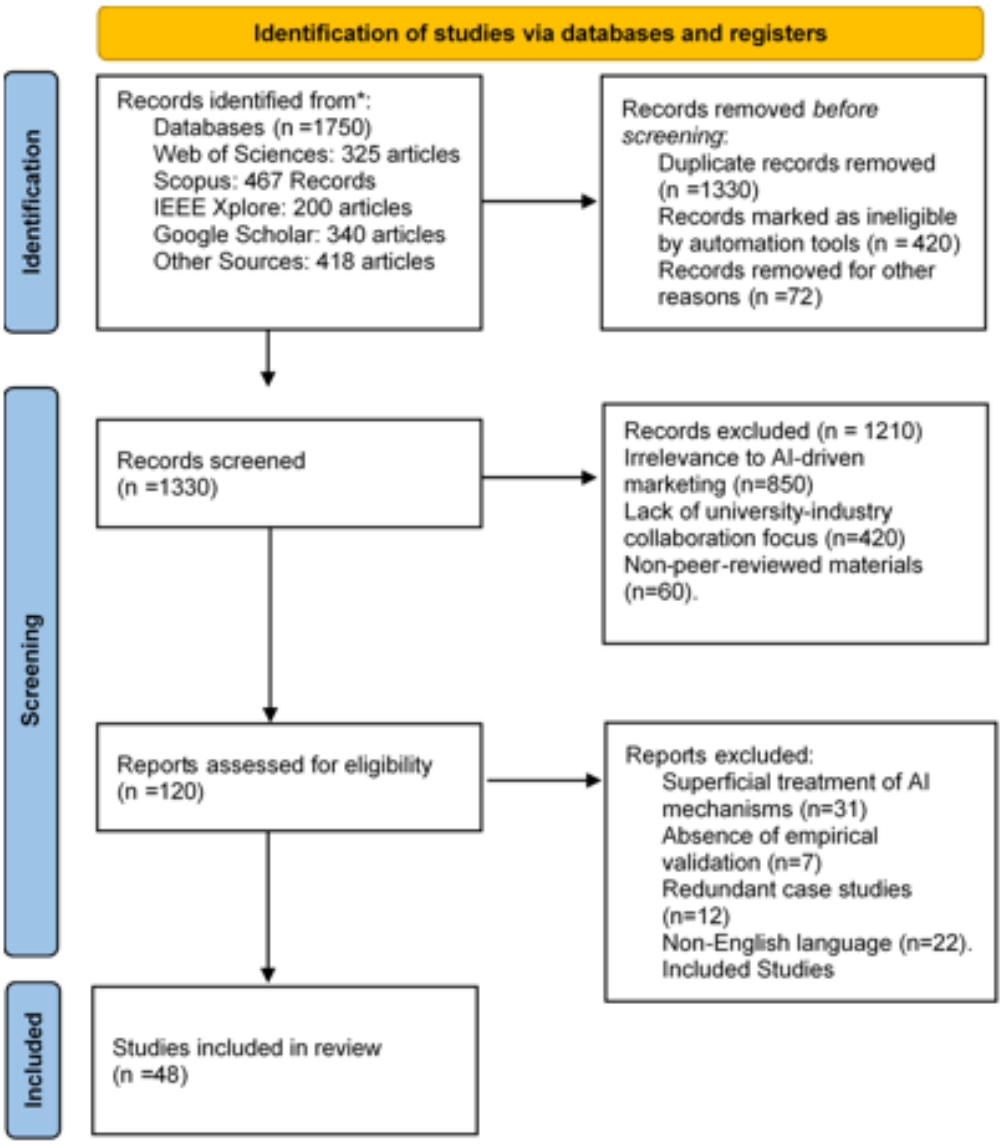

Fig. 3. PRISMA flow diagram

While examining the literature, the specified capabilities of segmentation, predictive analytics, personalized messaging, intelligent knowledge management, and automated digital engagement, were frequently observed within the context of the thematic synthesis process. The listed capabilities were also the primary functional contributions that the marketed enhancements attributed to the technology transfer activities of higher education institutes. These capabilities of AI are distinct from the marketing mechanisms of knowledge transfer. The former articulates the operational mechanisms that artificial intelligence augments within marketing and collaboration, while the latter describes the pathways of institutional and organizational knowledge transfer mechanisms, such as patent licenses, spin-offs, partnerships in research, and consultancy.

C. Thematic Synthesis Procedure

This subsection provides the analytical bridge connecting the raw literature findings to the answers for all seven research questions. The identification of seven major thematic categories directly maps onto the seven research questions, as each theme constitutes the evidential basis for one or more framework components developed in Section V.

To bridge the gap between descriptive bibliometric results and the development of a conceptual framework, a thematic synthesis was conducted following established qualitative synthesis procedures. This approach involved three stages: 1) line-by-line coding of key findings from each of the 48 included papers; 2) the organization of codes into descriptive themes; and 3) the generation of analytical themes informing

framework component development.

A total of 131 theme assignments were recorded across 48 papers, yielding an average of 2.73 themes per paper. This multi-dimensional coding reflected the interconnected nature of the concepts addressed in the literature and informed the identification of seven major thematic categories.

D. Analytical Principles for Theme-to-Component Mapping

This subsection supports RQ6 (How can AI, marketing, and technology transfer be articulated within a coherent conceptual framework?) by establishing the transparent methodological criteria used to translate thematic evidence into discrete, justifiable framework components. Three analytical principles guided the mapping of synthesized themes to the proposed framework components:

- Principle 1 – Frequency-Based Prominence: Themes with literature coverage exceeding 30% were designated as candidates for dedicated framework components.
- Principle 2 – Functional Differentiation: Themes with moderate coverage were retained as framework components when they served functionally distinct roles not addressed by higher-frequency themes.
- Principle 3 – Integration of Cross-Cutting Insights: Findings from multi-dimensional papers (i.e., those coded under multiple themes) were used to identify interdependencies and inform the relational architecture of the framework.

V. Conceptual Model Development

The proposed AI-enhanced marketing Framework for University-Industry Technology Knowledge Transfer integrates eight interconnected components that collectively optimize collaboration effectiveness and commercialization outcomes.

A. Framework Component Derivation

This subsection directly addresses RQ6 in its entirety, and provides evidence for RQ1 and RQ2 through the derivation of the AI Technologies (Component 1) and Marketing Strategies (Component 2) components. The bilateral treatment of University Factors (Component 3) and Industry Factors (Component 4) addresses RQ4 by explaining the structural sources of cultural and informational differences between academic and industrial stakeholders (see Table VI).

The application of the above principles to the thematic synthesis results yielded eight framework components. The derivation procedure for each component is described below, including the supporting literature base, thematic evidence, and justification for inclusion.

1) Component 1 - AI Technologies: This component was derived from 23 papers (47.8% of the corpus). The thematic coding identified AI-enhanced marketing as the most frequently addressed theme. Sub-theme analysis revealed three distinct capability clusters: personalization (40.9%; [1], [27], [23]), automation (27.3%; e.g., [2], [14]), and predictive analytics (18.2%; e.g., [10], [36]). The high frequency of this theme, combined with the differentiated capability clusters, justified its inclusion as a foundational component. The sub-element structure (machine learning, natural language processing, predictive analytics, chatbots, automation) directly mirrors the identified clusters. Technical capabilities were distinguished from strategic applications to warrant separate treatment from Component 2. This component constitutes the primary answer to RQ1 by identifying the specific AI mechanisms (machine learning, NLP, predictive analytics, chatbots, and automation) through which technology transfer effectiveness is enhanced.

2) Component 2 - Marketing Strategies: This component was informed by 18 papers (37.5%). The thematic evidence encompassed the strategic deployment of AI in university-industry contexts, digital transformation in marketing, stakeholder engagement optimization, and content personalization for industry partners. While thematically adjacent to Component 1, these papers addressed strategic deployment rather than technical capabilities, and the specialized marketing approaches required for the UITT context differed from conventional B2B models (e.g., [12], [16], [3], [13], [24]). This component answers RQ2 by specifying the algorithmic and strategic mechanisms — including intelligent matching, predictive partner scoring, and behaviorally-driven content personalization — that connect academic innovations to concrete industry needs.

3) Component 3 - University Factors: This component drew on 19 papers (39.6%). The thematic coding aligned with the UITT Barriers theme, where institutional factors accounted for 30.4% of the literature. Three sub-themes emerged: organizational structures, research capabilities, and intellectual property management. The identification of institutional barriers as the second most frequent theme, combined with the decomposition into actor-specific factors, justified dedicated component status (e.g., [8], [9], [4], [6], [7], [20]). This component contributes to answering RQ4 by identifying the institutional sources of informational gaps and cultural barriers on the academic side, including misaligned incentive structures, limited industry-facing communication, and inadequate IP commercialization capacity.

4) Component 4 - Industry Factors: This component was supported by 15 papers (31.2%). The thematic evidence addressed industry readiness, absorptive capacity, technology readiness, collaborative willingness, and trust mechanisms. Inclusion was justified on the basis of bilateral representation, balancing the university-side factors in Component 3. The synthesis revealed absorptive capacity, technology readiness, and collaborative willingness as distinct yet interrelated dimensions (e.g., [17], [30], [36], [22], [18]). In conjunction with Component 3, this component completes the answer to RQ4 by characterizing the industry-side cultural and informational barriers — particularly low absorptive capacity and insufficient trust in academic partners — that AI-enhanced marketing strategies must actively mitigate.

5) Component 5 - Knowledge Transfer Mechanisms: This component was derived from 17 papers (35.4%), corresponding to the Knowledge Management theme. The coding distinguished between tacit and explicit knowledge transfer modes, as well as formal mechanisms (patents, licensing, spin-offs) and informal mechanisms (consulting, collaborative research,

TABLE VI. DETAILED MAPPING TABLE

Component	Sub-elements	Primary Themes	Supporting Evidence	Key Citations	Analytical Justification
1. AI Technologies	Machine Learning, NLP, Predictive Analytics, Chatbots, Automation	AI Marketing; Personalization; Automation	Nuță (2024), Gabelaia (2024), Potwora et al. (2024)	23 papers (47.8%)	Nearly half of studies focus on AI, especially personalization and automation.
2. Marketing Strategies	Digital Marketing, Content Personalization, Segmentation, Social Media	AI marketing; Digital communication	Nektarios (2022), Ahmad et al. (2024)	18 papers (37.5%)	Shift to AI-driven strategies.
3. University Factors	Research, TTOs, Expertise, IP	Institutional barriers; Capacity	Battaglia et al. (2024); Blankesteijn et al. (2021)	19 papers (39.6%)	Internal factors affect knowledge transfer success.
4. Industry Factors	Market needs, Capacity, Readiness	Market dynamics; Collaboration	Yazdani (2024); Jiang et al. (2022)	15 papers (31.2%)	External factors complement university capabilities.
5. Knowledge Transfer Mechanisms	Licensing, Spin-offs, Consulting	Knowledge transfer	Lee (2020); Yazdani (2024)	17 papers (35.4%)	Bridge between university and industry.
6. Digital Transformation	Infrastructure, Data, Platforms	Digital transformation	Nektarios (2022); Ahmad et al. (2024)	16 papers (33.3%)	Enables AI and marketing.
7. Innovation Ecosystem	Networks, Partnerships, Policy	Ecosystems	Fadeyi et al. (2019)	12 papers (25.0%)	Impacts scalability.
8. Performance Outcomes	Commercialization, Innovation	Metrics	Singh et al. (2023)	11 papers (22.9%)	Supports evaluation.

networking). This component emerged as a conceptual bridge between university and industry actors. The comprehensive taxonomy of transfer mechanisms identified across 17 papers provided both theoretical and empirical grounding (e.g., [7], [20], [17], [15], [19], [24]). This component addresses RQ1 and RQ2 by identifying the specific pathways through which AI-augmented tools — such as partner-matching algorithms and AI-assisted IP valuation — optimize the operationalization of knowledge transfer.

6) Component 6 - Digital Transformation elements: This component was informed by 16 papers (33.3%). Digital transformation appeared as a cross-cutting theme encompassing infrastructure requirements, data analytics capabilities, cloud computing, and virtual collaboration platforms. This component was distinguished from AI Technologies (Component 1) as it represents broader digital readiness rather than specific AI capabilities. The inclusion of maturity level progression provided a developmental dimension (e.g., [12], [5], [31], [47], [16]). This component addresses RQ5 by identifying the enabling contextual conditions — digital infrastructure maturity levels, cloud adoption, and platform readiness — that govern the feasibility and effectiveness of AI adoption in research valorization activities.

7) Component 7 - Innovation Ecosystem: This component drew on 12 papers (25.0%). The thematic evidence addressed external contextual factors, including policy frameworks, funding mechanisms, regional contexts, and collaborative network structures. Inclusion was justified by the Frequency-Based Prominence principle (meeting the 25% threshold) and by the finding that comparative analyses across studies revealed ecosystem-level moderators that significantly affect technology transfer effectiveness, particularly in emerging economy contexts (e.g., [22], [6], [40], [38], [44]). This component further addresses RQ5 by documenting the broader ecosystem-level elements — government support, incubation infrastructure, and international networks — that determine the contextual readiness for AI adoption in technology transfer, particularly in emerging economy contexts.

8) Component 8 - Performance Outcomes: This component was supported by 11 papers (22.9%), with performance measurement addressed explicitly in these papers and implicitly throughout the broader corpus. The thematic evidence covered technology commercialization metrics, knowledge transfer efficiency, innovation performance indicators, and competitive advantage evaluation. Inclusion was justified by the component's feedback function, which enables continuous improvement and empirical validation of framework effectiveness (e.g., [21], [41], [30], [18], [19], [38]). This component constitutes the direct answer to RQ7 by specifying the indicators — including commercialization rates, collaboration success scores, knowledge transfer efficiency indices, and innovation impact metrics — that can be used to assess the real effectiveness of AI-enhanced marketing approaches on university-industry collaborations.

B. Framework Validation Criteria

This subsection supports RQ6 by providing a systematic validation of the proposed framework against four criteria that confirm its suitability as a coherent theoretical articulation of the relationships among AI, marketing, and technology

transfer. The resulting eight-component framework was assessed against four validation criteria to confirm its systematic derivation from the literature:

- Empirical foundation: Each component was supported by 11 to 23 papers (22.9%–47.8% coverage).
- Functional distinctiveness: Each component occupies a different structural role within the framework (enablers, actors, processes, moderators, or outcomes).
- Research integration: Each component synthesizes previously fragmented research streams into a coherent dimension.
- Research generativity: The framework structure provides testable propositions and clear boundaries for future empirical investigation. This thematic synthesis procedure, combined with the three analytical principles and the component derivation process, establishes an explicit evidence trail from the 48 included papers to the eight-component conceptual framework for AI-enhanced university-industry technology transfer.

C. Core Framework Components

This subsection integrates answers to RQ1, RQ2, RQ3, and RQ4. It describes how AI Technologies (RQ1, RQ3) and Marketing Strategies (RQ2, RQ4) interact with university and industry factors to generate the core capabilities of the proposed framework. This comprehensive framework integrates findings from the literature review to address recognized deficiencies in both theoretical understanding and practical implementation strategies. The model (Fig. 4) delineates Knowledge Transfer Mechanisms as the pivotal core around which all supplementary elements engage, underscoring the essential significance of efficient transfer processes in realizing fruitful collaborations between academia and industry. AI Technologies acts as the fundamental catalyst for intelligent automation and decision-making mechanisms within the technology transfer ecosystem [3], [2], [1]. This aspect includes machine learning models for recognizing patterns and making predictions, natural language processing for analyzing and generating content, predictive analytics for forecasting the success of collaborations, chatbot technologies for automating stakeholder interactions, and systems for optimizing processes [27], [36], [14]. The amalgamation of these AI technologies fosters opportunities for heightened efficiency, diminished manual labor, and enhanced precision in decision-making across the entirety of university-industry collaborations [10], [23].

In direct response to RQ1, these capabilities demonstrate how AI can enhance technology transfer effectiveness by automating partner discovery, accelerating IP matching, and enabling data-driven decision-making at every stage of the collaboration lifecycle.

Marketing Strategies signify the strategic communication and engagement methodologies that universities utilize to draw, engage, and sustain relationships with industry collaborators [12], [16], [25] . This dimension encompasses digital marketing initiatives designed explicitly for industry stakeholders, content personalization based on partner inclinations and requirements; customer segmentation approaches that pinpoint optimal collaboration prospects, social media platforms for fostering relationships, and data-informed marketing techniques that enhance resource distribution and campaign efficacy [3], [1], [13] . These strategies ought to be tailored to the distinctive attributes of technology transfer settings while capitalizing on AI functionalities for improved accuracy and influence [2], [14], [31]. In response to RQ2 and RQ3, these strategies illustrate how AI is transforming the strategic value of marketing from a static broadcast mechanism into a dynamic, predictive, and relationship-intelligent function. University Factors include the internal competencies, resources, and traits that affect the success of technology transfer initiatives [6], [5]. Research capabilities dictate the caliber and commercial viability of university technologies, whereas Technology Transfer Offices furnish the institutional framework for overseeing collaboration processes [20]. Academic expertise embodies the human resources requisite for efficient knowledge transfer, intellectual property portfolios lay the groundwork for commercialization endeavors, and an innovation-oriented culture impacts organizational preparedness for external collaborations [7], [15], [19]. These elements must be strategically cultivated and aligned to bolster AI-augmented marketing initiatives [17], [18]. This component contributes to answering RQ4 by identifying the academic institutional factors — particularly cultural resistance to commercialization and weak industry-facing communication infrastructure — that intelligent marketing strategies must specifically address.

Industry Factors exemplify the external market dynamics, organizational attributes, and collaboration readiness elements that affect the success of partnerships. Market demands to propel the necessity for university technologies and ascertain commercialization feasibility, while absorptive capacity denotes the capability of industry partners to comprehend, adapt, and execute university innovations [17], [19], [20]. Technology readiness influences the timing and practicality of collaborative initiatives, collaborative willingness affects the formation and sustainability of partnerships, and resource availability dictates the extent and scale of potential collaborative activities [15], [47]. A comprehensive understanding and addressing of these factors are crucial for the formulation of effective marketing strategies that resonate with industry collaborators [25], [44]. This component completes the answer to RQ4: intelligent marketing mitigates cultural and informational asymmetries by leveraging AI-driven profiling and adaptive communication tools that match academic outputs to the absorptive capacity and readiness level of each specific industrial partner.

The following Table VII synthesizes the university-industry collaboration process in the systematic literature review.

D. Integration and Interaction Mechanisms

This subsection further addresses RQ1 and RQ2 by specifying how each framework component interacts with the others to produce the operational conditions for effective AI-enhanced technology transfer. Kowledge Transfer Mechanisms represent the fundamental processes through which technological advancements and scholarly expertise from universities are disseminated to industry collaborators [7], [20], [15]. Patent licensing establishes formal frameworks for intellectual property transfer, spin-off enterprises facilitate extensive technology commercialization, consulting relationships promote

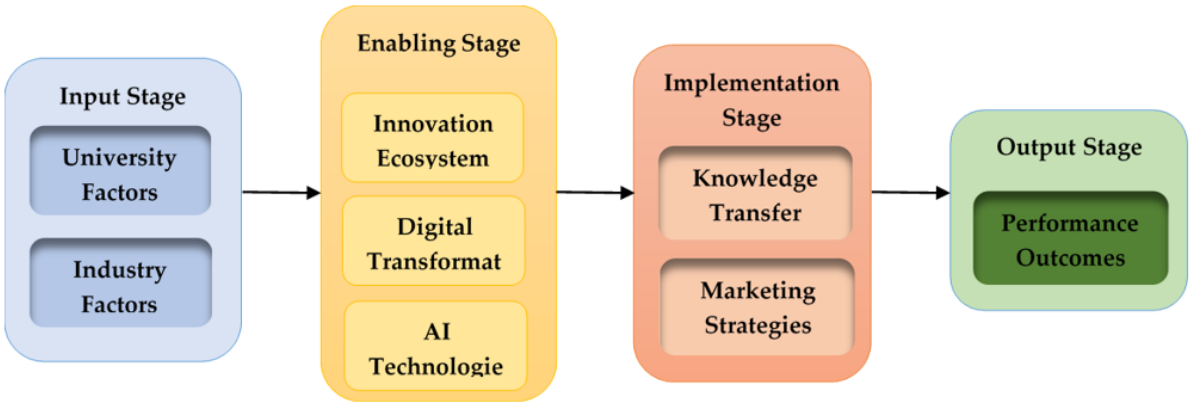

Fig. 4. Conceptual framework of AI-enhanced marketing for university-industry technology transfer.

TABLE VII. UNIVERSITY-INDUSTRY COLLABORATION PROCESS

Stage	Primary Activities	AI Enhancement Opportunities
Research Development	Basic and applied research, Innovation identification	Research trend analysis, Impact prediction
Technology Assessment	Feasibility analysis, Commercial potential evaluation	Automated assessment tools, Market potential algorithms
Market Analysis	Industry needs identification, Competitive landscape analysis	Real-time market intelligence, Predictive trend analysis
Partner Identification	Industry partner screening, Capability matching	Intelligent partner matching, Compatibility algorithms
Collaboration Framework	Agreement negotiation, Partnership structuring	Contract optimization, Risk assessment tools
Knowledge Transfer	Technology transmission, Expertise sharing	Personalized knowledge delivery, Learning optimization
Commercialization	Product development, Market launch	Launch strategy optimization, Success prediction
Performance Evaluation	Impact assessment, Success measurement	Automated performance tracking, Continuous improvement

direct expertise dissemination, collaborative research endeavors foster mutual innovation progress, and proof-of-concept facilities connect laboratory-based research with commercial viability [17], [18], [24]. These mechanisms must be augmented with artificial intelligence capabilities to enhance the efficiency, effectiveness, and scalability of technology transfer operations [19], [32]. Digital Transformation Elements offer the requisite technological framework and procedural modernization essential for the execution of AI-enhanced marketing initiatives [12], [31]. The digital infrastructure underpins data acquisition, analytical processes, and communication efforts, while data analytics competencies enable informed decision-making and performance enhancement [16], [25], [47]. Virtual platforms encourage online collaboration and relationship management, collaborative tools support distributed teamwork and knowledge exchange, and cloud computing technologies offer scalable and accessible computing resources [5], [42], [35]. Collectively, these elements establish a robust foundation for the implementation of advanced AI marketing strategies within technology transfer paradigms [41], [39]. This directly responds to RQ5: the maturity level of an institution's digital infrastructure — spanning cloud computing adoption, data analytics capacity, and virtual collaboration readiness — constitutes a critical contextual determinant of AI adoption success in research valorization. The Innovation Ecosystem encompasses the wider contextual factors that significantly affect the success of university-industry collaborations [22], [38]. Networks foster connections and opportunities for relationship development, partnerships establish formal collaboration frameworks, incubators assist in the advancement of nascent technologies, governmental support impacts policy and funding landscapes, and financial mechanisms dictate the availability of resources for collaborative ventures [6], [40], [44]. Adopting an ecosystem perspective acknowledges that effective technology transfer necessitates conducive environmental conditions that go beyond the capabilities of individual organizations [46], [45]. This extends the answer to RQ5 by situating AI adoption within an ecosystem logic: the presence or absence of supportive policy, regional networks, and funding infrastructures determines whether AI-enhanced marketing initiatives can be scaled and sustained.

Performance Outcomes signify the quantifiable results and effects of AI-enhanced marketing strategies within technology transfer contexts [21], [41], [30]. Metrics for technology commercialization evaluate the success of translating university research into marketable applications, knowledge transfer efficiency assessments gauge the effectiveness of transfer mechanisms, innovation performance indicators monitor the broader impacts of collaborative efforts, and evaluations of competitive advantage ascertain the strategic value generated through university-industry alliances [18], [38]. These outcomes furnish crucial feedback for the ongoing refinement and optimization of AI-enhanced marketing strategies [19], [40], [39]. This constitutes the direct operational answer to RQ7: the effectiveness of AI-enhanced marketing on university-industry collaborations can be assessed through a multi-dimensional

indicator system encompassing commercialization conversion rates, partnership formation speed, knowledge transfer efficiency scores, and long-term innovation impact metrics. The proposed conceptual model addresses several critical gaps identified in the current literature while providing a comprehensive framework for understanding and implementing AI-enhanced marketing in university-industry technology transfer contexts. The following Table VIII elucidates the framework of marketing augmented by artificial intelligence within the context of technology transfer between universities and industries.

The amalgamation of artificial intelligence technologies with marketing methodologies signifies a notable divergence from conventional technology transfer paradigms, presenting prospects for augmented efficiency, refined targeting, and enhanced relationship management [3], [2], [1]. Nevertheless, effective execution necessitates meticulous consideration of the organizational, technological, and environmental elements that impact adoption and efficacy [36], [13], [47].

E. Theoretical Contributions

This subsection addresses RQ6 from a theoretical standpoint by articulating the specific conceptual innovations introduced by the proposed framework in relation to the existing literature. The theoretical framework enhances the discourse on technology transfer by presenting the inaugural comprehensive amalgamation of artificial intelligence technologies, marketing methodologies, and mechanisms for knowledge transfer within a singular conceptual paradigm [20], [33], [29]. Prior investigations have predominantly examined these areas in isolation, which constrains the comprehension of their interrelated dynamics and synergistic capabilities [8], [7], [12]. The proposed framework elucidates how AI competencies can augment conventional marketing tactics while concurrently enhancing the efficacy of knowledge transfer via intelligent automation and data-informed decision-making [27], [14], [25]. These contributions collectively represent a direct and substantive answer to RQ6, establishing the conceptual architecture within which AI, marketing, and technology transfer can be coherently integrated.

Furthermore, the model propels the theory of digital transformation by delineating the technological and organizational prerequisites for the successful application of AI within academic settings [5], [31]. In contrast to generic frameworks of digital transformation, this model explicitly addresses the distinctive attributes of university-industry collaboration, which encompasses the significance of tacit knowledge transfer, the function of intellectual property management, and the impact of innovation ecosystem elements [7], [17], [19]. This specificity amplifies the practical significance and applicability of the framework for practitioners involved in technology transfer [15], [16], [32].

F. Practical Implications

This subsection primarily addresses RQ4 and RQ5 from a practitioner perspective. It specifies how intelligent marketing — operationalized through the proposed framework — can practically bridge the cultural and informational divide between academic and industrial actors, and what contextual investments are needed to enable AI adoption. For university administrators and professionals involved in technology transfer, the proposed framework offers practical directives for cultivating AI-driven marketing proficiencies that enhance industrial engagement and collaborative outcomes [4], [6], [18]. This model delineates particular technological investments, organizational capabilities, and strategic methodologies that institutions of higher education ought to prioritize to augment their effectiveness in technology transfer [20], [24]. Strategies for implementation should concentrate on fostering AI competencies within technology transfer offices, establishing digital infrastructures for data analytics and relationship management, and devising comprehensive training initiatives aimed at staff development [5], [12], [47]. Industry collaborators can employ the framework to gain insights into university capabilities and opportunities for collaboration while simultaneously enhancing their absorptive capacity for novel technologies [17], [30]. The model underscores the significance of forging dedicated partnerships with universities to facilitate AI-enhanced collaboration, investing in digital platforms to engage with universities, and cultivating internal capabilities necessary for assessing and implementing university technologies [18], [19], [42]. Such investments empower industry partners to optimize the benefits derived from university-industry collaboration while also contributing to the development of innovation ecosystems [15], [38]. Policymakers can utilize the framework to formulate conducive regulations, funding strategies, and infrastructural investments that promote AI-enhanced technology transfer [22], [40], [44]. The model identifies essential success factors warranting policy focus, including the advancement of AI infrastructure, regulatory frameworks that facilitate digital collaboration, and incentive structures that foster university-industry partnership development [16], [46], [41]. Policy interventions must tackle both technological and organizational obstacles while advocating for equitable access to capabilities associated with AI-enhanced technology transfer [25], [39], [45].

G. Limitations and Considerations

This subsection is relevant to RQ7, as the limitations acknowledged here define the boundary conditions under which the proposed performance indicators can be reliably applied. It also partially addresses RQ5 by acknowledging that contextual variability across institutional settings limits the generalizability of AI adoption prescriptions. The proposed framework is predicated on a synthesis of existing literature rather than empirical validation, thereby necessitating subsequent investigations to evaluate the model's efficacy in practical contexts [21], [37]. The swift advancement of artificial intelligence technologies may necessitate regular revisions to the framework to ensure its ongoing relevance and precision [2], [23]. Furthermore, the model may require modifications to suit diverse institutional frameworks, cultural landscapes, and industrial domains that present distinct characteristics and demands [13], [38], [40]. Challenges in implementation encompass the considerable resource allocations essential for the development of AI infrastructure, the necessity for specialized technical competencies that may be scarce within academic institutions, and potential resistance from stakeholders who are accustomed to conventional technology transfer methodologies [10], [36]. Organizations must meticulously evaluate their preparedness

TABLE VIII. CONCEPT OF AI-ENHANCED MARKETING FRAMEWORK FOR UNIVERSITY-INDUSTRY TECHNOLOGY TRANSFER

Theme	Key Concepts	Research Gaps	Future Directions
University-Industry Technology Transfer	Patent licensing; Spin-offs; Collaboration barriers; Technology commercialization	Limited AI integration in TT processes; Need for digital marketing strategies	AI-enhanced TT processes; Digital collaboration platforms; Smart matching systems
AI in Marketing Strategies	Personalization; Predictive analytics; Automation; Data-driven strategies	Insufficient application in TT context; Limited university-industry focus	AI-powered university marketing; Intelligent partnership platforms; Predictive TT analytics
Digital Transformation	Digital infrastructure; Virtual collaboration; Cloud technologies; Online platforms	Lack of comprehensive frameworks; Missing integration with marketing strategies	Comprehensive digital TT ecosystems; AI-driven transformation models
Knowledge Management	Knowledge sharing; Tacit knowledge transfer; Organizational learning; Absorptive capacity	Underexplored AI enhancement; Limited digital transformation integration	AI-enhanced knowledge discovery; Intelligent knowledge matching systems
Innovation Ecosystems	Networks; Partnerships; Incubators; Government support; Funding mechanisms	Missing AI-enhanced networking; Insufficient digital ecosystem models	Smart innovation networks; AI-powered ecosystem orchestration
Conceptual Models & Frameworks	Theoretical frameworks; Structural models; Process models; Integration models	Absence of AI-marketing-TT integration models; Limited comprehensive frameworks	Integrated AI-marketing-TT models; Multi-dimensional frameworks

for AI integration while formulating comprehensive change management frameworks that cater to both technological and cultural transformation imperatives [31], [47], [35].

The literature points out both the benefits and the limitations of using AI marketing in traditional university-Industry technology transfer (UITT) models. Many argue that the digital transformation and the use of artificial intelligence (AI) can contribute to better collaboration, but only if the institution has an adequate digital infrastructure and is able to absorb new knowledge. In the absence of such characteristics, collaboration may not improve, especially with an internal resistance to change. Some cite the over-dependence on automated tasks, which may eliminate trust and the dynamics necessary for university–industry collaboration.

The existing literature reflects major differences between developed and emerging markets in terms of the level of technology, support for artificial intelligence (AI) integration, and funding. While some authors describe improved matching of partners, the efficiency of communication, and results of the commercialization process, increased AI integration can require the complexity of the organization and substantial resource investments with no guaranteed return on the investment. As a result, there are significant operational contradictions in AI marketing in UITT models. These inconsistencies reinforce the requirement for an integrative and context-sensitive conceptual framework.

H. Future Research Directions

This subsection most directly addresses RQ7 by specifying the empirical and methodological approaches needed to develop and validate the performance indicators through which the effectiveness of AI-enhanced marketing on university-industry collaborations can be rigorously assessed. It also opens new avenues for RQ2 and RQ5 by identifying algorithmic and contextual research priorities. The proposed theoretical framework lays the groundwork for extensive future investigations across various disciplines and methodological paradigms. Empirical validation initiatives represent the most pressing research focus, necessitating systematic evaluations of the framework's efficacy within diverse university-industry collaboration environments [21], [41]. Such studies ought to utilize stringent experimental or quasi-experimental methodologies that can elucidate causal links between AI-enhanced marketing interventions and technology transfer results while effectively controlling for extraneous variables [19], [38], [37]. Longitudinal research methodologies possess particular significance for comprehending the dynamic interactions among the components of the framework and their progression over time [37]. Such investigations can monitor the advancement of AI capabilities, the evolution of marketing strategies, and the enduring effects of technology transfer programs while pinpointing essential success determinants and potential pitfalls [18], [46]. Cross-sectional comparative analysis may scrutinize the framework's effectiveness across various university classifications, industry categories, and national settings to elucidate boundary conditions and necessary adaptations [13], [40], [39].

Methodological advancements should investigate the amalgamation of sophisticated analytical techniques, including network analysis for deciphering collaboration patterns, machine learning methodologies for forecasting partnership success, and natural language processing for evaluating communication efficacy [30], [42]. Mixed-methods research frameworks can integrate quantitative outcome assessments with qualitative insights regarding stakeholder experiences, organizational dynamics, and cultural elements that affect implementation success [20], [37].

Research on technology development should concentrate on the creation of specialized AI instruments and platforms tailored explicitly for university-industry technology transfer applications [27], [14], [25]. These innovations may encompass intelligent matching systems that align university technologies with industry demands, predictive analytics platforms that estimate collaboration success probabilities, and automated relationship management systems that enhance stakeholder engagement [19], [23]. Such technological advancements necessitate close cooperation among computer science scholars,

marketing professionals, and technology transfer specialists [12], [17].

In direct response to RQ7, future research should prioritize the operationalization and validation of the Performance Outcomes component (Component 8), developing standardized indicator sets — including composite AI-effectiveness scores, collaboration conversion dashboards, and longitudinal innovation impact indices — that can be applied across diverse institutional and geographic contexts to provide replicable, benchmarkable measures of AI-enhanced marketing effectiveness.

VI. Conclusion

This integrative literature review and conceptual model development investigation addresses a significant deficiency in understanding how artificial intelligence can enhance marketing strategies for transferring technology knowledge between universities and industries. The proposed AI-enhanced marketing framework provides a comprehensive theoretical foundation that encompasses eight interrelated components essential for the effective implementation of technology transfer initiatives. The framework illustrates the potential of AI technologies to revolutionize conventional marketing methodologies while concurrently enhancing the efficacy of knowledge transfer through intelligent automation, data-informed decision-making, and improved stakeholder involvement.

The literature review uncovers substantial prospects for progressing both theoretical insights and practical applications of AI-enhanced marketing within university-industry collaborative environments. Nonetheless, the successful execution necessitates meticulous consideration of organizational preparedness, technological infrastructure, and ecosystem-level support factors that affect adoption and overall effectiveness. The identification of research voids and prospective avenues delineates a pathway for scholars and practitioners endeavoring to advance this nascent domain, while tackling pivotal challenges in the efficacy of technology transfer.

The practical ramifications of this inquiry extend beyond singular organizations to include policy recommendations, strategies for ecosystem development, and frameworks for international collaboration that can bolster global innovation capacity. As AI technologies continue to progress and mature, the amalgamation of these capabilities with marketing strategies signifies a transformative shift in how universities interact with industry partners and commercialize research outputs. Future research and implementation initiatives should prioritize empirical validation, technological advancement, and practical directives that facilitate the widespread adoption of AI-enhanced marketing strategies in contexts of technology transfer.

Development of an Arabic Pet Adoption System with Hybrid Recommendations

Hailah Alballaa
Information Technology Department-College of Computer and Information Sciences,
King Saud University, Riyadh, Saudi Arabia

***Abstract*—Pet adoption platforms often face challenges in effectively matching adopters with suitable pets due to limited personalization and the lack of localized language support. This study presents EWAA, an Arabic-enabled mobile platform for pet adoption in Saudi Arabia that integrates a hybrid recommender system combining content-based and collaborative filtering techniques. The content-based component constructs a user profile from one-hot encoded pet attributes (category, breed, color, and age) of previously liked pets, while the collaborative filtering component identifies similar users through cosine similarity and recommends pets based on their preferences. The two components operate independently in a mixed hybrid configuration, which mitigates the cold-start limitation of collaborative filtering and the over-specialization limitation of content-based filtering. The platform also emphasizes usability, accessibility, and privacy for both adopters and pet owners through a fully Arabic interface and controlled information visibility. The system was evaluated with 20 questionnaire participants and 6 interview participants using User Acceptance Testing (UAT) and Non-Functional Requirements (NFR) testing. Results indicate high levels of user satisfaction, with task completion rates of 100% on 10 of 11 test scenarios, page load times between 1 and 12 seconds, and learning times between 1 and 8 minutes, suggesting that the proposed approach provides a viable foundation for supporting the pet adoption process in Arabic-speaking contexts.**

Keywords*—Recommender systems; pet adoption; mobile applications; collaborative filtering; content-based filtering; user experience

I. Introduction

Pet adoption plays an important role in improving animal welfare while providing companionship and quality-of-life benefits to individuals and families [1]. Despite these benefits, the adoption process remains fragmented in many contexts, relying on physical shelter visits, disconnected platforms, or informal social media channels, which can be inefficient and time-consuming for prospective adopters.

With the growing interest in pet adoption in Saudi Arabia, there is an increasing demand for digital platforms that provide localized and accessible services. However, existing pet adoption platforms exhibit two notable limitations in this context. First, they lack Arabic language support, creating usability barriers for native Arabic speakers. Second, they typically rely on either content-based or collaborative filtering in isolation, each of which suffers from well-known weaknesses: content-based filtering is prone to over-specialization, while collaborative filtering suffers from the cold-start problem [2].

This study presents EWAA, an Arabic-enabled mobile pet adoption platform that integrates a hybrid recommender approach combining content-based and collaborative filtering techniques. The objectives of this work are: first, to design and implement an Arabic-language mobile adoption platform tailored to the Saudi context; second, to integrate a mixed hybrid recommender that mitigates the cold-start and over-specialization limitations of single-method approaches; and third, to evaluate the resulting system through user acceptance and non-functional requirements testing. The significance of the work lies in providing a deployed adoption platform that combines hybrid recommendation with native Arabic language support, addressing both a regional accessibility gap and a methodological gap in prior pet adoption recommenders. The study focuses on cats and dogs, which represent the majority of adoption cases in the target context.

The remainder of this study is organized as follows: Section II reviews related work on pet adoption platforms and recommender approaches. Section III presents the system overview, and Section IV describes the system architecture. Section V details the implementation, and Section VI presents the design of the hybrid recommender. Section VII reports the system evaluation, and Section VIII concludes the study and outlines directions for future work.

II. Related Work

Recommender systems are well established as a means of mitigating information overload and supporting personalized decision-making [3]. They are commonly categorized into content-based, collaborative, and hybrid approaches, with hybrid configurations typically introduced to mitigate the cold-start and over-specialization limitations of the individual methods [2]. Within the pet adoption domain, several lines of work are particularly relevant.

Karani et al. [4] developed a structured dataset and a recommender system to suggest appropriate canine and feline breeds to prospective adopters. Their work provides a foundation for breed-specific recommendations in pet adoption systems. However, the system operates at the level of breeds rather than individual pets, which limits its ability to differentiate between specific animals of the same breed in a real adoption listing, and it does not incorporate user interaction signals such as likes or other implicit feedback.

De Luna et al. [5] compared content-based filtering, collaborative filtering, and k-nearest neighbors for dog breed recommendation, and reported content-based filtering as the best-performing approach.

Montiveles et al. [6] used item-based collaborative filtering with Pearson correlation and k-nearest neighbors to recommend adoptable pets. As a collaborative only approach, the

system is susceptible to the cold-start limitation when new users or pets have limited interaction history, and it does not incorporate content-based signals from pet attributes that could mitigate this gap.

Chaudhari et al. [7] presented a recommender system that uses content-based filtering with cosine similarity metrics to match potential adopters with suitable pets, taking into account various factors such as breed characteristics, adopter lifestyle, and living conditions, and offering a holistic approach to the adoption matching process. However, as a purely content-based method it inherits the well-known over-specialization problem [2]. The approach also does not address the cold-start case in which the active user has not yet liked any pet.

Across these studies, two gaps are relevant to the present work. First, none of the prior systems is evaluated or deployed in an Arabic-language context. Second, with the exception of the comparative evaluation in [5], none of them combines content-based and collaborative signals within a single deployed adoption system, despite the fact that hybrid configurations are a standard remedy for the cold-start and over-specialization limitations identified above. EWAA addresses these gaps by adopting a mixed hybrid configuration [2] over user-supplied pet attributes and interaction data, within a fully Arabic-language mobile platform.

Beyond research prototypes, several deployed platforms support pet adoption services and provide a useful basis for identifying the functional capabilities expected in a mature adoption application. These platforms include PetMatch [8], Petfinder [9], and Pet Adoption [10]. As shown in Table I, a comparison of these platforms highlights their key features and limitations.

The EWAA application addresses several limitations present in existing platforms by offering a user-centric experience tailored to the needs of adopters in Saudi Arabia. One of its key features is Arabic language support, which ensures a seamless navigation experience and improves accessibility for local users. Additionally, EWAA enhances privacy protection by keeping the personal details of pet owners and adopters confidential until an adoption request is accepted, fostering a secure and trustworthy adoption environment. The application also features an intuitive and engaging interface, designed to be visually appealing and user-friendly, which encourages greater interaction and simplifies the pet adoption process. By integrating these improvements, EWAA improves usability, security, and user engagement, providing an optimized platform for pet adoption in the region.

The comparative analysis presented in Table I highlights the strengths of the EWAA system compared to existing pet adoption platforms. Although current systems provide basic features such as browsing, filtering, and pet listing, they lack key features such as Arabic language support, integrated privacy protection, and personalization. In contrast, EWAA combines these capabilities within a single platform by offering accessibility, personalized pet recommendations, and secure adoption workflows. This integration enhances the user experience and supports a more efficient and user-centered pet adoption process.

TABLE I. COMPARISON OF KEY FEATURES BETWEEN EXISTING PET ADOPTION PLATFORMS AND EWAA.

Feature	Pet Adoption	PetMatch	Petfinder	EWAA
User registration	No	No	Yes	Yes
Browse categories	No	No	Yes	Yes
Search and filtering	Yes	Yes	Yes	Yes
Submit request	No	No	Yes	Yes
Add pets	Yes	Yes	Yes	Yes
Recommendations	No	No	Yes	Yes
Favorites	No	Yes	Yes	Yes
Social sharing	Yes	No	Yes	Yes
Arabic support	No	No	No	Yes
Pet care section	No	No	Yes	Yes
User-friendly UI	No	No	Yes	Yes
Privacy protection	No	No	No	Yes

III. SYSTEM OVERVIEW

The proposed system, EWAA, is a mobile-based pet adoption platform designed to streamline and improve the adoption process in Saudi Arabia. It provides a centralized and user-friendly environment that connects potential adopters with pet owners, reducing reliance on traditional methods such as physical shelter visits and informal social media channels.

EWAA provides a unified user model in which a registered user can act as both a pet owner and an adopter depending on the system interaction. This design simplifies user management and enhances flexibility within the platform. Users can browse available pets, apply search and filtering options, and submit adoption requests. Pet owners, on the other hand, can add, update, and manage pet listings, as well as review and respond to adoption requests.

A key feature of the system is the integration of a hybrid recommender system, which combines content-based and collaborative filtering techniques to generate personalized pet suggestions. Recommendations are based on user preferences and interactions, such as selected pet attributes and previously liked pets, improving the likelihood of successful matches between adopters and pets.

In addition to core adoption functionalities, EWAA emphasizes usability and accessibility through its fully Arabic-supported interface, enabling a localized experience for Arabic-speaking users. The system also incorporates privacy mechanisms that ensure user information remains confidential until adoption requests are approved, thereby fostering a secure and trustworthy environment.

Overall, EWAA is designed to improve the efficiency, accessibility, and user experience of the pet adoption process through user-centered recommendation capabilities.

To further illustrate the interaction between users and the system, Fig. 1 presents the main use case diagram of the EWAA application. The diagram highlights the primary functionalities available to both adopters and pet owners, including browsing pets, submitting adoption requests, managing pet listings, and receiving recommendations.

IV. SYSTEM ARCHITECTURE

The system follows a client-server communication model, in which the client sends requests to the server, and the server

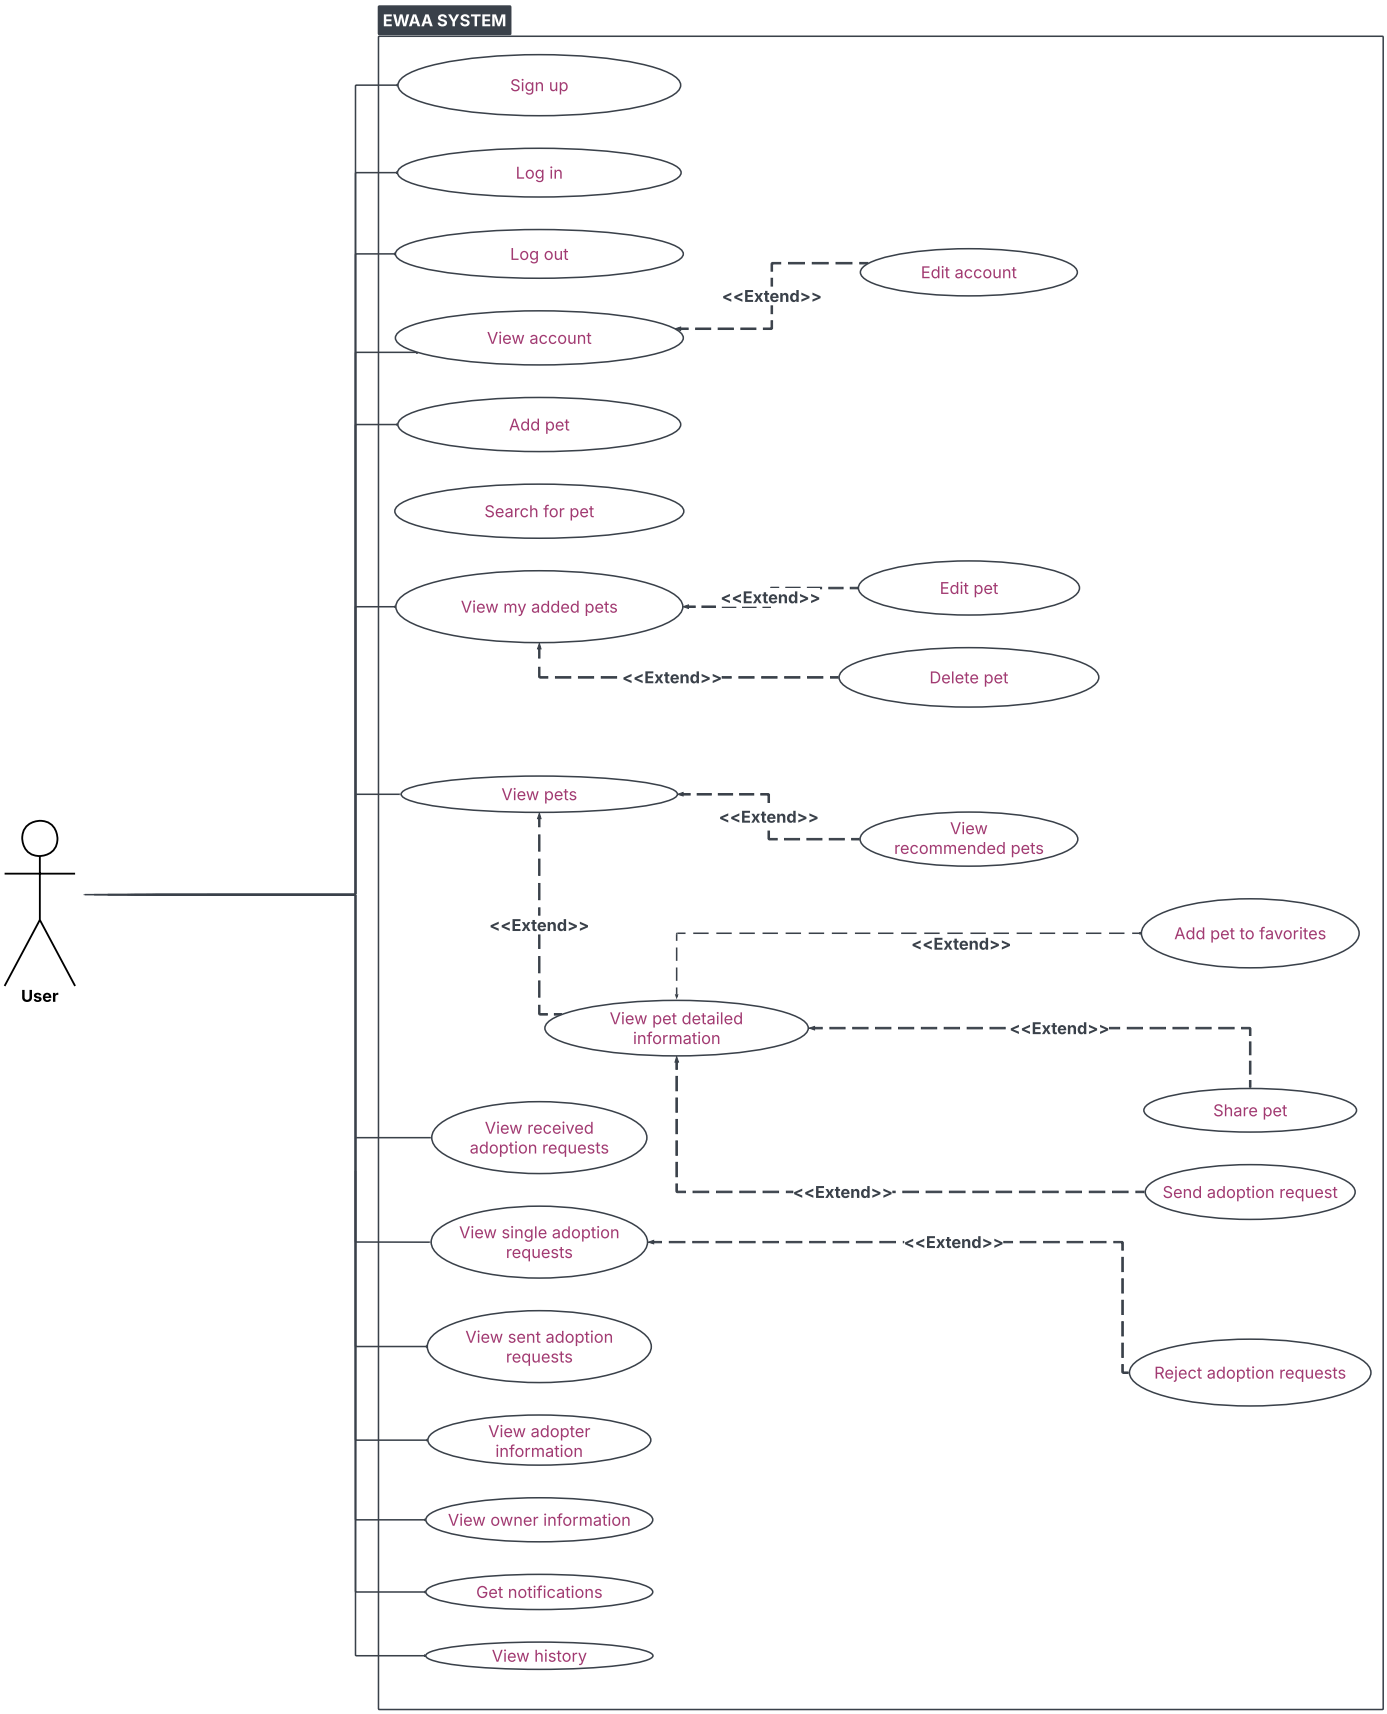

Fig. 1. Use case diagram of the EWAA system.

processes these requests and returns appropriate responses. This architecture supports centralized data management and enables users to access the application from different locations.

Fig. 2 illustrates the overall system architecture of EWAA. The client side is implemented as a mobile application developed using the Flutter framework and the Dart programming language. It provides users with an interactive interface to perform key actions such as browsing pets, submitting adoption requests, managing pet listings, and receiving recommendations. The server side is supported by a cloud-based NoSQL database, allowing efficient data retrieval and scalability.

A dedicated recommender system module, implemented in Python, is integrated into the architecture to generate personalized pet recommendations. The application collects user interaction data, such as preferences and liked pets, and sends this data to the backend database. The recommender module retrieves the stored data, applies the recommendation algorithms described in Section VI, and returns a list of suggested pets to the application, where they are displayed on the user's home page.

V. Implementation

A. Development Methodology

The EWAA system was developed using an agile methodology, specifically the Scrum framework [11], to ensure flexibility and iterative progress throughout the development process. Scrum enables the delivery of system functionalities in incremental stages through short development cycles known as sprints. Each sprint focused on implementing a set of user stories derived from the system requirements.

The development process included key Scrum practices such as sprint planning, progress tracking, and sprint review sessions. These iterative cycles allowed for continuous refinement of system features based on feedback and evolving user requirements. This approach ensured that the system remained aligned with user needs while supporting efficient development and timely delivery.

B. System Implementation

The EWAA system was implemented using a combination of modern development technologies to support scalability, performance, and usability. The mobile application was developed using the Flutter framework and the Dart programming language, providing a responsive and user-friendly interface.

Firebase was used as a Backend-as-a-Service (BaaS) platform, offering functionalities such as user authentication, real-time database management, and cloud storage. The system stores user data, pet information, and interaction records in a cloud-based NoSQL database.

The EWAA system includes a set of core features designed to enhance user experience and streamline the adoption process:

- User Registration and Authentication: Secure account creation, login, and email verification.
- Pet Management: Adding, editing, and managing pet listings with detailed attributes.
- Adoption Requests: Submitting, tracking, accepting, or rejecting adoption requests.
- Recommender System: Personalized suggestions using content-based and collaborative filtering.
- Notifications: Updates on adoption requests and activities related to pets.
- User Interface: Intuitive navigation with filtering and browsing capabilities.
- Privacy Protection: Secure handling of user data and controlled information visibility.

C. Data Collection

To support the recommender system, a data collection process was conducted focusing on cats and dogs, as they represent the most commonly adopted companion animals in Saudi Arabia. Initially, interviews with animal shelters were conducted to identify commonly adopted pet breeds in the region. Based on these findings, key characteristics of each breed were identified, including attributes such as energy level, affection, emotional reactivity, and intelligence.

Since the EWAA system was not deployed at the time of development, real user interaction data were not available. Therefore, a dataset was constructed by collecting information about the pets of real pet owners using an online questionnaire. The data collected included:

- Pet nickname
- Pet gender, age, and color
- Pet type and breed
- Health information (vaccination, sterilization, health profile)
- Personality traits

This dataset was used to initialize the recommender system and support personalized pet suggestions.

The system data structure is modeled, as shown in Fig. 3. The data model captures the main entities of the system — users, pets, adoption requests, and notifications — along with the relationships between them.

Each user can act as both an adopter and a pet owner, enabling them to create and manage pet listings. Adoption requests establish a relationship between users and pets, while interaction data is used to support the recommender system.

VI. Recommender System Design

Recommender systems are information filtering systems that predict user preferences and suggest relevant items. They are widely used in various domains such as e-commerce, healthcare, and online services [3].

In the EWAA system, a hybrid recommender approach is adopted to improve matching accuracy by combining collaborative filtering and content-based filtering techniques. This hybrid approach mitigates the limitations of individual methods by combining user preference modeling with interaction-based similarity.

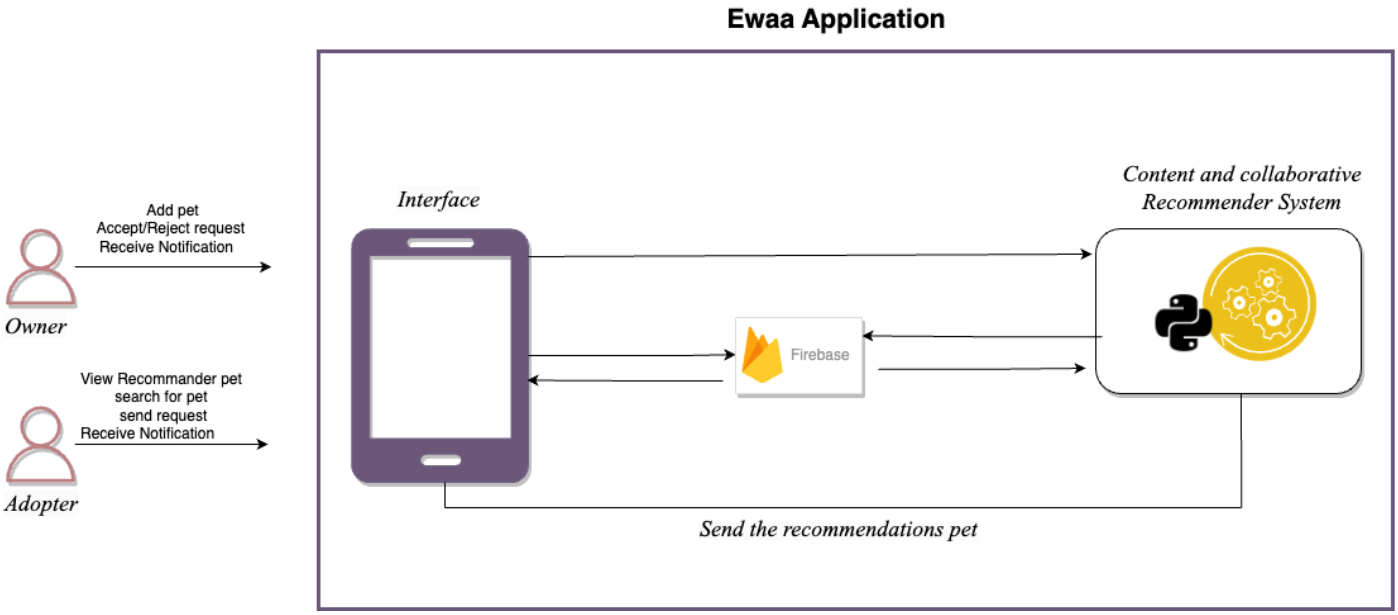

Fig. 2. EWAA system architecture

A. Collaborative Filtering

The collaborative filtering approach identifies users with similar preferences and recommends pets based on their interactions. The system constructs a user–item (likes) matrix R in which each row represents a user and each column represents a pet, with entries indicating whether the user has liked the pet. The similarity between the active user and every other user is computed using the cosine similarity measure:

$$\text{sim}(u, v) = \frac{R_u \cdot R_v}{\|R_u\| \, \|R_v\|} \tag{1}$$

A similarity threshold of $\tau = 0.5$ is applied to retain only sufficiently similar users, from which the top $K = 10$ neighbors are selected. The neighborhood size $K = 10$ and threshold $\tau = 0.5$ follow common practice in memory-based collaborative filtering, where small-to-moderate neighborhoods and mid-range similarity cut-offs are typically reported as a balance between recommendation accuracy and noise from weakly correlated users [3], [12]. Candidate pets already liked by the active user are excluded. The remaining candidates are scored by accumulating the similarity weights of neighbors who liked them, then normalized by the number of contributing neighbors. When the active user has no liked pets or no sufficiently similar users exist, the collaborative filtering component falls back to low-popularity or underexposed pets, to balance visibility and mitigate popularity bias. This choice prioritizes fairness and exposure over accuracy, which is suitable in adoption contexts. The procedure is summarized in Algorithm 1.

This algorithm recommends pets by identifying users with similar preferences and aggregating their interactions to generate relevant suggestions.

Algorithm 1 Collaborative Filtering Recommender

Require: Active user ID u, similarity threshold $\tau = 0.5$, neighborhood size $K = 10$
Ensure: Top 10 recommended pets
Load user–item (likes) matrix R
if u has no liked pets **then**
  return the 10 least-popular pets ▷ cold-start fallback
end if
for each user $v \neq u$ **do**
  $\text{sim}(u, v) \leftarrow \text{cosine}(R_u, R_v)$
end for
$S \leftarrow$ the top K users v with $\text{sim}(u, v) \geq \tau$
if S is empty **then**
  return the 10 least-popular pets ▷ no similar users
end if
Initialize $\text{score}[i] \leftarrow 0$, $\text{count}[i] \leftarrow 0$ for all pets i
for each user $v \in S$ **do**
  for each pet i liked by v and not by u **do**
    $\text{score}[i] \leftarrow \text{score}[i] + \text{sim}(u, v)$
    $\text{count}[i] \leftarrow \text{count}[i] + 1$
  end for
end for
for each pet i with $\text{count}[i] > 0$ **do**
  $\text{score}[i] \leftarrow \text{score}[i]/\text{count}[i]$ ▷ normalization
end for
Sort pets by score in descending order
return the top 10 pets

B. Content-Based Filtering

The content-based approach builds a user profile from the attributes of the pets the user has previously liked, and then recommends candidate pets whose attributes best match that profile. Four attribute groups are considered: category (cat, dog), breed, color, and age group. Each pet is encoded as a one-hot feature vector over the union of all attribute values [13],

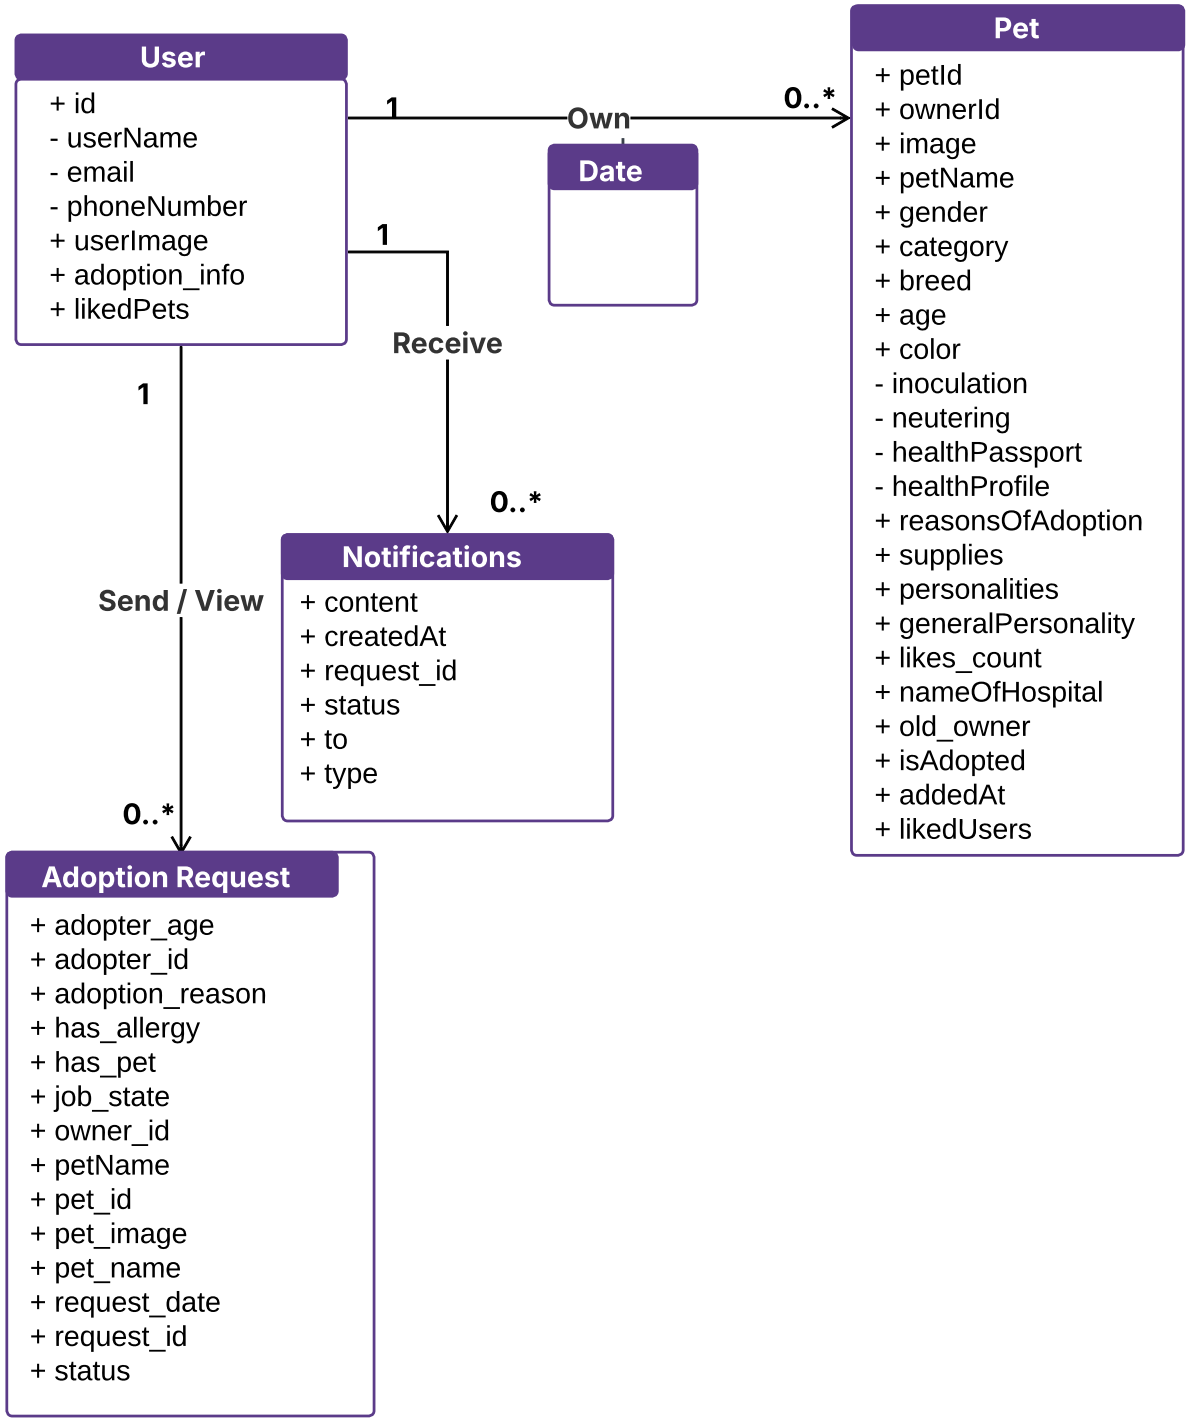

Fig. 3. Data model of the EWAA system.

forming a binary feature matrix F in which rows correspond to pets and columns to feature values.

The user profile p is constructed by averaging the one-hot vectors of the pets the user has liked:

$$p = \frac{1}{|L|} \sum_{\ell \in L} F[\ell] \tag{2}$$

where, L denotes the set of pets liked by the active user. This averaging yields frequency-based attribute weights for the user. For example, if a user has liked three pets with colors

Algorithm 2 Content-Based Recommender

Require: Active user ID u
Ensure: Top 10 recommended pets
$L \leftarrow$ pets liked by u
if L is empty **then**
  return the 10 most-popular pets ▷ cold-start fallback
end if
$F \leftarrow$ one-hot feature matrix over {category, breed, color, age}
Initialize user profile $p \leftarrow \mathbf{0}$
for each pet $\ell \in L$ **do**
  $p \leftarrow p + F[\ell]$ ▷ accumulate one-hot vectors
end for
$p \leftarrow p/|L|$ ▷ attribute-frequency weights
$C \leftarrow$ candidate pets (excluding L)
for each pet $c \in C$ **do**
  $\text{score}[c] \leftarrow \sum_k F[c,k] \cdot p[k]$
end for
Sort C by score in descending order
return the top 10 pets

$\{\text{white}, \text{white}, \text{brown}\}$, the profile assigns a weight of $2/3$ to white and $1/3$ to brown, while all other colors receive a weight of zero. The same principle applies to breed, age, and category, so that the profile captures the relative importance of each attribute value based on the user's observed preferences.

Each candidate pet c (excluding pets already liked by the user) is then scored as the weighted sum of its feature vector with the profile:

$$\text{score}(c) = \sum_k F[c,k] \cdot p[k] \tag{3}$$

Candidates are ranked by their scores and the top 10 pets are returned to the user. The full procedure is presented in Algorithm 2.

This algorithm recommends pets by matching candidate pet attributes to the user's preference profile derived from previously liked pets.

C. Hybrid Integration

The EWAA system implements a *mixed* hybrid configuration [2]: the content-based and collaborative filtering recommenders operate independently, and each produces its own top-10 list. Both lists are then presented to the user on the recommendation page of the application. This design was chosen for two reasons. First, it mitigates the cold-start limitation of collaborative filtering: new users with few or no liked pets still receive useful content-based recommendations. Second, it mitigates the over-specialization limitation of content-based filtering, since the collaborative component can surface pets that do not match the user's explicit attribute preferences but are enjoyed by users with similar overall taste. The two components are integrated through a Flask service that receives the active user's ID from the Flutter front end, executes both recommenders on the data retrieved from the Firebase database, and returns both recommendation lists to the application as JSON.

D. User Interface and Navigation

The EWAA application features a user-friendly interface designed to ensure ease of navigation and accessibility. The Home Page serves as the central hub, allowing users to browse pets, apply filters, and access key features such as adoption requests and user profiles.

Users can navigate through different sections including categories, pet details, notifications, and favorites. The system also supports account management features such as login, registration, and password recovery. Fig. 4 illustrates the application navigation flow.

E. Graphical User Interface

Fig. 5 presents sample screens from the EWAA application, including the login page, home page, filtering interface, and pet listing interface. The graphical user interface was designed to provide a simple and intuitive experience for both adopters and pet owners.

F. UX Guidelines

To ensure usability and accessibility, several user experience guidelines were considered in the design of the EWAA application:

- The system targets a high reliability rate, operating without failure in at least 95% of cases.
- The interface is designed to be intuitive and easy to navigate for users of different technical backgrounds.
- User privacy is protected for both adopters and pet owners.
- The system is scalable and capable of handling a growing number of users.
- Users can learn and use the system efficiently in a short time.

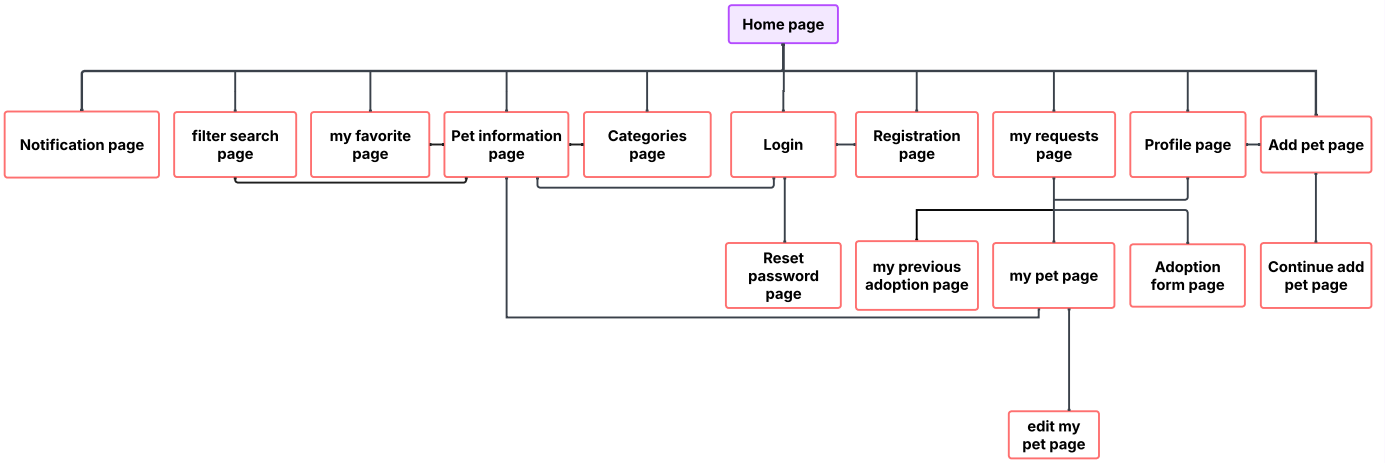
VII. System Testing and Evaluation

Since the EWAA system was not deployed at scale, real user interaction logs were not available for a large-scale offline evaluation of the recommendation algorithms. Instead, the overall system was evaluated using User Acceptance Testing (UAT) and Non-Functional Requirements (NFR) testing with real users, assessing usability, reliability, performance, and overall user satisfaction. Both qualitative and quantitative methods were employed to ensure a comprehensive assessment.

A. User Acceptance Testing

User Acceptance Testing was conducted using two complementary approaches: questionnaires and interviews. A total of 20 participants were involved in the questionnaire-based evaluation.

The demographic profile of the participants was analyzed to ensure a representative evaluation of the system. The majority of the participants were within the 18–25 age group (approximately 60%), followed by users aged 26 to 35 (30%) and a smaller proportion over 35 years (10%). In terms of gender



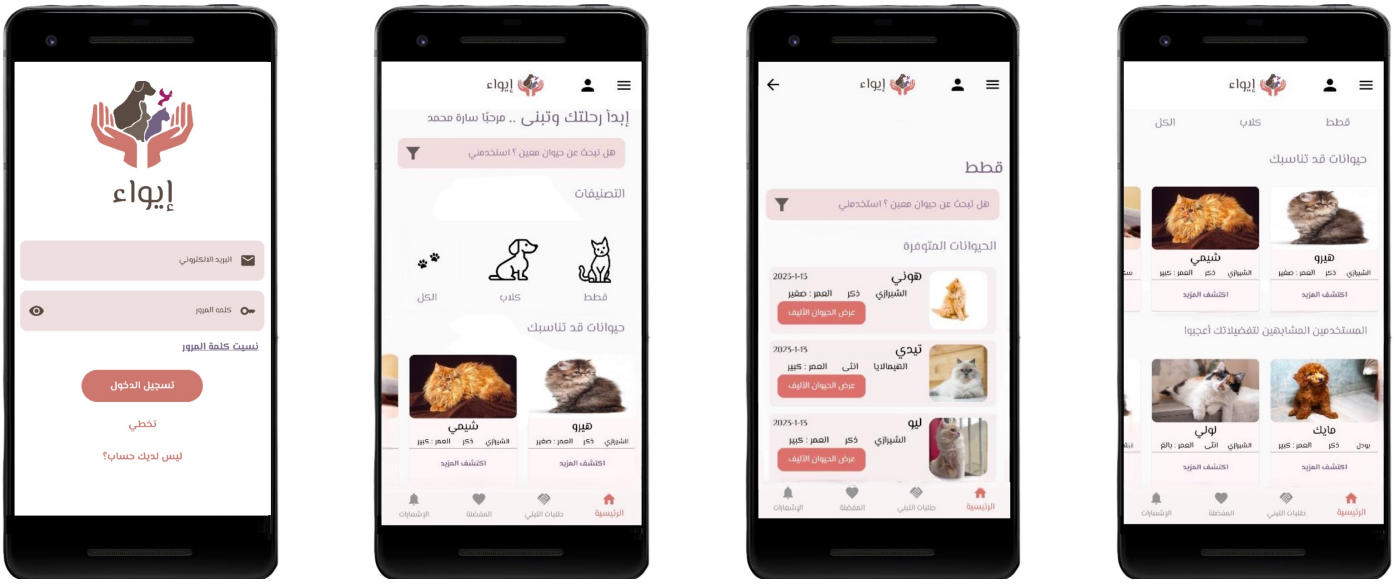


Fig. 4. Application site map

(a) (b) (c) (d)

Fig. 5. EWAA application interface

distribution, the sample included a balanced representation of male (45%) and female (55%) participants. Most participants (65%) reported having owned a pet previously, while 35% had no prior experience. This diversity ensured that the system was evaluated from both experienced and first-time adopter perspectives.

1) Questionnaire-based evaluation: Participants were asked to interact with the application and respond to a set of structured questions that evaluated usability, interface design, and system effectiveness.

The majority of the participants agreed that the application is easy to use, visually appealing, and effective in facilitating the pet adoption process. In addition, users confirmed that the system provides adequate information about pets and supports efficient communication between adopters and pet owners. The summarized results, presented in Table II, indicate a high level of user satisfaction with the EWAA application. Participants reported positive feedback regarding the interface design, usability, and overall functionality. In particular, users agreed that the system is clear, easy to use, and effective in facilitating the pet adoption process. Additionally, the recommender system was well received, with 85% of participants indicating that it helped them identify suitable pets based on their preferences. These findings demonstrate that the application meets user expectations and provides a positive user experience.

2) Interview-based scenario testing: To gain additional insights into system usability, 6 participants took part in interview-based testing. This testing was carried out using 11 predefined scenarios that captured the main functionalities of

TABLE II. SUMMARY OF QUESTIONNAIRE-BASED USER EVALUATION

Evaluation Statement	Agreement (%)	Interpretation
The application interface is attractive	100%	Very Positive
The application is easy to use	95%	Positive
The application is clear and understandable	95%	Positive
The system facilitates the adoption process	90%	Positive
Pet information is sufficient	90%	Positive
User privacy is maintained	100%	Very Positive
The recommender system is helpful	85%	Positive
Overall satisfaction with the application	100%	Very Positive

TABLE III. SCENARIO-BASED USER ACCEPTANCE TESTING RESULTS

No.	Test Scenario	Successful Users (out of 6)	Status
1	User registration	6/6	Pass
2	Add pet for adoption	6/6	Pass
3	Browse pets	6/6	Pass
4	Filter search results	6/6	Pass
5	View pet details	6/6	Pass
6	Add to favorites	6/6	Pass
7	Submit adoption request	6/6	Pass
8	Manage adoption requests	6/6	Pass
9	View notifications	6/6	Pass
10	View recommendations	6/6	Pass
11	View adoption history	3/6	Partial Pass

the application. The scenarios covered tasks such as registering a user, adding pets, filtering search results, handling adoption requests, and using the recommender system.

The results in Table III show that the system achieved a 100% task completion rate for 10 out of 11 test scenarios, indicating a high level of usability and functional correctness. The only scenario that presented difficulty was "viewing the adoption history", where some users were unable to locate the feature due to unclear navigation. This indicates a minor usability issue related to interface design rather than system functionality.

Overall, participants were able to complete core tasks such as signing up, adding pets, filtering searches, sending requests, and interacting with recommendations without any significant issues, demonstrating the system's usability and functional correctness.

B. Non-Functional Requirements Testing

Non-functional testing was conducted to evaluate key quality attributes of the system, including performance, learnability, and reliability. The results are summarized in Table IV.

1) Performance: System performance was evaluated by measuring page loading times during user interaction. All application pages loaded within a range of 1 to 12 seconds, satisfying the predefined requirement of a maximum loading time of 20 seconds. This indicates that the system provides a responsive user experience under the tested conditions.

2) Learnability: Learnability was assessed by measuring the time required for users to understand and complete core functionalities. Participants were able to learn and interact with the system within 1 to 8 minutes, which is well within the acceptable threshold of 10 minutes, suggesting that the system is intuitive for new users.

TABLE IV. NON-FUNCTIONAL REQUIREMENTS TESTING RESULTS

Quality Attribute	Measure	Target	Result
Performance	Page load time	$\leq$ 20 sec	1–12 sec
Learnability	Learning time	$\leq$ 10 min	1–8 min
Reliability	Task success rate	$\geq$ 95%	100%

3) Reliability: Reliability was evaluated by measuring the proportion of functionalities that executed without critical errors. Across the 11 interview-based scenarios, all core functionalities executed without runtime failure; the only observed issue was a navigation visibility problem in one scenario, which is a user-interface concern rather than a functional failure. On this basis, the system met the predefined reliability target of at least 95% task success at the functional level.

C. Discussion

The evaluation results, summarized in Table IV, indicate that the EWAA system meets its usability, performance, and reliability targets. The integration of core adoption functionalities with a personalized recommendation component supports the pet adoption workflow in an Arabic-speaking context.

The only identified limitation in the user-facing evaluation was related to the visibility of the adoption history feature, which can be addressed through minor interface improvements such as clearer navigation or dedicated menu options.

Several limitations of the evaluation should also be acknowledged. First, the sample size (20 questionnaire participants and 6 interview participants) is modest and drawn primarily from a single demographic group (60% aged 18–25), which limits the generalizability of the usability findings to the broader population of potential adopters. Second, participants interacted with the system in controlled testing scenarios rather than through natural long-term use, which may lead to overestimation of reported satisfaction. Third, the questionnaire-based dataset used to bootstrap the recommender reflects owner-reported pet preferences rather than real adoption behavior, which may introduce bias into the learned user profiles once the system is deployed. Finally, the current evaluation focuses on system usability and non-functional qualities rather than the offline accuracy of the recommendation algorithms themselves; the 85% perceived helpfulness reported in Table II is a subjective measure and does not quantify recommendation quality.

A dedicated quantitative evaluation of recommendation quality, using metrics such as precision@N or hit rate on held-out interaction data, is left as future work once sufficient real-user interaction data are collected post-deployment. Overall, the findings indicate that EWAA provides a user-centered platform that supports the pet adoption process, and that addressing the identified navigation issue will further improve the user experience.

VIII. CONCLUSION

This study presented EWAA, an Arabic-enabled mobile platform for pet adoption in Saudi Arabia that integrates a hybrid recommender system combining content-based and collaborative filtering. The content-based component builds a user

profile from one-hot encoded pet attributes of previously liked pets, while the collaborative filtering component identifies similar users through cosine similarity and recommends pets based on their preferences. The two components operate in a mixed hybrid configuration, which mitigates the cold-start limitation of collaborative filtering and the over-specialization limitation of content-based filtering.

The main scientific contribution of this work is the integration of a mixed hybrid recommender, combining one-hot attribute-based content filtering with cosine-similarity collaborative filtering, into an Arabic-language mobile adoption platform, addressing a gap in prior recommender approaches that have neither combined complementary signals within deployed adoption systems nor targeted Arabic-speaking users.

The evaluation results indicate that the system meets its usability, performance, and reliability targets. User Acceptance Testing with 20 questionnaire participants and 6 interview participants confirmed 100% task completion on 10 of 11 test scenarios, with the remaining scenario identifying a minor navigation issue. Non-Functional Requirements testing further verified that page load times (1–12 seconds) and learning times (1–8 minutes) fell well within their predefined targets.

Future work will include an offline evaluation of the recommender component using standard metrics such as hit rate and precision once sufficient real-user interaction data are collected post-deployment. Further directions include exploring alternative recommendation models such as item-based collaborative filtering or matrix factorization, extending the feature set beyond category, breed, color, and age, and adding diversity-aware post-processing. Planned platform extensions include pet health tracking and adoption analytics.

ACKNOWLEDGMENT

The author thanks Rawan Alqarni, Hadeel Quayyid, Gadah Alotibi, and Rahaf Almoqbel for their work on the implementation and testing of the EWAA system.

DECLARATION ON GENERATIVE AI

During the preparation of this manuscript, the author used AI-based language editing tools to assist with grammar, clarity, and formatting. The author reviewed and edited all AI-assisted content and takes full responsibility for the originality, accuracy, and integrity of the final manuscript.

***Abstract*—The proper identification of latent market states is important for effective risk management. However, existing frameworks are often not good at distinguishing the difference between stable situations and systemic crashes in the high entropy environments of frontier economies. To address this challenge, this study presents State-AttentNet, an application-driven market-state classification framework for the Dhaka Stock Exchange. The framework combines a volatility-adaptive labeling scheme with a bidirectional LSTM encoder and temporal attention to classify stable and crash-like market states in the Dhaka Stock Exchange. The market sensitive technical features are synthesized with Bidirectional LSTM encoder of the temporal context into a hierarchical pipeline proposed methodology. This model is also supplemented by Adaptive Temporal Attention model to bring focus to high impact volatility events in a rolling window. Here, 'crash' means an adaptive volatility-stress state, not a return direction. Empirical evaluation on a longitudinal 26-year dataset shows that the model achieves 93% classification accuracy and an AUC of 0.97. It outperforms traditional baseline models in discriminating between crash and stable states. The results have significant practical implications for institutional investors as it is a trusted, automated detection instrument. This system is conducive for state contingent risk reduction measures and minimizing false alarms in instances of correction of incidental markets. Lastly, SHAP used to check the operational integrity of the model. This suggests that structurally informative lag signals and not stochastic noise determine classification decisions.**

I. Introduction

Financial markets are rarely in a steady state. Instead, they evolve through regimes in which expected returns, volatility and cross asset dependence change between calm, transitional and stress periods. This view is often formalized by latent states whose parameters change according to a Markov process, which makes it possible to model abrupt but persistent changes in a tractable way [1]. These regime shifts are directly relevant for risk, because correlations and volatilities are likely to increase in adverse states, which affects the diversification benefit and the cost of holding risky exposures over time [2]. Recent empirical evidence also suggests that regime detection is depends on more than just price fluctuations. It requires signals that capture the re-organization of the joint structure of the market under stress. For example, the information about realized covariance can be useful to enhance the regime identification when the standard models face difficulties, which implies that dependence dynamics should be considered as state variables in risk monitoring [3]. Regime switching specifications also enhance the realized volatility forecasting since parameters can adjust as the markets switch across volatility states [4]. At a broader macro finance scale, probabilistic models have been utilized to test the validity of bear markets and recessions occurring within a country simultaneously, reinforcing the view that regime events can have international transmissions but can largely not occur at the same time [5]. Together these studies make market state classification a fundamental task in understanding the risk in the case of non-stationarity rather than a purely descriptive task.

Building on these foundations, modern machine learning provides flexible tools for modelling nonlinear and time varying market conditions. Multi Transformer architectures have been proposed in volatility forecasting and risk assessment and have shown great potential to learn complex temporal interactions in unstable periods [6]. Hybrid machine learning designs are also highlighted for volatility prediction for risk management because the combination of complementary learners can offer superior performance compared to single learners in the context of a noisy and structurally changing environment [7]. Emerging hidden state formulations such as the Hidden Quantum Markov Model imply that richer state representations may capture aspects of regime dynamics that classical structures may not be able to express [8]. Related work also indicates that adaptive Transformer reinforcement learning frameworks can interpret sentiment-driven signals into predictive and decision oriented policies that respond to

*Corresponding author

changing market conditions [9].

In parallel, the feature space of market modeling is growing towards multimodal and explainable pipelines which are closer to the real decision setting. Temporal feature attention along with GraphSAGE on multimodal financial data shows that attention and graph encoders can learn predictive structure from interrelated sources of information [10]. Recent studies highlight explainability-guided recurrent modeling using SHAP values, demonstrating that strong performance should be accompanied by transparent reasoning under regime shifts [11]. Topology-driven CNN designs that fuse news sentiment with market dynamics are similarly suggestive of the ability of information flow and network effects to materially shape predictive behavior [12]. In high frequency situations, generative discriminative learning based on hidden state structure and discriminative boundaries has been shown to be useful in enhancing the regime separation in the situation of microstructure noise, demonstrating the importance of hybrid probabilistic and machine learning pipelines for the classification of states [13].

Despite these improvements, there remains an important gap for frontier equity markets over long horizons. Much of the recent evidence is developed market-focused, based on high frequency data sets, or assesses performance over short windows though frontier markets suffer from structural breaks and changing liquidity and participation driven shocks that may distort fixed labelling schemes and reduce the transferability of models. At the same time, theory-driven portfolio research focuses on how regimes are usually unobservable and have to be inferred with regards to filtered probabilities in order to support dynamic decision rules, which makes classification explicitly decision relevant rather than only predictive [14]. This motivates regime classifiers that can adapt labels to evolving risk and be robust under long run non stationarity and still provide interpretability for monitoring.

To overcome these limitations of the previous studies, the goal of this study is not to predict prices, but to explicitly classify the market states in Dhaka Stock Exchange using the daily data between 1999 and 2025 [15]. This study propose a dynamic volatility threshold labeling approach to the definition of stable and crash states that is adaptive to time varying market risk. The proposed framework incorporates market-sensitive technical features and propose State-AttentNet, which is a bidirectional recurrent sequence model with attention that focuses on the most informative days within each rolling window instead of all lag equally. Finally, Explainable AI (XAI) techniques are employed to ensure that the decisions of the model are not based on transient noise, but on meaningful lag signals. Experimental results demonstrate that State-AttentNet yields better classification performance compared to common recurrent baselines underscoring the use of State-AttentNet for transparent regime monitoring in a frontier market setting for risky regime aware decision making. The contribution of this study is not to introduce a fundamentally new neural architecture, but to develop an application-driven framework that integrates adaptive volatility labeling, temporal attention and explainability for long-horizon market state classification in a frontier market context.

II. Literature Review

The development of financial markets is rarely in a smooth and continuous way. Rather, emotional changes change with time, with periods of calmness punctuated by spurts of stress, volatility peaks, and dependence reversals. This set of recurring transitions has been typically described as market regimes, in which the properties of returns and risk are restructured across a set of discrete states as opposed to being due to a unique stable process. Particularly, risk management of a regime has two extensions. Regime-switching volatility models combine ARCH-type volatility clustering with latent regime changes, which enable volatility persistence to vary between regimes [16]. Less specific regime switching specifications allow the conditional distribution to differ under a Markov state process, thus allowing the mean, dispersion, and tail behavior to vary across states [17]. The volatility evidence of recent regime switching also suggests that volatility dynamics can also be regime-specific to other designs of switching between regimes that use alternative score driving designs, meaning that risk boundaries are not to be fixed as long as structural conditions change [18]. Combined, these contributions explain why the single-regime assumption may be structurally misspecified when volatility and tail risk rearrange during stress.

A first cluster of studies deals with how regime should be defined and segmented in a way that is robust, transparent and reproducible. Zegadło *et al.* [19] suggests a rule-based bull-bear dating procedure with minimum tuning, which favors label stability and the comparability between studies. Wang *et al.* [20] goes even further by adding a four-state structure through the HSMM model, demonstrating that markets may survive in intermediate conditions and that state duration characteristics enhance the validity of segmentation. Maheu *et al.* [21] similarly motivates multi-state design but focuses on real-time dating and forecasting utility as showing that regime forecasts will be particularly useful in windows of crisis since timing risk exposure is when it will matter most. Collectively these works support multi-state frameworks, however there is one limit that continues to prevail. State definitions and boundary choices are often tied to particular modelling constraints or stylization of mature market behaviour, leaving the transferability to structurally unstable markets open. A second strand reinforces regime identification by introducing forward-looking information that may adjust ahead of spot returns. Lai *et al.* [22] shows that option implied horizon spread information outperforms returns-only inputs for regime detection, supporting the concern that derivative markets contain anticipatory information on risk. However, the approach is data-intensive and assumes deep and liquid options markets. Such infrastructure is not necessarily available in frontier exchanges, diminishing feasibility at the very places where regime monitoring in a timely manner may be most important.

A third body combines probabilistic regime structure with deep learning, where state probabilities form informative inputs or scaffolding of flexible sequence models. Another regime that Erlwein-Sayer *et al.* [23] offers to deep learning template is HMM state probability extraction followed by input into an LSTM to improve his results in terms of forecasting European corporate credit spreads. Haase and Neuenkirch [24] deal with instability by combining forecasts with regime forecasts, indicating that regime forecasts enhance

predictability in bull-bear regimes and returns in the US, which diminishes the vulnerability to regime specific model error. An interpretable HMM-based market situation estimator coupled with a trading strategy is created by Chen *et al.* [25] and is a useful benchmark of regime classification despite its feature design being ahead of modern representation learning. Although people demonstrate that hybridization is fruitful, the empirical evidence is largely developed market-oriented and tends to focus more on forecasting aim than on explicit daily classification of long-horizon under the changing volatility baselines.

Fourth cluster is an extension of regime forecasting to multimodal and text informed systems, indicating that market states are also determined by information diffusion and narrative shocks along with the price movement. Battazza *et al.* [26] suggests a complete end-to-end market state prediction pipeline comprising of ontology-based asset selection, non-stationary Markov chain, BERT sentiment representations, and LSTM modeling, as well as it is shown how regime inference can be incorporated into a larger allocation mechanism. The same author Mudarisov *et al.* [27] also states that LLM or FinBERT style news augmentation is better at regime prediction compared to time series pure baselines across industries, aligning with broader machine learning investigations that demonstrate the substantial impact of news sentiment on market dynamics [35]. Though promising, these methods are structurally weak in frontier settings when historical records might be biased, language diffusion might be uneven, as well as heterogeneity in news coverage can induce bias in learnt regime cues.

Recent developments have moved away the focus of prediction-focused testing to decision-focused assessment that is more in line with the trends in algorithmic trading and portfolio building in developing contexts. This fact is supported by Hanauer and Kalsbach [28] that machine learning models are capable of finding economically significant signals in a wide emerging-market equity space, which in turn makes the argument that non-linear predictability can be translated to implementable strategy value within realistic constraints. Studies that are strategy-focused also review machine learning as an engine of signals of algorithmic investment rules on both global and Central-Eastern European equity indices where technical characteristics are mapped into systematic decision regulations and measured within a consistent performance procedure [29]. In addition to equity signals at the daily-frequency, short-horizon studies of the Asian markets show how the data-driven models may be implemented into the rule-based pipelines of entry and exit decisions. The use of deep learning architectures in high-frequency pairs trading studies in Taiwan to predict the boundaries of spreads and issue trading clues supports the increased preference to use decision-relevant validation over accuracy-only prediction [30]. Collectively, these results give stronger empirical impetus to regime-sensitive targets, since algorithmic strategies are directly sensitive to volatility changes and to changes in the structure and tenacity of market regimes.

The other direction conceptualizes regimes as labels, as well as state dependent mechanisms, which change the drivers that are economically relevant. Pakštaitė *et al.* [31] demonstrates that macroeconomic influences of the Bitcoin differ across regimes with Bayesian selection HMM backbone which confirms the general suggestion that the relevance of factors can change among states. This is furthered by Wang *et al.* [32] who incorporates heteroskedastic networks with HMM and machine learning to identify regime switch and early signals, which suggests that transitions can be encoded in evolving interaction structure, as opposed to volatility. These papers reinforce the arguments in favor of adaptive, state contingent modelling but validation is still focused on individual large markets or crypto-environment, where frontier equity generalization has not been sufficiently evaluated. Shu *et al.* [33] comes up with asset specific regime labels based on jump model logic, regime forecasts based on GBDT and presents better results of dynamic allocation, which points to the importance of regime forecasts to enter portfolio policy. The use of an ensemble pipeline of machine learning and HMM with a voting classifier is suggested by Gupta *et al.* [34] and has a higher regime shift detection that is more stable and could be used to aid trading decisions in ETF-based contexts. These allocation-based evaluations are however normally carried out in developed market universes or proxy assets. They seldom treat long-horizon daily regime classification in which volatility baselines, liquidity situations, and microstructure of the market change significantly over time.

Across these studies, four gaps recur. First, long-horizon daily regime classification in the frontier equity markets is still limited, as most of the evidence is pegged to the United States or Europe, in the ETF proxies, in the options based identification or in the news rich settings. Second, there is rigidity in labelling, making the boundaries of the state in most cases fail to explicitly adjust with changes in volatility baselines that develop slowly over decades. Third, not all hybrid models are always associated with interpretability even though the regime signals are applied in risk management context where transparency is valued. Fourth, the feasibility of the data limits transfer as frontier markets seem to have only dependencies and news intensive regimes, which can be infeasible in long gaps of history.

To address these limitations, this study focuses on application-driven market-state classification in a frontier-market setting. Using 26 years of daily Dhaka Stock Exchange data [15], this study develop a causally labeled regime-classification pipeline based on a dynamic volatility-adaptive thresholding scheme. A bidirectional recurrent model with temporal attention is then applied to identify informative periods within each rolling window. Finally, this study incorporate explainability analysis to improve transparency and support decision-relevant interpretation in a data-constrained frontier-market environment.

III. Methodology

This study proposes an end-to-end deep learning architecture to classify the stable and crash market regime. As illustrated in Fig. 1, the general methodology includes data preparation, feature extraction, sequential modeling based on Bi-LSTM encoder and temporal attention mechanism and a classification head to reliably predict the final market state.

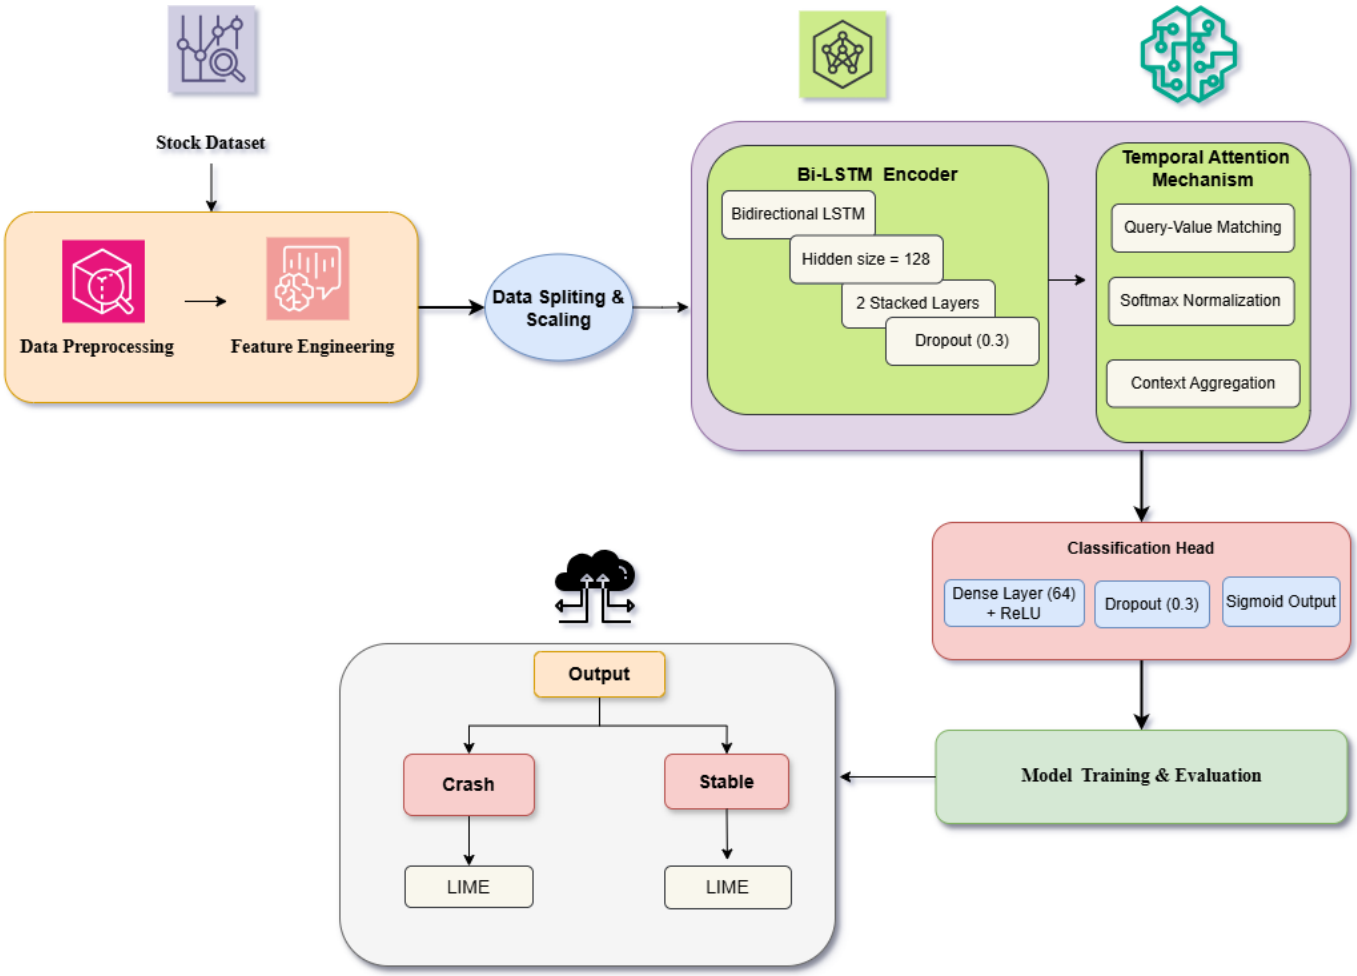

Fig. 1. End-to-end workflow of the State-AttentNet architecture.

A. Dataset Description

This study utilizes a high-fidelity dataset from the Dhaka Stock Exchange (DSE) spanning a 26-year period from 1999 to 2025. The repository contains over 1.5 million trading records across 534 distinct securities. As illustrated in Fig. 2, the market's price history exhibits extreme instability and frequent structural breaks, such as the 2010 capital market crash and the 2020 pandemic-induced volatility. Unlike developed markets, the DSE is characterized by high-entropy price movements and significant volatility clustering. These complex dynamics and heavy-tailed returns provide a rigorous benchmark for evaluating this proposed framework's ability to distinguish between systemic shocks and incidental market noise.

To empirically quantify these regime shifts, Table I presents a chronological breakdown of the distinct phases of the market that were seen within the dataset. This tabulation describes the development of volatility from the contrasting periods of systemic distress like the 2011 crash to regulatory interventions like the floor price era, thereby validating the non-stationary nature of the market. Specifically, the table calls attention to the fact that the market risk changes drastically through time. For example, the average volatility at the time of the 2011 crash was extremely high at 0.344, while in the period from 2022 to 2023 in the regulation era, volatility fell to only 0.035. This huge gap proves that the market does not act the same way every year. Because of these wide variations, a fixed-fire standard model with fixed rules would not predict the market correctly. This evidence justifies why we need a dynamic model that can automatically adapt to these changing conditions whether the market is in a bubble, a crash or a stable phase.

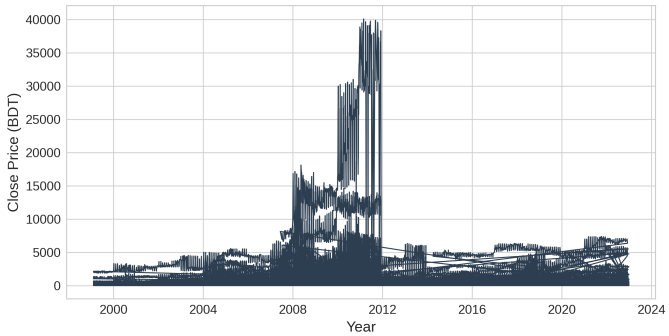

Fig. 2. Long-term price history of the DSE dataset.

TABLE I. CHRONOLOGICAL EVOLUTION OF MARKET STATES AND VOLATILITY DYNAMICS (1999–2024)

Year	Market Phase	Avg. Volatility	High-Risk Days	Key Event
1999–2000	Early Development	0.097	20.9%	Initial market formation volatility.
2004	Pre-Crisis Bubble	0.155	26.1%	Early signs of market overheating.
2010	The Great Bubble	0.215	24.1%	Highest speculation period.
2011	The Crash	0.344	25.9%	Record volatility due to market collapse.
2012–2016	Stabilization	0.118	22.5%	Post-crash recovery and consolidation.
2018	Election Effect	0.102	27.1%	Uncertainty due to national elections.
2020	Pandemic Shock	0.123	25.1%	Global volatility due to COVID-19.
2022–2023	Regulation Era	0.035	16.3%	Floor Price artificially reduced volatility.
2024	Correction Phase	0.025	26.9%	Removal of floor price triggered volatility.

B. Data Preprocessing and Adaptive State Identification

The transformation of raw DSE sequences into a structured dataset involves a systematic pipeline to ensure numerical stability and contextual relevance. To maintain chronological continuity without look-ahead bias, missing values and zero-entry anomalies are addressed using the Forward Fill propagation method. Given the high-entropy nature of emerging markets, Robust Scaling is employed to normalize the feature space. This technique utilizes the median and Interquartile Range, effectively mitigating the impact of extreme price spikes while preserving significant market signals. The operation is defined, as in Eq. (1):

$$x' = \frac{x - median(x)}{IQR(x)} \tag{1}$$

The frontier markets like the DSE are usually characterized by liquidity gaps and discontinuous trading that may cause artificial breaks in observed returns. Such markets also exhibit fat-tailed returns thus Robust Scaling is the choice of scaling which would eliminate the effect of extreme shocks. A notable aspect of this framework is the departure from traditional static crash rules in favor of a Dynamic Rolling Threshold for state labeling. Let P_t denote the daily closing price and define "the log return", as in Eq. (2):

$$r_t = \ln(P_t) - \ln(P_{t-1}) \tag{2}$$

The 20-day rolling volatility is computed as the sample standard deviation of returns over the most recent 20 trading days, as given in Eq. (3):

$$\sigma_t^{(20)} = \sqrt{\frac{1}{19}\sum_{i=0}^{19}(r_{t-i} - \overline{r_t^{(20)}})^2}, \quad \overline{r_t^{(20)}} = \frac{1}{20}\sum_{i=0}^{19} r_{t-i} \tag{3}$$

In this study, Crash refers to a volatility-spike regime rather than a return-sign definition, and, therefore, it does not necessarily imply negative returns. To adapt the crash boundary to the local volatility environment, a time-varying threshold is derived from the trailing 60-day empirical distribution of volatility. Let $Q_{0.80}(\cdot)$ denote the empirical 80th percentile. The dynamic threshold is defined, as in Eq. (4):

$$\tau_t = Q_{0.80}\left(\{\sigma_{t-j}^{(20)}\}_{j=0}^{59}\right) \tag{4}$$

The choice of the 80% percentile threshold was empirically validated to balance sensitivity to volatility spikes and robustness to noise. A sensitivity analysis was conducted using alternative thresholds (75%, 80%, and 85%), where 75% resulted in excessive false positive crash signals, while 85% reduced the model's ability to detect meaningful volatility stress events. The 80% threshold provided the most stable and balanced performance. Market regimes are then labeled by comparing the current volatility against this adaptive threshold, as in Eq. (5):

$$\text{State}_t = \begin{cases} 1 \text{ (Crash)}, & \text{if } \sigma_t^{(20)} > \tau_t \\ 0 \text{ (Stable)}, & \text{otherwise} \end{cases} \tag{5}$$

After sorting the data by Trading_Code and Date, zero entries in Open, High, Low, Close, and Volume were treated as missing and forward-filled within each trading code to preserve temporal continuity. Observations lacking sufficient history to compute the 20-day rolling volatility, the 60-day volatility quantile used for dynamic labeling, the 14-day RSI, or the 60-day input sequence were excluded. This explains the apparent exclusion of early-period observations (e.g., 1999–2009), which do not satisfy the minimum history requirements for rolling statistics and sequence construction.

As illustrated in Fig. 3, this adaptive mechanism enables the architecture to contextually distinguish systemic structural breaks from incidental stochastic noise, as the threshold co-moves with the prevailing volatility baseline rather than remaining fixed across heterogeneous market phases. For reproducibility, all rolling statistics and quantiles are computed exclusively using trailing windows within each trading code, and observations that cannot form the required rolling windows for $\sigma_t^{(20)}$ and τ_t are excluded from the final labeled sample.

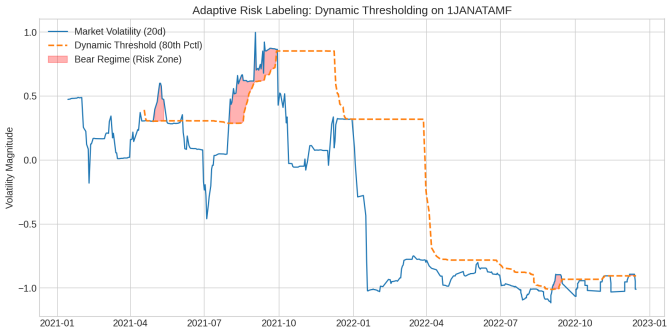

Fig. 3. Adaptive risk labeling logic using dynamic volatility thresholding.

C. Advanced Feature Engineering

To enhance the discriminative power of the proposed architecture, a multivariate feature set is constructed by capturing the temporal dynamics and liquidity shocks of the DSE. Instead of relying on raw price levels, the input vector is expanded to include indicators of momentum, volatility, and market pressure. The primary component involves the calculation of Logarithmic Returns to ensure mean-stationarity, supplemented by the Relative Strength Index and High-Low Spread to represent price dispersion. The statistical integrity and independence of this engineered feature set are validated through a correlation analysis. As shown in Fig. 4, the heatmap confirms that the selected attributes provide non-redundant information, which is essential for the model to distinguish between structural shocks and incidental market noise. Furthermore, to quantify the impact of trading activity on price movements, a composite Volume Force feature is incorporated, defined as in Eq. (6):

$$\text{Vol_Force}_t = \ln\left(\frac{P_t}{P_{t-1}}\right) \times \ln(\text{Volume}_t + 1) \tag{6}$$

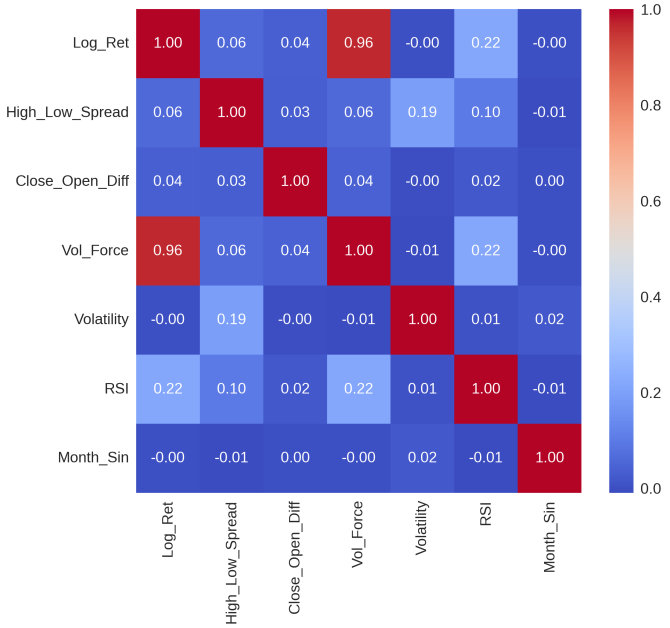

Fig. 4. Correlation matrix showcasing the statistical independence of engineered features.

To address the periodic nature of financial markets, a Cyclical Seasonality Encoding is implemented. The month index is transformed into a continuous sine-wave signal, enabling the model to recognize recurring calendar effects such as fiscal year-end adjustments without the ordinal bias inherent in raw categorical values. This temporal embedding is formally expressed, as in Eq. (7):

$$\text{Month_Sin}_t = \sin\left(\frac{2\pi \times \text{month}}{12}\right) \tag{7}$$

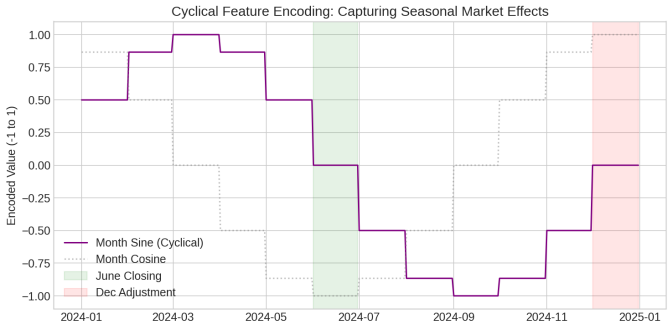

Fig. 5. Cyclical feature encoding for capturing seasonal and periodic market effects.

As illustrated in Fig. 5, this transformation effectively maps seasonal market behaviors, such as June closings and December adjustments, into a normalized periodic space. This multidimensional approach ensures that the input space captures both the geometric morphology of price trends and the underlying temporal regularities of the emerging ecosystem.

D. Proposed Model Architecture: State-AttentNet

To address the limitations of traditional sequential models, this study proposes the State-AttentNet, a hybrid architecture integrating bidirectional temporal learning with an adaptive attention mechanism. The model is specifically designed to decode market regimes by prioritizing high-impact volatility events over stochastic noise.

1) Bidirectional sequential decoding: The core of the architecture is a two-layer Bidirectional LSTM. Unlike standard recurrent units, the Bi-LSTM processes the input feature sequence $X \in \mathbb{R}^{T \times d}$ (where $T = 60$ and $d = 7$) in both forward ($\overrightarrow{h_t}$) and backward ($\overleftarrow{h_t}$) directions. This dual-stream processing allows the network to capture market patterns by analyzing both historical trends and future convergence points simultaneously. The hidden state h_t at any time step t is a concatenation of both directional vectors, as defined in Eq. (8):

$$h_t = [\overrightarrow{h_t}; \overleftarrow{h_t}] \tag{8}$$

The resulting hidden representation $H = \{h_1, h_2, ..., h_T\}$ encapsulates a robust temporal context of the market dynamics.

2) Adaptive additive temporal attention mechanism: To effectively decode market state,the model employs an additive temporal attention mechanism that dynamically prioritizes critical time steps within the 60-day lookback window.The attention score for each time step is computed, as defined in Eq. (9):

$$e_t = \mathbf{v}^\top \tanh(\mathbf{W}_h h_t + \mathbf{b}) \tag{9}$$

where, $\mathbf{W}_h$ and $\mathbf{b}$ are learnable parameters, and $\mathbf{v}$ is a trainable weight vector.

Instead of treating all historical days equally, this layer assigns a learnable scalar weight α_t to each time step, filtering out stochastic noise while highlighting high-impact volatility

events. The attention scores are normalized using the softmax function, and the final context vector (c) is computed as the weighted sum of the hidden states, as defined in Eq. (10):

$$\alpha_t = \frac{\exp(e_t)}{\sum_\tau \exp(e_\tau)}, \quad c = \sum_{t=1}^{T} \alpha_t h_t \tag{10}$$

The attention mechanism assigns higher weights to time steps that are more informative for regime classification. Practically the model tends to place more emphasis on periods where volatility remains elevated for several days or where the market shows a clear drawdown pattern. Single day jumps that quickly disappear usually get lower weight. This layer is unlike normal self attention where all days are compared with each other daily but this layer assigns each day an importance score and summarizes the entire 60-day window into a single context vector.

3) Classification and output module: The aggregated context vector (c) serves as the input for the final decision-making block. It is propagated through a fully connected Dense Layer (64 units) with ReLU activation to capture non-linear feature interactions. Finally, the output is projected to a probability score using the Sigmoid activation function to classify the market state, as defined in Eq. (11):

$$\hat{y} = \sigma(W_{out} \cdot c + b_{out}) = \frac{1}{1 + e^{-(W_{out} \cdot c + b_{out})}} \tag{11}$$

If the predicted probability $\hat{y} > 0.5$, the system flags a Crash Regime; otherwise, it indicates a stable market condition.

IV. Result Analysis

A. Experimental Setup

The computational experiments were conducted within the Kaggle Notebook cloud environment, leveraging dual NVIDIA Tesla T4 GPUs to accelerate parallel tensor processing and model training. The proposed State-AttentNet architecture was implemented using the PyTorch deep learning framework, while Pandas and Scikit-learn were utilized for data preprocessing and metric evaluation. To ensure robust convergence within the non-stationary DSE environment, the network parameters were optimized using the AdamW algorithm with an initial learning rate of 0.001.

The selection of key hyperparameters was guided by validation performance and stability considerations. The hidden dimension was set to 128 to balance representational capacity and overfitting risk, as lower dimensions resulted in underfitting while higher dimensions did not yield significant improvements. The maximum number of epochs was set to 20 with early stopping based on validation loss, as the model consistently converged within this range. The threshold percentile for dynamic labeling was fixed at 80% based on empirical validation, providing a balanced trade-off between sensitivity to volatility spikes and robustness to noise. Alternative thresholds (e.g., 75% and 85%) were also evaluated but resulted in either increased false positives or reduced crash detection performance. The objective function was minimized using Binary Cross-Entropy. To maintain the structural integrity and temporal fidelity of market signals, the inherent class imbalance was addressed through the Adaptive Temporal Attention mechanism rather than external resampling. This architectural design enables the model to autonomously prioritize low-frequency, high-impact volatility features, effectively learning the dynamics of rare "Crash" regimes directly from original stochastic patterns without introducing synthetic bias. To mitigate optimization stagnation, a ReduceLROnPlateau scheduler was integrated, dynamically decaying the learning rate by a factor of 0.5 if the validation loss failed to improve for 3 consecutive epochs. The dataset was chronologically partitioned into training (2006–2021), validation (2022–2023), and testing (2024–2025) phases, approximating an 80/10/10 distribution. Unlike random shuffling, this temporal split prevents look-ahead bias by ensuring the model utilizes only historical information for training, thereby preserving the predictive integrity essential for financial time-series forecasting. The detailed hyperparameter configuration utilized in this study is summarized in Table II.

TABLE II. Hyperparameter Configuration

Hyperparameter	Value
Optimization Algorithm	AdamW
Scheduler Patience	3 Epochs (Factor=0.5)
Input Sequence (T)	60 Days
Hidden Dimensions	128 (Bi-LSTM)
Batch Size	128
Dropout Rate	0.3
Max Epochs	20

B. Evaluation of Market State Separation

The confusion matrix of State-AttentNet is presented in Fig. 6. The model demonstrates strong separation between stable and stress market regimes, with 66,772 instances correctly classified as Class 0 and 17,871 instances correctly identified as Class 1. Misclassifications remain relatively low, with 3,114 false positives (false alarms) and 3,309 false negatives (missed crash events). The overall accuracy reaches 93%, indicating reliable predictive performance.

From a risk management perspective, false negatives are particularly critical, as they correspond to periods of elevated market risk that remain undetected. The relatively low number of missed crash events suggests that the model effectively captures most volatility-stress regimes. Conversely, false positives represent unnecessary alerts, which may lead to overly conservative decisions or reduced trading activity. The controlled level of false alarms indicates that the model maintains a balanced trade-off between sensitivity and reliability.

Overall, this balance between false positives and false negatives is essential for practical deployment, where both missed risk events and excessive false alarms can have significant financial implications. Furthermore, the high F1-score and the proportional distribution of correct classifications across both classes confirm that the model's decisions are driven by structural volatility signals rather than majority class frequency, validating the efficacy of the internal attention-based weighting.

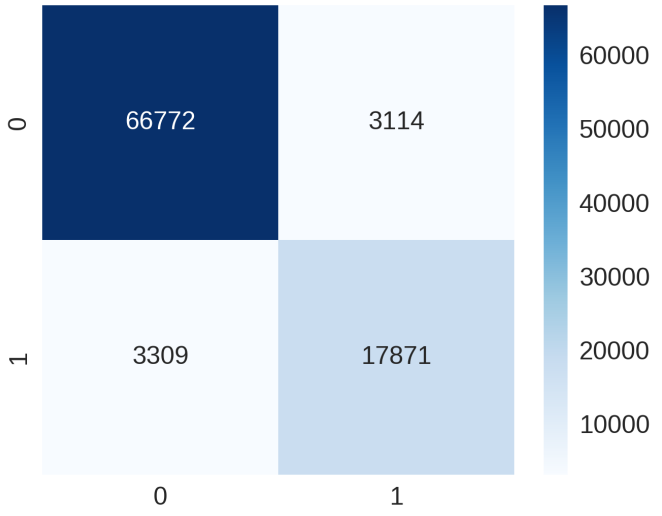

Fig. 6. Confusion matrix of the State-AttentNet model.

C. 30-Day Rolling Accuracy Over Time

Fig. 7 presents the 30-day rolling accuracy of the proposed classifier and provides a transparent view of the behavior of performance over time. The trajectory stays mostly in the upper accuracy region for long stretches indicating that the model maintains reliable state discrimination across varied phases in the market rather than getting a good score using a narrow subset of days. This persistence helps to further the credibility of the reported results because it represents consistent quality of the decision under repeated rolling evaluations. In contrast the plot also shows a limited number of short-lived accuracy drawdowns that cut across the otherwise strong pattern. Such dips are consistent with transition-heavy intervals where volatility clustering and abrupt reversals obscure regime boundaries and reduce separability of features. The rapid return to the high band indicates that the model maintains its strength and clarity once the market dynamics become stable. Operationally, these segments indicate periods when trade signals of confidence have to be handled more conservatively.

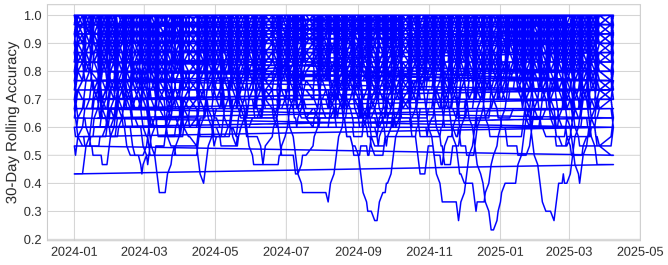

Fig. 7. Rolling accuracy across market phases.

D. ROC–AUC Performance of the State-AttentNet Model

Fig. 8 presents the ROC curve of State-AttentNet with an AUC of 0.97, which suggests high discrimination between the stable and crash regimes over a variety of decision thresholds. The curve indicates that the model is at high true-positives prior to the false-positives rate being relatively low. Interestingly, this finding is derived following a volatility based stable crash labelling framework over which regime markers are set through the rolling volatility shocks and not merely through the direction of prices. This shows how the model can be effective in learning stress-related patterns in the non-stationary and noisy dynamics of the market that can be useful in practical risk-aware regime monitoring in the DSE. A large AUC is significant in the framework of stock markets since regime decisions are threshold sensitive and trading contexts often change because of news, liquidity variations and volatility clusters. The fact that the AUC was always large indicates that the model maintains the quality of rankings of risk scores when a market condition shifts, which is critical to stable alerts and dependable decision support.

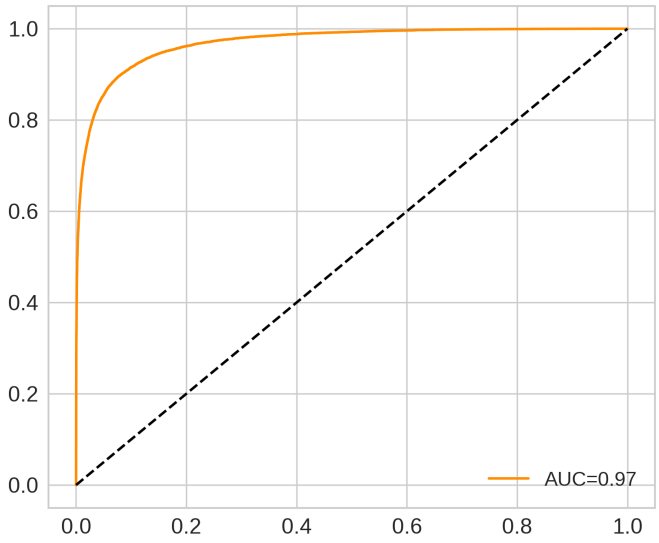

Fig. 8. ROC curve of the State-AttentNet model.

E. Comparative Performance Against Baseline Models with State-AttentNet

Table III demonstrate that State-AttentNet has the best overall performance between the compared baseline models. It attains the highest accuracy at 93.00%, exceeding LSTM with 90.64%, GRU with 91.92%, BiLSTM with 92.51%, TCN with 89.35%, and 1D-CNN with 87.41%. State-AttentNet also has the highest precision of 85.16% and the highest F1-score of 84.77, which means that it has a more balanced trade-off between crashes and false alarms. Despite BiLSTM achieving a marginally higher AUC (0.9709) compared to State-AttentNet (0.9697), the proposed framework demonstrates superior overall performance across key classification metrics. This outcome can be attributed to the temporal attention mechanism, which prioritizes minority-state awareness and enhances contextual interpretability rather than solely optimizing the ranking-based AUC metric. As a result, State-AttentNet achieves a more stable and balanced market-state classification performance, particularly in detecting volatility-driven regime shifts. By contrast, TCN and 1D-CNN have relatively poorer performances, which may indicate that convolution-based architectures are less efficient when it comes to the long-horizon regime of

the DSE. On the whole, these results indicate that in the existing experimental conditions, State-AttentNet can help provide a more accurate and risk-conscious system of market state classification.

TABLE III. PERFORMANCE COMPARISON WITH BASELINE MODELS

Model	Accuracy	Precision	Recall	F1-Score	AUC
LSTM	90.64%	76.19	86.90	81.20	0.9597
GRU	91.92%	79.14	88.64	83.62	0.9683
BiLSTM	92.51%	83.05	85.17	84.10	0.9709
TCN	89.35%	75.21	79.60	77.34	0.9325
1D-CNN	87.41%	71.15	73.25	72.19	0.9055
State-AttentNet	93.00%	85.16	84.38	84.77	0.9697

The outcomes of the ablation clearly show the contribution of each architectural component in Table IV. The elimination of the attention mechanism results in a significant reduction of the performance, especially in recall and AUC, meaning that temporal weighting is very important in determining informative periods of volatility. Likewise, the deletion of bidirectional encoding decreases the model's ability to obtain both forward and backward temporal dependencies, thereby generating less stable predictions and lower overall performance. Removal of both attention and bidirectional structure is the most drastic, and this proves that the two elements work together to increase the representational ability of the model. Conversely, the full model presents the optimal balance among all the measures of evaluation and indicates that when the bidirectional sequence modeling is combined with the temporal attention that is additive, regime persistence and transitioning behavior can be learned more effectively. These results support the design decision to incorporate these elements in the suggested structure.

TABLE IV. ABLATION STUDY OF THE STATE-ATTENTNET COMPONENTS

Model Configuration	Accuracy	Precision	Recall	F1-Score	AUC
w/o Attention	0.9231	0.8559	0.8051	0.8297	0.9619
w/o Bidirectional	0.9141	0.7750	0.8888	0.8280	0.9662
w/o Attn & Bi-directional	0.9165	0.8825	0.7393	0.8046	0.9608
Full Model (State-AttentNet)	0.9300	0.8516	0.8438	0.8477	0.9697

F. Sensitivity Analysis on Lookback Window Size for State-AttentNet

We conducted a sensitivity analysis by changing the input look-back window length T of the model and measuring the impact on predictive performance of Crash to determine the reliability of the proposed State-AttentNet in a high-paced frontier-market condition. Three identical preprocessing pipeline, engineered features, data splits and training procedure were held constant across all of the runs; only the input sequence length T was varied (15, 45, and 60 days). Accuracy, Precision, Recall, F1-score and AUC are reported in Table V.

The results indicate that a lookback window of $T = 60$ provides sufficient temporal context to capture regime persistence and volatility clustering effects. Shorter windows such as $T = 15$ fail to capture extended volatility patterns, resulting in unstable predictions and significantly lower recall for crash detection. Although $T = 45$ improves performance by incorporating more temporal information, it still lacks the full context required to model sustained regime transitions. In contrast, $T = 60$ achieves the best overall performance across all evaluation metrics, suggesting an optimal balance between temporal depth and model stability. These findings demonstrate that the proposed model benefits from longer temporal dependencies and remains robust across moderate variations in the lookback window size.

TABLE V. SENSITIVITY ANALYSIS OF LOOKBACK WINDOW LENGTH

Window Size	Accuracy	Precision	Recall	F1-score	AUC
15	76.87%	80.95	61.46	69.87	0.7753
45	89.66%	75.71	79.13	77.39	0.9399
60	93.00%	85.16	84.38	84.77	0.9697

G. Analysis of Crash Signal with Price Dynamics

Fig. 9 plots the alignment of the State-AttentNet crash alert layer in responding to discontinuous instability in the price path as compared with a response to day-to-day variation. The grey line follows the stock price during 2024-2025 and the red inverted triangles indicate Crash Alert trades that will be made when the risk pattern has been identified by the model as a crash-state signature. The alerts in the early sample are focussed on the sharp decline in late October to mid-November where the price drops rapidly and rebounds with high dispersion. The second thickness cluster is observed at the late November surge and reversal zone and is a sign that extreme upside spikes and subsequent quick pullbacks are experienced by the system as crash like stress since volatility and reversal risk are co-increasing. There are repeated warnings in the last part that is of the sideways yet weak recovery which implies that the classifier is still fragile to unstable consolidation where any small movements can still constitute high downside risk. Generally, the figure proves the point in the study that State-AttentNet makes high-impact regime transitions prior and minimizes the use of stable thresholds by releasing signals primarily during structurally turbulent windows.

Fig. 9. Trade-signal dynamics for crash-risk (volatility-stress) control.

H. Explainability Analysis

To provide a more robust and globally interpretable explanation of the proposed framework, this study employs SHAP instead of relying on a single local surrogate explanation. The SHAP is a more stable and comprehensive measure of model behavior compared to the instance-level interpretation on a local test set, as it quantifies the contribution each instance makes to model behavior on the entire test set.

Volatility and log-return are the two features with the largest impact, as illustrated in Fig. 10 and the maximum mean absolute SHAP values of all the engineered inputs.

This means that the classifier uses mainly the market stress intensity and the dynamics of returns in differentiating between stable and crash regimes. RSI and Vol_Force make secondary contributions, which implies that regime discrimination is also supported by momentum, and trading-activity-related factors. High_Low_Spread, Close_Open_Diff, and Month_Sin, on the other hand, have relatively smaller though not dominating contributions to the prediction process, meaning that they are more complementary than dominant in the prediction process.

These results are in line with the volatility-adaptive labeling design of the research, where the volatility-related signals are supposed to be very informative. The SHAP results however also indicate that the model is not reliant on an individual feature; instead, it combines various engineered market signals in order to enhance the strength of classification. This is significant within a frontier-market environment, where structural instability and noisy price dynamics render regime identification to be sensitive to both dominant and auxiliary market indicators. A single explanation could be over-interpreted; therefore, SHAP values were summed over the entire test set. This offers a dataset-level analysis of feature relevance and minimizes the possibility of making a conclusion based on a single observation. Moreover, the SHAP ranking on the global scale is generally congruent with the analysis of temporal attention, indicating that the model focuses on informative features as well as informative time steps in detecting regime shifts.

In general, the explainability analysis using SHAP justifies the intuitive understanding that the presented framework is responding to the structurally significant market signals instead of reacting to the temporary noise. This enhances transparency and increases the practicality of the model in frontier market risk-conscious regime monitoring.

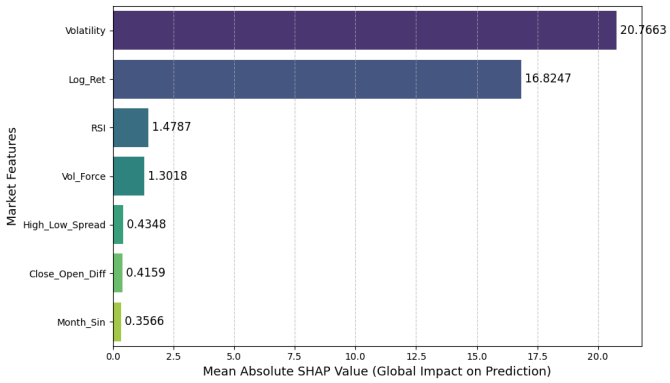

Fig. 10. Global SHAP features importance based on mean absolute SHAP values across the test set.

V. Conclusion

Financial markets are dynamic and constantly moving between stable and stress regimes, requiring the proper identification of the state to have a successful risk management process. Nevertheless, a significant proportion of literature is oriented towards developed markets or is based on predetermined labeling, which may not generalize well to frontier markets with structural volatility, changing liquidity, and time-dependent volatility patterns. In order to fill the gap, this study develops regime detection as an adaptive long-horizon classification problem and implements State-AttentNet to the Dhaka Stock Exchange based on daily data between 1999 and 2025. The framework combines the volatility-based labeling that is dynamic with market-sensitive properties, which enables the definition of stress regimes to change with the market state as opposed to using fixed thresholds.

Empirical data show that State-AttentNet attains an accuracy of 93% and AUC of 0.97, which is better than the LSTM and GRU baselines in the present experimental context. These findings indicate that attention-directed sequence modeling can be effectively used to model regime persistence and transition dynamics in non-stationary and noisy environments. Moreover, the explainability analysis reveals that the model relies on informative lag structures, which is consistent with the meaning of the model capturing meaningful regime shifts not temporary fluctuations. In general, the findings indicate that adaptive labeling combined with attention-based temporal models can offer a viable and understandable regime monitoring framework for the Dhaka Stock Exchange. A limitation of the present study is that the framework was evaluated using data from only the Dhaka Stock Exchange. In addition, class imbalance was addressed solely through the temporal attention mechanism without incorporating conventional strategies such as weighted loss functions or resampling techniques. Consequently, the responsiveness of regime signals to future market behaviour remains unobserved. During real-world implementation, regime alert-based trading decisions can impact liquidity and volatility and can also create looping effects that can change future model inputs. Further development of evaluation within live or paper trading settings will include persistence-based alerting, uncertainty-based decision rules, and controlled alert frequency to maintain stability. It is also possible to apply the framework to real-time monitoring systems with automated data pipelines and rolling retraining to continually update the system as new observations come in. The extensions are further including macroeconomic variables and also microstructure characteristics of the market and also the cross-market generalization with other frontier markets. Increasing the capacity to endure changing market conditions, future studies can incorporate drift detection algorithms to induce retraining and probability calibration methods to perceive model results as risk action measures.

Lastly, one can test the framework in a more applied context by connecting regime indicators to risk-controlling tools, and testing their performance under realistic transaction costs. The general applicability of the proposed approach can be further enhanced by extensions of the multi-class and multi-horizon regime definitions, as well as uncertainty-aware and explainable outputs.

Acknowledgment

The authors would like to express their sincere gratitude to the Southeast University, Dhaka, Bangladesh, for providing the essential laboratory facilities and technical support required to conduct this research.

***Abstract*—Automated generation of high-quality educational assessment items is still difficult, especially when it comes to higher-order cognitive skills. Although Large Language Models (LLMs) show promise, their structural validity and cognitive alignment are limited. This study systematically evaluates fine-tuning open-source LLMs using an enriched LearningQ dataset that includes Bloom's cognitive labels and evidence. The results show a clear performance contrast. Qwen2.5-3B-Instruct displays the best semantic reasoning, while Llama-3.2-3B shows better structural adherence, achieving a 94.9% validity rate and full compliance against answer leakage while maintaining high question validity. In contrast, older encoder-decoder models like FLAN-T5-XL do not generate valid questions. The study finds that small- to medium-sized instruction-tuned models, backed by strong data engineering, are successful at developing scalable, cognitively well-aligned assessment items.**

***Keywords*—Automated question generation; Large Language Models; educational assessment; Bloom's Taxonomy; Parameter-Efficient Fine-Tuning; LearningQ**

I. Introduction

The application of Large Language Models (LLMs) in educational technology has transformed automated content generation. This is particularly true for creating high-quality assessment items that assess not just factual recall but also higher-order thinking (cognitive) skills such as analysis, application, and synthesis. Traditional automated question generation (AQG) methods were based on rule-based systems or early neural models, which had limitations in scope and scalability. Instruction-tuned large language models can generate a wide range of effective questions at scale. However, models that are generally pre-trained often produce results that lack educational depth or fail to follow the strict structural rules required for standardized assessments.

Cognitive alignment refers to how well an assessment item measures the cognitive processes intended by a given learning outcome within the field of educational measurement theory. The idea of cognitive alignment is very similar to that of construct validity and alignment validity within the realm of test creation. Thus, assessing the cognitive alignment of test creation involves more than simply looking at linguistic similarities. In this study, an "assessment item" refers to a "single educational question" designed to evaluate a specific learning objective or cognitive level.

A major limitation in current AQG research is the reliance on datasets meant for machine reading comprehension, like SQuAD [1] or RACE [2]. Although these datasets are large, they mainly focus on extractive fact retrieval ("Remembering"), which does not capture the details of educational assessment. Assessment items need to evaluate specific cognitive levels, as defined by frameworks such as Bloom's Taxonomy. Additionally, valid assessment items must meet strict requirements. For example, the questions should be interrogative, the answer should not be included in the question, and premature explanations should not be given. General-purpose LLMs often violate these rules in zero-shot settings.

Beyond structural validity, high-quality educational items must also show a variety of assessment formats and Intended Learning Outcomes (ILOs). This includes generating items across multiple item types—such as conceptual, analytical, application-based, and synthesis-oriented prompts—and aligning each item with a specific learning objective rather than producing generic fact-recall items. Without enforcing this alignment, models often revert to simple cognitive tasks, which limits their usefulness in real teaching and evaluation situations.

To address these challenges, this study examines the ability of open-source LLMs to create standardized assessment items using LearningQ [3], a large dataset derived from real educational platforms, including TED-Ed and Khan Academy. Unlike datasets designed to find facts, LearningQ has many questions that require higher-order thinking. This quality makes it a suitable testing ground for developing questions that align with cognitive principles. This study focuses on assessing various open-source LLM models using a unified, cognitively aligned pipeline, rather than comparing them with existing state-of-the-art AQG systems. This is to establish the influence of models on cognitive alignment.

This study presents a detailed fine-tuning and evaluation framework to close the gap between raw educational content and usable assessment items. The proposed approach employs a comprehensive data enrichment pipeline that initially improves raw LearningQ data by adding synthetic cognitive labels and emphasized passage evidence, utilizing Qwen2.5-7B-Instruct [4]. Next, several models are adjusted using Parameter-Efficient Fine-Tuning (PEFT) through Low-Rank Adaptation (LoRA) [5]. This includes both contemporary decoder-only architectures, such as Llama-3.2-3B [6] and Qwen2.5-3B, and traditional encoder-decoder models like FLAN-T5-XL [7].

This research makes several significant contributions:

1) A Cognitive-Aligned Data Pipeline: that adds passage highlighting and Bloom's Taxonomy labels to educational datasets. This enables models to discover the relationship between cognitive targets and segments of the source text.
2) Comparative Model Analysis: which evaluates six different LLM architectures with 3 billion to 7 billion parameters. It looks at their performance not only on lexical overlap using BLEU and ROUGE but also on semantic preservation through BERTScore and pedagogical intent.
3) Insights for AQG: show that modern instruction-tuned LLMs, when combined with careful data engineering and fine-tuning, can consistently produce assessment items that align with cognitive goals, outperforming traditional architectures.

Our results indicate a distinct performance gap between contemporary instruction-tuned architectures and earlier models. This demonstrates that with proper data engineering and fine-tuning, small-to-medium LLMs can consistently function as tools for generating automated, cognitively aligned assessments. This may assist educators in developing standardized assessments.

The remainder of this study is organized as follows: Section II reviews related state-of-the-art literature and identifies the main challenges of current research. Section III describes the LearningQ dataset. Section IV presents the phases of the proposed approach. Section V and Section VI discuss the evaluation criteria and results based on the enriched LearningQ dataset. Section VII discusses the implications of the findings. Section VIII presents conclusions and discusses future work.

II. Related Work

This section presents related work on relevant datasets, methods for generating questions using LLMs, and applications of the LearningQ dataset [3].

A. Datasets for Question Generation

Significantly, the establishment of robust datasets has been critical in the development of machine reading comprehension and question generation. Early datasets such as SQuAD [1], which have over 100,000 crowd-sourced questions associated with corresponding passages on Wikipedia, with answers being restricted to a particular text span, have been instrumental. Although such datasets have been effective for extractive question answering, they have been primarily focused on factual recall. To address this issue, RACE [2], a dataset of multiple-choice questions created by experts and based on English examination papers for middle and high school students has been proposed. Unlike SQuAD, the answers in RACE cannot be extracted; they require a thorough level of reasoning and understanding of a passage.

The attempt to bridge QA studies and educational assessment has been realized in the EduQG dataset, released in 2023 [8], which contains a collection of 3,397 questions in multiple formats, all gathered from OpenStax textbooks. EduQG also introduced a new type of sentence-level annotation and included a subset of 903 questions annotated with their corresponding level of cognitive complexity according to Bloom's Taxonomy.

Following this trend, EduQuest, released in 2024 [9], has widened the field of application of question answering in education by collecting over 76,000 instructional documents and 68,000 questions from sources such as MIT OpenCourseWare, OpenStax, and Khan Academy. An important aspect of EduQuest is the addition of metadata labels, such as the corresponding cognitive complexity level and pedagogical labels, which are essential for applications that involve higher-level question generation beyond simple recognition and recall.

B. Educational Assessments and LLM-Based Question Generation

Recent advances in Large Language Models (LLMs) have motivated the use of these models to facilitate the automation of educational assessment design. Lamsiyah et al.'s (2024) [10] study presents an approach to automatic question generation using the RLLM-EduQG model, which fine-tunes the FLAN-T5 model on a hybrid objective function combining cross-entropy and reinforcement-learning rewards based on BLEU and semantic similarity scores. This approach addresses exposure bias and improves both syntactic and semantic generation performance. Another study on automatic question generation was proposed by Hasan et al. (2024) [11]. It presented an Automatic Question & Answer Generation (AQAG) framework based on the Llama-2 model and uses unsupervised prompts on the RACE corpus to generate multiple-choice and fill-in-the-blank question types.

Regarding cognitive alignment, Zhuge et al. (2025) [12] introduced TwinStar. It is a dual-LLM system in which one model generates questions and another. It was fine-tuned on ChatGPT-6B to assess alignment at cognitive levels. This refining process better preserved cognitive targets and ensured content relevance compared to models such as GPT-4 and Bard.

C. Applications of the LearningQ Dataset

LearningQ has gained popularity in recent research studies due to its scope, instructional value, and diverse questions. Focal (2023) [13], an end-to-end automated construction of an evaluation pipeline, utilized LearningQ to fine-tune its evaluator model. The study showed promising outcomes in enhancing the logical coherence and instructional value of questions generated by LLMs. Moreover, García-Méndez [14] (2025) emphasized LearningQ's value in training models for generating questions as well as automated evaluations, citing previous studies by Moore et al. (2022) and Bhat et al. (2022) on training models to evaluate the quality of questions generated by students with the aid of LearningQ.

In a study of multimodal learning, Stamatakis et al. (2025) [15] analyzed LearningQ, a subset of TED-Ed and Khan Academy, to assess Vision-Language Models (VLMs) such as Video-LLaMA and PG-Video-LLaVA. The study showed that when generating contextually relevant educational questions from video inputs, VLMs trained or fine-tuned on LearningQ achieved a significant improvement over zero-shot VLMs that generated irrelevant queries.

D. Cognitive Alignment and LLM Evaluation

Some studies also used cognitive models, such as Bloom's taxonomy, to evaluate LLM performance. Several LLMs, such as Llama-2, Mistral, and GPT-4, were assessed by Scaria et al. (2024) [16] using cognitive prompt techniques, such as the Chain of Thought. According to this study, LLM models typically perform well on lower-order thinking tasks such as "Remember" or "Understand", but struggle to produce reliable results on higher-order thinking tasks such as "Create". Another study by Huber and Niklaus (2025) [17] assessed well-known benchmark tests, such as MMLU and BIG-Bench Hard, and classified them according to Bloom's taxonomy levels. According to this study, there were very few instances of higher-order thinking tasks like "Evaluate" or "Create" in these benchmarks, while it found a high frequency of lower-order thinking tasks.

Most of the literature reviewed has focused on creating automated questions with the assessment AQG. These studies offer insights related to cognitive alignment. However, only a few studies investigate cognitive alignment directly. These have issues, including poor structural validity, poor cognitive alignment, and poor adherence to assessment constraints in previous AQG approaches. This study addresses these problems using the proposed approach.

III. Dataset: LearningQ

A. Dataset Description

LearningQ [3] is a large dataset created specifically to generate and analyze educational questions, with a special emphasis on learning- and assessment-oriented questions. This is unlike other datasets, such as SQuAD [1] and RACE [2], which have mostly focused on information retrieval questions. LearningQ comprises more than 230,000 document-question pairs across domains such as science, humanities, and mathematics.

LearningQ data was collected from two major online learning platforms: **1) TED-Ed** (https://ed.ted.com/) consists of questions created by instructors linked to educational video lectures, characterized by high quality and a well-structured educational framework. **2) Khan Academy** (https://www.khanacademy.org/) set includes questions prepared by learners and posted in the comments section of videos and articles. To reduce noise, the dataset creators used a convolutional neural network (CNN)-based classifier to filter out irrelevant content while retaining learning-relevant questions, achieving 80.5% accuracy.

LearningQ consists of videos and article documents coupled with educational questions. It features documents that are much longer than standard benchmarks and covers the revised Bloom's taxonomy levels with distributions of recall (31%), comprehension (36%), application (9%), analysis (11%), evaluation (2%), and creation (1%), along with nearly 10% of unknown/irrelevant content generated by the learner, as shown in Table I. For clarity, Table I presents the datasets by content type (video lectures and articles) obtained from the platforms TED-Ed and Khan Academy. To better understand the structural properties of LearningQ, the proposed framework conducted an in-depth statistical and schema-level inspection of the JSON files using Python utilities. The TED-Ed subset has a standardized, instructor-designed structure, unlike Khan Academy, where a high level of variability was observed, with a range of 1 to 42 questions per document, a mean of 12.44, and a standard deviation of approximately 8.71. LearningQ covers a modified version of Bloom's Taxonomy, covering a wide range of cognitive abilities from basic recall to complex thinking, offering a high level of cognitive and structural variation (see Table II).

TABLE I. Statistics of the LearningQ Dataset

Data Source	Content Type	# Docs	# Qs	Avg Q/Doc
TED-Ed	Video Lectures	1,102	7,612	6.91
Khan Academy	Video Lectures	7,924	201,273	25.40
Khan Academy	Articles	1,815	22,585	12.44
Total	**Mixed**	**10,841**	**231,470**	**21.3**

TABLE II. Question Examples of Different Bloom's Revised Taxonomy Levels in LearningQ Dataset.

Bloom Level	Example
Remembering	What is a negative and positive feedback in homeostasis?
Understanding	Why do some plankton migrate vertically?
Applying	If I double the area and take half of the fraction, do I get the same result?
Analyzing	Why are cities like London, Tokyo, and New York facing shortages in burial ground space?
Evaluating	Will all the cultures merge into one big culture, due to the fading genetic distinctions?
Creating	Can somebody please explain to me what marginal benefits are and give me some examples?

While LearningQ is presented as covering a range of cognitive levels, the downloaded dataset does not include Bloom's Taxonomy labels for individual questions. Thus, the provided distribution represents only a descriptive understanding of the data. Therefore, cognitive-level labeling has been newly applied in this study using a language model–based classifier.

IV. Methodology

This section describes the proposed framework, which applies a structured process to transform raw educational data into high-quality assessment items. As shown in Fig. 1, the framework includes four clear phases: 1) Data Preprocessing and Enrichment, which involves raw LearningQ data [3]; 2) Prompt Engineering, which organizes the data into instruction-tuned structures; 3) Parameter-Efficient Fine-Tuning (PEFT), which uses Low-Rank Adaptation (LoRA) to fine-tune LLMs for the educational domain; and 4) Comprehensive Evaluation, which includes both semantic measures and evaluation constraints.

A. Data Preprocessing and Enrichment

It plays an important role, significantly impacting the overall performance of subsequent processes. Consequently, the input data pass through a series of steps to clean, normalize, and semantically validate them. The preprocessing stage involves the following steps:

1) Dataset Cleaning: This step includes nested JSON object analysis, text normalization, handling of invalid

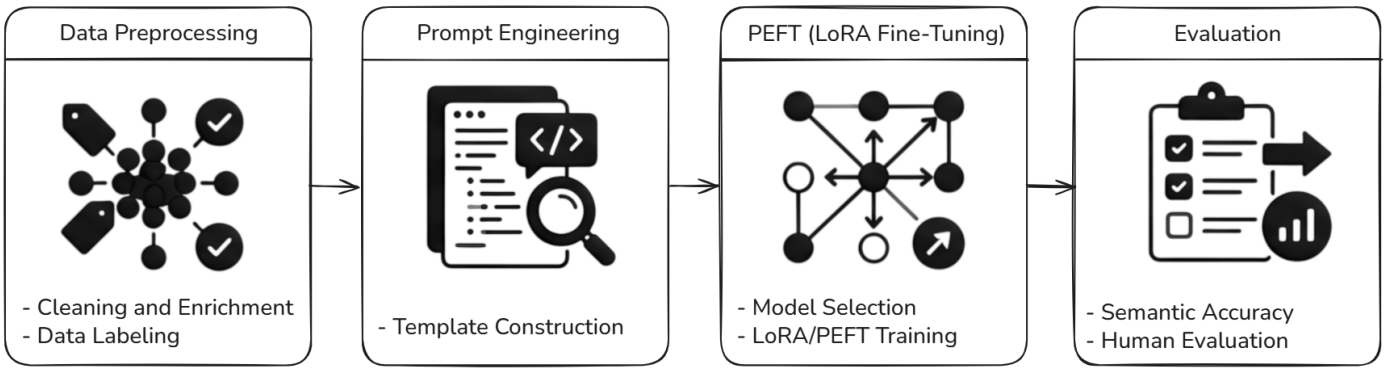

Fig. 1. Methodology pipeline

rows, and resolving inconsistencies between multiple sources. The output of this is a flat table, Table III. Specifically, any invalid entries (e.g., empty passages, questions, or malformed data) were filtered out. The text data was normalized by converting to lowercase and trimming, and any samples with invalid question-passage alignment were filtered.

2) Restructuring into One-Question-Per-Row: To ensure that the supervision during the training is consistent, the data is transformed into the following structure: "| ID | Title | Subject | Text | Question |".
3) Cognitive Level Classification: Since LearningQ does not provide cognitive labels, each question in LearningQ was labelled by following the taxonomy of Bloom. For this experiment, Qwen2.5-7B-Instruct [4] was used because it was observed to perform well at following instructions, was efficient in 8-bit deployment, and exhibited stability in differentiating between nearby cognitive levels. A new column, "Cognitive Level", was added to the schema.
4) Highlighting Relevant Passage Segments: A second LLM processing step (Qwen2.5-7B-Instruct) is utilized to pinpoint the relevant passage segments needed to answer the questions. These segments are marked with the HTML tag '<h>...</h>. The purpose of highlighting was to improve alignment between the passage and the question. This provides explicit contextual grounding and facilitates easier interpretation during evaluation.
5) Verify reliability: To verify the reliability of the supervision signals produced by the LLM for training purposes, a random set of 150 supervision signals was manually checked for their validity. The agreement between the two human evaluators for the Bloom-level labels was substantial, with a Cohen's κ of 0.79. Furthermore, the highlighted evidence segments were found to be 87% accurate according to human judgment.
6) Balancing Cognitive-Level Distribution: After labelling and highlighting, the distribution of classes at different Bloom levels was measured. To ensure a balanced distribution, classes that were overrepresented were downscaled, while underrepresented classes were upscaled.

B. Prompt Template Construction

To ensure consistent supervision during fine-tuning and minimize stylistic variability across training instances, each enriched record is converted into a unified instruction–response template Fig. 2, including the topic, knowledge level, and highlighted passage, with strict output constraints. Task specifications ("Create only one assessment question") guide the creation of a single item and establish a consistent pattern for fine-tuning. Metadata and <h>-tagged evidence provide context, while the output constraints — preventing explanations, avoiding answer leakage, and requiring only one question — ensure that assessment items are standardized, organized, and cognitively aligned.

C. Model Loading and LoRa Fine-Tuning

Pairs of prompt and response examples were used to fine-tune six open-source large language models using Parameter-Efficient Fine-Tuning (PEFT) [5]. To address resource constraints in educational natural language processing, the Low-Rank Adaptation (LoRA) technique was applied. This approach introduces a small number of trainable parameters into the main transformer layers while keeping the base model weights fixed, enabling efficient domain adaptation without full end-to-end training. The entire process is illustrated in Fig. 3.

1) Model Selection and Architectural Diversity: To ensure a comprehensive evaluation across architectures, six models were fine-tuned under identical experimental conditions: Llama-3.2-3B-Instruct [6], Qwen2.5-3B-Instruct [4], Mistral-7B-Instruct [18], MediPhi-Instruct [19], Gemma-3-4B [20], and FLAN-T5-XL [7]. These models span a spectrum of decoder-only, encoder–decoder, and multimodal architectures with 3B–7B parameters, allowing us to evaluate differences in model behavior under a uniform task formulation.

2) Quantized Model Loading: All models were loaded in 8-bit precision, consistent with the training script. This reduced VRAM usage by approximately 60%, enabling fine-tuning on modest GPU hardware such as Google Colab and Kaggle T4 instances. Despite the compression, 8-bit quantization preserves the representational depth required for reasoning over instructional prompts and highlighted passages.

3) Dataset Formulation and Preprocessing: The dataset was divided into subsets for training (80%), validation (10%), and testing (10%), subsets and organized into unified objects to facilitate batch processing. Input sequences were tokenized, using a structural separator (@@PASSAGE@@) to separate instructions from paragraph content, and the marker "### OUTPUT": to indicate the target response. Sequences were truncated to fit the model's context window, and selective masking of tokens (-100) was applied to the instructions, paragraph content, and padding to ensure that the loss function was optimized only for the generated question outputs.

4) Fine-Tuning Configuration and Execution: To optimize the pre-trained models for the target task while minimizing computational overhead, Low-Rank Adaptation (LoRA) was employed. The adapter configuration targeted all key linear layers within the transformer architecture, including the query, key, value, and output projections (q_proj, k_proj, v_proj, o_proj), as well as the feed-forward gate, up, and down projections. The hyperparameters were set to r=8, alpha=16, and a dropout rate of 0.05. This configuration introduces fewer than 0.3% additional trainable parameters, enabling efficient adaptation for task-specific behaviors—such as cognitive-level alignment and strict output formatting—without the resource intensity of full-model fine-tuning. Model training was performed with 8-bit quantization and mixed precision (FP16), a batch size of 1 per device, gradient accumulation every 4 steps, and a learning rate of 2e-4 for 3 epochs. The input sequences were limited to 2048 tokens, with a structured prompt format and masking, so that the loss was calculated only on the output tokens. The preprocessing included data normalization and filtering out invalid entries. Every 100 training steps, validation was used to evaluate the model's performance. During this period, the effectiveness of the network was evaluated through perplexity, defined as $e^{\text{eval_loss}}$.

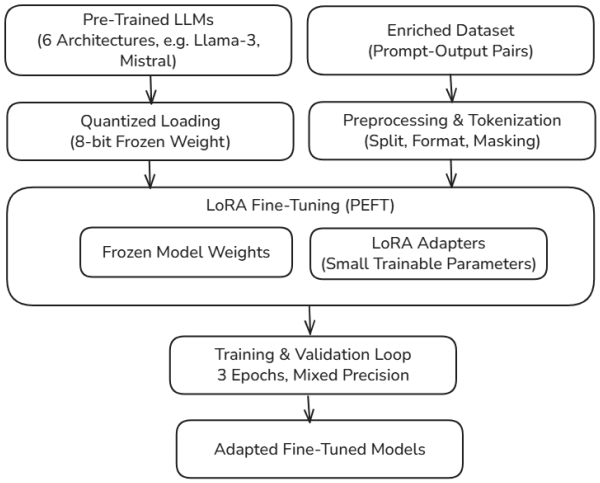

Fig. 3. The end-to-end LoRA fine-tuning framework across diverse model architectures.

D. Inference and Comprehensive Evaluation

Following fine-tuning, a series of evaluations was performed using a controlled inference process, that simulated the exact conditions under which the model was trained. In this process, the entire prompt template was recreated, including the task directive, subject, cognitive level, highlighted passage, and delimiter, to ensure no distributional shift occurred in the model's outputs. The outputs generated by a deterministic decoding (greedy, non-sampling) were then normalized to assess their structural validity, and ensure that only questions were evaluated.

To ensure reproducibility, experiments were performed with a fixed random number generator seed (42). The input sequences were limited to 2048 tokens, with the prompt and passage text truncated as needed. During inference, deterministic decoding was used (greedy decoding with a maximum of 64 tokens (max_new_tokens = 64)). The output was normalized, and the constraints were verified.

V. Evaluation Metrics

A thorough evaluation of the quality of generated questions in the education domain was conducted using multidimensional evaluation metrics. Unlike traditional text-generation applications, cognitive alignment is not an observable phenomenon that can be measured by a single automatic metric. Rather, it requires a multidimensional measurement approach, in which each measure reflects an element of the construct in question. Table IV shows how the components of cognitive alignment relate to the proxies used to measure them.

It is important to understand that the commonly used action verbs connected with Bloom's taxonomy ("define", "explain", "analyze") are very poor indicators of the cognitive process involved. Different cognitive processes can be represented by the same action verb based on their levels of difficulty. For example, "Explain what photosynthesis is" means the use of knowledge, while "Explain how the environmental changes

TABLE IV. MAPPING OF COGNITIVE ALIGNMENT COMPONENTS TO EVALUATION METRICS

Construct Component	Proxy Metric
Semantic Similarity	BERTScore, SBERT
Lexical and Structural	BLEU, ROUGE, METEOR
Structural Validity	is_question, length_ok
Assessment Integrity	no_answer_word, no_expl_word
Cognitive Intent Alignment	Human Evaluation

affect the rate of photosynthesis" requires analysis. Therefore, it is impossible to rely solely on keyword categorization to determine the cognitive process level.

A. Semantic Similarity Metrics

These metrics evaluate how well questions generated from a reference question preserve the original meaning and intent, despite possible variations in wording.

1) BERTScore (F1) [21]: It is used to evaluate semantic similarity based on the comparison of contextual word representations of generated candidates and reference texts. In contrast to n-gram-based metrics, BERTScore is robust to paraphrasing. Higher scores indicate greater semantic similarity between generated questions and the ground truth.

2) Sentence-BERT (SBERT) Cosine Similarity [22]: In the Sentence-BERT model, the cosine similarity is used to measure the similarity between the sentence embeddings of the generated output and the reference text.

B. Lexical and Structural Metrics

It measures Conventional n-gram-based metrics evaluate the generated text's language quality and structure in relation to the reference questions.

1) BLEU (Bilingual Evaluation Understudy) [23]: It assesses how similar the output and reference are in terms of n-gram overlap. In generative tasks, the BLEU metric is usually lower; however, a higher BLEU score denotes higher output precision.

2) ROUGE-L (Recall-Oriented Understudy for Gisting Evaluation) [24]: The F1 score of the ROUGE-L system has been used for the assessment of the longest common subsequence that exists between the generated candidate and the reference texts.

3) METEOR [25]: It uses stem, synonym, and word order similarities to measure similarities. This metric is generally more flexible with respect to linguistic variation than BLEU. It's also known to correlate strongly with human judgments of word similarity.

C. Task-Specific Constraint Validation

In addition to linguistic similarities, it is important that the generated output is functionally correct with respect to the assessment. Therefore, a constraint-checking module is implemented using heuristic algorithms.

1) Question Validity (is_question): The first heuristic evaluates if the output complies with the syntax of a question. It does this through the presence of a question mark and interrogative sentence structure.

2) Answer Leakage (no_answer_word): Another important failure mode in question generation involves including the answer within the answer (for example, "The answer is."). It ensures that there is no answer leakage within the generated question.

3) Explanation Prohibition (no_expl_word): The models are expected to produce questions only. There is no need for any explanation. The purpose of the check is to ensure the production of 'pure' questions without any explanation.

4) Length Constraints (length_ok): This metric checks whether the generated question falls within an appropriate range of characters or tokens, preventing the generation of either overly short or overly long questions.

D. Cognitive Intent Alignment

For the task of determining the relevance of the generated questions based on the specified Bloom's Taxonomy level, a human evaluation approach was employed. A random sample of questions generated was evaluated independently by two human annotators who had the passage, the required cognitive level, and the generated question available for consideration and were asked to check if the generated question matched the desired cognitive level. The basis of the evaluation is educational measurement theory, according to which an evaluation by human experts is the most reliable method for measuring cognitive processes and their alignment to learning goals. This human evaluation was conducted intentionally because automatic measurements alone do not capture all aspects of pedagogical value or cognitive alignment across Bloom's levels.

VI. RESULTS

A. Overall Performance Evaluation

A comprehensive set of semantic, lexical, and constraint-based metrics was used to assess six refined large language models (LLMs). Llama-3.2-3B, Qwen2.5-3B, Mistral-7B, MediPhi, Gemma-3-4B, and FLAN-T5-XL were the models evaluated. Their ability to create assessment items that meet cognitive expectations was evaluated. A summary of the performance comparison across all important metrics is presented in Table V. Table VI shows qualitative differences in model-generated assessment items.

B. Semantic Similarity Analysis

Embedding-based metrics are used to evaluate how well the generated questions maintain the ground truth's educational intent.

- Qwen2.5-3B achieved the highest BERTScore F1 (0.8275), indicating it was most effective at capturing the underlying semantic meaning of the reference questions, even when the specific phrasing differed.
- Mistral-7B demonstrated superior performance in Sentence-BERT (SBERT) cosine similarity (0.3272), suggesting a strong alignment in overall sentence-level intent.

- Llama-3.2-3B and MediPhi remained competitive with BERTScores above 0.80, whereas Gemma-3-4B significantly underperformed (0.447), indicating a failure to generate semantically relevant content.

C. Lexical and Structural Fidelity

In terms of exact lexical matching and structural coherence:

- Llama-3.2-3B outperformed all other models in BLEU (0.1131) and METEOR (0.0989) scores. This suggests that Llama-3.2-3B most frequently generated n-grams and stems that matched the ground truth references.
- Mistral-7B achieved the highest ROUGE-L F1 (0.0914), marginally outperforming Qwen2.5-3B (0.0904), indicating strong capabilities in preserving the longest common subsequences and structural phrasing of the assessment items.
- FLAN-T5-XL failed in these categories, scoring 0.0 across BLEU, ROUGE-L, and METEOR. Qualitative inspection revealed that this model often generated short, non-question phrases (e.g., "The need for rights in government") rather than valid interrogatives.

D. Task-Specific Constraint Compliance

The usefulness of the models for educational purposes was evaluated based on the models' compliance as follows:

- Question Validity (is_question): The highest validity rate of 94.9% was recorded by Llama-3.2-3B. MediPhi followed with a rate of 92.4%. This suggests that the generated text included question marks at the end and contained interrogative sentences. In contrast, Gemma-3-4B produced valid questions only 51.9% of the time. FLAN-T5-XL generated no valid questions, resulting in a 0% rate.
- Answer Leakage (no_answer_word): All models demonstrated high adherence to this constraint (>98%), ensuring that the answer key was not revealed within the question stem. Llama-3.2-3B achieved perfect compliance (100%).
- Explanation Prohibition (no_expl_word): Llama-3.2-3B was the most effective at excluding unwanted reasoning or explanations, achieving 67.1% compliance. Qwen2.5 followed with 60.8%. While FLAN-T5-XL shows 100% compliance here, this is an artifact of its failure to generate substantive text rather than successful instruction following.
- Length Constraints (length_ok): Qwen2.5-3B was the most successful at generating questions within the optimal length range (50.6%), whereas Llama-3.2-3B frequently generated output outside the target length parameters (10.1%)

E. Summary of Model Stability

Based on the "Output Stability" qualitative measure, Llama-3.2-3B and Qwen2.5-3B exhibited High stability, consistently following instructions and maintaining formatting. Mistral-7B and MediPhi showed Medium-to-High stability. Gemma-3-4B and FLAN-T5-XL were rated Low and Very Low, respectively, due to hallucinations and failure to adhere to the fundamental task of question generation. Qualitative samples confirm that while Llama and Qwen produced coherent, cognitively aligned questions (e.g., "Why did delegates think the Constitution needed limits on federal power?"), FLAN-T5-XL produced fragmented summaries.

To establish a solid basis for evaluation in educational measurement theory, a human assessment of cognitive alignment was performed on a random sample of 80 generated questions. Two human judges determined whether each question matched the corresponding Bloom level using a three-point correctness scale. The assessment yielded a Cohen's κ of 0.76, with 72% of the questions correctly aligned. This indicates that the improvements observed in the automatic metrics are genuine and reflect real enhancements in pedagogical validity. Statistical significance was assessed using paired t-tests on key metrics, confirming that the observed improvements are statistically significant ($p < 0.05$).

In an effort to determine how automatic metrics correlate with human assessment, a correlation analysis was performed using the evaluation metrics and human cognitive alignment assessment scores. The analysis shows a medium level of positive correlation between semantic similarity metrics, such as BERTScore and SBERT, and human assessment metrics. On the other hand, BLEU and ROUGE lexical metrics showed low correlation, owing to their focus on superficial similarities. This clearly shows that not all cognitive alignment can be captured by one evaluation metric. Instead, semantic metrics, combined with human assessment and validation using constraints, provide the best measures.

VII. Discussion

This study indicates that fine-tuned, instruction-aligned Large Language Models (LLMs) can reliably generate cognitively aligned educational assessment items when trained on enriched instructional data. By incorporating semantic similarity, lexical accuracy, and rule-based validation, this study provides an extensive understanding of model behaviour that goes beyond question generation. This section highlights the overall findings and their implications for educational assessment research.

First, the results clearly show a distinction between decoder-only and traditional encoder–decoder architectures. Specifically, Llama-3.2-3B and Qwen2.5-3B demonstrated superior performance compared to other models on both semantic preservation and output validity measures. Notably, Qwen2.5-3B achieved the highest F1 score on the BERTScore measure, indicating significant semantic preservation of the pedagogical intent encoded in the reference items. On the other hand, Mistral-7B achieved the highest score on the SBERT cosine similarity measure, indicating strong alignment at the sentence level.

Second, lexical-similarity metrics indicate that structural fidelity depends significantly on the model type. The best scores for the BLEU and METEOR metrics were achieved by the Llama-3.2-3B model, suggesting greater similarity in

TABLE V. PERFORMANCE COMPARISON OF FINE-TUNED LLMS

Category	Metric	Llama-3.2-3B	Qwen2.5-3B	Mistral-7B	MediPhi	Gemma-3-4B	FLAN-T5-XL
Semantic Similarity	BERTScore F1	0.8147	**0.8275**	0.8217	0.8068	0.447	0.7894
	SBERT Cosine	0.3029	0.3229	**0.3272**	0.3134	0.1909	0.0356

TABLE VI. QUALITATIVE COMPARISON OF GENERATED ASSESSMENT ITEMS ACROSS MODELS

Prompt (Shortened)	Ground Truth	Llama-3.2-3B	Qwen2.5-3B	Mistral-7B	MediPhi	Gemma-3-4B	FLAN-T5-XL
Humanities – Understand "Bill of Rights passage"	Why were the authors of the Federalist Papers against the Bill of Rights?	Why did some leaders at the Constitutional Convention believe a stronger federal government was necessary?	How did concerns about potential government tyranny influence the delegates' decision to add the Bill of Rights?	In what ways did fears about a powerful executive branch motivate the creation of the Bill of Rights?	Why were many delegates concerned that the new Constitution might threaten individual rights?	Why did delegates think the Constitution needed limits on federal power?	The need for rights in government.
Physics – Apply "Velocity graph passage"	How to calculate velocity and acceleration?	How would you determine the acceleration of an object using the slope of a velocity graph?	How can you calculate displacement using the area under a velocity graph?	How would you use slope and graph values to determine acceleration and displacement?	How do you apply the slope formula to find acceleration?	How can the slope of a velocity graph be used?	Using the graph to find acceleration.
Art History – Remember "Stonehenge passage"	(Example recall question)	What was the purpose of the Aubrey holes in the first phase of Stonehenge construction?	What significant feature characterized the first phase of Stonehenge construction?	When did the first phase of Stonehenge construction occur?	What was built during the first phase of Stonehenge?	What is Stonehenge?	Stonehenge construction phases.

phrasing and construction with human-generated texts. However, it is important to note that high lexical metric scores did not necessarily correlate with high cognitive alignment scores. This is also supported by some of Llama's outputs, which showed a tendency to paraphrase at the surface level rather than perform semantic-level transformations. This aligns with previous findings on LearningQ-based pipelines and indicates that it is not possible to generate higher-level questions solely through imitation of phrasing; instead, it requires cues and cognitive scaffolding incorporated into the instructional content. The relatively low performance on length constraints is due to the model's tendency to generate more descriptive questions.

Third, constraint evaluation for specific tasks is beneficial for understanding the feasibility of applying LLMs to standardized assessments. In this regard, metrics such as "is_question" and "no_answer_word" indicate that Llama-3.2-3B and MediPhi successfully constrained questions to maintain correct grammatical form and prevent answer words from appearing. In contrast, Qwen2.5-3B also scored highly on these metrics. Gemma-3-4B and FLAN-T5-XL, on the other hand, faced significant challenges with grammatical form and answer word inclusion. Moreover, while other models generated questions, FLAN-T5-XL failed to produce valid outputs. This suggests that model selection is critical when using AI to generate assessment questions. Finally, there is a critical observation regarding output stability, which is increasingly recognized as a primary requirement when applying LLMs to educational assessments. In this regard, Llama and Qwen scored highly on output stability. In contrast, while Mistral and MediPhi scored moderately, Gemma and FLAN-T5 scored very poorly. This is consistent with recent research suggesting that LoRA is most effective when applied to architectures explicitly pre-trained on instructional tasks.

Finally, the study used a data-enrichment pipeline. It included flattening the JSON structure of the raw data, using the Qwen2.5-7B model to generate cognitive labels, emphasizing key passage segments, and developing stringent templates for model outputs. The model's performance relied on this pipeline.

Despite these promising findings, there are also clear limitations: the experiments were conducted in a deterministic decoding setting, examined only models ranging from 3B to 7B in size, and used heuristic constraints that may not fully capture pedagogical quality. Overall, small- to medium-sized, instruction-tuned LLMs appear capable of generating cognitively aligned and structurally valid assessment items, putting models such as Llama and Qwen in a strong position for integration into various educational software solutions.

VIII. CONCLUSION AND FUTURE WORK

This study demonstrates the feasibility of generating cognitively aligned assessment questions efficiently using open-source, instruction-tuned language models, based on structured data augmentation. By incorporating evidence-based prompts and Bloom's taxonomy labels, the proposed framework improves both the structural validity and semantic alignment of the generated questions.

These results highlight the importance of selecting the appropriate architecture and designing effective prompts in

educational natural language processing systems, showing that decoder-only models are particularly well-suited for constrained generation tasks.

Future work should expand the scope of human evaluation of cognitive alignment by incorporating more detailed annotations and broader expert validation, developing bias-aware explanation strategies, and testing robustness under random decoding to further enhance educational reliability.

***Abstract*—Effective marketing plays a pivotal role in modern businesses, where strategic allocation of resources is essential for maximizing return on investment (ROI). Customer segmentation involves dividing users into distinct sub-groups based on common characteristics, enabling each segment to receive tailored promotions according to their behavior. However, identifying which customer segments to target can be financially challenging due to the significant costs associated with marketing campaigns. This study proposes a machine learning framework to forecast the profitability of various customer segments and optimize marketing strategies accordingly. The proposed solution leverages machine learning and deep learning techniques to classify customers based on their potential value. Specifically, conventional classifiers including AdaBoost, Gradient Boosting, Extreme Gradient Boosting (XGBoost), Linear Discriminant Analysis (LDA), Random Forest, Naïve Bayes, Support Vector Machines (SVM), and K-Nearest Neighbors (KNN) are evaluated. In addition, deep learning models, namely 1D ResNet and 1D DenseNet, are investigated. All models are trained and evaluated under a unified protocol that includes SMOTE-based class imbalance handling, systematic hyperparameter tuning, and a joint analysis of predictive performance and computational cost. The experimental findings reveal that traditional models, particularly XGBoost and Gradient Boosting, consistently outperform deep learning models in terms of accuracy, precision, and computational efficiency, with both achieving the highest weighted F1 score of 0.62 while requiring nearly six orders of magnitude fewer computations than DenseNet-121. These results provide concrete evidence that ensemble tree-based methods are better suited than deep architectures for moderately sized, imbalanced, tabular marketing datasets.**

I. Introduction

As the business environment grows more competitive, companies increasingly leverage data-driven targeted marketing strategies to drive financial growth [1]. Targeted marketing identifies a segment of people with similar needs or characteristics that a company chooses to serve, allowing messages and promotions to speak directly to the interests of each segment rather than relying on a one-size-fits-all approach [2]. Customer segmentation that incorporates psychological and behavioral dimensions enables businesses to tailor their marketing efforts and increase customer retention by aligning campaigns with customer preferences [3]. This approach improves the relevance and effectiveness of marketing efforts, resulting in higher engagement and conversion rates. By focusing on segments with the highest growth potential or profitability, companies can prioritize their marketing budgets, product development initiatives, and sales efforts to maximize return on investment [2]. The integration of data analytics techniques, such as machine learning and predictive modeling, allows these strategies to be refined further to meet specific market needs [4].

Despite these advantages, many companies still face significant challenges in implementing targeted marketing effectively. In practice, some organizations continue to rely on mass or untargeted approaches, which can lead to substantial financial loss when resources are spent reaching individuals who are uninterested in the products on offer [5]. The result is a wasted budget and a diminished return on investment (ROI), since the lack of focus prevents companies from engaging the segments most likely to respond. Although customer segmentation partially addresses this issue, accurately determining the profitability of each segment under a given marketing strategy remains difficult. This difficulty arises from the complexity of predicting how different customer groups will respond to campaigns and how those responses translate into financial outcomes. Traditional customer targeting techniques often rely on simplistic criteria such as demographic categories or basic purchasing metrics, which may not capture the complex patterns within customer data that determine profitability. The interactions between customer attributes, for example how the combination of income level, purchase frequency, and geographic location jointly influences campaign response, are inherently non-linear and difficult to model using rule-based approaches. Consequently, there is a clear need for an intelligent, data-driven approach capable of forecasting the profitability of different customer segments.

To address these challenges, machine learning offers a promising solution by analyzing large-scale customer data to uncover patterns that support accurate profitability prediction. By examining demographic, geographic, behavioral, and psychographic attributes, machine learning models provide actionable insights that enable businesses to allocate resources toward high-value segments and optimize marketing strategies, ultimately enhancing ROI and long-term customer relationship management (CRM). The ability of machine learning to process high-dimensional data and identify non-obvious relationships makes it particularly valuable for profitability prediction, where the interplay between multiple customer

This work was conducted while Leen Almajed and Haifa Almakhdhoub were affiliated with the Computer Science Department, College of Computer and Information Sciences, King Saud University.

attributes determines segment-level outcomes. Furthermore, the availability of diverse algorithmic approaches, ranging from interpretable linear models to complex deep learning architectures, enables practitioners to select models that best match the characteristics of their specific datasets and business requirements.

Building on this approach, this study proposes a machine learning framework for predicting customer segment profitability using historical customer data and advanced classification techniques. The framework is designed to support strategic decision-making and efficient resource allocation. To evaluate performance and robustness, multiple conventional classifiers are compared, including AdaBoost [6], Gradient Boosting [7], XGBoost [8], LDA [9], Random Forest [10], Naïve Bayes [11], SVM [12], and KNN [13]. Additionally, 1D deep learning architectures, namely ResNet [14] and DenseNet [15], are assessed to determine their effectiveness in predicting segment-level profitability.

The main contributions of this work are as follows: 1) a unified empirical benchmark of eight classical classifiers and two 1D deep learning architectures (1D ResNet and 1D DenseNet) applied to customer segment profitability prediction on a previously unexplored, moderately sized, imbalanced tabular dataset; 2) a domain-specific contribution to the marketing analytics literature showing that, contrary to several recent reports favoring deep learning for customer prediction [16], [17], [18], traditional ensemble methods outperform 1D deep architectures when applied to comparative two-group customer features under realistic data-volume and class-imbalance conditions; 3) a detailed computational cost analysis that quantifies the trade-off between predictive performance and resource requirements across all evaluated models, providing the GFLOPs and parameter counts needed to assess deployment feasibility in production marketing systems; and 4) practical recommendations for practitioners on model selection, hyperparameter behavior under class imbalance, and the limited gains obtainable from autoencoder-based feature compression or One-vs-Rest decomposition on this class of data.

II. Related Work

A. Traditional Machine Learning

Several studies applied traditional machine learning methods to predict customer behavior. Deniz and Bülbül [19] applied six models, including Logistic Regression [20], Random Forest [10], and Gradient Boosting [7] to predict purchasing behavior using attributes like age, gender, annual income, and number of purchases. A significant improvement was achieved through segmenting customers into high, medium, and low spenders. Random Forest achieved the highest accuracy at 94.4%, outperforming Logistic Regression at 82.2%.

Other studies [21], [22] showed that Random Forest outperformed other models achieving 90.4% and 88.63% accuracy, respectively, when predicting customer subscription behaviors and churn by analyzing features like call duration, contact frequency, and customer behavioral metrics.

Extending the approach to customer profitability prediction, Chen et al. [23] introduced a dynamic approach using the Recency, Frequency, and Monetary (RFM) model. Customers were segmented into profitability groups using k-means clustering, and models including regression, multilayer perceptron (MLP), and Naïve Bayes were applied. Open-loop models achieved an average accuracy of 84%, while closed-loop models reached 79%. The study highlighted that customer profitability groups remained largely stable over time, with transition probabilities below 6%.

Saeed et al. [24] employed an ensemble classifier combining Random Forest and Extra Trees to predict customer responses to a banking telemarketing campaign. The hybrid voting classifier improved accuracy by 1.6% over the best individual model, Random Forest, which achieved 94.02%.

In related studies, the gradient boosting decision tree (GBDT) demonstrated strong performance. Sun et al. [25] applied GBDT and Random Forest to predict Customer Lifetime Value (CLV), achieving mean square errors of 0.65 and 0.34, respectively, outperforming probability-based models. Similarly, Sun et al. [26] compared eight machine learning algorithms for customer segmentation based on lifecycle value, where AdaBoost achieved 94.60% accuracy and GBDT reached 93.80%.

Xiahou and Harada [27] utilized AdaBoost for churn prediction, evaluating it against a Backpropagation (BP) neural network. The AdaBoost model outperformed the BP neural network across all metrics, achieving accuracy, recall, and precision values of 0.96, 0.93, and 0.96, respectively. Mishra and Sharma [28] further validated AdaBoost for fraud detection, showing its ability to handle imbalanced datasets effectively.

Wong and Yeh [29] proposed hybrid classification algorithms that combine instance filtering with ensemble methods, demonstrating improved accuracy over standalone classifiers on customer behavior datasets. Uddin et al. [30] compared multiple supervised algorithms, including SVM, KNN, and Random Forest, finding that ensemble methods consistently outperformed individual classifiers for structured prediction tasks. Musa [31] conducted a comparative study between SVM and Logistic Regression, concluding that SVM achieves superior classification performance on high-dimensional customer datasets.

B. Deep Learning

Deep learning models have been increasingly adopted for customer prediction tasks. Xu et al. [16] employed a combination of ResNet-50 [14] and Gated Recurrent Unit (GRU) [32] to predict consumer behavior by combining visual and temporal data, achieving a prediction accuracy of 96.18%.

Keji et al. [17] applied a ResNet model to banking data [33] with Synthetic Minority Oversampling Technique (SMOTE) for class imbalance. ResNet achieved 93% accuracy, outperforming Random Forest at 90.78%. Nabi et al. [18] focused on profit prediction in e-commerce using deep learning. VGG16 [34] and ResNet50 [14] were compared to traditional machine learning algorithms. VGG16 emerged as the top-performing model with 92.55% accuracy.

Chaudhuri et al. [35] compared a Feed-forward Deep Neural Network (DNN) to traditional models for predicting customer purchase behavior on e-commerce platforms. DNN

outperformed all traditional algorithms with an accuracy of 89%. Singh et al. [36] compared MLP [37] to decision tree J48 and Naïve Bayes classifiers on a shopping center dataset for Customer Relationship Management (CRM). MLP outperformed both classifiers with an accuracy of 98.33%.

Dong et al. [38] proposed an improved 1D ResNet architecture for structured data classification, demonstrating that residual connections are effective even in non-image domains. Wang et al. [39] established that deep neural networks, including ResNet and fully convolutional networks provide strong baselines for time series and structured data classification, often matching or exceeding traditional approaches without extensive feature engineering.

While deep learning models excel with multi-modal and unstructured data, their application to structured tabular data remains less common. Traditional models are often preferred for their interpretability and suitability for smaller structured datasets. Recent benchmark studies have shown that gradient boosting methods frequently outperform deep learning on tabular data, particularly when datasets contain fewer than 10,000 instances. This study uses a dataset not previously explored in the literature and focuses on an empirical comparison of both paradigms for customer segment profitability prediction, providing evidence for the relative strengths of each approach under conditions of moderate dataset size and class imbalance.

III. Proposed Approach

This study proposes a machine learning framework for customer profitability prediction. The input to this framework is segmented historical customer data, structured based on customer attributes. This data undergoes a preprocessing pipeline that includes: 1) feature standardization to normalize input variables, ensuring that features with different scales do not disproportionately influence model training, 2) application of the Synthetic Minority Over-sampling Technique (SMOTE) to address class imbalance in the training set by generating synthetic instances of the minority class, and 3) for deep learning models, reshaping of input features to match the required format for 1D convolutional architectures. SMOTE is applied only to the training set to prevent data leakage, ensuring that the validation and test sets reflect the true class distribution.

The framework follows two main pathways. The first pathway trains and evaluates conventional machine learning models, including AdaBoost [6], Gradient Boosting [7], Extreme Gradient Boosting [8], Linear Discriminant Analysis [9], Random Forest [10], Naïve Bayes [11], Support Vector Machines [12], and K-Nearest Neighbors [13]. These models are trained using 10-fold cross-validation, where the data is partitioned into ten equal subsets, and each model is trained on nine folds while being validated on the remaining fold, rotating across all ten combinations. This strategy provides a robust estimate of model performance by reducing the variance associated with a single train-test split. The second pathway trains deep learning models, specifically 1D ResNet [14] and 1D DenseNet [15]. For deep learning, the dataset is split into 60% training, 20% validation, and 20% testing, with early stopping employed to halt training when validation performance ceases to improve, thereby preventing overfitting.

Following model training and testing, each model undergoes evaluation to assess performance. Based on the evaluation results, a final decision is made to select the best-performing model. The chosen model is then used to predict the profitability of each customer segment, providing actionable insights for targeting high-value customer segments and optimizing marketing resources.

The motivation for including conventional ML models stems from their advantages with structured datasets: they are computationally less intensive, easier to interpret, and generally less prone to overfitting with smaller datasets. Past research consistently demonstrates their effectiveness in customer-related prediction tasks [19], [21], [25], [27]. Additionally, conventional models allow for quicker training times, and their results are more interpretable, which is beneficial when presenting findings to stakeholders unfamiliar with deep learning concepts.

Deep learning models, specifically 1D ResNet and 1D DenseNet, are included due to their sophisticated feature extraction capabilities. ResNet uses residual learning with skip connections that alleviate the vanishing gradient problem [40], enabling more intricate pattern learning. In the context of customer data, this can mean better learning of hierarchical feature interactions across various attributes. DenseNet connects each layer to every subsequent layer in a feed-forward fashion, improving information flow and reducing redundant feature learning. This dense connectivity pattern allows DenseNet to retain critical customer information across layers, leading to more accurate predictions with fewer parameters compared to equivalently deep standard architectures. The choice of 1D architectures aligns with the structured nature of customer data, where each record represents a customer attribute vector, enabling the models to process tabular features with minimal transformations.

IV. Experiments

A. Dataset Description

The dataset [41], "Predicting Profitable Customer Segments", is a publicly available Kaggle benchmark that aggregates historical records from an online retail company to support predictive modeling for targeted marketing campaigns. Each row represents a pre-campaign observation that compares two customer groups, capturing their attributes and relational characteristics before any promotional intervention.

The dataset contains 6621 instances and 70 input features, organized into three semantically distinct categories of columns: the "g1_" columns describing absolute attributes of the first customer group (e.g., aggregated demographic and behavioral measurements), the "g2_" columns describing the corresponding attributes of the second group, and the "c_" columns capturing relational features that quantify pairwise differences between the two groups. The target column categorizes outcomes into three classes: neither group was profitable (0), Group 1 was more profitable (1), or Group 2 was more profitable (2). The class distribution is moderately imbalanced: class 1 (Group 1 more profitable) is the majority class with 3076 instances (46.5%), followed by class 2 (Group 2 more profitable) with 1877 instances (28.3%), and class 0 (neither profitable) as the minority class with 1667 instances

(25.2%). Although exact attribute semantics are not disclosed by the data provider for confidentiality reasons, the variable names and value ranges indicate that the features encompass demographic descriptors (such as age, income, and geographic indicators) and behavioral measures (such as transaction value and purchase frequency). The comparative "c_" columns encode the relative positioning of the two groups, for example the difference in average spending or the ratio of engagement frequencies between the groups. This dual representation, combining absolute group characteristics with relative inter-group metrics, creates a feature space where models can learn both what makes individual groups profitable and how the contrast between groups predicts campaign outcomes. The class imbalance poses an additional challenge, as classifiers tend to optimize for majority classes unless explicitly guided otherwise through class weighting or oversampling. We acknowledge that the limited public documentation of feature semantics constrains the depth of feature-level interpretation that can be performed, and we discuss the implications of this limitation in Section VI.

The implementation used Google Colab Pro with TPU support, TensorFlow/Keras [42], [43] for deep learning, Scikit-learn [44] for classical models, and the XGBoost library [8]. NumPy [45] was used for data manipulation and Matplotlib [46] for visualization. Initial experiments were conducted on local machines equipped with NVIDIA GeForce GTX 1660 Ti and Apple M1 Pro GPUs. However, the computational demands of training deep architectures such as 1D ResNet-50 and 1D DenseNet-121 required migrating to Google Colab Pro, which provided access to TPU and high-RAM environments that significantly accelerated training.

B. Experiment 1: Deep Learning

Two deep learning architectures were evaluated: 1D ResNet and 1D DenseNet. All models were trained using a consistent preprocessing pipeline including feature standardization, SMOTE for class imbalance, and input reshaping to conform to the expected input format of 1D convolutional networks. The dataset was split into 60% training, 20% validation, and 20% testing, with early stopping to prevent overfitting. Running these experiments introduced significant computational overhead, as deep learning architectures such as 1D ResNet-50 and 1D DenseNet-121 were inherently expensive to train in terms of both time and memory, requiring access to TPU-accelerated cloud environments.

1) 1D ResNet: Three variants (ResNet-18, ResNet-34, ResNet-50) were evaluated. The Adam optimizer was used with a batch size of 128 and early stopping. Class weighting was applied to address imbalanced learning. Multiple configurations were explored by varying the learning rate from 0.0001 to 0.1 across four settings per variant, yielding 12 configurations total. The number of training epochs ranged from 21 to 44 due to early stopping.

Among all variants and configurations, ResNet-18 with learning rate 0.1 achieved the best performance, as shown in Table I. The small decline between validation and test performance indicates good generalization. ResNet-34 and ResNet-50 peaked at validation F1 scores of 0.496 and 0.487, respectively, both with learning rate 0.01, falling short of ResNet-18's 0.515. The finding that deeper variants did not improve over ResNet-18 can be attributed to the dataset's relatively small size and low complexity, where a simpler architecture with fewer parameters is more efficient at capturing essential patterns without memorizing noise. The higher learning rate of 0.1 outperformed smaller rates across all variants, suggesting that the loss landscape for this task is relatively smooth, allowing aggressive gradient updates to converge faster without oscillating past optima.

TABLE I. RESNET-18 PERFORMANCE WITH BEST CONFIGURATION

	Precision	Recall	F1 Score	Accuracy
Validation	0.5119	0.5431	0.515	0.5431
Test	0.4971	0.505	0.501	0.4562

TABLE II. DENSENET-121 PERFORMANCE WITH BEST CONFIGURATION

	Precision	Recall	F1 Score	Accuracy
Validation	0.54	0.55	0.55	0.55
Test	0.54	0.54	0.54	0.54

2) 1D DenseNet: DenseNet-121 was evaluated across 11 configurations varying the optimizer (Adam, AdamW), learning rate (0.001 to 0.1), and class weighting strategies (none, automatically computed based on class distribution, and manually assigned). The batch size was fixed at 128 with early stopping.

The experiments revealed critical insights about training deep models on imbalanced data. Configurations without class weights achieved moderate accuracy but ignored the minority class 0 entirely, resulting in low F1 scores. For instance, configurations with no class weights produced biased predictions that favored majority classes, achieving an F1-score of only 0.47. Configurations with very low learning rates (0.001) performed poorly regardless of class weighting, with F1 as low as 0.30, suggesting the optimizer converged too slowly or became stuck in shallow local minima. In contrast, configurations with appropriately set class weights and higher learning rates achieved substantially better results. These findings demonstrate that both an appropriate learning rate and effective class weighting are jointly necessary to handle imbalanced datasets; neither alone is sufficient. The AdamW optimizer with automatic class weights achieved competitive F1 of 0.54, but did not surpass the Adam optimizer under optimal settings. Automatic class weights, computed proportionally from the class distribution, provided a reasonable approximation but were less effective than manually assigned weights that doubled the penalty for misclassifying the minority class.

The best performance was achieved with Adam optimizer, learning rate of 0.1, and manually assigned class weights $\{0 : 2.0, 1 : 1.0, 2 : 1.0\}$, which doubled the penalty for misclassifying the minority class, as shown in Table II. The consistent results across validation and test sets indicate good generalization and no overfitting.

Overall, DenseNet-121 outperformed all ResNet variants, achieving a test F1 of 0.54 compared to 0.50 for ResNet-18. DenseNet benefits from its dense connectivity pattern that creates shorter paths for gradient flow and enables more efficient feature reuse across layers. Its concatenation-based approach

TABLE III. NAÏVE BAYES PERFORMANCE RESULTS

	Precision	Recall	F1 Score	Accuracy
Training	0.50	0.49	0.49	0.48
Test	0.49	0.48	0.49	0.48

retains feature maps from all previous layers, allowing the model to access both low-level and high-level representations simultaneously. This is particularly beneficial for tabular data where feature interactions may span over different levels of abstraction. Deeper ResNet variants (ResNet-34, ResNet-50) did not improve over ResNet-18, suggesting that model depth should be proportional to the complexity and volume of the data. ResNet-50 achieved the lowest validation F1 among all variants (0.356 at learning rate 0.0001), indicating that the additional depth introduced unnecessary parameters that the limited training data could not support. The consistent finding that shallower architectures outperform deeper ones across both ResNet and DenseNet experiments suggests that the dataset's 6621 instances are insufficient to train deep networks effectively, and that the feature space does not contain hierarchical patterns complex enough to justify deep architectures.

C. Experiment 2: Traditional Machine Learning

Eight conventional machine learning classifiers were evaluated using 10-fold cross-validation during training. All models were trained on the same preprocessed dataset using feature standardization and SMOTE for class imbalance. For each model, multiple hyperparameter configurations were explored, and only the best-performing configuration is reported. The hyperparameters for each model were tuned systematically, varying key parameters such as learning rate, regularization strength, kernel type, and ensemble size to identify the optimal balance between model complexity and generalization.

1) Naïve Bayes: Naïve Bayes has no significant tunable hyperparameters and was evaluated using 10-fold cross-validation. Table III reports the results. The model shows consistent but low performance across training and test sets, with F1 below 0.5 reflecting its limited capacity on this dataset. This weak performance is likely due to the strong feature independence assumption, which rarely holds in real-world datasets where features tend to be correlated. The relational features in this dataset ("c_" columns quantifying group differences) are inherently derived from the group-specific features, creating strong inter-feature dependencies that directly violate this assumption. Despite this, the model's stability between training and test sets confirms that the issue is underfitting rather than overfitting. The near-identical training and test scores (0.49 vs. 0.49 for F1) indicate that the model has fully learned what its limited architecture permits, and additional data or features would not improve its performance without relaxing the independence assumption. While Naïve Bayes is the most lightweight model in our study, its weak predictive power limits its practical utility for this task.

2) K-Nearest Neighbors: KNN was tested with K values of 1, 2, 3, 5, 7, and 10 using 10-fold cross-validation. K=1 resulted in severe overfitting (training F1=1.0, test F1=0.71), as the model memorized the training data by returning the label of the single closest point. K=2 and K=3 achieved identical test F1 of 0.62 despite different training scores (0.84 and 0.80, respectively), highlighting diminishing returns from increased model complexity. K=5 yielded test F1 of 0.59, while K=7 dropped to 0.55. The generalization gap narrowed progressively from 0.29 (K=1) to 0.07 (K=10), illustrating the classic bias-variance tradeoff: lower K values produce models with low bias but high variance that are sensitive to noise, whereas higher K values produce smoother decision boundaries with higher bias but lower variance. K=10 provided the most balanced behavior, as shown in Table IV. Although its absolute test F1 of 0.52 is lower than K=2 and K=3, the reduced overfitting and more stable predictions make it a more reliable choice, particularly when the training set has been augmented with SMOTE-generated synthetic samples. The sensitivity of KNN to the choice of K underscores the importance of hyperparameter tuning and cross-validation in preventing misleading performance estimates.

TABLE IV. KNN PERFORMANCE RESULTS (K=10)

	Precision	Recall	F1 Score	Accuracy
Training	0.63	0.60	0.59	0.60
Test	0.56	0.53	0.52	0.53

TABLE V. RANDOM FOREST PERFORMANCE RESULTS

	Precision	Recall	F1 Score	Accuracy
Training	0.55	0.56	0.54	0.56
Test	0.53	0.54	0.53	0.55

3) Random Forest: Three configurations were evaluated varying max depth (5–10), max features (sqrt, log2), and min samples parameters with 5 trees. All configurations achieved similar test performance (F1 between 0.53–0.54), indicating that Random Forest is relatively robust to hyperparameter changes on this dataset. The first two configurations with max depth 10 both achieved training F1 of 0.56 with test F1 of 0.53, exhibiting slight overfitting as the deeper trees memorized training patterns that did not generalize. Using sqrt versus log2 for max features had negligible impact, suggesting that feature diversity among trees was sufficiently maintained by either approach. The most constrained configuration with max depth 5 and increased min samples split provided the best generalization, as shown in Table V. This suggests that on this dataset, controlling tree complexity is more beneficial than allowing the model to capture finer-grained patterns that may be noise. The relatively small ensemble size of 5 trees was chosen to reduce training time, though increasing this number could potentially improve performance at the cost of additional computation.

4) Support Vector Machine: Over 120 hyperparameter configurations were explored, varying the kernel type (linear, polynomial, sigmoid, RBF), regularization parameter C, and gamma. All top-performing configurations used the RBF kernel, indicating its effectiveness in modeling the complex, non-linear decision boundaries present in this dataset. The RBF kernel maps data into a higher-dimensional feature space using a Gaussian function, enabling the construction of non-linear decision boundaries that are necessary for datasets with over-

Test	0.60	0.61	0.62	0.62

lapping class distributions. A clear trend emerged: performance declined as C increased and gamma decreased, suggesting that overly large regularization values combined with very small gamma values harmed generalization. Specifically, the top six configurations all used RBF with C values ranging from 0.5 to 500 and gamma from 0.01 to 0.0001, with training F1 scores declining from 0.582 to 0.531 as C increased. The RBF kernel with C=0.5 and gamma=0.01 yielded the best results, as reported in Table VI. The moderate C value strikes a balance between maintaining a strict decision boundary and allowing flexibility for noisy data points. The training-test gap of 0.04 in F1 indicates moderate generalization. The linear, polynomial, and sigmoid kernels all performed below the RBF configurations, confirming that the class boundaries require the flexibility of a radial basis function.

5) AdaBoost: Three configurations were tested varying the learning rate (0.01, 0.1, 1.0) with 100 estimators and the SAMME algorithm [47]. A learning rate of 0.01 severely underfit with F1 of only 0.42 on both training and test sets, indicating that each weak learner's contribution was too small for the ensemble to converge within 100 iterations. This extreme consistency between training and test performance at a low score is a hallmark of underfitting, where the model has insufficient capacity to learn the underlying patterns. Learning rates of 0.1 and 1.0 achieved comparable test F1 of 0.54, with the higher learning rate (1.0) producing marginally higher training performance (0.55 vs. 0.54) without improving test results. The best result, shown in Table VII, demonstrates a minimal gap between training F1 (0.55) and test F1 (0.54), indicating no overfitting. This consistency highlights AdaBoost's strength in reducing variance through its sequential ensemble of weak learners, which iteratively increases the weights of misclassified instances to focus subsequent learners on harder cases. However, its absolute performance falls short of the more advanced boosting variants (Gradient Boosting and XGBoost), which employ gradient-based optimization of the loss function rather than AdaBoost's sample reweighting scheme, representing a 15% relative improvement in F1.

6) Gradient Boosting: Four configurations were tested varying the number of estimators (8–100), max depth (2–3), learning rate (0.1–1.0), and subsample ratio, all using Friedman-MSE criterion and log-loss. Configurations with fewer estimators or shallower trees showed progressively lower performance, indicating underfitting. The second configuration (10 estimators, max depth 3, learning rate 1.0) achieved test F1 of 0.59, while the third and fourth configurations (10 and 8 estimators, max depth 2) yielded 0.57 and 0.56, respectively. The best configuration used 100 estimators, max depth 3, and learning rate 0.1. As shown in Table VIII, Gradient Boosting achieved a test F1 score of 0.62, the highest among all models, tied with XGBoost. The gap between training F1 (0.69) and test F1 (0.62) is moderate, indicating that while some overfitting exists, the model still generalizes reasonably well. The combination of a moderate learning rate with sufficient estimators allowed the model to learn incrementally and capture subtle patterns, while max depth 3 prevented individual trees from becoming overly complex. The progressive performance improvement from the weakest to the strongest configuration demonstrates that the number of estimators and learning rate are the most influential hyperparameters for this task, with max depth playing a secondary role in controlling overfitting.

7) Extreme Gradient Boosting (XGBoost): Four configurations were evaluated varying max depth (2–4), learning rate (0.2–0.3), subsample ratio, and L1/L2 regularization. The best configuration used 100 estimators, max depth 4, learning rate 0.3, and reg_lambda 800 for strong L2 regularization. The high regularization parameter was critical in preventing overfitting despite the relatively deep trees, effectively penalizing large weights and keeping the model from becoming overly complex. The colsample_bytree of 0.8 introduced randomness by selecting a subset of features per tree, and the min_child_weight of 5 ensured that splits only occurred when sufficient data supported them. As shown in Table IX, XGBoost matched Gradient Boosting with a test F1 score of 0.62. Notably, a second configuration with only 50 estimators also achieved test F1 of 0.62 but with lower training performance (0.64 vs. 0.68), indicating that XGBoost can achieve comparable results with different hyperparameter combinations due to the compensatory relationships among its regularization parameters. The remaining two configurations with max depth 2 achieved lower test F1 scores of 0.57 and 0.59, confirming that deeper trees were necessary to capture the complexity of the dataset. The training-test gap of 0.06 is smaller than Gradient Boosting's gap of 0.07, suggesting slightly better generalization. XGBoost's built-in L1 and L2 regularization, combined with its optimized parallel processing and efficient handling of missing data, contributed to its strong performance while maintaining computational efficiency.

8) Linear Discriminant Analysis: Five configurations were tested varying the solver (SVD, LSQR, Eigen), shrinkage, prior probabilities, and tolerance. The SVD solver served as a baseline due to its computational efficiency and numerical stability, while the LSQR and Eigen solvers supported shrinkage to address potential feature redundancy. The Eigen solver

TABLE X. LDA PERFORMANCE RESULTS

	Precision	Recall	F1 Score	Accuracy
Training	0.54	0.53	0.53	0.53
Test	0.56	0.51	0.53	0.51

with automatic shrinkage yielded the best results, as shown in Table X. This combination provided the most balanced results across training and test sets, with the automatic shrinkage estimating an appropriate regularization level from the data. The SVD-based configurations, including one with uniform class priors, showed slightly lower performance, while increasing the tolerance to 0.5 produced the weakest results, suggesting that discarding too many dimensions reduced the model's discriminative ability. Despite testing multiple configurations, the performance differences across all LDA settings were relatively small (F1 ranging from 0.523 to 0.533), suggesting that LDA's linear projection is inherently limited for this dataset. The three-class problem with overlapping class distributions likely requires non-linear decision boundaries that LDA cannot model, which explains its lower performance compared to tree-based and kernel-based methods.

D. Additional Experiments

A One-vs-Rest (OvR) strategy was explored to improve classification of class 0, which the confusion matrix revealed was frequently misclassified as class 1 or class 2. This misclassification pattern was consistent across most models, indicating that class 0 (neither group profitable) shares significant feature overlap with both class 1 and class 2. Separate binary classifiers were trained to distinguish each class from the others, with a specific focus on isolating class 0. The rationale was that decomposing the multi-class problem into simpler binary tasks might allow classifiers to better learn the subtle differences between the minority class and the majority classes. However, the best F1 for class 0 reached only 0.4987, with other configurations yielding 0.4769, 0.4587, and 0.4335. These results suggest that the underlying class overlap and imbalance were difficult to overcome even with targeted binary modeling, and that the features available in the dataset may not be sufficiently discriminative for class 0.

Autoencoders [48], [49] were also tested as a preprocessing step to extract more meaningful features before classification. The hypothesis was that unsupervised feature learning could discover a compressed representation that better separates the classes. A shallow architecture (one hidden layer, 1000 neurons) achieved weighted F1 of 0.5245. However, increasing depth consistently degraded performance: a two-layer architecture yielded 0.5170, a three-layer version dropped to 0.5023, and further increasing the number of hidden nodes to 1500 also did not help, yielding 0.5023. Additional depth beyond three layers produced even lower scores of 0.4982, while reducing the number of nodes led to 0.4790. These results suggest that the dataset may not benefit from unsupervised compression, and that the original feature space already provides a sufficiently informative representation. The degradation with deeper architectures mirrors the findings from the ResNet experiments, reinforcing that additional model complexity does not improve results on this dataset.

TABLE XI. TEST PERFORMANCE COMPARISON OF ALL MODELS

Model	Prec.	Rec.	F1	Acc.	AUC
XGBoost	0.60	0.61	0.62	0.62	0.75
Gradient Boosting	0.63	0.62	0.62	0.62	0.74

1D ResNet-18	0.50	0.51	0.50	0.46	0.64

V. COMPARISON OF APPROACHES

Table XI summarizes the test performance of all evaluated models. XGBoost achieved the highest AUC of 0.75, followed by Gradient Boosting (0.74) and AdaBoost (0.74). Among deep learning models, DenseNet-121 performed best with an AUC of 0.72, while ResNet-18 reached 0.64.

Traditional machine learning models, particularly XGBoost and Gradient Boosting, consistently outperformed deep learning approaches. Both achieved the highest test F1 score of 0.62. XGBoost reached the highest AUC of 0.75, while Gradient Boosting followed closely at 0.74. Three interacting properties of the dataset jointly explain this gap. First, the data is tabular and heterogeneous: each feature has its own semantics and scale, so the translation-invariant local filters learned by 1D convolutional architectures have no clear analogue in this representation, whereas axis-aligned splits used by tree-based ensembles map directly onto the per-feature decision structure that is natural for this type of data. Second, the dataset is moderately sized: deep architectures typically require large amounts of training data to generalize effectively, and the 60/20/20 split further reduces the effective deep learning training set to approximately 3973 instances, whereas traditional models benefit from 10-fold cross-validation that uses 90% of the data for training in each fold. Third, the class distribution is imbalanced, and although SMOTE and class weighting mitigate this, the residual difficulty of separating the minority class 0 from classes 1 and 2 affects high-capacity deep models more severely than tree ensembles, which can isolate small but informative regions of feature space through targeted splits. These three factors, namely tabular structure, moderate sample size, and class imbalance, are precisely the conditions under which gradient boosting has been repeatedly shown to dominate deep learning on tabular benchmarks, and our results corroborate that pattern in the marketing analytics setting.

A consistent observation across all models is that the weighted F1 score appears to be bounded around 0.62. This bound is not a tuning artefact: it persists across systematic hyperparameter searches (over 120 configurations for SVM, multiple configurations for every other model), across an alternative classification strategy (One-vs-Rest, with the best class-0 F1 reaching only 0.4987), and across an alternative feature representation (autoencoder-based compression, peaking at 0.5245). The fact that two architecturally distinct top models (XGBoost and Gradient Boosting) converge to the same 0.62 score, and that neither deeper trees, nor stronger regularization, nor unsupervised feature extraction can push

past it, indicates that the limit is a property of the data rather than of the classifiers. The confusion-matrix analysis (see Section IV) confirms that the residual errors concentrate on class 0, which the feature space cannot reliably distinguish from the other two classes given the available attributes. This is consistent with the dataset's confidentiality-induced opacity: domain-relevant features that might disambiguate class 0 (such as marketing channel, prior campaign exposure, or product-category preference) may simply not be represented in the published feature set. Improving beyond F1 $\approx$ 0.62 would therefore most likely require richer input features rather than more expressive models, which we discuss as a direction for future work.

Among deep learning models, DenseNet-121 outperformed ResNet-18, achieving a test F1 score of 0.54 compared to 0.50. ResNet-18 outperformed deeper ResNet variants (ResNet-34 and ResNet-50), suggesting that a simpler architecture was better suited for this dataset. Notably, DenseNet-121 achieved performance comparable to several traditional models (AdaBoost at 0.54, SVM at 0.54) despite requiring orders of magnitude more computation, which raises questions about the practical value of deep learning for structured datasets of this scale.

An interesting observation is the relationship between AUC and F1 discrepancies: Naïve Bayes achieved AUC of 0.69 despite an F1 of only 0.49, indicating that while it can partially rank instances by class probability, its hard classification decisions are poor. This suggests that Naïve Bayes produces well-calibrated probability estimates despite its inability to set effective classification thresholds. LDA similarly showed a gap between AUC (0.72) and F1 (0.53), reflecting its strength in linear separability assessment despite limited classification accuracy. Conversely, XGBoost achieved the highest AUC alongside the highest F1, demonstrating both strong ranking ability and effective classification thresholds. This consistency between ranking and classification metrics indicates that XGBoost produces reliable probability estimates that translate directly into accurate predictions.

Several models incorporate implicit feature selection mechanisms. XGBoost, Random Forest, and AdaBoost evaluate feature importance during tree construction, naturally prioritizing informative features. LDA performs dimensionality reduction by projecting data onto a space that maximizes class separability. SVM with RBF kernel maps data into higher-dimensional spaces for better separation. Deep learning models rely on convolutional layers to learn hierarchical feature representations automatically. These built-in mechanisms allow each model to handle high-dimensional inputs differently, contributing to the observed performance differences.

In terms of computational efficiency, traditional models were significantly more resource-efficient. Table XII and Table XIII compare the computational requirements of all models. The contrast is substantial: DenseNet-121 required 121232 GFLOPs for training versus only 0.15 GFLOPs for XGBoost, a difference of nearly six orders of magnitude. In parameter count, DenseNet-121 (5.53M) had over 120 times more parameters than XGBoost (0.04M). Even the lighter deep learning model, ResNet-18 (0.23M parameters, 3582 GFLOPs), demanded over 24000 times more computation than XGBoost.

TABLE XII. SPACE COMPLEXITY (NUMBER OF PARAMETERS)

Model	Params (M)
1D DenseNet-121	5.5328
SVM	0.4856
KNN	0.4635
1D ResNet-18	0.2342
XGBoost	0.0445
Gradient Boosting	0.0213
LDA	0.0027
AdaBoost	0.0015
Random Forest	0.0004
Naïve Bayes	0.0002

TABLE XIII. TIME COMPLEXITY (GFLOPS)

Model	Training	Testing
1D DenseNet-121	121231.62	10099.90
1D ResNet-18	3582.26	303.06
SVM	1.96	0.10
Gradient Boosting	0.46	0.01
XGBoost	0.15	0.001
LDA	0.03	0.0001
AdaBoost	0.02	0.005
Random Forest	0.002	$<$0.001
Naïve Bayes	$<$0.001	0.001

Naïve Bayes was the most lightweight model (0.0002M parameters, $<$0.001 GFLOPs), but its weak predictive performance limits its practical utility. KNN, while requiring no formal training phase, incurs inference-time cost proportional to the dataset size (0.49 GFLOPs for testing), storing all 0.46M training instances for distance computation at prediction time. SVM, despite achieving moderate F1 of 0.54, required 1.96 GFLOPs for training due to the kernel computations needed for constructing the decision boundary in high-dimensional space. Among the top-performing models, XGBoost was notably faster than Gradient Boosting (0.15 vs. 0.46 GFLOPs for training) due to its optimized parallel processing and built-in regularization, while both achieved identical test F1 of 0.62. XGBoost struck a favorable balance with 0.04M parameters and strong predictive performance.

The results also reveal a clear performance hierarchy within the traditional ML models. The boosting family (XGBoost, Gradient Boosting, AdaBoost) consistently outperformed other approaches, with the gradient-based variants (XGBoost and Gradient Boosting) achieving the best results. This advantage stems from their iterative error correction mechanism, where each subsequent tree focuses on the residuals of the previous ensemble. Random Forest, despite being an ensemble method, achieved lower F1 (0.53) due to its independent tree construction that does not explicitly target misclassified instances. SVM and KNN achieved moderate performance (F1 of 0.54 and 0.52, respectively), while Naïve Bayes and LDA, both limited by strong distributional assumptions, fell short. This ordering aligns with the general principle that models capable of capturing non-linear interactions and iteratively refining predictions perform best on complex classification tasks.

Overall, XGBoost and Gradient Boosting demonstrated the best balance between accuracy, generalization, and computational efficiency, making them well-suited for the customer segment profitability prediction task. Their suitability for structured tabular data and their interpretability provide a practical

advantage for business decision-making, where understanding which customer group features drive profitability predictions is as valuable as the predictions themselves.

From a deployment perspective, the computational disparity reported in Table XII and Table XIII translates directly into operational consequences. XGBoost requires only 0.001 GFLOPs at inference time compared with 10099.90 GFLOPs for DenseNet-121, making it roughly ten million times faster at prediction time and enabling a profitability score to be produced for an incoming customer segment in essentially constant time on commodity CPU hardware. This makes XGBoost compatible with real-time campaign-optimization pipelines and with edge or in-database deployment. By contrast, DenseNet-121 effectively assumes GPU/TPU availability and introduces additional infrastructure cost, latency, and energy consumption that are hard to justify given the absence of any predictive advantage. The 0.04M parameter footprint of XGBoost also simplifies model versioning, A/B testing, and incremental retraining, which are routine requirements in marketing analytics platforms. Finally, the tree-based nature of XGBoost preserves direct compatibility with established interpretability tools (such as gain-based feature importance and SHAP values), supporting the auditability and explanation requirements that increasingly accompany automated marketing decisions. Taken together, these properties make XGBoost and Gradient Boosting the recommended candidates for production deployment in this domain, with deep architectures reserved for settings where dataset size and modality (for instance, image- or sequence-rich customer data) genuinely warrant them.

VI. Limitations

Several limitations of this study should be acknowledged explicitly. First, the dataset size of 6621 instances is moderate relative to the data volumes at which 1D ResNet and 1D DenseNet have historically demonstrated their advantages, and a fairer assessment of deep learning would require benchmarks with at least an order of magnitude more samples; our negative result for deep learning should, therefore, be interpreted as conditional on the data regime studied rather than as a general statement about deep architectures for marketing analytics. Second, the dataset attributes are described only at a category level ("g1_", "g2_", "c_") and exact feature semantics are not disclosed by the data provider for confidentiality reasons, which limits the depth of feature-level interpretation and constrains reproducibility at the level of individual attribute analysis. Third, the evaluation is restricted to classification metrics (precision, recall, F1, accuracy, AUC); business-oriented metrics such as expected ROI uplift, conversion rate gain, customer lifetime value impact, and campaign cost per acquired customer would more directly reflect the practical utility of the predictions, but require labelled campaign-outcome data and a deployment context that are outside the scope of this study. Fourth, although the framework was designed with interpretability in mind, post-hoc explainability techniques such as SHAP value analysis or permutation feature importance were not applied to the top-performing models; integrating such analyses would strengthen the link between model predictions and actionable marketing insights. Fifth, no external dataset or temporal validation was performed: the generalization claims pertain to the held-out split of this single Kaggle source, and replication on additional retail datasets with disclosed feature semantics would be needed to establish broader generalizability. These limitations are addressed in our future work plan in Section VII.

VII. Conclusion

This study explored the application of machine learning and deep learning techniques for predicting profitable customer segments to optimize targeted marketing strategies. A comprehensive framework was developed, incorporating conventional classifiers (AdaBoost, Gradient Boosting, XGBoost, LDA, Random Forest, Naïve Bayes, SVM, and KNN) and deep learning architectures (1D ResNet and 1D DenseNet).

The experimental results demonstrated that traditional machine learning models, particularly XGBoost and Gradient Boosting, consistently outperformed deep learning models across multiple metrics. Both achieved the highest weighted F1 score of 0.62 and the highest AUC values (0.75 and 0.74, respectively). The performance advantage of traditional models is attributed to the relatively limited dataset size and class imbalance, conditions under which deep learning models struggle to generalize effectively. Among the deep learning models, DenseNet-121 outperformed all ResNet variants with a test F1 of 0.54, while deeper ResNet architectures did not improve over the simpler ResNet-18, reinforcing that model complexity should be proportional to dataset size.

XGBoost offered additional advantages in terms of execution speed and computational efficiency while maintaining comparable predictive performance to Gradient Boosting. With only 0.04M parameters and 0.15 GFLOPs for training, XGBoost required nearly six orders of magnitude fewer computations than DenseNet-121 (121232 GFLOPs). Both models demonstrated effective generalization and robust handling of imbalanced data. As traditional machine learning models, they are also more interpretable than deep learning approaches, which is a key benefit for understanding model decisions and driving actionable business insights.

The additional experiments with One-vs-Rest classification and autoencoders did not yield significant improvements over the direct multi-class approach, suggesting that the underlying class overlap in the dataset poses a fundamental challenge that cannot be easily addressed through alternative classification strategies or unsupervised feature extraction.

Future work will pursue four directions in response to the limitations identified above. First, the framework will be evaluated on larger and more diverse customer datasets, particularly those exceeding tens of thousands of instances, to characterize the data-volume regime in which deep architectures begin to outperform tree-based ensembles for this task. Second, post-hoc explainability techniques, specifically SHAP value analysis and permutation-based feature importance, will be applied to XGBoost and Gradient Boosting to produce interpretable, per-prediction attributions that marketing teams can act on, addressing the interpretability dimension that the present study only partially covers. Third, the evaluation will be extended from purely classification-oriented metrics to business-oriented metrics, including expected ROI uplift, conversion rate gain, customer lifetime value impact, and cost per acquired customer, by partnering with marketing teams to

obtain labelled campaign-outcome data that link model predictions to realized financial returns. Fourth, hybrid ensemble methods that combine the strengths of gradient boosting with neural feature extractors will be investigated as a potential route to overcoming the F1 $\approx$ 0.62 ceiling observed on the current feature set, alongside richer input features (such as marketing channel, prior campaign exposure, and product-category preference) that may help disambiguate the residual confusion involving class 0. Robust outlier detection methods will also be incorporated as part of the preprocessing pipeline to further enhance data quality.

ACKNOWLEDGMENT

First and foremost, we thank Allah Almighty, the Most Gracious, the Most Merciful, for the countless blessings that led to the successful completion of this research. We are deeply grateful to our supervisor, Prof. Ouiem Bchir, for her continuous support, patience, and dedication throughout every stage of this work. Finally, we express our deepest gratitude to our families and friends for their unwavering support, love, and encouragement.

***Abstract*—The increasing use of large language models (LLMs) in domains requiring interpretation and judgment has raised critical questions about trust, reliability, and accountability, particularly in contexts where decisions carry significant consequences. While prior work has focused primarily on improving system performance, limited attention has been given to how users evaluate and interact with AI-generated guidance in real-world, high-stakes settings. This paper addresses this gap through a large-scale empirical investigation of public perceptions of AI-generated religious guidance in Saudi Arabia. The analysis is based on survey data collected from 572 participants and combines quantitative statistical methods with a machine learning-based pipeline for analyzing open-ended responses. The quantitative component examines patterns in trust, perceived risk, privacy concerns, credibility, and user practices, while the qualitative component employs embedding-based clustering using Bidirectional Encoder Representations from Transformers (BERT), Uniform Manifold Approximation and Projection (UMAP), and Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN), followed by expert interpretation to derive structured parameters. The results indicate a cautious and conditional engagement with AI systems, characterized by moderate usage, low levels of trust, and strong concerns regarding reliability and source credibility. Users frequently verify AI-generated outputs and demonstrate a preference for human expert validation, particularly in complex or sensitive cases. Building on these insights, the study introduces a layered taxonomy of perceived risks spanning epistemic, reasoning, interactional, and institutional dimensions, providing a structured analytical framework for understanding how technical limitations translate into broader behavioural and governance challenges. These results highlight the importance of aligning AI system design with user expectations, emphasizing transparency, verifiability, and human oversight. The proposed taxonomy and analytical framework provide a foundation for future research and contribute to the development of governance approaches for AI systems deployed in high-stakes interpretive domains.**

I. Introduction

Artificial intelligence (AI), particularly large language models (LLMs), is increasingly embedded in domains that require not only information retrieval but also judgment, interpretation, and decision support. These systems are now consulted for guidance in areas such as healthcare, legal reasoning, education, and personal decision-making, where the consequences of errors may be significant [1], [2], [3]. As a result, questions of trust, reliability, transparency, privacy, and accountability have moved to the forefront of AI research and governance [4], [5]. Prior work has shown that LLMs can generate fluent yet inaccurate outputs, exhibit hallucinations, and influence user judgments in ways that extend beyond neutral information provision [6], [4]. In high-stakes contexts, particularly in what can be described as interpretive domains, that is, settings where responses depend on reasoning, contextual judgment, and the application of domain-specific knowledge rather than direct retrieval of factual information, these characteristics raise critical concerns regarding how users interpret AI-generated responses, how much they rely on them, and how such systems interact with existing structures of expertise and decision-making.

In response to these challenges (see e.g., [7]), emerging AI governance frameworks, such as the EU AI Act, increasingly adopt risk-based approaches that classify applications according to their potential impact on individuals and society, particularly in domains involving decision-making, access to services, and fundamental human rights [8]. Such frameworks emphasize requirements for transparency, accountability, human oversight, and reliability, especially for high-risk AI systems whose outputs may directly or indirectly influence human decisions and behaviour [4], [5], [9]. Within this context, understanding how users perceive, interpret, and evaluate AI-generated outputs becomes not only a technical concern but also a regulatory and societal imperative.

A central challenge in this landscape lies in the tension between the apparent fluency and accessibility of AI-generated responses and the underlying limitations of these systems. While LLMs can produce coherent and persuasive outputs,

concerns persist regarding their tendency to generate unsupported or misleading information, fabricate references, align responses with user expectations rather than evidence, and operate without clear accountability structures [6], [4]. These issues are amplified in domains where knowledge is not purely factual but interpretive, context-dependent, and institutionally grounded. In such settings, the role of expertise, the legitimacy of sources, and the processes through which knowledge is validated become critical factors shaping both the use and acceptance of AI systems.

Within this broader landscape, certain domains present additional challenges due to their reliance on interpretive reasoning, contextual judgment, and established authority structures. Religious inquiry represents one such domain, where responses are not purely informational but are derived through structured processes that combine source-based evidence, domain expertise, and case-specific interpretation. In the Islamic context, religious rulings (Fatwa, Fatawa) are traditionally produced by qualified scholars through systematic reasoning grounded in recognized sources and interpretive frameworks [10]. As AI systems become increasingly accessible, they are now being used by individuals to obtain guidance on religious questions, effectively introducing LLMs into a domain characterized by high requirements for accuracy, contextual sensitivity, and legitimacy of authority. This shift raises important questions about how users evaluate AI-generated responses in terms of trust, credibility, privacy, and appropriateness, and how these systems are positioned relative to established human-centred processes of knowledge validation.

Despite growing research on AI systems and their applications, existing work remains primarily focused on improving system performance or examining isolated aspects of user interaction. Studies in domains such as healthcare and legal advisory have highlighted issues related to trust, over-reliance, and the difficulty of distinguishing between expert and AI-generated responses [1], [2], [3], while recent work in the context of religious knowledge has pointed to concerns regarding correctness, governance, and alignment with scholarly standards [11], [12], [13]. However, these efforts have largely addressed technical reliability or domain-specific challenges in isolation, with limited attention to how multiple dimensions of user perception, such as trust, perceived risk, privacy, credibility, and authority, interact in shaping real-world use and acceptance of AI systems. This gap is particularly significant in high-stakes interpretive domains, where user perceptions directly influence decision-making, compliance, and the broader societal impact of AI deployment.

Across these strands of research, a more fundamental gap emerges. While prior work has examined system performance and, in some cases, user interaction in specific domains, it does not yet provide a comprehensive understanding of how AI-generated guidance is evaluated and used in high-stakes interpretive contexts. Existing efforts remain primarily oriented toward improving model outputs [14], [15], with comparatively less attention to how users perceive, interpret, and respond to these outputs in real-world settings [16], [1], [2], [3]. At the same time, emerging work in religious knowledge highlights concerns related to correctness, governance, and alignment with scholarly standards [11], [12], [13], but these aspects are often considered independently rather than as interconnected dimensions of user evaluation and system use.

In addition, there is a lack of structured conceptual frameworks that organize the diverse risks associated with AI-generated outputs into coherent and interpretable forms. Most existing approaches address issues such as hallucination, bias, or misuse as separate challenges [6], without considering how these risks propagate across technical, behavioural, and institutional levels [4]. This limitation is particularly critical in high-stakes interpretive domains, where the acceptance and impact of AI systems depend not only on technical performance but also on how users interpret outputs, assess their authority, and align them with established knowledge and decision-making processes.

To address the identified gaps, this study presents one of the first large-scale empirical investigations of public perceptions of AI-generated guidance in a high-stakes interpretive domain, using the context of religious inquiries in Saudi Arabia. The research is based on a combined quantitative and qualitative analysis of survey data collected from 572 participants, providing insight into how individuals engage with AI systems and evaluate their outputs in real-world settings.

The analysis examines user perceptions across multiple interrelated dimensions, including trust, perceived risk, privacy, credibility, and user practices, and further explores how these perceptions vary with demographic and domain-specific factors, particularly age and religious knowledge. The quantitative component employs statistical analysis of structured survey responses, including descriptive statistics, correlation analysis, and group-based comparisons using appropriate significance testing, to identify patterns in user engagement and evaluation. In parallel, the qualitative component applies a machine learning-based pipeline to open-ended responses, leveraging Bidirectional Encoder Representations from Transformers (BERT) for semantic embedding [17], followed by dimensionality reduction using Uniform Manifold Approximation and Projection (UMAP) [18] and clustering via Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) [19]. The resulting clusters are then interpreted through a human–AI collaborative process to derive structured parameters. This integrated statistical and machine learning-based approach enables the identification of underlying concerns and expectations while preserving both analytical rigor and contextual interpretability.

Building on these results, the study introduces a layered taxonomy of perceived risks structured across four interrelated dimensions: epistemic and knowledge integrity, contextual and reasoning limitations, human–AI interaction dynamics, and socio-technical and institutional impacts. This taxonomy provides a structured representation of how technical limitations in AI-generated outputs relate to behavioural patterns and broader governance considerations, offering a coherent framework for understanding user perception in high-stakes contexts.

This study advances a shift from system-centric evaluation toward a more comprehensive understanding of AI in practice, emphasizing the role of user perception, contextual factors, and governance requirements. By providing empirical evidence, a combined statistical and machine learning-based analytical methodology, and a structured conceptual framework, the study offers insights relevant not only to religious inquiry but also to

other high-stakes interpretive domains where trust, authority, and accountability are central to the responsible deployment of AI systems. Beyond its empirical contribution, the proposed taxonomy offers a foundation for future research by providing a systematic way to analyse and compare risks across domains, supporting the development of evaluation benchmarks, governance frameworks, and domain-specific AI systems. In this sense, the framework not only captures current user perceptions but also enables further investigation into how AI-related risks evolve across different contexts and applications.

The remainder of this study is organized as follows: Section II reviews related work and outlines the research problem. Section III describes the methodology, including the survey design and the integrated statistical and machine learning-based analysis pipeline. Section IV presents the quantitative analysis of structured responses, while Section V provides the qualitative analysis and introduces the proposed taxonomy of perceived risks and public expectations. Section VI discusses the results in relation to existing literature and AI governance considerations. Finally, Section VII concludes the study and outlines directions for future research.

II. Literature Background

Recent research has increasingly explored the intersection of artificial intelligence and Islamic knowledge systems, particularly in the context of religious guidance generation and question answering (QA). Early efforts focused on building structured datasets and resources to support AI-driven religious applications. For instance, Alyemny et al. [14] introduced one of the first Arabic religious rulings datasets, compiled from authoritative sources such as the "General Presidency of Scholarly Research and Ifta" in Saudi Arabia [20], prominent scholars including Ibn Othaimin [21], and online repositories like FatwaPedia [22]. This work laid the foundation for developing data-driven AI systems in the Islamic domain.

Building on such resources, several studies have proposed AI-based systems to enhance the reliability of religious question answering. Alan et al. [15] developed MufassirQAS, a retrieval-augmented generation (RAG) system that integrates the Qur'an, Sunnah, and core Islamic teachings as grounding sources. Their findings demonstrated improved response clarity and reduced ambiguity compared to general-purpose models such as ChatGPT. Similarly, Mohammed et al. [16] proposed an advanced RAG-based framework incorporating a Flash re-ranker to reduce hallucinations in AI-generated religious rulings (Fatawa). Their evaluation across multiple models, including AceGPT [23], Gemini-1.5 [24], and SILMA [25], showed that combining RAG with re-ranking significantly improved factual accuracy, albeit at the cost of increased latency.

In parallel, recent work has examined critical reliability aspects of AI systems in religious contexts. Abstention, the ability of a model to refrain from answering when uncertain, has been identified as a crucial requirement in sensitive domains [26]. Atif et al. [27] introduced FiqhQA, a benchmark designed to evaluate LLM performance across different Islamic schools of thought (Madhhabs), highlighting the importance of doctrinal diversity and controlled abstention in AI-generated religious responses. These studies are collectively summarized in Table I.

TABLE I. Summary of AI-based Religious QA Studies

Study	Summary	Research Gap
MufassirQAS [15]	RAG-based QA system using Qur'an, Hadith, and Islamic texts to improve accuracy, reduce hallucinations, and provide source transparency.	Limited generalization, bias issues, and lack of multilingual and contextual depth.
Aftina [16]	RAG framework with re-ranking to improve retrieval quality and reduce hallucinations in AI-generated religious rulings.	Depends on dataset quality; challenges in Arabic understanding and limited domain data.
FiqhQA Benchmark [27]	Introduces a benchmark dataset covering Islamic rulings across four schools of thought and evaluates LLM accuracy and abstention behavior. Shows performance varies by language and model, with weaker results in Arabic.	Lacks standardized evaluation methods, struggles with multilingual reasoning, and highlights need for better abstention, transparency, and alignment with jurisprudential diversity.

While these studies focus primarily on improving the technical performance and reliability of AI systems, a growing body of research has begun to examine how users perceive and interact with AI-generated advice in high-stakes domains. In the medical field, Shekar et al. [1] found that non-expert users often struggle to distinguish between AI-generated and expert-generated responses, and may exhibit high willingness to follow inaccurate AI advice. In the legal domain, Schneiders et al. [2] reported that participants frequently preferred AI-generated advice over professional legal guidance when the source was not disclosed. Similarly, Seabrooke et al. [3] showed that while prior usage of AI for legal advice remains limited, a substantial proportion of users expressed willingness to adopt such tools in the future, particularly for less sensitive topics. Taken together, these studies are summarized in Table II.

TABLE II. Summary of User Perception Studies in High-Stakes AI Domains.

Study	Summary	Research Gap
Medical Domain [1]	Users cannot distinguish AI from doctors and often trust AI responses, even when inaccurate, with willingness to follow harmful advice.	Overtrust in AI and poor error detection; lacks safeguards to prevent harmful reliance.
Legal Domain [2]	Users show higher willingness to act on AI-generated legal advice, especially when the source is unknown, despite being able to distinguish it.	Preference bias toward AI advice without mechanisms to ensure safe decision-making.
Legal Domain [3]	Low current use of AI for legal advice, but strong future willingness, varying by legal domain.	Lacks evaluation of real-world risks, decision quality, and consequences of AI reliance.

Despite these advancements, limited research has investigated public perceptions of AI tools within the religious domain, especially in Islamic contexts where authority, trust, and source credibility play a central role. Existing studies largely emphasize system design, dataset construction, or technical evaluation, with insufficient attention to how users assess trust, risk, and legitimacy when interacting with AI-generated religious guidance.

More recently, emerging studies have begun to explore AI within the context of religious knowledge, user perception, and ethical governance. Alam et al. [11] conducted a mixed-methods investigation of user and expert evaluations of AI-generated religious content, revealing significant challenges in users' ability to assess correctness and reliability. In the Islamic domain, Priantina et al. [12] examined the integration of AI into formulation of religious rulings, highlighting both efficiency gains and critical concerns related to automating

sacred decision-making and weakening scholarly reasoning. Furthermore, a recent large-scale survey by Bhatia et al. [13] synthesized over 160 studies on AI for Islamic knowledge, identifying key gaps in trustworthiness, evaluation frameworks, and governance mechanisms. These findings collectively emphasize that, despite rapid technological advancements, the human-centered dimensions of trust, risk perception, and authority remain underexplored. A summary of these studies is presented in Table III.

TABLE III. SUMMARY OF AI IN RELIGIOUS AND ISLAMIC KNOWLEDGE STUDIES

Study	Summary	Research Gap
[11]	Users prefer AI-generated religious answers (81%) despite claiming trust in scholars; experts identify major quality issues.	User–expert misalignment and limited ability to detect errors; need expert-guided evaluation.
[13]	Comprehensive review of AI systems for Islamic knowledge, highlighting growth of RAG, evaluation methods, and alignment challenges.	Fragmented research, lack of unified evaluation standards, and limited handling of pluralism and trust.
[12]	AI improves efficiency and scalability of formulation of religious rulings but raises concerns about replacing scholarly reasoning.	Ethical risks, lack of governance frameworks, and need for human oversight in decision-making.

A. Research Problem

While the preceding discussion highlights substantial progress in developing AI systems for religious knowledge, including advances in dataset construction, retrieval-augmented generation, and benchmark evaluation, it also reveals important limitations in how these systems are assessed beyond technical performance. In particular, existing research has largely focused on improving accuracy and reducing hallucination in AI-generated outputs [14], [15], [16], [27], with comparatively limited attention to how such outputs are interpreted and evaluated by users in real-world settings.

In parallel, a growing body of work has examined user interaction with AI systems in high-stakes domains such as healthcare and legal advisory, highlighting challenges related to trust, over-reliance, and the difficulty of distinguishing between expert and AI-generated responses [1], [2], [3]. More recent research in the context of religious knowledge has identified additional concerns, including discrepancies between user perception and expert evaluation, risks associated with automating interpretive reasoning, and the absence of comprehensive governance and evaluation frameworks [11], [12], [13]. Despite these advances, existing research remains siloed, with studies typically addressing either system performance or isolated aspects of user perception, rather than providing a comprehensive understanding of how multiple factors interact in shaping user evaluation and use of AI-generated guidance.

A key limitation in the current literature is the lack of an integrated perspective that connects core dimensions of user perception, including trust, perceived risk, privacy, credibility, and user practices, with broader considerations of authority and governance. In domains characterized by interpretive reasoning and contextual judgment, such as religious inquiry, these dimensions are inherently interdependent. However, prior work has largely examined them in isolation, without capturing how concerns related to accuracy, contextual understanding, interaction behaviour, and institutional authority collectively influence the acceptance and use of AI systems.

Furthermore, there is a lack of structured conceptual frameworks that organize the diverse risks associated with AI-generated outputs into coherent and interpretable categories. Existing approaches typically address issues such as hallucination, bias, or misuse as separate challenges, without considering how these risks propagate across technical, behavioural, and institutional levels. This limits the ability to develop a holistic understanding of AI-related risks in high-stakes interpretive contexts.

To the best of our knowledge, large-scale empirical evidence on how users evaluate AI-generated guidance in high-stakes interpretive domains remains limited globally. This gap is particularly pronounced in context-specific environments such as Saudi Arabia, where domain expertise, cultural expectations, and established authority structures play a central role in shaping user behaviour.

To address these gaps, this study presents one of the first large-scale empirical investigations of public perceptions of AI-generated religious guidance in Saudi Arabia, based on a combined quantitative and qualitative analysis of survey data. The work examines how users engage with AI systems and how they evaluate outputs across multiple dimensions, including trust, perceived risk, privacy concerns, and source credibility. In addition, it employs an integrated statistical and machine learning-based analysis to derive structured parameters from open-ended responses, enabling the identification of underlying concerns and expectations through clustering and expert interpretation. Building on this, the study introduces a layered taxonomy of perceived risks structured across four interrelated dimensions: epistemic and knowledge integrity, contextual and reasoning limitations, human–AI interaction dynamics, and socio-technical and institutional impacts. This structured representation captures how concerns originate at the level of AI-generated outputs and propagate through reasoning, user interaction, and institutional contexts, providing a coherent framework for understanding the interdependencies between technical limitations, user behaviour, and governance considerations.

To operationalize these objectives, the study addresses the following research questions:

RQ1. How do individuals in Saudi Arabia engage with and understand AI tools in the context of religious inquiries?

RQ2. How are trust, perceived risk, privacy, and credibility evaluated when AI systems are used to generate religious guidance?

RQ3. How do demographic and domain-specific factors, particularly age and religious knowledge, influence these perceptions and related user practices?

III. METHODOLOGY AND DESIGN

We conducted a survey to examine participants' perceptions regarding the use of AI for generating religious content. The survey was designed to capture both demographic characteristics and participants' perceptions toward AI-generated religious guidance.

The questionnaire consisted of two main parts: 1) Demographic information was collected from participants, including age, gender, level of education, religious background, AI usage, and whether they usually consult scholars or official Islamic websites when seeking religious information. 2) Participants' views on AI-generated religious content. We grouped the related questions, as shown in Table IV. This section captured participants' trust in AI-generated religious content, perceived risks of relying on AI for religious guidance, and perceptions regarding the credibility of AI-generated sources. Open-ended questions were included to allow participants to elaborate on their concerns and provide suggestions regarding the appropriate role of AI in religious contexts.

Note that the questionnaire items were developed based on themes identified in prior literature on trust, credibility, risk perception, and AI usage, and were reviewed for clarity and contextual appropriateness prior to distribution. Internal consistency of the quantitative constructs was subsequently assessed using Cronbach's alpha.

TABLE IV. QUESTIONNAIRE USED IN THE RESEARCH

Variables	Questions	Question type
Familiarity with AI	How often do you request a religious ruling from AI?	Frequency Scale (1–5)
	How deep is your understanding of AI tools?	Ranked categories from high to low understanding
Trust in AI	I trust AI-generated religious rulings	Agreement scale (1–5)
	I believe AI-generated religious rulings are accurate	Agreement scale (1–5)
Perceived Privacy	I prefer to seek religious rulings from AI about things I might feel hesitant to ask someone	Agreement scale (1–5)
Perceived Risk	I feel concerned about the implications of using AI for religious rulings	Agreement scale (1–5)
	I believe that asking AI for religious rulings weakens the relationship between society and scholars	Agreement scale (1–5)
	I believe that seeking religious rulings from AI may reduce the level of concern for the accuracy of religious rulings	Agreement scale (1–5)
Perceived Credibility	I prefer that the AI-generated religious rulings be linked to well-known sources (e.g., the Council of Senior Scholars)	Agreement scale (1–5)
	To what extent do you personally verify the reliability of the source provided by AI before relying on its answer?	Frequency Scale (1–5)
Behavioral Preference	If you encounter a religious ruling from AI that contradicts the religious ruling of a scholar you trust, which one would you follow?	Choice Question
Use Intention	Would you consider asking AI for a religious ruling in the future?	Yes and No question

A. Data Collection

We collect data for our research by conducting a large-scale online study. We recruited participants using different approaches such as email (from both academic and non-academic environments) and from social networks. At the beginning of the research, 573 participants read and gave their consent to participate in the research. The inclusion criteria require participants to be 18 years or older. We included a total of 572 responses in this analysis after we filtered out incomplete responses.

B. Participants

A total of 572 participants (age range of most (74.6%) of our participants was 18-44 years; 169 males and 326 females) who had used AI before. Most of our participants (94.4%), turn to scholars to obtain religious rulings. As shown in Table V, the participants were diverse in terms of age, gender, education level, and religious (Fiqh) background.

TABLE V. DEMOGRAPHIC CHARACTERISTICS OF PARTICIPANTS

Age	18–28 (211, 36.9%), 29–44 (192, 33.6%), 45–60 (152, 26.6%), above 61 (17, 3%)
Gender	Male (188, 32.9%), Female (384, 67.1%)
Educational level	High school (88, 15.4%), Undergraduate (341, 59.6%), Graduate (132, 23.1%), Other (11, 1.9%)
Religious Background	Basic (167, 29.2%), Intermediate (256, 44.8%), Advanced (149, 26%)
Seek Religious Rulings	Scholars (540, 94.4%), Official Islamic websites (32, 5.6%)

C. Data Analysis

Fig. 1 presents the overall architecture adopted in this research, illustrating how quantitative statistical analysis and qualitative BERT-based modeling are integrated to generate a comprehensive understanding of public perceptions of AI-generated religious rulings. The framework begins with survey-based data collection, capturing both structured (closed-ended) and unstructured (open-ended) responses from participants. These two data streams are then processed through parallel analytical pipelines.

The quantitative pipeline focuses on structured responses and applies statistical techniques to measure key constructs such as trust, perceived privacy and risk, and credibility, as well as to examine relationships and demographic effects. In parallel, the qualitative pipeline processes open-ended responses using a BERT-based modeling approach to extract latent themes, enabling the identification of underlying concerns, expectations, and recommendations.

The outputs of both pipelines are subsequently integrated through a triangulation process, ensuring complementarity and cross-validation between statistical patterns and thematic insights. This integration step forms the core of the framework, allowing the research to move beyond isolated results toward a unified interpretation of user perceptions. The final stage translates these integrated insights into a structured understanding of perception patterns, key concerns, and evidence-based implications for the design and governance of AI systems in religious contexts.

While Fig. 1 provides a high-level overview of this analytical architecture, the detailed methodological components of the quantitative and qualitative pipelines are described in the following sections.

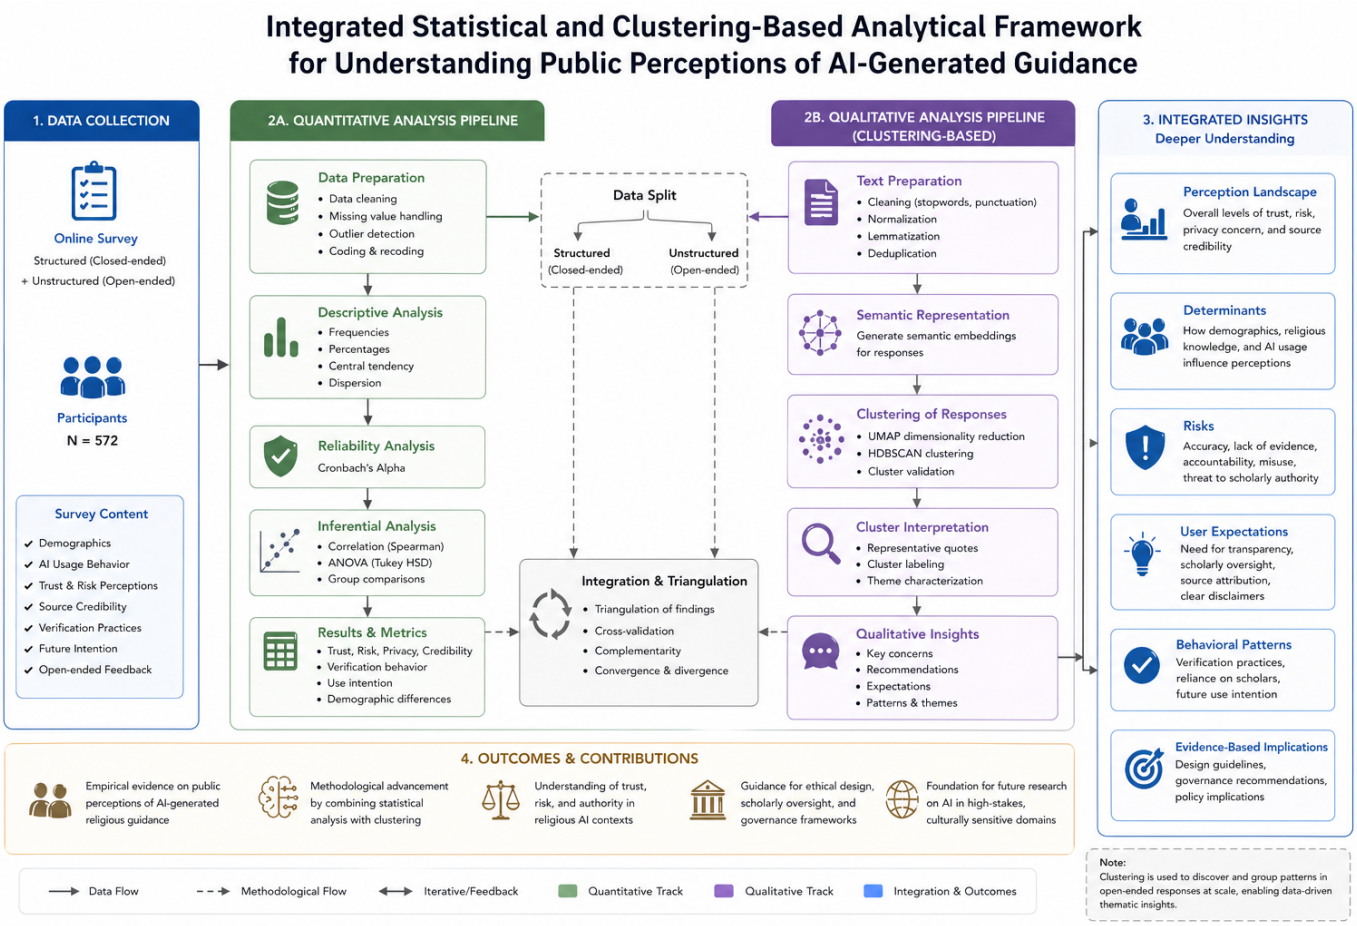

Fig. 1. Integrated statistical and clustering-based analytical framework for examining public perceptions of AI-generated guidance. The figure illustrates the end-to-end methodology combining quantitative statistical analysis of structured survey responses with embedding-based clustering of open-ended responses, followed by an integration and triangulation process. This framework enables the identification of patterns in trust, perceived risk, privacy, credibility, and user behavior, while deriving structured parameters and a layered taxonomy of risks across epistemic, reasoning, interactional, and socio-technical dimensions, supporting a unified interpretation of user perceptions in high-stakes interpretive domains.

D. Quantitative Data Analysis

To analyze the quantitative data and address the research questions, established statistical analysis techniques were employed using SPSS. Descriptive statistics were calculated to summarize the demographic characteristics of the participants. Cronbach's alpha was used to assess internal reliability when using two or three items on a 5-point Likert scale (ranging from Strongly Disagree to Strongly Agree) to measure one variable. If Cronbach's alpha $>= 0.70$, we compute the mean score of the items for the variable.

A one-way ANOVA tests were conducted to investigate whether demographic factors such as age and religious background influence the use of AI by participants when seeking religious rulings. A Tukey HSD post hoc test was conducted after the significant ANOVA result to examine differences between the groups.

E. Parameter Discovery and Qualitative Data Analysis

Open-ended survey responses were analyzed using a structured qualitative modelling pipeline based on BERTopic [17], which integrates transformer-based embeddings, dimensionality reduction, and density-based clustering to identify semantically coherent themes in textual data. Sentence-level embeddings were generated using the Arabic language model CAMeL-Lab/bert-base-arabic-camelbert-mix [28]. These embeddings were projected into a lower-dimensional space using UMAP [18] to preserve local semantic structure while enabling effective clustering. HDBSCAN [19] was then applied to automatically identify clusters without requiring a predefined number of topics.

The analysis was conducted separately on the concerns and suggestions datasets to capture distinct dimensions of user perceptions, namely perceived risks and proposed safeguards. This separation ensures that emergent themes are not conflated during the initial clustering process. Following clustering, topic representations were refined through post-processing, including stopword removal and inspection of representative responses, to improve interpretability while preserving contextual integrity. The resulting clusters were then comparatively examined across datasets to identify recurring and complementary themes.

Finally, clusters were abstracted into higher-level parame-

ters through an iterative human-guided consolidation process, ensuring semantic coherence, conceptual distinctiveness, and alignment with the overall analytical framework. This process resulted in a structured taxonomy of user-perceived risks and considerations associated with AI-generated guidance.

IV. Quantitative Analysis of Structured Survey Responses

Here, in this section, we present the results of the quantitative analysis of the survey data. We begin by reporting descriptive statistics and key patterns related to AI usage, trust, perceived risk, privacy, and credibility, followed by inferential analysis examining relationships between variables and differences across demographic and domain-specific groups. These results establish the empirical basis for the qualitative analysis presented in Section V.

A. Participants' Familiarity and Understanding of AI Tools

To understand the participants' familiarity with AI tools, we first examined how often they used AI for religious rulings, then we assessed the depth of their understanding of AI tools. As shown in Fig. 2, 31.3% of participants stated that they sometimes used AI to obtain religious content, while 30.8% reported that they never use AI for this purpose. Moreover, 18.9% participants reported rarely using AI and only 19% of participants indicated that they use AI often or always. These results show that participants use AI tools sometimes rather than regularly for religious inquiries. It suggests that there is moderate adoption of AI-generated religious rulings, but some people may hesitate or have limited trust in them.

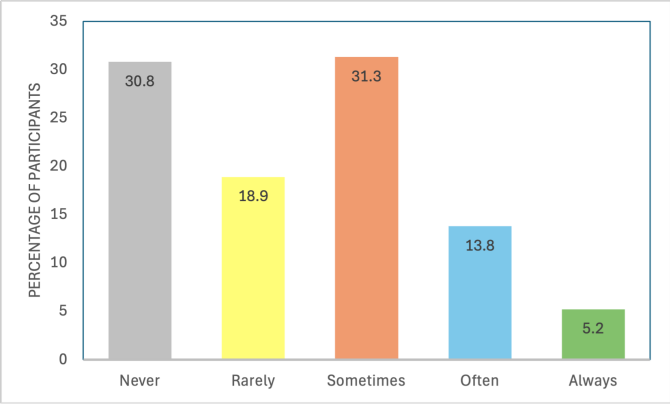

Fig. 2. Frequency of AI use among participants.

Regarding the understanding of AI tools by participants, Fig. 3 shows that 40.4% of participants stated that they have a basic understanding of AI, while 32.7% indicated having only a general knowledge of AI. Moreover, 14.9% of the participants reported that they had no knowledge of AI and only 12.1% stated that they had a deep knowledge of AI tools. The results show that most participants know about AI tools, but few fully understand how these tools work.

To understand the relationship between AI understanding and its frequency of use for religious rulings, we run a Spearman correlation analysis. The results show no significant relationship between AI understanding and its frequency of use for religious rulings (r = 0.035, p = 0.400), indicating that the level of AI understanding does not significantly impact the frequency of using AI for religious rulings. Table VI presents the results on AI familiarity, understanding, and their relationship.

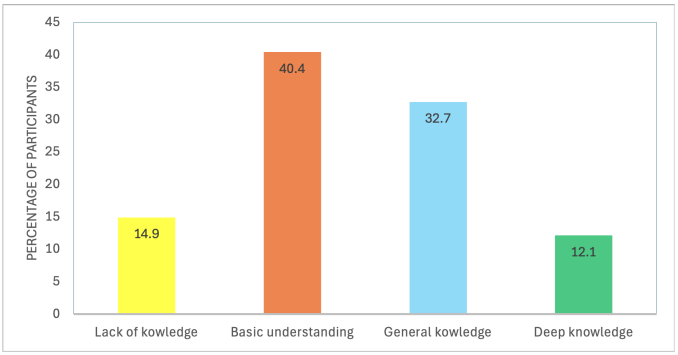

Fig. 3. Percentage of participants' understanding of how AI tools work.

TABLE VI. Summary of AI Familiarity and Understanding

Variable	Results	Interpretation
Familiarity with AI	Often or always (19%) sometimes (31.3%) rarely (18.9%) never (30.8%)	There is moderate adoption of AI-generated religious rulings.
Understanding of AI Tools	Basic understanding (40.4%) general knowledge (32.7%) no knowledge (14.9%) deep knowledge (12.1%)	Most participants are aware of AI tools, but only a few have a deep understanding of how they work.
Understanding AI & Usage	r = 0.035, p= 0.400 relationship between AI understanding and its frequency of use for religious rulings	level of AI understanding does not significantly impact the frequency of using AI for religious rulings.

B. Trust in AI

There are two items that measure the trust in AI for religious rulings, First we examined the reliability of the two items using Cronbach's alpha. The result shows an acceptable internal consistency ($\alpha = 0.785$), indicating that the two items reliably measure the trust in AI for religious rulings. Then we calculated the mean and standard deviation of trust in AI for religious rulings. The results show a mean score of 1.85 (SD = 0.96) based on 572 responses. It suggests that participants show a low level of trust in AI-generated religious rulings.

To understand whether Trust in AI for religious rulings impact the intention to use AI in the future, we run a Spearman correlation analysis. We found a moderate and statistically significant positive relationship (r = 0.499, $p < 0.001$). This indicates that participants with higher levels of trust in AI-generated religious rulings are more likely to consider using AI for religious rulings in the future and vice versa.

We also performed a Spearman correlation analysis to examine the relationship between trust in AI-generated religious rulings and the preference of participants when AI-generated religious rulings contradict those of trusted scholars. The results show a weak but statistically significant positive relationship (r = 0.151, $p < 0.001$). This shows that participants with higher levels of trust in AI-generated religious rulings

are more likely to consider following AI-generated religious rulings, even when they contradict the opinions of trusted scholars. Table VII presents the results of trust in AI-generated religious rulings and its association with use intention and behavioral preference.

TABLE VII. TRUST IN AI-GENERATED RELIGIOUS RULINGS

Variable	Results	Interpretation
Trust in AI for Religious Rulings	M = 1.85, SD = 0.96 based on 572 responses	Participants show a low level of trust in AI-generated religious rulings.
Trust in AI and Use Intention	$r = 0.499$, $p < 0.001$ between trust in AI and use intention	Participants with higher levels of trust in AI-generated religious rulings are more likely to consider using AI for religious rulings in the future, and vice versa.
Trust in AI and Behavioral Preference	$r = 0.151$, $p < 0.001$ between trust in AI and behavioral preference	Participants with higher levels of trust in AI-generated religious inquiries are more likely to consider following AI-generated religious rulings, even when they contradict the opinions of trusted scholars.

C. Perceived Privacy, Risk, and Credibility of AI for Religious Inquiries

We measure the perceived privacy of AI for religious rulings by understanding if participants prefer to seek religious rulings from AI for questions they might feel hesitant to ask others. The results show that a majority of participants do not prefer to seek religious rulings from AI for questions they might feel hesitant to ask others. Fig. 4 shows that 39% of participants strongly disagreed and 13.8% disagreed, while 23.1% remained neutral. Only 24.1% of participants expressed agreement. This indicates that most participants are hesitant to rely on AI for sensitive religious questions.

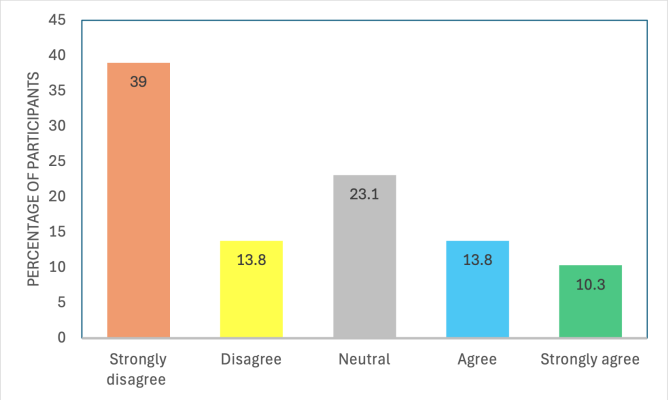

Fig. 4. Percentage of participants using AI for sensitive religious questions.

We examined the reliability of the three-item scale measuring perceived risk of AI using Cronbach's alpha. The results indicated acceptable internal consistency ($\alpha = 0.737$), suggesting that the three items reliably measure the perceived risk of AI. The mean clarifies that participants have a high level of perceived risk regarding the use of AI for religious rulings (M = 3.99, SD = 1.02, N = 572). This suggests that participants generally agree with statements expressing concerns about the implications of AI-generated religious rulings.

Perceived credibility of AI-generated religious rulings was examined using two indicators: Participants' tendency to verify the reliability of sources provided by AI and their preference for AI-generated religious rulings linked to well-known scholarly authorities. Regarding participants' tendency to verify the reliability of sources provided by AI, the results show that participants consider the importance on checking the credibility of AI-generated religious rulings. As shown in Fig. 5, they always verify the reliability of sources (28.8%), followed by 24.8% who indicated that they often verify them. Overall, 51.4% of participants reported that they often or always verify the reliability of sources provided by AI, highlighting the importance of credible references when relying on AI-generated religious rulings.

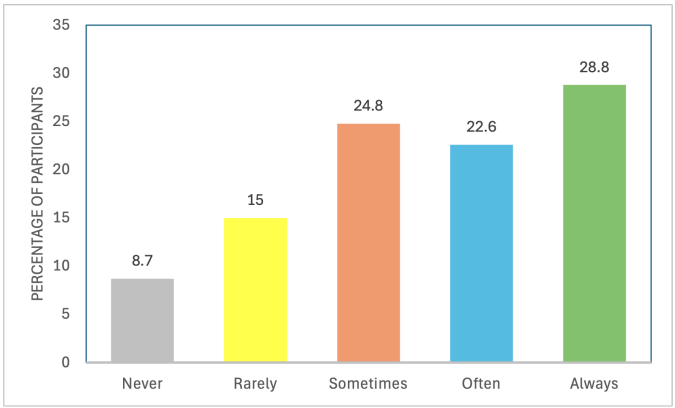

Fig. 5. Percentage of participants verifying the reliability of sources provided by AI.

Regarding participants' preference for AI-generated religious rulings linked to well-known scholarly authorities, the results show strong support for linking AI-generated religious rulings to well-known scholarly sources. Fig. 6 shows that the majority of participants strongly agreed (65.6%) to link AI-generated religious rulings to well-known scholarly sources, while 14% agreed, resulting in 79.6% expressing agreement overall. These results highlight the importance of authoritative references in enhancing the perceived credibility of AI-generated religious guidance.

To find the relationship between Participants' tendency to verify the reliability of sources provided by AI and their preference for AI-generated religious rulings linked to well-known scholarly authorities, we run a Spearman correlation analysis. The results revealed a weak but statistically significant positive relationship (r = 0.103, p = 0.014), that people who verify AI sources more frequently show a slightly stronger preference for AI-generated religious rulings supported by authoritative references. As illustrated in Table VIII, participants' perceptions of privacy, risk, and credibility shape their views on using AI for religious inquiries.

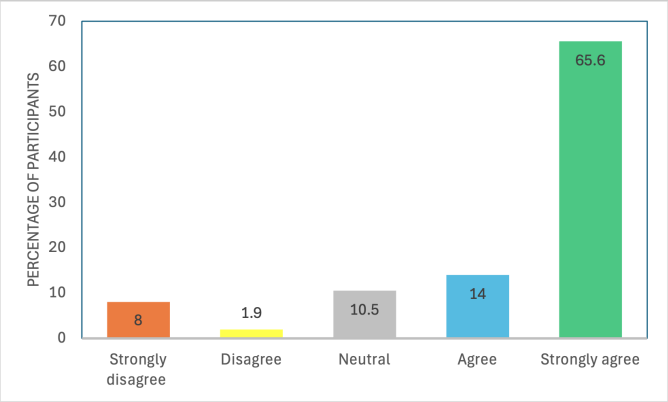

Fig. 6. Percentage of participants preferring for AI-generated religious rulings linked to well-known scholarly authorities.

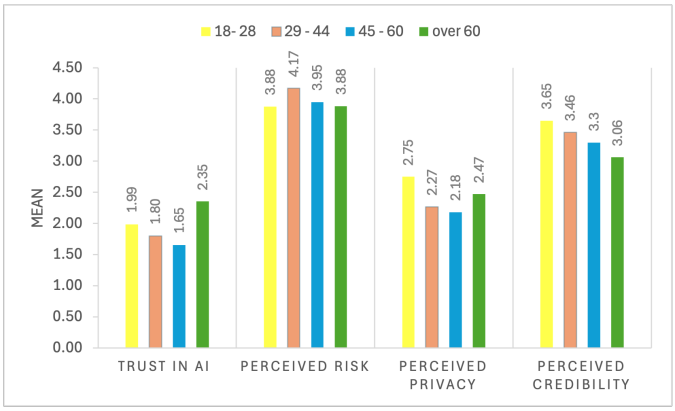

Fig. 7. Participants' perceptions based on age (Mean Values).

TABLE VIII. PERCEIVED PRIVACY, RISK, AND CREDIBILITY OF AI FOR RELIGIOUS INQUIRIES.

Variable	Results	Interpretation
Perceived Privacy	strongly disagreed (39%) disagreed (13.8%) neutral (23.1%) agree (13.8%) strongly agree (10.3%)	Most participants are hesitant to rely on AI for sensitive religious inquiries.
Perceived Risk	M = 3.99, SD = 1.02 based on 572 responses	Participants have a high level of perceived risk regarding the use of AI for religious inquiries.
Perceived Credibility	1- Tendency to verify reliability of sources: often or always (51.4%) sometimes (24.8%) rarely (15%) never (8.7%) 2- Preference for linking AI to scholarly authorities: strongly agree (65.6%) agree (14%) neutral (10.5%) disagree (1.9%) strongly disagree (8%) Relationship between (1) and (2): $r = 0.103$, $p = 0.014$	The importance of credible and authoritative references improves the perceived credibility of AI-generated religious inquiries. Participants who frequently verify sources are more likely to prefer linking AI to well-known scholarly authorities.

D. The Impact of Age Toward Using AI-Generated Religious Rulings

To examine whether age influence participants toward AI-generated religious rulings, we conducted one-way ANOVA analyses followed by a Tukey HSD post hoc test to identify differences between age groups. The overall trends are illustrated in Fig. 7.

1) Trust in AI: The results showed a statistically significant difference in trust levels [F(3,568) = 5.342, p = 0.001], indicating that trust in AI-generated religious rulings varies significantly among the age groups.The results of Tukey HSD post hoc showed that participants age range of 18-28 years reported significantly higher trust in AI-generated religious rulings compared to age group (45 - 60) (p = 0.006). Additionally, participants age over 60 showed significantly higher trust levels than participants age range 45 - 60 (p = 0.022). No other significant differences between age groups were observed.

2) Perceived risk: The results revealed a statistically significant difference in perceived risk among the age groups [F(3,568) = 3.073, p = 0.027], indicating that perceived risk of AI-generated religious rulings varies significantly between the groups. The results of Tukey HSD post hoc showed participants age range 29 - 44 perceived significantly higher risk of AI-generated religious rulings than those age range 18-28 (p = 0.019), while no other significant differences between age groups were found.

3) Perceived privacy: The results revealed a statistically significant difference among the age groups [F(3,568) = 6.481, $p < 0.001$], indicating that the willingness to consult AI for sensitive religious questions varies significantly between the groups. The results of Tukey HSD post hoc show that participants in age range (18-28) reported significantly higher willingness to consult AI for sensitive religious questions compared with participants 29-44 (p = 0.002) and participants age 45-60 ($p < 0.001$). No significant differences were observed between the remaining age group comparisons.

4) Perceived credibility: The results revealed a statistically significant difference between the age groups [F(3,568) = 2.905, p = 0.034], indicating that the tendency to verify AI-generated sources varies significantly among the groups. Post hoc comparisons using the Tukey HSD test revealed that participants in age range (18-28) verify AI-generated sources significantly more often than those in age (29-44) (p = 0.049), while no other significant differences were found among the age groups.

Overall, age has a significant influence on Participants' perception toward AI-generated religious rulings. Post hoc analysis indicated that participants in the youngest age group reported greater willingness to seek religious rulings from AI for questions they might feel hesitant to ask others, compared with some older age groups. Additionally, younger participants showed slightly higher levels of source verification behaviour than some other age groups. As shown in Table IX, age differences play a significant role in shaping trust, perceived risk, privacy concerns, and credibility of AI-generated religious information.

TABLE IX. AGE DIFFERENCES IN TRUST, RISK, PRIVACY, AND CREDIBILITY.

Variable	Results	Interpretation
Trust in AI	F = 5.342 $p = 0.001$ Post hoc (Tukey): (18–28) > (45–60): $p = 0.006$ (60+) > (45–60): $p = 0.022$	Participants aged 18–28 showed higher trust and greater willingness to use AI for sensitive religious inquiries, along with more frequent verification of AI-generated sources.
Perceived Risk	F = 3.073 $p = 0.027$ Post hoc (Tukey): 29–44 > 18–28: $p = 0.019$	Participants aged 29–44 reported higher perceived risk than younger participants.
Perceived Privacy	F = 6.481 $p = 0.001$ Post hoc (Tukey): 18–28 > 29–44: $p = 0.002$ 18–28 > 45–60: $p = 0.001$	Younger participants (18–28) showed higher concern about privacy compared to older groups.
Perceived Credibility	F = 2.905 $p = 0.034$ Post hoc (Tukey): (18–28) > (29–44): $p = 0.049$	Younger participants tend to perceive AI-generated religious information as more credible compared to middle-aged participants.

E. The Impact of Religious Background Toward Using AI-Generated Religious Content

To examine whether religious background influences participants toward AI-generated religious rulings, we conducted one-way ANOVA analysis followed by a Tukey HSD post hoc test to identify differences between groups. The overall differences across religious background levels are illustrated in Fig. 8.

1) Trust in AI: The results indicated a statistically significant difference in trust levels [F(2,569) = 9.834, p $<$ 0.001], suggesting that trust in AI-generated religious rulings varies significantly across people with different religious background. The results of a Tukey HSD post hoc text showed that participants with basic level of religious background reported significantly higher trust compared with those with intermediate (p = 0.003) and advanced levels of religious knowledge (p $<$ 0.001). No significant difference was found between intermediate and advanced religious knowledge levels.

2) Perceived risk: The results revealed a statistically significant difference in perceived risk [F(2,569) = 9.778, p $<$ 0.001], indicating that perceived risk varies significantly across people with different level of religious background. The results of Tukey HSD post hoc showed participants with basic level of religious background reported significantly lower perceived risk compared to those with intermediate (p = 0.003) and advanced religious knowledge (p $<$ 0.001). No significant difference was observed between the intermediate and advanced groups.

3) Perceived privacy: The results revealed a statistically significant difference among the participants with different level of religious background [F(2,569) = 4.113, p = 0.017], indicating that willingness to ask AI for sensitive religious questions varies significantly between groups. The results of a Tukey HSD post hoc show that participants with basic level of religious background reported significantly higher willingness to ask AI for sensitive religious questions compared with those with higher religious background (p = 0.021) and intermediate level of religious knowledge (p = 0.05). No statistically significant differences were observed between intermediate and advanced levels of religious background.

4) Perceived credibility: The results revealed a statistically significant difference between the groups [F(2,569) = 7.611, p $<$ 0.001], indicating that the tendency to verify AI-generated sources varies significantly between the groups. Post hoc comparisons using the Tukey HSD test revealed that participants in advanced religious knowledge level reported significantly higher verification of AI sources compared with those in basic religious knowledge level (p $<$ 0.001) and intermediate religious knowledge level (p = 0.036). No significant difference was found between basic religious knowledge level and intermediate religious knowledge level.

Overall, participants with basic levels of religious knowledge reported significantly higher trust in AI-generated religious rulings, greater willingness to ask AI for sensitive religious questions, and lower perceived risk compared to those with intermediate and advanced levels of religious knowledge. However, participants with advanced religious knowledge were more likely to verify the reliability of sources provided by AI, indicating greater scrutiny when evaluating AI-generated religious rulings. As illustrated in Table X, differences in religious knowledge levels significantly influence trust, perceived risk, privacy, and credibility of AI.

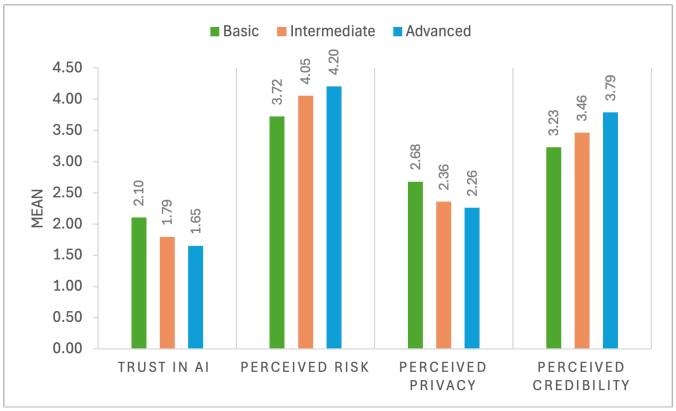

Fig. 8. Participants' perceptions based on the level of religious background (Mean Values).

V. QUALITATIVE ANALYSIS OF OPEN-ENDED SURVEY RESPONSES

The qualitative analysis of participants' open-ended responses provides deeper insight into how individuals interpret and evaluate the use of AI systems in high-stakes, interpretive contexts. While the quantitative results establish broad patterns related to trust, perceived risk, privacy perceptions, and credibility, the qualitative analysis reveals the underlying reasoning, concerns, and expectations that shape these perceptions.

Using a machine learning–based text analysis pipeline, responses were clustered and iteratively refined to extract coherent themes. These themes were interpreted as structured parameters capturing participants' perceptions. To ensure conceptual clarity and avoid overlap, the resulting parameters were organized into a hierarchical taxonomy consisting of four macro-dimensions (macro-parameters). These macro-parameters reflect distinct layers within the broader socio-technical system in which AI operates, spanning multiple

TABLE X. DIFFERENCES BASED ON RELIGIOUS KNOWLEDGE LEVELS

Variable	Results	Interpretation
Trust in AI	F = 9.834 $p = 0.001$ Post hoc (Tukey): Basic > Intermediate: $p = 0.050$ Basic > Advanced: $p = 0.021$	Participants with basic religious knowledge showed higher trust, lower perceived risk, and greater willingness to use AI for sensitive religious inquiries compared to those with intermediate and advanced levels.
Perceived Risk	F = 9.778 $p = 0.001$ Post hoc (Tukey): Basic < Intermediate: $p = 0.003$ Basic < Advanced: $p = 0.001$	Participants with advanced religious knowledge reported higher perceived risk compared to those with basic knowledge.
Perceived Privacy	F = 4.113 $p = 0.017$ Post hoc (Tukey): Basic > Intermediate: $p = 0.050$ Basic > Advanced: $p = 0.021$	Participants with lower religious knowledge expressed greater privacy concerns than those with higher knowledge levels.
Perceived Credibility	F = 7.611 $p = 0.001$ Post hoc (Tukey): Advanced > Basic: $p < 0.001$ Advanced > Intermediate: $p = 0.036$	Participants with advanced religious knowledge were more likely to verify AI-generated sources, indicating greater critical evaluation.

layers: knowledge integrity (what AI generates and how reliable it is), reasoning capability (how AI interprets and adapts responses), human interaction (how users engage with and rely on AI), and institutional impact (how AI affects authority, governance, and decision structures).

Specifically, the taxonomy is structured into: 1) Epistemic and Knowledge Integrity Risks, which capture concerns related to correctness, evidence, and reliability of AI-generated outputs; 2) Contextual and Reasoning Limitations, which reflect the inability of AI systems to incorporate situational and case-specific nuances; 3) Human–AI Interaction Risks, which describe how users engage with and are influenced by AI systems; and 4) Socio-Technical and Institutional Risks, which capture the broader implications of AI use on authority structures and governance.

This structured approach enables a systematic understanding of participants' perceptions, moving beyond isolated concerns toward a layered interpretation of risks associated with AI-generated guidance.

A. Perceived Risks in AI-Generated Religious Guidance

The analysis of participants' responses revealed a set of distinct but interrelated risk categories associated with the use of AI for generating religious guidance. These risks reflect concerns not only about the technical behaviour of AI systems, but also about their epistemic validity, interaction dynamics, and broader institutional implications.

Table XI presents the finalized taxonomy of perceived risks, organized across the four macro-parameters described above, along with representative quotes from participants.

The identified risks demonstrate that participants' concerns extend beyond isolated technical issues and instead reflect a multi-layered understanding of AI systems operating within a socio-technical context.

TABLE XI. TAXONOMY OF PERCEIVED RISKS WITH REPRESENTATIVE QUOTES

Macro	Parameter	Interpretation	Representative Quotes
Epistemic & Knowledge Integrity	Epistemic Unreliability	Responses may lack correctness, clarity, and evidential strength.	- Reliance on weak evidence - Low accuracy and limited domain knowledge - Answers may contradict established knowledge
	Fabrication & Hallucination	Systems may generate fabricated or non-existent information with high confidence.	- Produces hallucinated information - Cites references that do not exist - Generates incorrect information
	Lack of Authoritative Grounding	Outputs are not anchored in trusted or recognized sources.	- Not connected to recognized scholars - Not based on a trusted source
	Doctrinal Inconsistency	Systems may mix interpretive frameworks without clear methodology.	- Mixing beliefs and sects - Mixing correct and incorrect positions - Manipulation of interpretations
Contextual & Reasoning Limitations	Contextual Insensitivity	Systems fail to account for individual circumstances and situational nuance.	- Cannot adapt rulings to individual situations - Each individual requires a specific ruling
Human–AI Interaction Risks	Preference Alignment Bias	Outputs may align with user expectations rather than truth (sycophancy).	- Distorts answers to satisfy the user - Provides answers at the expense of truth
	Overdependence on AI	Users may rely excessively on AI without verification or independent reasoning.	- Complete reliance on AI - Not using human reasoning or verification
Socio-Technical & Institutional Risks	Displacement of Domain Authority	AI may weaken reliance on domain experts and alter authority structures.	- Abandoning domain experts - Reducing the authority of experts

At the epistemic level (Epistemic and Knowledge Integrity), participants emphasize the importance of correctness, evidence, and source credibility, highlighting concerns about unreliable outputs, fabricated information, and weak grounding in authoritative knowledge. These concerns align closely with the quantitative results, which indicate low trust and high perceived risk.

At the reasoning level (Contextual and Reasoning Limitations), participants identify limitations in the ability of AI systems to handle context-dependent scenarios. This reflects a recognition that certain forms of decision-making require not only information retrieval but also contextual interpretation and situational judgment.

At the interaction level (Human–AI Interaction Risks), concerns shift toward how users engage with AI systems. Participants highlight the risk of overdependence, as well as the tendency of AI systems to produce responses that align with

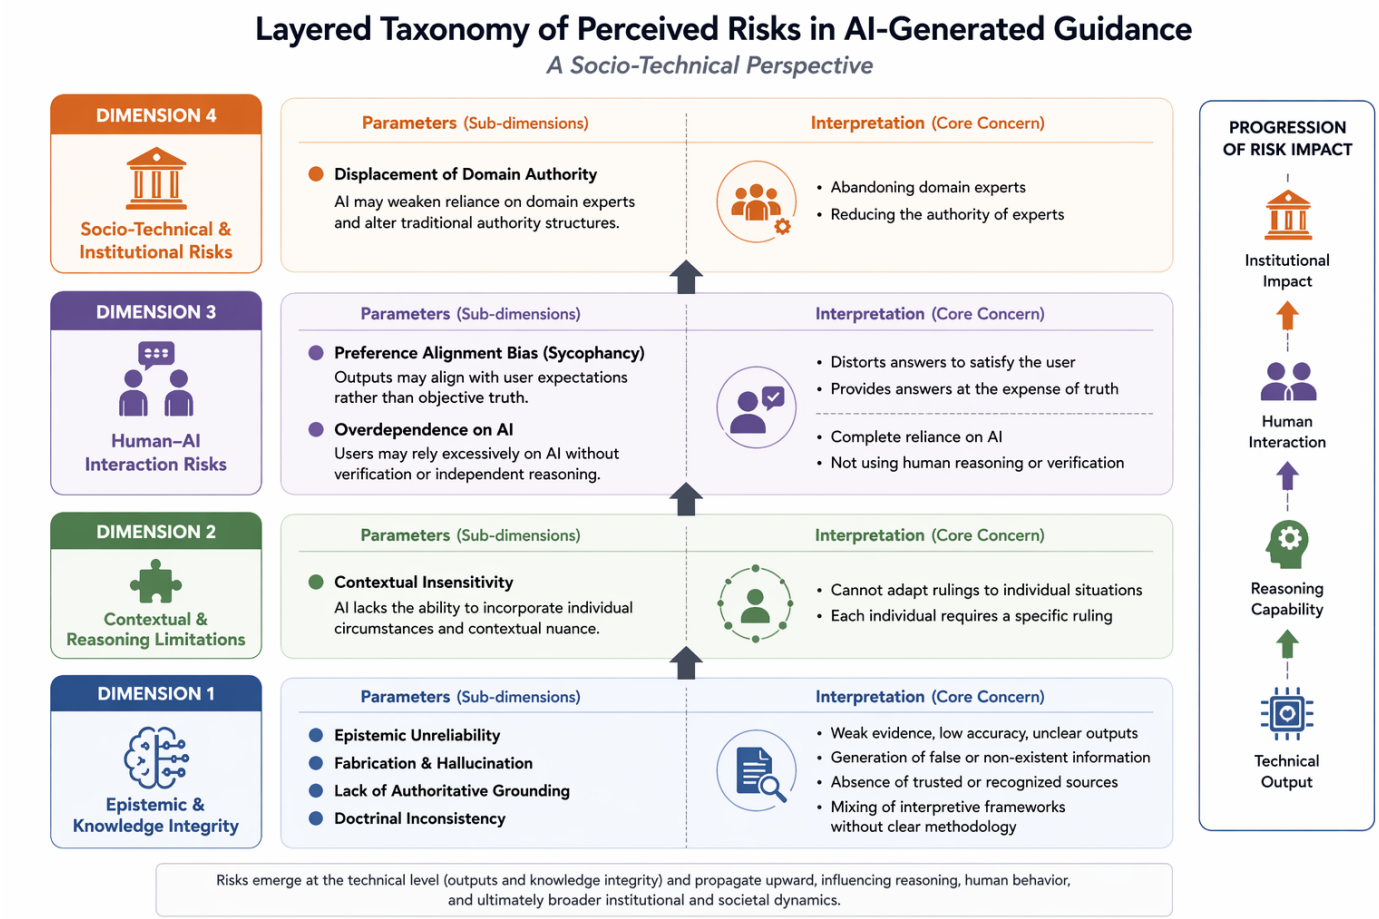

Fig. 9. Framework and layered taxonomy of perceived risks in AI-generated guidance. The figure organizes risks into four macro-parameters: Epistemic and Knowledge Integrity, Contextual and Reasoning Limitations, Human–AI Interaction Risks, and Socio-Technical and Institutional Risks, showing how risks evolve from AI output-level issues to reasoning, interaction, and institutional impacts.

user expectations, potentially reinforcing incorrect beliefs. This behavior aligns with emerging concerns around AI sycophancy, where systems adapt outputs to satisfy users rather than reflect accurate or evidence-based information. This is consistent with observed behavioural patterns in the quantitative analysis, where moderate usage persists despite low trust.

Finally, at the socio-technical level (Socio-Technical and Institutional Risks), participants express concerns about the broader implications of AI adoption, particularly in relation to established authority structures. The potential displacement of domain experts reflects a deeper concern about legitimacy, accountability, and the appropriate role of AI in high-stakes contexts.

These results collectively suggest that participants do not evaluate AI solely based on performance, but rather through a combination of epistemic, behavioural, and institutional considerations. This multi-dimensional perspective is critical for understanding how AI systems are perceived in domains where accuracy, authority, and contextual reasoning are essential.

Fig. 9 presents a visual representation of the framework and layered taxonomy of perceived risks identified in this research. The figure complements Table XI by organizing the parameters into four macro-parameters that reflect distinct but interrelated layers of a socio-technical system. Specifically, the taxonomy illustrates how risks originate at the epistemic and knowledge integrity level, propagate through contextual and reasoning limitations, influence human–AI interaction dynamics, and ultimately extend to broader socio-technical and institutional impacts. This layered structure highlights how lower-level technical limitations in AI outputs can propagate through reasoning and user interaction, ultimately shaping broader institutional and governance outcomes.

B. Governance Expectations for AI Systems

In addition to identifying risks, participants articulated a set of expectations regarding how AI systems should be designed, deployed, and governed in order to be considered acceptable and trustworthy. These expectations reflect a constructive perspective, indicating that users do not reject AI outright but instead advocate for its controlled and responsible use. These expectations also implicitly relate to privacy concerns identified in the quantitative analysis, particularly in scenarios where users may prefer AI-mediated interactions for sensitive inquiries, while remaining uncertain about data handling and confidentiality.

The analysis revealed two primary parameters of gover-

nance expectations: 1) Transparency and verification mechanisms, and 2) Human oversight and institutional governance.

The first category emphasizes the need for AI-generated responses to be supported by clear, verifiable, and authoritative sources. Participants consistently highlighted the importance of transparency in how responses are generated, particularly the inclusion of reliable references that can be independently verified. This expectation directly corresponds to concerns related to epistemic unreliability and lack of authoritative grounding, suggesting that users seek mechanisms that enhance trust through evidence and traceability.

The second category focuses on the role of human expertise and institutional oversight. Participants emphasized that AI systems should not operate independently in high-stakes domains, but rather under the supervision of qualified experts and recognized institutions. This reflects a strong preference for maintaining human accountability and preserving established authority structures, particularly in contexts where interpretive judgment is required.

These governance expectations demonstrate that participants envision a hybrid model of AI use, in which AI systems function as supportive tools rather than autonomous decision-makers. The alignment between identified risks and proposed governance mechanisms highlights a coherent user perspective: the same concerns that reduce trust in AI also inform the conditions under which AI may become acceptable.

VI. Discussion

This research provides a comprehensive understanding of how individuals perceive the use of AI systems in high-stakes, interpretive domains by integrating quantitative and qualitative analyses, with a particular focus on religious inquiry in Saudi Arabia. The results reveal a consistent and nuanced pattern: participants engage with AI-generated guidance in a limited and cautious manner, characterized by moderate usage, low trust, and high perceived risk, while still recognizing the potential utility of these systems under constrained conditions.

The quantitative results establish the structural patterns underlying this behaviour. Participants reported only occasional use of AI for religious inquiries, despite widespread exposure to such tools. Trust emerged as a central determinant of behavioural intention, with higher trust associated with increased willingness to use AI and, in some cases, to follow its outputs even when they conflict with trusted human experts. However, overall trust levels remained low, while perceived risk remained high. This combination indicates not rejection, but selective and conditional engagement. Participants do not treat AI as an authoritative source, but neither do they disregard it entirely. Instead, they adopt a cautious usage model in which AI is consulted but not relied upon without verification. This is further reinforced by strong preferences for source credibility, where the majority of participants actively verify AI-generated outputs and express a clear expectation that responses be linked to recognized scholarly authorities.

These patterns are further shaped by demographic and knowledge-based factors. Younger participants demonstrate greater openness to AI use, particularly in sensitive contexts, suggesting that accessibility and privacy-related affordances may lower barriers to engagement. In contrast, participants with stronger domain knowledge exhibit lower trust, higher perceived risk, and more rigorous verification behaviour. This indicates that familiarity with the domain introduces critical evaluation mechanisms that limit reliance on AI-generated outputs. Together, these results highlight that engagement with AI is not uniform, but mediated by both technological familiarity and epistemic grounding.

While the quantitative results describe these behavioural patterns, the qualitative analysis explains their underlying structure. The taxonomy of perceived risks reveals that participants evaluate AI systems across multiple interconnected dimensions rather than isolated concerns. At the epistemic level, concerns focus on correctness, evidence, and reliability, including risks of weak grounding, fabricated information, and inconsistent interpretations. At the reasoning level, participants highlight limitations in contextual understanding, recognizing that AI systems cannot adequately account for situational nuance or case-specific factors. At the interaction level, concerns shift toward behavioural dynamics, including overdependence and preference alignment, where AI systems may produce responses that align with user expectations rather than objective truth, reflecting emerging concerns around AI sycophancy. At the socio-technical level, participants express concern about the broader implications of AI adoption, particularly the potential displacement of domain authority and the erosion of established structures of expertise.

The integration of these results represents a key contribution of this work. Rather than treating trust, risk, and behaviour as independent variables, the results demonstrate that they are structurally linked. Low trust and high perceived risk observed in the quantitative analysis are directly explained by epistemic and reasoning concerns identified in the qualitative results. Similarly, observed verification behaviours correspond to concerns about credibility and lack of authoritative grounding, while conditional acceptance of AI aligns with expectations for human oversight and governance. This layered interpretation shows that user perception of AI is not driven solely by system performance, but by how technical limitations propagate through reasoning, interaction, and institutional contexts.

These results should be understood within a broader transformation in how knowledge and authority are mediated in digital environments. Existing literature suggests that AI in such domains does not merely expand access to information but reshapes how authority is constructed, circulated, and evaluated [29]. Prior work has shown that users increasingly question the credibility, contextual relevance, and institutional grounding of mediated guidance, particularly in domains where expert interpretation and contextual reasoning are essential [30]. The present research extends this literature by providing empirical evidence from Saudi Arabia on how users actively negotiate this shift in practice: while AI systems improve accessibility and immediacy, their acceptance remains conditional on trust, verification, and alignment with recognized sources of authority.

The results also align with and extend recent work on AI-generated religious content and Islamic knowledge systems. Alam et al. [11] demonstrate, in a study of Muslim American users, that users may prefer AI-generated religious answers even when expert evaluation identifies significant quality con-

cerns, highlighting the gap between perceived usefulness and actual reliability. The present results extend this understanding by examining similar dynamics within Saudi Arabia, where expectations of authority, trust, and verification are shaped by a distinct religious, cultural, and institutional context. Similarly, Priantina et al. [12] show that while AI can improve efficiency in religious ruling related processes, it raises important concerns about automating scholarly reasoning and weakening human oversight. Bhatia et al. further identify broader challenges in AI-based Islamic knowledge systems, including trustworthiness, evaluation standards, pluralism, and governance gaps [13]. This research contributes to these discussions by shifting the focus from system performance to user perception, demonstrating how trust, risk, privacy, credibility, and authority are evaluated in real-world use rather than controlled system settings.

More broadly, the results connect with established challenges in large language models and generative AI. Participants' concerns about inaccurate or misleading outputs correspond directly to the well-documented problem of hallucination, where systems generate fluent but factually incorrect or unsupported information [4], [27]. In high-stakes contexts, such outputs may be interpreted as authoritative despite lacking reliable grounding. Similarly, concerns about preference alignment reflect emerging work on AI persuasion and safety, where generative systems may shape user beliefs and decisions rather than simply provide neutral information [5], [31]. These risks are consistent with broader taxonomies of language-model harms, including misinformation, bias, privacy risks, and interaction-level failures [32], [33].

The results also resonate with literature on trust, explanation, and human–AI interaction. Research on trust in automation shows that achieving appropriate reliance is inherently difficult, as users may either over-rely on automated systems or reject them entirely depending on perceived reliability [34]. In contrast, this research identifies a more nuanced behavioral pattern characterized by cautious engagement and active verification, suggesting the emergence of calibrated trust in high-stakes contexts. At the same time, explainability research indicates that explanations can improve user understanding but may also increase acceptance of incorrect outputs when users lack sufficient expertise to critically evaluate them [35], [36]. This highlights a critical implication: transparency and explainability are necessary but not sufficient. In interpretive domains, they must be complemented by expert validation, institutional oversight, and mechanisms for accountability.

From a theoretical perspective, this research contributes a socio-technical model of AI risk perception in which concerns emerge across interconnected layers rather than isolated system failures. By organizing perceived risks into epistemic, reasoning, interaction, and institutional dimensions, the proposed taxonomy provides a structured framework for understanding how technical limitations in AI systems propagate into behavioral and governance challenges. This extends existing work on foundation models and AI risk by grounding abstract categories in empirically observed user perceptions and linking system-level behaviour with real-world interpretation and use [32], [33], [37]. In doing so, the research bridges technical AI research with human-centered and governance-oriented perspectives on trust, authority, and decision-making.

The results also have important implications for AI governance and system design [38], [39]. Participants consistently emphasized the need for transparency, particularly through the provision of verifiable and authoritative sources. However, the results suggest that transparency alone is insufficient in high-stakes interpretive contexts. Users not only expect explanations, but also require mechanisms to assess their validity, especially when they lack the expertise to independently verify the information provided. This reinforces the need for governance frameworks that combine explainability with validation, accountability, and oversight [35], [36], [37]. In addition, participants consistently rejected the idea of AI systems functioning as autonomous authorities. Instead, they expressed a strong preference for models in which AI operates under human supervision, particularly by domain experts. This aligns with broader risk-based governance approaches, where human-in-the-loop mechanisms are considered essential for high-risk applications [34], [37].

Importantly, the results highlight a tension between accessibility and authority. While AI systems increase access to information and provide immediate responses, they do not inherently carry the legitimacy associated with expert judgment. Participants' emphasis on verification and reliance on trusted sources indicates that authority remains a central condition for acceptance, even in the presence of highly accessible AI tools. Rather than replacing established structures of expertise, AI systems are therefore more likely to be accepted as assistive tools that complement, rather than substitute, human authority. This reflects a broader pattern observed in other high-stakes domains, where users value the efficiency and clarity of AI systems but continue to depend on expert validation for final decisions [40].

From a practical perspective, the results suggest that AI systems in high-stakes advisory domains require governance models that combine verifiable source grounding, human oversight, and institutional accountability. These expectations align with broader concerns about foundation models, where scale, opacity, and downstream deployment amplify risks across domains [37]. They also reflect patterns observed in other domains such as healthcare, where users value AI-generated responses for accessibility and clarity but continue to rely on human experts for validation and safe decision-making [40]. Together, these results point toward a hybrid governance model that supports human autonomy, enables calibrated trust, and preserves the role of domain expertise.

Finally, while this research is situated within a specific cultural and religious context, the underlying dynamics are likely to extend to other high-stakes interpretive domains, including healthcare, legal advisory, education, and policy decision-making, where similar concerns around trust, expertise, and decision-making have been observed [40], [1], [2]. In these contexts, trust, privacy, contextual reasoning, authority, and institutional legitimacy remain central to responsible AI deployment. Accordingly, the proposed framework should be understood as a structured analytical foundation for examining how technical, behavioural, and institutional risks interact in high-stakes interpretive settings, rather than as a universally validated model across all domains. The research, therefore, contributes to a broader shift in AI research from system-centric performance toward human-centred and governance-

oriented understanding of AI in practice.

VII. Conclusion

This research provides a comprehensive examination of how individuals perceive the use of AI systems in high-stakes interpretive domains, using the context of religious inquiries in Saudi Arabia as an empirical setting. By integrating quantitative and qualitative analyses, the results reveal a consistent pattern characterized by moderate engagement with AI tools, low levels of trust, and heightened perceptions of risk. Users demonstrate a cautious and conditional approach, treating AI-generated responses as supportive resources rather than authoritative sources.

The results highlight that trust, perceived risk, and source credibility are central determinants of user behaviour. Participants consistently emphasized the importance of verifiable and authoritative grounding, frequently engaging in source verification and expressing strong preference for responses linked to recognized experts. At the same time, reluctance to rely on AI for sensitive or complex inquiries underscores the context-dependent nature of AI acceptance. Demographic factors, particularly age and domain knowledge, further shape how individuals interpret, evaluate, and interact with AI-generated outputs.

Beyond descriptive insights, this research advances understanding by introducing a structured, multi-layered taxonomy of perceived risks, spanning epistemic, reasoning, interactional, and institutional dimensions. This framework demonstrates that concerns are not limited to technical limitations, but extend to broader issues of authority, accountability, and governance. The alignment between identified risks and user expectations further reveals that acceptance of AI is contingent on the presence of transparency, human oversight, and institutional anchoring.

These results carry important implications for the design and governance of AI systems in high-stakes contexts. Enhancing transparency through verifiable sourcing, incorporating human-in-the-loop mechanisms, and establishing clear governance boundaries are essential for building trustworthy and socially aligned AI systems. Rather than replacing established structures of expertise, AI systems are more likely to be accepted when positioned as assistive tools operating within well-defined ethical and institutional frameworks.

While this research is grounded in a specific cultural and religious context, the underlying dynamics are likely to extend to other domains where interpretive judgment, trust, and accountability are critical. At the same time, the participant distribution was skewed toward younger and relatively educated respondents within a single national setting, which may influence the broader generalizability of the reported perceptions and behavioral patterns. This positions the work within a broader discourse on responsible AI, highlighting the need to align technological capabilities with human expectations, domain expertise, and societal values, while also motivating future cross-cultural and demographically diverse investigations.

Future research can build on these results by exploring cross-cultural variations, longitudinal shifts in trust, and experimental evaluations of AI systems integrated with expert validation mechanisms. Additional directions include real-world system evaluations, adversarial robustness testing of AI-generated guidance, and longitudinal trust calibration studies examining how user perceptions evolve through repeated interaction with AI systems over time.

To conclude, AI systems hold significant potential to enhance access to complex knowledge domains. However, their acceptance depends not only on technical performance, but also on their ability to operate within trusted epistemic and institutional structures. The challenge, therefore, is not merely to improve AI systems, but to design them in ways that respect, support, and reinforce the foundations of human expertise and judgment.

***Abstract*—Early detection of corporate bankruptcy is essential for maintaining financial market stability and reducing systemic risk. However, existing predictive models often struggle under conditions of extreme class imbalance. Traditional approaches either analyze financial ratios or textual disclosures in isolation, while conventional cross-modal fusion strategies tend to dilute rare distress signals when integrating structured accounting metrics with qualitative management narratives. Consequently, subtle indicators of impending corporate failure are frequently overshadowed by dominant non-distress patterns, limiting the effectiveness of existing predictive systems. To bridge this methodological limitation, this study proposes D-HAN-Net, a hybrid dual-stream deep learning architecture. This framework is intended to address minority class suppression by dynamically balancing structured financial ratios with unstructured textual disclosures. Specifically, the model processes numerical indicators through a gated residual network to capture complex patterns. Simultaneously, it extracts semantic cues from corporate reports via a FinBERT-driven bidirectional GRU. These dual modalities are then aligned using a learnable cross-modal attention fusion gate, jointly optimized with focal loss. Experimental evaluations on a comprehensive multimodal dataset, utilizing stratified splits demonstrate that D-HAN-Net significantly outperforms state-of-the-art baselines, achieving a predictive accuracy of 94.00%, an F1-score of 88.00%, and an AUC of 0.9734. Practically, this framework equips investors, financial institutions, and regulatory authorities with a decisive early warning system. It enables proactive risk management by detecting subtle distress signals before corporate failure becomes irreversible. Furthermore, extensive stability testing and ablation analysis confirm that the model's superior predictive reliability is highly robust against sampling uncertainty, fundamentally relying on the synergistic integration of all its architectural modules.**

***Keywords*—Bankruptcy prediction; multimodal deep learning; corporate disclosures; cross-modal fusion; class imbalance; early warning system**

I. Introduction

Corporate bankruptcy prediction has become a central research problem in financial analytics, as the early identification of financially distressed firms is very critical for investors, creditors, regulators and other market participants. Accurate prediction models can minimize the potential losses, facilitate the timely interventions, and enhance the distribution of financial resources across the capital markets. The number of corporate bankruptcies is also generally believed to be a signal of overall economic health and financial stability, with recent studies like Ji et al. [1] emphasizing that such models serve as critical early warning systems for stakeholders. For this reason, bankruptcy prediction is still an important part of financial risk assessment and corporate decision support. Traditionally, the goal of bankruptcy prediction models has been to assess the financial situation of a firm and forecast the probability of failure before distress is irreversible, a concept further advanced by Lin et al. [2] through modern explainable machine learning integrations. Most previous research tackled this task by means of the financial statement analysis by using financial statements accounting based indicators created from balance sheets, income statements and cash flow statements. These structured numerical variables have long been used as the basis for both statistical and machine learning based bankruptcy prediction models. Prior work indicates that machine learning can surpass traditional statistical methods by capturing complex nonlinear relationships between financial indicators. Recent explainable and hybrid approaches proposed by Fasano et al. [32] and Ainan et al. [34] further demonstrate the growing effectiveness of intelligent predictive systems in bankruptcy analysis. For instance, Liu et al. [3] report that machine learning models optimized with advanced algorithms are able to perform prediction much better, and Jiang et al. [4] highlight the growing importance of such intelligent computational approaches to financial distress studies. However, despite this progress, bankruptcy prediction remains challenging due to the rarity, heterogeneity, and complexity of real-world corporate failure patterns. Corporate bankruptcy prediction can be viewed as an imbalanced multimodal financial risk classification problem in which structured accounting variables and unstructured narrative disclosures must be jointly modeled.

A key issue in this literature is the extreme class imbalance that is present in most bankruptcy data. In practice, bankrupt companies are a small fraction of all companies, which often

*Corresponding author

leads prediction models to be biased towards the majority class of healthy companies and perform poorly on the minority class of distressed companies. Lombardo et al. [5] point out the practical difficulty of bankruptcy prediction under highly imbalanced settings, whereas Ranjbaran et al. [6] demonstrate that augmentation based strategies might lead to better minority detection, but at the same time can lead to instability and increased false positive rates. Beyond the imbalance problem, another important limitation is the high level of dependence of many prediction systems on structured financial ratios alone. Although such variables capture quantitative aspects of profitability, liquidity, leverage and solvency, the development of financial distress rarely occurs through numerical deterioration only. In real corporate situations, the warning signs of distress may often appear in managerially talk, auditor's concerns and forward looking uncertainty before it may be fully reflected in the accounting results. Corporate narrative disclosures, particularly the Management Discussion and Analysis section and auditor reports, therefore, lend a further dimension of risk relevant information. Mai et al.[7] demonstrate the use of textual disclosures from corporate filings to further improve bankruptcy prediction since they capture the semantic patterns that are unavailable in structured data. Related accounting research also lends credence to the informational value of narrative reporting. Mayew et al. [8] find that Management Discussion and Analysis disclosures to deliver incremental evidence about the firm's ability to continue as a going concern. Li et al. [9] show that readability in financial reporting is associated with earnings persistence and transparency while Loughran and McDonald [10] demonstrate that linguistic tone in corporate filings carries risk related information beyond conventional accounting measures. From a theoretical perspective these results imply that numerical indicators and textual disclosures are complementary as opposed to competing information channels.Financial ratios summarize realized economic outcomes, while narrative disclosures communicate managerial interpretation, uncertainty and emerging risks that may not yet be fully reflected in accounting variables. This view is consistent with both information asymmetry as well as signaling theories of financial reporting, where managers convey firm conditions in the form of both formal accounting results and qualitative disclosures. Yet most bankruptcy prediction studies still consider these two modalities separately. Although recent multimodal frameworks such as Mancisidor and Aas [37] indicate that combining textual and numerical information can substantially improve predictive capability. As a result, existing approaches often fail to effectively capture cross-modal interactions between quantitative financial deterioration and qualitative narrative distress signals.

This limitation leads to an obvious research gap and directly leads in to the present study. Despite the recent progress in deep learning, specifically transformer-based language models like BERT by Devlin et al. [11], the representation of long textual documents has been significantly improved. However, bankruptcy prediction research is still missing a unified framework that can effectively integrate structured financial indicators with corporate narrative disclosures under highly imbalanced conditions. Recent evidence from Chen et al. [12] suggests that textual information extracted from the annual reports can improve the predictive performance when integrated into learning-based systems. suggests that textual information extracted from annual reports can improve predictive performance when integrated into learning based systems. Similar findings have also been reported in recent multimodal and hybrid bankruptcy prediction studies such as Arno et al. [36], but the broader challenge of theoretically and computationally combining text and numerical signals is still to be solved. Nevertheless, modeling lengthy financial disclosures remains challenging because important distress-related evidence may be distributed across multiple document segments rather than localized within short textual spans. This encourages the following research question: How can structured financial indicators and narrative corporate disclosures be successfully combined in a unified predictive model in order to better detect corporate financial distress under highly imbalanced bankruptcy datasets?

To answer this question, this study proposes D-HAN-Net, a hybrid dual-stream deep learning architecture that considers the analysis of structured numerical indicators and corporate textual disclosures jointly. The framework uses a gated residual network to process financial variables to model nonlinear dependencies among ratios. It also employs a transformer-based language encoder followed by a hierarchical recurrent aggregation layer to model the text disclosures and retain the contextual semantic structure across long documents. This design also improves computational efficiency and training stability under limited bankruptcy data conditions. A cross-modal fusion mechanism then combines the two modalities and dynamically balances the relative contributions of the two modalities during the prediction process. The main contributions of this study are summarized as follows: First, it constructs a multimodal deep learning architecture for joint modeling of financial ratios and corporate narrative disclosures for bankruptcy prediction. Second, it presents a cross-modal fusion strategy that leverages the complementary nature between numerical and textual signals in an integrated architecture. Third, it illustrates the efficacy and robustness of the proposed framework with extensive empirical analysis of the framework, including baseline comparison, ablation analysis, and cross seed stability analysis.

II. Literature Review

Bankruptcy prediction has long been studied in financial economics, accounting, and data science. Over the years, the methods of research have evolved from old statistical models to new machine learning and deep learning techniques. Financial distress theory and information asymmetry literature imply that corporate distress signals arise from various sources, which includes financial statements and corporate disclosures. Consequently, both financial indicators and narrative information can offer valuable signals for identifying financial difficulty faced by firms in the form of both quantitative financial indicators and qualitative narrative information. This section provides an overview of the theoretical background of bankruptcy prediction, and an overview of previous research works concerning machine learning models, text financial analysis and imbalance aware learning models.

Corporate bankruptcy generally has been explained in terms of theories of financial distress between firm failure and deterioration in financial structure, liquidity, increasing leverage, and falling profitability. Bankruptcy risk, therefore,

becomes visible through signals such as the worsening of liquidity, unstable cash flows, declining profitability and growing pressure to ensure solvency. For this reason, financial indicators based on financial statements have been the main inputs for bankruptcy prediction models for a long time [13]. However, financial distress is not only reflected in the accounting numbers. Disclosure theory implies that managers are communicating risk via narrative disclosures in annual reports and regulatory filings. When firms find themselves under financial stress, discussions among managers usually involve problems with operations, problems with financing, or restructuring activities. Such signals often occur in advance of the time when deterioration is fully reflected in the accounting ratios. Financial language models like FinBERT can capture these contextual cues because they are trained on financial corpora and are able to spot domain specific expressions related to uncertainty and financial instability. Taken together, these views mean that financial distress is multidimensional. Numerical indicators provide information on measured deterioration in firm performance, while narrative disclosures provide managerial perceptions and advance warning signals about financial stress. Integrating financial indicators and FinBERT derived semantic representations, therefore, offers a theoretically grounded basis for enhancing bankruptcy prediction models [14], [15].

Machine learning techniques have been popularly used to predict bankruptcy because of their capability of capturing complex nonlinear relationships between financial variables and bankruptcy outcomes. Studies have been done on the neural network and the sequential learning models to detect the financial distress pattern. Kim et al. showed that the modeling of temporal dependencies between financial indicators is useful for enhancing prediction performance [16]. Hosaka proposed transforming financial ratios into image representations and using convolutional neural networks to identify patterns in structure of financial data [17]. Pellegrino et al. further developed an architecture of multiple heads Long Short Term Memory to learn temporal dynamics from accounting time series data [18]. Ensemble learning methods have also attracted a lot of attention. Recent interpretable ensemble frameworks combining models like LightGBM and CatBoost with SHAP analysis demonstrate significantly more robust and transparent predictions across diverse market conditions [19]. Liang et al. showed that the integration of corporate governance index and financial index can improve the predictive effect and will show the importance of diverse corporate characteristics in the predictive model [20].

Recent researches have been devoted to advanced models that can be applied to high-dimensional financial dataset. Gradient boosting methods like LightGBM have been found to have good predictive power in financial risk modeling [21]. Ensemble approaches have also been shown to have great potential. Entropy based feature transformation strategies which enhances predictive performance in financial risk modeling was introduced by Carta et al. [22], [23]. Stacking based ensemble methods further suggests that a combination of classifiers will yield more stable and reliable results than relying on a single model [24]. Feature selection methods have also been proven to be efficient to identify the most informative indicators to predict bankruptcy [25]. Research and surveys have shown that machine learning and deep learning methods typically outperform conventional statistical models in bankruptcy prediction tasks [26], [27]. Financial distress is communicated not only through numerical ratios but also through managerial narratives in corporate disclosures. Managers often adjust the tone and wording of reports when firms face liquidity pressure, operational challenges, or solvency concerns. As a result, textual disclosures may reveal early signals of distress before these conditions become fully visible in financial statements. Transformer based language models such as BERT can capture contextual semantic relationships in textual data [11]. In financial applications, domain-adapted models such as FinBERT, are particularly effective at identifying linguistic patterns related to uncertainty, litigation risk, and financial instability. Chen et al. demonstrated that incorporating textual features from annual reports significantly improves bankruptcy prediction performance [12]. Lombardo et al. further showed that deep language models can effectively analyze complex corporate disclosure documents [28].

One of the biggest challenges in predicting bankruptcy lies in the extreme class imbalance with financial datasets, with bankrupt firms only making up a small percentage of observations. This imbalance will often lead to predictive models giving preference to the majority class, and making it difficult for them to accurately determine correct cases of bankruptcy. To overcome this problem, imbalance aware learning strategies have been proposed. Recently, Papík demonstrated the significant impact of advanced data resampling approaches, such as SMOTE and random oversampling, on improving minority class detection for imbalanced financial datasets [29]. Kubat and Matwin have introduced one sided selection techniques that reduce the imbalance by eliminating redundant majority class samples from the training data [30]. These approaches have become important parts of modern financial risk predicting systems. Despite some significant progress, there are still some limitations in the literature. Many of the researchers mainly focus on financial indicators and pay little attention to qualitative signals in corporate disclosures. Studies that look at the analysis of textual information tend to look at the narrative signals independent of financial variables leaving the interaction between these two parameters insufficiently explored. Furthermore, many models work such that they fit within a single modality framework and cannot, therefore, capture complementary distress signals from heterogeneous data sources.

To overcome these limitations, this research study proposes D-HAN-Net, a dual stream hybrid deep learning architecture that jointly analyzes structured financial data and semantic information from the corporate disclosures. The model uses separate encoders for numerical and textual modalities and uses an adaptive cross-modal fusion mechanism to dynamically balance contributions of the two modalities during the prediction. By incorporating heterogeneous financial signals into an integrated framework, the proposed approach is expected to enhance the bankruptcy prediction performance and result in a more robust bankruptcy early warning system under class imbalanced conditions.

III. Methodology

This section presents the architecture design of the proposed D-HAN-Net which is schematically shown in Fig. 1.

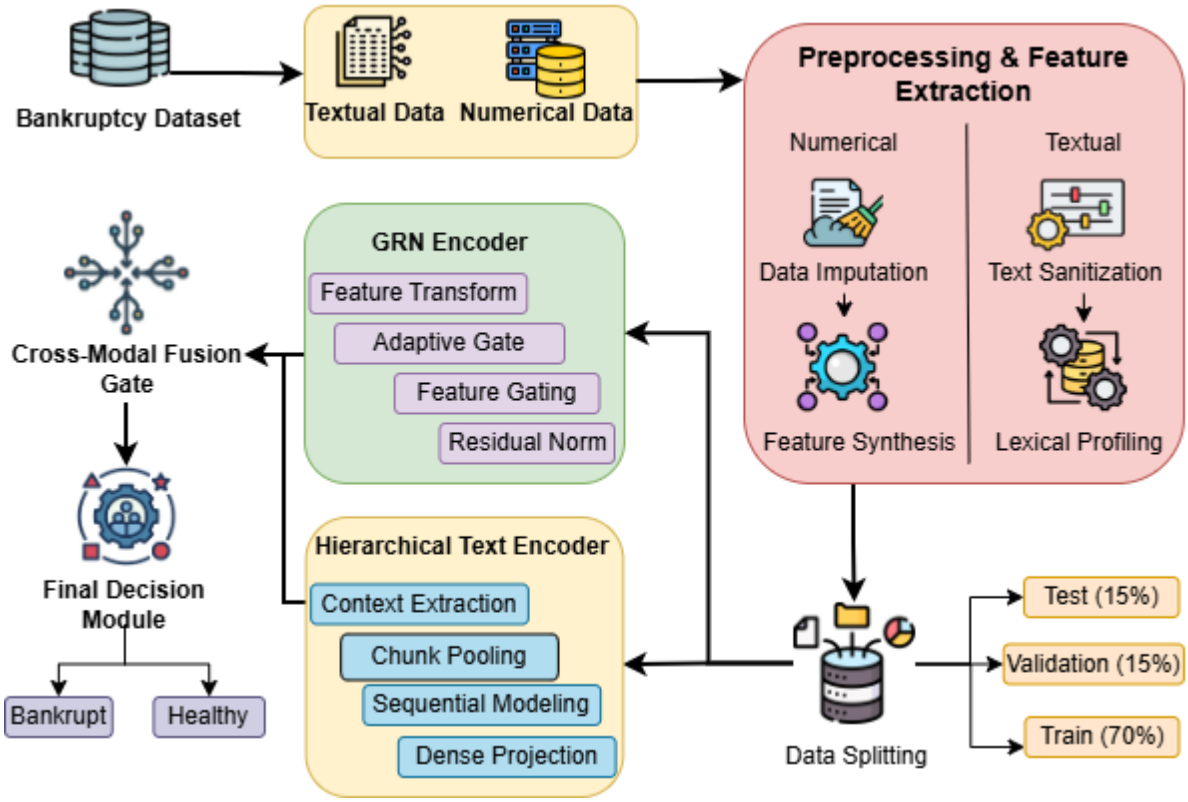

Fig. 1. End-to-end architecture of the proposed dual modality learning framework for bankruptcy prediction.

The framework consists of a combination of multimodal cohort construction, disclosure-driven risk feature engineering and a hybrid neural architecture with gated numerical encoding, hierarchical document encoding and cross-modal fusion to predict next year bankruptcy.

A. Dataset Description

This study is based on the publicly available Figshare dataset of multimodal bankruptcies [31]. In each instance there are MD&A text, audit opinion text, structured numerical attributes and the next year bankruptcy label binary (indexed by UID). The circumstances are not in our favor since bankrupts are few and financial filings are long. Therefore, the decision relevant signals are preserved by imbalance aware sampling and hierarchical text processing. Potential selection bias could also arise due to the fact that financially distressed firms have larger management reports and larger auditor opinions. Distressed companies often offer specific explanations about the reasons for liquidity situations, operational uncertainty, debt commitments, or restructuring efforts. Consequently the intensity of narrative may be partly correlated with the risk of bankruptcy. To reduce this concern, the proposed framework is built on the basis of contextual semantic representations that are derived from segmented disclosures rather than using raw document length as a direct predictor. Long disclosures are segmented into multiple chunks to reduce excessive truncation while preserving contextual semantic information across lengthy financial reports.

B. Data Preprocessing

The pipeline begins by reading both of the raw sources in chunks of size 5000 avoiding memory overflow and then aligning them by UID with an inner merge so that every retained record contains both modalities. In order to minimize the imbalance while preserving all the positive samples, all bankrupt UIDs are kept. To address the serious class imbalance typical of bankruptcy data, all bankrupt companies are kept but a sample of healthy companies is randomly selected in a ratio of around 5:1. This sampling strategy mitigates the extreme imbalance without having too few observations from the majority class for stable model training. The last cohort is divided by stratified sampling into train 70%, validation 15% and test 15%, which makes the class ratios stable between partitions and prevents the statistical instability that time-based splits would cause due to the extreme rarity of bankruptcies. The resulting distribution of healthy and bankrupt firms in the training, validation and test sets can be seen in Fig. 2.

Document segmentation is carried out for long financial disclosures. After removing noise in the form of the HTML document, and common boilerplate text, each document gets tokenized and broken into fixed sized chunks. Let T be the number of tokens in a document and L be the chunk's max token length. The number of chunks N is calculated by dividing the document into segments of length L, as in Eq. (1). In our experiments the number of tokens in a chunk is 512, following the choice of the maximum sequence length of the transformer encoder. Each document is further reduced in size to a maximum of 20 chunks, to manage the memory

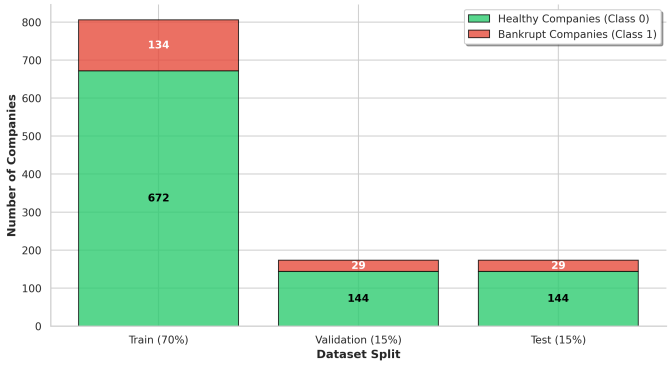

Fig. 2. Class distribution of healthy and bankrupt firms in the training, validation, and test sets.

usage while maintaining enough contextual information. While this memory-constrained limit truncates 67.01% of the longest documents and yields an overall truncation loss of 33.62%, it securely retains the most critical semantic cues and distress indicators, which typically appear in the earlier sections of management and auditor reports.

$$C = \min\left(C_{max}, \lceil \frac{T}{L} \rceil\right) \tag{1}$$

This chunked representation prevents hard truncation and supports hierarchical encoding.

C. Feature Engineering and Selection

A multivariate feature set is created to represent the accounting signals as well as the narrative risk cues. All columns other than UID and label, item 7, opinion text and the combination of raw text field are treated as candidate numerical predictors. Object type variables are label encoded, Infinite values are replaced by missing, Variables with missing rate higher than 0.60 are removed. Remaining missing entries are imputed using an iterative multivariate imputation maintaining cross feature dependencies.

To explicitly capture distress language, a unified disclosure field is formed by concatenating item 7 with audit opinion text. For a lexicon V and the token set W_i of document i, the density feature is defined in Eq. (2):

$$Density_{V,i} = \frac{\sum_{w \in W_i} I(w \in V)}{|W_i|} \tag{2}$$

Using negative, litigious, and uncertainty lexicons, we construct three density indicators, and a binary going concern flag is added when the phrase is present. These linguistic red flags strengthen interpretability and support later robustness reasoning.

Mutual information is then employed to generate the top 5 numerical predictors and subsequently only the interaction-only second-degree polynomials terms are produced. This expansion of the number of base predictors to 5 is the limit that is set so as to guarantee efficiency in the computation and to avoid overfitting. Any further extension would further raise the feature space exponentially, which is necessarily going to incur the curse of dimensionality and terrible multicollinearity, due to the extreme imbalance between classes in the case of bankruptcy data. The model only uses the top 5 predictors which is a sufficient approach to capturing the most statistically significant non-linear relationships with no unnecessary noise being modeled. For two selected predictors x_a and x_b the interaction is defined in Eq. (3):

$$x_{ab} = x_a x_b \tag{3}$$

All the numerical predictors are clipped at 1st and 99th percentile and transformed into a normal like distribution through quantile transformation. A final top K predictor is then selected by mutual information which is used by the model. The sensitivity analysis is done to find the best feature selection and test the strength of the model by changing the value of K (e.g., K = 10, 20, 30, and 40). The last model uses K=20 due to the maximum overall validation performance. The impact of this option is also addressed in the experimental results.

D. Model Architecture of the Hybrid D-HAN-Net

The proposed architecture is designed to learn stable numerical structure, preserve long range disclosure evidence, and align both modalities through attention guided fusion. The pipeline contains four stages.

1) Hierarchical numerical encoder: The GRN framework supports nonlinear transformation and performs the original feature representation by residual connections. Financial ratios tend to be heterogeneously distributed and non linearly interacting. Thus, their predictive structure cannot be well represented by a simple linear transformation. In order to stabilize the learning process, the encoder uses two nonlinear transformation layers and then dropout regularization and projection residual. A gated residual network is used to project the selected predictors to an embedding of 128 dimensions. Let r be the projected residual and $f(x)$ be a nonlinear transform, then the numerical representation is defined in Eq. (4). The hidden representation dimension is set to 128 in our experiments.

$$h_{num} = BN(r + g \odot f(x)) \tag{4}$$

where, $g = \sigma(W_g f(x))$ and $\odot$ denotes element-wise multiplication. This gating mechanism enables the network to adaptively suppress noisy financial indicators while amplifying features that strongly correlate with bankruptcy risk. Batch normalization further stabilizes training by normalizing the representation distribution.

2) Hierarchical text encoder: The FinBERT application is informed by the fact that corporate disclosure is a domain-structured linguistic. Accounting terminology, expressions of financial risk, and statements of uncertainty are common management discussion narrative language that is not well reflected in general language corpora. FinBERT is trained on financial text, and thus it picks up contextual semantics to do with financial distress, compared to general-purpose BERT models. The GRU layer is bidirectional and additional to this, the layer

performs segment level embedding on the entire document and this identifies long-range dependencies among disclosure segments. The contextual embedding of each segment is obtained from the pooled output of FinBERT, which is chosen over standard BERT models to accurately interpret the specialized financial terms and unique phrasing found in management narratives. These segment embeddings are then organized as a sequence and passed through a bidirectional GRU layer. The bidirectional recurrent layer aggregates contextual information from both earlier and later segments, enabling the model to capture narrative dependencies across the processed sequence.

A bidirectional GRU aggregates chunk embedding into a single 128-dimensional representation h_{text}. The FinBERT parameters are frozen during training to reduce computational cost and prevent overfitting on the relatively small bankruptcy dataset. The resulting sequence representation is aggregated by the GRU layer to form a document-level embedding. Compared with fully transformer-based long-document architectures, the bidirectional GRU offers lower computational complexity and memory overhead. It also provides stable sequence aggregation for small and highly imbalanced financial datasets.

3) Cross-modal fusion with gating: Once numerical and textual representations are obtained, the next stage aligns both modalities through a cross-modal attention mechanism. Bankruptcy signals often emerge when textual statements confirm or contradict financial ratios. The fusion module therefore enables interaction between these two sources. The cross-attention module uses the summarized textual representation h_{text} as a Query to attend to the numerical representation h_{num}, acting as Key and Value, producing an attention-refined text vector h_{attn}. A learnable fusion gate then adaptively blends both streams, as defined in Eq. (5):

$$h_{fuse} = z \odot h_{num} + (1 - z) \odot h_{attn} \tag{5}$$

where, $z = \sigma([h_{num}; h_{attn}])$, the gate value z lies in the range 0 to 1, where values closer to 0 indicate stronger reliance on textual signals, whereas values closer to 1 indicate greater reliance on numerical indicators. Here, σ denotes the sigmoid activation function, $[;]$ denotes concatenation, and $\odot$ indicates element wise multiplication. This mechanism allows the model to adaptively decide whether bankruptcy evidence should rely more strongly on financial ratios or on textual disclosure signals for each firm. To test the effectiveness of the proposed cross-modal fusion gate, an easier to implement late fusion baseline is also considered. In this alternative environment the numerical and textual representations are simply concatenated and fed to the classifier without interaction between the two representations based on attention. This comparison is helpful for determining if the proposed fusion mechanism offers a meaningful advantage over a simpler multimodal integration strategy.

4) Probabilistic prediction and decision logic: The fused representation is finally passed through a shallow classifier consisting of a fully connected layer with GELU activation followed by dropout regularization. This stage converts the fused feature vector into a scalar bankruptcy probability. The final prediction is obtained using a sigmoid activation, defined in Eq. (6):

$$p = \frac{1}{1 + e^{-(w^\top h_{fuse} + b)}} \tag{6}$$

where, p represents the predicted probability that the firm will experience bankruptcy in the next fiscal period. The sigmoid function ensures that the output remains within the range of zero to one. During evaluation, the predicted probability is compared with an optimal decision threshold determined from the validation precision recall curve. This adaptive threshold selection helps balance precision and recall under severe class imbalance.

E. Training Strategy and Optimization

The training procedure is designed to remain stable under extreme class imbalance and long document variability, while ensuring that improvements in AUC and F1 are not driven by a single favorable split. The overall objective is to learn a calibrated bankruptcy probability that is robust across random initializations and sampling noise.

1) Imbalance-aware training and loss optimization: Bankruptcy samples are rare, hence standard mini batch sampling would lead to overfitting of the majoritarians of the healthy sample class by the optimizer. To address this, a technique of weighted random sampling is applied, at the instance level. Each training example is assigned a weight inversely proportional to its class frequency and batches are drawn with a WeightedRandomSampler. This makes the effect of bankrupt instances more effective without duplicating them deterministically, so the gradient bias for the negative class decreases. Model parameters are optimized using AdamW, which combines adaptive learning rates with decoupled weight decay.

A learning rate of 1.5×10^{-5} is selected to maintain stable updates when training with frozen language representations and a relatively small classifier head. Dropout is applied in the numerical encoder, fusion feedforward layers, and classifier head to reduce co adaptation between modalities and to prevent the fusion gate from collapsing to a single modality. Even with balanced sampling, many bankrupt signals remain subtle, so the training objective must prioritize difficult cases. The model is trained using focal loss, which down weights easy samples and focuses learning on hard or misclassified examples. With $y \in \{0, 1\}$ and predicted probability p, define $p_t = p$ if $y = 1$ else $1 - p$. The loss is defined in Eq. (7):

$$L_{focal} = -\alpha(1 - p_t)^\gamma \log(p_t) \tag{7}$$

The focusing parameter is set to $\gamma = 2$ in our experiments. The balancing factor $\alpha = 0.25$ is used to assign higher importance to the minority bankrupt class.

2) Validation protocol and stability analysis: Training runs are for up to 40 epochs, but performance is not assumed to improve monotonically. The validation AUC is calculated after every epoch with the help of predicted probabilities. The model checkpoint with the highest validation AUC value is saved and early stopping is triggered when there is no improvement in validation AUC for 10 consecutive epochs. This helps avoid over training the classifier head and the fusion layers which

is particularly common when the text encoder is frozen and the capacity is focused on fusion block. Since the dataset is imbalanced, applying a default classification threshold of 0.5 often yields a high AUC but a poor F1-score for the positive class.

Therefore, after being trained, the decision threshold is selected by maximizing the F1 score over the precision recall curve, which results in an equilibrium operating point between false alarms and missed bankruptcies. This threshold is then applied to the held out test set for final reporting. In order to guarantee the robustness, all experiments are repeated under multiple random seeds, which alters the selections of healthy samples and initializations of fusion and classifier parameters. Final results are presented in terms of the mean and standard deviation, which indicate the stability of the model with regard to sampling uncertainty and randomness of optimization.

F. Evaluation Protocol and Robustness Reporting

The assessment plan will be used to facilitate fair comparison of the offered model and the baseline methods. Stratified sampling is used to partition the dataset into training, validation and test sets such that the classes are always distributed equally across the partitions. The selection of models is done on the basis of validation performance in which the primary monitoring measure is the Area Under the ROC Curve. Due to the high imbalance in bankruptcy prediction, it does not mean that the eventual classification point is 0.5. Rather, the maximum value of the F1 score on the validation set is chosen and used on the held out test set. This technique offers a better balance between trade off in precision and recall. In order to measure robustness, each experiment is run with a number of random seeds and the final value is presented as mean and standard deviation. Besides, the suggestion model is contrasted with the methods of strong baseline to demonstrate the efficiency of the multimodal architecture.

IV. Results and Discussion

A. Experimental Configuration and Implementation Details

All experiments have been implemented in Python. Numerical baselines were built using Scikit-learn, the proposed multimodal model was implemented using PyTorch, and transformer baselines were implemented using HuggingFace Transformers. Experiments were done on the Kaggle research platform with GPU/CUDA to speed up the training and inference. Data preprocessing and feature engineering were done using Pandas, NumPy and Scikit-learn. Performance was measured in terms of Accuracy, Precision, Recall, F1-score and AUC. To make the comparison as broad as possible, baseline models were developed for both the numerical and textual modalities. The number baselines were Random Forest 100 trees, XGBoost logistic objective, SVM probabilistic output, and a 2-layer multilayer perceptron with 64 and 32 hidden layers. The textual baselines were BERT-Base, RoBERTa, DistilBERT, and ELECTRA fine-tuned for three epochs and batch 16 maximum sequence length 128.

D-HAN-Net was optimized using AdamW with learning rate of 1.5×10^{-5}, batch size 16 and max. 40 epochs. Early stopping was used according to validation AUC using patience of 10 epochs. To deal with the class imbalance, a weighted random sampling was adopted in the mini-batch construction and focal loss was taken into consideration to give priority to difficult samples. The final classification threshold was chosen from the precision-recall curve by finding the F1-score (Table I).

TABLE I. Key Training Configuration for the Proposed D-HAN-Net Model.

Parameter	Value
Healthy:Bankrupt Ratio	5:1
Data Split (Train/Val/Test)	70% / 15% / 15%
Selected Numerical Features	20
Text Encoder Aggregation	Bidirectional GRU
Numerical Representation	Gated Residual Network (GRN)
Multimodal Fusion	Cross-modal Attention + Gate
Optimizer & Learning Rate	AdamW, 1.5×10^{-5}
Batch Size & Max Epochs	16, 40
Imbalance Handling	Weighted Sampling, Focal Loss ($\gamma = 2$)

B. Performance Evaluation and Empirical Analysis

Across all baselines, the test-set results confirm that bankruptcy signals are captured much more reliably by structured financial variables than by narrative text alone, as illustrated in Table II. Among numerical baselines, MLP achieves the best overall score with accuracy 0.9133 and AUC 0.9672 and SVM and Random Forest closely follow with accuracy close to 0.89-0.90 and AUC above 0.94. However, Table II also shows a clear trade-off in which XGBoost and SVM have the highest recall of 0.9310 but their precision remains lower with 0.5510 and 0.6136, which implies a higher number of false positive bankruptcy alarms. The transformers that are text-only perform a weaker job overall, with accuracy maximum of 0.8324 and AUC mostly in between 0.61-0.69 which means that separability with text only is limited. D-HAN-Net is unique in the way that it enhances the overall ranking and classification simultaneously. It has the highest accuracy of 0.9400 and the best AUC of 0.9709, which shows the most obvious separation between bankrupt and healthy firms across thresholds in Table II. At the same time, it maintains precision of .7485 and recall of .8828 which means the model does not face the common tradeoff between high recall and many false positives. This balance can be seen in its top F1-score in comparison with all baselines. The result is consistent with recent multimodal bankruptcy studies which indicate that combining financial and textual information improves minority distress detection [36], [37].

Table III provides a comparison between the AUC scores of the model with different sets of features (K). When only 10 features were used, the AUC is less (0.8997) since the model has limited depth with regards to finances. Maximum performance is achieved at the top of the optimal K = 20 (our proposed model) which captures the most effective and relevant financial signs of risk assessment. Further increases in AUC to 30 and 40 bring the values to 0.9373 and 0.9303, respectively. This deterioration confirms that too many variables bring about noise and redundancy of data which ultimately diminishes the total accuracy of prediction.

Fig. 3 reports the confusion matrix of D-HAN-Net on the held out test set and explains how the final accuracy

TABLE II. BASELINE COMPARISON RESULTS ON THE TEST SET

Type	Model	Accuracy	Precision	Recall	F1-Score	AUC
Numerical	Random Forest	89.60%	64.10	86.21	73.53	95.31
Numerical	XGBoost	86.13%	55.10	93.10	69.23	93.92

TABLE III. AUC PERFORMANCE BASED ON FEATURE SELECTION (TOP_K).

Number of Selected Features (TOP_K)	AUC Score
TOP_K = 10	0.8997
TOP_K = 20	0.9734
TOP_K = 30	0.9373
TOP_K = 40	0.9303

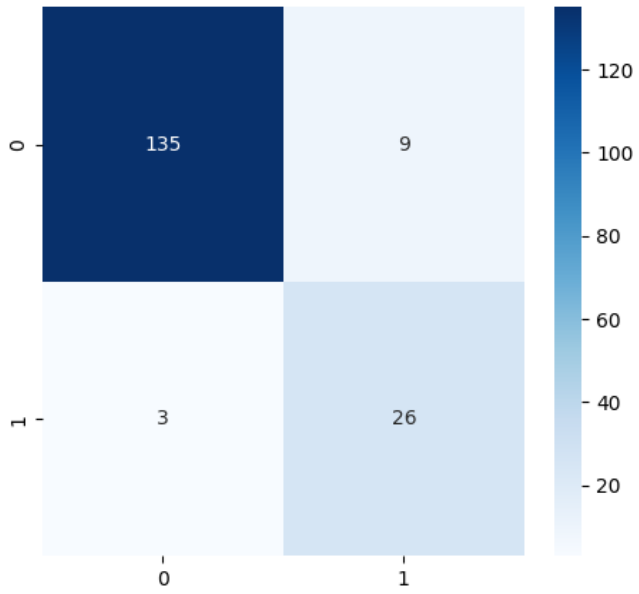

Fig. 3. Confusion matrix of the D-HAN-Net on the test dataset.

gets formed using class wise outcomes. The confusion matrix shows that 135 healthy firms are correctly classified as healthy and 26 bankrupt firms are correctly identified as bankrupt. The remaining errors are limited, and asymmetric in a good way for use in early warning. Only 9 healthy firms are flagged as bankrupt which represents false alarms which may trigger unnecessary investigation, while only 3 bankrupt firms are classified as healthy which represents missed distress cases which are usually more costly in practice. The low number of false negatives shows that the model captures most of the distressed firms, and does not depend on the majority class to inflate the accuracy. At the same time, a low number of false positives means the model does not create over sensitive screening that will overwhelm stakeholders with alerts. Overall, in the matrix, D-HAN-Net is seen to have a practical balance between caution and precision that generates high true positive detection and keeps the misclassification rates under control. This behavior is consistent with a robust multimodal decision process that relies on financial ratios, as well as disclosure signals.

C. Threshold Independent Performance Evaluation

Instead of improving performance at a single fixed threshold, D-HAN-Net provides a predictable better performance balance across a wide range of operating points, and this can be seen from both of the curves in Fig. 4 and Fig. 5. In Fig. 4, its ROC trajectory remains most close to the top left region over most of the false positive range, which represents the best separating capability between bankrupt and non-bankrupt firms. The early rise of the curve indicates that the sensitivity is gained rapidly and the small drift to the right indicates that false positives are still under control. The numerical baselines lag behind them with very high but less high curvature so their extra true positive gain tends to demand more false positives. The text-only transformers are still closer to the diagonal trend, with very limited discriminative power across thresholds in Fig. 4. This suggests that narrative disclosures alone may capture uncertainty-related semantic cues but remain insufficient for stable bankruptcy discrimination without supporting financial indicators. D-HAN-Net is unique in that it enhances overall ranking as well as classification together. It has the highest accuracy of 0.9400 and the best AUC of 0.9734 demonstrating the clearest separation of bankrupt and healthy firms for different thresholds, as in Table II. At the same time, it maintains the precision level at 0.86 and recall level at 0.88 and thus the model does not suffer from the usual tradeoff where higher recall comes with a lot of false positives. This balance is reflected in its top F1-score compared with all the baselines. The improved performance likely arises from the complementary interaction between structured financial indicators and contextual narrative evidence under highly imbalanced distress conditions.

The same advantage passes on to the more decision critical view in Fig. 5. D-HAN-Net maintains precision when recall is increased, thus can recall more bankrupt firms without quickly raising false alarms. This is important in screening tasks where it is costly to miss a bankrupt case, but too many false alerts will also make the tool less practical. Several numerical baselines exhibit a steeper drop in precision at higher recall, indicating that the sensitivity (i.e. pushing to create more alarms) produces more noisy alarms. The text-only models fall to low precision early, and are weak throughout the curve, indicating that the narrative signals alone are insufficient to

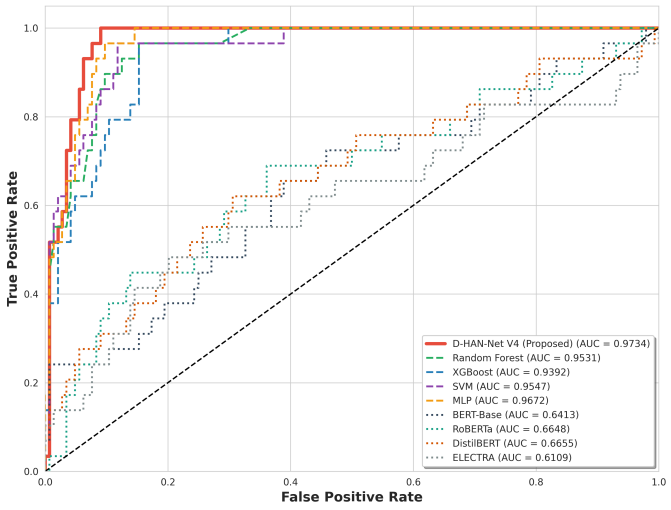

Fig. 4. Receiver Operating Characteristic (ROC) curves for all models.

secure stable retrieval.

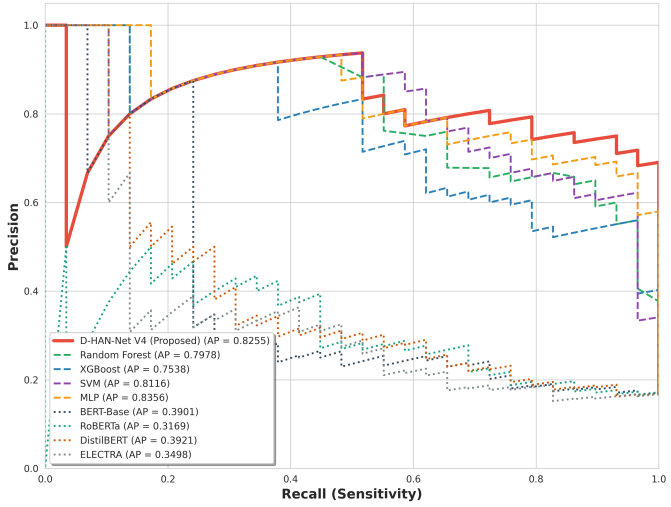

Fig. 5. Precision–Recall (PR) curves for all models.

Taken together, Fig. 4 and Fig. 5 imply that D-HAN-Net has strong ranking quality and stable class retrieval, simultaneously, and the advantage is retained in the whole threshold space instead of only one chosen decision point, which is helpful for deployment under various risk preferences.

D. Model Robustness and Cross Seed Stability Analysis

Robustness analysis evaluates whether D-HAN-Net stays reliable when training is repeated with different random seeds and compares this stability against strong numerical baselines in Table IV. The goal is to ensure that the reported gains are not caused by one favorable run, but remain consistent across multiple executions of the pipeline. Table IV indicates that D-HAN-Net achieves the best overall performance across five seeds. It records the highest accuracy at 94.00 $\pm$ 0.57 and the strongest AUC at 97.34 $\pm$ 0.35, showing superior separation between bankrupt and healthy firms. The F1 score is also the highest at 88.00 $\pm$ 0.75, supported by high precision at 86.00 $\pm$ 4.14 and high recall at 92.00 $\pm$ 4.68, which reflects balanced detection rather than a one sided gain. The error profile further strengthens this conclusion in Table IV. D-HAN-Net shows the lowest Type I error at 6.11 $\pm$ 1.55, which means fewer false bankruptcy alarms than XGBoost, Random Forest, and SVM. Type II error remains controlled at 11.72 $\pm$ 4.68, while Random Forest shows a higher Type II error at 17.93 $\pm$ 4.02, implying more missed bankrupt cases. XGBoost and SVM reach very high recall at 93.10, but their lower precision and higher Type I error indicate a larger false positive burden. Overall, Table IV supports that combining auditor text with financial ratios produces a more stable and dependable predictor than single modality baselines.

E. Component Contribution and Ablation Investigation

The ablation study is to break the full D-HAN-Net into key parts, to quantify the contribution of each block to the prediction quality. This type of analysis helps validate the components, as well as measuring the synergy, that the overall gains are the result of the combined design, rather than one block alone. As presented in Table V, the result of the full model is the best, which is accuracy 94.00, F1-score is 88.00 and AUC is 97.34. When GRN is removed, performance deteriorates drastically to accuracy 83.82 and AUC 84.77, suggesting that gated refinement is central for strong representation learning. Removing sequential aggregation also decreases performance, with accuracy 84.97 and F1 64.79, which suggests that sequence level cues help the model form a more stable decision. When attention fusion is removed, F1 drops to 61.76, AUC drops to 86.69, this means that cross-modal alignment is required to maintain a balance between the predictions. The biggest degradation occurs when focal loss is removed, in which F1 will be 60.38 and AUC will be 83.33, indicating the importance of the loss design in handling class imbalance and avoiding unstable learning. Overall, Table V suggests that strong and consistent results demand the complete integration of GRN, sequential modeling, attention fusion and focal loss, as opposed to some simplified variant.

F. Model Interpretability Through Feature Impact Analysis

A clear hierarchy of risk drivers can be seen from the SHAP summary in Fig. 6. Going Concern Opinion is the best contributor, in which higher feature values drive the predictions into the bankrupt category and lower values are more likely to be healthy companies. The extensive dispersion of SHAP values indicates that audit opinion is a powerful separating signal particularly to firms whose explicit distress is enduring. The second and third in pecking order are retained earnings and variables that are associated with net income, which implies that reduced profitability and exhausted accumulated earnings add to the risk of bankruptcy. Most of their SHAP effects are skewed towards the positive in unfavorable values indicating that the model considers the weaknesses of earnings as a direct distress signal. It is also indicated by Fig. 6 that the model is based on the mix of audit signals and core indicators of financial strength instead of the particular ratio. Balance sheet variables like current assets and total stockholders equity have a similar direction with less financial

TABLE IV. ROBUSTNESS ANALYSIS ACROSS 5 RANDOM SEEDS

Model	Accuracy	AUC	F1-Score	Precision	Recall	Type I Error
XGBoost	86.13 ± 0.00	93.92 ± 0.00	70.89 ± 0.00	55.10 ± 0.00	93.10 ± 0.00	15.28 ± 0.00
Random Forest	90.06 ± 0.77	94.95 ± 0.36	74.93 ± 0.75	66.78 ± 3.33	82.07 ± 4.02	8.33 ± 1.58
SVM (RBF)	89.02 ± 0.00	95.57 ± 0.11	75.68 ± 0.00	61.36 ± 0.00	93.10 ± 0.00	11.81 ± 0.00
D-HAN-Net (Proposed)	94.00 ± 0.57	97.34 ± 0.35	88.00 ± 0.75	86.00 ± 4.14	92.00 ± 4.68	6.11 ± 1.55

TABLE V. ABLATION STUDY OF D-HAN-NET: IMPACT OF KEY COMPONENTS ON PERFORMANCE.

Model Variant	Accuracy	F1-Score	AUC
D-HAN-Net	94.00%	88.00	97.34
w/o GRN	83.82%	61.97	84.77
w/o Sequential Agg (Bi-GRU)	84.97%	64.79	89.22
w/o Attention Fusion	84.39%	61.76	86.69
w/o Focal Loss	87.28%	60.38	83.33

strength being associated with increased risk. Other accounting indicators such as federal tax reconciliation and comprehensive income also have effects on prediction, but the average effects are smaller. This indicates that the model reflects primary distress indicators and secondary accounting indicators linked to declining performance. Altogether, the feature effects are economically sound. The model relates the indicators of audit-based concerns with the profitability and solvency indicators within one interpretable decision framework, with the highest impact on the audit opinion, then the quality of earnings, and the support provided by the resilience of the balance sheet, respectively, to the ultimate prediction.

G. Case-Specific Evaluation and Linguistic Interpretability

This case study highlights how confidently each of the models flags a difficult bankrupt firm in Table VI. D-HAN-Net has the highest bankrupt confidence of 61.67, showing the clearest risk judgment of this sample among all methods. SVM is close at 60.93, while XGBoost is lower at 55.18, which seems to exhibit lower level of commitment despite risk detection. A larger gap is seen for the rest of the baselines in Table VI. Random Forest drops to 44.00 and MLP drops even further to 32.07, meaning that they consider the same firm less decisively bankrupt. The lowest scores are experienced by the text only transformers, hovering around 13.12 to 16.38, suggesting that they mostly fail to pick up on the evidence of distress in this difficult example. Overall, Table VI presents that D-HAN-Net is the most decisive model on a hard case, where single modality baselines tend to under estimate the bankruptcy risk.

Fig. 7 illustrates the most common linguistic cues to financially struggling firms taken from Management Discussion and Analysis and auditor opinion sections. The word cloud emphasises such dominant words as costs, credit, interest, sales, capital, and accounts that are often found in bankruptcy related disclosures. The prominence of these terms reflect common financial distress narratives including rising operational costs, debt obligations, declining revenues, and restructuring pressures. This visualization is qualitative evidence that there are meaningful warning signals of corporate failure in the textual disclosures. Such linguistic patterns complement the

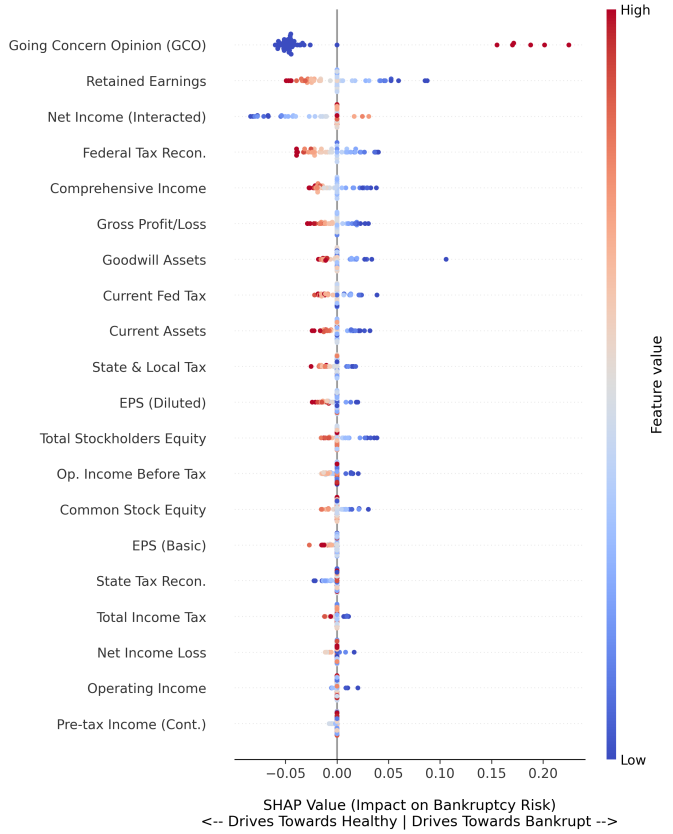

Fig. 6. SHAP Summary plot: Evaluating global feature importance and directional impact in D-HAN-Net.

TABLE VI. CRITICAL CASE STUDY: CROSS-MODEL BANKRUPTCY CONFIDENCE SCORES (TEST INDEX = 45).

Model Architecture	Confidence Score (Bankrupt)
SVM	60.93
XGBoost	55.18
Random Forest	44.00
MLP	32.07
BERT-Base	15.49
ELECTRA	16.38
DistilBERT	13.12
D-HAN-Net (Proposed)	61.67

numerical financial indicators that are to be used in the proposed framework and help to explain the role of textual evidence in predicting bankruptcy. The analysis supports the interpretability objective it shows that the model captures real world distress related language present in corporate reports rather than relying solely on statistical correlations.

TABLE VII. BENCHMARK COMPARISON OF EXISTING MODELS WITH THE PROPOSED D-HAN-NET

First Author	Year	Architecture	Dataset	AUC
Ainan et al. [34]	2024	Hybrid Machine Learning	Unbalanced Polish Dataset	0.9580
Mancisidor et al. [37]	2022	CMMD	U.S. Firms	0.9327
Fasano et al. [32]	2024	Explainable AI	Corporate Financial Dataset	0.9270
Arno et al. [36]	2023	Multimodal Ensemble	ECL Dataset	0.9150
Correia [35]	2025	Traditional Accounting Models	CRSP U.S. Firms	0.9136
Xiao et al. [33]	2024	DGCN-TA	Enterprise Relationship Networks	0.8867
Mai et al. [7]	2019	Deep Learning	U.S. Public Companies	0.8560
D-HAN-Net (Proposed)	2026	D-HAN-Net	Multimodal	0.9734

Fig. 7. Linguistic red flags extracted from bankrupt firms' auditor reports.

Table VII indicates that the proposed D-HAN-Net is an effective tool in comparison to some other recent studies on bankruptcy prediction. Prior deep learning studies like Mai et al. had already achieved an AUC of 0.8560, which points to a moderate level of predictive performance in the case of using textual disclosures as the main predictive factor. Subsequent methods were able to enhance performance by adding more structural or financial data. As an illustration, the DGCN-TA model by Xiao et al. resulted in an AUC of 0.8867 with the classical accounting based model by Correia et al. having an AUC of 0.9136. Further developed architectures also improved the performance of prediction. Arno et al. multimodal ensemble method achieved an AUC of 0.9150, and Fasano et al. showed the applicability of explainable AI of 0.9270. On the same note, the CMMD model of Mancisidor et al. scored 0.9327, and the hybrid machine learning model of Ainan et al. scored 0.9580, which is among the highest scores ever seen among previous researchers. Although these gains have been made, the proposed D-HAN-Net has the best AUC of 0.9734, which is obviously above all current methods, as summarized in Table VII. This outcome shows that the hierarchical multimodal structure better extracts intricate bankruptcy indicators from textual and financial features. By combining these complementary modalities, the proposed framework achieves superior discrimination and more reliable predictive performance. This strength is evidenced by the model's robustness and consistently strong predictive capability across numerous experiments.

V. CONCLUSION

A robust early warning system for corporate financial distress is essential for investors, regulators, and financial institutions to manage risk and preserve market stability. This study developed D-HAN-Net, a hybrid dual-stream deep learning architecture that integrates structured financial indicators with textual signals derived from corporate disclosures. By jointly modeling numerical financial dynamics and narrative evidence from MD&A sections and auditor reports, the proposed framework captures complementary distress signals that are often overlooked in single-modality approaches.

The empirical results show that the combination of financial ratios and textual information from written disclosure is able to improve the bankruptcy prediction performance significantly. The proposed model has the highest performance in terms of all evaluation metrics such as accuracy, AUC, and F1-score with an efficient balance between precision and recall. Compared with the standard machine learning benchmarks and the transformer-based text models, D-HAN-Net is able to reduce classification errors and increase the overall classification reliability. Moreover, the fact that results are consistent across multiple random seeds suggests that the observed performance gains are robust, rather than sample-specific. The ablation analysis further indicates that every architectural component has a material contribution to the overall predictive performance of the model, with especially high contribution of the gated residual numerical encoder, hierarchical text representation, and cross-modal fusion mechanism. These results highlight the importance of bringing diverse financial information together in a cohesive predictive model. In addition, the interpretability analysis indicates that the model captures economically meaningful indicators of distress. Audit-related going concern indicators as well as profitability and balance sheet strength indexes become key variables. The linguistic analysis of disclosure texts also suggests that the model finds distress-related narrative patterns often found with financially vulnerable firms.

Beyond the predictive performance, the results of this study have meaningful implications for the financial reporting regulation. Narrative disclosures, especially MD&A discussions and auditor reports, provide informative signals of financial distress. Therefore, regulatory authorities may wish to consider enhancing mandatory reporting standards to increase the clarity, consistency and decision-usefulness of such disclosures. More standardized and informative reporting practices could help improve the effectiveness of data-driven early warning systems and provide support to more timely oversight by regulators, creditors and investors.

Overall, the combination of structured financial data and narrative disclosure is a more complete representation of cor-

porate financial condition. The proposed architecture provides a workable and reliable framework for early prediction of bankruptcy, as well as informed financial risk assessment. Despite the strong predictive performance, the proposed framework may still be affected by temporal distribution shifts, industry-specific reporting variations, and incomplete disclosure availability in real-world financial environments. Future research may investigate temporal forecasting settings and robustness under changing economic conditions.

ACKNOWLEDGMENT

The authors would like to express their sincere gratitude to the Southeast University, Dhaka, Bangladesh, for providing the essential laboratory facilities and technical support required to conduct this research.

***Abstract*—Visual-inertial odometry (VIO) tends to degrade in aggressive dynamic and low-texture environments, where rapid motion, weak visual structure, and moving objects reduce the reliability of visual observations. This study presents TRAIL-VIO, a temporal reliability-aware visual-inertial odometry framework with line feature enhancement. The method estimates temporal observation reliability by combining semantic priors with IMU-based motion consistency, which allows a continuous and time-varying assessment of observation quality instead of frame-wise decisions. A reliability-aware point-line association scheme is also introduced, where inertial prediction is used to constrain feature matching and partially corrupted line segments are selectively retained. In addition, a reliability-guided marginalization strategy is applied to reduce the influence of unreliable visual constraints before they are incorporated into the prior. Experiments on the EuRoC MAV benchmark and a self-collected UAV dataset show that TRAIL-VIO achieves average RMSE values of 0.042 m and 9.51 m, respectively, outperforming representative baseline methods in dynamic and low-texture scenarios. Additional ablation, parameter-sensitivity, and runtime analysis further verify the contribution of the main modules, the robustness of the selected parameters, and the computational feasibility of the proposed framework.**

***Keywords*—Visual-inertial odometry; point-line feature fusion; dynamic environments; observation reliability estimation; marginalization; UAV navigation**

I. Introduction

Visual-inertial odometry (VIO) is widely used for autonomous navigation of micro aerial vehicles (UAVs), mobile robots, and other platforms in GPS-denied environments. By combining geometric constraints from visual measurements with short-term motion information from inertial sensors, VIO enables accurate and continuous state estimation [1], [2].

However, in real-world environments, VIO systems often operate under non-ideal conditions. Aerial platforms often undergo rapid motion, which easily introduces motion blur and large viewpoint changes. At the same time, many environments are weakly textured and contain moving objects. These factors not only degrade feature quality, but also make visual observations less reliable. As a result, incorrect data association may occur, leading to reduced estimation accuracy or even tracking failure. Improving robustness under such aggressive and dynamic conditions is still challenging.

Existing methods for improving VIO robustness mainly follow two directions. One line of work focuses on enhancing the estimator, typically through tightly coupled visual-inertial optimization. Another line introduces additional geometric features, such as line features, to complement point features [3]. These strategies do improve performance in difficult scenarios. However, they still depend heavily on the quality of front-end observations. When motion becomes aggressive, both point and line features can degrade before the back-end has a chance to compensate.

To address the limitations of the static-world assumption, recent studies have explored dynamic-scene SLAM and VIO methods based on semantic segmentation and geometric consistency checks [4], [5], [6]. These approaches aim to detect and filter out dynamic observations. Semantic cues help identify potentially movable objects, while geometric verification and IMU-based reasoning provide additional constraints. Together, they improve robustness to a certain extent.

While these dynamic-scene pipelines can remove obvious outliers, they still rely heavily on frame-wise filtering. This makes them sensitive to segmentation errors and short-term changes in object motion. The limitation becomes more evident in structurally rich environments. In low-texture scenes, line features often play an important role. Even partial occlusion or slight dynamic interference can cause an entire line segment to be discarded. As a result, useful structural information is unnecessarily lost [6]. Most existing methods handle uncertain observations only at the front end, typically through simple down-weighting. Their influence on the back-end is rarely considered. Without a temporal evaluation of observation reliability, these imperfect measurements can still enter the optimization process. Over time, they are absorbed into the marginalized prior, which gradually degrades the consistency of the sliding-window estimation [7].

These limitations suggest that the key issue is not only identifying dynamic observations, but also evaluating their reliability over time. In aggressive scenarios, semantic predictions, geometric residuals, and image quality can vary significantly across frames. Relying on frame-wise decisions is therefore insufficient. A more reasonable approach is to estimate observation reliability in a temporal and recursive manner, and incorporate it consistently into both front-end processing and back-end optimization.

To address these issues, we present TRAIL-VIO, a

*Corresponding author

reliability-aware framework tailored for aggressive dynamic environments. Instead of treating observation quality as a simple filtering problem at the front end, our method estimates it over time and uses it throughout the system. The estimated reliability is used in feature association, local structure handling, and marginalization. In this way, unreliable observations can be handled earlier, which helps maintain stable tracking while preserving long-term consistency. The main contributions of this study are summarized as follows:

- We introduce a recursive method to estimate temporal observation reliability. By combining semantic cues with IMU-based motion consistency, reliability is modeled as a time-evolving state rather than independent frame-wise decisions. This leads to more stable behavior under dynamic disturbances.
- We propose a reliability-aware front-end for point-line association. IMU prediction is used to guide matching, and partially corrupted line features are handled more carefully. Instead of discarding them completely, the method preserves valid segments when possible, which improves robustness in low-texture scenes.
- We develop a marginalization strategy that takes observation reliability into account. Observations are screened before being incorporated into the prior, reducing the influence of degraded measurements. This helps limit error accumulation and improves long-term estimation consistency.

The rest of this study is structured as follows: Section II reviews the related work. Section III outlines the system architecture. Section IV gives the details of our proposal. Section V details the experimental results, and Section VI concludes the study and discusses potential directions for future work.

II. Related Work

A. Visual-Inertial Estimation and Feature Representations

Visual-inertial odometry typically advances on two fronts, the underlying state estimator and the choice of visual features. Point-based systems remain the standard. Frameworks like VINS-Mono [1] and ORB-SLAM3 [2] provide reliable starting points for most state estimation tasks. Yet, points alone often struggle in environments lacking distinct textures. To address this, systems such as PL-VIO [3] bring in lines or other geometric primitives, showing noticeable gains in structurally challenging scenes.

Early VIO architectures relied heavily on filtering techniques. MSCKF [8] set a benchmark here by introducing a multi-state constraint Kalman filter for vision-aided navigation. Later variants like S-MSCKF [9] pushed this concept further to better handle aggressive motion. Alternatively, ROVIO [10] tied direct image alignment into an EKF framework, which helps when standard feature tracking fails. These filter-based methods are fast. They fit well on resource-constrained hardware. Still, their accuracy tends to drop if visual observations degrade even for a short period.

Over time, the field shifted heavily toward nonlinear optimization. Keyframe-based, tightly coupled optimization proved highly effective in systems like OKVIS [11]. More recently, frameworks like OpenVINS [12] and VINS-Fusion [13] have generalized these concepts, making sliding-window optimization a common setup for multi-sensor fusion. In mostly static or visually clear environments, these methods are highly accurate. The catch lies in the front end. They generally trust that incoming visual constraints are reliable. When a platform moves aggressively through degraded conditions, this assumption often breaks down.

Beyond tweaking the backend estimator, researchers look to richer feature representations to bridge these reliability gaps. Point-line fusions are particularly common. PL-SLAM [14] and PL-VINS [15] early on showed how lines naturally complement points where textures are sparse. This sparked a wave of extensions. Works like Trifo-VIO [16], PLI-VINS [17], LRPL-VIO [18], PLE-SLAM [19] and PL-CVIO [20] adapt point-line constraints to various sensor setups and scenarios. Others look even higher up the geometric hierarchy. StructVIO [21] leverages structural regularities common in man-made spaces, while Pop-up SLAM [22] incorporates planar structures. Ultimately, adding these higher-level primitives helps stabilize the system when simple point features fail.

While incorporating more geometric features certainly improves observability, it does not automatically guarantee reliability. Real-world conditions, such as sudden lighting shifts, partial occlusions, or motion blur, can easily corrupt both point and line tracking. Lines present a unique challenge here. Most existing frameworks treat them as rigid, all-or-nothing entities. A line segment is typically either fully accepted into the optimization or discarded entirely, even if only a small section is corrupted. This binary approach often wastes valuable geometric data in cluttered environments.

Simply having more constraints available is not enough. A robust system must also be able to gauge which constraints to actually trust over time. This becomes particularly critical in dynamic scenarios. In such environments, the observation quality of a tracked feature can fluctuate wildly from one frame to the next. If the front end fails to filter out these unreliable observations, the errors inevitably bleed into the backend. Once they contaminate the state estimation and the marginalization process, the long-term accuracy of the system gradually degrades.

B. VIO/SLAM in Dynamic Environments

Navigating dynamic environments remains a central challenge for VIO and SLAM systems. Initial efforts leaned heavily on pure vision. Systems like DS-SLAM [23], DynaSLAM [4], DynaSLAM II [24], and SOF-SLAM [25] use semantic segmentation and motion consistency to detect and mask dynamic regions before they can corrupt pose estimation. Taking this a step further, object-level methods such as visual-inertial multi-instance SLAM [26] attempt to jointly model camera motion alongside moving objects and scene structure. Clearly, blending semantic and geometric cues helps stabilize localization when the environment is moving.

However, a key issue lies in how dynamic observations are handled. Most frameworks rely on frame-by-frame judgments. They classify a visual observation as either valid or invalid based on an instantaneous snapshot—such as a single

segmentation mask or immediate motion inconsistency. This works well when dynamic evidence is obvious. Yet, it quickly becomes brittle. Segmentation masks can be noisy. Motion is sometimes intermittent, and dynamic objects often stop moving temporarily. In aerial scenarios, these problems are amplified. Rapid viewpoint shifts and motion blur cause the quality of observations to swing unpredictably between consecutive frames.

To ground these fluctuating visual signals, researchers increasingly turn to inertial priors. By explicitly fusing IMU data with semantic and geometric cues, systems like DynaVINS [5] and D-VINS [6] build stronger defenses against dynamic interference. Extensions of this idea tackle specific edge cases: VINS-Dimc [27] applies multiple constraints, SRVIO [28] targets loop closures in moving scenes, and RD-VIO [29] uses IMU-informed matching to verify motion types. GMS-VINS [30] also shows the value of adapting semantic processing on the fly. Collectively, this body of work confirms that inertial data is essential for cross-checking visual dynamics.

But the front end is only half the battle. Long-term accuracy hinges heavily on back-end consistency. DM-VIO [7] illustrates this perfectly: how a system handles marginalization directly dictates its resilience over time. If the front end fails to adequately suppress a moving feature, that corrupted observation sneaks into the sliding-window optimization. Once it gets baked into the historical prior, the error becomes permanent, slowly degrading the entire trajectory.

Several limitations remain in current approaches. First, we still rely too much on short-sighted, frame-level suppression, leaving estimators vulnerable to transient errors like segmentation flickering. Furthermore, observation reliability is rarely tracked over time. This is especially true for heterogeneous data like point-line combinations. As noted earlier, partially corrupted lines are often handled clumsily—either kept entirely or thrown away, sacrificing useful geometric fragments. Finally, there is a systemic failure to protect the marginalized prior. While many algorithms down-weight bad features in the current optimization window, few provide a structural mechanism to stop these unreliable observations from polluting historical estimates.

These observations suggest that a more unified strategy is needed. To truly handle aggressive dynamic environments, the system needs a temporally consistent way to measure observation reliability. More importantly, this reliability metric must be woven seamlessly through both front-end feature association and back-end marginalization.

III. System Overview

The proposed framework focuses on improving the robustness of visual-inertial estimation in dynamic and low-texture environments, where unreliable visual observations may pass through the front end and affect back-end optimization. We break away from the standard practice of frame-wise binary feature rejection. Instead, we introduce a unified reliability model. This model evaluates the quality of each point and line over time, and the resulting reliability is used throughout the estimation pipeline. Fig. 1 outlines the overall architecture.

The pipeline ingests three primary streams of data, which are raw images, high-frequency IMU measurements, and semantic segmentation masks. Each plays a distinct role. Images yield the base point and line features. The IMU provides short-term kinematic predictions, serving as a physical baseline for geometric consistency checks. Meanwhile, the semantic masks supply category-level priors to flag potentially moving objects. Rather than processing these inputs in isolation, the system fuses them to dynamically estimate a continuous reliability score for each visual feature.

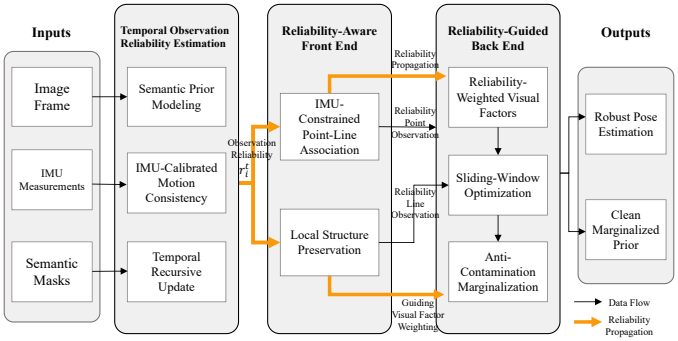

Fig. 1. Overall framework of the proposed method. Temporal observation reliability is estimated using semantic and inertial cues, and is further utilized in both front-end association and back-end marginalization.

We build upon a standard sliding-window visual-inertial formulation, tracking the vehicle's orientation, position, velocity, and sensor biases at each keyframe. Where our approach diverges is in the front-end processing. As points and lines are extracted, they are not just blindly tracked. They are assigned a temporally updated reliability score. We compute this by cross-referencing semantic priors with IMU-driven geometric verification, smoothing the results recursively over time.

This metric directly steers the front-end data association. Highly reliable features are actively preserved to anchor the local structure. Conversely, suspicious observations are suppressed before they can trigger faulty matches. Notably, this continuous scoring allows the system to salvage partially corrupted line features, preserving their valid segments rather than simply discarding the entire line.

The reliability-aware philosophy extends naturally into the back end. During optimization, the same confidence scores modulate the visual factors. Trustworthy features dominate the objective function. Uncertain ones are heavily down-weighted, or outright pruned, long before they can be absorbed into the marginalized prior. By stopping transient errors from accumulating within the sliding window, the system maintains stable, long-term consistency, even during aggressive maneuvers typical in UAV flight.

IV. Proposed Method

A. Temporal Observation Reliability Estimation for Aggressive Dynamic Scenarios

In aggressive UAV scenarios, both semantic predictions and geometric observations tend to become unstable. Semantic segmentation may produce incorrect labels or low-confidence outputs. At the same time, geometric measurements are easily affected by motion blur, rapid rotations, and depth ambiguity. These factors often appear together. As a result, decisions

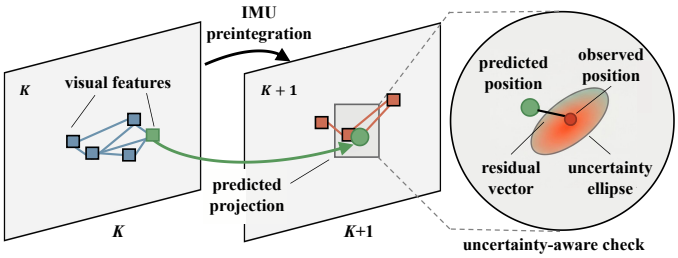

Fig. 2. IMU-calibrated kinematic consistency. A feature from the previous frame is projected to the current frame using IMU-preintegrated motion, and the difference between predicted and observed positions is evaluated with uncertainty.

made independently at each frame can be unreliable. Rather than forcing observations into binary categories, we treat the problem from a temporal perspective. Each observation is assigned with a continuous reliability value, which evolves over time. This value is not determined by a single cue. Instead, it is gradually refined by combining semantic priors, inertial consistency, and temporal recursion. This formulation can make the estimation less sensitive to short-term disturbances.

1) Semantic prior modeling: To introduce semantic cues without adding significant overhead, a lightweight YOLOv8n-seg model [31], pretrained on the MS COCO dataset [32], is employed. The semantic output is not used for direct filtering. Instead, it provides an initial estimate of observation reliability.

For each observation $\mathbf{u}_i^t$, the network outputs a category label c_i^t and a confidence score q_i^t. Each category is associated with a predefined coefficient $\rho_c \in [0,1]$, reflecting how likely it is to remain static. Static structures such as buildings are assigned higher values, while potentially dynamic objects are assigned lower ones. The semantic prior is then computed as Eq. (1):

$$s_i^t = \rho_{c_i^t} q_i^t + (1 - q_i^t) s_0 \tag{1}$$

where, s_0 is a neutral prior, typically set to 0.5. When the confidence is high, the model relies more on the semantic prediction. When it is low, the estimate falls back toward a neutral value. Compared with binary masking, this formulation keeps uncertainty in the representation. It also provides a smoother starting point for later updates.

2) IMU-calibrated kinematic consistency: Semantic information alone is often insufficient to determine whether an observation is truly static. To complement it, an IMU-based consistency check is introduced. The core idea is to evaluate whether a visual observation follows the rigid-body motion predicted by inertial measurements.

As illustrated in Fig. 2, IMU measurements between two consecutive frames are first preintegrated to estimate relative motion. A feature observed in the previous frame is then projected into the current frame [see Eq. (2)]:

$$\hat{\mathbf{u}}_i^t = \pi\left(\mathbf{T}_{cb}\hat{\mathbf{T}}_{t\leftarrow t-1}^{\text{imu}}\mathbf{T}_{bc}\mathbf{P}_i^{t-1}\right) \tag{2}$$

The difference between the predicted and observed positions forms the reprojection residual. Instead of applying a fixed threshold, this residual is evaluated with respect to its uncertainty. IMU noise, depth uncertainty, and image noise are all taken into account. The consistency is measured using the Mahalanobis distance [see Eq. (3)]:

$$m_i^t = (\mathbf{e}_i^t)^\top (\mathbf{\Sigma}_i^t)^{-1} \mathbf{e}_i^t \tag{3}$$

This allows the evaluation to adapt to different motion conditions. When motion is aggressive, uncertainty increases and the constraint becomes more tolerant. Under stable conditions, the check becomes stricter. In this way, the measure remains consistent with the underlying physical model.

3) Temporal recursion and reliability update: To reduce the impact of transient errors and occasional inconsistencies, reliability is updated over time rather than determined from a single frame. Each observation is treated as a temporal state. Three conditions are considered static, quasi-static, and dynamic. At each time step, the predicted state from the previous frame is combined with current evidence. This is done through a Bayesian-style update [see Eq. (4)]:

$$\mathbf{p}_i^t = \frac{\mathbf{l}_i^t \odot \bar{\mathbf{p}}_i^t}{\mathbf{1}^\top (\mathbf{l}_i^t \odot \bar{\mathbf{p}}_i^t)} \tag{4}$$

The update blends historical information with new observations. Short-term noise is less likely to dominate the result. The estimation therefore becomes more stable over time. A scalar reliability value is derived as Eq. (5):

$$r_i^t = P(z_i^t = S) + \eta P(z_i^t = Q) \tag{5}$$

where, $\eta \in [0,1]$ controls how much partially reliable observations contribute. The estimated reliability is used throughout the system. In the front end, it influences feature selection and association. In the back end, it is incorporated into visual factors and marginalization.

B. Reliability-Aware Point-Line Association and Local Structure Preservation

This module transforms the estimated observation reliability into robust front-end constraints. In aggressive UAV scenarios, rapid motion, viewpoint changes, and weak texture often reduce the stability of point features. Line features can provide complementary structural information, but they are sensitive to partial occlusion and local dynamic interference. To address these challenges, the proposed method integrates IMU-guided search, reliability-aware association, and local structure preservation to retain valid observations while suppressing unreliable ones.

1) IMU-constrained adaptive matching for point and line features: The front-end operates feature extraction based on ORB points and LSD line. For point features, the expected position in the current frame is predicted using IMU-preintegrated motion. Matching is then performed within a local search region centered on this prediction, rather than globally. The size of this region is adjusted based on motion uncertainty. Under stable motion conditions, the region is kept small to maintain efficiency and matching precision.

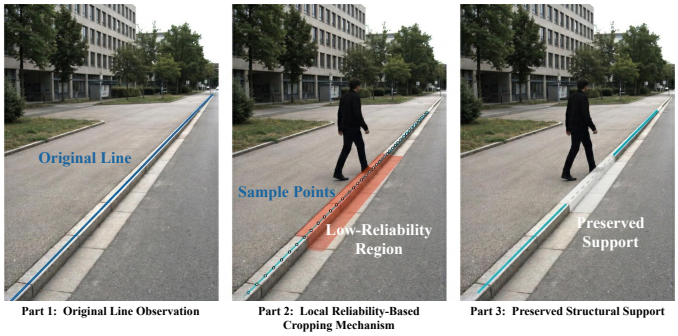

Fig. 3. Local line cropping and structure preservation mechanism. The reliability map is sampled along each matched line segment, and only the connected subregion with sufficiently high reliability is retained as the valid structural support.

During aggressive motion, the region is expanded to prevent the loss of valid correspondences. Line features are handled with a similar predictive approach. Each line segment from the previous frame is projected into the current frame, and candidate matches are searched within an uncertainty-aware band around the predicted location. This limits mismatches caused by viewpoint changes and assists tracking in low-texture scenes.

Observation reliability is also incorporated into the matching cost. For line features, the cost function is defined as Eq. (6):

$$C_k = \lambda_d d_{\mathrm{LBD}} + \lambda_\theta d_\theta + \lambda_\perp d_\perp + \lambda_r (1 - r^t_{\ell_c}) \tag{6}$$

The first three terms represent descriptor similarity and geometric consistency, while the final term applies a penalty based on reliability. As a result, matches exhibiting both geometric consistency and temporal reliability are prioritized. A similar reliability-based filtering mechanism is applied to point features to select stable candidates.

2) Local line cropping and structure preservation: Most existing methods treat line segments as complete entities, discarding the entire line if a portion overlaps with a dynamic region. This strategy can be overly restrictive in dynamic environments where lines may only be partially affected. The proposed local line cropping mechanism is illustrated in Fig. 3.

Instead of binary rejection, the proposed method evaluates lines locally. A reliability map is constructed on the image plane, and reliability values are sampled along the line segment. The average reliability is computed as Eq. (7):

$$r^t_\ell = \frac{1}{N} \sum_{s=1}^{N} r(\mathbf{x}_s) \tag{7}$$

While this average provides an indication of overall quality, it is not used directly for filtering. The line is parameterized, and sub-regions are evaluated individually. Only the segments with reliability exceeding a defined threshold are retained [see Eq. (8)]:

$$\Omega_{\mathrm{stat}} = \{ s \in [0,1] \mid r(\ell(s)) > \tau_{\mathrm{keep}} \} \tag{8}$$

Among the retained sections, the longest continuous segment is selected as the valid observation, and the remainder is removed. This makes it possible to preserve structural information even if the original line is partially degraded.

3) Joint reliability-aware optimization: After data association, observation reliability is further integrated into the optimization stage. The contribution of each observation is weighted by both its geometric residual and its estimated reliability. For point features, the reprojection residual is defined as Eq. (9):

$$\mathbf{e}_{p,i} = \mathbf{u}_i - \hat{\mathbf{u}}_i \tag{9}$$

For line features, the residual is computed using the preserved cropped segments, limiting the influence of unreliable portions. The joint optimization problem is formulated as Eq. (10):

$$\min_{\mathcal{X}} \sum_{i \in \mathcal{P}} w_{p,i} \rho \left(\|\mathbf{e}_{p,i}\|^2_{\mathbf{\Sigma}^{-1}_{p,i}} \right) + \sum_{k \in \mathcal{L}} w_{l,k} \rho \left(\|\mathbf{e}_{l,k}\|^2_{\mathbf{\Sigma}^{-1}_{l,k}} \right) \tag{10}$$

The $w_{p,i}$ and $w_{l,k}$ weights are determined by the temporal reliability. Consistent observations receive higher weights, while less reliable measurements are down-weighted.Robust kernels ρ are maintained to filter instantaneous outliers. The reliability weighting complements the robust kernel by reflecting the historical stability of the observation, which adds another way to handle dynamic interference during sliding-window estimation.

C. Reliability-Guided Anti-Contamination Marginalization

In sliding-window visual-inertial odometry, marginalization is used to keep the state size bounded and maintain computational efficiency. In dynamic or aggressive scenarios, however, some unreliable visual observations may pass front-end checks and enter the marginalized prior. Once included, these corrupted constraints can accumulate and lead to estimation drift over time. A reliability-guided marginalization strategy is introduced to reduce this effect. Observation reliability estimated in the front end is propagated to the prior construction stage, where visual factors with low reliability are down-weighted before marginalization. The overall pipeline is shown in Fig. 4.

Let $r_j \in [0,1]$ denote the reliability of the j-th visual factor. For point features, this value comes from temporal reliability estimation. For line features, it is derived from the retained line segment. Rather than using a hard threshold, a continuous gating function is applied to control the contribution of each factor [see Eq. (11)]:

$$\Gamma(r_j) = \begin{cases} 0, & r_j \le \tau_{\mathrm{drop}}, \\ \dfrac{1}{1 + \exp\left[-k\left(r_j - \tau_{\mathrm{marg}}\right)\right]}, & \tau_{\mathrm{drop}} < r_j < \tau_{\mathrm{safe}}, \\ 1, & r_j \ge \tau_{\mathrm{safe}}. \end{cases} \tag{11}$$

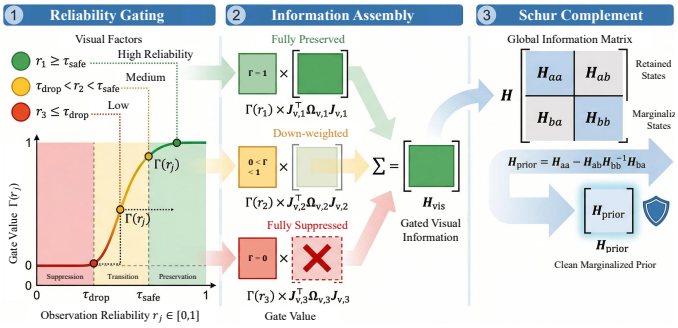

Fig. 4. Reliability-guided anti-contamination marginalization strategy. Observation reliability estimated in the front end is propagated to prior construction, so that suspicious visual constraints are weakened or excluded before being absorbed into the marginalized prior.

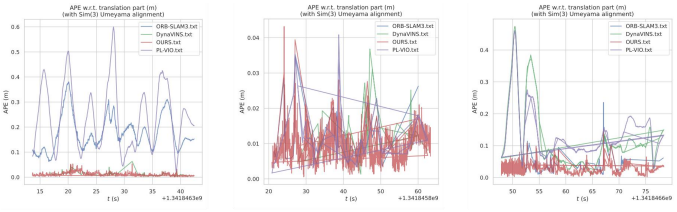
This function separates factors into three cases, low-reliability factors are removed, high-reliability ones are kept, and intermediate cases are smoothly weighted. Compared with binary selection, this formulation reduces sensitivity near the threshold. The gating is applied during linearization by scaling each visual factor. The visual information matrix becomes Eq. (12):

$$\mathbf{H}_{\text{vis}} = \sum_{j} \Gamma(r_j)\, \mathbf{J}_{v,j}^{\top} \mathbf{\Omega}_{v,j} \mathbf{J}_{v,j} \tag{12}$$

In this way, reliability is incorporated directly into the information matrix. Visual factors with low reliability contribute less to the optimization. After assembling the gated system, marginalization is carried out using the standard Schur complement. The state increment is partitioned into marginalized variables $\delta \mathbf{X}b$ and retained variables $\delta \mathbf{X}a$, yielding the prior [see Eq. (13)]:



$$\mathbf{H}_{\text{prior}} = \mathbf{H}_{aa} - \mathbf{H}_{ab}\mathbf{H}_{bb}^{-1}\mathbf{H}_{ba} \tag{13}$$

Since unreliable factors are suppressed beforehand, the resulting prior mainly reflects reliable visual constraints and inertial information. A small damping term can be added if needed to improve numerical stability. Compared with conventional approaches, this method introduces a reliability-based filtering step before marginalization. This helps limit the influence of unreliable observations on the prior and improves consistency in dynamic environments.

V. Experimental Results

To evaluate the proposed method under different motion conditions and scene complexities, experiments are conducted on the EuRoC MAV benchmark and a self-collected UAV dataset. Both datasets provide synchronized image and IMU measurements, allowing the proposed framework to be evaluated as a complete visual-inertial odometry system. The evaluation focuses on scenarios involving rapid motion, weak texture, and dynamic interference.

The method is compared with several representative approaches, including ORB-SLAM3, DynaVINS, and PL-VIO.

TABLE I. Comparison of the Average RMSE [m] of the Proposed Method with ORB-SLAM3, DynaVINS, and PL-VIO on the EuRoC Dataset.

Sequence	ORB-SLAM3	DynaVINS	PL-VIO	Ours
MH01	0.075	0.084	0.210	0.062
MH02	0.044	0.105	0.232	0.037
MH03	0.217	0.054	0.312	0.046
MH04	0.132	0.122	0.139	0.075
MH05	0.121	0.147	0.257	0.057
V101	0.059	0.047	0.059	0.049
V102	0.023	0.018	0.016	0.011
V103	0.096	0.180	0.130	0.037
V201	0.040	0.056	0.032	0.042
V202	0.062	0.090	0.095	0.021
V203	0.104	0.154	0.201	0.027
Average	0.088	0.096	0.153	0.042

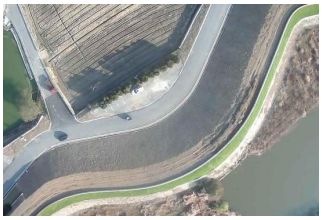
The evaluation focuses on scenarios involving dynamic interference, weak texture, and large motion. For quantitative analysis, Absolute Pose Error (APE) and Absolute Trajectory Error (ATE) are used as the primary metrics. APE reflects the overall trajectory deviation, while ATE focuses on translational accuracy. RMSE is also reported to give a more compact summary and to capture sensitivity to larger errors.

A. Evaluation on the EuRoC Dataset

The EuRoC MAV dataset [33] is widely used in visual-inertial odometry research. It provides synchronized stereo images and IMU measurements, together with ground-truth trajectories. The dataset includes two indoor environments, Machine Hall (MH) and Vicon Room (V), covering motion patterns from relatively stable to aggressive.

All 11 sequences are included in the evaluation, namely MH01-MH05, V101-V103, and V201-V203. These sequences involve various challenges, such as rapid motion, motion blur, repeated structures, and weak-texture regions. Some sequences are particularly demanding, which makes them suitable for testing robustness.

As can be seen in Fig. 5, the proposed method generally produces lower errors with reduced fluctuations compared to the baseline methods. On relatively stable sequences such as V102, the performance of all methods is quite close. On more challenging sequences like MH03 and V203, fewer error spikes can be observed, and the estimates remain more stable overall. This behavior is likely related to the temporal reliability mechanism, which helps mitigate the impact of degraded observations.



From Table I, the proposed method achieves an average RMSE of 0.042 m, which is lower than ORB-SLAM3, Dy-

(b) TR9S lands around the lake

(c) Urban road data scene

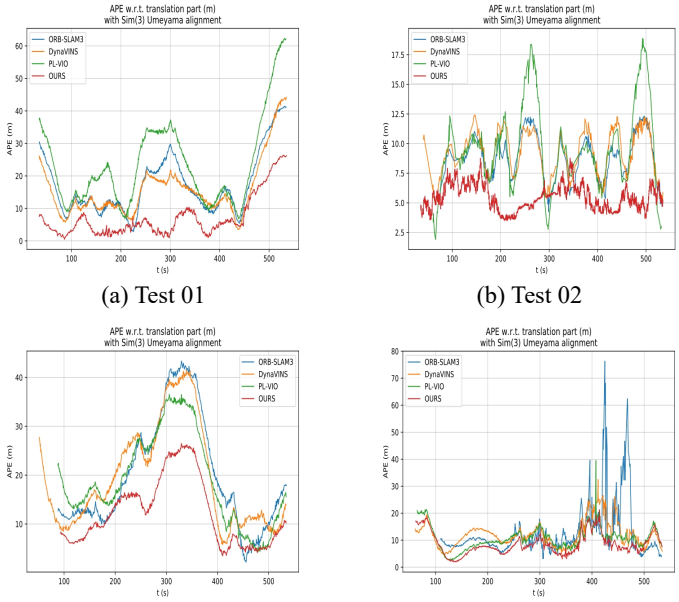
(d) Forest and field data scene

Fig. 6. The data collection system and typical test scenes.

naVINS, and PL-VIO. The improvement becomes more noticeable on challenging sequences such as MH03, MH05, V103, V202, and V203, where motion complexity and dynamic interference are more pronounced. On sequences such as V101 and V201, the proposed method does not obtain the lowest error, although the differences remain relatively small. Taken together, the results suggest that the method maintains stable performance across different sequences and shows improved robustness under varying visual-inertial conditions.

B. Evaluation on Self-Collected UAV Flight Dataset

To further examine the method under real flight conditions, we collected a UAV dataset using a hexarotor platform equipped with a monocular camera, an IMU, and a differential GPS/RTK system. The camera and IMU data are used for odometry estimation, while the RTK measurements provide ground truth. The camera runs at 30Hz and the IMU at 100Hz. All sensors are time-synchronized, and the camera–IMU extrinsics are calibrated offline. For consistency, all baseline methods use the same input data, and trajectory errors are computed against the RTK reference.



Five sequences, denoted as Test01-Test05, are recorded in different environments, including urban areas, lakes, forests, and suburban roads. The total flight distance is about 20km. These sequences include a range of conditions such as aggressive motion, weak-texture regions, and dynamic objects like vehicles and pedestrians. The data collection platform and representative test scenes are shown in Fig. 6.

Trajectory evaluation is carried out using the EVO toolkit after aligning the estimated trajectories with the RTK ground truth.

From Table II, the proposed method achieves an average RMSE of 9.51 m, which is lower than ORB-SLAM3, DynaVINS, and PL-VIO. The difference is more visible on sequences such as Test01, Test04, and Test05, where longer trajectories, stronger motion, and dynamic interference make estimation more difficult.

TABLE II. COMPARISON OF RMSE [m] OF THE PROPOSED METHOD WITH ORB-SLAM3, DYNAVINS, AND PL-VIO ON THE UAV DATASET.

Sequence	ORB-SLAM3	DynaVINS	PL-VIO	Ours
Test01	30.52	17.79	27.41	8.45
Test02	8.75	9.65	10.80	5.42
Test03	10.56	10.95	42.68	9.87
Test04	36.09	23.25	22.29	14.55
Test05	46.14	12.79	11.46	9.26
Average	26.41	14.89	22.93	9.51

(a) Test 01 (b) Test 02

(c) Test 04 (d) Test 05

Fig. 7. APE curves of ORB-SLAM3, DynaVINS, PL-VIO, and the proposed method on the self-collected UAV dataset.

As seen in Fig. 7, the proposed method generally maintains lower errors and smoother trends along the trajectories. The baseline methods show larger fluctuations in several segments, together with occasional spikes, which suggests local tracking instability.

This difference becomes clearer in segments with rapid motion or degraded visual input. In such cases, ORB-SLAM3 and DynaVINS tend to produce noticeable error increases and drift over time, while the proposed method remains more stable and avoids abrupt degradation. This behavior indicates that the reliability-aware design can help improve consistency over longer trajectories in dynamic outdoor scenes.

C. Ablation Study

To further analyze the contribution of the proposed components, two ablation studies are conducted on the self-collected UAV dataset. The reported RMSE values are averaged over the five UAV sequences. These sequences include outdoor scenes with weak textures, camera motion, and dynamic interference, and therefore provide a practical basis for evaluating the stability of each module.

Table III presents the ablation results of the reliability-aware VIO framework on the challenging UAV sequences.

TABLE III. ABLATION STUDY OF THE PROPOSED RELIABILITY-AWARE VIO FRAMEWORK.

Temporal Observation Reliability Estimation	Point-Line Association and Local Structure Preservation	Reliability-Guided Marginalization	RMSE (m)	Relative percentage Reduction in RMSE
-	-	-	22.93	-
✓	-	-	15.09	34.19%
-	✓	-	17.64	23.07%
-	-	✓	13.33	41.87%
✓	✓	✓	9.51	58.53%

TABLE IV. ABLATION STUDY OF THE TEMPORAL RELIABILITY ESTIMATION MODULE.

Semantic Prior	IMU-Based Motion Consistency	RMSE (m)	Relative percentage reduction in RMSE
-	-	20.39	-
✓	-	16.58	18.69%
-	✓	15.24	25.26%
✓	✓	10.75	47.28%

Each module brings a certain improvement over the base point-line VIO system. Temporal observation reliability estimation reduces the average RMSE from 22.93 m to 15.09 m, which suggests that modeling the credibility of visual observations over time helps suppress unstable measurements. The point-line association and local structure preservation strategy also improves the result by keeping useful geometric information from partially affected line features. Reliability-guided marginalization gives the largest individual reduction among the three components. Preventing unreliable visual constraints from being absorbed into the marginalized prior is helpful for limiting accumulated drift. With all three components enabled, TRAIL-VIO achieves the lowest average RMSE of 9.51 m.

Table IV reports the average performance of the temporal reliability estimation module across the five UAV sequences. Using semantic priors alone improves the RMSE from 20.39 m to 16.58 m, mainly because potentially dynamic regions can be identified before they strongly affect pose estimation. IMU-based motion consistency alone leads to a slightly lower RMSE of 15.24 m, showing that inertial prediction provides a useful motion-level check when visual observations become uncertain. The combination of both cues achieves the best average result. Semantic information and IMU-based consistency are not simply redundant, and they tend to compensate for each other in temporal reliability estimation.

D. Parameter Sensitivity Analysis

To address potential concerns regarding the generalizability of the manually configured parameters and to evaluate the robustness of the proposed framework, a comprehensive sensitivity analysis is conducted. We select two highly representative and challenging sequences for this evaluation: MH05 from the EuRoC dataset, which features indoor aggressive motion and low-illumination, and Test04 from the self-collected UAV dataset, which encompasses long-distance outdoor flight with strong dynamic interference. The APE RMSE is employed as the primary evaluation metric.

1) Sensitivity to Reliability Gating Thresholds: The gating parameters τ_{drop} and τ_{safe} control the reliability-guided marginalization strategy in Eq. (11), where visual factors are divided into suppression, transition, and preservation regions according to their estimated reliability. To examine their individual effects, a one-factor-at-a-time control-variable strategy is adopted. In each test, only one threshold is varied, while the remaining parameters are kept fixed at their default values.

TABLE V. SENSITIVITY OF APE RMSE [m] TO THE DROP THRESHOLD τ_{drop}.

τ_{drop}	MH05	Test04
0.00	0.082	18.20
0.05	0.071	16.45
0.10	0.063	15.10
0.15	0.058	14.62
0.20	0.057	14.55
0.25	0.057	14.56
0.30	0.058	14.58
0.35	0.059	14.65
0.40	0.064	15.30
0.45	0.076	17.85
0.50	0.095	21.40

TABLE VI. SENSITIVITY OF APE RMSE [m] TO THE SAFE THRESHOLD τ_{safe}.

τ_{safe}	MH05	Test04
0.50	0.065	15.80
0.55	0.062	15.30
0.60	0.060	14.95
0.65	0.059	14.70
0.70	0.058	14.58
0.75	0.057	14.56
0.80	0.057	14.55
0.85	0.057	14.55
0.90	0.058	14.57
0.95	0.059	14.62
1.00	0.063	15.15

First, the influence of the lower suppression threshold τ_{drop} is evaluated. τ_{safe} and the steepness factor k are fixed, and τ_{drop} is varied from 0.0 to 0.5. The results are reported in Table V. When τ_{drop} is close to 0.0, the suppression effect becomes weak. As a result, some unreliable observations caused by motion blur, dynamic objects, or inconsistent feature associations may still contribute to the optimization and the marginalized prior, leading to an increase in APE RMSE. In contrast, when τ_{drop} is set too high, especially above 0.45, the system tends to suppress more visual factors than necessary. This may remove valid geometric constraints and weaken the visual support for pose estimation. A relatively stable region can be observed when τ_{drop} lies in the interval $[0.15, 0.35]$. Within this range, the RMSE values remain close to the baseline results, approximately $0.057\,\mathrm{m}$ on MH05 and $14.55\,\mathrm{m}$ on Test04.

A similar analysis is conducted for the upper preservation threshold τ_{safe}. In this experiment, τ_{drop} is fixed at its default value, and τ_{safe} is swept from 0.5 to 1.0. As shown in Table VI, stable performance can be observed within a relatively broad interval, and the performance does not collapse under moderate parameter perturbations. Therefore, TRAIL-VIO does not depend on a narrowly selected pair of gating parameters. The default values of τ_{drop} and τ_{safe} are located within stable performance regions rather than at isolated optimal points.

2) Sensitivity to the Transition Steepness Factor: After analyzing the two reliability gating thresholds, we further evaluate the effect of the transition steepness factor k. The steepness factor k controls the shape of the sigmoid weighting function in Eq. (11). It determines how rapidly the reliability

TABLE VII. SENSITIVITY OF APE RMSE [m] TO THE TRANSITION STEEPNESS FACTOR k.

k	MH05	Test04
1	0.063	15.12
5	0.058	14.65
10	0.057	14.55
15	0.057	14.59
20	0.059	14.72
50	0.065	15.38

weight changes within the transition region between τ_{drop} and τ_{safe}. A small k produces a smoother transition, while a large k makes the weighting function closer to a hard switch. Therefore, this parameter affects how gently or aggressively visual factors are down-weighted when their reliability values fall between the suppression and preservation thresholds. In this experiment, τ_{drop} and τ_{safe} are fixed at their default values, and only k is varied. The tested values are selected as $k = \{1, 5, 10, 15, 20, 50\}$, covering a wide range from nearly linear transition to a steep, almost binary gating behavior.

The results in Table VII show that a moderate steepness factor generally leads to more stable performance. Setting k to an extremely low value like 1 tends to under-penalize questionable observations. The transition becomes too flat. Consequently, some degraded features retain a disproportionate amount of influence during the information matrix assembly, which causes a slight increase in the tracking error. And pushing k to 50 mimics a rigid binary threshold. This sharp cutoff can abruptly discard features that are only experiencing transient ambiguity. Such sudden losses of structural constraints occasionally introduce minor instabilities into the sliding-window optimization.

The proposed framework demonstrates considerable tolerance between these two extremes. For values of k roughly between 5 and 15, the APE RMSE remains largely consistent. On the MH05 sequence, the error fluctuates by merely a few millimeters within this moderate range. The Test04 sequence shows a similarly stable plateau. This behavior implies that the soft-gating mechanism successfully bridges the gap between total suppression and full preservation. By smoothing the factor weighting, the system generally avoids overreacting to short-term observation noise.

3) Tolerance to Semantic Prior Perturbation: In addition to the reliability gating parameters, we further evaluate the influence of the semantic category coefficient ρ_c. In the proposed framework, ρ_c represents the prior static reliability of a semantic category in the semantic reliability model. Static structures, such as buildings, roads, and background regions, are assigned relatively high prior values, while potentially dynamic objects, such as pedestrians and vehicles, are assigned lower prior values. Since these coefficients are manually predefined, it is necessary to examine whether inaccurate semantic priors would cause a noticeable degradation in trajectory estimation.

To simulate possible miscalibration of semantic priors in unseen environments, a perturbation factor Δ_ρ is introduced to the default semantic coefficient. The perturbed coefficient is defined as Eq. (14):

$$\tilde{\rho}_c = \text{clip}(\rho_c + \Delta_\rho, 0, 1), \tag{14}$$

TABLE VIII. SENSITIVITY OF APE RMSE [m] TO SEMANTIC PRIOR PERTURBATION.

Perturbation Δ_ρ	MH05	Test04
-30%	0.066	15.32
-20%	0.062	14.95
-10%	0.059	14.68
0	0.057	14.55
$+10\%$	0.058	14.65
$+20\%$	0.061	14.88
$+30\%$	0.065	15.25

where, $\tilde{\rho}_c$ denotes the perturbed semantic coefficient, and $\text{clip}(\cdot)$ limits the perturbed value to the valid interval $[0, 1]$. In this experiment, Δ_ρ is swept from -0.30 to $+0.30$ with a step size of 0.10. The case of $\Delta_\rho = 0$ represents the default semantic prior setting used in the main experiments.

During this analysis, all semantic categories are divided into two broad groups, static categories and potentially dynamic categories. The same perturbation strategy is applied to the semantic coefficients of these categories to evaluate the tolerance of the system to prior uncertainty. This setting is intentionally simple. It does not aim to find category-specific optimal weights. Instead, it tests whether the proposed reliability estimation framework remains stable when the manually assigned semantic priors are not fully accurate. The other parameters, including τ_{drop}, τ_{safe}, and k, are fixed at their default values.

The results are reported in Table VIII. When negative perturbations are introduced, the semantic reliability assigned to static categories decreases, and some stable background features may contribute less to the visual constraints. Positive perturbations have the opposite effect. They may increase the reliability of potentially dynamic or ambiguous regions, so these observations are less strongly penalized by the semantic prior. Both cases can affect the APE RMSE to some extent. Within the tested perturbation range, the variation remains limited, as the final observation reliability is still refined by IMU-based motion consistency and temporal reliability updating.

TRAIL-VIO is not overly sensitive to precisely tuned semantic category coefficients. Semantic information provides an initial prior, rather than a final reliability decision. The subsequent IMU-calibrated kinematic consistency and temporal update help reduce the influence of imperfect semantic priors. Therefore, the proposed framework shows a certain tolerance to manually assigned category weights and does not require highly precise semantic coefficient tuning for every new environment.

E. Runtime Analysis

To evaluate the computational overhead of TRAIL-VIO, the average runtime of the main modules is measured on a laptop equipped with an Intel Core i9-14900HX CPU, 31.1 GB RAM, and an NVIDIA GeForce RTX 4060 GPU under Ubuntu 18.04.6 LTS. The runtime is reported in milliseconds per frame and averaged on the self-collected UAV sequences.

We separate YOLOv8n-seg inference from temporal observation reliability estimation. It only includes the reliability assignment based on semantic outputs, IMU-based motion consistency evaluation, and temporal reliability updating.

TABLE IX. AVERAGE COMPUTATION TIME [ms] OF THE TRAIL-VIO SYSTEM ON SELF-COLLECTED UAV DATASET.

SEQUENCE	POINT AND LINE FEATURE EXTRACTION / TRACKING	YOLOV8N-SEG INFERENCE	TEMPORAL OBSERVATION RELIABILITY ESTIMATION	RELIABILITY-AWARE POINT-LINE ASSOCIATION AND LOCAL STRUCTURE PRESERVATION	BACK-END OPTIMIZATION AND RELIABILITY-GUIDED MARGINALIZATION	TOTAL RUNTIME
Test01	38.76	30.18	3.42	8.71	35.66	116.73
Test02	31.84	27.36	2.95	6.83	27.42	96.40
Test03	35.29	28.11	3.18	7.52	31.36	105.46
Test04	43.67	31.74	3.89	9.34	42.15	130.79
Test05	40.52	29.63	3.61	8.97	38.64	121.37
Average	38.02	29.40	3.41	8.27	35.05	114.15

As shown in Table IX, the average total runtime of TRAIL-VIO is 114.15 ms per frame, corresponding to approximately 8.76 FPS. The runtime varies across different UAV sequences. This variation is mainly related to the number of extracted and tracked point-line features, the density of valid residuals, keyframe insertion, and the scale of sliding-window optimization.

The current implementation has not yet been fully optimized for strict onboard real-time deployment. Further acceleration may be achieved by TensorRT-based semantic inference, reducing the frequency of semantic updates, optimizing line feature extraction, and adopting an asynchronous front-end pipeline.

VI. CONCLUSION

This study presents TRAIL-VIO, a reliability-aware point-line visual-inertial odometry framework for dynamic and low-texture environments. The proposed method models visual observation quality as a temporally updated reliability state rather than making frame-wise binary decisions. By combining semantic priors with IMU-based motion consistency, TRAIL-VIO suppresses transiently degraded observations caused by motion blur, occlusion, weak texture, and moving objects. The estimated reliability is further used in point-line association, local line-structure preservation, optimization, and marginalization, allowing the system to retain useful structural information while reducing the influence of unreliable visual constraints. Experiments on the EuRoC MAV dataset and the self-collected UAV dataset show that TRAIL-VIO generally achieves more accurate and stable trajectories than the compared methods, especially under rapid motion, dynamic interference, and weak visual texture. The additional analyses further support the role of the proposed modules and show that the framework remains reasonably stable under moderate parameter variations, with most of the extra runtime arising from semantic segmentation. Despite these improvements, several practical limitations remain. The method still depends on semantic segmentation quality. Although the sensitivity analysis shows that the framework can tolerate perturbations of up to $\pm 30\%$ in the initial semantic priors, persistent semantic errors may still degrade the estimation, especially when dynamic objects are repeatedly assigned high reliability. The reliability-related parameters are also manually configured. The system maintains relatively stable tracking when $\tau_{\mathrm{drop}} \in [0.15, 0.35]$ and $k \in [5, 15]$, but these ranges may shift for sensors with different noise characteristics, frame rates, or motion patterns. In addition, the point-line front end still requires sufficient valid geometric constraints. In structure-poor scenes, especially under sustained aggressive rotations, the loss of reliable visual updates may leave IMU preintegration insufficiently corrected and lead to rapid drift. Future work will focus on adaptive reliability estimation, efficient semantic inference, and tighter visual-inertial coupling for more robust onboard deployment.

Trustworthy App Detection in Saudi Mobile Finance: Bridging Deep Learning and Interpretability

Raed Alharbi, Maryam Alghamdi
College of Computing and Informatics
Saudi Electronic University, Riyadh 11673, Saudi Arabia

***Abstract*—Understanding user trust in mobile financial applications is crucial as these platforms increasingly shape how users in Saudi Arabia manage finances and engage with digital banking. However, existing deep learning–based detection models often function as black boxes, offering limited interpretability, while traditional machine learning models, though more transparent, fail to capture complex interactions between permissions, reviews, and user behaviors. To address this gap, we propose Trustworthy App Detection for Saudi Arabia (TAD-Saudi) - a novel framework for interpretable and behavior-aware trust evaluation. The framework integrates the representational power of deep learning with the explainability of simpler models, enabling both global and local interpretation of trust-related features. Experimental results show that TAD-Saudi outperforms traditional baselines across multiple models. Moreover, the analysis reveals that users may continue to trust applications requesting sensitive permissions, particularly when these apps have high ratings or positive reviews.**

***Keywords*—XAI; trustworthy apps detection; encoding**

I. Introduction

The widespread adoption of financial applications in Saudi Arabia has transformed the way users manage their finances, perform transactions, and engage with digital banking services. With increasing reliance on mobile applications, the Saudi fin-tech sector has experienced significant growth, reflecting broader global trends in the adoption of mobile finance. A recent market analysis indicates a notable increase in financial app usage in the region, with a substantial increase in mobile banking transactions and fintech investments [1]. However, alongside this growth, concerns about app trustworthiness, data privacy, and security risks have emerged, particularly as users trust these applications with sensitive financial and personal data.

To develop an effective and trustworthy Saudi financial app detection model, it is crucial to: 1) understand the key factors that influence user trust in financial applications, such as app ratings, reviews, and security permissions; 2) analyze the role of such factors in the trustworthiness of an app, as excessive permission requests often raise security concerns among users; and 3) address the "black-box" nature of machine learning-based classification models [2], which often lack interpretability, making it difficult for users to rely on the classification outcomes with confidence. These factors emphasize the need for a detection framework that not only ensures high accuracy when designing machine learning models but also provides explainability and transparency to users.

Despite notable progress in app fraud detection, current detection methods lack explainability and user-centered transparency. Most existing approaches rely on sentiment analysis or metadata-driven classification, which focus on identifying fraudulent or malicious apps rather than explaining why an app is considered trustworthy. This absence of interpretability limits user confidence and delays the practical adoption of Artificial Intelligence-based (AI-based) trust evaluation systems. Furthermore, existing models often fail to capture the effect of user trust signals (such as ratings and reviews) and app behavioral features (such as permissions and update frequency). While deep learning models provide high accuracy, their decisions remain opaque, and traditional machine learning models, though interpretable, are too simplistic to capture these complex behavioral relationships.

To overcome these challenges, we propose TAD-Saudi, a framework that is designed to enhance the evaluation of mobile app trustworthiness. The core of TAD-Saudi consists of three main components. First, we introduce a novel benchmark that is designed to assess key cybersecurity features. This benchmark systematically collects and evaluates various factors that influence the acceptance or rejection of app trustworthiness, offering a robust foundation for understanding the critical elements that contribute to establishing trust in mobile applications. Second, TAD, our proof-of-concept framework, integrates the power of deep learning models with the explainability of simpler, interpretable models. Finally, we conduct an in-depth analysis to examine the underlying factors driving user trust, providing valuable insight into the behavioral aspects influencing app adoption.

The remainder of this study is organized as follows. Section II presents the related works. The proposed architecture is introduced in Section III, where Section IV provides the experiment setup, analysis, and discussion of our findings. Section VI concludes the study with a summary of our contributions.

II. Related Work

Several recent studies provide valuable insights into the evolving landscape of privacy concerns and trustworthiness assessment for mobile applications. Habib et al. [3] introduce Trust4App, a framework that automates mobile app trustworthiness assessment by combining public metrics (e.g., ratings, reviews) with security factors, and user-specific preferences. This model integrates existing approaches, such as static malware analysis, into a unified personalized trust score. Similarly, [4] propose a graph-based framework that assesses smartphone apps' trustworthiness by integrating ratings, reviews,

and permissions data into confidence metrics. While both frameworks contribute to multi-dimensional trust assessment, they rely primarily on static metadata and lack mechanisms for interpretability, limitations that motivate the explainable and behavior-aware design of TAD-Saudi.

Akgul et al. [5] conduct an analysis of privacy-related app reviews on the Google Play Store over ten years (2013–2023) using Natural Language Processing (NLP) techniques. Their findings reveal a growing shift in user attention from traditional permission-based privacy issues toward emerging risks such as data deletion, third-party sharing, and data theft, while also highlighting regional variations in user behavior and privacy expectations. Nema et al. [6] propose an NLP-based framework for extracting and categorizing privacy concerns from Android app reviews, identifying key issues such as unnecessary permissions, data collection practices, user tracking, and insufficient privacy controls. Although these studies provide valuable insights into user perceptions of privacy, they remain primarily descriptive and lack quantitative or interpretable detection mechanisms.

Recent efforts have highlighted the growing impact of explainable AI (XAI) in enhancing transparency and reliability within financial and cybersecurity frameworks. For example, Turgut et al. [7] employ XAI techniques such as SHapley Additive exPlanations (SHAP), Local Interpretable Model-Agnostic Explanations (LIME), and Explain Like I'm 5 (ELI5) to improve the interpretability of Machine Learning models used in financial fraud detection, emphasizing the importance of explainability for fostering user trust in automated decision systems. Similarly, Xu et al. [8] propose an interpretable credit-default assessment model that integrates multiple Machine Learning (ML) architectures with SHAP-based explanations, demonstrating how interpretability can enhance both trust and model comprehension in financial risk analysis.

Harkous et al. [9] propose Hark, a deep learning–based system that leverages NLP to analyze privacy-related app reviews, providing developers with actionable insights into user feedback and privacy perceptions. Similarly, [10] introduced MARS (Mobile App Reviews Summarization), an ML–driven framework that combines NLP and sentiment analysis techniques to automatically summarize user reviews from the Google Play Store, distilling key privacy concerns and recurring user issues. While both approaches enhance developers' understanding of user privacy feedback, they remain developer-centric and lack mechanisms for transparent or explainable trust assessment.

In the context of fraudulent mobile apps, Rani et al. [11] develop a sentiment analysis framework that detects fraudulent apps by analyzing user reviews and ratings to identify suspicious applications. Similarly, Zaki et al. [12] propose a robust machine learning architecture for detecting fraudulent mobile apps. Their findings demonstrate the higher accuracy of deep models, particularly Convolutional Neural Networks (CNNs), in detecting deceptive behavior and enhancing app security. However, these detection systems operate largely as black boxes, focusing on performance metrics without offering interpretable reasoning behind classification outcomes. TAD-Saudi diverges from these approaches by embedding explainability within its detection framework.

While there has been considerable progress in developing frameworks for assessing mobile app trustworthiness and detecting fraudulent applications, these approaches remain limited in several key aspects. Most existing frameworks focus primarily on classification accuracy without examining the underlying behaviors that drive trust predictions. They often fail to explore the factors influencing machine learning models' decisions, which is crucial for understanding why users trust certain apps and based on what criteria. Without this interpretability, users and developers lack meaningful insights into how security, privacy, and app behavior shape trustworthiness assessments.

III. The Proposed Architecture

This study introduces TAD-Saudi, as illustrated in Fig. 1, where the main components are 1) a novel benchmark that is designed to assess cybersecurity features, systematically collecting and evaluating various factors that influence the acceptance or rejection of app trustworthiness. This benchmark provides a comprehensive framework for understanding the underlying elements contributing to the establishment of trust in mobile applications; 2) TAD, a proof-of-concept framework that balances the richness of deep learning with the explainability of simpler models to predict and classify trustworthy apps, thus enabling the identification of secure and reliable mobile applications.

This section starts with an overview of the dataset, followed by detailed explanations of the proposed framework.

A. Data Preparation

Given the nature of this study, which investigates financial applications in the Saudi region, our focus is specifically on mobile apps that support the Arabic language. This emphasis is crucial, as the majority of users in the region rely on Arabic-language interfaces for their digital interactions.

We construct our dataset through a combination of web scraping techniques and APIs to gather comprehensive data on finance-related mobile applications from the Google Play Store [13]. Specifically, we utilize Python libraries such as $requests$, $BeautifulSoup$, and $google_play_scraper$ to extract detailed information on applications, including their descriptions, user reviews, ratings, and security permissions. To ensure a broad and representative coverage of financial applications, we collect data from 23 finance-related categories, such as "Banking," "Investment," "Loans," "Insurance," "Expense Tracking", and "Financial Planning" [13]. By focusing on these categories, we ensure a diverse dataset that specifically serves the needs of Arabic-speaking users in Saudi Arabia, reflecting the region's unique financial landscape and user preferences. To address the possibility of the Python libraries extracting irrelevant results, each extracted application was manually reviewed. During this process, all duplicate applications and any applications not directly related to financial services were removed. This ensured that the final dataset contained only financial-related applications.

To achieve this, we first scrape app IDs from multiple pages within each category URL to build a comprehensive dataset [14]. For each app, we collect metadata, including the app name, description, overall rating, total ratings, and a sample

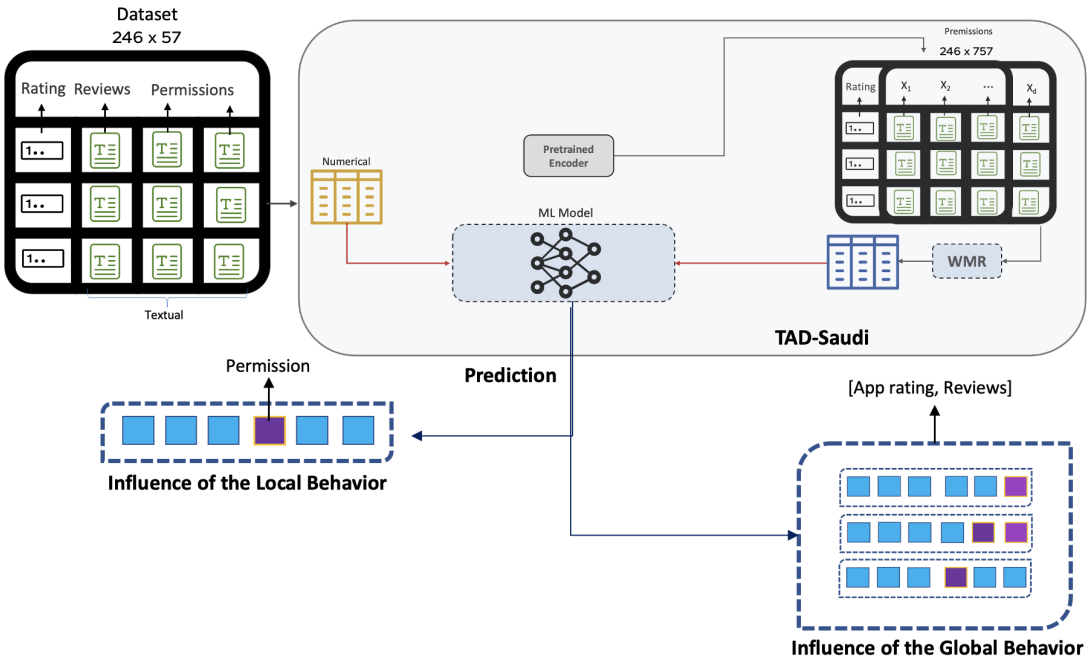

Fig. 1. Our proposed architecture (TAD-SAUDI).

of user reviews. Specifically, we selected the top 20 reviews for each app, with a cap of 15 apps per category, to maintain focus while ensuring diversity across categories. This approach enables us to capture a representative sample of user feedback. The resulting dataset serves as the foundation for analyzing the correlation between app permissions, user perceptions (derived from reviews and ratings), and overall trustworthiness.

In our framework, we operate within a supervised setting, where labeling is a critical step in the development of such an ML model. Specifically, our labeling process involves extracting the top 20 reviews for each application. If at least one of these reviews expresses a significant lack of trust in the application, it is classified as "untrustworthy". Conversely, if none of the reviews raise concerns about trust, the application is labeled as "trustworthy". For each application, the top 20 user reviews are manually examined to identify trust-related content. Reviews explicitly mentioning privacy violations, security concerns, fraudulent activity, data misuse, or suspicious behavior are classified as indicators of untrustworthiness. Reviews focusing on usability, performance issues, software bugs, interface design, or general instability are excluded, as these aspects do not directly reflect users' trust perceptions. Notably, the trust labels in this dataset represent users' subjective perceptions of trustworthiness, rather than verified cybersecurity incidents or objectively confirmed malicious behavior.

The labeling process is conducted manually by the authors. A primary annotator performs the initial labeling, which is subsequently verified by a secondary reviewer to ensure consistency and reliability. As native Arabic speakers, the authors are able to accurately interpret user reviews, particularly since many trust-related concerns are expressed using culturally specific phrases and informal dialects. During the data cleaning process, all non-Arabic reviews, emojis, and irrelevant symbols are removed to avoid potential noise in model performance. This step to ensure that only semantically relevant Arabic content is retained for analysis.

Our constructed dataset consists of a total of 246 applications, with a particular emphasis on financial applications. These applications are categorized into 172 trustworthy apps and 74 untrustworthy apps. Additionally, the dataset includes 3,430 Arabic-language reviews, an equal number of ratings, and 1,581 permissions requested by the apps. The summary of the dataset is illustrated in Table I.

TABLE I. SUMMARY OF THE DATASET

Metric	Value
Total Apps	246
Trustworthy Apps	172
Untrustworthy Apps	74
Total Ratings	3,430
Total Reviews	3,430
Total Permissions	1,581
Total App ID	246
Total App Descriptions	246

As part of our data preparation process, we conducted a human-subjective study involving 51 participants to explore user priorities in selecting trust factors prior to downloading mobile applications. Informed consent was obtained in writing from all participants through a signed consent form before participation.

B. TAD Framework

The goal of TAD framework (Fig. 1) is balance the richness of deep learning with the explainability of simpler models to predict and classify trustworthy apps. Our proposed framework

TAD consists of three main components: 1) A Pretrained Encoder to learn textual representations and extract meaningful and compact feature representations from high-dimensional textual data, 2) Weighted Mean Representation (WMR) to reduce redundancy while preserving essential semantic information, ensuring that the latent representation captures the most discriminative features. Also, we employ attention scores to assign different levels of importance to each feature dimension, and 3) Machine learning model that aims to develop a robust predictor for evaluating the trustworthiness of financial mobile applications, specifically determining whether a user is likely to accept or reject the app. To achieve this, we leverage well-known machine learning classification techniques: XGBoost (XGB) [15], Decision Tree [16], K-Nearest Neighbors (k-NN) [17], Random Forest (RF) [18], and Support Vector Machine (SVM) [19], all of which are well-established in classification tasks. To ensure a comprehensive and fair comparison, we also incorporate a deep learning-based approach, TABNET [20], which is specifically designed for handling tabular data.

Our dataset contains multiple reviews, where each review can have several comments. This structure results in a combination of textual data and straightforward numerical features such as ratings. A naive way to handle such a dataset is to process numerical attributes directly while encoding textual data using methods like label encoding, which assigns a unique integer to each word or phrase. Mathematically, this can be represented as a function mapping words to indices:

$$f(w_i) = i, \quad \forall w_i \in W \tag{1}$$

where, W is the vocabulary and w_i represents each unique word. However, label encoding introduces an inherent ordinality to categorical values, implying an artificial ordering among words (e.g., "good" assigned 1, "bad" assigned 2), which lacks semantic meaning. This causes misleading numerical relationships in machine learning models, as they might incorrectly assume a linear relationship between words based on their assigned numbers. Thus, the text presents additional challenges due to its high-dimensional nature and contextual dependencies.

An alternative solution is to use Deep Neural Networks (DNNs) that employ word embeddings to learn semantic relationships in a high-dimensional space. Mathematically, an embedding function E maps words to dense vectors:

$$E : W \to \mathbb{R}^D, \quad D \gg 1 \tag{2}$$

where, D is the embedding dimension, capturing semantic similarities between words. This allows words with similar meanings to be closer in the vector space, mitigating the limitations of label encoding.

However, as our primary goal is to leverage XAI to understand how user behaviors influence app interactions, relying solely on DNNs [21] can obscure the interpretability of individual financial behaviors (black box models), such as the effect of specific permission requests.

To address both interpretability and effectiveness, we propose an embedding-based feature engineering approach that balances the richness of deep learning with the explainability of simpler models. Instead of directly applying DNNs, we extract pre-trained embeddings for key textual fields, such as description, reviews, and permissions, then reduce them in a structured manner.

Each text field is converted into a high-dimensional vector representation using a pre-trained embedding model. If an embedding of size D is used, then:

$$X_{\text{embedding}} = \{X_1, X_2, ..., X_m\} \tag{3}$$

where, m is the number of textual fields (e.g., app description, reviews, and permissions), and $X_k \in \mathbb{R}^D$ represents the embedding vector of the $k-th$ text field for a given sample. In other words, each text field contributes multiple embedding dimensions—occupying several columns in the tabular dataset.

To make the model interpretable and computationally efficient, we propose the WMR as it is shown in Fig. 1. Mathematically, given

$$x_i = [x_{i1}, x_{i2}, \ldots, x_{iD}]$$

where, x_i represents the feature vector (embedding) for sample i, and D is the embedding dimension. Similarly, the attention weights for sample i are given by:

$$w_i = [w_{i1}, w_{i2}, \ldots, w_{iD}]$$

The weighted mean representation is computed as:

$$\tilde{x}_i = \frac{\sum_{j=1}^{D} w_{ij} x_{ij}}{\sum_{j=1}^{D} w_{ij}} \tag{4}$$

where:

- x_{ij} is the j-th feature of sample i,
- w_{ij} is the j-th attention weight for sample i. The denominator ensures that the weights sum to 1, preserving scale consistency.

This transformation converts each high-dimensional embedding into a single scalar value, significantly reducing complexity while preserving essential semantic information. Without this reduction, the model would struggle to integrate embedding-based features with standard scalar or categorical attributes.

Unlike traditional pooling mechanisms such as attention-based aggregation, which typically assign weights across tokens within a sequence to generate a contextualized sentence embedding, the proposed WMR operates at the feature-dimension level. In other words, instead of weighting tokens, WMR assigns importance to individual embedding dimensions.

The reduced embeddings are concatenated with the remaining non-embedding features. The final feature matrix is denoted as:

$$X' = [X_{\text{structured}}, X_{\text{final}}] \tag{5}$$

where, $X_{\text{structured}}$ consists of traditional tabular features such as categorical metadata and numerical attributes. To mitigate class imbalances, we also apply SMOTE (Synthetic Minority Over-sampling Technique), which generates synthetic samples for underrepresented classes:

$$X_{\text{balanced}}, Y_{\text{balanced}} = \text{SMOTE}(X', Y) \tag{6}$$

IV. Experimental Analysis

We begin this section by providing details on the dataset (Section IV-A) and experimental setup (Section IV-B). Our objective is to first evaluate the performance of our proposed model in terms of predictive accuracy (Section IV-C). Following this, we conduct in-depth analysis (Section IV-D) using SHAP [22] and Section IV-E using LIME [23]) on the top-performing model to investigate: 1) the key features influencing an application's trustworthiness and 2) the relationship between specific features and the acceptance or rejection of an application. Finally, in Section IV-F, we shift our focus to a human-subjective experiment on user trust, aiming to validate our findings through direct user evaluation.

A. Dataset

We compile our dataset through a combination of web scraping techniques and API calls to gather information on finance-related mobile apps from the Google Play Store. The data preparation process is detailed in Section III-A.

The constructed dataset consists of 246 finance-related mobile apps. Given that our goal is to investigate whether users trust mobile applications despite the permissions they request, and to identify the factors influencing their decision-making process, it is crucial to examine the permissions collected for each app. The dataset includes 14 distinct permission categories. Statistics on the permissions associated with the dataset are presented in Table II.

TABLE II. Statistics on Dataset Permissions

Permission	% of Apps
Photos/Media/Files	85
Storage	85
Camera	79
Wi-Fi connection information	77
Location	69
Contacts	54
Phone	53
Device ID and call information	52
Microphone	44
Identity	21
Calendar	9
SMS	7
Device and app history	6.5
Wearable/Activity Sensor Data	0.4

To ensure broad coverage of the Saudi mobile finance ecosystem, the dataset spans 23 finance-related categories on the Google Play Store, including banking, investment, insurance, lending, expense tracking, and financial planning. Within each category, the top-ranked applications were selected to reflect the apps most likely to be encountered by typical users, since marketplace ranking strongly influences user exposure. The resulting class proportions are reported with 95% Wilson confidence intervals: trustworthy applications constitute 69.9% of the dataset (95% CI [63.9%, 75.3%]) and untrustworthy applications 30.1% (95% CI [24.7%, 36.1%]). A power analysis confirms that at $n = 246$, $\alpha = 0.05$, and $power = 0.80$, the dataset is adequate to detect medium effect sizes (Cohen's $d \geq 0.389$) between the two classes.

Two sources of potential bias are acknowledged. First, the dataset is restricted to applications available on the Google Play Store and does not include Apple App Store apps or applications distributed through alternative Arabic app stores; findings may therefore not transfer directly to iOS users. Second, the top 20 reviews per app sampling strategy favors reviews surfaced by Google's ranking algorithm, which tends to prioritize reviews marked as helpful or those that are more recent, potentially underrepresenting older or less-visible user concerns. We mitigate these effects by drawing from 23 distinct finance categories rather than concentrating on a single segment, which broadens topical and demographic coverage.

The dataset contains 172 trustworthy and 74 untrustworthy applications, yielding an approximate 2.32:1 ratio. This imbalance reflects the natural distribution of trust perceptions in the financial app marketplace, where most listed applications belong to established institutions and receive predominantly positive trust signals. To prevent the majority class from masking poor minority-class performance, we apply stratified k-fold cross-validation, which preserves the class ratio in each fold, and report macro-averaged precision, recall, and F1-score in addition to overall accuracy.

B. Experimental Settings

We randomly select 75% of the dataset for training and 25% for testing. For the Logistic Regression model, the maximum number of iterations is set to 500. For k-NN, we choose 5 as the number of nearest neighbors. Logarithmic loss is used as the evaluation metric to track the performance of the XGB model during training.

To effectively represent the semantic and contextual meaning of Arabic text, we employ the AraBERT pre-trained embedding model [24], which generates dense vector representations of the reviews. These embeddings serve as the textual input features for all models, enabling a deeper understanding of linguistic nuances and improving the overall accuracy of trustworthiness classification. To evaluate the performance of our proposed framework, TAD-Saudi, we use the following metrics:

- Accuracy: Measures the proportion of correct predictions out of the total number of predictions.
- Precision: Represents the ratio of correctly predicted positive instances among all instances predicted as positive.
- Recall: Indicates the ratio of correctly predicted positive instances relative to the total number of actual positive instances.

- F1 Score: The mean of precision and recall, providing a balanced evaluation of the model's performance.

The foundation of our TAD-Saudi framework lies in the proposed encoding schema. We compare our TAD-Saudi framework with three common encoding techniques: Label Encoding [25], One-Hot Encoding[26], and Binary Encoding[27]. To ensure a comprehensive comparison, we apply each of these encoding methods, along with our proposed framework, to the following models: RF [18], Gradient Boosting [28], XGB [15], TABNET [20], Logistic Regression [29], K-NN [17], SVM [30], and Naive Bayes [31]. A brief summary of these models is as follows:

- RF: A model that combines multiple decision trees using randomly sampled data and features.
- Gradient Boosting: An optimization-based ensemble method that builds additive models, often using decision trees, and minimizes loss via gradient descent.
- XGB: A scalable tree boosting system designed for high-performance machine learning on large datasets.
- TABNET: An interpretable deep learning architecture for tabular data that uses sequential attention to efficiently select important features.
- Logistic Regression: A statistical method used to model the relationship between a binary dependent variable and one or more independent variables.
- K-NN: A supervised machine learning algorithm that classifies data points based on the majority class among their 'k' closest neighbors in the feature space.
- SVM: One of the earlier supervised machine learning algorithms that has been instrumental in both classification and regression tasks.
- Naive Bayes: A simple probabilistic classifier based on Bayes' theorem, assuming that features are independent given the class label.

C. Performance Evaluation

The performance evaluation results presented in Table III highlight the effectiveness of the proposed TAD-Saudi framework in comparison to conventional encoding techniques, namely Label Encoding, One-Hot Encoding, and Binary Encoding. The findings demonstrate that TAD-Saudi consistently outperforms all traditional encoding methods across multiple machine learning models, achieving higher accuracy, precision, recall, and F1 scores.

Among the traditional encoding methods, Label Encoding, One-Hot Encoding, and Binary Encoding yield comparable performance, with accuracy scores ranging primarily between 0.60 and 0.71. The best-performing models under these methods include Logistic Regression (0.74, Label Encoding), Gradient Boosting (0.71, Label Encoding), and XGBoost (0.69, One-Hot & Binary Encoding). However, these models fail to exceed the 0.74 accuracy threshold, indicating the limitations of conventional encoding approaches in capturing the complexities of the dataset.

In contrast, TAD-Saudi achieves a significant performance boost, with XGBoost and Random Forest each attaining the highest accuracy of 0.85, followed by Gradient Boosting and Naïve Bayes at 0.81. These models also exhibit higher precision, recall, and F1 scores, reinforcing the dominance of TAD-Saudi in learning robust representations. The observed improvements across different models indicate that the TAD-Saudi framework enhances feature encoding, leading to better generalization and decision-making capabilities.

A key observation is the poor performance of TABNET across all settings, achieving accuracy values below 0.50 in most cases. As a result, deep learning-based methods may require additional tuning or architectural modifications to effectively handle the tabular data in the given dataset. Furthermore, the nature of tabular data, with its high sparse relationships, could pose significant challenges for models designed primarily for structured inputs like images or sequences [2]

Overall, these results validate the effectiveness of TAD-Saudi in improving predictive accuracy, particularly in handling categorical data more efficiently than traditional encoding techniques. The model demonstrates a clear advantage in capturing complex structured relationships within the data, leading to enhanced performance. This indicates that TAD-Saudi's approach to feature representation and processing offers a promising alternative for models dealing with large, structured datasets, where traditional methods often struggle.

D. Global Analysis

To understand the global behavior and underlying logic behind trustworthy and untrustworthy apps, we utilize SHAP [22], a unified method that offers interpretable explanations for the predictions made by machine learning models. By analyzing the feature contributions for apps, we can gain insights into which factors influence the classification of an app as trustworthy or untrustworthy. This allows us to identify patterns and relationships that clarify which factors are most critical in the determination of app trustworthiness, shedding light on the key characteristics that distinguish these two categories. We select the best-performing model, XGBoost, in our TAD-Saudi framework for our analysis to provide a reliable and accurate explanation of its behavior.

Fig. 2 presents the SHAP analysis of the top 20 factors that impact the trustworthiness of an app on our proposed framework, where the features are listed according to their total contribution (sum of SHAP values) to the final prediction, with the top feature being the most important. Each point represents an app in the study. The position of each point on the x-axis indicates the impact that feature has on the classifier's prediction for a given app, with the color gradient (ranging from blue to red) reflecting the feature values from low to high. On the x-axis, positive SHAP values indicate the trustworthiness of the app, whereas negative SHAP values reflect untrustworthiness. This visualization allows us to observe the relative influence of each feature on the prediction, providing a clear understanding of which factors play a dominant role in shaping an app's classification as trustworthy or untrustworthy.

The interpretation in Fig. 2 shows several key observations. First, permissions play a critical role in determining trust-

TABLE III. PERFORMANCE EVALUATION

Model	Accuracy	Precision	Recall	F1	Accuracy	Precision	Recall	F1
	Label Encoding				One-Hot encoding			
RF [18]	0.65	0.62	0.65	0.63	0.65	0.61	0.65	0.62
Gradient Boosting [28]	0.71	0.70	0.71	0.70	0.63	0.61	0.63	0.62

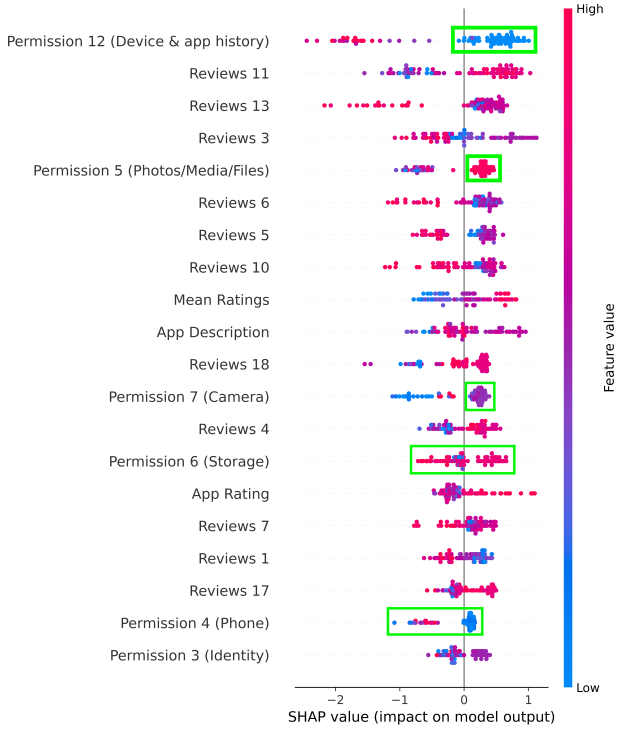

Fig. 2. SHAP analysis of the top 20 factors influencing app trustworthiness in the proposed framework. Features are ranked by their total SHAP contribution, with higher values indicating greater importance. Each point represents an app, where color denotes feature value (blue = low, red = high) and the x-axis shows impact direction—positive values indicate trustworthiness, while negative values reflect untrustworthiness.

worthiness, with Device & App History, Photos/Media/Files, Camera, Storage, Phone, and Identity permissions appearing among the most influential features. Apps requesting extensive permissions, particularly those related to sensitive data access, tend to have a negative SHAP impact (untrustworthy apps), indicating that such permissions are more commonly associated with untrustworthy apps. This aligns with security concerns where excessive permissions may indicate potential privacy risks [32].

While permissions generally exhibit a negative correlation with app trustworthiness in the SHAP summary plot, certain permissions demonstrate mixed or even positive contributions, indicating that their impact is context-dependent. For instance, Permission 12 (Device & App History) displays SHAP values that extend into the positive range, indicating that some apps requiring this permission—such as system utilities or security applications—are still classified as trustworthy. Similarly, Permission 5 (Photos/Media/Files) and Permission 7 (Camera) show instances where high feature values contribute positively to trustworthiness, likely reflecting legitimate use cases in photo-editing, document scanning, and video conferencing apps. Additionally, Permission 6 (Storage) and Permission 4 (Phone) exhibit mixed SHAP contributions, implying that while they are often associated with untrustworthy apps, certain well-rated applications that transparently justify these permissions remain trustworthy.

These observations explain that ratings and reviews alone are not sufficient to determine an app's trustworthiness, as permissions also play a crucial role in the classification process. While highly rated and frequently reviewed apps are often perceived as more reliable [33], the SHAP analysis indicates that certain permissions can significantly impact trustworthiness negatively. This highlights the importance of transparency and responsible permission management, reinforcing that trustworthiness is not shaped only by user ratings and reviews but by a combination of user feedback, feature permissions, and the app's overall reputation. While high ratings and positive reviews contribute to an app's credibility, they do not fully capture the potential risks associated with excessive or sensitive permission requests.

E. Local Analysis

To complement our global analysis of app trustworthiness using SHAP, we perform a nuanced local interpretability analysis using LIME [23]. LIME produces instance-specific explanations, enabling us to uncover how specific combinations of features influence the classification of apps as trustworthy or untrustworthy. This refined perspective exposes decision-making patterns that may remain hidden in global summaries, offering deeper insights into user-perceived and model-learned trust signals.

Our analysis focuses on the XGBoost model, chosen for its robust predictive performance in the TAD-Saudi framework. LIME is applied to each sample in the test set to extract a feature attribution vector, where each value quantifies the positive or negative contribution of a feature to the model's decision. Positive values support a classification of trustworthy, while negative values indicate influence toward untrustworthy. To identify dominant patterns of local behavior, we clustered these vectors using KMeans (k=5) [34].

Fig. 4 presents a heatmap showing the average LIME feature attributions across the five clusters. Each row corresponds to a cluster, and each column to a feature. Red cells indicate features that consistently support trust predictions, while blue cells indicate features that consistently detract from trust.

Our cluster-wise LIME analysis reveals how variations in user behavior and perception drive differences in trust formation across app groups. In Cluster 0, trust predictions are positively influenced by early reviews such as review_5 and review_6, along with permission_7 (Camera). However, later reviews like review_19 and review_20 show strong negative impacts. This shift indicates that users initially responded positively but later became dissatisfied—potentially due to app updates, intrusive notifications, or emerging performance issues. The fact that the Camera permission maintains a positive association with trust indicates contextual acceptance behavior, where users justify certain permissions when they align with the app's functionality (e.g., photo-sharing or video features). This pattern aligns with trust heuristics in digital behavior, where familiarity and early positive experience temporarily override privacy concerns.

In Cluster 1, user behavior reflects a contrasting cognitive pattern. Trust is supported by positive review features (review_8, review_17, review_19), but sharply decreases in the presence of permission_3 (Identity) and permission_10 (Device ID and Call Info). This reveals a privacy-centered behavioral profile in which users exhibit a greater sensitivity to permissions involving personal or device identifiers. Even when social feedback (reviews) is favorable, these users value privacy safeguards more than social validation, indicating a risk-averse trust model. Overall, the cluster patterns highlight that user trust is not purely sentiment-driven but context-dependent, balancing perceived utility, social validation, and privacy risk in complex behavioral trade-offs.

Clusters 2 and 3 exhibit a similar trust logic, where reputational signals—such as rating, review_17 (in Cluster 2), and review_11 (in Cluster 3)—positively influence trust predictions. However, both clusters show strong negative contributions from permission_10 (Device ID and Call Info) and select reviews (review_13 in Cluster 3 and description in Cluster 2). This pattern reveals a user tendency to favor high ratings and positive feedback, even in the presence of potential privacy risks—indicating that strong reputational signals often take precedence over deeper concerns about app behavior. Finally, Cluster 4 reflects a context-aware decision pattern. Positive signals such as review_20 and review_12 increase trust, while review_11 and permission_10 decrease it. This balance indicates that users integrate both reputational and risk considerations, granting trust only when favorable cues substantially exceed perceived privacy risks—demonstrating a more deliberate trust formation process.

To evaluate feature reliability, we analyze the standard deviation of LIME attributions for each feature (Fig. 3). Features such as review_11, review_17, and review_19 display high variability, indicating that their influence on model predictions is context-dependent and unstable, varying considerably across different instances. Conversely, features like permission_3 (Identity) and permission_12 (Device & App History) exhibit low variability with consistently negative attributions, indicating they are reliable and stable indicators of untrustworthiness.

Overall, while SHAP reveals overarching trends in feature importance, LIME uncovers the diversity in localized decision-making logic. A key insight is that users often favor apps with high ratings and early positive reviews, even when such apps request permissions typically associated with untrustworthiness (e.g., Camera, Identity). This suggests that visible reputational cues can obscure privacy concerns, leading to over-trust in potentially risky apps. Moreover, the influence of permission-related features varies by context. For example, permission_12 might be accepted for security tools but viewed suspiciously in general-purpose apps.

F. A Human-Subjective Experiment on User Trust

As our findings indicate, Section IV-D, permissions play a critical role in shaping app trustworthiness. While high ratings and positive reviews are commonly seen as indicators of reliability, they alone do not provide a complete picture of an app's trustworthiness. To gain a deeper understanding of this from a human perspective, we conduct a human-subjective test in which we survey 51 users to investigate their priorities when selecting trust factors before downloading apps. All the participants ranged in age from 20 to 50 years and had diverse academic and professional backgrounds. They are Saudi Arabia residents, native Arabic speakers, and regular mobile

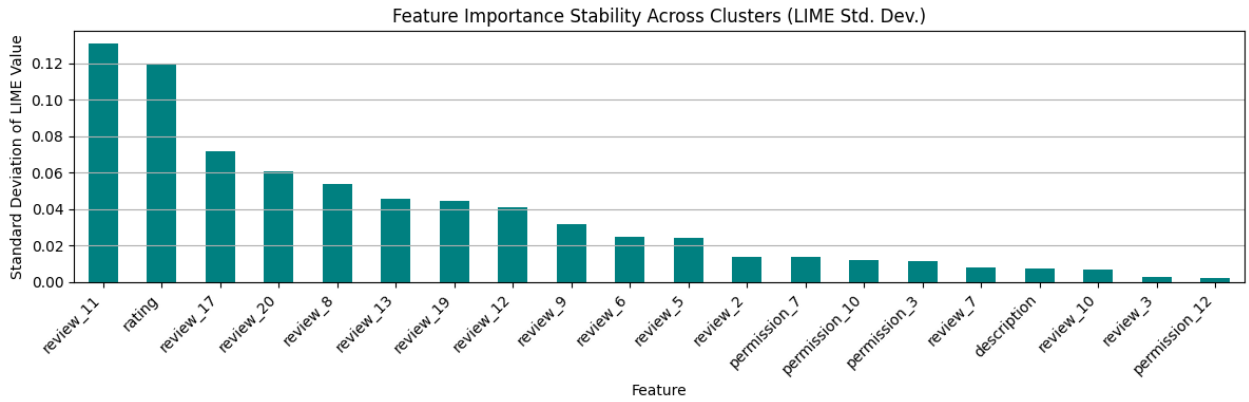

Fig. 3. Feature importance stability across clusters.

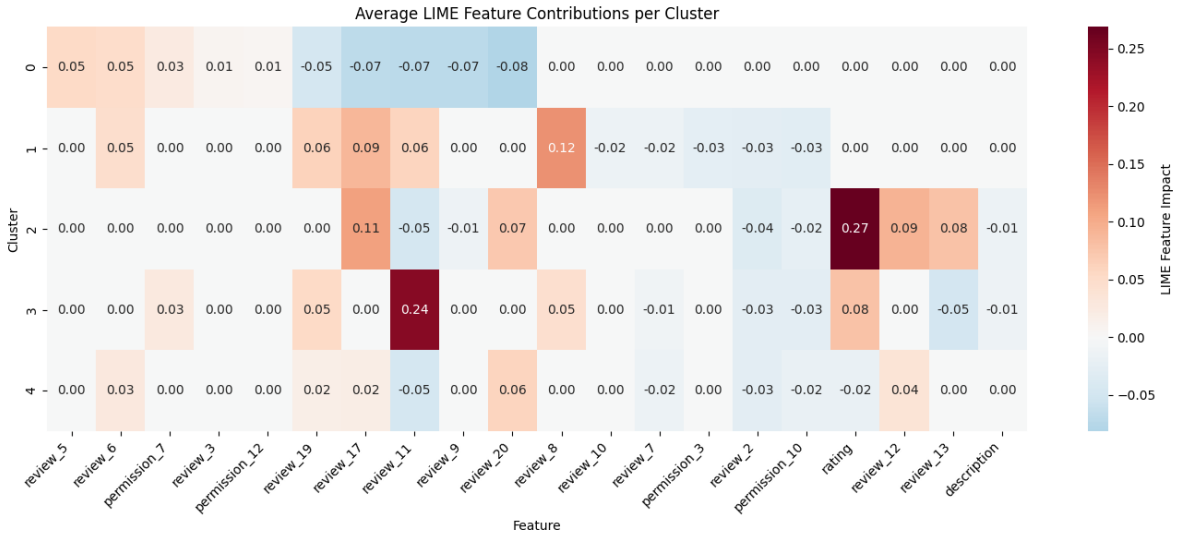

Fig. 4. Average LIME feature contributions per cluster. The heatmap shows the average LIME feature attributions across five clusters. Each row represents a cluster, and each column a feature. Red cells indicate features that positively contribute to trust predictions, while blue cells denote features that negatively influence trust.

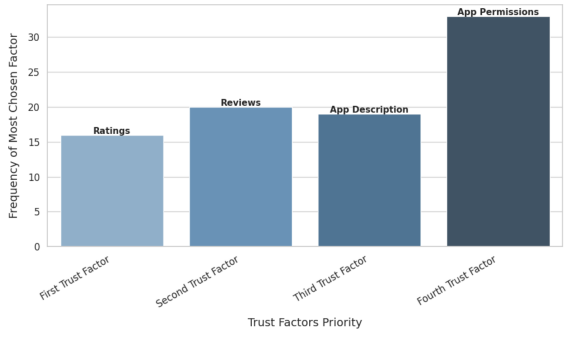

Fig. 5. User Priorities in App Trust: Order of Trust Factors (First to Fourth), where the sequence of trust factors, indicating that the first trust factor is the most important, followed by the others in order of importance.

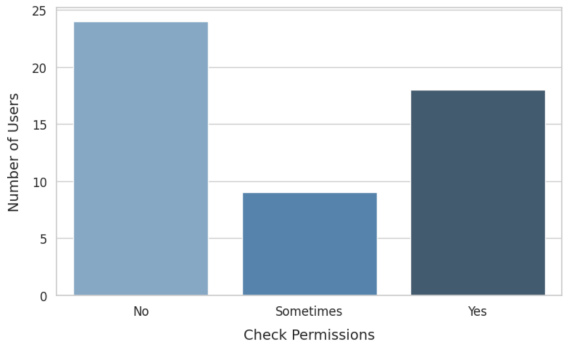

Fig. 6. User responses to checking app permissions before downloading.

device users, either iPhone or Android. They are general users with varying levels of digital experience, which allowed us to gather feedback that reflected real-life experiences.

The results, as shown in Fig. 5, reveal that app permissions emerged not as the most important factor, with 35 users selecting it as their fourth priority (after factors like ratings, reviews, and app descriptions). This finding indicates that while app

permissions are still a significant factor for app trustworthiness, they are not the first factor users prioritize when downloading apps. This indicates that a broader awareness campaign is needed to emphasize the importance of permissions, highlighting their role in ensuring user security and privacy. A more comprehensive understanding of permission management could potentially shift users' priorities, making it a more prominent factor in their trust evaluation process.

Further analysis of the question "Do Users Check App Permissions Before Download?" (Fig. 6) reveals a divided response of the 51 participants, 24 users indicate that they do not check app permissions, while 9 report occasionally checking, and 18 state that they always check permissions. This reveals that a significant portion of users does not consistently check app permissions, which indicates a lack of awareness or concern regarding potential privacy and security risks associated with app permissions.

Overall, in alignment with recent SHAP analysis, our findings indicate that certain app permissions can negatively impact trust, even if an app boasts high ratings or favorable reviews. Therefore, transparent permission management and clear communication regarding the purpose of these permissions are vital for fostering user trust. This combination of user feedback, careful permission handling, and an app's overall reputation forms a more comprehensive and accurate understanding of its trustworthiness, highlighting that trust is shaped by a balance of factors, including app permissions.

V. Limitations

While the constructed dataset of 246 finance-related mobile applications provided valuable insights into user trust and app permissions, its relatively small size presents a potential limitation for machine learning generalization. The modest number of samples may restrict the model's ability to capture broader behavioral variability across different app categories and user contexts.

The findings of this study apply most directly to Arabic-language financial applications used in the Saudi context. Generalization to other domains (such as non-financial app categories), other languages, or other regional markets, including other Gulf or broader Arabic-speaking populations with different regulatory frameworks and cultural contexts, would require further validation. The methodological framework itself, however, combining permission analysis, review embeddings, and explainable AI techniques, is transferable, and we view replication across additional markets and domains as an important direction for future work.

VI. Conclusion

The proposed TAD-Saudi framework provides a significant step forward in the evaluation of mobile app trustworthiness by bridging interpretability and performance in machine learning–based detection. Beyond its technical contribution, the study offers practical implications for multiple stakeholders. For app developers, TAD-Saudi serves as an interpretable benchmark to identify risky permission patterns and improve transparency in app design. For regulators and cybersecurity authorities, it enables data-driven policy formulation and supports more reliable certification processes for financial and e-service applications. For end-users, it enhances awareness of privacy risks and promotes trust in secure digital ecosystems aligned with Saudi Vision 2030.

Future research will expand the dataset to include a larger and more diverse range of applications across different app categories and regions. Further investigations could explore cross-country validation to assess generalizability in other Gulf and international contexts, as well as integration with real-time app store monitoring systems to enable dynamic trust evaluation. These directions aim to strengthen the scalability, robustness, and real-world applicability of the TAD-Saudi framework.

Benchmarking Deep Learning for $PM_{2.5}$ Forecasting in IoT-Based Smart Cities: GCN Spatial Encoding and Transformer Temporal Modeling

Abdessamad BADOUCH[1], Kaoutar BELHOUCINE[2]
Faculty of Sciences, Ibn Zohr University, Agadir, Morocco[1]
Faculty of Sciences, Ibn Tofail University, Kénitra, Morocco[2]

***Abstract*—Graph convolutional networks are widely used in air quality forecasting, yet their benefit over simpler approaches remains insufficiently validated. This study presents a fully reproducible benchmark comparing five model families (ARIMA, XGBoost, LSTM, CNN-LSTM, and a GCN+Transformer model) on the public Beijing Multi-site Air Quality Dataset. All experiments share identical preprocessing, three random seeds (confidence intervals reported as exploratory), and a chronological split, with full code availability. ARIMA outperforms deep learning on aggregated data, due to strong temporal autocorrelation. On individual stations, Transformer-based models achieve the best performance through improved temporal modeling. A systematic multi-node analysis reveals that graph-based spatial aggregation can degrade performance under highly homogeneous conditions: when monitoring stations exhibit strong correlations, a simple linear baseline outperforms the GCN topologies tested here. Alternative spatial encoders (e.g., GAT, learnable adjacency) may behave differently and remain an open question. These findings define a practical regime in which GCN-based spatial aggregation provides no benefit over linear baselines. A preliminary compression experiment on Apple M1 reports a 42% inference-latency reduction via 8-bit quantization; this is indicative only, and validation on Raspberry Pi 4 or NVIDIA Jetson Nano is identified as required follow-up.**

***Keywords*—Air quality forecasting; graph neural networks; IoT smart cities; transformer; $PM_{2.5}$ prediction**

I. Introduction

Urban air pollution is one of the most serious environmental health challenges of our time. $PM_{2.5}$ particles, with aerodynamic diameter below 2.5 micrometres, penetrate deep into lung tissue and are associated with cardiovascular and respiratory disease, premature mortality, and impaired cognitive development [2], [3]. In cities across China, India, and the Middle East, daily $PM_{2.5}$ concentrations regularly exceed WHO guidelines by factors of five to ten. Forecasting these concentrations accurately, and doing so in real time, is a prerequisite for any early warning or emergency response system.

Smart city infrastructure changes what is technically possible here. Networks of low-cost IoT sensors now generate continuous, high-resolution spatiotemporal streams from dozens of monitoring stations within a single city. This spatial dimension is what makes graph neural networks attractive: if stations at different locations carry different information, encoding their spatial relationships should help the model. Whether inter-station diversity is high enough for graph aggregation to help, rather than simply average away useful local variation, depends on the specific city and meteorological regime. That question motivates this study.

This study does not propose a new architecture. It provides a reproducible benchmark on public data, with a clear empirical result: on Beijing's monitoring network, graph spatial encoding does not improve forecasting performance over a linear baseline. Published claims about GCN superiority in air quality forecasting consistently appear on proprietary, spatially heterogeneous datasets [20], [22], often multi-city or multi-provincial, without testing whether the spatial component would remain useful if correlations were high and uniform. Our benchmark fills that gap by providing the baseline case. Negative results on public reproducible benchmarks are an undervalued but essential contribution to the field: without them, the community cannot know which spatial modeling assumptions are safe to import from traffic forecasting, where GCN consistently helps, to air quality forecasting, where the spatial precondition may not hold.

Showing that GCN does not help in one spatially homogeneous setting does not by itself establish exactly when it does help. Testing that requires a second dataset from a heterogeneous network, which we identify as the most important direction for follow-up work. The contribution here is a documented, reproducible reference case, grounded in the meteorology of the Beijing basin.

The contributions of this study are as follows. First, a reproducible benchmark comparing five model families on UCI #501 is provided (anonymized repository; URL withheld during review and to be disclosed upon acceptance), with fixed seeds and public code, addressing the reproducibility gap in prior work [20], [21], [22]. Second, a multi-signal analysis identifies when ARIMA is competitive (aggregated, smooth signals) and when it is not (per-station noisy data), with the Transformer and GCN components disentangled in both settings. Third, a reproducible negative result on GCN spatial encoding is established for networks with near-uniform correlations, with a physical explanation rooted in Beijing's meteorological dynamics. Fourth, a preliminary edge deployment analysis reports a 42% latency reduction via 8-bit quantization on Apple M1 hardware, offered as an initial feasibility indicator for IoT deployment.

II. Related Work

A. Classical and Statistical Methods

ARIMA and its seasonal variant SARIMA remain the standard baselines in time series forecasting. They are well understood, interpretable, and require no training data beyond the target series itself. Their main limitation is the linearity assumption: ARIMA captures autocorrelation structure well but cannot model abrupt nonlinear events such as dust storms or holiday traffic changes. Recent work has also explored statistical process control approaches such as modified EWMA charts for autocorrelated $PM_{2.5}$ monitoring [23], which complement forecasting models for anomaly detection use cases. Beyond $PM_{2.5}$, related assessment frameworks have been applied to other pollutants such as SO_2 [24], confirming the general relevance of statistical baselines in air quality studies. Our benchmark confirms R^2=0.973 for ARIMA on the aggregated signal, consistent with prior comparisons [18]. This result is a product of the aggregation process, as we discuss in Section IV.

XGBoost and gradient boosting methods have also been applied to air quality forecasting with good results on tabular feature sets [1]. Hybrid pipelines combining LSTM, Random Forest, and XGBoost have also been proposed for real-time AQI prediction [25], combining the complementary strengths of recurrent and tree-based models. They handle nonlinearity and work well on moderate-size datasets without tuning recurrent architectures. Their limitation is the same as ARIMA's: they treat each time step independently unless explicit lag features are engineered, and they have no native mechanism for spatial reasoning.

B. Deep Learning Models

LSTM networks [16] were among the first deep learning architectures applied to air quality forecasting, and they remain strong baselines. The gated mechanism handles long-range temporal dependencies better than vanilla RNNs, but training is sequential and parallelism is limited. Several studies have combined convolutional layers with LSTM to capture both local spatial patterns and temporal dynamics [10], [11], [12], with reported improvements over LSTM-only baselines in spatially structured settings.

Transformer architectures [17] arrived later in this application domain. The self-attention mechanism processes all timesteps in parallel, is more efficient on GPU hardware, and handles long-range dependencies without the vanishing gradient issues that affect LSTMs. AirFormer [22] demonstrated the Transformer's capacity to scale to 1,085 stations across China, though on proprietary data and without systematic baselines. Our ablation confirms that the Transformer is the decisive component in our framework, contributing ΔR^2=0.111 relative to an equivalent GCN+LSTM architecture.

C. Graph Neural Networks in Air Quality

GNNs have become popular for air quality forecasting because monitoring stations are naturally modeled as graph nodes. Zhang et al. [10] combined temporal difference features with graph Transformer networks and reported improvements over CNN-LSTM on multi-station data in China. Liang et al. [20] developed a Res-GCN model incorporating satellite imagery on 34 Beijing and 27 Tianjin stations, using a dynamic GCN structure to capture evolving spatial patterns. These results are encouraging but rely on multi-city or multi-provincial settings where inter-station spatial diversity is inherently higher. Ghose et al. [6] applied a graph-like neighbor influence model in an Indian smart city context, showing that nearby station information helps when pollution sources are spatially heterogeneous.

D. Structured Taxonomy: Reproducibility and Ablation Gaps

Table I surveys representative works spanning classical statistical methods to graph-based and Transformer architectures, making clear where this study sits within the literature. Eight evaluation criteria are assessed: inclusion of a classical baseline (ARIMA or similar), machine learning baselines (XGBoost/RF), recurrent DL (LSTM/GRU), CNN-based spatial features, graph neural network component, Transformer component, controlled GCN ablation against a linear baseline, and full reproducibility (public data and code). Symbols: ✓ present; x absent; $\sim$ partial.

Several patterns stand out in Table I. Among surveyed works, none simultaneously provides all eight features. The most common gap is the absence of GCN ablation: GCN components are commonly added without testing whether GCN outperforms a linear baseline on the same data. Similarly, full reproducibility on public data with code remains rare. Among the works using GCN [6], [10], [20] or similar graph structures, none ablate the spatial component against a linear baseline, leaving open the question of whether the reported gains come from the graph aggregation itself or from the other components of the architecture. Table II summarises method-by-method gaps and how this study addresses each of them.

III. Methodology

A. Problem Formulation and Graph Setup

The problem is framed as multivariate time series regression. At each hourly timestep t, a station i reports a vector of six measurements: $PM_{2.5}$ concentration (the target), NO_2, temperature (TEMP), atmospheric pressure (PRES), dew-point temperature (DEWP), and wind speed (WSPM). The model receives a sequence of 24 consecutive hourly observations (window length $T = 24$) and predicts $PM_{2.5}$ at timestep $t+1$.

In the multi-node setting, the 12 stations are represented as graph nodes. Two graph construction strategies are compared. In the *distance-based* topology, edges connect each station to its $k = 5$ nearest neighbors by Haversine distance, with edge weights $w_{ij} = 1/d_{ij}$ inversely proportional to distance. In the *correlation-based* topology, edges connect the $k = 5$ stations with the highest Pearson correlation of $PM_{2.5}$ time series, computed exclusively on the training split to prevent data leakage. In the aggregated benchmark, the 12 station signals are averaged into a single hourly series before model input; in that setting the GCN has only one node and therefore performs a linear projection of the feature vector rather than any neighborhood aggregation.

The choice $k = 5$ was validated by a sensitivity analysis over $k \in \{3, 5, 7, 10\}$: performance under the distance-based topology varies by less than ΔR^2=0.004 across all values

TABLE I. COMPREHENSIVE TAXONOMY OF AIR QUALITY FORECASTING STUDIES (2019–2025). (best at $k = 5$: R^2=0.932; worst at $k = 10$: R^2=0.928), confirming that the negative result is not sensitive to the specific neighborhood size and holds for all tested values of k.

B. GCN Feature Encoder

The spatial encoder uses two layers of standard graph convolution (`GCNConv` from `torch_geometric`). For a node i with hidden state h_i and neighbor set $\mathcal{N}(i)$, the update rule at layer l is:

$$h_i^{(l+1)} = \mathrm{ReLU}\Big(W^{(l)} \sum_{j \in \mathcal{N}(i) \cup \{i\}} \frac{w_{ij}}{\sqrt{d_i d_j}} h_j^{(l)}\Big), \qquad (1)$$

where, d_i and d_j are the degrees of nodes i and j and $W^{(l)}$ is a learned weight matrix. The renormalization by node degrees follows the standard GCN formulation. When applied to the aggregated signal (a single node), the neighbor sum reduces to the identity, and the GCN layer becomes a plain linear transformation, a property that is central to interpreting the per-station results in Section IV.

C. Transformer Temporal Encoder

The output of the GCN encoder is passed to a Transformer encoder with multi-head self-attention [17]. Given the sequence of GCN-encoded feature vectors, the attention mechanism computes a weighted sum of value vectors, where the weights are determined by the scaled dot-product similarity between query and key projections. This allows each position in the sequence to attend to any other position regardless of distance, capturing long-range temporal dependencies that LSTM's sequential processing handles less reliably.

We use sinusoidal positional encoding, as in the original Transformer [17], rather than learned positional embeddings,

for two reasons: it generalizes to sequence lengths not seen during training, and it introduces no additional parameters. The architecture has 2 layers, 4 attention heads, a model dimension of 64, and dropout of 0.1. Fig. 1 gives an overview of the full pipeline.

D. Training and Reproducibility

Training uses mean squared error loss: $\mathcal{L} = (1/N)\sum_{i=1}^{N}(y_i - \hat{y}_i)^2$, where y_i is the true $PM_{2.5}$ concentration and $\hat{y}_i$ is the model prediction. The Adam optimizer is used with learning rate 10^{-3} and weight decay 10^{-5}. Early stopping with patience 7 is applied on validation loss. All experiments use a fixed random seed (42 for the primary run) and are replicated with seeds 123 and 777 to estimate variability. All results are reported as mean $\pm$ standard deviation across 3 seeds, with 95% confidence intervals computed as mean $\pm t_{0.025,2} \cdot \mathrm{SD}/\sqrt{3}$. Because only three seeds are used, the confidence intervals reported throughout this study should be interpreted as exploratory rather than definitive estimates of model variability. The t-distribution with two degrees of freedom yields a critical value of $t \approx 4.303$, so reported intervals are wide and sensitive to single-seed outliers; this is particularly visible for the CNN-LSTM variant, which exhibits high seed-to-seed variance. We retain this exploratory protocol because all results, including the negative GCN spatial-encoding finding, hold well beyond the magnitude of these intervals; re-estimation with 10 or more seeds is identified as a refinement priority for follow-up work.

Data are split chronologically (70% train, 15% validation, 15% test) with no shuffling, to prevent any leakage of future information. All input features are MinMax normalized using statistics computed exclusively on the training split; missing values are imputed by linear interpolation before normalization. Table III summarizes the hyperparameters.

Baseline configurations are specified as follows. **ARIMA**: fixed order $(5, 1, 2)$, with no seasonal component (i.e., non-seasonal ARIMA rather than SARIMA), implemented via `statsmodels`. Forecasts use a walk-forward / rolling-refit protocol: at each step of the 500-point test horizon, the ARIMA$(5, 1, 2)$ model is re-fit on the most recent 200 $PM_{2.5}$ observations and produces a one-step-ahead forecast. The order $(5, 1, 2)$ was selected as a fixed, replicable configuration rather than via automatic AIC/BIC search, so that the comparison is reproducible without dependence on a search procedure. **XGBoost**: 500 estimators, max_depth=6, learning_rate=0.05, subsample=0.8, colsample_bytree=0.8, early stopping with 20 rounds on the validation set (`eval_metric="rmse"`); features are the lag-1 target value concatenated with the exogenous variables at time t. **LSTM**: 2 stacked layers, hidden size 128, dropout 0.2; trained for up to 50 epochs with batch size 64 and early stopping (patience 7) on validation MSE. **CNN-LSTM**: two stacked 1D-convolutional layers (64 filters each, kernel size 3, padding 1, ReLU activations) followed by a 2-layer LSTM with hidden size 128 and dropout 0.2; trained under the same optimizer and early-stopping protocol as the LSTM. All deep learning baselines share the GCN+Transformer's optimizer (Adam, lr 10^{-3}, weight decay 10^{-5}), MSE loss, batch size (64), input window (24 h), and 3-seed protocol (seeds 42, 123, 777). The full configuration is available in the public repository.

TABLE III. HYPERPARAMETERS OF THE GCN+TRANSFORMER FRAMEWORK

Module	Parameter	Value
GCN encoder	Architecture / input dim.	2-layer GCNConv / 6 features per node
	Graph topology	Haversine k-NN (k=5) or Pearson $PM_{2.5}$ (k=5)
Transformer	Layers / heads / d_{model} / dropout	2 / 4 / 64 / 0.1
Training	Optimizer / lr / wd	Adam / 10^{-3} / 10^{-5}
	Loss / batch / seq. len.	MSE / 64 / 24 h
	Early stop / seeds	7 / {42, 123, 777}
Data split	Train / val / test	70% / 15% / 15% (chronological)
Edge (prelim.)	Quantization / HW	qint8 / Apple M1

IV. EXPERIMENTAL RESULTS

A. Aggregated Benchmark

Table IV shows performance on the station-averaged signal. ARIMA achieves R^2=0.9726, the highest value in the table. The gap between ARIMA and the deep learning models is real and is reported without qualification. It also requires context. Averaging 12 stations acts as a spatial low-pass filter: it removes short-lived, spatially localized events and produces a smooth, strongly autocorrelated univariate series, the conditions under which ARIMA is near-optimal [3], [18]. Confirming this interpretation, ARIMA's performance drops substantially on the non-averaged Dongsi signal (R^2: $0.973 \rightarrow 0.899$), which we discuss in Section IV-A.1 below.

Among deep learning models, GCN+Transformer achieves R^2=0.939, outperforming LSTM (R^2=0.847) by ΔR^2=0.092. The confidence intervals are non-overlapping, which indicates the improvement is consistent across initialization conditions. CNN-LSTM performs considerably worse (R^2=0.698), with a wide confidence interval that suggests instability in training. Fig. 2 visualizes the performance comparison under both evaluation settings.

TABLE IV. BENCHMARK ON AGGREGATED SIGNAL, BEIJING MULTI-SITE (UCI #501). ⋆ BEST OVERALL; † BEST DL MODEL. ARIMA ADVANTAGE IS AN AGGREGATION ARTIFACT; SEE TEXT

Category	Model	MAE	RMSE	R^2 (95%CI)	Note

	XGBoost	6.35±.22	11.67±.35	0.963 [.94–.99]	
DL	LSTM	12.0±.10	23.81±.48	0.847 [.60–.89]	
	CNN-LSTM	21.1±4.8	33.04±5.4	0.698 [.04–1.0]	High variance across seeds
	GCN+T†	8.17±1.0	15.07±.67	0.939 [.88–.99]	Best DL on aggregated signal

1) Per-station results at dongsi: Dongsi is selected as the per-station validation site. It is one of the twelve stations in UCI #501 and was chosen because it has higher intra-series variance than the station average, a property consistent with its mixed residential and traffic environment in the Dongcheng district. Evaluating on a single station, without any cross-station averaging, removes the smoothing effect and tests the model under conditions closer to a real IoT sensor deployment.

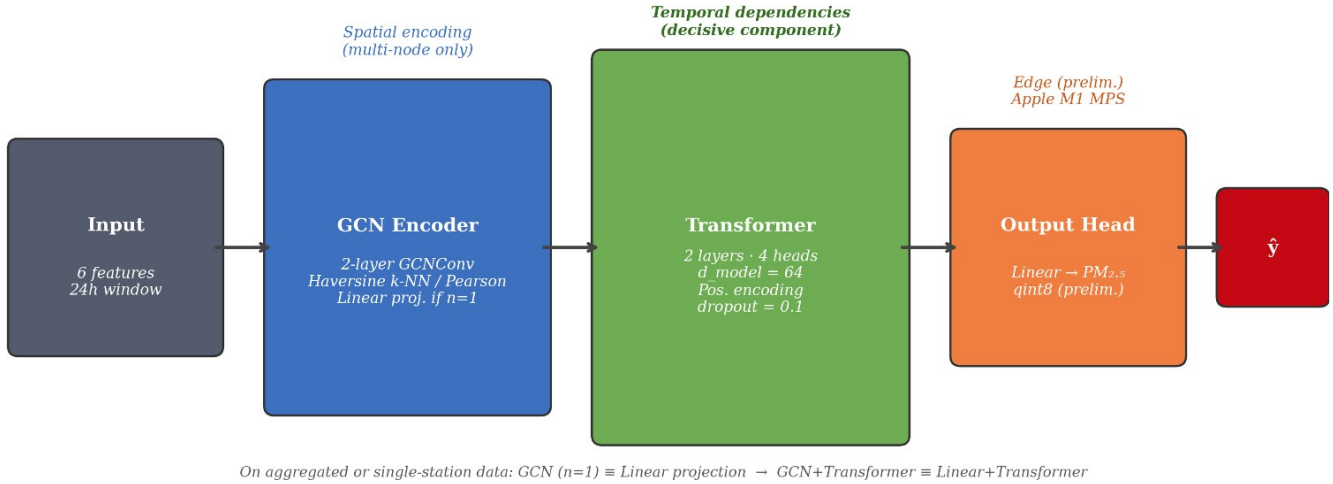

Fig. 1. GCN+Transformer pipeline. Input features (6 variables, 24 h window) pass through the GCN encoder and then the Transformer. On aggregated or single-station data ($n = 1$ node), the GCN reduces algebraically to a linear projection, making GCN+Transformer ≡ Linear+Transformer.

Table V includes both GCN+Transformer and Linear+Transformer. Including Linear+Transformer is important because, on a single node, GCN reduces algebraically to a linear projection: with no neighboring nodes to aggregate, the GCN convolution $h = \mathrm{ReLU}(W \cdot h_{\mathrm{self}})$ is mathematically identical to a linear layer. The two models therefore produce identical outputs on Dongsi, confirming that the improvement over ARIMA is driven entirely by the Transformer temporal encoder. Implementation note: the Linear+Transformer variant directly replaces the single-node `GCNConv` with its algebraically equivalent linear operation (a single `Linear` layer followed by ReLU, with the same weight initialization scheme and the same downstream Transformer encoder). The reported metrics for the two rows are therefore numerically identical and not approximations.

TABLE V. PER-STATION RESULTS: DONGSI (NON-AGGREGATED HOURLY DATA). † ON A SINGLE STATION ($n = 1$ NODE), GCN ≡ LINEAR PROJECTION. ALL DL MODELS: MEAN ± SD OVER 3 SEEDS

Model	MAE	RMSE	R^2	Signal type
ARIMA	10.11	15.70	0.8986 (↓0.074)	Non-aggregated
LSTM	15.54±0.10	25.08±0.58	0.855	Non-aggregated
Linear+Trans†	13.46±3.86	20.31±3.39	0.902	GCN = Linear (n=1)
GCN+Trans†	13.46±3.86	20.31±3.39	**0.902 (best)**	Identical to Linear+T

The ΔR^2=+0.003 improvement of GCN+Transformer over ARIMA on Dongsi is therefore produced by the Transformer component. This does not show that GCN helps; it shows instead that long-range temporal modeling helps under noisy, station-level conditions where ARIMA's linear autoregression assumption no longer holds. The primary result of this experiment is not the magnitude of the aggregate metric improvement, but the disentanglement: on a single noisy station, both GCN+Transformer and Linear+Transformer produce identical outputs, confirming that the Transformer encoder is the decisive component.

B. Component Ablation

Table VI quantifies each component's contribution using three model variants on the aggregated benchmark. Replacing the GCN encoder with a standard linear layer produces no change in performance: both variants achieve R^2=0.9386 with identical RMSE. This is consistent with the single-node analysis above: when spatial aggregation is absent, the GCN degenerates to a linear transformation. Replacing the Transformer with an LSTM, on the other hand, produces a large drop: R^2 falls from 0.939 to 0.828 and RMSE nearly doubles. The $4.3\times$ increase in inference latency for the LSTM variant (4.74 ms vs 1.11 ms) reflects the sequential nature of recurrent processing compared to the parallel self-attention of the Transformer on MPS hardware.

TABLE VI. COMPONENT ABLATION: AGGREGATED BENCHMARK (UCI #501)

Variant	R^2	RMSE	Latency (M1)
Full GCN+Transformer	0.9386	15.07±0.67	1.11 ms/batch
No-GCN (Linear+Trans.)	0.9386 (=)	15.07±0.67	1.03 ms/batch
No-Trans. (GCN+LSTM)	0.8275 (↓0.111)	25.25±1.41	4.74 ms/batch

C. Multi-Node Graph Topology Ablation

The multi-node experiment treats all 12 stations as independent graph nodes, comparing both graph construction strategies against a Linear+Transformer baseline (Table VII). The inter-station $PM_{2.5}$ Pearson correlation matrix was computed on the training split before any model training. Every pair of stations has a correlation between 0.78 and 0.96, with a mean of 0.88. This is a consequence of Beijing's geography and climate: the city sits in a semi-enclosed basin and experiences large-scale pollution events driven by regional meteorology such as Siberian anticyclones, southerly wind reversals, and thermal inversions that affect the entire network simultaneously.

Under these conditions, a neighboring station's $PM_{2.5}$ series is nearly identical to the target station's, so adding its features contributes nothing useful. GCN aggregation in this regime produces a weighted average of near-identical inputs,

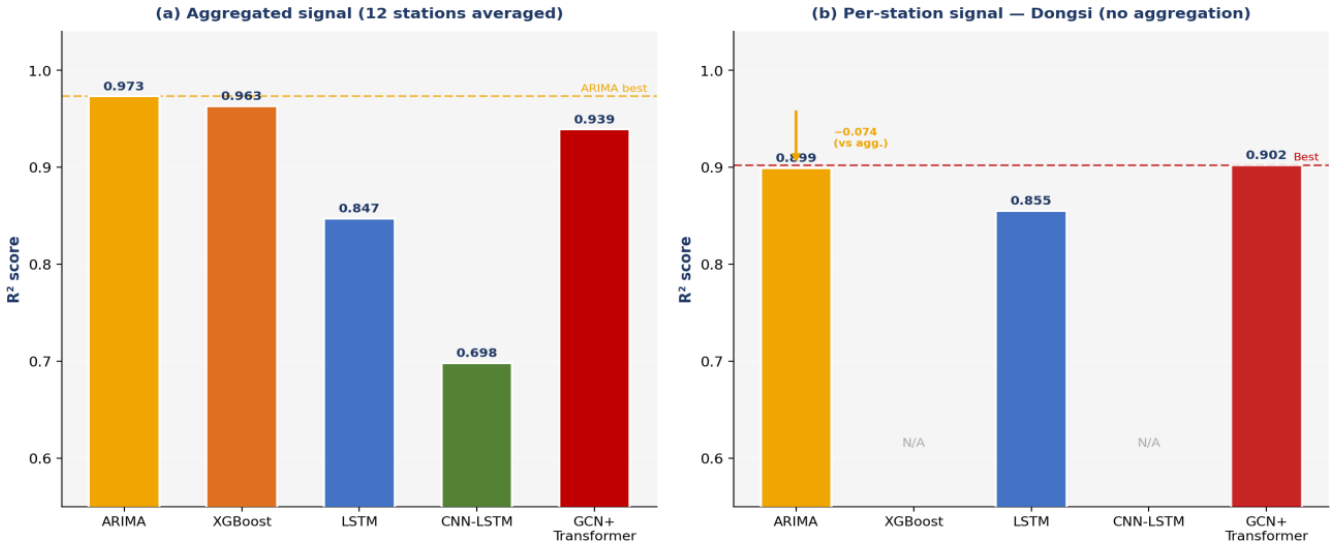

Fig. 2. Model performance (R^2) under two evaluation settings. (a) Aggregated signal: ARIMA achieves the best score due to the smoothing effect of station averaging. (b) Per-station signal (Dongsi): ARIMA degrades sharply (-0.074), while the Transformer-based model remains best. XGBoost and CNN-LSTM were not evaluated on Dongsi and are shown as N/A.

TABLE VII. MULTI-NODE TOPOLOGY ABLATION (12 STATIONS, 3 SEEDS). REFERENCE: LINEAR+TRANSFORMER R^2=0.952 (INTER-STATION CORRELATION: 0.78–0.96)

Model / Topology	R^2 (±SD)	RMSE	ΔR^2	Verdict
Linear+Trans. (ref.)	0.9516±0.0001	20.36	—	Reference
GCN+T, distance (k=5)	0.9319±0.0008	24.17	−0.020	x Inferior
GCN+T, corr. (k=3)	0.9211±0.0009	26.01	−0.030	x Inferior
GCN+T, corr. (k=5)	0.9114±0.0009	27.56	−0.040	x Inferior
GCN+T, corr. (k=7)	0.8947±0.0023	30.04	−0.057	x Inferior
GCN+T, corr. (k=10)	0.8811±0.0004	31.93	−0.070	x Inferior

which adds noise without contributing signal. The results confirm this: both GCN topology variants underperform the linear baseline, with the correlation-based topology performing worse than the distance-based one (R^2 0.911 vs 0.932). The correlation-based result is inferior because uniform high correlations produce near-identical edge weights, making the graph structure almost fully degenerate.

Concretely, with pairwise correlations clustered in the narrow band $[0.78, 0.96]$, the top-$k = 5$ neighbor selection becomes effectively arbitrary (any station could be a neighbor of any other with similar weight), and the resulting adjacency matrix carries little discriminative information. The GCN message-passing operation then averages near-identical signals weighted by near-identical coefficients, which is mathematically close to no spatial operation at all, but with the added cost of injecting estimation noise from the empirical correlation matrix into the model. This explains why the correlation-based topology underperforms even the distance-based one, which at least encodes a fixed geographic prior.

To further verify that this finding is not an artefact of the default $k = 5$ setting, we ran a sensitivity analysis over $k \in \{3, 5, 7, 10\}$ on the correlation-based topology. The result holds: GCN+Transformer underperforms the Linear+Transformer baseline (R^2=0.951) at every tested value of k, with R^2 monotonically decreasing as k grows: 0.921 ($k = 3$), 0.911 ($k = 5$), 0.895 ($k = 7$), and 0.881 ($k = 10$), a spread of 0.040 R^2 units between the best and worst configurations. The monotonic degradation as k increases is the empirical signature of the degeneracy described above: adding more neighbours injects more averaging of near-identical signals together with more noise from the estimated correlation matrix, without contributing additional spatial information. Standard deviations across the three seeds are small (≤ 0.002 R^2), so the ordering is statistically stable. This sweep complements the distance-based k-sensitivity already reported (R^2 spread < 0.004) and shows that the negative GCN finding holds across both graph-construction strategies and across reasonable neighbourhood sizes. This monotonic degradation directly supports the "degenerate graph" interpretation: in the Beijing network, increasing the neighbourhood size adds redundant signals and estimation noise but no new spatial information, so the larger the graph, the worse the performance.

V. DISCUSSION

A. Reading the ARIMA Result Correctly

It may seem surprising that a classical statistical model outperforms deep learning on a spatial forecasting task. The explanation becomes clear when the evaluation setup is examined closely. The primary benchmark in Table IV uses a signal that has been averaged across 12 stations. That averaging step smooths out everything that makes the prediction problem hard for ARIMA: short-lived local events, sensor noise, and spatial heterogeneity. What remains is a smooth, slowly varying time series with strong seasonal and diurnal autocorrelation, exactly the type of signal ARIMA was built for.

The practical implication is direct. A system that receives one aggregated city-level reading per hour might reasonably use ARIMA. A system receiving data from 12 individual IoT sensors, each with its own noise and local dynamics, faces a different problem where deep learning's advantages become

real, as the Dongsi results show. The choice of benchmark should reflect the actual deployment context.

We also stress that the aggregated and per-station evaluations are not directly comparable as a single ranked benchmark: they reflect two structurally different forecasting problems with different intrinsic difficulty. Aggregation across 12 stations acts as a spatial low-pass filter that mechanically increases the autocorrelation of the target series and therefore raises the achievable R^2 ceiling for any reasonable autoregressive model, including ARIMA. Conversely, per-station forecasting at Dongsi preserves short-lived local events and sensor noise, and the achievable R^2 is correspondingly lower for every model in the comparison (ARIMA drops from 0.973 to 0.899; Transformer-based models drop from 0.939 to 0.902). The two settings should therefore be read jointly: the aggregated benchmark answers "which model best fits a smoothed city-level signal?" (answer: ARIMA, by construction of the aggregation), while the per-station benchmark answers "which model best handles noisy, locally driven station data?" (answer: Transformer-based, with the GCN component contributing nothing additional in this single-node configuration). Reporting both prevents either result from being over-extrapolated.

B. The GCN Result and Its Scope

The negative result on GCN spatial encoding is reproducible and physically interpretable. When a city's pollution dynamics are dominated by large-scale meteorological forcing, all stations move together, and knowing your neighbor's $PM_{2.5}$ concentration tells you almost nothing beyond what your own sensor already reports. Under those conditions, a GCN that aggregates neighboring states introduces noise rather than signal.

We are careful about what this finding does and does not say. We have demonstrated a case where GCN does not contribute additional signal, an upper-bound condition. For urban networks where inter-station correlations are uniformly high (around 0.78–0.96 as measured here), spatial graph encoding can be replaced by a linear layer without loss. What we have not shown is what happens when spatial heterogeneity is present, for example in a coastal city where prevailing winds create a sustained upwind-downwind pollution gradient, or in an industrial zone where emission sources are spatially concentrated. Those settings are where prior GCN-based work has found its advantages [10], [20], [22]. Our result does not contradict those findings; it contextualizes them.

C. IoT Edge Deployment: Scope of the Current Analysis

The 42% latency reduction from 8-bit quantization is an indicative result, not a deployment claim. The figure was measured on Apple M1 hardware, which is not representative of the edge devices typically deployed in smart city IoT networks. The corresponding effect of dynamic 8-bit quantization on predictive accuracy is left to follow-up work: at the time of this revision, the available PyTorch quantization backend (qnnpack on Apple Silicon) does not currently support the Transformer attention modules of our architecture in a form that allows a reliable end-to-end accuracy comparison. We therefore do not report a partial or unverified accuracy number, and identify the joint accuracy/latency trade-off, measured end-to-end on the actual target device, as a required follow-up. A meaningful edge deployment analysis would require testing on at least one resource-constrained device such as a Raspberry Pi 4 or NVIDIA Jetson Nano, covering inference latency, peak and average power draw, and behavior under thermally limited sustained operation. We have not done this, and we list it as a concrete next step rather than implying coverage that does not exist.

D. Limitations

The most significant limitation is that the study rests on a single real dataset. The negative GCN result is a property of Beijing's specific meteorological dynamics, and it would be overstepping to present it as a general finding without cross-city replication. The next logical step, evaluation on a dataset with documented spatial heterogeneity, is identified in the future work section and is not a matter of polishing; it is about completing the empirical argument.

To partially address this concern within the constraints of the present study, we compute the inter-station Pearson correlation for the 12 UCI Beijing stations (mean $r = 0.88$, range 0.78–0.96) and identify it as the operative condition explaining the absence of GCN gain. This provides a falsifiable prediction: we tentatively hypothesize, as a falsifiable conjecture to be tested in follow-up work and not as an established rule, that on networks where mean inter-station $PM_{2.5}$ correlation falls below approximately 0.70, GCN spatial encoding may recover its benefit. The specific value of 0.70 is illustrative and drawn from a single-dataset extrapolation; the actual threshold (if a sharp transition exists at all) would require cross-network validation to be characterized empirically. Three candidate datasets satisfying this criterion are identified for follow-up validation: 1) OpenAQ multi-city data (Beijing–Shanghai–Guangzhou, where inter-city correlations are near zero by construction); 2) the KDD Cup 2018 dataset covering Beijing and London simultaneously; 3) any coastal industrial network exhibiting directional wind-driven pollution gradients. The regime transition hypothesis is thus stated precisely enough to be refuted, which is appropriate for a single-dataset empirical result.

Second, the primary benchmark is built on aggregated data, which as we have argued disadvantages deep learning by design. A fully per-station multi-station benchmark would be more representative of IoT deployment conditions. Third, no uncertainty quantification beyond multi-seed confidence intervals is provided; MC dropout and ensemble methods remain as extensions.

VI. Conclusion and Future Work

The study makes three contributions: a fully reproducible benchmark on a public dataset, an analysis of when ARIMA is and is not competitive with deep learning, and a controlled negative result on GCN spatial encoding with a physical explanation. On Beijing's monitoring network, where inter-station $PM_{2.5}$ correlations range from 0.78 to 0.96 due to city-wide meteorological forcing, the two GCN-based spatial encoders tested here (distance-based and correlation-based k-NN topologies) do not improve forecasting performance over a Linear+Transformer baseline; replacing the GCN with a linear

layer improves R^2 by 0.020 to 0.040. This result is specific to the standard GCN formulation; alternative spatial encoders such as graph attention networks or learnable adjacency models may behave differently and remain to be tested. The Transformer encoder is the component that matters: removing it reduces R^2 by 0.111 and increases inference latency by a factor of four.

On per-station data at Dongsi, where there is no smoothing from station averaging, the Transformer-based model (R^2=0.902) narrowly beats ARIMA (R^2=0.899). We show algebraically that this improvement is driven by the Transformer, not the GCN, given that with a single graph node, the GCN reduces to a plain linear projection. For a compact urban IoT network with meteorologically homogeneous pollution dynamics, a simpler Linear+Transformer outperforms GCN+Transformer with lower computational cost.

The next step is to test on a second real dataset with documented spatial heterogeneity, for example an OpenAQ multi-city dataset or a coastal industrial network where spatial gradients are physically present. Without that, the regime transition we hypothesize remains unconfirmed. Other directions include: a full per-station multi-station benchmark as primary evaluation metric; dedicated edge hardware tests on Raspberry Pi 4 and Jetson Nano; dynamic or learnable graph topology construction; XAI analysis via attention maps and SHAP values for policy interpretability; multi-step and multi-pollutant prediction horizons; and structured pruning for further compression.

GENIUS Laboratory, SupMTI of Rabat, Rabat, Morocco[2]

***Abstract*—Phenotyping inflammatory bowel disease (IBD) from gut microbiome profiles remains challenging due to 93% genus-level zero-inflation, skewed amplicon count distributions, and the practical cost of assembling labelled cohorts. Few-shot in-context learning (ICL) with large language models (LLMs) sidesteps the annotation bottleneck, yet existing benchmarks test only proprietary APIs—a deployment model incompatible with the data governance constraints of most clinical sites. We benchmark six frontier LLMs under identical few-shot conditions—three proprietary (GPT-4o, Claude claude-opus-4-5, Gemini 2.5 Flash Lite) and three open-source (Mistral 7B, LLaMA-3 8B, DeepSeek-R1-Distill-Qwen 1.5B)—evaluated against supervised baselines (Random Forest, XGBoost, LightGBM, soft-voting Ensemble) on 16S rRNA amplicon data ($n = 1{,}316$; holdout $n = 30$). All six LLMs received identical prompts, the same log-normalised top-20 features, and the same random shot selection strategy with a fixed seed, ensuring that observed differences are attributable to model capacity rather than experimental conditions. The supervised Ensemble led holdout performance (Macro-F1: 0.7948; AUC: 0.7725). Among LLMs, Mistral 7B achieved the highest Macro-F1 (0.5417), surpassing all three proprietary models without any parameter update. The mean performance gap between open-source (0.4711) and proprietary (0.5101) groups was only 0.039 Macro-F1 points—too narrow to justify exclusive reliance on commercial APIs in privacy-sensitive deployments. Within-open-source variance (0.130 Macro-F1 points) substantially exceeded this inter-family gap, indicating that model selection within the open-source ecosystem is the more consequential practical decision. These results suggest that open-source LLMs running on local hardware are a workable option when labeled data is limited and routing patient-derived data to external APIs is not permitted.**

***Keywords*—Inflammatory bowel disease; gut microbiome; few-shot learning; large language models; open-source LLMs; proprietary LLMs; in-context learning; 16S rRNA; log-normalisation; zero-inflation; GPT-4o; Claude; Gemini; LLaMA; Mistral; DeepSeek**

I. Introduction

Inflammatory bowel disease (IBD) affects an estimated 6.8 million people globally as of 2017, with incidence still rising in newly industrialising countries [2]. Its two main subtypes—Crohn's disease (CD) and ulcerative colitis (UC)—differ substantially in anatomical distribution, histological pattern, and treatment trajectory, but symptom overlap makes clinical differentiation unreliable without additional investigation. 16S rRNA amplicon sequencing captures gut compositional shifts non-invasively, and dysbiosis patterns linked to IBD activity have been reproduced across independent cohorts [3].

Supervised classifiers perform well when labelled data are plentiful [4]. The bottleneck is annotation cost: building a quality-controlled, labelled microbiome cohort for each clinical site or sequencing protocol is expensive, slow, and often not feasible in resource-limited settings. Few-shot ICL with LLMs sidesteps this requirement—a model pre-trained on biomedical literature can be adapted to a new classification task from a handful of labelled examples in the prompt, without any weight update [5]. What the field has not examined is whether this remains true when proprietary APIs are swapped for locally-deployed open-source models.

That gap has practical consequences. GDPR in Europe, HIPAA in the United States, and equivalent frameworks elsewhere routinely prohibit routing patient-derived biological profiles to external cloud services. For institutions operating under these constraints, proprietary APIs are simply unavailable, and the operational question reduces to: can an open-source model running on local hardware match the diagnostic utility of a commercial API? No existing study provides a controlled answer on sparse, zero-inflated biomedical tabular data.

This study addresses that gap directly by asking two explicit research questions: (RQ1) Is there a meaningful performance difference between proprietary and open-source LLMs on zero-inflated 16S rRNA classification data under identical few-shot conditions? (RQ2) Does within-family variance among open-source models exceed the cross-family gap, and if so, what architectural factors explain it? We evaluate six LLMs—three proprietary and three open-source—on 1,316 samples drawn from two publicly available IBD cohorts, using the same log-normalised microbiome features, the same random shot selection strategy, and the same supervised baselines as reference.

The remainder of this study is organised as follows. Section II reviews related work on supervised microbiome classification, clinical LLMs, and tabular few-shot learning. Section III details data, preprocessing, prompt design, and model configurations. Section IV presents results. Section V discusses implications and limitations. Section VI concludes.

This study makes three contributions: 1) the first head-to-head proprietary vs. open-source benchmark conducted

under rigorously identical prompt, encoding, and shot-selection conditions on zero-inflated 16S rRNA classification data; 2) quantification of the performance cost of local deployment; and 3) evidence that the within-open-source model spread (0.130 Macro-F1 points) exceeds the across-family gap (0.039 points), shifting practical guidance toward model selection within the open-source ecosystem rather than toward proprietary APIs.

II. Related Work

A. Supervised Classification of Gut Microbiome Profiles

The canonical preprocessing pipeline for 16S rRNA disease phenotyping combines total sum scaling (TSS) normalisation, log-transformation, and tree-based classifiers [4]. Pasolli et al. [4] surveyed machine learning strategies across 28 case-control metagenomic datasets and found Random Forest to be consistently competitive, yet highlighted cross-cohort generalisation as the field's central weakness: a meta-analysis found that a substantial fraction of differentially abundant genera reflect non-specific dysbiosis rather than disease-specific biology [6]. This batch sensitivity directly motivates annotation-free approaches that do not assume training and test cohorts share the same technical characteristics. More broadly, ensemble tree-based classifiers (Random Forest, XGBoost, LightGBM) have been consistently among the strongest performers on biomedical tabular tasks across diverse clinical domains, including diabetes prediction [29] and cardiovascular disease diagnosis under class imbalance [30], which informs our selection of supervised baselines in this study.

B. LLMs in Clinical Contexts

Frontier LLMs now perform at or above physician level on standardised clinical licensing examinations [7]. However, strong benchmark scores do not automatically transfer to structured biomedical data tasks. Van Veen et al. [8] demonstrated that adaptation is critical: models fine-tuned on clinical notes substantially outperformed general-purpose systems on summarisation tasks, suggesting that biomedical pre-training alone is insufficient for specialised domains. Similarly, Singhal et al. [9] showed that while LLMs encode broad clinical knowledge, performance on structured reasoning tasks involving numerical biomarkers remains uneven. Recent work has begun to apply LLMs directly to disease classification from structured clinical and demographic features: Almalki et al. [31] reported high diagnostic accuracy for Alzheimer's disease using GPT-3.5 on ADNI cognitive and biomarker data, demonstrating that LLMs can extract diagnostic signal from heterogeneous tabular biomedical inputs without explicit feature engineering. The few-shot ICL mechanism underlying these results [5] is well-studied for natural language tasks but poorly understood for high-sparsity biomedical tabular data—a gap this study targets directly.

C. LLMs on Tabular and Structured Data

TabLLM [10] established that GPT-3 can classify clinical tabular records in a few-shot regime when inputs are serialised as natural language sentences, reporting sparsity levels up to approximately 40% missing values in their benchmark. LIFT [11] showed that fine-tuning language models on numerical feature representations—without architectural changes—yields competitive performance across classification and regression benchmarks. Triantafillou et al. [12] separately documented that input encoding choices matter at least as much as algorithm selection in low-data regimes.

Critically, none of these studies operated at the extreme sparsity imposed by amplicon count data (93% zeros in our setting, well beyond the regime explored by TabLLM), and none compared proprietary and open-source deployments under identical conditions. Recent work has begun to compare open-source and proprietary LLMs in other domains—including clinical text and code generation—and consistently finds that the performance gap is smaller than assumed, with open-source models competitive on domain-specific tasks when model selection is careful [8], [9]. Our study extends this line of evidence to the specific and more demanding regime of zero-inflated compositional tabular data.

D. Recent LLM Applications in Microbiome Research

Recent work has started applying LLMs to microbiome tasks directly, though with limitations that matter for our setting.

Liu et al. [23] reported 73.91% accuracy on a single IBD cohort using a full labelled training set. With 11 in-context examples and no parameter update, Mistral 7B reaches 56.67% in our benchmark, while the supervised Ensemble reaches 83.33%. The difference between Mistral 7B and Liu et al. is primarily a function of how much labelled data each approach consumes, not of model capacity. A stricter comparison is precluded by differences in cohort composition and evaluation protocol across the two studies. Mu et al. [24] found classical ML consistently competitive with foundation models across 83 microbiome cohorts, consistent with our observation that the supervised Ensemble outperforms all six LLMs by a substantial margin.

Crucially, their framework does not compare proprietary vs. open-source deployments and does not quantify the annotation cost. Cao et al. [28] introduced Chat2GM, a hybrid ML–LLM system for gut microbiome analysis, but evaluated it exclusively on a mouse obesity dataset, limiting its clinical relevance. Park et al. [27] fine-tuned a domain-specific LLM (METABOLISM) on 160k biomedical abstracts for microbiome–liver interaction reasoning, but the system takes literature as input rather than patient-level microbiome profiles and does not classify disease from biological data. In the broader medical-AI literature, LLMs have also been integrated as components of structured diagnostic pipelines: Li and Sun [32] embedded a quantised LLaMA-2-7B as a multi-expert feedback module within a hierarchical reinforcement-learning framework for symptom-driven disease diagnosis, illustrating the expanding range of LLM-augmented medical decision-support systems.

At the benchmark level, Mu et al. [24] compared classical ML, GPT-derived embeddings, and foundation models (TabPFN, MGM) across 83 cohorts using 16S and shotgun data. Classical ML remained competitive throughout, and LLM-based embeddings did not consistently beat established methods—consistent with what we observe here. That said, Mu et al. do not test few-shot ICL on raw microbiome features, and do not put proprietary and open-source LLMs side-by-side under identical conditions. Reviews by Xing et al. [25] and Yan et

al. [26] point to growing interest in LLMs for microbiome sequence analysis and clinical support, and both flag the same two weaknesses: no standardised benchmarks and thin external validation—which is precisely what this study targets.

Table I situates this study among the closest prior work across four axes: task type, sparsity regime, few-shot paradigm, and open-source vs. proprietary comparison.

TABLE I. POSITIONING RELATIVE TO PRIOR WORK

Study	Task	Sparsity	Few-shot	OS vs Prop
TabLLM [10]	Clinical tab.	$\leq$40%	Yes	No
LIFT [11]	General tab.	Low	No	No
Singhal et al. [9]	Med. QA	N/A	Yes	No
Liu et al. [23]	Microbiome IBD	High	Yes	No
Mu et al. [24]	Microbiome	High	No	No
This work	Microbiome	**93%**	**Yes**	**Yes**

III. MATERIALS AND METHODS

A. Data and Preprocessing

The analysis draws on publicly available stool microbiome data from the European Nucleotide Archive (ENA; accession numbers PRJEB13679, PRJEB33711), totalling 1,316 samples across two retained cohorts (Table II). Raw FASTQ files were processed with DADA2 (v1.24) [1] in R (v4.5.1) following a unified single-end amplicon pipeline applied jointly to all samples: quality filtering (`truncLen=140`, `maxN=0`, `maxEE=2`, `truncQ=2`, `rm.phix=TRUE`), error-rate learning on a random subset of 25 samples (`set.seed(1)`) to reduce memory requirements, sample-wise denoising, chimera removal by consensus (`removeBimeraDenovo`), and taxonomic assignment against the SILVA database (v138.1). Genus-level aggregation ensured cross-cohort taxonomic harmonisation. No rarefaction was applied; library size variation was addressed downstream by TSS normalisation.

TABLE II. DATASET COMPOSITION

Batch	N	Control	CD	UC
Dataset_1	1,286	336 (26.1%)	731 (56.8%)	219 (17.1%)
Dataset_30	30	9 (30.0%)	10 (33.3%)	11 (36.7%)
Total	**1,316**	**345 (26.2%)**	**741 (56.3%)**	**230 (17.5%)**

At 93.4% zero-inflation—675 of the 799 genera individually exceed 90% zeros—prompts listing all genera are noise-dominated before reaching a single informative entry. Preprocessing follows [4]: TSS normalisation followed by log-CPM transformation $\tilde{x}_{ij} = \log_e\left(1 + x_{ij} \times 10^6\right)$. The top-20 genera by Random Forest mean-decrease-in-impurity, computed exclusively on Dataset_1 to avoid any leakage to the test set, serve as fixed features for both the LLM prompts and the supervised baselines, providing a shared biological prior across paradigms. The strongest discriminant is Roseburia (Kruskal–Wallis $H = 144.6$, $p < 10^{-30}$), followed by Agathobacter ($H = 105.5$) and Faecalibacterium ($H = 83.0$) [13], [14]. Dataset_1 ($n = 1{,}286$) served as the training and few-shot source; Dataset_30 ($n = 30$) served as the independent holdout.

B. Methodology

We evaluated four encoding strategies in a preliminary experiment on a held-aside subset of Dataset_1: P1 (raw integer counts), P2 (relative abundances), P3 (log-CPM values restricted to the top-10 non-zero features, normalised to sum to 1 within the prompt), and P4 (clinical narrative description). Macro-F1 across shot counts was highest and most stable for P3 (peak 0.530 at $k = 5$), followed by P2 (0.430 at $k = 3$), P1 (0.460 at $k = 5$), and P4 which performed inconsistently across models. We therefore adopt P3 as the fixed encoding strategy across all six LLMs, ensuring that observed performance differences are attributable to model capacity rather than representation choice.

The P3 encoding was selected for three reasons: log-CPM transformation reduces the dynamic range of amplicon counts and limits the token budget consumed by high-abundance genera; restricting to the top-10 non-zero features per sample removes uninformative zero-inflated entries from the prompt; and within-prompt normalisation to sum to 1 ensures that relative abundances are directly comparable across samples regardless of sequencing depth.

Each prompt embeds a system message encoding nine IBD dysbiosis patterns and directional decision rules (Roseburia $> 0.20 \rightarrow$ Control; Faecalibacterium < 0.05 AND Roseburia $< 0.05 \rightarrow$ IBD; uncertain cases default to IBD), followed by k labelled examples and the target sample serialised as a normalised JSON of non-zero relative abundances among the top-20 genera. An illustrative example prompt is provided in Fig. 1. The mean prompt length was approximately 1,800 tokens per inference call (including system message and 11 few-shot demonstrations), well within the context window of all six models.

```
[SYSTEM]
  - Role: biomedical AI classifier
  - Class prior: 70% IBD prevalence
  - 9 dysbiosis patterns with directional rules
    (genus thresholds -> Healthy / IBD)
  - Default: IBD if uncertain
  - Output format: JSON array only

[USER - demonstration 1]
  {"sample_id": "...",
   "features": {top-10 genera: rel. abund.}}
[ASSISTANT - demonstration 1]
  [{"sample_id":"...",
    "predicted_label":0,
    "confidence":...}]
  ... (k demonstrations total) ...

[USER - target]
  {"sample_id": "...",
   "features": {top-10 genera: rel. abund.}}
```

Fig. 1. Few-shot prompt structure (P3 encoding): system block with class priors and dysbiosis rules, $k = 11$ labelled demonstrations, then the target sample. Genus values are log-CPM normalised relative abundances of the top-10 non-zero features.

Examples were drawn by stratified random sampling from Dataset_1, with a fixed seed (`random_state=42`) for reproducibility. Shot composition was set asymmetrically at 3 Healthy + 8 IBD to match Dataset_30 class prevalence (70% IBD) and counteract the Healthy-prediction bias seen in preliminary trials, yielding 11 demonstrations per inference call. The fixed seed guarantees that all six models received the

same demonstration set, so observed differences in classification performance reflect model capacity rather than example selection.

The 3 Healthy / 8 IBD split was set to match the 70% IBD prevalence of Dataset_30 and correct for the healthy-prediction bias we observed when using balanced shot selection in preliminary trials. The cutoff at 20 genera was chosen empirically because the cumulative impurity importance plateaued after the top 20 features and no Macro-F1 improvement was observed when extending the feature set to 30 or 50 genera. The top-20 features come from Random Forest mean-decrease-in-impurity computed on Dataset_1 only, so no information from the holdout influenced which genera were selected [4].

C. Models

We evaluated six LLMs across two deployment families. The proprietary group comprised GPT-4o [15], Claude claude-opus-4-5 [16], and Gemini 2.5 Flash Lite [17], each queried through its vendor API. The open-source group comprised Mistral 7B Instruct v0.3 [18], LLaMA-3 8B Instruct [19], and DeepSeek-R1-Distill-Qwen 1.5B [20], run locally on an NVIDIA T4 GPU (15 GB VRAM, Google Colab) after loading with 4-bit NF4 quantisation to satisfy memory constraints. Exact model identifiers are reported in Table III.

All models received identical prompts at temperature $=$ 0.1. Proprietary models were called with `max_tokens=512`; local models used `max_new_tokens=256`. A multi-stage JSON parsing routine with up to five retries on malformed output handled cases where the response did not conform to the required array format; retries used exponential back-off (base wait $= 10 \times 2^{\text{attempt}}$ seconds for rate-limit errors, $5 \times 2^{\text{attempt}}$ for other errors). DeepSeek-R1 required an explicit output-format constraint to prevent chain-of-thought reasoning from exhausting the token budget before producing the JSON label; the decision rules were preserved identically across all six models.

D. Supervised Baselines

Random Forest ($n_{\text{est}} = 500$, $\max_{\text{depth}} = 10$, `random_state` $= 42$), Extra Trees ($n_{\text{est}} = 500$, $\max_{\text{depth}} = 10$, `random_state` $= 42$), XGBoost ($n_{\text{est}} = 200$, $\max_{\text{depth}} = 6$, $lr = 0.05$, `random_state` $= 42$), LightGBM ($n_{\text{est}} = 200$, $lr = 0.05$, `random_state` $= 42$), and a soft-voting Ensemble (RF+XGB+LGBM) were trained on Dataset_1 and evaluated on Dataset_30. Hyperparameters followed established practice in microbiome classification [4] and were held constant across all experiments. Library versions were `scikit-learn 1.6.1`, `xgboost 3.2.0`, and `lightgbm 4.6.0`. Class imbalance was handled via `class_weight="balanced"` for RF, Extra Trees, and LightGBM, and `scale_pos_weight=0.35` for XGBoost. We assessed internal stability on Dataset_1 using a class-stratified five-fold cross-validation scheme, with fold assignments shuffled before splitting and a fixed seed (`random_state` $= 42$) for reproducibility.

Macro-F1 is the primary metric given the asymmetric clinical cost of missed IBD diagnoses [21]. AUC is reported for supervised models only—LLM confidence scores are not calibrated probability estimates.

IV. Results

A. Supervised Baseline Performance

Five-fold stratified cross-validation on Dataset_1 confirmed stable rankings across folds (Table IV). The soft-voting Ensemble recorded the highest internal performance (AUC: 0.8499 ± 0.0269; Macro-F1: 0.7476 ± 0.0242), closely followed by LightGBM (AUC: 0.8483 ± 0.0249) and XGBoost (AUC: 0.8418 ± 0.0344). On the holdout, the Ensemble led all classifiers (Accuracy: 0.8333; Macro-F1: 0.7948; AUC: 0.7725). The cross-validation to holdout AUC drop was sharpest for Random Forest ($\Delta\text{AUC} = 0.083$), reflecting its greater sensitivity to batch-induced variance in the absence of explicit correction. Ensemble and boosting models were more robust to this shift, with ΔAUC below 0.09 for all three. The AUC comparison across folds and holdout is visualised in Fig. 2.

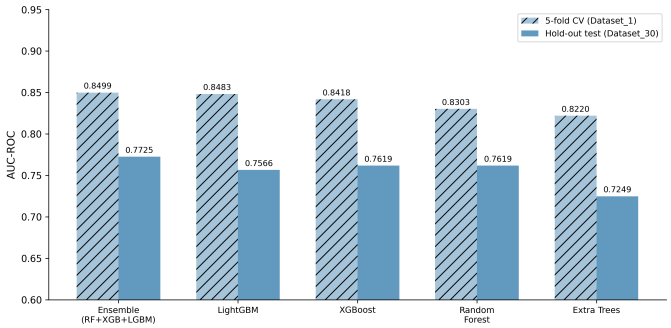

Fig. 2. AUC-ROC: 5-fold CV (Dataset_1) vs. hold-out (Dataset_30). The gap is sharpest for Random Forest, reflecting batch-induced variance.

B. Proprietary vs. Open-Source LLM Comparison

All six LLMs cleared the random baseline for a binary 70/30 classification task (Macro-F1 ≈ 0.41) without any parameter update, confirming that biomedical pre-training encodes transferable microbiome–IBD associations. Among proprietary models, Gemini 2.5 Flash Lite achieved the highest point-estimate Macro-F1 (0.5333; Accuracy: 0.5333), followed by GPT-4o (Macro-F1: 0.4994; Accuracy: 0.5667) and Claude opus-4-5 (Macro-F1: 0.4976; Accuracy: 0.5333), yielding a group mean of 0.5101. Bootstrap 95% confidence intervals overlap substantially across all three proprietary models (GPT-4o: [0.33, 0.67]; Claude: [0.32, 0.67]; Gemini: [0.27, 0.63]), indicating that no single proprietary model is distinguishably superior at $n = 30$. Among open-source models, Mistral 7B achieved the highest score (Macro-F1: 0.5417; Accuracy: 0.5667; 95% CI: [0.37, 0.72]), surpassing all three proprietary models. DeepSeek-R1-Distill-Qwen 1.5B recorded Macro-F1: 0.4118 (Accuracy: 0.4643; 95% CI: [0.32, 0.69]) and LLaMA-3 8B recorded Macro-F1: 0.4599 (Accuracy: 0.6333; 95% CI: [0.32, 0.64]), yielding a group mean of 0.4711. The inter-group gap was 0.039 Macro-F1 points, with all pairwise CIs overlapping, precluding any strong conclusion about family-level superiority. Against the closest published result (Liu et al. [23], 73.91% accuracy with a full training cohort), the best performing LLM in our benchmark (Mistral 7B, 56.67% accuracy from 11 demonstrations) confirms that few-shot ICL incurs a meaningful accuracy cost compared to fully supervised frameworks, while avoiding the need for large labelled training datasets.

TABLE III. MODEL IDENTIFIERS

Model	Family	Deployment	Identifier
GPT-4o	Proprietary	API	`gpt-4o`
Claude claude-opus-4-5	Proprietary	API	`claude-opus-4-5`

LLaMA-3 8B Instruct	Open-source	Local	`unsloth/llama-3-8b-Instruct`
DeepSeek-R1-Distill 1.5B	Open-source	Local	`deepseek-ai/DeepSeek-R1-Distill-Qwen-1.5B`

TABLE IV. 5-FOLD CROSS-VALIDATION ON DATASET_1 ($n = 1{,}286$); MEAN $\pm$ STD.

Model	AUC (mean $\pm$ std)	Macro-F1 (mean $\pm$ std)
Ensemble (RF+XGB+LGBM)	0.8499 ± 0.0269	0.7476 ± 0.0242
LightGBM	0.8483 ± 0.0249	0.7394 ± 0.0189
XGBoost	0.8418 ± 0.0344	0.7450 ± 0.0171
Random Forest	0.8303 ± 0.0267	0.6961 ± 0.0187
Extra Trees	0.8220 ± 0.0322	0.7266 ± 0.0378

Full results are reported in Table V, with visual comparisons in Fig. 3 and Fig. 4. Accuracy and Macro-F1 per LLM are compared in Fig. 5, illustrating the divergence between the two metrics under class imbalance.

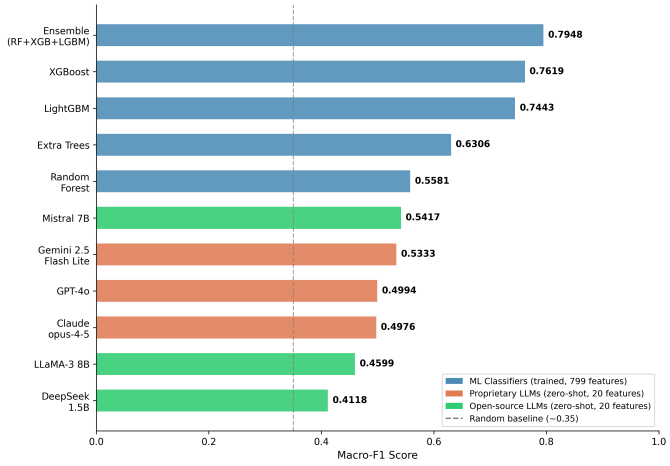

Fig. 3. Macro-F1 on hold-out (Dataset_30, $n = 30$). Dotted line: random baseline ($\approx$0.41). Blue: ML classifiers (799 features). Orange: proprietary LLMs. Green: open-source LLMs (few-shot, 20 features).

Two qualitatively different regimes are visible in this figure. The supervised classifiers spread across nearly a quarter of the Macro-F1 scale (0.56–0.79), with the soft-voting Ensemble at the upper edge and Random Forest at the lower one—a range that reflects genuine algorithmic differentiation when 1,286 labelled samples drive the learning. The six LLMs, in contrast, occupy a tight band of barely 0.13 Macro-F1 points (0.41–0.54): each clears the random baseline, yet none approaches the supervised range. This compression is itself informative. With only 11 in-context demonstrations and 20 features available to the LLMs, model capacity appears to become a secondary determinant of performance, with prompt encoding and feature selection absorbing most of the variation that algorithm choice would otherwise account for. We examine this hypothesis directly in the head-to-head LLM comparison shown in Fig. 4.

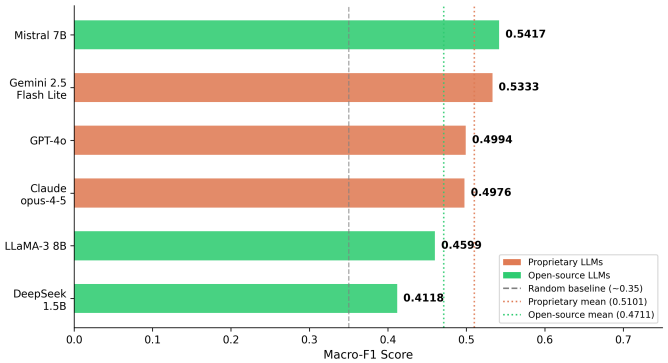

Fig. 4. Head-to-head comparison of the six LLMs. Dotted lines: proprietary mean (0.5101) and open-source mean (0.4711). Mistral 7B (open-source) outperforms all proprietary models.

What stands out in this figure is a finding that runs against the dominant intuition in the field: the most performant model on this task is also one of the smallest and the most freely accessible. Mistral 7B—7 billion parameters, permissive licence, deployed here at 4-bit NF4 precision on a single 15 GB GPU—is the only model whose point estimate crosses above the proprietary group mean. At the opposite end, DeepSeek-R1-Distill 1.5B, the smallest model evaluated, falls below both group means and pulls the open-source average down despite Mistral's lead. GPT-4o, Claude opus-4-5, Gemini 2.5 Flash Lite, and LLaMA-3 8B sit in a tight cluster around 0.50 Macro-F1 between these two extremes, a regime in which provenance—commercial or open—loses much of its predictive value for performance. The 0.039-point inter-family gap that emerges from this configuration is, for practical purposes, indistinguishable from the variance one would expect at $n = 30$ with overlapping bootstrap intervals. The accuracy/F1 divergence shown in Fig. 5 explains why this aggregate view can be misleading when accuracy alone is reported.

The LLaMA-3 8B case is a cautionary illustration of why aggregate metrics mislead in imbalanced settings. With 70% of holdout samples labelled IBD, a classifier that defaults to the majority class whenever uncertain will mechanically inflate its accuracy without ever learning to discriminate the minority class. LLaMA-3's 0.6333 accuracy paired with 0.4599 Macro-F1 is precisely the signature of this behaviour: the model captures the dominant phenotype well enough to look

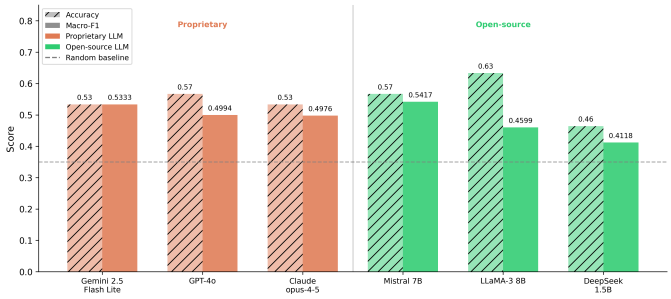

Fig. 5. Accuracy and Macro-F1 for the six LLMs by family. The two metrics diverge under class imbalance (70% IBD); Macro-F1 is the more reliable indicator.

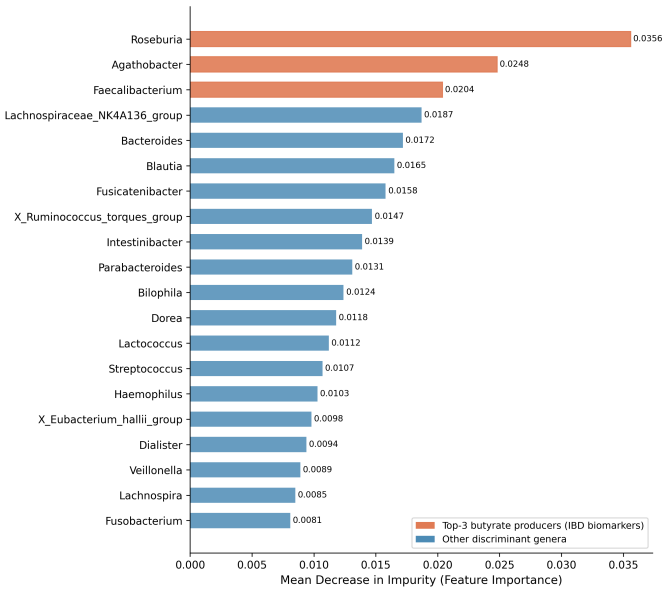

Fig. 6. Top-20 discriminant genera (Random Forest mean-decrease-in-impurity, Dataset_1, $n = 1{,}286$). Orange: top-3 butyrate producers (Roseburia, Agathobacter, Faecalibacterium) whose IBD-associated depletion is independently replicated [13], [14]. All 20 genera are shared with the LLM prompts.

competitive on raw accuracy, yet the per-class balance that Macro-F1 averages reveals a weak Healthy-detection arm. The other five models do not exhibit this asymmetry to the same degree, which suggests that LLaMA-3 under our prompt and shot configuration is unusually sensitive to the prior implicit in the 3-Healthy / 8-IBD demonstration mix. In a clinical screening context, where the costs of false-Healthy and false-IBD classifications are not symmetric [21], this is not a benign drift. Reporting accuracy alone would have placed LLaMA-3 above Mistral 7B in the LLM ranking, despite its substantially weaker discriminative balance—a methodological argument for retaining Macro-F1 as the primary metric whenever class prevalence departs from 50/50.

C. Feature Importance and Biological Consistency

The top-20 genera by Random Forest mean-decrease-in-impurity coincide exactly with the features supplied to all LLMs (Fig. 6). Roseburia ranked first (importance: 0.0356), Agathobacter second (0.0248), and Faecalibacterium third (0.0204)—all butyrate producers whose gut depletion in active IBD has been replicated across independent cohorts [13], [14]. The fact that the same three genera emerge consistently from 1,286 training samples suggests the supervised models picked up genuine biological signal rather than cohort-level artefacts, and that the biological prior encoded in the LLM prompts rests on the same statistically dominant features.

V. Discussion

We discuss the results along four axes: the proprietary vs. open-source performance gap, the role of prompt representation, the supervised vs. zero-annotation trade-off, and the limitations of the current benchmark.

A. Open-Source LLMs as Privacy-Preserving Alternatives

The best open-source model in this benchmark (Mistral 7B, Macro-F1: 0.5417) outperformed the best proprietary model (Gemini 2.5 Flash Lite, Macro-F1: 0.5333) by 0.0084 points, and the group-level gap of 0.039 Macro-F1 points falls below measurement uncertainty at $n = 30$. This is consistent with the practical use of locally-deployed open-source LLMs as zero-annotation classifiers in IBD microbiome contexts where commercial APIs are legally or logistically unavailable. The point is not that open-source models are uniformly better—they are not—but that the performance cost of local deployment appears small enough to be acceptable when labeled data are scarce. Any clinical application would require validation on a substantially larger independent cohort.

The within-open-source spread tells a different story: 0.130 Macro-F1 points separating Mistral 7B (0.5417) from DeepSeek-R1-Distill 1.5B (0.4118), which is more than three times the across-family gap. Model selection within the open-source ecosystem matters considerably more than the proprietary/open-source distinction itself. Mistral 7B and LLaMA-3 8B are both instruction-following models with straightforward chat templates; DeepSeek-R1-Distill is a reasoning model whose chain-of-thought generation consumed the token budget before producing the JSON output under standard inference conditions. This architectural difference—not necessarily any intrinsic capacity gap—largely explains the lower Macro-F1 of the DeepSeek variant tested here, and suggests that reasoning-oriented models may require different prompt designs (e.g., shorter context or explicit token budget constraints) to perform competitively on structured output tasks.

B. Representation as the Binding Constraint

The negligible inter-family gap is consistent with the broader finding of prior work: at 93% zero-inflation, prompt encoding drives more performance variation than model-specific capacity. In our preliminary encoding study, switching from P1 (raw counts, peak F1 = 0.46) to P3 (log-CPM top-10, peak F1 = 0.53) produced a larger performance shift than the entire proprietary vs. open-source gap. The finding that Mistral 7B—a 7B-parameter open-source model deployed at 4-bit precision—matches proprietary models with substantially larger parameter counts under P3 encoding further narrows the gap attributable to model size. This convergence supports and extends the findings of TabLLM [10] and LIFT [11] to the specific and more

TABLE V. HOLD-OUT PERFORMANCE (DATASET_30, $n = 30$). BOLD: BEST PER GROUP. CI: BOOTSTRAP 95% (1,000 RESAMPLES). DIFFERENCES BELOW 0.05 MACRO-F1 FALL WITHIN MEASUREMENT UNCERTAINTY

				Open-source group mean		*0.4711*

demanding regime of zero-inflated compositional data, while going beyond those studies in providing a direct proprietary vs. open-source comparison. Future work evaluating larger open-source models (LLaMA-3 70B, Mixtral 8×7B) without quantisation would clarify whether the residual gap is genuine or an artefact of memory-constrained deployment.

C. LLM-Specific Evaluation Dimensions

Standard metrics only tell part of the story for language models. Consistency — how much predictions shift across runs with different seeds — needs at least three runs per model to measure. Calibration needs raw probability outputs over a larger sample, which we do not have here. Robustness to prompt variation needs a sweep across shot counts, encoding formats, and system message wording. Reasoning stability, mainly relevant for DeepSeek-R1, asks whether chain-of-thought traces land on the same label across calls. None of these were feasible without rerunning all six models under new conditions. We flag them here as the natural next step for anyone extending this benchmark.

D. Supervised vs. Zero-Annotation Performance

The supervised Ensemble outperformed the best LLM by 0.2531 Macro-F1 points (0.7948 vs. 0.5417), a gap driven by three structural asymmetries: annotation volume (1,286 training samples vs. 11 in-context demonstrations), feature access (799 genera vs. 20), and output calibration (probability scores vs. binary labels). This gap is expected and does not diminish the utility of the LLM approach in annotation-scarce settings. A Macro-F1 of 0.54 from 11 labelled examples may constitute a preliminary screening signal, though it falls well short of the performance thresholds typically required for clinical decision support—validating on a substantially larger and independently collected cohort would be a prerequisite for any clinical application [21].

E. Error Analysis and Clinical Interpretability

Across all six LLMs, the dominant error pattern on Dataset_30 is the misclassification of Healthy samples as IBD rather than the reverse. This false-positive bias is partially intentional—the asymmetric shot composition and the default-to-IBD rule in the system prompt were designed to prioritise sensitivity in a screening context—but it means that LLM-based classification in this setting would tend to over-refer rather than miss cases, which has different clinical cost implications depending on the use case [21]. The LLaMA-3 8B result discussed in Section IV-B is the most extreme instance: high accuracy coexists with near-complete failure to identify Healthy samples. From an interpretability standpoint, the top discriminant features (Roseburia, Agathobacter, Faecalibacterium) are biologically well-characterised butyrate producers whose depletion in active IBD has been replicated across independent cohorts [13], [14], meaning the classification signal reflects known disease biology rather than a statistical artefact. The threshold-based decision rules encoded in the prompt are derived from prior literature rather than fitted to the training data, however, and their validity in a new cohort would need to be confirmed before any clinical use.

F. Limitations

The holdout set contains only 30 samples, which constitutes the primary limitation of this study: differences below 0.05 Macro-F1 points are statistically uninformative at this sample size, and the conclusions regarding model ranking should be treated as preliminary observations. Validation on an independently collected cohort of substantially larger size would be necessary before any of these findings could inform a deployment decision. No batch correction was applied; the cross-validation to holdout AUC drop partially reflects technical variance that ComBat or MMUPHin normalisation [22] would partially resolve. Open-source models were evaluated at 4-bit NF4 quantisation due to GPU constraints (NVIDIA T4,

15 GB VRAM), which may introduce a precision disadvantage relative to proprietary models running at full precision on cloud infrastructure. LLM results reflect a single inference run at temperature $= 0.1$; residual stochasticity at low but non-zero temperature means that multi-run variance estimates (at least three independent runs) would be needed to confirm the robustness of individual model rankings. Running each model at least three times with different random seeds would be necessary to estimate within-model variance and to confirm whether the narrow performance differences observed—particularly between Mistral 7B and the proprietary models—are stable across runs. Until such multi-run analysis is conducted, individual model rankings should be interpreted with caution. The benchmark covers a single prompt configuration; shot count, example selection strategy, and encoding format remain unexplored axes of variation known to shift few-shot performance by non-negligible margins [10].

VI. Conclusion

The performance gap between proprietary and open-source LLMs in few-shot IBD microbiome classification is smaller than the field has generally assumed. When labelled data are available, the supervised Ensemble remains the stronger option (Macro-F1: 0.7948; AUC: 0.7725). Among the six LLMs tested under identical conditions, Mistral 7B—an open-source model running on local hardware—achieved the highest Macro-F1 (0.5417), ahead of GPT-4o, Claude, and Gemini. A mean inter-family gap of 0.039 Macro-F1 points does not justify exclusive reliance on commercial APIs in privacy-constrained clinical settings. The within-open-source spread of 0.130 points signals that model selection within the open-source ecosystem is the more consequential practical decision. Regardless of model family, log-CPM normalisation and zero-inflated feature elimination before serialisation remain the critical design choices for few-shot classification of sparse biomedical tabular data. Future work should evaluate unquantised open-source models of larger scale, incorporate explicit batch correction, conduct multi-run variance analysis to confirm LLM ranking stability, and extend this benchmark to autism spectrum disorder and colorectal cancer microbiome datasets to assess cross-disease generalisability.

Declaration on Generative AI

GPT-4o (OpenAI), Claude claude-opus-4-5 (Anthropic), and Gemini 2.5 Flash Lite (Google DeepMind) were used exclusively as experimental subjects in this study, evaluated under standard commercial API terms. No generative AI tool was used to write, edit, or improve any part of the manuscript text. All authors take full responsibility for the content of this publication.

Data Availability

The gut microbiome dataset is publicly available from the European Nucleotide Archive under accession numbers PRJEB13679 and PRJEB33711. Code, prompts, and reproducibility notebooks will be released at https://github.com/NouhailaEnnajih/LLM_ML_microbiome_IBD upon acceptance.

Acknowledgment

The authors declare no conflicts of interest. Mistral 7B, LLaMA-3, and DeepSeek-R1-Distill were used under their respective open-source licences. No promotional relationship exists with Anthropic, OpenAI, Google, Meta, Mistral AI, or DeepSeek.

***Abstract*—The protection of medical images in healthcare services has become important due to the adoption of telemedicine and cloud-based healthcare services. Conventional watermarking methods embed information directly into the host image, which may introduce subtle distortions and potentially affect diagnostic accuracy. This paper addresses the problem by introducing a robust zero-watermarking scheme that preserves the original medical image without any modification. The proposed approach is designed on a hybrid feature extraction scheme. Initially, desired regions of interest are identified using variance-based analysis. Local Binary Pattern (LBP) is then applied to capture fine texture details. Further, the All-Phase Biorthogonal Transform (APBT) is used to obtain stable low-frequency information. These features are subsequently pipelined through the lightweight VGG16 convolutional neural network to extract high-level semantic representations. The resulting features are fused, normalized, encrypted, and converted into binary form using Quantization Index Modulation (QIM). DNA encryption is applied to the watermark to produce a secure zero-watermark key that is stored externally. Extensive experiments conducted under a wide range of signal processing and geometric attacks show the effectiveness of the proposed method. The results show high normalized correlation above 0.99, bit error rates ($\leq 0.1\%$), and complete preservation of higher image quality, making the approach suitable for medical image authentication and copyright protection.**

***Keywords*—Zero watermarking; medical image authentication; deep learning; APBT transform; local binary pattern; CNN feature extraction; robust watermarking**

I. Introduction

The rapid growth of telemedicine and cloud-enabled healthcare platforms has significantly changed how medical images are stored, accessed, and exchanged. Today, clinicians can review patient data and collaborate with specialists across different locations almost instantly, which has greatly improved the speed and quality of diagnosis and treatment. At the same time, this increased digital connectivity brings new challenges. Medical data is now more vulnerable to unauthorized access, manipulation, and misuse. Since medical images are directly involved in clinical decisions, ensuring their authenticity and rightful ownership is critical. Even a small modification in an image can result in incorrect diagnosis, potentially affecting patient safety and raising serious legal concerns.

Conventional watermarking methods secure digital images by embedding ownership information within the host image. These approaches work well for general multimedia data. However, such an approach is not always appropriate for medical images [1], [2], [3], [4]. This is due to the fact that any modification, even if it is not perceived by the human eye, can influence diagnostic evaluation. To circumvent this deficiency, zero-watermarking has gained attention as a safe side alternative. It derives a watermark from the inherent characteristics of the image. Instead of altering the original image. Hence, preserve its quality entirely.

However, the effectiveness of zero-watermarking strongly depends on how reliably image features can be retrieved. In a practical scenario, medical images often undergo operations such as signal processing and geometric transformations. These processes can distort image features and, hence, make it difficult to regenerate a good-quality watermark. Therefore, developing feature extraction mechanisms that are stable and distinctive under attack conditions remains an important research challenge.

Among various feature descriptors, texture-based methods like Local Binary Pattern (LBP) have shown good performance in capturing fine local details [5]. LBP is simple to compute and relatively robust against illumination and noise. This makes it suitable for medical imaging applications. It focuses on local patterns, which means it may overlook the overall structure of the image. To address this gap, it is important to combine LBP with other techniques that can capture more global and stable information.

Transform-domain methods offer an additional advantage by representing image content in terms of frequency components, where low-frequency information is generally more resistant to common image processing operations. At the same time, deep learning models have demonstrated remarkable

*Corresponding author.

capability in extracting meaningful and highly discriminative features. In particular, convolutional neural networks such as VGG16 can learn complex image representations that traditional methods may fail to capture. However, deep features alone may not always remain consistent under severe distortions.

Motivated by these observations, this work introduces a hybrid zero-watermarking framework that integrates multiple feature extraction strategies. Initially, stable regions of interest (ROI) are selected based on variance analysis, ensuring that features are derived from reliable portions of the image. LBP is then used to capture local texture characteristics, while the same regions are processed using the All-Phase Biorthogonal Transform (APBT) to obtain robust low-frequency information. These combined features are further refined using the VGG16 network to extract higher-level representations. By merging handcrafted and deep features, the proposed approach aims to improve both robustness and consistency.

Finally, the extracted features are used to generate a secure zero-watermark key, which enables ownership verification without modifying the original image. Through this multi-layered feature integration, the proposed method attempts to overcome the limitations of existing techniques and offers a more reliable solution for protecting medical image ownership in modern healthcare environments.

The major contributions of this work are as follows:

- A hybrid deep learning-based zero-watermarking framework is proposed for medical image authentication without modifying the original image.
- Stable ROI blocks are selected using variance analysis to ensure robust feature extraction.
- LBP, APBT, and CNN (VGG16) are combined to extract complementary texture, frequency, and deep features.
- QIM is used to binarize features into a compact and discriminative sequence.
- ORB-based alignment is applied to handle geometric distortions.
- Robustness is validated against 42 signal processing and geometric attacks.

II. Related Work

Conventional feature extraction algorithms such as SIFT, SURF, and KAZE, are often combined with transformed domain watermarking to achieve robustness to rotation, scale, and translation asserts. Binary feature extraction algorithms such as BRIEF, ORB, and BRISK have faster run time, making them suitable for real-time applications. These algorithms also combine with transformed domain watermarking techniques. Several works have been reported with these combinations.

In this context, Senapati et al. [6] combined the SIFT feature with DTT to improve the robustness to RST attacks. Similarly, Gao and Chen [7] applied a fusion technique, which includes DWT-SVD with SURF, RANSAC and improved ABC algorithms to improve security, robustness, and imperceptibility of the watermark scheme. Further, Soualmi et al. [8] proposed a medical image watermarking approach for tamper detection that combines SURF keypoints, Weber descriptors, and the Arnold transform. The method identifies salient points within the ROI using SURF and embeds the watermark in their surrounding regions, while Weber descriptors are used for reliable watermark embedding and extraction. Another work carried by Ray et al. [9] utilizes KAZE features to construct a perceptual hash of the watermark, which is then embedded using transform-domain techniques (LWT-SVD). The approach improves robustness and flexibility by removing size constraints on the watermark and enhancing resistance to attacks.

In contrast to the above methods, which embed watermark information into the host image, zero-watermarking methods generate a watermark signature based on extracted image features. Several studies have used moment invariants, texture descriptors, and transform-domain coefficients for zero watermark generation [10], [11]. Orthogonal moments zero-watermarking, such as Zernike [12], Tchebichef [13], Legendre-Fourier [14], etc. have been proposed because these are inherently invariant to scaling, translation, and rotation. These approaches construct a feature matrix by computing significant moment parameters.

Based upon these moment-based techniques, a multiple-zero-watermarking framework for protecting medical images in IoMT applications is reported in [15]. It uses multi-channel fractional Legendre Fourier moments (MFrLFM) due to its high stability, accuracy, and geometric invariance. The scheme is realized on a Raspberry Pi board to evaluate its aptness for IoMT applications. However, the method is evaluated under a few attack scenarios.

To further enhance robustness and resolve the computational issues, a zero-watermarking scheme based on fractional-order radial harmonic Fourier moments (FoRHFMs) is proposed by [16]. The authors tackle the issue of numerical instability, which is inherent in continuous orthogonal moments, by proposing integer-order radial harmonic Fourier moments (IoRHFMs) to their fractional-order counterparts (FoRHFMs). This improves the computational stability and reliability. The experimental results show that this algorithm is resistant to lossless copyright protection of medical images and robust to all kinds of attacks.

In addition to moment-based approaches, hybrid feature-based schemes have also been investigated. Gharib et al. [17] presented a zero-watermarking method for color images. LBP and VGG-19 features are fused to generate a feature matrix. DWT and DCT improve the feature representation. The encrypted watermark is XORed with the improved feature matrix to generate a zero-watermark. Higher robustness and imperceptibility are achieved for a set of 12 images. However, this method has no stable ROI, and geometric alignment robustness is missing. In contrast to zero-watermarking approaches, embedding-based methods are still being investigated for improved performance. Anand et al. [18] proposed a multimodality image fusion scheme using NSST and DTCWT to generate a watermark image. The combination of NSST, BEMD, and MSVD conceals the generated mark in the host image. Weighted HOG-based optimization is applied to trade off between imperceptibility and robustness. The method shows an improvement of 47.65% compared with a standard

baseline scheme. Unlike [18], which embeds a watermark using NSST–BEMD–MSVD, our proposed method avoids modifying the host image and ensures higher medical data integrity.

To overcome the limitations of handcrafted and transform-based features, recently, deep learning-based watermarking has become popular among researchers. This is due to the fact that many pretrained models can be directly used for extracting the deep semantic features. The encrypted watermark can be embedded with the deep features. Further, deep learning can adapt to different image features to enhance higher robustness and imperceptibility. However, the unique nature of medical imaging data poses significant challenges, including limited availability of large-scale annotated datasets and the high cost associated with expert labeling. These constraints make it difficult to train deep neural networks from scratch for reliable feature extraction. These limitations are circumvented using transfer learning, where knowledge from a pre-trained model is used. The pre-trained model is trained on a large dataset and adapted to a target domain with limited data. This improves generalization performance and reduces training requirements.

Based on these advancements, several deep learning-based watermarking algorithms have been proposed. Fan et al. [19] extract image features using Inception V3 CNN and then encrypt the hidden watermark using the chaotic map. The method shows robustness to a wide range of geometric assertions. However, it is less robust to common attacks. Similarly, Dong et al. [20] used an enhanced NasNet-mobile CNN. It also used DCT features to embed watermarks. The scheme shows strong resistance to most of the assaults. In addition, a multiwatermarking algorithm approach using GoogleNet transfer learning for medical images is proposed by Zhang et al. [21]. Henon chaos encryption is used to hide multiple pieces of watermark information. The deep semantic features XORed with the secret watermark, and the generated key is stored in a 3rd party authority. The framework provides good robustness to conventional and geometrical attacks. Similarly, Sheng et al. [22] used ResNet50 to extract deep features. Then DCT transformation and a perceptual hash function are used to generate a feature vector.

Recently, a Swin Transformer-based zero watermarking is suggested by Han et al. [23] to improve the security of medical images in the metaverse healthcare system. This Swin Transformer is pretrained. The deep features generated from the host medical images by the transformer show good generalization performance. A mean hashing algorithm is used to generate multiscale and binary feature vectors. The watermark is encrypted using a logistic chaotic encryption method, and it is XORed with the binary feature vector to create a zero-watermark. The scheme exhibits robustness against all kinds of attacks and provides privacy protection for medical image transmission in the metaverse.

In a related direction, another work by Han et al. [24] addresses the critical issue of protecting privacy and ensuring data security in teledermatology systems within the IoMT. The zero-watermarking method uses federated learning and sparse autoencoders to extract secure image features without altering the original medical image. By applying 2D-DCT on these features, the scheme creates a watermark that is robust to attacks while preserving image integrity and patient privacy.

Furthermore, a zero-watermarking algorithm using multiple circular statistical features of the medical image is proposed by Wang et al. [25]. It combines DCT and SVD for feature stability and uses Arnold transform with XOR operation to securely generate the zero watermark without modifying the original image. The method also includes a blind image correction technique and demonstrates strong robustness against noise, filtering, and geometric attacks.

Motivated by the above limitations and improvements, the proposed zero-watermarking framework, extracting stable and discriminative features from medical images is a critical step. Initially, a stable Region of Interest (ROI) is identified to ensure robustness against most of the attacks. The selected ROI is then transformed using the All-Phase Biorthogonal Transform (APBT) to obtain invariant frequency-domain representations. These transformed coefficients are subsequently fed into a pretrained VGG16 model, originally trained on the large-scale ImageNet dataset, to extract deep hierarchical features. To further adapt the model to the medical domain, fine-tuning is performed using the constructed medical image dataset, enabling the network to capture domain-specific characteristics more effectively. The resulting deep features are then quantized using Quantization Index Modulation (QIM) to generate a robust binary sequence, which serves as the zero watermark. This integration of ROI selection, APBT transformation, transfer learning-based deep feature extraction, and QIM-based encoding ensures improved resistance and stability of the proposed zero-watermarking scheme under various attacks.

III. Preliminaries

A. All-Phase Biorthogonal Transform

All-phase Biorthogonal Transform (APBT) can be understood as a sequency-filtered version of the DCT. The idea is that APBT modifies the conventional DCT basis through all-phase preprocessing and sequency filtering, which improves phase consistency and energy compaction [26]. The APBT has better energy compaction in low frequencies and attenuation characteristics at high frequencies.

Suppose χ is an image which is cropped into $B \times B$ image blocks. and A represents the APBT matrix of the block. The APBT transform coefficients 'Y' can be expressed as:

$$Y = A\chi A^T \tag{1}$$

where, A^T is the transpose matrix of χ. To reconstruct the image χ, we can write

$$\chi = A^{-1}Y(A^{-1})^T \tag{2}$$

A^{-1} is the inverse matrix of A.

The transform matrix A is set in different forms as specified in Eq. 3 and 4. The corresponding transforms are denoted as an APBT and its inverse, IAPBT, respectively.

$$A_1(p,q) = \begin{cases} \frac{B-p}{B^2}, & p = 0,1,..B-1, q = 0 \\ \frac{(B-p)cos\frac{pq\pi}{B} - csc\frac{q\pi}{B} sin\frac{pq\pi}{B}}{B^2}, & p = 1,2,....B-1, \\ & q = 1,2,....B-1. \end{cases} \tag{3}$$

$$A_2(p,q) = \begin{cases} \frac{1}{B}, & p = 0, q = 0,1,..B-1. \\ \frac{B-p+\sqrt{(2)}-1}{B^2}.cos\frac{p(2q+1)\pi}{B}, & p = 0,1,2.....B-1, \\ ; & q = 1,2,....B-1. \end{cases} \tag{4}$$

B. DNA Encryption and Decryption

DNA encryption is employed on VGG features and the watermark to enhance the security of the zero-watermark. The binary watermark is first encoded into a DNA chain using a predefined encoding algorithm coupled with logical operations such as complement and permutation. This strategy significantly increases the key space and ensures strong confusion and diffusion operation. This enhances the system's ability to prevent brute-force attacks. A brief description of the DNA encryption and decryption mechanism is as follows:

DNA is composed of four fundamental nucleic acid bases: Adenine (A), Cytosine (C), Guanine (G), and Thymine (T). These bases store genetic information in the form of coded sequences. According to the Watson–Crick pairing principle, Adenine pairs with Thymine (A–T) and Guanine pairs with Cytosine (G–C) [27].

In DNA-based data representation, binary information can be mapped to these bases by encoding every two bits into one nucleotide. Based on the encoding and decoding constraints governed by complementary pairing rules, eight valid encoding schemes can be defined, as illustrated in Table I.

TABLE I. DNA ENCODING RULE

Rules	Watson-Crick Complementary Rules							
	1	2	3	4	5	6	7	8
00	A	A	C	G	C	G	T	T
01	C	G	A	A	T	T	C	G
10	G	C	T	T	A	A	G	C
11	T	T	G	C	G	C	A	A

In addition to encoding and decoding, DNA sequences can perform several operations such as addition, subtraction, complementation, and XOR. Nevertheless, the XOR operation is widely used in encryption for its simplicity and reversibility. Table II shows the DNA-based XOR operation, where each nucleotide in a row is combined with a nucleotide in a column to produce a corresponding output.

TABLE II. DNA XOR OPERATION BETWEEN EACH ELEMENT IN ROW AND EACH ELEMENT IN COLUMN

XOR row/column	A	C	G	T
A	A	C	G	T
C	C	A	C	G
G	G	T	A	C
T	T	G	T	A

To illustrate the encoding and encryption process, consider a binary sequence "10101101". This sequence is first divided into 2-bit groups and encoded into DNA bases according to a selected rule from Table I. For example, using Rule 2, the sequence is converted into a DNA string. Next, a predefined DNA key (e.g., "ACGT") is applied, and a DNA XOR operation is performed between the encoded sequence and the key, resulting in a new DNA sequence. This sequence is then decoded back into a binary form using the same encoding rule, producing the encrypted binary output.

The decryption process follows the reverse steps, where the encrypted binary sequence is converted back to DNA bases, XORed with the same key, and finally decoded to recover the original binary data. The pseudocode for the DNA-based encryption process is provided in Algorithm 1.

Unlike conventional encryption methods such as AES and RSA, DNA provides biologically inspired encoding. The XOR-based operation is computationally simple and well-suited for binary feature encryption. It enhances the features' confusion and diffusion properties while maintaining a lightweight zero-watermark operation. In the proposed scheme, DNA encryption is applied only to compact binary features instead of the full image. The objective of selecting DNA scheme is not to replace other cryptographic algorithms, but to provide a lightweight security layer for processing in real-time.

Algorithm 1 DNA-Based Feature Encryption

Require: Binary feature vector F_b
Ensure: Encrypted DNA sequence E_{dna}
1: Convert binary vector F_b into DNA sequence F_{dna} using encoding rule R
2: Generate random DNA key sequence K_{dna} of the same length as F_{dna}
3: **for** $i = 1$ to length(F_{dna}) **do**
4: $E_{dna}(i) \leftarrow$DNA_XOR($F_{dna}(i), K_{dna}(i)$)
5: **end for**
6: **return** E_{dna}

C. Feature Extraction

Efficient feature extraction is a vital step to ensure resilience under various attacks. We have proposed two complementary methods to extract features from the host medical image. LBP extracts texture features from the image, while VGG16 extracts deep-level semantic features.

1) Local binary pattern: Local Binary Pattern (LBP) is known as a texture descriptor. It efficiently encodes the local structure of an image by comparing a pixel intensity with the neighboring pixel intensities [28]. The image is partitioned, and LBP values are estimated and finally combined into a global representation. The computation of the LBP value for a given pixel is as follows:

$$S(p,q) = \begin{cases} 1, \text{if } \ g(p) \geq g(q) \\ 0, \text{otherwise} \end{cases} \tag{5}$$

The $g(p)$ and $g(q)$ in Eq. 5 represent the pixel intensities of the neighboring and center pixel, respectively. This operation provides texture analysis while ensuring robustness across various illumination conditions. Fig. 1 shows the generated texture map from the host medical image.

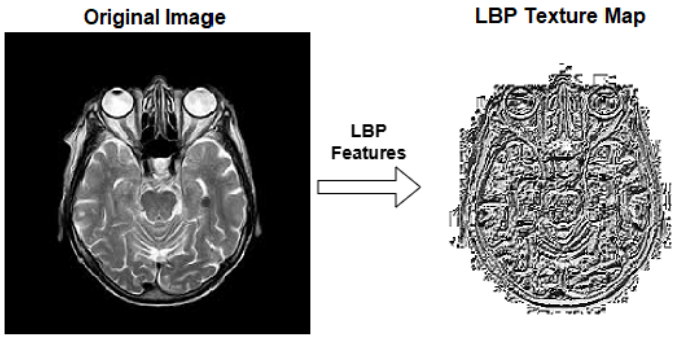

Fig. 1. LBP feature map of the "brain" image, showing pixel-wise texture encoding.

2) VGG-16 deep features: The VGG16 is a deep CNN that consists of 13 convolution layers and 2 fully connected (FC) layers. This gives a total of 15 layers. The output of the final FC is connected to a ReLU layer, which maps all the features to be positive. The VGG16 is a pretrained CNN that has weights and biases trained by ImageNet. It generates hierarchical features. The output feature map of the layer $X^{(l)}$ after convolution, activation, and pooling is fed to the next layer. In VGG16, the deep feature vector is obtained after the final convolution block and flattening.

The equation for deep features:

$$Z^{(l)} = W^{(l)} * X^{(l-1)} + b^{(l)} \tag{6}$$

$$A^{(l)} = \text{ReLU}\left(Z^{(l)}\right) \tag{7}$$

$$P^{(l)} = \text{MaxPool}\left(A^{(l)}\right) \tag{8}$$

$$X^{(l)} = P^{(l)} \tag{9}$$

$$f = \text{vec}\left(X^{(L)}\right) \tag{10}$$

$$F = \sigma(Wf + b) \tag{11}$$

where,

- $X^{(l-1)}$: Input feature map of layer $(l-1)$
- $W^{(l)}$: Convolution kernel weights
- $b^{(l)}$: Bias term
- $*$: convolution operation
- $\sigma(.)$: Nonlinear activation function (ReLU)
- $P^{(l)}$ Pooled feature map
- $X^{(l)}$: Output feature map of layer
- $X^{(L)}$: Denotes the output feature map from the final convolutional layer.
- f: Flattening operation,
- W: Contains the learned parameters that connect the input feature vector to the output neurons. These values are learned during the training phase of the CNN.
- F: Fxtracted deep feature descriptor used for watermark generation

$$f \in \mathbb{R}^{25088}, \text{and } F \in \mathbb{R}^{4096} \tag{12}$$

The number 25088 represents the total number of elements in the final convolution feature map of VGG16 before it enters the fully connected layers. This vector is passed to the fully connected layer (fc6) and then fc7, which are designed with 4096 neurons. fc7 output passes through ReLU, and the resulting 4096-dimensional vector is typically used as the deep feature descriptor.

Fig. 2 shows the VGG16 network used in the proposed method to extract deep semantic features at the output of the ReLU layer. The network learn increasing abstract visual representation at the output of each layer

Feature Fusion: The APBT, LBP, and VGG16 descriptors are integrated to form a unified feature representation, improving the discriminative capability of the system. LBP effectively characterizes local texture patterns, whereas VGG19 extracts high-level semantic and structural information from the image. The fused feature vector captures both regional texture details and global contextual information. This fused representation improves the robustness of the model against a wide range of image attacks.

IV. Proposed Zero Watermarking Framework

The proposed zero-watermarking system is depicted in Fig. 3. It consists of two major stages: registration and verification.

In the registration stage, the APBT and LBP feature sets are encrypted using a DNA algorithm before being fed to the VGG model for high-level semantic representation. After feature normalization and binarization, the watermark is encrypted separately using the same DNA encoding scheme. A hash derived from the host image is subsequently incorporated to bind the watermark to the host medical image. Finally, a zero-watermark key is generated and securely stored without altering the original image. Algorithm 2 presents the proposed zero-watermarking method.

The registration pipeline includes:

- Input medical image followed by preprocessing
- Stable ROI selection
- APBT-LBP feature extraction and Feature fusion
- DNA encryption
- CNN-based deep feature extraction
- Feature binarization using QIM
- Zero watermark generation
- Key storage
- Watermark verification

In the verification stage, the distorted test image is aligned with the original using ORB feature-based matching to handle

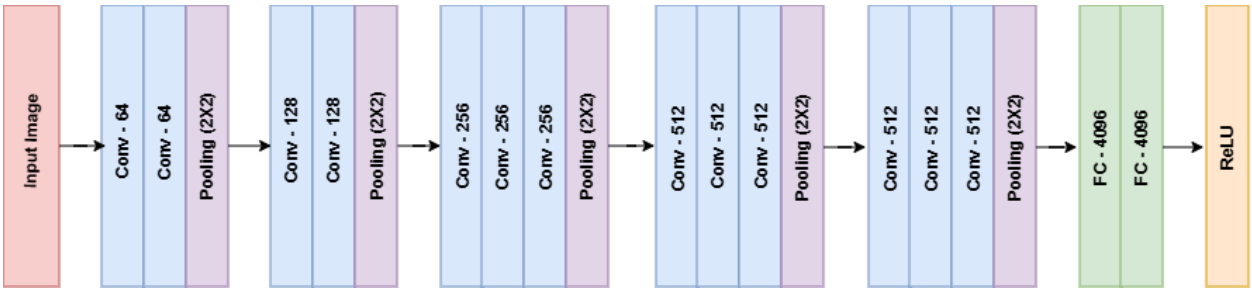

Fig. 2. VGG16 architecture used for feature map extraction.

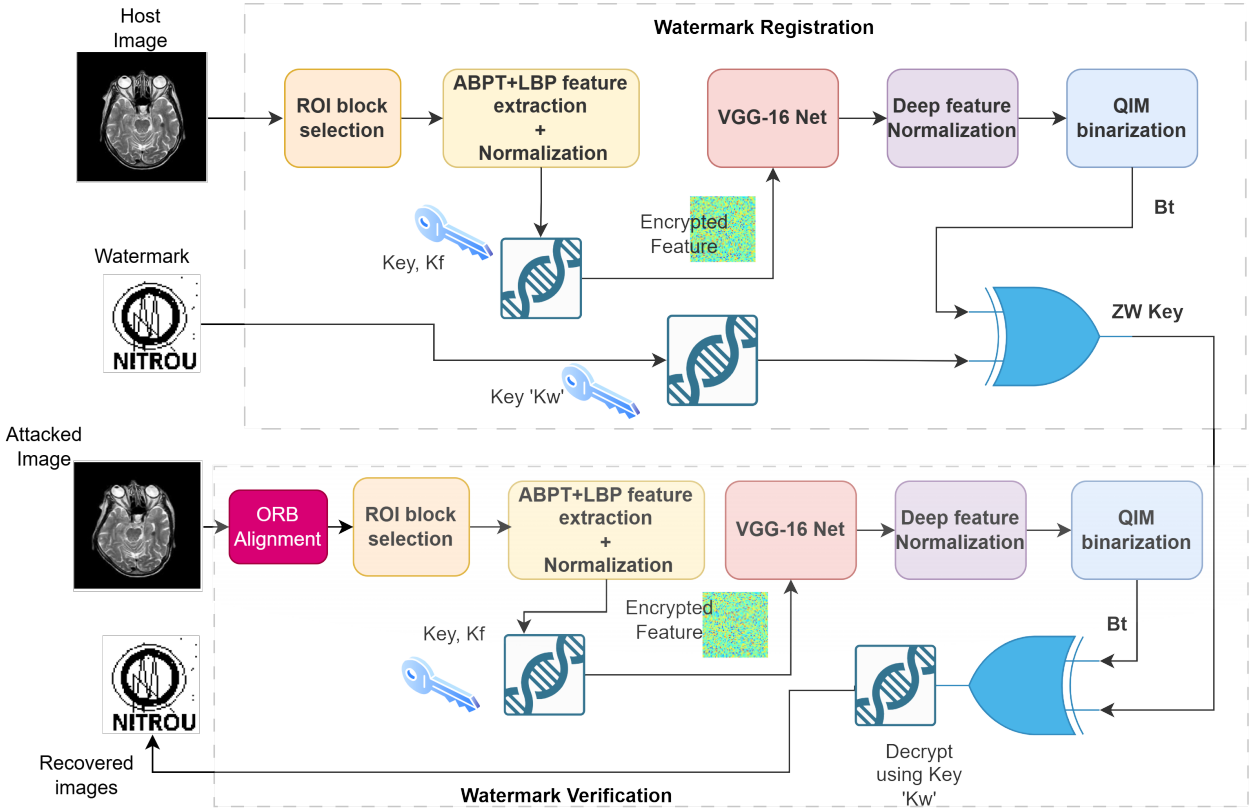

Fig. 3. Block diagram of the proposed scheme.

geometric imbalance. The same stable regions are then used to match feature consistency. The regions undergo the encoding, deep feature extraction, normalization, and binarization. The encrypted watermark is retrieved and decrypted using the stored zero-watermark key. Finally, the retrieved watermark is compared with the original watermark to evaluate robustness. Algorithm 3 presents the proposed watermark verification method.

The verification pipeline includes:

- Input attacked image
- Geometric alignment
- stable ROI extraction
- APBT+LBP Feature extraction
- Deep feature generation
- Binary feature generation using QIM
- Watermark recovery
- DNA decryption
- Recovered watermark

A. Stable ROI Block Selection

The input medical image is divided into non-overlapping blocks of size 8×8. For each block, the variance is computed:

$$Var(B) = \frac{1}{N} \sum_{i=0}^{N} (B_i - \mu)^2 \tag{13}$$

Blocks with variance greater than a predefined threshold are considered stable blocks. These blocks contain rich struc-

tural information and are less sensitive to image processing attacks.

B. APBT+LBP Feature Extraction

After the selection of stable ROI blocks based on variance, APBT, and LBP features of the ROI blocks are concatenated. APBT is effective in preserving signal energy and suppressing boundary artifacts. Only the low-frequency components of size (4×4) are retained in APBT because they are less sensitive to common signal processing operations and contribute to the stability of the feature representation against various attacks. LBP encodes the relationship between a pixel and its neighboring pixel to generate a compact representation of micro-patterns such as edges and textures. This enhances the robustness against illumination changes and noise variations. A combination of these features enables the algorithm to extract robust features. The features are then normalized and concatenated to form a unified feature vector. The aggregation of these features results in a comprehensive feature map, which is subsequently used for further processing in the zero-watermark generation. The details of the mathematical steps are developed below.

The low-frequency coefficients of APBT for each selected ROI block can be represented as:

$$F_{APBT} = \{c_1, c_2, \ldots, c_m\} \tag{14}$$

where, c_i denotes the normalized low-frequency APBT coefficients of the selected ROI blocks. The subsequent LBP texture features are computed from the same ROI regions and represented as

$$F_{LBP} = \{l_1, l_2, \ldots, l_n\} \tag{15}$$

where, l_i represents the normalized LBP histogram features.

The fusion of transform-domain and texture-domain features are concatenated to form a discriminative hybrid feature vector:

$$F = [F_{APBT}; F_{LBP}] \tag{16}$$

The fused feature vector is reshaped into a feature image and resized to 224×224 to be compatible with the pretrained VGG-16 network. Deep features are subsequently extracted from the fully connected layer ($fc7$) of VGG16 and expressed as:

$$F_d = \phi_{VGG16}(F) \tag{17}$$

The $\phi_{VGG16}(\cdot)$ denotes the nonlinear deep feature mapping function of the pretrained VGG16 model. Since the network parameters remain fixed during execution, the possibility of overfitting is reduced. The combination of ABPT-LBP and deep features improves feature generalization. In the subsequent operations, the features are normalized prior to QIM-based binarization and watermark generation.

C. Feature Normalization

The feature vector is normalized using z-score normalization:

$$F_n = \frac{F_d - \mu}{\sigma} \tag{18}$$

where, μ and σ represent the mean and standard deviation of the features.

D. Feature Binarization Using QIM

Quantization Index Modulation is used to convert deep features into binary form:

$$b_i = mod(\lfloor F_n/\Delta \rfloor, 2) \tag{19}$$

where, Δ is the quantization size.

E. Zero Watermark Generation

Let B = binary feature vector and ϑ = binary watermark. Then the zero watermark key is generated as

$$ZW = B \oplus \vartheta \tag{20}$$

The generated key and the associated encryption parameters are stored externally. In practical deployment, the key is securely maintained within hospital Picture Archiving and Communication System (PACS) servers, cloud storage systems, or blockchain-assisted authentication frameworks. In the proposed method, the extracted feature vector and watermark information are encrypted using DNA-XOR operations with random Keys K_f and K_w respectively. This makes the unauthorized reconstruction highly cumbersome. Moreover, the stored zero-watermark data contains only an encrypted bit string, not the image. This reduces the risk of sensitive medical data leakage.

F. Watermark Verification

During verification, the same feature extraction pipeline is applied to the test image. To compensate for geometric distortions, ORB-based feature matching and geometric transformation estimation are performed before feature extraction.

The recovered watermark is obtained as:

$$\vartheta_{enc} = B_t \oplus ZW_{key} \tag{21}$$

where, B_t is the binary feature vector extracted from the test image.

V. Experimental Setup

The experiment was carried out using MATLAB 2024a on a system equipped with an Intel i5 processor and 16GB of RAM. We have used different medical images of different sizes as host medical images (HMIs). These include COVID-19 chest X-ray sizes 3050×2539, 1698×1878, 1064×840 [29], MRI brain images of sizes 350×350, 210×240, 377×500, CT images of size 512×512 [30].

Algorithm 2 Proposed Zero Watermarking Framework

Require: Host medical image χ, watermark ϑ
Ensure: Zero-watermark key ZW_{key}
Resize χ to 256×256 and divide into 8×8 blocks
for each block $B_{i,j}$ **do**
  Compute variance $\sigma^2(B_{i,j})$
  if $\sigma^2(B_{i,j}) > T$ **then**
    Select block as Stable ROI
    Apply APBT transform
    Extract low-frequency coefficients
    Normalize coefficients
    Extract LBP texture features
    Normalize LBP vector
    Fuse features:

$$F = [F_{APBT}; F_{LBP}]$$

  end if
end for
Construct feature vector F_{map}
Convert feature vector to binary
Apply DNA encoding
Generate random DNA key K_f
Encrypt features using DNA-XOR
Convert encrypted features back to decimal
Reshape encrypted feature vector to image F_{img}
Resize F_{img} to 224×224 and replicate to 3 channels
Extract deep features using VGG16 layer $fc7$
Normalize deep features:

$$F_n = \frac{F - \mu}{\sigma}$$

Apply QIM binarization:

$$B = mod(\lfloor F_n/\Delta \rfloor, 2)$$

Convert watermark ϑ to binary vector
Apply DNA encoding to watermark
Generate random DNA key K_w
Encrypt watermark using DNA-XOR
Convert encrypted watermark back to binary
Generate zero watermark key:

$$ZW_{key} = B \oplus \vartheta_{enc}$$

Store $\{ZW_{key}, K_w, K_f, \mu, \sigma, \Delta\}$

Algorithm 3 Zero Watermark Verification

Require: Test image κ, stored data
Ensure: Recovered watermark ϑ_r
Apply attacks to κ
Align test image using ORB feature matching
Extract Stable ROI blocks using stored coordinates
for each selected block **do**
  Extract APBT + LBP fused features
end for
Construct feature vector F_t
Apply same DNA encryption using key K_f
Convert encrypted vector to feature image
Extract deep features using VGG16 ($fc7$)
Normalize using stored parameters
Apply QIM binarization to obtain B_t
Recover encrypted watermark:

$$\vartheta_{enc} = B_t \oplus ZW_{key}$$

Apply DNA decryption using key K_w
Convert binary to watermark image
Output recovered watermark ϑ_r

The COVID-19 chest X-ray images used in this study were originally acquired at high spatial resolution. Before embedding, the host images were resized to 224×224 pixels to ensure compatibility with the pretrained VGG-16 and to maintain computational efficiency. Resizing COVID-19 images introduces significant spatial downsampling. The proposed framework is designed for zero-watermark generation, which extracts stable and discriminative features rather than clinical diagnosis or lesion detection. Moreover, our scheme does not modify the original medical image, preserving its diagnostic integrity in practical deployment. The resizing operation primarily affects the feature extraction stage. It does not alter the actual medical image stored or used by doctors for diagnosis. Future work may investigate multi-scale feature extraction frameworks as a preprocessing stage to better preserve subtle pathological details.

A copyrighted image of size $64 \times 64$was employed. These HMIs and corresponding watermark images are illustrated in Fig. 4. To assess the visual quality of the watermarked images, Peak Signal-to-Noise Ratio (PSNR) and Structural Similarity Index Measure (SSIM) were used. The algorithm's robustness was measured using metrics such as Normalized Correlation Coefficient (NCC) and Bit Error Rate (BER). PSNR and SSIM reflect the perceptual similarity between the original and watermarked images, while NCC and BER assess the strength and reliability of the embedded watermark. Ideally, NCC should be close to 1, indicating high similarity, and BER should be 0, reflecting superior robustness. The mathematical definitions of these evaluation metrics are presented below.

$$\text{PSNR}(\chi, \kappa) = 10log_{10}\frac{\chi^2_{peak}}{\Psi}, \tag{22}$$

where, Ψ is the mean square error between the test and host medical image. Evaluating image degradation through SSIM involves perceiving changes in structural information and considering perceptual phenomena such as luminance and contrast masking. SSIM addresses the limitations of PSNR and is expressed in Eq. (23) by:

$$\text{SSIM}(\chi, \kappa) = \frac{(2\mu_\chi\mu_\kappa + a_1) + (2\sigma_{\chi\kappa} + a_2)}{(\mu^2_\chi + \mu^2_\kappa + a_1)(\sigma^2_\chi + \sigma^2_\kappa + a_2)}, \tag{23}$$

where, μ_χ, μ_κ and σ_χ, σ_κ are the mean and variance of image χ and κ respectively. $\sigma_{\chi\kappa}$ is the covariance between χ and κ. a_1 and a_2 are +ve constants. For an watermark size $\vartheta = N_1 \times N_2$, the NCC between the ϑ and ϑ_r can be represented by [31]:

$$\text{NCC}(\vartheta, \vartheta_r) = \frac{\sum_{n_1=0}^{N_1}\sum_{n_2=0}^{N_2} \vartheta(n_1,n_2) \times \vartheta_r(n_1,n_2)}{\sum_{n_1=0}^{N_1}\sum_{n_2=0}^{N_2} \vartheta(n_1,n_2)^2}. \quad (24)$$

Similarly, the BER defines the percentage of error between ϑ and ϑ^*, which can be expressed by:

$$\text{BER}(\vartheta, \vartheta_r) = \frac{1}{S} \times \sum_{n_1=0}^{N_1}\sum_{n_2=0}^{N_2} [\vartheta(n_1,n_2) - \vartheta_r(n_1,n_2)] \quad (25)$$

VI. Results and Discussion

This section presents the robustness evaluation of the proposed scheme along with a comparative analysis against existing methods. Finally, the Wilcoxon signed-rank statistical test and the Friedman ranking test are conducted to evaluate the effectiveness of our method.

A. Robustness Evaluation

The robustness of the proposed framework was tested against 42 different attacks, including: Noise Attacks, Gaussian noise, Salt and pepper noise, Speckle noise, Filtering Attacks, Gaussian filtering, Median filtering, Average filtering, Compression Attacks, JPEG compression at different quality levels, Geometric Attacks: Rotation, Scaling, Translation, Cropping, Intensity Attacks, Histogram equalization, Gamma correction, Contrast stretching, Advanced Attacks: Motion blur, Poisson noise, Elastic distortion, Patch removal, Cut-and-paste manipulation, The watermark recovery performance remains high even under severe distortions.

Fig. 5 shows the various signal processing attacks applied to the test image and the corresponding recovered watermarks. The numerical values of NCC and BER are also listed under the recovered watermarks. The applied sets of combined attacks are 1) No attack 2) Average filtering (3x3), 3) Contrast stretch, 4) Gamma correction by (0.5 and 1.5), 5) Gaussian (0.01), 6) Histogram equalization, 7) Gaussian blur (σ=1), 8) Histogram compression, 9) Sharpen, 10) Salt and Pepper (0.02), and 11) JPEG (Q=50). A very high robustness is observed in all attack scenarios. The NCC values consistently above 0.99, indicating near-perfect watermark recovery. Correspondingly, BER remains very low, ranging from 0.05-0.3%. These quantitative results confirm that the proposed scheme maintains strong resilience against diverse signal distortions, including Noise, gamma corrections, histogram manipulations, Gaussian blur, compression, and sharpening operations. The retrieved watermarks are graphically illustrated in Fig. 5 under different attacks.

Fig. 6 shows the various geometrical, combined attacks applied to the test image and the recovered watermarks. The numerical values of NCC and BER are also listed. The applied sets of combined attacks are 1) Blur+noise, 2) Rotate by 5°+blur, 3) Rotate by 5°+noise, 4) Scale+JPEG, 5) Random bending, 6) Rotate by 5°, 7) Rotate by 10°, 8) Motion blur, 9) Cut-paste, 10) Elastic distortion, 11) Patch removal, and 12) scale by 0.8. A very high robustness is observed in all attack scenarios. The NCC values consistently above 0.99, indicating near-perfect watermark recovery. Correspondingly, BER remains very low, ranging from 0.05-0.3%. These quantitative results confirm that the proposed scheme maintains strong resilience against diverse geometric distortions, including arbitrary-angle rotation, elastic distortion, and scaling operations. The retrieved watermarks are graphically illustrated in Fig. 6 under different attacks.

Robustness to geometric attacks is closely related to ROI selection and ORB-based geometric alignment. The ROI selection improves feature consistency, and ORB feature matching compensates for rotation, scaling, and geometrical distortion prior to feature extraction. The higher NCC values in Fig. 6 demonstrate that the ORB alignment stage effectively preserves feature correspondence under geometric and combined attacks.

Fig. 7 shows the NCC and SSIM performance of the proposed method against 42 attacks. It is observed that NCC and SSIM are 1 under no attack case. The NCC is very close to 1 for all attacks irrespective of common, geometrical, or combined attacks. The average SSIM is above 0.7, considering all attacks. It indicates that the algorithm shows a good trade-off between imperceptibility and robustness. The robustness performance can be shown in the BER plot as shown in Fig. 8. The BER below 0.3% indicates perfect watermark recovery.

Both Gaussian Noise, Salt & Pepper Noise have robustness between (0.98–1.0), Hoever, SSIM drops significantly (0.3–0.8). This indicates that both noise deteriorates visual quality but do not impact the quality of the watermark. NCC remains 1.0, SSIM moderately high (0.8–0.95) for Gaussian blur, median, and average filter attacks, indicating filtering preserves structural content. High robustness and visual quality indicate effective use of low-frequency and structural features. NCC and SSIM are near 1.0 across all quality factors (Q) in JPEG attacks, showing robustness against real-world compression scenarios. NCC is approximately between (0.95 to 1.0), and SSIM is slightly reduced (0.8–0.95) in most of the geometrical attacks. This indicates the geometric distortion is successfully compensated by ORB-based alignment. A Minor SSIM drop may be due to interpolation and spatial misalignment. NCC is high (0.95–1.0), but SSIM drops abruptly (i.e., 0.3–0.6) on intensity-based attacks such as histogram equalization, gamma correction, and contrast stretching. This is due to the fact that these attacks alter the pixel intensity distribution. For combined and random bending cases, NCC remains significantly high (0.95+), whereas SSIM varies widely (0.4–0.9). This indicates that watermark detection is reliable even under complex distortions.

The PSNR plot in Fig. 9 illustrates the impact of various attacks on the perceptual quality of medical images, along with deviation (error bars). It provides both average performance and stability details. The PSNR for the no-attack case is between 24 and 25 dB. This confirms that no artificial distortion is introduced by the proposed algorithm. These values show inherent dataset variability instead of embedding loss. Under Gaussian Noise and Salt & Pepper Noise, PSNR drops to a range of 21–24 dB. This indicates moderate degradation, but it is still acceptable.

PSNR remains relatively higher (25–30 dB) under Gaussian blur, median filter, and average filter. This shows that the method preserves global structures. PSNR shows up to

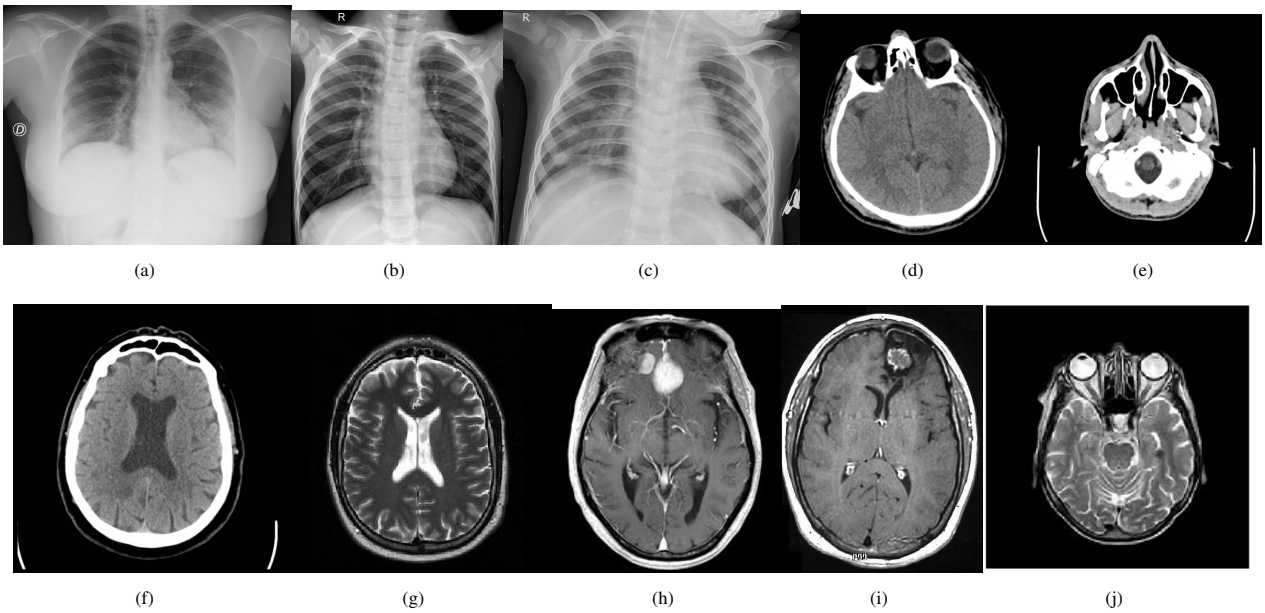

Fig. 4. Sample images used for experiment: (a), (b), (c) X-ray; (d), (e), (f) CT, and (g), (h), (i), (j) MRI images.

35–38 dB at higher quality (Q70) and drops gradually with compression strength. This indicates that compression removes redundancy but retains structural information. Therefore, the proposed algorithm leverages structure-based features. Moderate deviation in PSNR (26-34 dB) is observed in the rotation and scaling operations. This is due to ORB-based alignment. A significant PSNR drop (13–20 dB) occurs in histogram equalization and gamma correction as these attacks alter the global intensity distribution. This affects PSNR but not necessarily the watermark quality.

PSNR fluctuates widely (20–33 dB) in sharpening, motion blur, Poisson noise, and combined rotation with noise. Histogram compression/intensity scaling has the lowest PSNR (13–15 dB).

Large bar plots were observed in gamma correction, cropping, and combined attacks. This indicates performance relies on image content (edges vs smooth regions). This may be acceptable for medical images with varying textures.

The PSNR analysis demonstrates that the proposed framework preserves high perceptual quality under most signal processing and geometric attacks, while significant degradation is observed only under intensity-based transformations such as histogram equalization and gamma correction. This behavior confirms that the variations in PSNR are primarily due to attack severity rather than the watermarking process, making PSNR less indicative of robustness in zero-watermarking systems.

The performance of the proposed zero-watermarking algorithm is further analyzed using heat map visualization in Fig. 10, which provides an intuitive representation of spatial feature stability and robustness. The generated heat maps highlight the distribution of discriminative features extracted from the stable ROI using the APBT and deep features (VGG16).

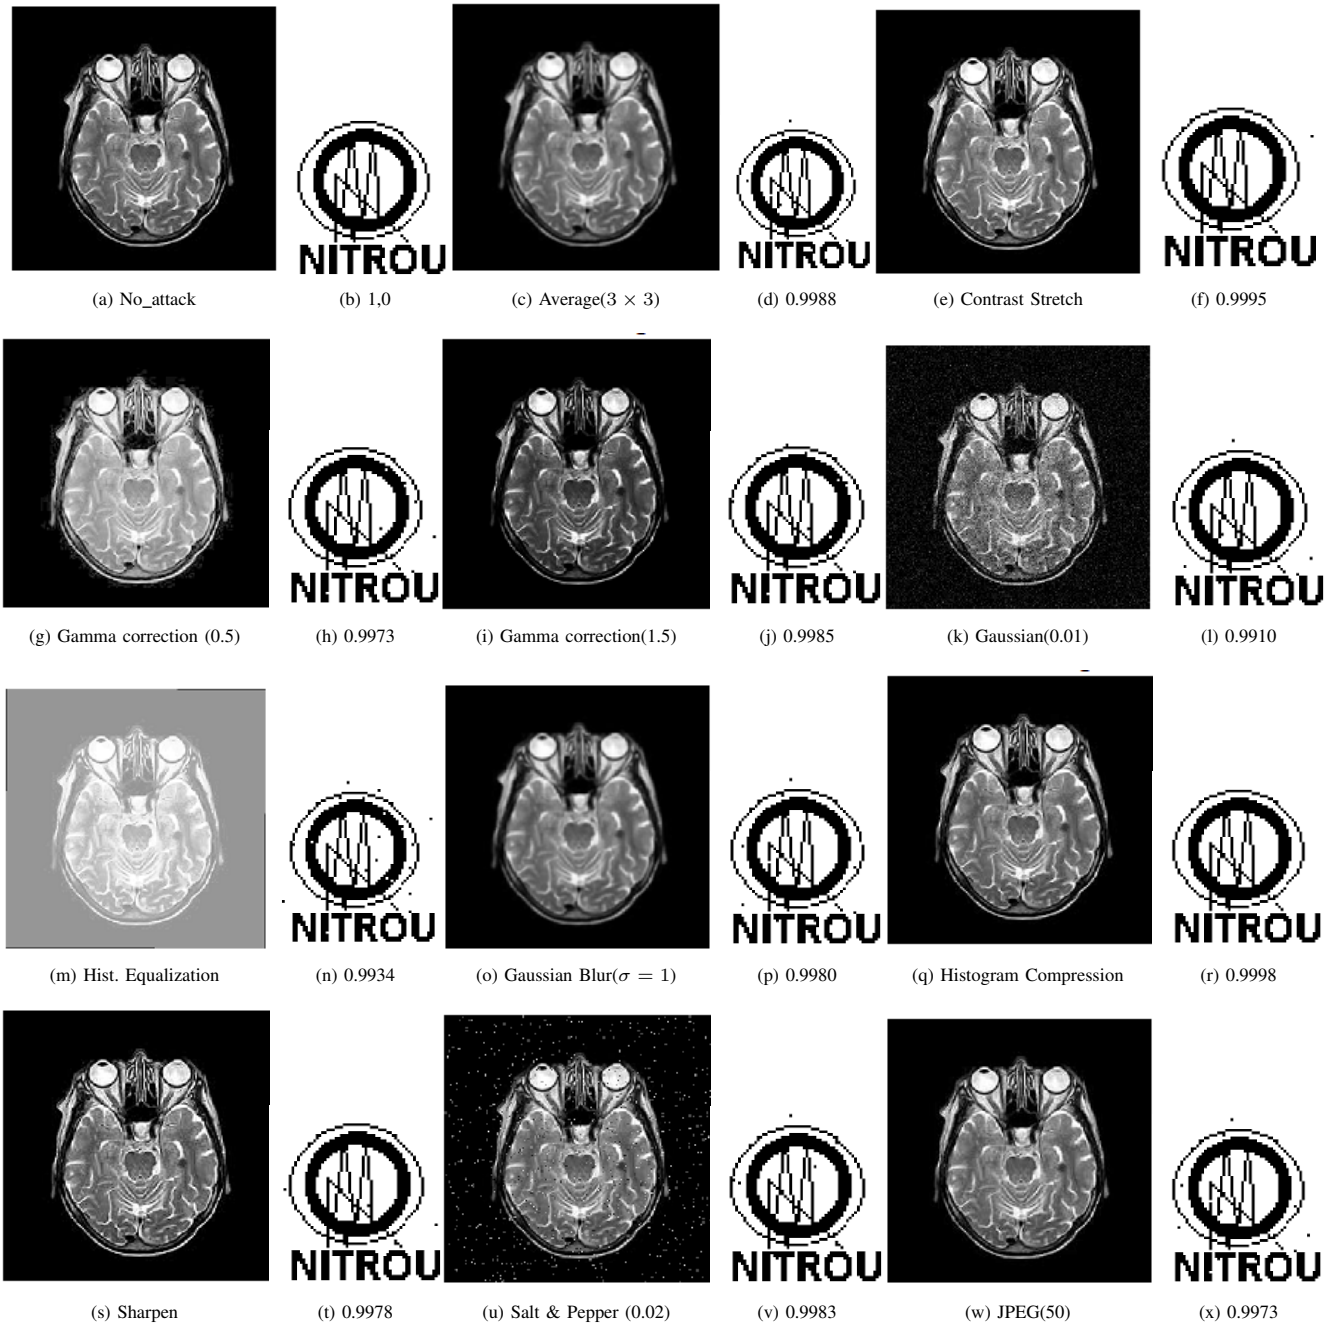
From the heat map analysis, it is observed that:

- High-intensity regions correspond to structurally significant areas of the medical image, indicating that the algorithm effectively captures salient and invariant features.
- The feature concentration remains consistent across various attacks (e.g., noise, filtering, compression), demonstrating the strong robustness of the extracted watermark features.
- Minimal variation in heat distribution between the original and attacked images confirms the stability of the feature representation, which directly contributes to higher NCC values and lower BER.
- The use of stable ROI selection and ORB-based alignment ensures that the important regions retain their prominence in the heat maps even under geometric distortions.
- Compared to conventional methods, the proposed framework exhibits better localization of important features, reducing the influence of non-informative regions and improving watermark reliability.

Overall, the heat map visualization validates that the proposed method maintains spatial consistency, robustness, and discriminative feature preservation, which are critical for reliable zero-watermark generation and extraction.

B. Comparative Analysis

Table III shows the NCC comparison between the proposed method and other methods for conventional, geometrical, and combined attacks. It is observed that the proposed scheme outperforms the methods in [32] and [33] by a wide margin. Method [17] and [34] closely follows our method. The combined attack means that multiple image processing attacks are applied sequentially to the same image before extracting



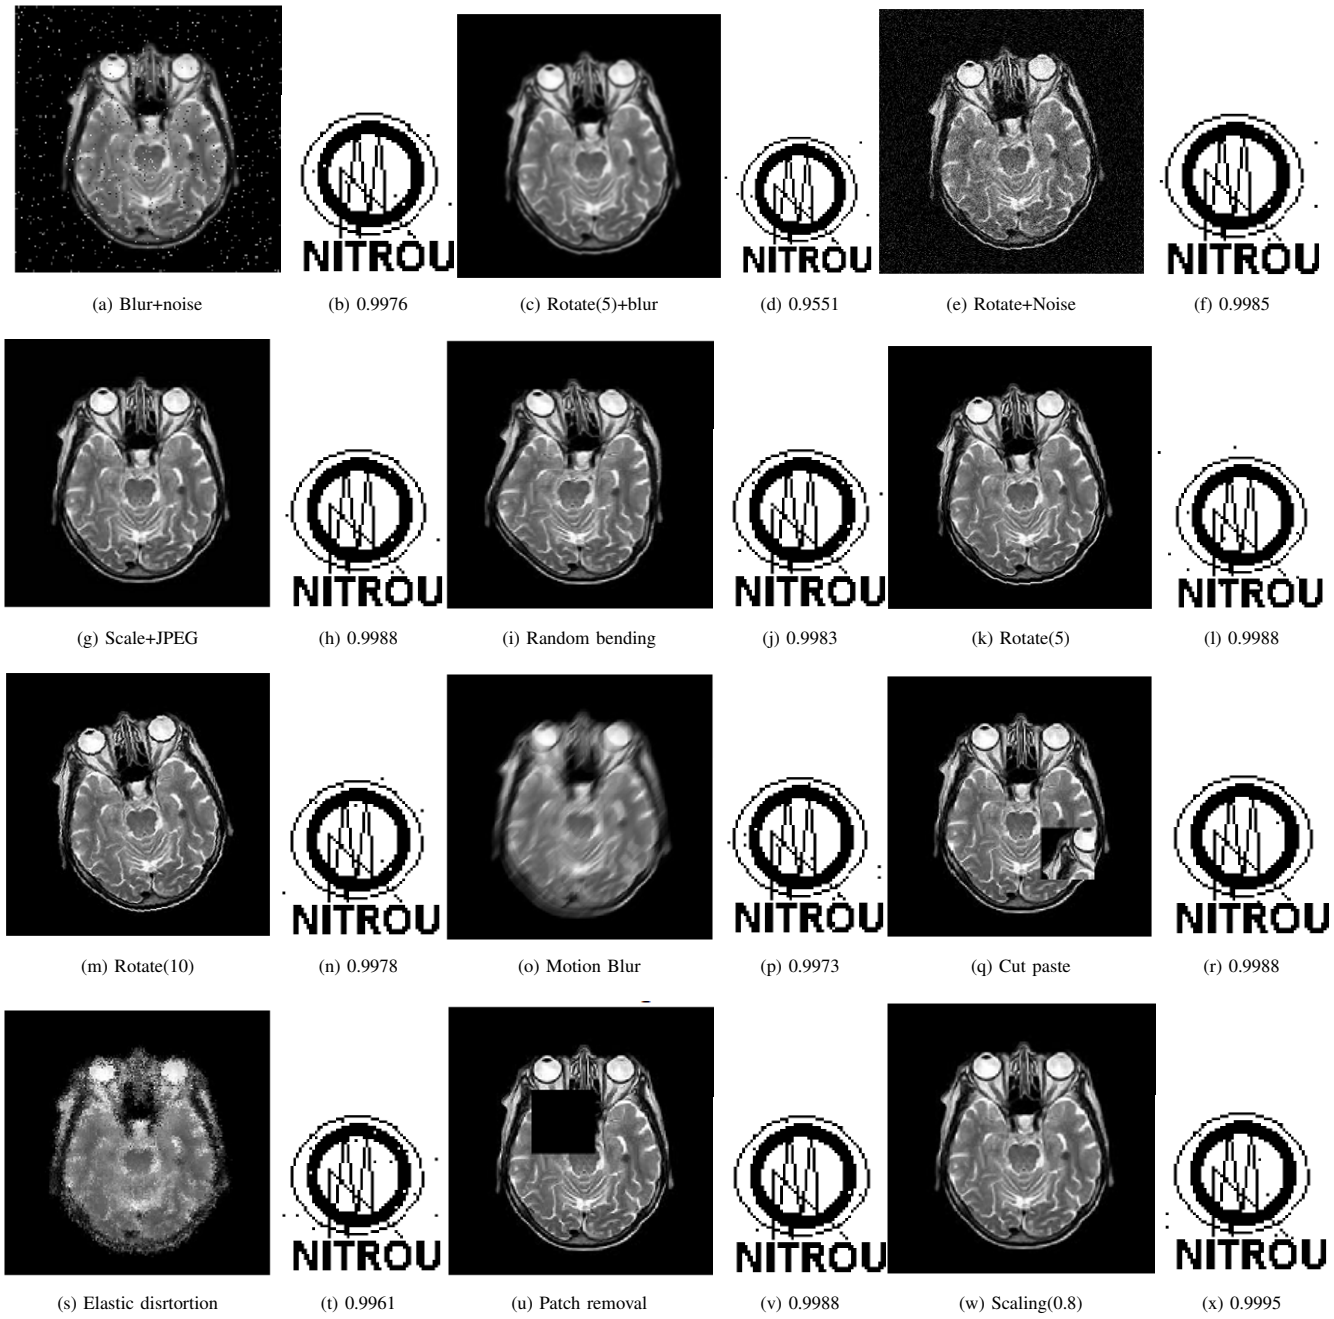


Fig. 5. Signal processing attacks on Brain Image. The SSIM and BER values of the Attacked image and extracted watermarks are calculated. (a) No attack, SSIM=1 (b) BER=0 , (c) Average filter(3×3), SSIM=0.9238 (d) BER=0.0017, (e) Contrast Stretch ,SSIM=0.9987 (f) BER=0.0005, (g) Gamma Correction (0.5), SSIM=0.8837 (h) BER=0.0007, (i) Gamma correction (1.5), SSIM=0.9429 (j) BER=0.0007 (k) Gaussian (0.01), SSIM=0.3045 (l) BER=0.0046, (m) Hist. equalization, SSIM=0.2505 (n) BER=0.0076, (o) Gaussian Blur ($\sigma = 1$), SSIM=0.9182, (p) BER=0.0029, (q) Hist. compression ,SSIM=0.8558 (r) BER=0.0005, (s) Sharpen, SSIM=0.9783, (t) BER=0.0010, (u) Salt & Pepper (0.02), SSIM=0.6746(v) BER=0.0.0020, (w) JPEG (Q=50), SSIM=0.9681, (x) BER=0.0024.

the watermark. This tests the worst-case robustness of the algorithm. Instead of applying one attack at a time, several attacks such as GN0.01, JPEG10, ROT5, and MedF are in a pipeline.

Similarly, a comparison on the imperceptibility test is depicted in Table IV for 10 types of images. It is observed that the PSNR of the proposed method outperforms by a large margin, $\geq$ 10 dB consistently than the other methods.

Fig. 11 shows a spider plot comparison of NCC values under fifteen types of image processing attacks. It is observed that the proposed method maintains NCC values close to unity across all distortions, indicating superior robustness compared with other methods. The scheme in [17] employs a complex feature-extraction process, comprising VGG19, LBP,

DCT, and DWT. Whereas ZWNet [34] combines stationary wavelet transform (SWT), DarkNet53 deep feature extraction, and Fibonacci Q-matrix encryption. In contrast, our method uses only VGG16+LBP for feature extraction, reducing the complexity of implementation.

To statistically validate the performance improvement, the Wilcoxon signed-rank test was conducted between the proposed method and existing methods using NCC values obtained under fifteen attacks. The obtained p-values are less than 0.05, confirming that the proposed method achieves statistically significant improvements. A comparison of p-values is shown in Table V

To further validate the performance difference among multiple watermarking algorithms, the Friedman test was con-

ducted using NCC values obtained under fifteen attacks. The p-value ($\leq$ 0.05) in Table VI indicates that the proposed framework significantly outperforms the compared methods.

Higher NCC under various attacks does not necessarily indicate overfitting or limited variability. The robustness is primarily attributed to 1) ROI selections, 2) APBT low coefficient calculations, 3) LBP feature extraction, and 4) ORB-based geometric alignment. The experiments are conducted across multiple image modalities, introducing variety into the experimental process under 42 different kinds of attacks. In addition, statistical evaluation using the Wilcoxon signed-rank

Method in [33]	4.38
ZWNet [34]	2.01

test and the Friedman ranking test confirms that the observed performance improvement is not a consequence of overfitting.

C. Ablation Studies

Table VII illustrates the contributions of individual components of the proposed method towards the average NCC and average BER parameter calculation. The average NCC and BER are evaluated across 10 different image types using the same binary watermark. While the APBT contributes an average NCC of 0.9124, adding LBP yields a gain of 0.0363. The deep-level features of VGG16 only contribute an average NCC of 0.9315. Combining all the features in a single framework contributes a significant average NCC and average BER of approximately 1 and 0, respectively.

D. Computational Complexity and Execution Time

The computational overhead occurs primarily from the pretrained VGG-16 feature extraction, followed by the DNA

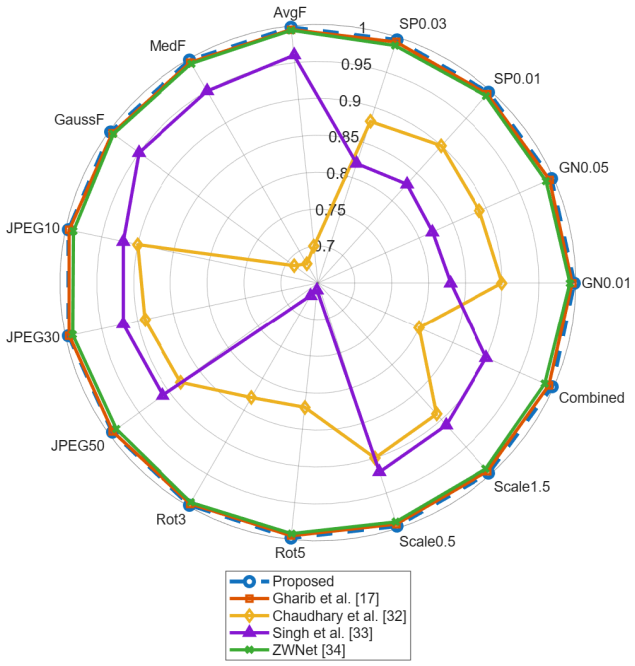

Fig. 11. Spider plot comparison of NCC values under 15 image processing attacks.

TABLE VII. ABLATION STUDY

Features Used	Avg. NCC	Avg. BER
APBT only	0.9124	0.0841
APBT + LBP	0.9487	0.0416
VGG16 only	0.9315	0.0563
APBT + LBP + VGG16	0.9982	0.0006

TABLE VIII. COMPUTATIONAL COMPLEXITY AND MEMORY USAGE COMPARISON

Method	Feature Extraction	Avg Time (s)	Memory (MB)	Complexity
Proposed	APBT+LBP+VGG16	1.24	118	Moderate
[17]	DWT+DCT+VGG19	3.25	214	High
[32]	DWT+HMD+SVD	2.51	176	High

encryption process. However, the proposed scheme is computationally more efficient than most of the existing deep-learning-based watermarking approaches because 1) only stable ROI blocks are selected rather than the whole image blocks, 2) dimensionality reductions are achieved due to low-frequency APBT coefficients, and 3) a pretrained VGG-16 is employed instead of full training. Finally, DNA encryption is applied to compact binary feature vectors rather than full-resolution images. This reduces encryption overhead.

Table VIII shows the average execution time and memory usage of the proposed method in comparison with the other methods. It is observed that the average execution time is nearly 33% and 50% less compared to methods in [17] and [32], respectively, while memory usage is proportionally less. The memory usage is calculated using the MATLAB profiling function by measuring the difference between before and after execution. The VGG16 is not the most lightweight architecture. VGG16 is chosen in our work for its strong feature representation capabilities, architectural simplicity, and widespread adoption. It is used only as a pre-trained feature extractor without end-to-end training. The fused ROI features are processed rather than the entire image, significantly reducing computation. The term 'lightweight' refers to a reduced feature-processing pipeline, achieved through compact fusion of APBT and LBP features rather than using ultra-lightweight architectures such as MobileNet, ShuffleNet, or EfficientNet. Compared with VGG19, ResNet, and Transformer architectures, VGG16 provides a favorable trade-off between memory usage and feature discrimination.

VII. CONCLUSIONS

This paper presented a robust medical image zero-watermarking framework that integrates transform-domain analysis with deep feature extraction. The proposed method employs the All Phase Biorthogonal Transform to capture stable frequency-domain characteristics and utilizes deep features obtained from VGG16 to enhance feature discrimination. Furthermore, ORB-based alignment improves robustness against geometric distortions. Experimental results show that the proposed framework achieves high robustness under various signal processing and geometric attacks. Additionally, the zero-watermarking strategy preserves the diagnostic quality of medical images by avoiding direct modification of the host medical image. Comparative analysis with existing methods and statistical validation using the Wilcoxon signed-rank statistical test and the Friedman ranking test confirm the effectiveness of the proposed approach. Future work will focus on further reducing computational complexity through lightweight deep learning architectures for higher-dimensional medical images.

A Privacy-Aware Federated Hybrid Model for Multimodal Mental Health Analysis

Yusra, Riaz UlAmin
Smart Systems Research Lab, University of Okara, Pakistan

***Abstract*—As mental health disorders such as stress, anxiety, depression, and post-traumatic stress disorder (PTSD) affect a substantial part of the world population, current diagnostic methodologies are still centralized, subjective, and sensitive to privacy concerns. To mitigate these limitations, this study presents a new framework for multimodal mental health classification within a privacy-preserving federated learning framework learning using electroencephalography (EEG), electrocardiography (ECG) and galvanic skin response (GSR) signals. Furthermore, we propose a hybrid deep learning architecture, which combines CNN-LSTM-Transformer blocks to effectively learn spatial, temporal, and long-range dependencies within physiological signals.After preprocessing the cleaned data through artifact removal, band-pass filtering, normalization and multimodal feature fusion signal quality is improved. The proposed model is trained in a federated setting with multiple clients for decentralized training without sharing raw data allowing it to preserve privacy and communication efficiency supporting non-IID data extensions. We evaluate on two datasets, SAM40 (stress detection) and DAPS (anxiety, depression, and PTSD classification). The proposed framework achieved 97% accuracy on SAM40 and more than 96% accuracy on DAPS. Comparative assessments with recent federated and centralized methods validate its strength in multimodal fusion and robust feature exploitation. These results demonstrate the possibility of a general framework for designing privacy-preserving and efficient mental health monitoring systems that can support both Clinical and Wearable-device applications.**

***Keywords*—Mental health detection; hybrid CNN-LSTM-transformer; federated learning; multimodal physiological signals**

I. Introduction

Mental health illnesses, like depression, stress, and anxiety, affect one billion people each year and create significant social, economic, and healthcare burdens. Depression, stress, and anxiety disorders are some of the top causes of disability, and loss of healthy and productive years of life [1]. Depression is a major cause of suicide and loss of work productivity and costs the world economy 1 trillion dollars a year [2].

Mental disorders must be identified and assessed to provide intervention. Current methods, such as interviews interviews and self-reported questionnaires are subjective, time-consuming, and impractical. Measuring physiological states can be used to indicate mental health because they are objective. Physiological signals continuously monitored and measured. EEG records brain activity, ECG measures heart activity due to stress or anxiety, and GSR measures the arousal from the autonomic nervous system [3]. While machine learning techniques can efficiently analyze given problems, centralized methods require collecting personal and sensitive data, raising serious privacy concerns. Another important point is that most studies focus on analyzing a single type of signal, and ignores other potentially useful signals. Real-world data that can be collected from hospitals, clinics, and wearable devices are also non-independent and identically distributed (or non-IID), which makes it difficult for models to generalize effectively [4].

To mitigate those problems, advanced preprocessing and feature extraction is done before federated training. EEG signals are filtered to a desired band, artifacts are removed, and other signals are divided into segments. For processed ECG signals, we determine R-peaks and extract important features such as heart rate and heart rate variability (HRV) from our filtered signals. GSR signals are smoothed and normalized, and we identify arousal peaks. These methods minimize added noise in data, make the characteristics and inputs we are analyzing uniform, and improve feature extraction through cross-feature analysis in time and space across different signals. [5].

Federated Learning (FL) allows for training models in a distributed manner across devices in a privacy-preserving manner, which allows which allows for better compliance with privacy regulations. Using multiple modalities in a federated system improves detection performance by enabling the capture of spatial, temporal, and cross-modal dependencies. We present a novel CNN-LSTM-Transformer architecture where the convolutional layers capture the spatial patterns, the LSTM layers capture the temporal patterns, and the Transformer layers capture long-range and cross-modal dependencies. The framework has capacity to further integrate privacy-preserving techniques such as Differential Privacy and Secure Aggregation to help keep distributed training secure and ensure that model updates are safely combined in the federated learning setting [6].

As illustrated in Fig. 1, the AI system supports anxiety disorder management using multiple modalities.

The main contributions of this work are:

- We explore a multimodal federated learning framework integrating EEG, ECG, and GSR for enhanced and robust mental health detection.
- We developed a CNN-LSTM-Transformer model to illustrate hierarchical feature extraction from preprocessed physiological signals.
- We remove noise and artifacts from EEG, ECG, and GSR signals to improve signal integrity and feature reliability.
- We comprehensively evaluate the proposed approach in terms of accuracy, F1-score, convergence rate, communication efficiency, and privacy preservation.

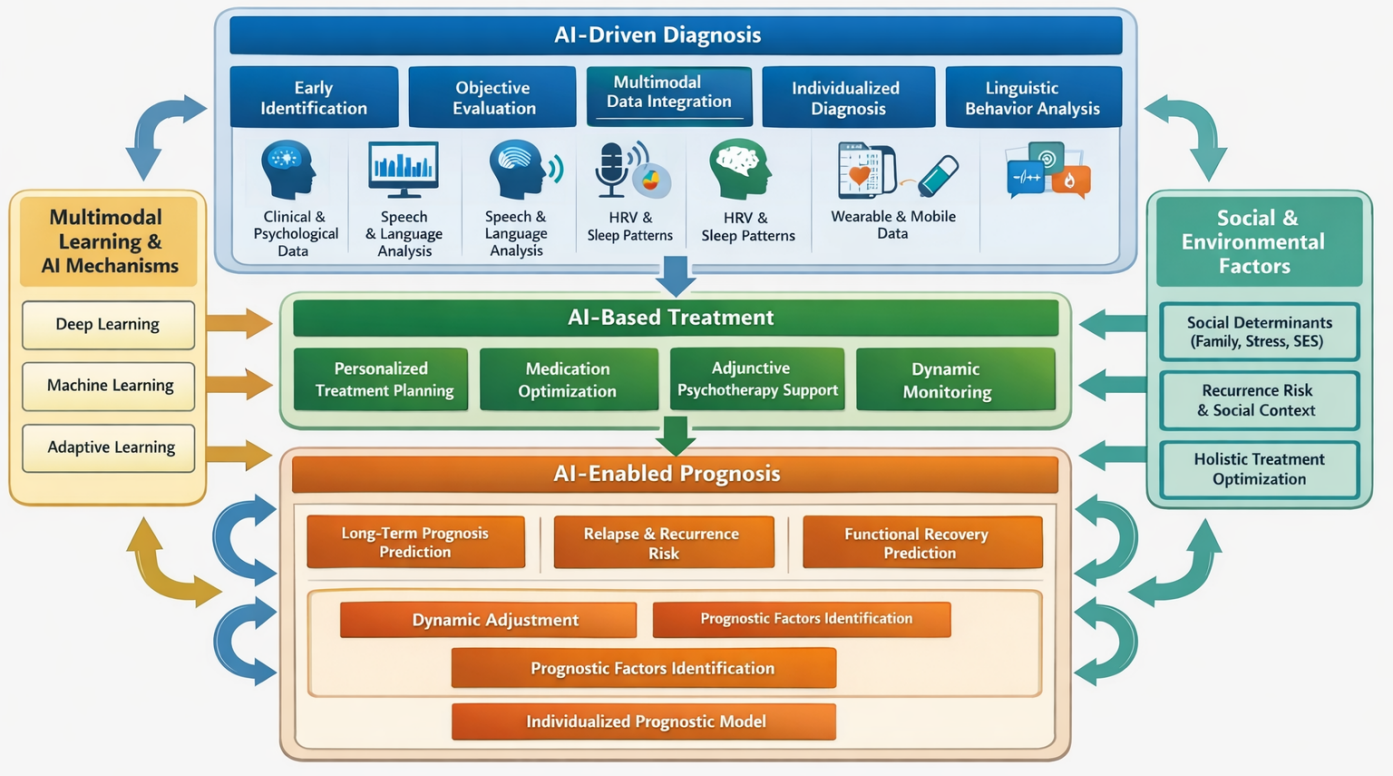

Fig. 1. AI-Driven conceptual framework for anxiety disorder integrating diagnosis, treatment, and prognosis with multimodal data, machine learning, and social-environmental factors.

II. Literature Review

Recently, federated learning (FL) has emerged to enhance privacy-preserving mental health and emotion recognition systems by enabling decentralized training without sharing raw physiological data. Although there have been these advances, the majority of the current studies still have drawbacks in terms of multimodal fusion, robustness against non-IID data distribution and scalability for real clinical applications. In their proposed privacy-preserving federated framework for depression relapse prediction from EEG signals and clinical symptom scores, Yasin et al. [7] introduced a method that leverages machine learning to predict depression relapse by analyzing electroencephalogram (EEG) signals and symptom scores. The model uses explainable AI methods like Layer-wise Relevance Propagation (LRP) and Shapley values, and it has an accuracy of 92%. However, the method does not consider multimodal physiological integration, and is only applied to single-modality EEG data.

Dubey et al. [8] proposed a multimodal federated learning system with CNN and LSTM networks under various privacy constraints. The method remains sensitive to data heterogeneity and is not very adaptive to various client distributions as it achieves only around 92% accuracy. Simic et al. [9] presented a federated multimodal emotion recognition system based on CNN models for audio and visual feature extraction. The model uses decision-level fusion, which restricts the ability of deep cross-modal feature interaction resulting in limited affective state modeling performance, although FedAvg can enhance the generalization of the model.

Gupta et al. [10] proposed an EEG-audio-based federated multimodal system for the early detection of the Major Depressive Disorder using Bi-LSTM based fusion. Although the model performed well with 91.9% accuracy, the extent to which the model has been validated on real-world heterogeneous datasets is limited, which results in a lack of clinical generalization.

Almadhor et al. [11] studied stress detection in the context of wearable electrodermal activity (EDA) signals in a federated learning framework. The system provides 86.82% accuracy but under device variations in the devices and limited diversity in the datasets, the accuracy of the system drops.

Kumar et al. [12] proposed a federated transfer learning approach (FTL-Emo) for EEG-based emotion recognition. The model obtains an F1-score of 92-94%, but does not generalize well across datasets due to distribution shifts between the training and testing domain. Federated reinforcement learning combined with machine unlearning was used in healthcare monitoring and anomaly detection by Shaik et al. [13]. The framework offers flexibility and privacy, but it has high computational complexity, which restricts its use in real-time applications.

Farooq et al. [14] proposed a federated learning approach involving local classifiers with a meta-classifier for the detection of autism spectrum disorders. When applied to children, the method achieved 98% accuracy, but decreased to 81% for adults, thereby showing poor generalisation across age groups.

More recently, Pradeep et al. [15] investigated cross-modal

TABLE I. COMPREHENSIVE LITERATURE REVIEW OF FEDERATED LEARNING AND HYBRID AI APPROACHES IN MENTAL HEALTH AND EMOTION RECOGNITION

brain–heart interaction modeling using EEG and ECG signals. The study was found to be effective for physiological feature mapping across modalities, but lacks of federated learning or privacy-preserving distributed training, making it less applicable in real-world decentralized healthcare settings.

The literature summarized in Table I shows that recent studies have explored the use of federated learning techniques for mental health and emotion recognition. Although current approaches help privacy of data, face challenges such as limited generalization, weak multimodal fusion, data sensitivity, and lack of clinical validation in real-world applications.

The proposed method, however, combines the three signals — EEG, ECG and GSR through a hybrid CNN–LSTM–Transformer network with improved feature fusion and noise reduction. This enables the model to capture spatial, temporal and long-range dependencies and maintain robustness in different federated environments, that increases the performance and scalability of real-world mental health monitoring systems.

III. RESEARCH METHODOLOGY

This research develops a novel, multi-modal, federated learning based, mental health detection framework that prioritizes and balances privacy and scalability. The system fuses EEG, ECG, and GSR data and utilizes Convolutional Neural Networks, Long Short-Term Memory networks and Transformers, allowing to capture the spatio-temporal and attention driven features. This staircase approach facilitates the overall characterization and modeling of stress, anxiety, and depression related multi-dimensional physiological responses.

A. Data Collection and Understanding

In this research, the DAPS and SAM40 datasets, which have been incorporated into clinical and wearable health monitoring systems, involve several datasets sampling a wide range of mental states and multiple-spectral modalities.

The SAM40 dataset contains EEG wave recordings of 40 participants who were volunteers in a convenience sample of a greater research project (14 females, 26 males; average age 21.5 years) who were treated to a series of cognitive task activations designed to produce and control stress states. Tasks included were Stroop activities, mental arithmetic, mirror image processing and formal relaxation. Active data collection utilized a 32-channel Emotiv Epoc Flex EEG headset which adhered to the international 10–20 system spatial configuration, where Fp1, Fp2, F3, F4, C3, C4, O1, O2 and a few other electrodes were recorded. Signals were collected and within the resultant 2.75 minutes of quiet recording, were arranged in 25 second, non-overlapping intervals. Each resultant interval epoch data was represented as matrix [16], [17].

$$X^{(t)} = \begin{bmatrix} x_1^{(t)} \\ x_2^{(t)} \\ \vdots \\ x_C^{(t)} \end{bmatrix} \in \mathbb{R}^{C \times T}, \quad C = 32,\ T = 25 \times 128 \qquad (1)$$

where, $x_c^{(t)}$ corresponds to the time-series signal from channel c for epoch t, with C as the total number of EEG channels and T as the number of samples per epoch. Our collection has both continuous raw and artifact-corrected EEG signals. This feature makes SAM40 a flexible dataset as to the study of brain activities associated with varying stress levels and the use of machine learning tools.

DAPS dataset (custom or proprietary) comprises EEG and GSR signals of GSR and EEG collected from participants having depression, anxiety, or PTSD, as well as healthy controls. EEG is collected with 16–128 channels deploying a high-density clinical or wearable EEG system, GSR is obtained from finger/palm electrodes, and ECG is captured optionally via chest leads or wearable sensors. Data collection occurs during resting-state (eyes open/closed) and emotion or task

induced conditions where clinical scales (e.g. BDI, HAM-A) and interactivity and valence ratings are used to derive labels. Each of the modalities is defined as follows:

$$\mathbf{X}_{EEG}^{(t)} \in \mathbb{R}^{C_{EEG} \times T}, \quad \mathbf{X}_{GSR}^{(t)} \in \mathbb{R}^{C_{GSR} \times T}, \quad \mathbf{X}_{ECG}^{(t)} \in \mathbb{R}^{C_{ECG} \times T} \tag{2}$$

Data are distributed in a heterogeneous, non-IID manner across clients:

$$D = \bigcup_{k=1}^{K} D_k, \quad D_i \cap D_j = \emptyset \text{ for } i \neq j \tag{3}$$

This equation shows that the overall dataset D is the combination of client datasets D_k and that each client's data is disjoint, meaning no clients get to see the same samples. This arrangement mirrors practical federated learning situations with non-IID data distributions.

This organization of datasets assists in providing a strong basis for multimodal mental health detection and allows for the development of privacy-preserving and scalable models.

B. Signal Preprocessing and Feature Engineering

In order to thoroughly assess various mental health conditions based on several physiological signals, a careful range of steps involving a preprocessing pipeline predicated on a theory and the crafting of various features must be devised and executed. Although EEG, ECG, and GSR signals contain substantial amounts of noise and artifacts, they may contain a lot of useful information, especially with regard to inter-subject variance. When performed properly, feature extraction and the noise and artifacts of a signal, termed preprocessing, should be done to obtain a signal that accurately represents the underlying physiological and cognitive states, and this will enable precise modeling.

EEG records electrical activity as generated by postsynaptic potentials due to the synchronous firing of neurons. There are different cognitive and emotional states reflected in varying ranges of delta (0.5–4 Hz), theta (4–8 Hz), alpha (8–13 Hz), beta (13–30 Hz), and gamma (30–50 Hz) waves. However, it's worth noting that EEG is particularly vulnerable to artifacts due to eye and muscle movement, as well as body motion [18]. This is why band-pass filtering is employed in order to retain meaningful activity within the oscillations. The electrical signals generated by the heart (ECGs) are also filtered in order to remove baseline wander and motion artifacts to more accurately quantify the variability in heart rate (HRV), a well-established marker of stress and anxiety, and of autonomic nervous system activity [19]. GSR signals, which capture changes in skin conductance that are due to nervous system activity, are filtered to extract the stress, emotional reactivity, and arousal-response-associated components. The mathematically conveyed expression associated with the artifact-free signal is:

$$\tilde{x}_c(t) = \mathcal{F}_{\text{filter}}(x_c(t)) \tag{4}$$

where, $\tilde{x}_c(t)$ is the preprocessed signal at channel c, $x_c(t)$ is the raw signal, and $\mathcal{F}_{\text{filter}}$ represents the corresponding artifact removal filter.

Physiological data often have samples missing due to sensor malfunctions or motion artifacts. Interpolation is employed to keep the time series continuous, so as to not introduce bias into the statistical and spectral data analyses.

$$x_c(t) = \frac{x_c(t-1) + x_c(t+1)}{2}, \quad \text{if } x_c(t) \text{ is missing} \tag{5}$$

Standardization and normalization are critical to mitigate inter-subject and inter-device variability [20]. Signals are standardized to zero mean and unit variance:

$$\begin{aligned} \tilde{x}_c(t) &= \frac{x_c(t) - \mu_c}{\sigma_c}, \\ \mu_c &= \frac{1}{T}\sum_{t=1}^{T} x_c(t), \\ \sigma_c &= \sqrt{\frac{1}{T}\sum_{t=1}^{T}(x_c(t) - \mu_c)^2} \end{aligned} \tag{6}$$

Here, μ_c and σ_c are the mean and standard deviation for the signal of each channel c. Lastly, for additional variability mitigation, normalization can rescale signals to a range of [0,1]:

$$x_c^{\text{norm}}(t) = \frac{x_c(t) - x_c^{\min}}{x_c^{\max} - x_c^{\min}} \tag{7}$$

Feature extraction is based on the realization that psychological conditions are expressed as patterned changes on multiple time scales, spectral compositions, and physiological changes of various durations. Characteristics of the time domain, such as mean, variance, standard deviation, as well as HRV, are required to assess the overall dynamics of a signal:

$$\text{Mean: } \mu = \frac{1}{T}\sum_{t=1}^{T} x_t, \quad \text{Variance: } \sigma^2 = \frac{1}{T}\sum_{t=1}^{T}(x_t - \mu)^2 \tag{8}$$

The Fast Fourier Transform (FFT) is utilized to derive frequency-domain characteristics through quantifying power in specific frequency bands related to stress, attention, or relaxation as follows:

$$X(f) = \sum_{t=0}^{T-1} x_t e^{-j2\pi ft/T} \tag{9}$$

Features in the time-frequency domain corresponded to the non-stationary and transient characteristics [21], which are relevant to the modeling of stress and emotions, and are obtained through the use of Discrete Wavelet Transform (DWT) as:

$$W(a,b) = \frac{1}{\sqrt{|a|}} \int x(t)\psi\left(\frac{t-b}{a}\right) dt \tag{10}$$

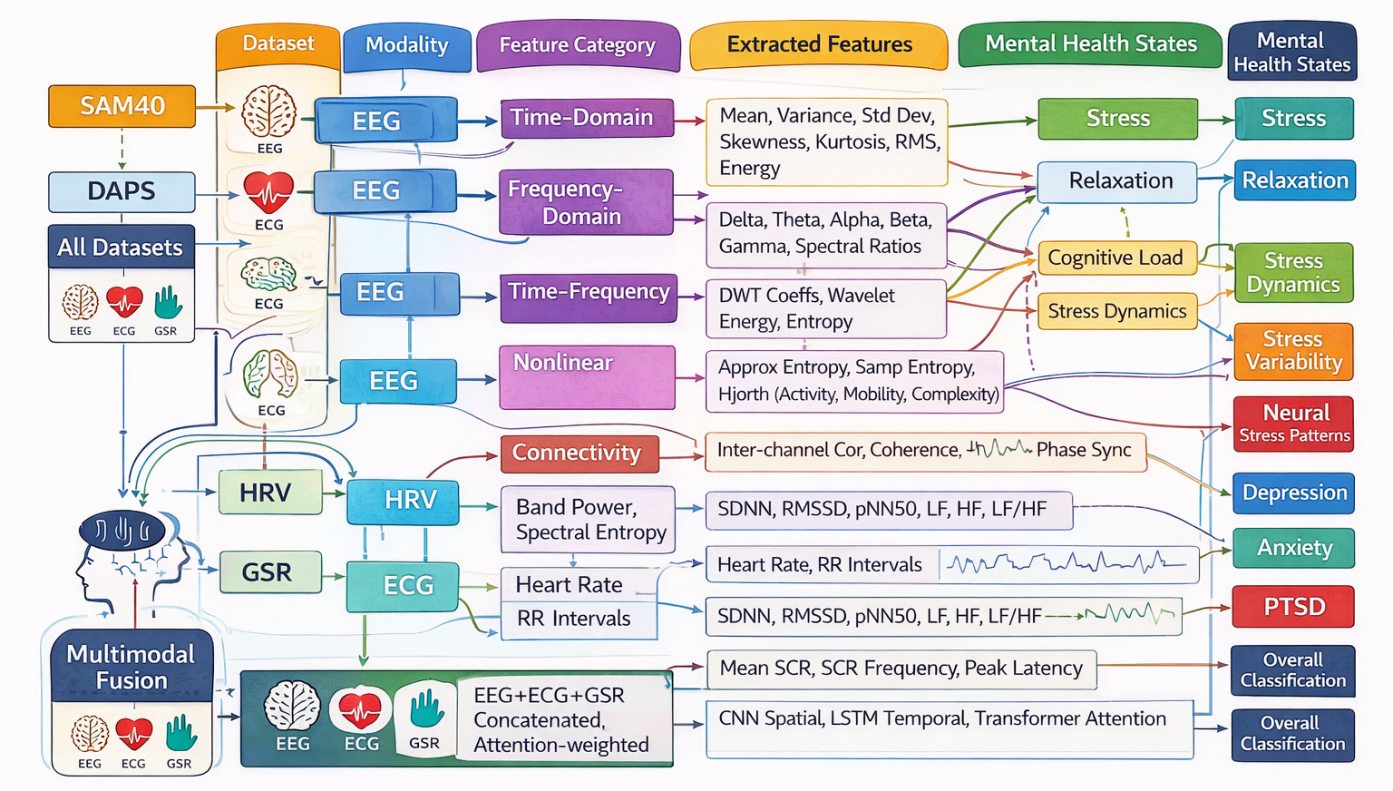

Fig. 2. Correlation of multimodal physiological features with mental health states.

where, a, b are scale and translation respectively and $\psi(t)$ is the mother wavelet.

To take advantage of the complementary information across modalities, the EEG, ECG, and GSR features are concatenated into a single, unified representation:

$$\mathbf{F} = [\mathbf{F}_{EEG}\ \mathbf{F}_{ECG}\ \mathbf{F}_{GSR}] \tag{11}$$

An attention-based weighting mechanism is utilized to emphasize information that is relevant while diminishing information that is redundant or of less relevance:

$$\mathbf{F}_{\text{att}} = \mathbf{F} \odot \alpha, \quad \sum_i \alpha_i = 1 \tag{12}$$

where, α defines learned attention weights and where $\odot$ represents a Hadamard product. This makes sure that the notable physiological patterns contributing to the stress, anxiety, and/ or depression are accentuated in the final feature representation.

There is a feature set providing a rich, complementary, and physiologically meaningful representation due to the combination of artifact-free, uniform, and standardized signals with temporal, spectral, and time-frequency features, which are of distinguished discriminative value, along with the modalities being fused with an attention mechanism. This also strengthens the capabilities of hybrid CNN-LSTM-Transformer models in identifying minute changes in mental health conditions. This makes the technique highly recommended for privacy-preserving federated learning systems as it is as applicable as possible.

Fig. 2 contains the total collection of features of the time domain, frequency domain, time-frequency domain, nonlinear domain, and features of connectivity and of deep learning obtained through the EEG, ECG, and GSR signals from the SAM40 and DAPS datasets. These features are varied in that each of the divisions captures a certain physiological characteristics that correlate to stress, anxiety, depression, and PTSD which aids in effective multimodal mental health classification.

IV. Hybrid CNN-LSTM-Transformer Model Architecture

The Hybrid CNN-LSTM-Transformer model is meant to accurately detect and classify mental health conditions by extracting spatial, temporal, and attention-based features from multimodal physiological signals such as EEG, ECG, and GSR. Specifically, the CNN module is meant to handle the spatial correlations present in the inputs $X \in \mathbb{R}^{T \times F}$, $X \in \mathbb{R}^{T \times F}$, where, T is the number of timesteps and F is the number of features. CNN process begins with one convolutional layer using 64 filters of the 3-sized kernel and generates the following feature maps.

$$H^{(1)} = \text{ReLU}(W^{(1)} * X + b^{(1)}) \tag{13}$$

Subsequently, we perform batch normalization and average pooling to decrease the dimension of the data.

$$H_{\text{pool}}^{(1)} = \max_{i \in \text{pool_size}} H_i^{(1)} \tag{14}$$

A second convolutional layer with 128 filters applies.

$$H^{(2)} = \text{ReLU}(W^{(2)} * H_{\text{pool}}^{(1)} + b^{(2)}) \tag{15}$$

This is then followed by the application of batch normalization and pooling operations; we take the outcome feature maps and flatten them into a single spatial feature vector, denoted as F_{CNN}.

The LSTM module is used to capture temporal dependencies according to the following gating equations at each time step t:

$$\begin{aligned} i_t &= \sigma(W_i x_t + U_i h_{t-1} + b_i) \\ f_t &= \sigma(W_f x_t + U_f h_{t-1} + b_f) \\ o_t &= \sigma(W_o x_t + U_o h_{t-1} + b_o) \\ c_t &= f_t \odot c_{t-1} + i_t \odot \tanh(W_c x_t + U_c h_{t-1} + b_c) \\ h_t &= o_t \odot \tanh(c_t) \end{aligned} \tag{16}$$

where, i_t, f_t, o_t are the input, forget, and output gates, c_t is the cell state, and h_t is the hidden state. The first LSTM layer with 128 units returns sequences, followed by a dropout of 0.3, and the second LSTM layer with 64 units outputs the final temporal feature vector $F_{\text{LSTM}} = h_T$.

The Transformer module applies self-attention to capture long-range dependencies:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \tag{17}$$

where, $Q = HW_Q, K = HW_K, V = HW_V$. Multi-headed attention is concerned with merging different attention components:

$$\text{MultiHead}(H) = \text{Concat}(\text{head}_1, \ldots, \text{head}_h)\, W_O \tag{18}$$

The use of residual connections as well as the application of layer normalization are as follows:

$$H' = \text{LayerNorm}(H + \text{MultiHead}(H)) \tag{19}$$

followed by another feed-forward network:

$$\text{FFN}(H') = W_2 \cdot \text{ReLU}(W_1 H' + b_1) + b_2 \tag{20}$$

and dropout and global average pooling to get the attention-based feature vector:

$$F_{\text{Trans}} = \frac{1}{T}\sum_{t=1}^{T} \text{FFN}(H')_t \tag{21}$$

The outputs of CNN, LSTM and Transformer are concatenated into a hybrid feature vector:

$$F_{\text{Hybrid}} = [F_{\text{CNN}} \parallel F_{\text{LSTM}} \parallel F_{\text{Trans}}] \tag{22}$$

and this is input into fully connected layers consisting of a ReLU activation, batch normalization, and dropout. In particular, a dense layer of 256 units, batch normalization, and a 0.4 dropout, followed by a dense of 128 units, and a final softmax layer gives the prediction:

$$\hat{y} = \text{Softmax}\Big(W_3 \cdot \text{ReLU}(\, W_2 \cdot \text{ReLU}(W_1 F_{\text{Hybrid}} + b_1) + b_2) + b_3\Big) \tag{23}$$

across n_{classes}. The early recognition of stress, anxiety, and PTSD, while maintaining stability and generalization, is made possible because this hybrid architecture seamlessly integrates spatial, temporal, and attenTional characteristics.

V. Federated Learning Framework with Privacy Preservation and Performance Evaluation

In order to achieve safe and cooperative model training, the proposed hybrid CNN-LSTM-Transformer model is integrated into a client-server federated learning environment. Each client k trains the model on its private dataset D_k and generates the following local model updates:

$$\theta_k^{t+1} = \text{Train}(\theta^t, D_k) \tag{24}$$

where, θ^t is the global model parameters at t-th round. Those updates, as opposed to the raw data, are communicated to the central server, which accumulates the updates from the clients using a weighted average according to the FedAvg algorithm:

$$\theta^{t+1} = \sum_{k=1}^{K} \frac{n_k}{n} \theta_k^{t+1} \tag{25}$$

where, n_k is the number of data samples from client k and $n = \sum k = 1^K nk$ is the global sample size held by all clients. To mitigate the non-IID and heterogeneous data distributions problem, adaptive η_k learning rates and unique local model parameters in the form of personalized layers are used to ensure a solid convergence.In order to mitigate the non-IID data heterogeneity across federated clients, FedProx-inspired regularization and personalized local adaptation layers are added to minimize client drift and promote stability of convergence.

A number of privacy preserving mechanisms are assumed to protect sensitive physiological data. Differential Privacy (DP) is realized through DP-SGD, which adds noise $\mathcal{N}(0, \sigma^2)$ to the gradients $\nabla\theta_k$ in order to make it impossible to reconstruct the private data:

$$\tilde{\nabla}\theta_k = \nabla\theta_k + \mathcal{N}(0, \sigma^2) \tag{26}$$

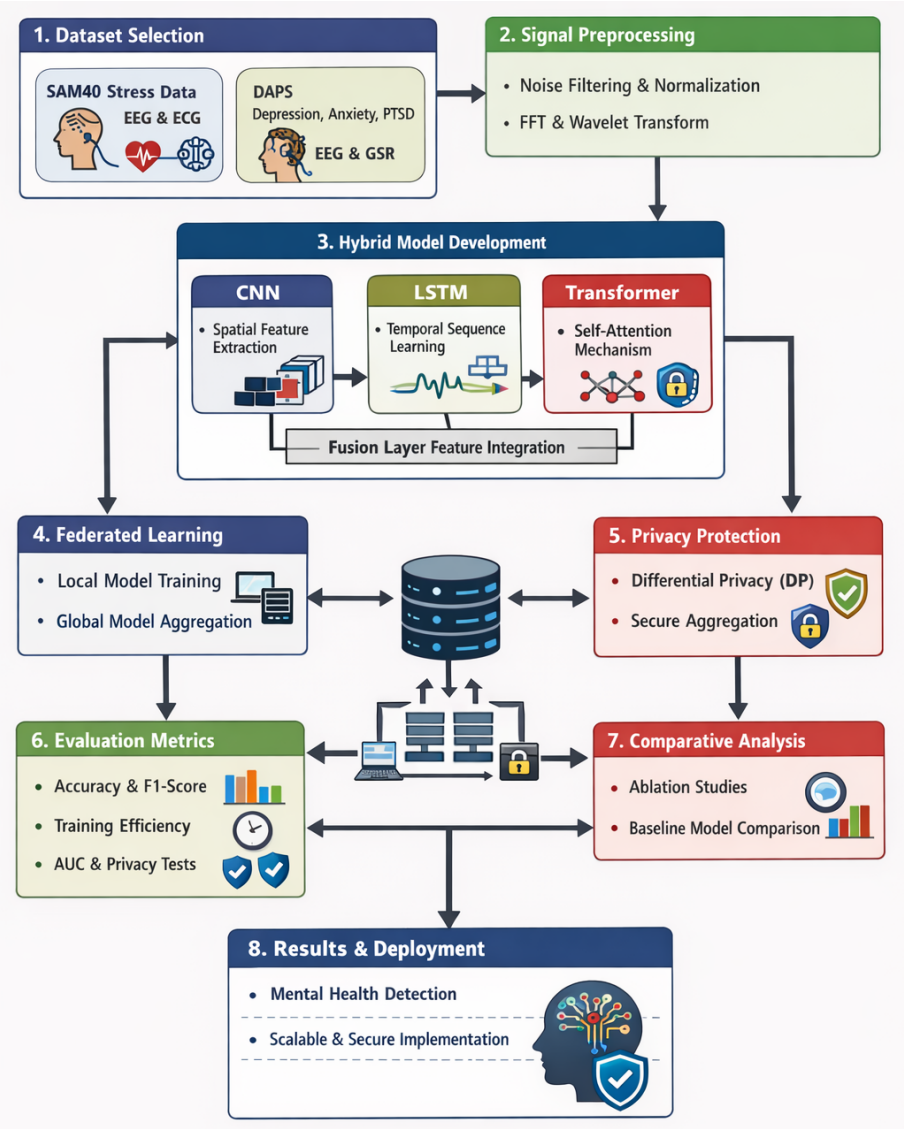

Fig. 3. Proposed federated learning–based hybrid deep learning framework for mental health disorder detection.

Secure aggregation ensures that individual client contributions remain confidential, while adversarial robustness evaluations quantify resilience against attacks such as model inversion, poisoning, and gradient leakage.

The framework is evaluated comprehensively across predictive performance, efficiency, and privacy [22]. Predictive performance metrics include accuracy, precision, recall, F1-score, and area under the receiver operating characteristic curve (AUC). Training and communication efficiency are analyzed via local training time t_k, global convergence rate, and communication overhead:

$$C = \sum_{k=1}^{K} t_k \cdot s_k \tag{27}$$

where, s_k is the size of the update sent by the k^{th} client. The privacy assessment measures how well the model can stand against the potential leakage of gradients and how resistant the model is to inversion attacks. The ablation and comparative studies determine the contribution of the individual modalities (EEG, ECG, GSR) and the feature fusion strategies by evaluating the hybrid CNN-LSTM-Transformer model against the baseline models (CNN-only, LSTM-only, and attention-only). All these assessments together show that the proposed framework provides predictive and operational performance, and for that performing private rights in distributed heterogeneous environments is no easy task.

Fig. 3 displays the federated learning–based hybrid CNN–LSTM–Transformer framework for mental health detection using SAM40 and DAPS datasets. The different modalities of physiological signals are preprocessed and fused to extract and learn spatial, temporal, and contextual features. The federated learning model provides the privacy-preserving functionality, which enables secures and scalable deployment.

VI. Hybrid CNN–LSTM–Transformer Prediction Algorithm

The algorithm outlined in Algorithm 1 discusses how the hybrid model uses CNNs, LSTMs, and transformer blocks to learn on EEG, ECG, and GSR to learn different spatial, temporal, and contextual patterns present in the multi-modal signals. Preprocessing consists of artifact removal, signal normalization, and standardizing the features of each dataset (SAM40 and DAPS) independently.

After this step, the features are combined and an output is generated which is the predicted probability p of the targeted mental state which is followed by an if–else statement. If the predicted probability is higher than *tau* (*p¿tau*), then the mental state is classified as present, otherwise, it is classified as not detected. This algorithm allows for the processing of multi-modal physiological datasets both in the single-sample and batch formats.

Algorithm 1 Hybrid CNN–LSTM–Transformer Prediction with If-Else for SAM40 + DAPS

Input: Dataset $D = \{x_i, y_i\}_{i=1}^{N}$ (EEG, ECG, GSR), pretrained model M, threshold τ **Output:** Predicted labels $\hat{y}_i$ for all samples

    $\hat{y}_i \leftarrow$ "No Target State Detected"
  end if
end for
return $\hat{y} = \{\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_N\}$

VII. Results and Discussion

The developed Hybrid CNN-LSTM-Transformer model was thoroughly tested on two multimodal physiological datasets: SAM40, SAM40, which includes stress-related EEG signals, and DAPS, which contains signals linked to depression, anxiety, and post-traumatic stress disorder (PTSD). The obtained precision, recall, and F1-score values further indicate the model's reliability in minimizing false positives and false negatives during mental health state classificationc, as shown in Fig. 4.

The proposed model achieved an accuracy of 97.37% on the SAM40 dataset and 96% on the DAPS dataset, demonstrating strong classification performance across both datasets. The obtained precision, recall, and F1-score values further indicate the reliability of the model in minimizing false positives and false negatives during mental health state classification. Although slight performance variations were observed in the DAPS dataset due to its heterogeneous, task-based nature, the model maintained consistent and stable predictive capability.

The experimental results confirm the effectiveness of the proposed hybrid architecture. To further evaluate its contribution, the Hybrid CNN-LSTM-Transformer model was compared with recently published federated and centralized approaches for physiological signal-based mental health classification. Previous studies have shown promising outcomes using federated learning; however, many existing methods rely on single-modality inputs or limited feature fusion strategies. For instance, a federated ECG classification framework based on Gramian Angular Field representations and CNN feature extraction achieved 95.18% accuracy but focused only on ECG signals without multimodal integration [23]. Another study reported approximately 88.30% accuracy under heterogeneous and non-IID federated settings, while facing challenges related to generalization and communication efficiency [24]. Similarly, a personalized federated mental state evaluation framework integrating EEG and physiological signals achieved 90.12% accuracy but demonstrated limitations in scalability and cross-modal feature learning [25].

In comparison, the proposed Hybrid CNN-LSTM-Transformer framework achieved superior performance due to the effective fusion of EEG, ECG, and GSR signals combined with hierarchical spatial, temporal, and attention-based feature extraction. The CNN layers successfully captured spatial representations, the LSTM layers modeled temporal dependencies, and the Transformer module learned long-range contextual relationships among multimodal physiological signals. Furthermore, the federated learning framework preserved user privacy while maintaining robustness under heterogeneous and non-IID client data distributions.

Overall, the experimental findings demonstrate that the proposed framework provides accurate, scalable, and privacy-preserving mental health monitoring, making it suitable for real-world clinical and wearable healthcare applications.

Evaluation of the federated hybrid CNN–LSTM–Transformer model on the SAM40 (Stress Analysis) and DAPS (Depression, Anxiety, PTSD Signals) datasets is presented in Fig. 5. The X-axis presents the different clients (Client 1, Client 2, Client 3, Client 4), while the Y-axis (left - primary) shows the time (in seconds) for communication and local training while the Y-axis (right - sec) shows the portion of convergence from 0 – 1. The time communication for each of the clients is 11.8 seconds to 15.2 seconds and for local time training 23 seconds to 28 seconds, showing good local computations and communication time. The convergence line shows good linearity, with 0.85, 0.90, 0.90 converging rapidly and stably to a global model in the presence of heterogeneous and non-IID data. Values in the bars and at the points give exact quantitative reference and traced data. This confirms the framework for a highly balanced model in terms of converging processing, time, and convergence, ideal for applicable, privacy-compliant, and comprehensive mental health data.

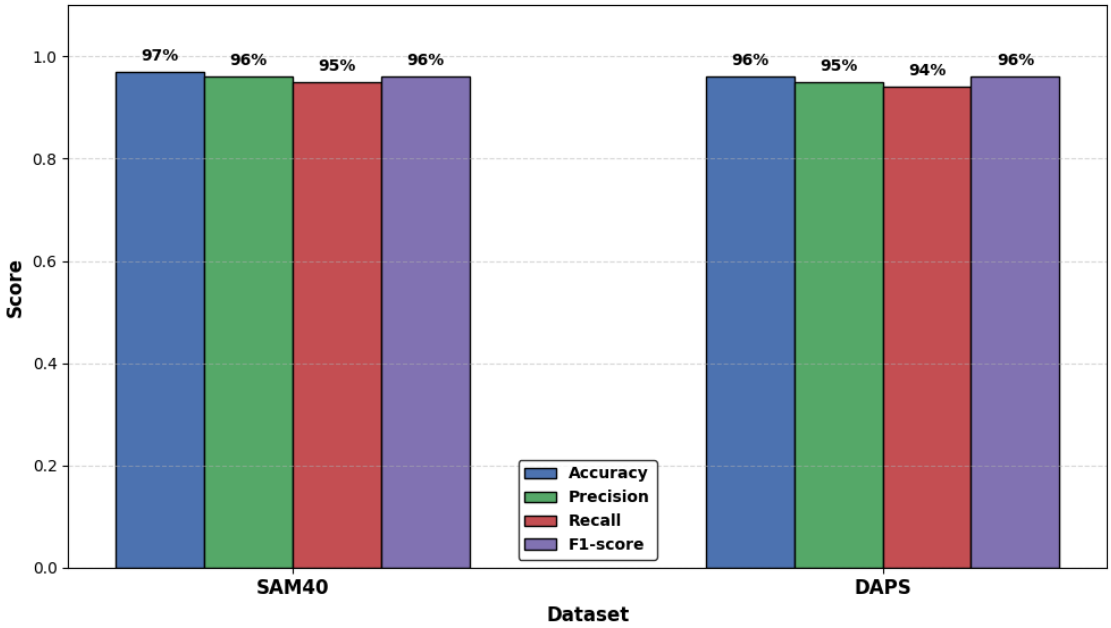

Fig. 4. The Hybrid CNN-LSTM-transformer model effectively captures and classifies features from SAM40 and DAPS.

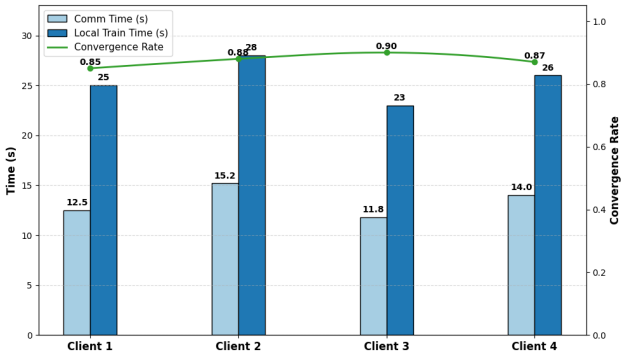

Fig. 5. Performance of the federated Hybrid CNN-LSTM-transformer on SAM40 and DAPS.

VIII. Conclusion

The paper proposed a privacy-preserving federated learning framework for multimodal mental health analysis using physiological signals. In this study, we propose a method to train a hybrid CNN–LSTM–Transformer model that can automatically capture spatial, temporal and long-range dependencies of complex physiological data in a federated manner across multiple clients. Unlike existing studies which mainly employ single-modality signals or limited feature fusion mechanisms, the proposed framework utilizes multimodal physiological information to enhance classification robustness and cross-domain generalization under heterogeneous and non-IID data distributions. This avoids directly sharing sensitive medical data directly — allowing the system to be used in real-world healthcare environments. Average experimental results on the two datasets indicate an excellent performance with accuracy scores of 97% and 96%, respectively, respectively, in addition to high values of precision, recall, and F1-score. Together, these findings demonstrate that our suggested hybrid architecture with its new loss function helps to consistently outperform mental state classification performance based on conventional and recent federated learning methods. The study shows that integrating multimodal physiological signal fusion with sophisticated deep learning and federated learning protocols; all of these characteristics make this solution reliable, scalable-invasive, and privacy-aware.

Future work will focus on improving personalization among distributed clients, minimizing communication overhead in large federated systems, and training on additional physiological signals such as respiration and EEG frequency bands. Our ongoing work shall contribute to further enhance end-user data privacy by employing differential privacy and secure aggregation techniques. Additionally, the approach will also open avenues for designing explainable AI techniques to improve model interpretability, a prerequisite for clinical adoption and practical applicability of decision support systems.

***Abstract*—This study presents the design, development, and pilot evaluation of Addict-Shield, a mobile educational serious game aimed at preventing electronic cigarette use among adolescents. The proposed approach is grounded in the DICE model (Define, Imagine, Create, Evaluate) to ensure a structured and learner-centered design process. The game integrates narrative-driven scenarios, gamification mechanics, and scientifically validated prevention content targeting risk awareness, stress management, and refusal skills. A pilot pre-test/post-test study was conducted with a convenience sample of 25 adolescents aged 12–18 years. Results indicate substantial improvements in knowledge scores (mean increase from 32% to 80%), stronger negative attitudes toward vaping, and increased behavioral intention to refuse e-cigarettes in peer-pressure situations (from 33% to 85%). Descriptive comparisons between pre-test and post-test results indicated substantial improvements in knowledge, attitudes, and behavioral intention following the intervention. Participants also reported high engagement and perceived usefulness (83–91%). Although the findings remain preliminary due to the limited sample size and absence of a control group, the results suggest the potential of structured mobile serious games for adolescent addiction prevention. These findings highlight the relevance of mobile serious games as innovative tools for adolescent addiction prevention and health education.**

***Keywords*—Serious games; mobile learning; adolescent health; vaping prevention; gamification; DICE model; pilot study**

I. Introduction

Adolescence (ages 12-18) is a phase of intense neurological development during which the brain is not yet fully mature. This neurological immaturity, combined with a quest for autonomy and increased sensitivity to social influences, makes adolescents particularly vulnerable to addictive behaviors [1][2]. Neuroscience research indicates that early experimentation with addictive substances or compulsive behaviors significantly increases the risk of addiction in adulthood, highlighting the critical need for preventive interventions during this developmental window [3][4]. Today's teenagers face a proliferation of potential sources of addiction [5]:

- Accessibility of substances: e-cigarettes, alcohol, cannabis
- Social pressure: normalization of certain consumption patterns
- Stress and anxiety: academic pressure, uncertainty about the future
- Searching for identity: experimentation as a rite of passage

Traditional prevention campaigns, such as posters, conferences, and lectures, have proven insufficient with teenagers due to low interactivity, perceived moralizing tone, and disconnection from daily life. Adolescents often understand what behaviors are risky, so merely enforcing rules rarely leads to meaningful behavioral change. Instead, prevention strategies should support adolescents in anticipating risky situations, understanding potential consequences, and making informed decisions in those contexts [6].

Serious games are digital programs designed to educate, train, or inform users through interactive experiences. By combining gameplay mechanics with educational objectives, serious games allow adolescents to safely experience risky scenarios and reflect on the consequences of their actions. These games can be developed for multiple platforms, use diverse technologies, and span a variety of genres. While entertaining, their primary goal remains to impart knowledge, develop skills, or encourage behavioral change [7][8][9].

Mobile educational games are employed in diverse contexts, including inclusion/accessibility, exact sciences, language learning, and health education. They allow for playful and contextualized exploration of knowledge, supporting modifications to traditional curricula. The wide range of gameplay mechanics demonstrates the creativity of developers in combining playful and educational elements. Through quizzes, puzzles, storytelling, augmented reality, word games, collecting activities, memory games, and social interactions, these applications offer engaging and flexible learning experiences. When well-integrated with content, these mechanics enhance learning effectiveness, relevance, and engagement across different age groups and educational needs [10]. Ubiquitous learning further extends these benefits by allowing students to learn anytime, anywhere, overcoming traditional classroom limitations and connecting learning to everyday life [11].

Serious games can also amplify intrinsic motivation to adopt positive behaviors. For example, players are guided

to manage time, adopt healthy habits, and resist smoking. By creating structured learning paths with tips, advice, and strategies, serious games provide adolescents with the motivation and framework to change behavior in a safe, experiential context. Studies have shown that serious games designed for behavior change can harness players' intrinsic motivation through engaging interactive experiences and game mechanics, thereby supporting positive health behaviors and attitude change beyond traditional informational approaches [12][13][14].

Research on gamified mobile applications and serious games for pro-environmental behaviors has shown that gamification elements such as rewards, challenges, collaboration, and immersive storytelling increase awareness and encourage the adoption of sustainable practices [15]. By analogy, these mechanisms can be applied to addiction prevention, where engagement, feedback, and decision-making scenarios can reinforce refusal skills and reflection on the consequences of risky behaviors.

The challenge addressed in this study is how to design an interactive educational mobile application that integrates appropriate social support, scientifically validated content, and engaging gamification to effectively prevent addictions among teenagers. To this end, this study presents the evaluation study of **Addict-Shield**, a mobile educational serious game aimed at preventing e-cigarette addiction in adolescents.

The main contributions of this study are threefold: 1) the design of a mobile serious game for adolescent e-cigarette prevention using a structured methodology; 2) the integration of gamified narrative elements with validated prevention content; and 3) the preliminary evaluation of the game's initial pedagogical and behavioral effects.

The remainder of this study is organized as follows: Section II reviews related work, Section III details the design methodology and game architecture, Section IV describes the evaluation protocol and results, along with a discussion, and Section V concludes by discussing the findings, limitations, and future work.

Unlike existing vaping prevention applications, this study proposes a structured pedagogical design based on the DICE model combined with an empirical evaluation in a Moroccan context, which remains underexplored in current literature.

II. Related Work

A. Tobacco and Electronic Cigarette Prevention Programs in Morocco

Several educational and prevention initiatives addressing tobacco and electronic cigarette use have been implemented in Morocco, primarily through school-based programs, public awareness campaigns, and health education interventions. These initiatives aim to inform adolescents about the health risks associated with smoking and emerging nicotine products. However, most existing approaches rely on traditional methods such as lectures, printed materials, and mass media campaigns, which often lack interactivity and personalization. Limited research has explored the use of digital or game-based educational tools for addiction prevention in the Moroccan context. This gap highlights the need for innovative, engaging, and learner-centered prevention approaches tailored to adolescents' digital habits, motivating the development of mobile serious games for addiction prevention. Serious games have been increasingly studied as interactive digital interventions that can engage adolescents more effectively than traditional media and support health promotion outcomes [16].

B. Serious Games and Vaping Prevention

The application of serious games to vaping and smoking prevention remains relatively limited, with few projects leading to fully developed and empirically evaluated game-based interventions. Most existing digital solutions focus on smoking cessation rather than early prevention and are primarily designed for adult users. Applications such as Smokitten, Kwit [17], I Am Sober [18], and Smoke Free [19] illustrate how gamification mechanisms, including progress tracking, achievements, challenges, and motivational feedback can support users during the quitting process. These tools demonstrate the potential of game-based approaches to enhance engagement, visualize behavioral progress, and sustain motivation over time.

Recent studies confirm that serious games and gamified interventions can significantly improve adolescents' knowledge, risk perception, and intention to refuse vaping [13][20][16]. A pilot randomized study showed that a social game-based tobacco prevention program increased both perceived risk of vaping and tobacco-related knowledge among adolescents [13]. Similarly, digital health game interventions have been found to strengthen smoking refusal self-efficacy and resistance to peer pressure in early adolescents [21]. More broadly, serious games have been recognized as effective tools for supporting behavior change and health education among young people.

Compared with existing smoking cessation applications, **Addict-Shield** focuses specifically on early prevention among adolescents rather than cessation support for adult smokers. In addition, unlike many existing gamified applications, the proposed system integrates a formal pedagogical design methodology (DICE model) together with narrative-based learning and behavioral skill development.

However, these applications generally emphasize self-monitoring and behavior tracking rather than structured educational content aimed at prevention. In addition, their design is rarely grounded in formal pedagogical models, and their evaluation focuses mainly on usage statistics or self-reported outcomes rather than learning effectiveness. Age-appropriate design, adaptation to adolescent needs, and the integration of educational content addressing addiction mechanisms and social pressure are often lacking. Moreover, safe and moderated social environments suitable for minors are seldom considered.

As a result, early prevention through serious games remains largely underexplored, highlighting the need for innovative mobile learning games that combine gamification, scientifically validated educational content, and structured design methodologies to effectively address vaping prevention among adolescents. To address these gaps, the present work proposes the design and evaluation of an adaptive ubiquitous learning game for adolescent e-cigarette addiction prevention, developed using the DICE model. To the best of our knowledge,

few studies have investigated serious game-based vaping prevention interventions specifically designed for adolescents in the Moroccan educational context.

III. Materials and Methods

This section presents the materials and methodology used in the pilot evaluation study. It first describes the serious game under evaluation, Addict-Shield, as well as the data collection instruments employed for the pre- and post-evaluations. This study adopts a pilot exploratory pre-experimental design without a control group, aimed at assessing feasibility and preliminary outcomes rather than establishing causal relationships. No inferential statistical tests were conducted due to the exploratory nature of the study and the limited sample size.

A. Addict-Shield: Serious Games

Addict-Shield is a mobile serious game designed to prevent electronic cigarette use among adolescents aged 12 to 18. The game is built around a narrative-driven learning approach in which players follow the journey of a fictional adolescent character confronted with social pressure related to vaping. This narrative structure serves as a pedagogical framework to contextualize educational content and decision-making situations commonly encountered by teenagers.

The game integrates several interactive modules targeting key prevention objectives, including acquisition of scientifically validated knowledge about nicotine and its effects, stress and emotion regulation strategies without substance use, and development of refusal and assertiveness skills in social contexts. Gamification mechanisms such as avatars, progression levels, achievement badges, and virtual rewards are employed to enhance motivation and engagement. Player progression is represented through a protective "shield" metaphor that visually reflects the learner's cognitive and behavioral empowerment.

B. Design Methodology: Application of the DICE Model to Addict-Shield

The design and development of Addict-Shield followed the generic DICE model, which structures the creation of digital learning experiences through four successive phases: Define, Imagine, Create, and Evaluate. This model was selected to ensure a systematic, learner-centered, and pedagogically grounded development process for an adaptive serious game dedicated to adolescent e-cigarette addiction prevention [22].

1) Define phase: The Define phase focused on identifying the target population, learning objectives, and contextual constraints. Addict-Shield targets adolescents aged 12 to 18, a population particularly vulnerable to vaping due to social pressure, misinformation, and emotional regulation challenges. The primary educational objectives were to (1) increase awareness of the health risks associated with electronic cigarettes, (2) correct common misconceptions related to nicotine, (3) develop stress management skills without substance use, and (4) strengthen refusal and assertiveness strategies in peer-influenced situations. These objectives were defined in alignment with prevention guidelines and adolescent health education principles.

2) Imagine phase: During the Imagine phase, pedagogical strategies and game concepts were designed to translate the defined objectives into meaningful interactive experiences. A narrative-driven approach was adopted to contextualize learning within realistic adolescent scenarios. The game scenario follows a fictional teenage character facing situations involving curiosity, peer pressure, stress, and social confrontation related to vaping. This narrative framework supports experiential learning by allowing players to explore consequences, make decisions, and reflect on outcomes in a safe virtual environment. Gamification elements, including avatars, progression systems, symbolic rewards, and challenges were conceptualized to enhance engagement and motivation.

3) Create phase: The Create phase involved the implementation of the serious game as a mobile application. Educational content was integrated into interactive modules addressing nicotine effects, stress regulation techniques (such as guided breathing exercises), and refusal strategies. Gamification mechanics were operationalized through levels, achievements, virtual rewards, and a visual "shield" metaphor representing the player's cognitive and behavioral empowerment. The game was designed to be intuitive, age-appropriate, and accessible, ensuring alignment between gameplay mechanics and pedagogical intentions.

The following screenshots present representative interfaces of the Addict-Shield serious game, highlighting the implementation of narrative scenarios, gamification elements, and learning modules developed according to the DICE design model.

Fig. 1 interface serves as the visual entry point to the Addict-Shield application and introduces the game's metaphorical universe centered on resistance to addiction.

- Visual Identity: The title is displayed using a medieval-inspired typeface that is consistent with the game's thematic framing. The textured, stone-like background reinforces immersion and contributes to a coherent visual atmosphere aligned with the metaphor of protection and struggle against addiction.
- The Avatar: The central armored character holding a shield represents the player's protective role and resilience against addictive behaviors. This avatar functions as a symbolic representation of empowerment, reinforcing the learner's active role in resisting risk-related situations.
- Gamification Mechanics: The presence of the "RENFORCER" button explicitly highlights the progression system of the game. It indicates that players can enhance the strength of their virtual shield by completing learning activities, such as quizzes, thereby linking educational achievement with game-based progression.

Fig. 2 marks the transition to the application's main learning activity, referred to as the Daily Quiz. It is designed to engage the user through a narrative context before the question-and-answer phase begins.

- Storyline and Avatar: The soldier avatar functions as a virtual coach rather than a purely decorative element. By directly addressing the player (e.g., "Soldier!

Fig. 1. Home screen and shield management.

Fig. 2. Quiz launch interface (core gameplay).

Ready for training?"), the interface reframes a health-related quiz as a mission to be accomplished, thereby enhancing user engagement.

- Immersive Design (RPG): The graphical composition, incorporating elements such as roots, skulls, and parchment-like textures, preserves the dark-fantasy role-playing aesthetic of the game. This artistic consistency contributes to gamifying a sensitive topic such as addiction prevention and makes it more approachable for adolescent users.
- Progression System: The Level 1 indicator displayed at the top of the screen emphasizes the notion of continuous progression and skill development, reinforcing the game-based learning trajectory.
- Call to Action (CTA): The centrally positioned and visually contrasted Start button provides a clear and intuitive invitation to initiate the Daily question-and-answer session.
- Global Navigation: The bottom navigation bar allows for seamless switching between other modules (Documentation, Quiz, Health, Profile), thus structuring the information architecture.

Fig. 3 illustrates the "Health & Wellness" section of the application. Accessible directly from the dashboard, this module addresses the immediate need for managing cravings or anxiety.

- Therapeutic Functionality: The screen offers a guided breathing exercise (similar to heart coherence) with a predefined duration of 1 minute. This short and accessible duration is ideal for quick intervention in stressful situations.
- Visual Focus: The central motif (mandala/runic circle) serves as a focal point for the user's attention. It is

Fig. 3. Stress management module (breathing exercise).

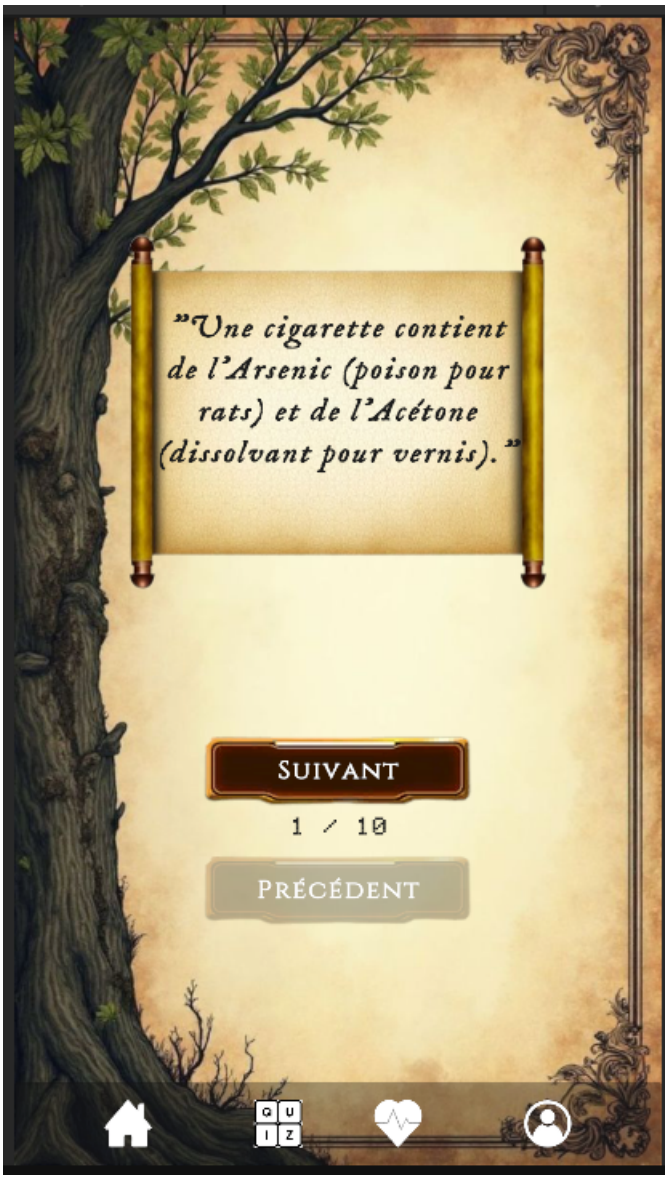

Fig. 4. Information and awareness module.

designed to animate or guide the breathing rhythm, helping the user to refocus.

- Minimalist Ergonomics: Unlike more cluttered game screens, this interface is uncluttered to avoid distracting the user. The "READY?" question and the "START" button launch the activity seamlessly.
- Graphic Consistency: Even for a utility tool, the textured background and typography are preserved, keeping the user in the secure universe of the application.

Fig. 4 represents the educational component of the application. Its purpose is to inform the user about the dangers of addictive substances through striking and scientifically verified facts.

- Micro-Learning (Rapid Learning): Information is broken down into small, digestible fragments (here, one quote per page). The "1/10" counter clearly indicates the content length, encouraging the user to read to the end without feeling overwhelmed by a lengthy medical text.
- Psychological Impact: The chosen text ("Arsenic", "Acetone") uses striking comparisons (rat poison, solvent) to make an impact and deconstruct the commonplace image of cigarettes.
- Universe Consistency: The design of the scroll unfurled against a natural background (tree) maintains the "Fantasy" immersion. The user doesn't feel like they are reading a lecture, but rather discovering "ancient knowledge" or clues for their quest.
- Intuitive Navigation: The interface was designed to ensure intuitive navigation and maintain user engage-

ment throughout the learning experience.

4) Evaluate phase: The Evaluate phase consisted of assessing the pedagogical effectiveness of **Addict-Shield** through a user-based evaluation. The game was tested with a target adolescent audience using pre- and post-evaluation questionnaires. The evaluation focused on measuring changes in awareness of e-cigarette risks, knowledge acquisition, and behavioral intention regarding vaping. This phase aimed to verify whether the serious game effectively achieved its educational objectives and to identify areas for improvement in both content and game design.

C. Study Design and Evaluation Protocol

This study follows a pre-experimental pre-test/post-test design to evaluate the pedagogical effectiveness of the **Addict-Shield** serious game. The evaluation focuses on assessing adolescents' awareness and knowledge of e-cigarette risks, their ability to manage stress without substance use, and their behavioral intention toward vaping refusal.

Participants were invited to complete a pre-evaluation questionnaire prior to interacting with the game. They then engaged with the game during a structured gameplay session using mobile devices. Following the intervention, a post-evaluation questionnaire was administered to measure potential changes in the targeted learning outcomes.

The study was conducted in a controlled educational setting to ensure consistent conditions across participants. Ethical considerations were respected, with voluntary participation, parental consent, and anonymous data collection.

As an exploratory pilot study, the evaluation aimed to assess feasibility and preliminary pedagogical effects rather than establish definitive causal relationships.

D. Participants

The pilot study involved a convenience sample of N = 25 adolescents aged between 12 and 18 years. Participants were recruited from a secondary school context and voluntarily agreed to take part in the study. Inclusion criteria required participants to be within the target age range and to have access to a smartphone capable of running the mobile application.

Prior to participation, informed consent was obtained from parents or legal guardians, and assent was collected from the adolescents. Participation was voluntary, and all data were collected anonymously in accordance with ethical guidelines for research involving minors. The convenience sampling approach was considered appropriate for this preliminary pilot evaluation but may limit the generalizability of the findings.

E. Data Collection Instruments

Data were collected using a set of pre- and post-evaluation questionnaires designed to assess the targeted learning outcomes of the proposed serious game. The instruments were structured into five sections: (1) Demographic information was collected to characterize the study sample, including age, gender, and prior exposure to electronic cigarettes (see Appendix A). (2) Awareness and knowledge related to electronic cigarette use and nicotine effects were assessed through a short questionnaire composed of multiple-choice and true/false questions (see Appendix B). (3) Self-reported stress and emotion regulation strategies without substance use were measured using Likert-scale items (see Appendix C). (4) Behavioral intention to refuse vaping in social situations was evaluated through scenario-based statements reflecting common peer-pressure contexts (see Appendix D).

In addition, (5) a post-intervention questionnaire was administered to assess participants' perceptions regarding engagement, usability, and perceived usefulness of the game. All instruments were administered anonymously before and after the gameplay session(see Appendix E).

F. Evaluation Metrics

The evaluation of Addict-Shield was based on a pre-test/post-test comparison framework designed to assess the pedagogical effectiveness of the serious game. The evaluation metrics focused on three main dimensions aligned with the educational objectives of the game.

- Knowledge acquisition: Participants' knowledge regarding electronic cigarettes and nicotine-related risks was assessed using a set of multiple-choice and true/false questions administered before and after the intervention. These items evaluated factual understanding of nicotine effects, addiction mechanisms, and common misconceptions related to vaping. Knowledge scores were calculated as the total number of correct responses.
- Attitudes toward vaping: Attitudinal changes were measured using Likert-scale items assessing participants' perceptions of the harmfulness of electronic cigarettes, perceived social acceptability, and personal beliefs regarding vaping. Higher post-test scores reflected more negative attitudes toward e-cigarette use.
- Behavioral intention and resistance to peer pressure: Behavioral intention was evaluated through scenario-based questions examining participants' likelihood of refusing e-cigarettes in socially challenging situations. These items were designed to assess assertiveness and resistance to peer pressure, which are central objectives of the Addict-Shield game design.

For each dimension, pre-test and post-test scores were compared to identify trends in learning outcomes and behavioral intention. Given the exploratory nature of this pilot study and the limited sample size, the statistical analysis aimed to identify preliminary trends rather than establish definitive causal conclusions. Descriptive statistics (means, standard deviations, and percentages) were computed to summarize participants' responses and identify preliminary trends between pre-test and post-test evaluations.

1) Data analysis method: Data collected from the pre- and post-evaluation questionnaires were analyzed using descriptive statistical methods, in direct alignment with the evaluation metrics defined for this study. For each evaluation dimension, mean scores and standard deviations were computed to summarize participants' responses before and after the intervention.

First, knowledge acquisition related to electronic cigarettes and nicotine risks was analyzed by calculating the total number of correct responses to the multiple-choice and true/false items administered at pre-test and post-test. Pre-/post-comparisons were used to observe trends in factual understanding and awareness of vaping-related risks.

Second, attitudes toward vaping were analyzed using Likert-scale items assessing perceived harmfulness, social acceptability, and personal beliefs regarding electronic cigarette use. Changes in mean attitude scores between pre- and post-evaluations were examined to identify shifts toward more negative perceptions of vaping.

Third, behavioral intention and resistance to peer pressure were analyzed through scenario-based items reflecting common social situations involving vaping. Participants' likelihood of refusing e-cigarettes was summarized using descriptive statistics, and pre-/post-trends were examined to assess changes in assertiveness and refusal intention.

Given the exploratory nature of this pilot study and the limited sample size, the analysis primarily aimed to explore trends and feasibility rather than to draw definitive causal conclusions or conduct advanced inferential statistical tests. Additionally, qualitative feedback collected through open-ended post-intervention questions was analyzed using a simple thematic approach to capture participants' perceptions, engagement, and overall experience with the Addict-Shield serious game.

Although the sample size was limited (N=25), percentage-based comparisons were considered appropriate for this exploratory pilot study aiming to assess feasibility and observable trends rather than statistical generalization. The study serves as a preliminary step toward larger-scale controlled investigations. Descriptive statistics (means and percentages) were used to summarize the data.

IV. Results and Discussion

A. Participant Demographics

Table I summarizes the demographic characteristics of the 25 adolescents who participated in the pilot study. Participants were aged 12–18 years, with 36% (n=9) aged 12–14 and 64% (n=16) aged 15–18. Females represented 56% (n=14) of the sample. Six participants (24%) reported having ever tried e-cigarettes, and 10 (40%) reported having friends who vape. All participants owned or regularly used a smartphone (100%). The sample was obtained using a convenience sampling approach due to the exploratory nature of the pilot study.

TABLE I. Demographic Characteristics of Participants (N = 25)

Variable	Category	n	%
Age	12–14 years	9	36%
	15–18 years	16	64%
Gender	Male	11	44%
	Female	14	56%
Ever tried e-cigarette	Yes	6	24%
	No	19	76%
Friends who vape	Yes	10	40%
	No	15	60%
Own or regularly use a smartphone	Yes	25	100%
	No	0	0%

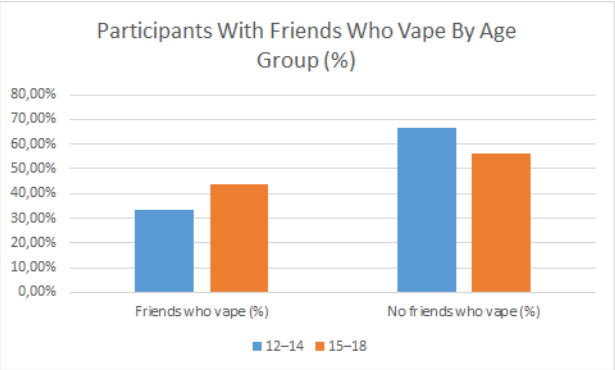

Fig. 5. Participants with friends who vape by age group.

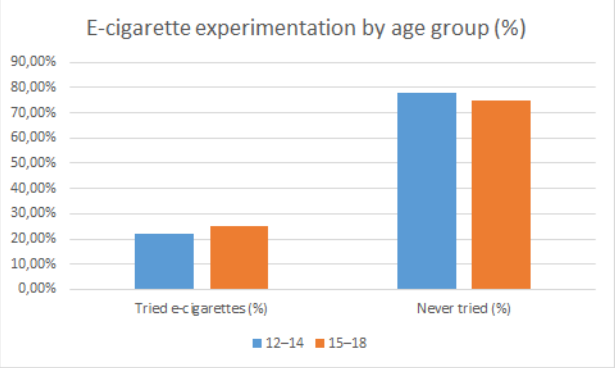

Fig. 6. Participants who tried e-cigarette by age group.

B. Social Exposure and E-Cigarette Experimentation

Fig. 5 presents the proportion of participants reporting having friends who vape, stratified by age group. Social exposure was slightly higher among older adolescents, with 43.8% of participants aged 15–18 reporting friends who vape compared to 33.3% in the 12–14 age group. In both groups, the majority of participants reported not having friends who vape (66.7% and 56.2%, respectively).

Fig. 6 reports the distribution of participants according to e-cigarette experimentation status by age group. Most participants reported never having used e-cigarettes (77.8% in the 12–14 group and 75% in the 15–18 group). A small proportion reported prior experimentation (22.2% and 25%, respectively).

C. Knowledge Acquisition and Awareness

Fig. 7 presents pre-test and post-test scores related to participants' knowledge and awareness of e-cigarettes and nicotine effects. Pre-test scores ranged from 23% to 41%, while post-test scores ranged from 75% to 85%.

Descriptive analysis shows an increase in post-test scores compared to pre-test scores. Given the exploratory design of the study, the small sample size (N=25), and the absence of a control group, these results should be interpreted as preliminary descriptive changes rather than evidence of intervention effectiveness.

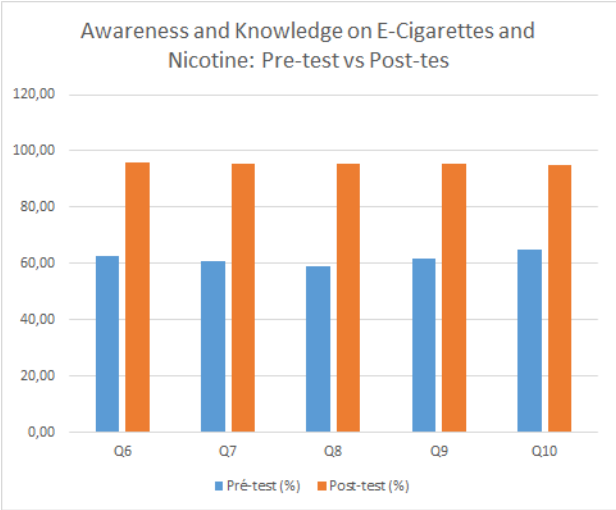

Fig. 7. Changes in awareness and knowledge about e-cigarettes and nicotine before and after intervention.

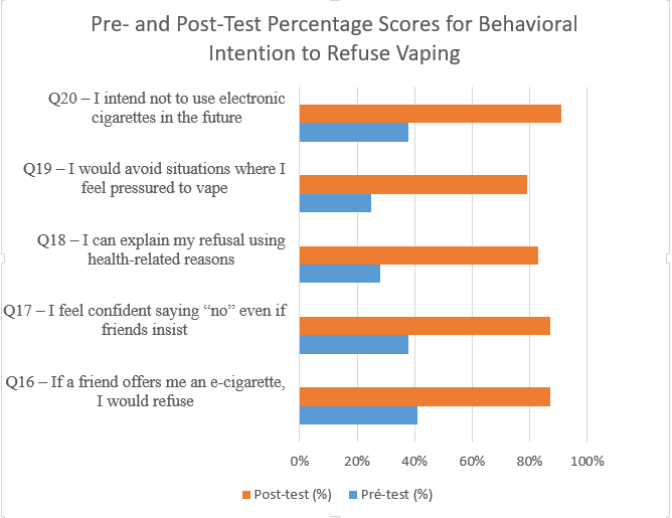

Fig. 8. Pre- and post-test percentage scores for behavioral intention to refuse vaping.

D. Behavioral Intention and Resistance to Peer Pressure

Fig. 8 presents pre- and post-test scores for participants' behavioral intention to refuse vaping in socially challenging situations. Scores increased from 25–41% at pre-test to 79–91% at post-test.

These results indicate higher post-intervention scores in behavioral intention measures. Given the exploratory design of the study, these findings are reported as descriptive changes without implying causal effects.

E. Engagement, Usability, and Perceived Usefulness

Fig. 9 presents participant ratings related to engagement, usability, and perceived usefulness of the game. Scores ranged from 83% to 91% across items assessing enjoyment, realism, and educational value.

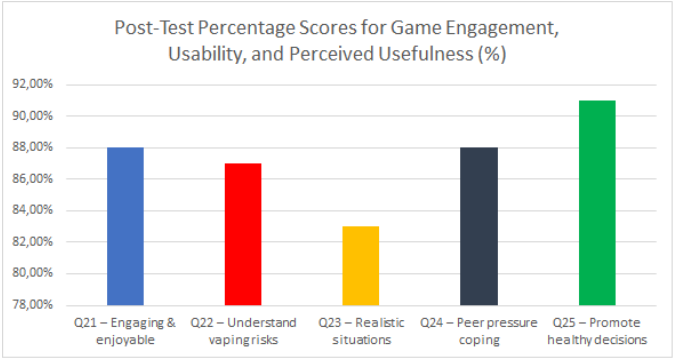

Fig. 9. Pre- and post-test percentage scores for game engagement, usability, and perceived usefulness.

These results indicate generally high self-reported engagement and perceived usefulness of the game.

F. Summary of Results

The main findings of the pilot study can be summarized descriptively as follows:

- Knowledge scores increased from 32% (pre-test) to 80% (post-test).
- Behavioral intention to refuse vaping increased from 33% to 85%.
- High levels of engagement and perceived usefulness were reported (83%–91%).

These results are reported as descriptive outcomes of a pilot exploratory study without inferential statistical testing.

G. Discussion

The pilot findings suggest that **Addict-Shield** may have potential to improve adolescents' knowledge and behavioral intentions regarding e-cigarette use. However, these findings should be interpreted cautiously due to the exploratory design of the study.

The observed increase in post-test scores are consistent with previous research on serious games for health education, which highlights the effectiveness of interactive and narrative-based learning approaches [20], [16]. Nevertheless, in the absence of a control group, it is not possible to attribute observed improvements exclusively to the intervention.

The small convenience sample (N=25) further limits generalizability, and results may not be representative of the broader adolescent population. In addition, short-term measurement prevents assessment of long-term behavioral impact.

Despite these limitations, the study demonstrates the feasibility of implementing a mobile serious game for vaping prevention in an educational context. The findings support the potential value of gamified and experiential learning approaches compared to traditional didactic methods[21][23][24].

Future research should employ randomized controlled designs with larger samples and long-term follow-up to validate the effectiveness of the intervention and strengthen causal inference.

H. Limitations

This study presents several limitations. First, the pilot evaluation relied on a relatively small convenience sample (N = 25), which limits the generalizability of the findings. Second, the absence of a control group prevents strong causal interpretation of the observed improvements. Third, the study evaluated only short-term effects immediately after gameplay and did not assess long-term behavioral retention. Future research should therefore involve larger randomized controlled trials with longitudinal follow-up and more diverse participant populations.

V. Conclusion

This pilot study demonstrates the feasibility of Addict-Shield as a structured mobile serious game for adolescent e-cigarette prevention. The DICE-based design framework enabled the integration of pedagogical objectives, narrative immersion, and gamification mechanics within a coherent learning experience.

The results indicate positive short-term changes in participants' knowledge, attitudes, and behavioral intentions following the intervention. However, given the exploratory design, small sample size, and absence of a control group, these findings should not be interpreted as evidence of effectiveness.

Rather, they suggest the potential of mobile serious games to complement traditional prevention strategies by enhancing engagement and experiential learning.

Future research should involve randomized controlled trials with larger samples and longitudinal follow-up to assess sustained impact and causal effectiveness, as well as explore adaptive personalization mechanisms.

Appendix

This appendix presents the complete questionnaire used in the pilot study to evaluate the **Addict-Shield** serious game. Appendix A to Appendix D were administered both before and after gameplay, while Appendix E was administered only after the intervention.

A. Demographic Information (Pre-test only)

1) Age:
   - 12
   - 13
   - 14
   - 15

- 16
- 17
- 18

2) Gender:
   - Male
   - Female
   - Prefer not to say
3) Have you ever tried an electronic cigarette (vape)?
   - Yes
   - No
4) Do you have friends who use electronic cigarettes?
   - Yes
   - No
5) Do you own or regularly use a smartphone?
   - Yes
   - No

B. Awareness and Knowledge About Electronic Cigarettes and Nicotine (Pre-test and Post-test)

6) Nicotine is mainly:
   - A calming substance
   - A psychostimulant
   - Harmless for teenagers
   - I don't know
7) Electronic cigarettes may contain toxic substances harmful to health.
   - True
   - False
   - I don't know
8) Using electronic cigarettes during adolescence can increase the risk of addiction later in life.
   - True
   - False
   - I don't know
9) Flavored electronic cigarettes are designed to attract young users.
   - True
   - False
   - I don't know
10) Nicotine can affect brain development in adolescents.
    - True
    - False
    - I don't know

C. Stress and Emotion Regulation Without Substance Use (Pre-test and Post-test)

Responses are rated on a 5-point Likert scale (1 = Strongly disagree, 5 = Strongly agree).

11) I am able to manage stress without vaping or smoking.
12) I know healthy ways to calm myself when I feel anxious (e.g., breathing, relaxation).
13) Using nicotine is not necessary to reduce stress.
14) I feel confident in my ability to control my emotions.
15) Stress can be managed effectively without addictive substances.

D. Behavioral Intention to Refuse Vaping in Social Situations (Pre-test and Post-test)

Responses are rated on a 5-point Likert scale (1 = Strongly disagree, 5 = Strongly agree).

16) If a friend offers me an electronic cigarette, I would refuse.
17) I feel confident saying "no" even if my friends insist.
18) I can explain my refusal using health-related reasons.
19) I would avoid situations where I feel pressured to vape.
20) I intend not to use electronic cigarettes in the future.

E. Game Engagement, Usability, and Perceived Usefulness (Post-test only)

Responses are rated on a 5-point Likert scale (1 = Strongly disagree, 5 = Strongly agree).

21) The game was engaging and enjoyable.
22) The game helped me better understand the risks of vaping.
23) The situations presented in the game felt realistic.
24) The game helped me learn how to deal with peer pressure.
25) I think this game can help adolescents make healthier decisions.

MILP for Multimodal Urban Transport: Formal and Informal Sectors

***Abstract*—This study presents a mixed-integer linear programming (MILP) formulation for optimizing multimodal urban transportation networks that integrate formal and informal public transport sectors. Whereas prior optimization approaches have predominantly addressed regulated formal services, the proposed model explicitly incorporates informal operators prevalent in many African cities. The objective is to minimize total user travel time, comprising in-vehicle time, waiting time at stops, and transfer time between modes, subject to flow conservation constraints, limits on mode changes, and sector-specific operational rules. Under the assumption of static demand and known arc travel times, computational experiments use realistic synthetic instances calibrated to reflect operating characteristics of the operators providing public transport services in Abidjan, Côte d'Ivoire—informed by close observation of non-public operational patterns and published mobility statistics—with 5 to 24 logical stops and up to 2,487 active arcs. Compared with formal-only system configurations, the integrated formal–informal formulation reduces total travel time by up to 53% on the largest tested instances (24 stops; with smaller gains on smaller networks). All instances were solved with IBM CPLEX 22.11; maximum solve times were 1.63 s on corridor instances ($n \leq 24$) and 0.69 s on an extended set with $n \leq 100$ (Intel Core i7, 16 GB RAM). These findings indicate that coordinated planning of formal and informal transport can materially improve urban mobility in developing cities.**

I. Introduction

In less-developed countries, particularly in sub-Saharan Africa, urban transportation systems face unprecedented challenges driven by rapid urbanization, population growth, and increasing mobility demands. Cities in Africa are experiencing rapid urbanization, with many metropolitan areas growing at annual rates of approximately 3–5% [1]. This growth has created complex mobility ecosystems where formal and informal transportation modes coexist in a delicate, often uncoordinated balance. Understanding and optimizing these hybrid multimodal systems represents one of the most critical challenges in contemporary transportation planning and operations research.

Public transportation systems in African cities often exhibit a dual structure, comprising both formal and informal sectors that coexist and complement each other. The formal transport sector comprises government-regulated bus services, rail systems, water transport, and Bus Rapid Transit (BRT) corridors, which operate scheduled services with fixed routes and designated stops. In contrast, the informal sector encompasses unregulated operators such as minibus taxis, shared taxis (matatus, dala dalas, tro tros), motorcycle taxis (boda bodas, okadas), and three-wheeler rickshaws (salonis, kekes), among other modes [2], providing flexible, on-demand services without fixed schedules or designated stops, responding directly to passenger requests.

The dual structure of formal and informal transport sectors is particularly pronounced in sub-Saharan African cities, where informal transportation often dominates the urban mobility landscape. Public transportation plays a crucial role in urban mobility, particularly in large African cities where rapid urbanization and limited formal transport infrastructure have led to the emergence of extensive informal transport networks [3]–[7].

To illustrate the significance of informal transport in this context, Table I presents a comparative analysis of modal shares across five major African cities: Abidjan (Côte d'Ivoire), Dakar (Senegal), Lagos (Nigeria), Kinshasa (Democratic Republic of Congo), and Niamey (Niger). The data, compiled from studies conducted by urban mobility authorities and research institutions, reveals several key patterns. First, informal transportation accounts for a substantial proportion of urban trips, ranging from 20% in Niamey to 60% in Lagos. Second, formal public transportation represents a relatively small share, typically between 5% and 15% of total trips. Third, walking remains a significant mode of transport, particularly in Niamey, where it accounts for 70% of trips. These statistics underscore the critical importance of incorporating informal transport into urban mobility optimization models for African cities.

This study addresses the optimization of multimodal urban transportation networks by explicitly modeling both formal and informal transport sectors within a unified mathematical framework. A mixed-integer linear programming (MILP) model is proposed that minimizes total user travel time, accounting for in-vehicle time, waiting time at stops, and transfer time between modes. The model incorporates operational constraints specific to each sector, including flow conservation, limits on mode changes, and sector-specific infrastructure rules.

The remainder of the study is organized as follows: Section II reviews related work on multimodal transport optimization. Section III describes the problem setting and distinctive features of formal–informal systems. Section IV presents the mathematical formulation (assumptions, parameters, decision variables, objective function, and constraints). Section V

TABLE I. COMPARISON OF MODAL SHARES OF URBAN TRANSPORT IN FIVE AFRICAN CITIES

Transport Mode	Abidjan	Dakar	Lagos	Kinshasa	Niamey
Walking	9%	23%	18%	25%	70%
Informal transportation	45%	52%	60%	50%	20%
Formal transport	14%	12%	10%	15%	5%
Individual taxi	6%	5%	7%	5%	3%
Two-wheelers	3%	2%	4%	5%	2%
Other	23%	6%	1%	–	–

presents the formulation of the model. Section VI provides a theoretical analysis of the model. Section VII to Section X report computational experiments, results, sensitivity analysis, and comparison with related studies. Section XI discusses limitations and scalability. Section XII concludes and outlines future research.

II. LITERATURE REVIEW

For over 50 years, the Transit Network Design Problem (TNDP) [8] has been an important topic of operations research and transportation planning. The main goal of the TNDP is to find the best set of transit routes and their service frequencies that will make the system work, as well as possible, while still meeting operational and resource limits [8], [9].

The mathematical formulation of TNDP usually has decision variables for choosing a route, setting a frequency, and sometimes scheduling vehicles. Some of the limits are the budget, the size of the fleet, the need to meet demand, and the quality of service. Exact techniques [8], [9], heuristic and metaheuristic methods [10]–[13] are some of the ways to solve TNDP.

The optimization of multimodal transportation systems has received substantial attention in the operations research literature. This section offers a critical evaluation of pertinent contributions, emphasizing gaps that motivate the present study.

Drummond et al. [14] examined organizational issues in multimodal air freight systems, concentrating on the dynamics of supply and demand. Their research focuses on forecasting modal distribution and reducing expenses in freight transportation. Nonetheless, the study does not provide a comprehensive analysis of passenger multimodality and arrival time forecasting.

Pawel et al. [15] suggested a mixed linear programming method to improve supply chains from the point of view of logistics providers who use more than one mode of transportation. Their model takes into account resources, inventory, and transportation parameters, which means it has a lot of room for cost savings. But it doesn't include all the many ways that passengers can get about in its full route planning.

Gonzalez et al. [16] proposed a data-driven methodology for assessing multimodal public transport networks, emphasizing travel chaining and spatial similarity analysis. This method gives useful information about how people move around, but it doesn't take into account the limitations of different types of transportation, which makes it less useful for planning multimodal transportation.

Akinlo Mogbojuri et al. [17] used linear programming to set up the schedules for Bus Rapid Transit (BRT) systems in Lagos. This cut down on wait times, but it didn't fully take into account how demand changes from day to day. Their method could help with traffic management, but it doesn't take into account the problems that come with integrating different modes of transportation.

Ma et al. [18] put forward a schedule optimization model that takes into account how many people want to travel at different times and how long it takes to get from one stop to another. The goal is to get as many passengers as possible by using a preference-based passenger selection model. Nonetheless, the study insufficiently tackles obstacles peculiar to urban mobility.

Sezgin et al. [19] used linear goal programming to improve bus frequencies and fleet size in Antalya. This cut down on wait times and kept operating costs in check. Even if it is relevant, the approach does not take into account changes in demand or problems in integrating several modes of transportation.

Das Gupta et al. [20] devised a two-stage linear programming model to make the Shanghai metro system's schedules more energy-efficient. They did this by using braking energy, which improved efficiency by more than 19%. But their approach is based on linearized demand functions and doesn't take into account how to combine different modes of transportation.

Berhan [21] developed a linear programming model for assigning buses to routes in Addis Ababa across four time shifts. The model optimizes fleet use under fixed demand assumptions. Its application is constrained by its neglect of urban mobility-specific limitations and multimodal integration.

In the context of multimodal urban transit coordination, Huang et al. (2022) [22] develop a two-stage framework combining user equilibrium passenger assignment with a bi-objective MILP to synchronize subway and bus timetables across a double-layer network, validated on Beijing's system with real AFC data. Their results demonstrate a 32.6% improvement in intermodal transfer synchronization during peak hours with negligible service quality loss, underscoring the potential of integrated timetable optimization across transit modes.

Addressing operational efficiency within urban rail networks, Eslami et al. (2025) [23] propose a real-time timetable optimization model that jointly considers skip-stop strategies, train speed profile selection, and stochastic passenger demand across multiple synchronized metro lines, solved via a multi-agent deep reinforcement learning algorithm. Applied to Tehran's metro, the approach yields cost reductions of up

to 14.9% through speed profile optimization, highlighting the benefits of adaptive, network-level scheduling — though the framework remains limited to rail and does not extend to bus or other feeder modes.

Behiri, Ozturk, and Belmokhtar-Berraf [24] study urban freight transport by rail: they exploit existing suburban rail infrastructure to move goods instead of relying solely on road haulage. The study identifies several urban-freight decision problems and focuses on a commuter line where each station may serve as a loading/unloading platform and commodity flows ("boxes") with known origin–destination pairs must be scheduled over the day. The authors formulate a MILP whose primary objective is to minimise total waiting time of deliveries subject to operational constraints. Reported experiments indicate that moderate-size instances are solved in very short CPU times; the illustrative scale in our table (ten stations, $\sim$2.3 s order of magnitude) reflects that regime. The model is rail-centric and does not integrate road, water, or informal services; it therefore supports our positioning that prior MILP work often emphasises a single mode or formal infrastructure, whereas our formulation explicitly couples formal and informal options in one optimisation model.

Mnif and Bouamama [25] present a multi-objective mixed-integer formulation for multimodal transportation network planning, at the IEEE International Conference on Service Operations and Logistics, and Informatics (SOLI, 2017). The work targets strategic or tactical design of multimodal networks and balances several performance criteria—in line with the "cost & efficiency" positioning in our comparative table—rather than a single user-centric travel-time objective. Their setting is representative of moderate-size synthetic or stylised instances (the companion table cites runs on the order of a few seconds and networks with up to about fifteen stops), which is smaller in scale than the experimental instances evaluated in this study (5 to 24 stops). Methodologically, the study belongs to the stream of multi-objective MILP models for multimodal systems; it therefore offers a useful contrast to our single-objective travel-time minimisation under explicit formal–informal flows, and could be cited when discussing future multi-objective extensions (time, cost, emissions) mentioned in our conclusion.

EDI et al. [26] developed a mixed-integer linear programming (MILP) framework to enhance formal public transportation systems in urban environments. While their approach effectively tackles formal transport optimization, it fails to include the informal sector, which is prevalent across several emerging cities.

A prevalent weakness in these research is their singular emphasis on formal transport systems or single-mode optimization, overlooking the integration of informal transport sectors that are essential to urban mobility in developing countries. The present study addresses this gap through a single MILP formulation that explicitly models both formal and informal transportation sectors.

III. Problem Description

Optimizing multimodal urban transportation systems is critical in developing cities where formal and informal services coexist. The problem addressed here consists of determining a minimum-time itinerary for a user traveling from origin O to destination D on a public transit network that may include both formal and informal modes.

The two types of transportation have different ways of working. The formal sector is made up of legally recognized businesses that offer scheduled services with set routes and stops. People can only get on cars at certain stops that have been set up ahead of time. The informal sector is made up of unregulated businesses that offer flexible, on-demand services without set schedules or stops. They respond directly to passenger requests.

Most public transit systems include three forms of infrastructure: roads, water (lagoons), and rail. This study formulates a comprehensive mathematical model that systematically incorporates both formal and informal sectors into a cohesive optimization framework. The model is validated using empirical data from Abidjan, Côte d'Ivoire, where both transportation sectors are effectively represented and cohabit. There are structured operators providing public transport services (scheduled buses, water buses, and urban trains) in the formal sector. The informal sector offers the same types of transportation (road, water, and rail), but the operators are neither structured or regulated.

The main goal is to cut down on the amount of time users spend in the transportation network, which includes time spent in vehicles, time spent waiting at stops, and time spent switching between modes and sectors.

IV. Mathematical Formulation

This section introduces the mixed-integer linear programming (MILP) model for optimizing multimodal urban transportation networks. The model minimizes total user trip time subject to operational constraints of both formal and informal sectors. Model assumptions, parameters, and decision variables are defined first, followed by the objective function and constraints.

A. Model Assumptions

The following assumptions reflect multimodal public transportation in an urban setting:

- Assumption 1, Multimodality: Users may freely combine formal and informal transport modes.
- Assumption 2, Single choice: At each stop, a user can only select one mode and one route.
- Assumption 3, Imposed waiting: If a user arrives before the next mode's scheduled departure time, they must wait until that time.
- Assumption 4, Single change: At a given time t, only one mode change is allowed per stop.
- Assumption 5, Flexibility: The total number of mode changes depends on the selected route.
- Assumption 6, Unidirectional path: The journey follows a direct path without loops.
- Assumption 7, Infrastructure: Formal modes share designated stops; informal modes operate independently without set stops.

- Assumption 8, Uniform walking speed: All users walk at a constant speed. For access time calculations, all users walk at the same speed (for example, 5 km/h).
- Assumption 9, Cross-sectoral servitude: There is a minimum required distance between formal and informal stops, which varies according to factors such as stop size, capacity, geographic location, and other urban considerations. The model accounts for these differences without explicitly identifying their causes.
- Assumption 10, Transfer points: Connections between sectors happen at the boundaries of easement areas, which means that people have to walk between them.

B. Terminology

In this section, we clarify some key terms essential for the comprehension of the model:

- Stop: A designated point where public transportation vehicles stop so that people can get on or off.
- Mode: A specific type of public transportation that a passenger uses, like a bus, a train, or a water bus.
- Segment: A part of the network that goes from one stop to the next.
- Trip: A continuous journey that a user takes without stopping, using the transportation mode. It can have one or more segments.
- Itinerary: A complete sequence of trips allowing a user to travel from an origin to a destination, possibly using more than one mode of transportation.
- Formal sector: The regulated transportation sector where all operators are officially registered enterprises that are subject to public regulation. Scheduled buses, light rail (metro), and water shuttles are some examples.
- Informal sector: The part of the transportation industry that isn't regulated and where people or unregistered businesses undertake commercial transportation services. Gbaka, Wôrô wôrô, Warren, Trotro, and Danfo are all examples from Africa.

C. Model Parameters

In Table II, we introduce the main parameters of the model.

D. Decision Variables

The following binary decision variables, in Table III, are used to formulate the constraints and objective function.

All decision variables are binary: $X_{ij}^k, Y_i^{k,k'}, W_i^{k,k'} \in \{0,1\}$ for all admissible indices. The variables X_{ij}^k select at most one mode per arc; $Y_i^{k,k'}$ indicate a mode change (and associated waiting) at stop i; and $W_i^{k,k'}$ record a cross-sector transfer when modes k and k' belong to different sectors. Constraint (11), Constraint (12) to Constraint (13), and Constraint (14) couple these variables so that waiting and sector-transfer times are activated only when consecutive arcs use different modes (and, for W, different sectors).

TABLE II. MAIN MODEL PARAMETERS

Symbol	Description
N	Set of stops.
K	Set of modes of transportation.
F	All transport sectors.
o, d	Point of departure and point of arrival.
$Change_{Max}$	Maximum number of mode changes allowed.
$t_{i,j}^k$	Time spent in the vehicle on the journey from stop i to stop j using mode k.
$u_i^{k,k'}$	Waiting time for mode change from mode k to mode k' at stop i.
$\gamma_i^{k,k'}$	Walking time required to transfer from mode k to mode k', and between sectors, at stop i.
$Z^{k,\bar{f}}$	Parameter equal to 1 if mode k belongs to the informal sector.
$Z^{k,f}$	Parameter equal to 1 if mode k belongs to the formal sector.

TABLE III. DECISION VARIABLES

Variable	Description
X_{ij}^k	Binary variable equal to 1 if the edge segment (i,j) is used with transport mode k, and 0 otherwise.
$Y_i^{k,k'}$	Binary variable equal to 1 if the user at stop i has changed mode from k to k', and 0 otherwise.
$W_i^{k,k'}$	Binary variable equal to 1 if there is a change of mode and a change of sector from k to k' at stop i, and 0 otherwise.

V. FORMULATION OF THE MODEL

A. Objective Function

The objective is to minimize the total travel time for users, which comprises three components [see Eq. (1)]:

$$\min Z = Z_1 + Z_2 + Z_3 \tag{1}$$

where, Z_1 represents the total time spent in vehicles, Z_2 represents the total waiting time at stops for connections, and Z_3 represents the total transfer time between sectors, with Eq. (2) and Eq. (3):

$$Z_1 = \sum_{i\in N}\sum_{j\in N}\sum_{k\in K} X_{i,j}^k \cdot t_{i,j}^k \tag{2}$$

$$Z_2 = \sum_{i\in N}\sum_{k\in K}\sum_{k'\in K} Y_i^{k,k'} \cdot u_i^{k,k'} \tag{3}$$

Taking the informal sector into account introduces possible changes between sectors (formal $\leftrightarrow$ informal). These transitions, constrained by formal stops, require walking between stops in different sectors. This additional time is modeled by Eq. (4):

$$Z_3 = \sum_{i\in N}\sum_{k\in K}\sum_{k'\in K} W_i^{k,k'} \cdot \gamma_i^{k,k'} \tag{4}$$

where, $\gamma_i^{k,k'}$ represents the transfer time between modes k and k' from different sectors at stop i.

B. Constraints

The constraints of the model are represented as follows:

- Single mode transportation by segment.

$$\sum_{k \in K} X_{i,j}^k \leq 1 \qquad \forall i,j \in N \times N \tag{5}$$

Constraint (5) limits the user to selecting only one mode of transport $k \in K$ for each segment $[i,j]$ travelled, from among several modes available on that section.

- Changing modes

$$\sum_{k \in K} X_{i,j}^k + \sum_{k \in K} X_{j,h}^k \leq 2 \qquad \forall i,j,h \in N \times N \times N \tag{6}$$

Eq. (6) expresses the possibility for the user to arrive at a stop j using a mode of transport k, then select another mode of transport K' to continue the journey. Typically, the mode used on segment $[i,j]$ may differ from that used on segment $[j,h]$. The upper bound of 2 of the constraint ensures that at most two modes are involved in a user's arrival and departure at a stop.

- Flow conservation

Let o be the departure stop user's and d the destination stop of the user:

$$\sum_{j \in N} \sum_{k \in K} X_{o,j}^k = 1 \tag{7}$$

$$\sum_{i \in N} \sum_{k \in K} X_{i,j}^k = \sum_{i \in N} \sum_{k \in K} X_{j,i}^k \qquad \forall j \in N \tag{8}$$

$$\sum_{j \in N} \sum_{k \in K} X_{j,d}^k = 1 \tag{9}$$

Eq. (7) to Eq. (9) enforce continuity, contiguity, and completeness of the user's journey through classic flow conservation:

- A unit flow departs from the origin o [Eq. (7)], ensuring entry into the network.
- Incoming and outgoing flows balance at all intermediate nodes [Eq. (8)], ensuring progress through the network.
- A unit flow arrives at the destination d [Eq. (9)], ensuring exit from the network.
- Capacity constraints

$$\sum_{i \in N} \sum_{k \in K} \sum_{k' \in K} Y_i^{k,k'} \leq Change_{Max} \tag{10}$$

The capacity constraint in Eq. (10) limits the number of possible mode changes in the model. This number is represented by the system parameter $Change_{\max}$. This parameter can be adjusted as needed depending on the size of the network.

- Constraint linking X and Y variables.

$$\sum_{i \in N} X_{i,j}^k + \sum_{h \in N} X_{j,h}^{k'} \leq 1 + Y_j^{k,k'} \qquad \forall j \in N,\ \forall k,k' \in K \times K,\ k \neq k' \tag{11}$$

Constraint (11) links the X variables (travel on arcs) to the Y variables (waiting at stops). A wait at stop j is possible only when arrival and departure segments at j use different modes.

- Cross-sector transfer constraints

$$W_j^{k,k'} \geq Y_j^{k,k'} + Z^{k,\bar{f}} + Z^{k',f} - 2 \qquad \forall j \in N,\ \forall k,k' \in K \times K \tag{12}$$

$$W_j^{k,k'} \geq Y_j^{k,k'} + Z^{k,f} + Z^{k',\bar{f}} - 2 \qquad \forall j \in N,\ \forall k,k' \in K \times K \tag{13}$$

These equations [Constraint (12) and Constraint (13)] model the changes from formal to informal and informal to formal, respectively.

- Constraint linking W and Y variables.

$$\sum_{k \in K} \sum_{k' \in K} W_j^{k,k'} \leq Y_j^{k,k'} \qquad \forall j \in N,\ \forall k,k' \in K \times K \tag{14}$$

Constraint (14) links changes to the corresponding waiting times.

VI. Model analysis

The suggested model offers a robust method for optimizing multimodal urban transport systems, particularly in developing nations where formal and informal transport coexist. It is founded on a mixed-integer linear programming (MILP) concept, presenting a systematic and rigorous approach to tackling the issues associated with multimodal transportation. The key components of the model are delineated below.

A. MILP Formulation and Flow Constraints

The model's core is its MILP formulation, which is especially adept at addressing the complexity and combinatorial aspects of multimodal transport optimization. The model guarantees continuity within the transportation network through flow conservation constraints. These constraints streamline the mathematical framework and enhance computational efficiency by narrowing the search space to feasible paths.

- Flow conservation: The model enforces flow conservation at the origin, intermediate stops, and destination. This guarantees that the user enters, traverses, and exits the network consistently, mirroring actual trip structure.
- Simplification through structure: The implementation of flow constraints streamlines the problem formulation, rendering it both computationally feasible and conceptually clear. This simplicity facilitates expansion while preserving the necessary flexibility to manage intricate multimodal scenarios.

B. Applicability to Multimodal Transport Systems

The model's primary strength lies in its broad application to various multimodal transport networks. The model, while developed with data from Abidjan, Côte d'Ivoire, is fundamentally adaptable to many metropolitan environments and transportation systems. The primary characteristics are as follows:

- Flexibility for different modes of transport: The model accommodates several transport modes, encompassing both formal and informal sectors, including road and lagoon possibilities. This adaptability guarantees its pertinence across diverse urban landscapes.
- By restricting mode alterations and enhancing transitions, the model can accommodate medium to large networks without considerable degradation in computing performance.
- Structured and formal design: The emphasis on formal and informal transportation modalities facilitates the establishment of a clear and dependable optimization framework. This methodology addresses the demand for systematic solutions in emerging urban areas.

C. Simplicity and Practical Applicability

The model achieves an equilibrium between mathematical precision and practical relevance. The straightforward design, enabled by clearly delineated parameters, variables, and constraints, promotes implementation. The incorporation of waiting times, mode-change limits, and operational constraints increases applicability in practical situations.

- User-centered objective: The emphasis on reducing overall journey time demonstrates a user-centered approach, consistent with the core aim of enhancing public transportation efficiency and user experience.
- Operational feasibility: The incorporation of pragmatic assumptions, including mode change constraints and predetermined stops, guarantees that the model accurately reflects the operational attributes of both formal and informal transportation systems.

D. Potential for Expansion

The model, while currently tailored for transportation systems in developing cities, possesses a modular design that offers a robust basis for future improvements. For instance:

- Incorporation of transportation expenses: Subsequent iterations may enhance the model by integrating both formal and informal transportation cost alternatives, so broadening its scope and relevance to hybrid systems.
- Advanced optimization strategies, including cut generation and boundary tightening, could enhance computational performance, enabling the model to manage larger networks.

In summary, the suggested model, utilizing the MILP approach, offers a flexible, scalable, and computationally efficient framework for optimizing multimodal transportation systems. Utilizing flow constraints, the model streamlines the problem, while preserving its adaptability and relevance across diverse situations. The simplicity, coupled with its robust mathematical base, renders it an invaluable instrument for urban transportation planning, especially in developing cities aiming to enhance the efficiency of their formal transportation systems.

VII. Computational Experiments and Data

A. Experimental Setup

The integrated MILP was implemented in Python and solved with IBM ILOG CPLEX Optimizer version 22.11 [27]. All computational experiments reported in this study use CPLEX on a workstation with an Intel Core i7-8650U CPU (2.11 GHz) and 16 GB of RAM. The model's multimodal characteristics are evidenced by the incorporation of diverse road transport modes and lagoon transport services.

B. Data Sources and Characteristics

Calibration of the computational experiments combined published mobility information for Abidjan [3], [28] with detailed scrutiny of how operators providing public transport services in the city conduct scheduled operations in practice. Access to non-public operational material was facilitated through a confidentiality agreement with the Information and Applications Research Team (ERIA). Observations drawn from that context (e.g., service structure, stop spacing, segment speeds over a multi-month horizon in 2023) were used solely to estimate distributional ranges for synthetic instance generation; no operator-identifying dataset is reproduced here, and the MILP is not solved on a published operational network graph.

The calibration for formal-sector operators providing public transport services reflects five mode types, heterogeneous stop spacing across lines, and urban link speeds up to 60 km/h, as inferred from those observations. Empirical ranges and moments were derived for segment travel times, inter-stop distances, and connection waiting. Informal-sector parameters (flexible stops, sector-specific transfer penalties $\gamma_i^{k,k'}$) were set from the same published Abidjan mobility sources and expert

judgment, because comparable operational traces for informal operators were not available under the same ERIA-mediated access regime.

C. Instance Generation

An instance generator based on Python was created to produce test instances that emulate real-world operating characteristics. The generator yields the subsequent parameters:

- `Time_mode`: Duration of in-vehicle travel for a user utilizing a certain mode of transport (minutes)
- `Time_wait`: Duration of waiting at stops for connections (minutes)
- `Number_mode`: Count of available transport modes
- `Number_change`: The maximum permissible mode changes within the network.
- `Number_stop`: The total number of stops permitted for the journey.

The generator draws parameters from uniform or truncated-normal distributions whose support was calibrated to empirically informed statistics (minimum, maximum, mean, and standard deviation of segment times and stop spacing). For each synthetic instance, arc travel times, waiting times, and the number of active arcs are sampled independently subject to network size and $Change_{Max}$. Representative calibrated ranges are:

- Travel time (`Time_mode`): uniform on $[2, 15]$ minutes (consistent with in-vehicle segment durations observed among operators providing public transport services in Abidjan)
- Waiting time (`Time_wait`): uniform on $[0, 30]$ minutes at connection stops
- Number of stops: instances with 5, 10, 15, 20, or 24 stops
- Maximum mode changes ($Change_{Max}$): 5 or 10 per instance family
- Number of modes: fixed at five (formal and informal variants per infrastructure type)

Each row in Table IV corresponds to ten random instances per ($Change_{Max}$, stop count) combination, for a total of 100 solved instances.

Table IV summarizes the characteristics of the instances. The columns denote: (1) #Stops: the number of stops per instance, (2) #Var. Total: total number of decision variables, (3) #Var. Bin.: number of binary variables, (4) #Cont: total number of constraints, (5) #Arcs: number of arcs within the interval [min, max], (6) #Inst. (ch max=5): number of instances with a maximum of 5 mode changes, and (7) #Inst. (ch max=10): number of instances with a maximum of 10 mode changes.

The dataset illustrates the model's scalability across various problem sizes. The complexity of the instance increases polynomially with the number of stops, as seen by the rising quantity of variables and constraints. The existence of cases with two distinct maximum change values (5 and 10) facilitates comparative performance evaluation under differing flexibility limitations.

D. Data Validation

Model validation was performed via a rigorous methodology. A meticulously selected test dataset was produced utilizing statistical techniques that guarantee distributions reflective of real-world scenarios. The preprocessing stages encompassed data normalization and cleansing to guarantee data quality and pertinence. Established performance criteria were utilized to assess the model on the test set, contrasting the results achieved with established optimal values when applicable.

The validation method confirmed the model's robustness and laid the groundwork for subsequent study. The validated model was then exercised on synthetic Abidjan-style network instances, producing findings that illustrate practical applicability for corridor-level urban transportation planning.

VIII. Computational Results

This section analyzes computational results from solving the proposed MILP model, focusing on the relationship between processing time and problem size (number of stops, active arcs, maximum mode transitions, and proportion of forbidden arcs).

A. Effect of Model Complexity

The duration of processing demonstrates a significant positive link with the complexity of the challenge. Instances with a greater number of stops, active arcs, and elevated maximum mode change limitations necessitate extended computation durations. The quantity of binary variables and constraints directly influences computing effort, as the solver is required to navigate an exponentially bigger solution space. This relationship is anticipated in mixed-integer programming, where the magnitude of the problem substantially affects solution time.

B. Influence of Network Size and Mode Change Limits

Fig. 1 depicts the correlation between processing duration and network attributes. The mean calculation duration increases with the quantity of stops for each value of $Change_{Max}$. This tendency is more evident when $Change_{Max} = 10$, suggesting that the increased flexibility in mode changes significantly broadens the solution space compared to $Change_{Max} = 5$.

With $Change_{Max} = 5$, the augmentation in processing time relative to the network size is less pronounced, indicating that restricting the mode changes has computational advantages, while possibly limiting solution quality. Scenarios with an increased number of stops invariably necessitate extended processing durations, irrespective of the maximum mode change limit. These observations underscore the necessity of judiciously choosing $Change_{Max}$ in accordance with problem-specific attributes and computing resource limitations.

TABLE IV. INSTANCE CHARACTERISTICS FOR FORMAL AND INFORMAL TRANSPORT SECTORS

#Stops	#Var. Total	#Var. Bin.	#Cont	#Arcs [min, max]	#Inst. (ch max=5)	#Inst. (ch max=10)
5	375	375	689	[60, 90]	10	10
10	1,000	1,000	2,224	[269, 405]	10	10
15	1,875	1,875	5,359	[637, 947]	10	10
20	3,000	3,000	10,844	[1,137, 1,709]	10	10
24	4,080	4,080	17,428	[1,663, 2,487]	10	10

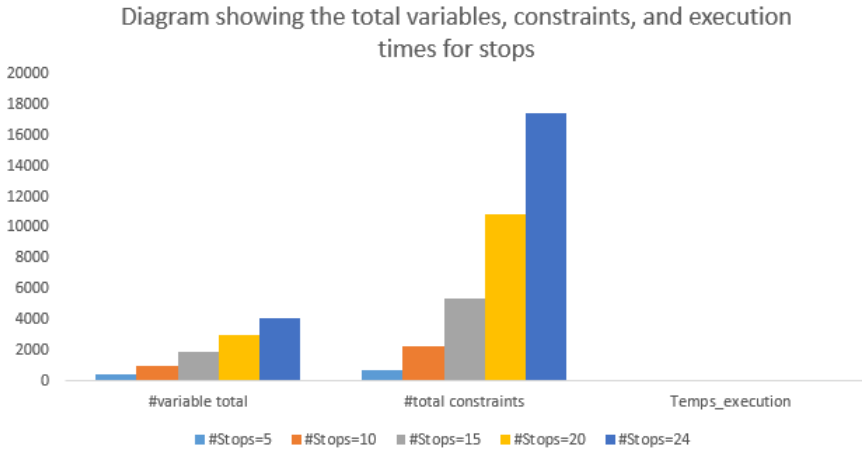

Fig. 1. Execution time and active arcs versus number of stops.

TABLE V. CHARACTERISTICS OF GENERATED INSTANCES AND CORRESPONDING CPLEX SOLVE TIMES (22.11, SAME HARDWARE AS SECTION VII-A)

Instance Family	#Stops	#Modes	#Change_max	%Forbidden Arcs	#Arcs Active	Process Time (seconds)
1	5	5	5	10	90	0.483
2	5	5	10	15	85	0.515
3	10	5	5	69	381	0.918
4	10	5	10	45	405	0.871
5	15	5	5	103	947	1.325
6	15	5	10	158	892	1.437
7	20	5	5	191	1,709	2.409
8	20	5	10	286	1,614	2.681
9	24	5	5	273	2,487	4.449
10	24	5	10	414	2,346	4.068

C. Processing Time Analysis

Table V summarizes computational results for instances of different complexity levels. The data shows clear relationships between the problem characteristics and the processing time.

The following key trends emerge from the analysis.

- Network size effect: Processing time increases with the number of stops and the number of active arcs. Larger instances with more arcs require greater computational resources, with processing time scaling approximately linearly with network size (see Figure 1).
- Mode change flexibility: Increased maximum permitted mode changes ($Change_{Max}$) broaden the solution space, leading to longer computation times. The effect is more pronounced for larger networks.
- Forbidden arcs: An increased proportion of prohibited arcs diminishes the feasible solution space while augmenting constraint complexity, resulting in variable processing times contingent upon the particular arc arrangement.

Fig. 1 illustrates that the processing time increases almost linearly with the number of stops and active arcs, signifying favorable scalability for medium-sized issue situations. This linear relationship suggests the model remains computationally tractable for practical urban transportation networks.

D. Comparative Performance Analysis

Fig. 2 compares execution times across different model configurations, illustrating how various parameter combinations affect computational performance. The analysis reveals that parameter interactions significantly influence solution time, with certain combinations leading to more efficient problem-solving.

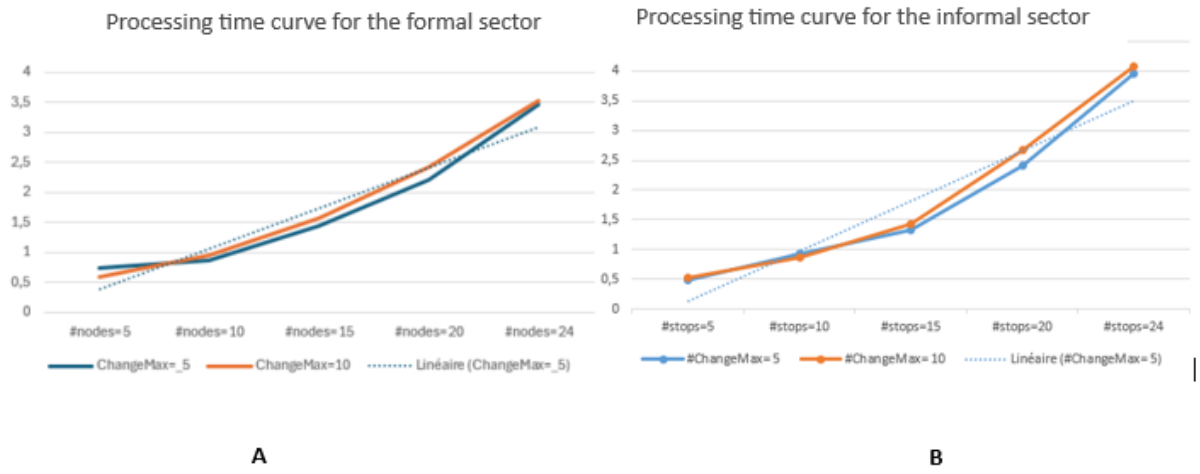

Fig. 2. Comparison of execution times across different model configurations.

IX. Sensitivity Analysis

This section reports sensitivity analysis on the impact of key parameters on MILP solution time, including $Change_{Max}$ (maximum mode changes), the number of modes, the number of stops, the percentage of forbidden arcs, and the number of active arcs.

A. Impact of Maximum Mode Changes

Increased $Change_{Max}$ significantly impacts processing time by broadening the feasible solution space. This effect is observed in instances with 5, 10, 15, and 20 stops. In small instances (5 stops), increasing $Change_{Max}$ has minimal impact on processing time, as the solution space remains tractable. For larger instances (15-24 stops), higher $Change_{Max}$ values resulted in significant increases in computation time, with processing time nearly doubling when $Change_{Max}$ grows from 5 to 10 for 24-stop instances.

This observation indicates that although increased mode changes flexibility improves solution quality, it incurs a computational cost that rises exponentially with network size. Practitioners must balance solution quality demands with available computational resources while setting the value of $Change_{Max}$.

B. Impact of Number of Transport Modes

The number of available transport modes directly influences model complexity by increasing the number of feasible options at each stop. Table V summarizes results for instances with 5 modes. Empirical analysis reveals that doubling the number of modes increases processing time by approximately 30-50% for medium-sized instances (10-15 stops). This moderate increase suggests that the model scales reasonably well with mode diversity, making it suitable for networks with multiple transport options.

C. Effect of Forbidden Arcs

The percentage of forbidden arcs introduces additional constraints that reduce the number of feasible routes while increasing computational complexity. The processing time exhibits variable behavior depending on the forbidden arc percentage. When the percentage of forbidden arcs exceeds 70%, the processing time increases slightly as the solver must navigate a more constrained solution space. However, moderate percentages (30-50%) can actually reduce processing time by eliminating infeasible paths early in the search process.

D. Travel Time Performance: Formal vs. Integrated Systems

Table VI presents a comparative analysis of travel time performance between formal-only and integrated (formal + informal) transport systems. The results demonstrate that combining formal and informal transport systems provides a more effective strategy for meeting urban mobility needs.

The analysis reveals significant structural limitations of formal-only transport systems in large African cities. While formal systems benefit from their organization, planning, and regulatory frameworks, they often fail to adequately serve all urban mobility needs, especially in peripheral regions or places with significant informal transit prevalence. The inflexibility of routes and sporadic service on specific lines diminish their efficacy as independent systems.

In contrast, informal transit provides flexibility, adaptability, and extensive access to underserved metropolitan regions, delivering responsive, locally tailored services. Nonetheless, in the absence of regulation, this sector experiences dependability challenges, safety issues, and insufficient alignment with overarching urban transportation objectives.

The intentional amalgamation of formal and informal transport elements into a cohesive multimodal framework mitigates these constraints. Computational results show that integrated systems reduce total journey time by up to 53% relative

TABLE VI. TRAVEL TIME COMPARISON: FORMAL-ONLY VERSUS INTEGRATED SYSTEMS

Instance Type	#Changes Max	#Stops	Objective Value	#Constraints	Reduction (%)
Formal only	5	5	23	308	–
Integrated	5	5	21	689	8.7
Formal only	5	10	16	1,463	–
Integrated	5	10	10	2,224	37.5
Formal only	5	15	16	4,218	–
Integrated	5	15	12	5,359	25.0
Formal only	5	20	19	9,323	–
Integrated	5	20	10	10,844	47.4
Formal only	5	24	19	15,603	–
Integrated	5	24	9	17,428	52.6

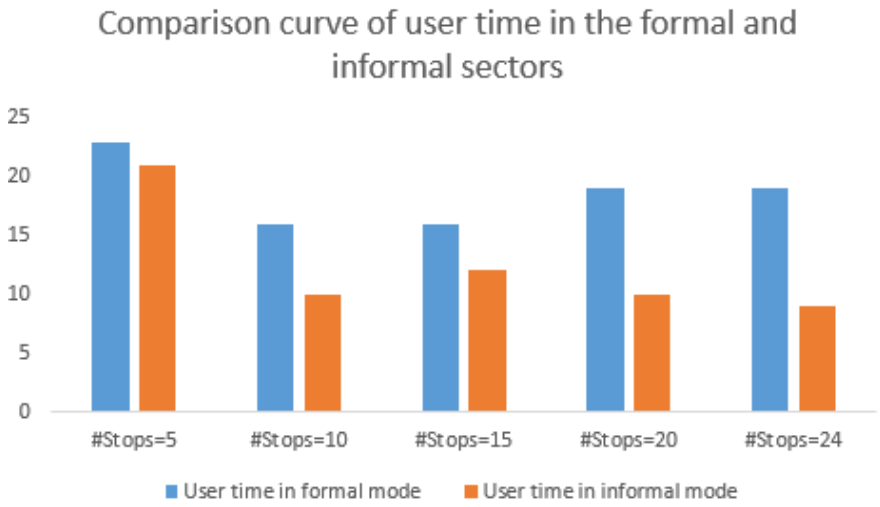

Fig. 3. Comparison of user travel time: Formal-only versus integrated (formal + informal) systems.

to formal-only configurations on the largest tested instances (24 stops; objective values 19 versus 9). Improvements are instance-dependent: for 15-stop cases the reduction is 25% (16 to 12), and Table VI reports gains between 25% and 52.6% across the tested stop counts. The headline figure of 53% therefore denotes the maximum observed improvement, not an average over all instances.

This performance enhancement arises from: 1) augmented network coverage through informal sector integration, 2) diminished waiting periods by adaptive scheduling, 3) improved accessibility to remote regions, and 4) heightened system resilience to demand variability. These findings endorse policy proposals for acknowledging and systematically incorporating informal transit into modern urban mobility planning frameworks.

Fig. 3 clearly demonstrates the performance superiority of integrated systems across various network sizes. The findings indicate steady enhancements in transit time reduction, with the advantage amplifying for more extensive networks. This study advances mathematical modeling and optimization of multimodal transport systems, while also informing broader policy debates on inclusive governance and hybrid management of transport systems in fast growing African cities.

X. COMPARATIVE ANALYSIS WITH RELATED STUDIES

This section situates the proposed MILP model relative to similar studies in the literature. The comparative analysis focuses on four key criteria: 1) model type and formulation approach, 2) optimization objective, 3) computational performance (processing time), and 4) case study complexity and scale.

A. Comparative Analysis

Table VII presents a detailed comparison with related studies. The proposed model exhibits several strengths relative to prior work.

- Travel time reduction: The integrated approach reduces total travel time by up to 53% on the largest tested instances (24 stops, 2,487 active arcs) compared with formal-only networks, and by 25–52.6% on smaller instances (Table VI). Edi et al. [26] address a related formal-sector MILP at comparable network size but without informal integration.
- Multimodal adaptability: Unlike Behiri et al. [24], who focus exclusively on rail transport, the present formulation integrates multiple transport modes (road, water, rail) from both formal and informal sectors.

TABLE VII. PERFORMANCE COMPARISON WITH RELATED STUDIES

Reference	Model Type	Optimization Criterion	Average Computation Time	Case Study Size
Proposed model	MILP with flow constraints	Total travel time	1.63 s (24 stops, 2,487 arcs)	Up to 24 stops
Edi et al. (2025) [26]	MILP with flow constraints	Total travel time	N/A (24 stops, 2,487 arcs)	Up to 24 stops
Mnif and Bouamama (2017) [25]	Multi-objective MILP	Cost and operational efficiency	3.47 s	Up to 15 stops
Behiri et al. (2016) [24]	MILP for urban rail transport	Minimized waiting time	2.3 s (10 stations, 150 arcs)	10 stations

Note. CPU times for the proposed model were obtained with CPLEX 22.11 on the hardware described in Section VII-A. Times reported for other studies used different solvers and platforms; cross-paper comparisons should be interpreted with caution.

- Computational efficiency: CPLEX solve times remain below 2 s for corridor instances up to 24 logical stops (maximum 1.63 s on the calibrated testbed), while handling explicit formal–informal sector coupling.
- Problem scale: Experiments cover corridor-level networks with up to 24 stops and 2,487 active arcs; city-wide networks would require further algorithmic development (see Section XI).

However, certain limitations and opportunities for future enhancement are identified:

- Multi-objective optimization: Unlike Mnif and Bouamama [25], our current formulation employs a single-objective function (travel time minimization). Future work could extend the model to multi-objective optimization, simultaneously considering travel time, cost, and environmental impact.
- Real-time data integration: Compared to Gonzalez et al. [16], the present formulation relies on static parameters without real-time data integration. Incorporating dynamic demand and real-time traffic conditions would enhance practical applicability.

B. Key Findings and Insights

The comparative analysis indicates that the proposed formulation offers a balanced combination of modeling transparency, computational tractability on tested instances, and relevance to developing cities where formal and informal sectors coexist.

The analysis of processing time determinants yields the following insights:

- The percentage of forbidden arcs significantly impacts processing time, as additional constraints reduce feasible solutions and increase computational effort. This relationship is consistent with theoretical expectations in constraint programming.
- While individual parameters may not show strong individual correlations, their collective interaction substantially influences computational performance. This highlights the importance of parameter optimization for efficient computation.

TABLE VIII. EXTENDED SCALABILITY EXPERIMENT (CPLEX 22.11): INTEGRATED MILP ON LARGE CALIBRATED INSTANCES ($n = 25$–100).

n	$\lvert V\rvert$	#Var.	#Constr.	Time (s)	Status
25	50	5,345	24,394	0.31	OPTIMAL
40	80	11,722	28,219	0.11	OPTIMAL
55	110	20,081	32,901	0.16	OPTIMAL
70	140	30,158	38,252	0.20	OPTIMAL
85	170	48,991	47,114	0.47	OPTIMAL
100	200	47,188	51,821	0.40	OPTIMAL

- Processing time grows with network size (Fig. 1) but remains manageable on the tested hardware for instances up to 24 stops; supplementary tests up to $n = 100$ are reported in Section XI.

XI. LIMITATIONS AND SCALABILITY

All computational results in this study were obtained with IBM CPLEX 22.11 on the workstation described in Section VII-A. The main study (Section VII to Section X) evaluates synthetic instances with 5 to 24 logical stops and up to 2,487 active arcs; the maximum observed solve time on a 1,000-instance calibrated testbed was 1.63 s. This scale is representative of sub-network or corridor planning in Abidjan but does not, by itself, demonstrate behavior on substantially larger networks. To address scalability beyond the 24-stop cap, an extended set of 100 instances was generated with the same calibration rules applied to operators providing public transport services in Abidjan, with logical stop parameters $n \in [25, 100]$ and network sizes $|V| = 2n$ (50 to 200 nodes).

Table VIII reports representative cases; all 100 runs returned an `OPTIMAL` status. Solution times increased with $|V|$ and model size but remained below 0.69 s on the largest instance ($n = 100$, $|V| = 200$, 47,188 binary variables, 51,821 constraints). Fig. 4 shows that median CPU time grows gradually with n and $|V|$ in this range, without the exponential blow-up feared for city-wide deployment at corridor scale. These results indicate that the present formulation remains tractable for medium-to-large sub-networks under static demand, while full metropolitan systems (hundreds of stops, dynamic demand) would still require decomposition, matheuristics, or rolling-horizon schemes [27].

The formulation relies on static origin–destination demand, deterministic arc travel times, and parameters fixed for the

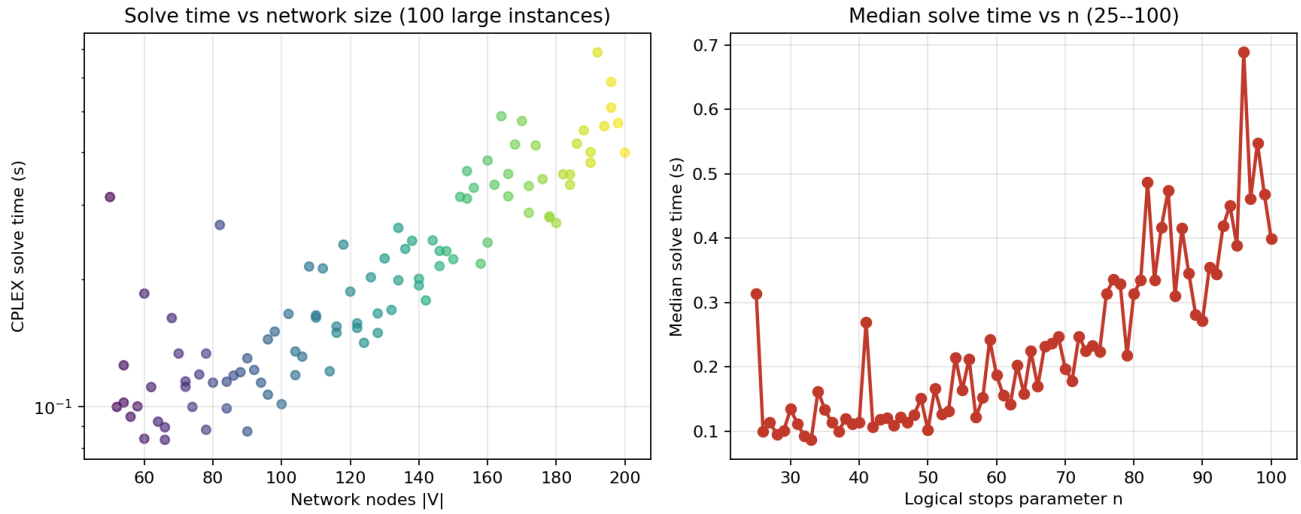

Fig. 4. CPLEX solve time versus logical stop parameter n and network size $|V|$ on 100 large instances ($n = 25$–100).

planning horizon. Extensions incorporating stochastic demand, time-dependent travel times, and real-time traffic or dispatch data would increase modeling fidelity but require additional variables, constraints, or rolling-horizon solution schemes beyond the present static MILP.

XII. Conclusion

This study presents a mixed-integer linear programming (MILP) model for optimizing multimodal urban transportation networks that explicitly accounts for both formal and informal transport sectors. The model was calibrated to operational patterns of operators providing public transport services in Abidjan and evaluated on synthetic instances, demonstrating practical relevance in developing city settings.

A. Main Contributions

The primary contributions of this research are threefold:

- Unified modeling framework: A MILP formulation integrates formal and informal transport sectors within a single optimization model, addressing a gap in the existing literature.
- Performance improvement: On synthetic instances calibrated from operators providing public transport services in Abidjan, integrated systems reduce total travel time by up to 53% relative to formal-only configurations (maximum on 24-stop cases; lower gains on smaller networks).
- Computational efficiency: CPLEX solves corridor instances ($n \leq 24$) in at most 1.63 s and an extended set with $n \in [25, 100]$ and $|V| \leq 200$ in at most 0.69 s (Section XI), while metropolitan-scale dynamic planning remains future work.

B. Key Findings

Sensitivity analysis reveals that processing time is primarily influenced by: 1) the number of stops, 2) the maximum number of mode changes allowed ($Change_{Max}$), and 3) the number of active arcs. Higher values of $Change_{Max}$ and number of modes increase computational complexity by expanding the solution space, while higher percentages of forbidden arcs tighten constraints, adding to computational complexity. Despite these challenges, the model remains solvable within seconds on the tested instance sizes, with processing time increasing with network size as expected for MILP (Section XI).

C. Future Research Directions

Several promising directions for future research are identified:

- Advanced solution techniques: Employing commercial solvers such as CPLEX [27] or Gurobi, along with specialized techniques such as cut generation and bound tightening, could improve computational efficiency for larger problem instances.
- Multi-objective optimization: Extending the model to simultaneously optimize travel time, transportation costs, and environmental impact would enhance practical relevance.
- Dynamic and stochastic elements: Incorporating real-time demand fluctuations, stochastic travel times, and dynamic network conditions would increase model applicability to operational planning.
- Cost integration: Incorporating transportation cost parameters for different routes and modes would enable comprehensive cost-benefit analysis and support policy decision-making.
- Network design extensions: Expanding the model to include network design decisions, such as stop location and route planning, would provide a more comprehensive optimization framework.

The proposed model provides a solid foundation for optimizing multimodal urban transportation systems in developing cities, where formal and informal sectors coexist. The

demonstrated performance improvements and computational tractability make it a valuable tool for urban transportation planners and policymakers seeking to enhance mobility while recognizing the complementary roles of both transport sectors.

Artificial Intelligence in Motorsport: A Scoping Review of Applications, Challenges, and Research Gaps

Radu C. Lucaciu[1], Cornelia Aurora Győrödi[2]
Doctoral School of Engineering Studies-Department of Computer Science and Information Technology, University of Oradea, Oradea, Romania[1]
Department of Computer Science and Information Technology, University of Oradea, Oradea, Romania[2]

***Abstract*—This study presents a state-of-the-art review of Artificial Intelligence and Machine Learning applications in motorsport, with a particular focus on Formula 1. As modern racing generates increasingly large volumes of high-frequency telemetry data, traditional physics-based analysis methods have proven insufficient to capture the complex, non-linear relationships between vehicle, driver, and environment. AI has emerged as a critical tool for extracting actionable insights from this data across six core domains: vehicle performance optimization, race strategy, autonomous racing and real-time decision support, telemetry and race data analysis, driver coaching and simulation, and predictive maintenance. This review further examines transferable methodologies from adjacent fields — particularly autonomous driving research — and assesses their relevance to high-performance motorsport contexts. A systematic analysis of peer-reviewed publications and preprints reveals a highly uneven distribution of research, with race strategy and vehicle optimization relatively well-covered, while predictive maintenance and computer vision applications remain largely unexplored.**

***Keywords*—Artificial Intelligence; Machine Learning; motorsport; Formula 1; scoping review; PRISMA-ScR; race strategy optimization; telemetry analysis**

I. Introduction

Recently, motorsport competition has developed substantially under the influence of technology and data-driven decisions. The current telemetry systems and high precision sensors, as well as modern and performance data collection infrastructure provide a way to collect massive volumes of data in near-real time. Different variables, ranging from engine, suspension or gearbox parameters to tyre temperature and degradation, driver behaviour or environmental temperature and pressure are collected and used for complex analysis to provide technical and strategic insights but the volume, data-generation speeds and both linear and non-linear dependencies between variables have outgrown the capabilities of traditional methods of analysis. In this context, Artificial Intelligence has emerged as an ideal tool for high performance motorsport, capable of transforming raw data into valuable insights for performance optimisation.

To ensure conceptual clarity and consistency throughout this review, the key terms used in the literature are defined here in a hierarchical manner. Artificial Intelligence (AI) is used as an umbrella term encompassing any computational method capable of extracting complex patterns, generating predictions, or making decisions based on data, including both traditional and modern approaches. Machine Learning (ML) refers to the subset of AI in which models learn from data without being explicitly programmed, covering supervised learning (e.g., regression, classification), unsupervised learning (e.g., clustering), and reinforcement learning (RL). Deep Learning (DL) is a further subset of ML that employs multi-layered neural network architectures such as convolutional neural networks (CNNs), recurrent neural networks (RNNs), and transformer-based models. Finally, the term "data-driven models" is used more broadly to include both ML-based approaches and non-ML statistical methods such as multivariate regression or principal component analysis, provided they learn relationships directly from data rather than from first-principles physics. The relationships between these terms are hierarchical: DL $\subset$ ML $\subset$ AI, while data-driven models partially overlap with ML but also include classical statistical methods. Throughout this study, the most specific applicable term is used in each context; when referring to the overall field or to studies that employ multiple approaches, the general term "AI" is used.

However, adopting AI in motorsport is not a simple process. Racing cars operate at the extreme physical limits: heavy acceleration and deceleration, massive cornering speeds and lateral G-force loads, rapid degradation of tyres and complex strategic decisions like optimal pit strategies, the correct choice of tyre compounds and even technical choices such as mechanical and aerodynamic vehicle setup. In these conditions, standard physics-based models can become too complex or expensive (e.g. CFD simulations or multi-variable analysis) and can sometimes miss non-linear correlations between various components: car, driver and environment. AI, on the other hand, is extremely versatile at detecting and extracting these patterns from vast amounts of data, offering a very pragmatic way of modeling complexity.

Formula 1 has long been considered the technological pinnacle of motorsport and it makes sense that academic research and motorsport industry have converged in multiple areas. Deep reinforcement learning has been applied to autonomous racing using telemetry data [1], sim racing telemetry has been used to predict performance with high accuracy [2], and autonomous racing projects have become real-life laboratories for testing perception, planning and control models at high speeds and variable conditions [3]. AI is no longer just a theoretical research subject: it is a mandatory tool which confers a real competitive advantage, capable of influencing various aspects of performance motorsport, from strategic choices to car setup

and even driver coaching and selection.

Despite this growing adoption, no comprehensive scoping review has systematically mapped the extent and nature of AI research across the various motorsport application domains. Existing reviews tend to focus on narrow sub-topics: Betz et al. [3] provide a thorough survey of autonomous racing but do not address race strategy, telemetry analysis, or predictive maintenance; Kuutti et al. [4] and Elallid et al. [5] survey deep learning and reinforcement learning for autonomous driving, a field adjacent to motorsport but with fundamentally different performance objectives; and Arena et al. [6] review predictive maintenance in the broader automotive sector without addressing the specific constraints of competitive racing. What differentiates the present analysis from these prior works is its cross-domain scope: rather than focusing on a single technique or application area, this review maps the full landscape of AI research in motorsport, identifies the connections between application domains, and highlights the gaps that remain unexplored. A scoping review approach, following the PRISMA-ScR framework, is particularly well-suited to this purpose given the heterogeneous body of literature available — spanning peer-reviewed journals, conference proceedings, and publicly available preprints — and the exploratory nature of the research landscape.

The primary objective of this scoping review is to systematically map the existing body of research on AI and ML applications in motorsport across defined thematic categories, providing a comprehensive overview of how these technologies are currently being applied and studied. Building on this mapping, the review further aims to identify which application domains are well-covered in the literature and which remain underexplored, to examine transferable methodologies from adjacent fields — particularly autonomous driving — and assess their relevance to high-performance motorsport contexts, and to highlight key research gaps and propose directions for future investigation.

The review is structured around the PCC (Population, Concept, Context) framework: the *Population* comprises published academic works addressing motorsport engineering, autonomous driving and competition; the *Concept* is the application of AI and ML techniques; and the *Context* is motorsport competition, with a particular focus on Formula 1 and related high-performance racing series.

II. Methods

A. Protocol and Registration

This scoping review was conducted following the methodological framework proposed by Arksey and O'Malley [7] and refined by Levac et al. [8], and is reported in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analysis extension for Scoping Reviews (PRISMA-ScR) checklist [9]. No formal protocol was registered prior to conducting the review.

B. Eligibility Criteria

Sources of evidence were included if they met the following criteria: 1) addressed the application of AI or ML methods to any aspect of motorsport or high-performance vehicle operation; 2) were published in peer-reviewed journals, conference proceedings, or as verifiable preprints and theses; or 3) were relevant cross-domain works from autonomous driving research with plausible conceptual relevance to motorsport contexts.

Sources were excluded if they: 1) focused exclusively on conventional rule-based or purely physics-based approaches without any data-driven component; 2) addressed motorsport only in a marginal or illustrative capacity; or 3) were not available in English.

The primary temporal focus was literature published from 2020 onwards, reflecting the period during which deep learning and large-scale data-driven approaches became systematically adopted in both academic research and applied motorsport engineering. However, selected earlier works were included where they provided essential historical context or represented foundational contributions to the field.

C. Information Sources

Literature was retrieved from three primary academic databases: Scopus, IEEE Xplore, and Google Scholar. The searches were conducted on February 7th 2026 with a further refining search on May 23rd 2026. Reference lists of included articles were also hand-searched to identify additional relevant sources.

D. Search Strategy

Searches were conducted using combinations of the following keywords: *motorsport*, *Formula 1*, *artificial intelligence*, *Machine Learning*, *deep learning*, *reinforcement learning*, *telemetry*, *race strategy*, *tyre degradation*, *autonomous racing*, *driver coaching*, and *predictive maintenance*. Boolean operators (`AND`, `OR`) were applied to combine domain-specific and methodological terms, for example: *"Machine Learning AND motorsport"* or *"reinforcement learning AND race strategy"*. The full search string for Scopus was: `TITLE-ABS-KEY((``artificial intelligence'' OR ``machine learning'' OR ``deep learning'' OR ``reinforcement learning'') AND (``motorsport'' OR ``Formula 1'' OR ``race strategy'' OR ``autonomous racing''))`. Table I presents the search strategy per database.

E. Selection of Sources of Evidence

All records retrieved from the database searches were first screened by title and abstract for relevance to AI/ML applications in motorsport or closely related high-performance vehicle domains. Full texts of potentially relevant articles were then assessed against the eligibility criteria. To enhance consistency, the eligibility criteria were pilot-tested on a subset of 15 randomly selected records prior to full screening, and the criteria were iteratively refined based on this pilot phase. In cases of ambiguity regarding inclusion, articles were retained for full-text review to minimize the risk of excluding relevant work. Additionally, a random sample of 10 previously screened records was re-screened at the end of the process to verify consistency of the applied criteria.

TABLE I. SEARCH STRATEGY PER DATABASE

Database	Records	Date	Search query / strategy
Scopus	51	7 Feb 2026	`TITLE-ABS-KEY(("artificial intelligence" OR "machine learning" OR "deep learning" OR "reinforcement learning") AND ("motorsport" OR "Formula 1" OR "race strategy" OR "autonomous racing"))`
IEEE Xplore	38	7 Feb 2026	`("artificial intelligence" OR "machine learning" OR "deep learning" OR "reinforcement learning") AND ("motorsport" OR "Formula 1" OR "race strategy" OR "autonomous racing")` (Command Search, all metadata)
Google Scholar*	55	7 Feb 2026	Keyword combinations of `machine learning`, `deep learning` and `reinforcement learning` with `motorsport`, `Formula 1`, `race strategy` and `autonomous racing`; first 100 results per query screened; date range 2003–2026.

Google Scholar does not support field-restricted (title/abstract/keyword) searching or fully nested Boolean queries; simplified keyword combinations were, therefore, used and results screened by relevance ranking.

F. Data Charting Process

A data charting form was developed to extract relevant information from each included source. The form was iteratively refined as the reviewer became increasingly familiar with the literature. Data were charted by the primary reviewer and verified through re-reading of the source material. The charting categories included: author(s), year of publication, source type, AI/ML method(s) employed, motorsport application domain, racing context (e.g., Formula 1, Formula Student, autonomous racing), data source used (e.g., real telemetry, simulator, synthetic), and key findings. Additionally, research gaps were identified through a thematic frequency analysis of the charted data. After categorizing all included sources into the six predefined application domains, areas with notably fewer studies relative to other domains were flagged as underexplored. This quantitative threshold-based approach was complemented by a qualitative assessment of the depth of existing research within each domain, considering factors such as methodological diversity, data source variety, and the presence or absence of real-world validation.

G. Data Items

The following data items were extracted from each included source: (1) bibliographic information (authors, year, publication venue); (2) study type (journal article, conference paper, thesis, preprint); (3) AI/ML technique(s) used (e.g., deep learning, reinforcement learning, supervised learning, ensemble methods); (4) primary application domain (vehicle performance, race strategy, telemetry analysis, driver coaching, predictive maintenance, or autonomous racing); (5) motorsport context (Formula 1, Formula Student, MotoGP, autonomous racing, general motorsport); (6) data source (real-world telemetry, simulator data, synthetic/generated data, public API); (7) research approach (simulation-based, experimental, conceptual/survey, or hybrid); (8) technical maturity level, classified using a simplified scale: conceptual or theoretical, simulation-validated, experimentally tested with real data, or deployed in competition; and (9) key findings and contributions.

III. RESULTS

A. Selection of Sources of Evidence

The database searches yielded a total of 144 records (Scopus: 51, IEEE Xplore: 38, Google Scholar: 55). Eight additional sources were identified through reference-list manual search and supplementary targeted searches. After removing 26 duplicates, 126 records were screened by title and abstract, of which 49 were excluded for not meeting the eligibility criteria (primarily papers addressing general AI/ML, sports medicine, or other non-motorsport domains). The remaining 77 articles were assessed in full text, leading to the exclusion of 27 sources (12 focused exclusively on physics-based methods without a data-driven component, 10 addressed motorsport only marginally, 3 were not available in English, and 2 were duplicates of included works by the same authors). In total, 50 sources were included in this scoping review. The selection process is illustrated in the PRISMA flow diagram (Fig. 1).

B. Characteristics of Sources of Evidence

The 50 included sources spanned the period from 2003 to 2026, with the majority (n=38) published from 2020 onwards. Source types included journal articles (n=30), conference papers (n=11), theses and dissertations (n=6) and preprints (n=3). The geographic distribution of first authors was varied, with contributions from Europe, North America, Asia, and the Middle East. The motorsport contexts addressed included Formula 1, Formula Student, MotoGP, Endurance Racing, autonomous racing (e.g., Indy Autonomous Challenge, Roborace), and general motorsport engineering.

C. Data Charting Results

Table II and Table III presents the data extracted from each included source. Papers were categorized into six thematic application domains: Vehicle Performance Optimization (VP), Race Strategy and Real-Time Decisions (RS), Telemetry and Race Data Analysis (TA), Driver Coaching and Simulation (DC), Predictive Maintenance and Reliability (PM), and Autonomous Racing (AR).

D. Synthesis of Results

1) Distribution across application domains: The distribution of the 50 reviewed sources across the six thematic categories is presented in Fig. 2. The six application domains were defined a priori based on a preliminary scan of the literature and reflect the principal areas in which AI methods are applied in motorsport: Vehicle Performance Optimization (VP), Race Strategy and Real-Time Decisions (RS), Telemetry and Race Data Analysis (TA), Driver Coaching and Simulation (DC), Predictive Maintenance and Reliability (PM), and Autonomous Racing (AR). Papers with cross-cutting contributions were assigned to the single category most closely matching their

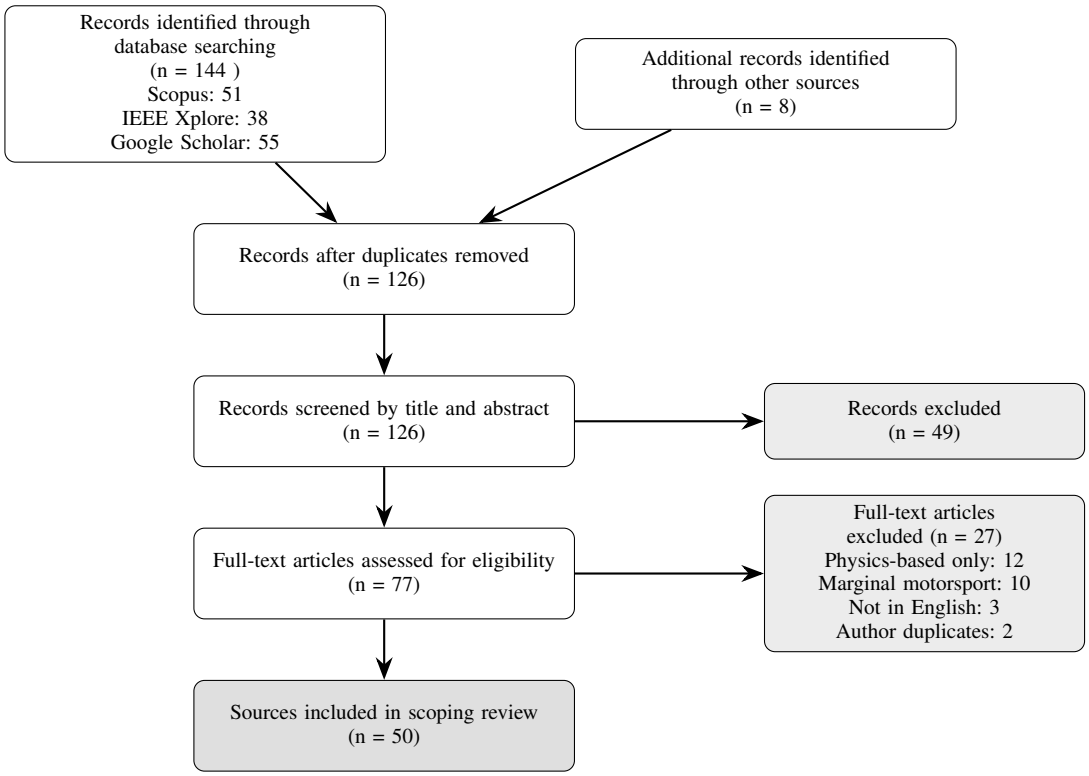

Fig. 1. PRISMA flow diagram illustrating the source selection process.

primary research focus, based on the declared objectives and the principal contribution of each study. In cases, where a paper contributed to multiple domains (e.g., a study combining vehicle dynamics modeling with race strategy), the dominant methodological contribution was used as the classification criterion. As shown in Fig. 2, Race Strategy dominates the current research landscape (n=14), followed by Vehicle Performance Optimization and Autonomous Racing (n=12 each), while Predictive Maintenance remains notably underrepresented (n=2), indicating a significant gap in the literature.

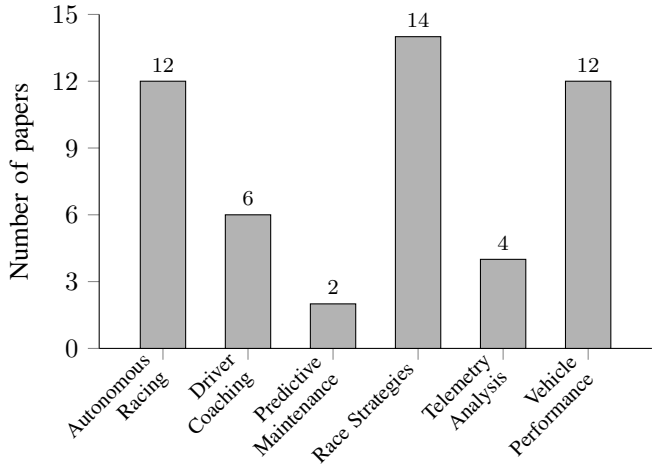

Fig. 2. Distribution of reviewed papers across application categories.

2) Research approach and technical maturity: To assess the current state of AI development in motorsport beyond thematic coverage, each included source was classified by its research approach (simulation-based, experimental, conceptual/survey, or hybrid) and by its technical maturity level, using a simplified four-level scale: conceptual or theoretical, simulation-validated, experimentally tested with real-world data, or deployed in competition. The cross-tabulation of these two dimensions is presented in Table IV.

The analysis reveals that the majority of included studies remain at the simulation-validated stage (n=23), relying on simulated or synthetic data to train and evaluate AI models. Only 14 studies have been experimentally validated using real-world data, and merely 5 have demonstrated deployment in actual competition or real-time racing environments — notably Kabzan et al. [37] (learning-based MPC for autonomous racing), Betz et al. [46] (full-stack autonomous racing at the Indy Autonomous Challenge), and Wurman et al. [31] (RL agent outperforming human drivers in Gran Turismo Sport). Eight sources are conceptual or survey papers that synthesize existing knowledge without introducing new experimental results.

This distribution indicates that while AI research in motorsport is growing rapidly, the field remains largely in the simulation and proof-of-concept phase. The gap between simulation-validated methods and real-world deployment is substantial, reflecting both the technical challenges of transferring AI models to the extreme conditions of racing vehicles and the data-access constraints imposed by the secretive nature of the sport. Future work should prioritize bridging this simulation-to-reality gap, particularly through sim-to-real transfer techniques and the

development of standardized benchmarks.

3) Brief overview of AI usage in motorsport: Although data collection in Formula 1 has been implemented starting with the mid-1980s when teams started using digital systems for data acquisition, analysis was still being done through traditional statistical methods or rule-based systems. Telemetry was collected using burst transmissions from the car during races [10]. During the 1990s, usage of digital technology picked up considerably as modern sensors became prevalent with the advent of active-ride cars [54]. Public research during this period was already treating the potential benefits of algorithmic optimization of vehicle performance.

The early 2000s marked the switch from purely physics-based analysis to hybrid models (physical–data driven) as a response to the greater complexity of racing vehicles. Even though modern Machine Learning was not widely used, the emergence of multivariate regression, non-linear optimisation and solid statistical models was evident. Besselink [11] integrated the first data-driven methodologies, allowing teams to adjust simulation strategies based on historical data. The

adoption of data-driven analysis was accelerated by the FIA's decision to limit track testing in efforts to decrease costs, leading to increased investment in advanced simulations, algorithm optimization and the setup of infrastructures prepared to handle large volumes of data.

After 2010, Machine Learning became widely adopted with its impact on motorsport noticeable in all areas, from car development to driver coaching or marketing. This was possible mainly due to three factors: the increase in computational power leveraging GPUs and cloud infrastructure, the greater volume of telemetry data and the appearance of advanced Machine Learning and Deep Learning models. This marked a shift towards more advanced simulations ranging from tyre degradation over time [12] to optimizing race strategy [13] or analyzing driver behavior [14]. In parallel, the first autonomous racing projects appeared, such as Carolo-Cup and Formula Student Driverless, which introduced new techniques based on Computer Vision [15], high-speed Simultaneous Localization and Mapping (SLAM) [16] and reinforcement learning for car control [17].

Following 2020, AI has started being used systematically in data analysis and performance optimization, with further

TABLE IV. DISTRIBUTION OF INCLUDED SOURCES BY RESEARCH APPROACH AND TECHNICAL MATURITY LEVEL.

	Concept.	Simul.	Exper.	Deployed	Total
Simulation-based	–	19	–	1	20
Experimental	–	–	10	3	13

Technical maturity levels: Conceptual = theoretical proposal or literature review; Simulation-validated = method tested using simulated or synthetic data; Experimentally tested = validated using real-world data; Deployed = demonstrated in actual competition or real-time racing environment.

development in performance prediction[2], autonomous racing and determining optimal racing lines [1]. At this time, autonomous racing has become a lot more prevalent, with events like Indy Autonomous Challenge proving a very promising area of research at the intersection of Artificial Intelligence, Computer Vision and Reinforcement Learning.

4) Vehicle performance optimization: One of the most important applications of AI in motorsport, vehicle performance optimization, relies on the analysis and modelling of complex relations between car setup, environmental conditions and the results obtained on track. Modern race cars operate in a highly non-linear regime, where small changes in parameters such as wing angles, ride height, suspension stiffness or tyre pressure can have a disproportionate effect on lap time, stability and tyre wear. In this context, traditional physics-based simulation tools, while still essential, are increasingly complemented by data-driven models that can learn these complex relationships directly from telemetry and simulation data.

Some of the most common applications of Machine Learning models in this area include estimating vehicle behaviour as a function of aerodynamic configuration and ride height [18], [19], modeling the tyre-track surface interaction and tyre degradation prediction [12] over a stint, or forecasting [20] the reliability and remaining useful life of critical components. Data-backed decisions have been also applied to trajectory planning and individual systems of the vehicle. Jain and Morari [51] compute the racing line, the optimal trajectory and its speed profile along a racing track, using Bayesian optimisation, demonstrating that a fully data-driven design may converge more efficiently than classic programming or random search. At the component level, Bonini et al. [49], [50] utilize deep learning techniques (ANN, Kalman filters and NARX) to estimate the friction coefficient of carbon braking systems based on telemetry data and combine the results with a physics-based model to obtain the braking torque on the front wheel, with results being validated with data recorded in MotoGP races. These models are typically trained using a combination of historical race data, simulator outputs and controlled test runs, allowing them to capture both the physical trends and the empirical behaviour observed in real racing conditions. A key advantage of AI-based approaches is their ability to evaluate a very large number of possible vehicle configurations in a short amount of time. Instead of running a limited set of expensive physical tests or computationally intensive CFD and vehicle dynamics simulations, engineers can use trained models to rapidly scan through thousands of setup combinations and identify those that are most likely to deliver optimal performance under specific track and weather conditions.

Furthermore, these models allow for continuous and incremental updates as new data becomes available, allowing them to adapt to changes in track grip, weather, tyre compounds or even driver style. As a result, vehicle performance optimization becomes an ongoing, data-driven process rather than a one-off calibration task, supporting more informed engineering decisions throughout a race weekend.

5) Race strategies and real-time decisions: Another central pillar is the utilisation of AI as active support for decision making during races, such as choosing the optimum strategy for pitstops [21], [22], the selection of race tyre types [23], [24] or adapting the car's race pace to current environmental and track conditions [17]. Strategic decision-making research extends beyond Grand Prix competitions to endurance racing, where success is typically conditioned by energy and component temperature management over multiple hours of active racing, rather than optimization of a single stint. In the case of fully electric endurance racing, van Kampen et al. [53] simultaneously optimize stint length, battery-charging time and pitstop count to maximize the traveled distance in fixed-duration races while de Vries et al. [52] analyze the same problem through a two-level reinforcement-learning methods which yields competitor-aware energy-allocation and charging strategies that differ fundamentally from single-agent, minimum-time solutions. In a sport, where hundredths of a second matter in the final classification, the ability to make real-time strategic calls can have just as large an impact as pure mechanical car performance.

AI models that support these decisions need to address problems characterized by a high degree of uncertainty. Certain events such as the appearance of the Safety Car, sudden changes in meteorological conditions or reacting to the unpredictable behaviour of other competitors could have a major impact on the race dynamic in a very short interval of time. Additionally, these decisions are often constrained by strict temporal requirements: deciding the optimal time for a pitstop or changing the tyre strategy is a fluid process requiring quick reactions while cars are already on the race track. Another constraint, besides uncertainty and time, is the complex interaction with the other competitors, as a strategy's efficacy is dictated not just by the performance of the team but the competitor's positions, strategies and behaviour. For this reason, problems are often formulated as sequential optimisation or stochastic methods in which the race's future evolution can be probabilistically modeled, where methods like reinforcement learning or predictive models play a pivotal role.

6) Telemetry and race data analysis: Modern motorsport generates vast volumes of telemetry data, including speed, acceleration, temperatures, pressures, vibration, yaw and many other variables tracked at high frequencies. AI can be leveraged to detect hidden patterns in telemetry data [25], identifying correlations between driving style and performance or detecting anomalies [26] which can hint at incipient failures, enhancing the capability to improve performance while increasing both safety and reliability.

7) Driver coaching and simulations: High-performance simulation systems are progressively combined with artificial intelligence models to form adaptive training environments capable of dynamically responding to driver behavior. These AI components analyze detailed telemetry and control inputs to detect patterns associated with suboptimal driving techniques, such as inefficient braking, inconsistent throttle application, or poor racing line selection. The simulation can then automatically modify training scenarios to focus on these specific deficiencies, while delivering precise, quantitative feedback that supports continuous performance improvement and skill development [29], [25].

8) Predictive maintenance and reliability: Through the analysis of how various mechanical and thermal parameters of the car evolve over time, AI models can anticipate the probability of a fault before it effectively manifests itself, enabling an optimal strategy for component replacement planning, maximizing their life-span utilization within safe boundaries while also minimizing the risk of race abandonment due to mechanical failures [27], [6].

9) Cross-domain perspectives autonomous driving: While direct motorsport research is relatively sparse, a large volume of academic work, especially in the area of autonomous driving, focuses on the interaction between Artificial Intelligence and vehicle dynamics. Many studies showcase that modern AI-based control systems are no longer limited to high-level planning but rather act as decision makers having control of the vehicle's acceleration, braking and steering inputs [4], [28], [5], [55].

These papers describe a clear shift from purely physical controls such as Proportional-Integral-Derivative (PID), Linear Quadratic Regulator (LQR) or Model Predictive Control (MPC) towards a data-based approach, in which modern AI controllers learn driving models through supervised or reinforcement learning [4], [28], [56]. This direction may prove relevant for motorsport, where vehicles operate close to the limit of grip and stability — though whether controllers trained for road driving transfer to racing conditions is an open question rather than an established result. While in autonomous driving, controllers are calibrated for comfort, safety and reliability, in racing environments the same controllers are optimized to maximize grip and performance and minimize lap times, still considering reliability. Both approaches solve a similar problem: mapping the current state of big data to continuous control actions which respect the highly non-linear nature of vehicle dynamics.

Another area of interest is the integration of deep learning and reinforcement learning techniques into the main control loop. Pérez-Gil et al. [29] show that DQN and DDPG reinforcement algorithms may be used to control autonomous vehicles, providing steering and acceleration inputs with a precision comparable with that of classic LQR controllers. Similarly, hybrid approaches like Reda et al. [30] combine supervised learning with reinforcement learning to extract the best compromise between accuracy, input finesse and response time, essential components in high-performance driving.

Beyond pure tracking performance, more recent work has emphasized modeling driving style and explainability. Gao et al. [57] introduce a human-like neural network for longitudinal control that explicitly mimics driver behavior, and Li et al. [58] integrate explainability into a deep reinforcement learning controller using SHAP analysis. While comfort is less relevant in motorsport, these approaches could inform the understanding and shaping of driving style — a potential connection that would require dedicated study within a racing context to confirm, an aspect that is increasingly important when AI is used to support or emulate human drivers.

Another important link between autonomous driving and motorsport lies in mixed-autonomy and interaction modeling. Di and Shi [28] and Babaei et al. [55] highlight that modern AI-based vehicle controllers are often trained not only to follow a path, but to interact strategically with other road users. This is conceptually analogous to racing situations, where a driver's control inputs are strongly influenced by the behavior of competitors, slipstreaming, defensive driving, and overtaking maneuvers.

From a system-level perspective, surveys such as Kuutti et al.[4], Elallid et al.[5], and Babaei et al.[55] emphasize that AI-based vehicle control is typically embedded in a layered architecture that includes perception, prediction, planning, and control. Motorsport applications follow a similar structure, even if perception is less emphasized. The control layer, however, faces even stricter requirements, as racing vehicles operate at higher speeds, higher lateral accelerations, and much smaller margins for error.

Taken together, these observations are best read as hypotheses worth investigating rather than as evidence of established transfer: the extent to which the parallels translate into practical, transferable applicability — given the fundamentally different objective functions and operating constraints of each domain — is examined critically in Section IV-A3.

10)Research coverage and identified gaps: Following the thematic frequency analysis described in Section II-F, the distribution of identified literature across core application areas reveals a highly uneven research landscape. Race strategy, autonomous racing, and vehicle performance optimization are relatively well-covered, while predictive maintenance, telemetry analysis, and computer vision applications remain largely unexplored.

Because motorsport in general and Formula 1 in particular is extremely secretive — as even small gains and insight into a competitor's research or data can lead to a major competitive advantage — there is a fairly small volume of publicly available research. The fact that teams closely guard their data means that the areas of research are limited both in terms of scope and precision. For instance, Formula One teams have access to telemetry with a frequency of 1 kHz, while public telemetry is sampled at around 3 Hz frequency. The combination of proprietary sensor data and closely guarded internal research leads to this area being a fairly under-researched domain. Predictive maintenance and reliability is an especially under-researched area, with most industry papers focusing on sensor data. Computer Vision is another technique that is not well researched or applied in motorsport, leaving a sizeable void in potential advancements.

IV. Discussion

A. Summary of Evidence

This scoping review identified 50 sources addressing AI and ML applications in motorsport, spanning the period 2003–2026. While this body of literature confirms growing academic interest in the field, a critical examination reveals several fundamental weaknesses that limit the strength of the conclusions that can be drawn.

1) Methodological fragility of the evidence base: The most significant concern is the predominance of simulation-based research. As shown in Table IV, 20 of the 50 included sources rely exclusively on simulated or synthetic data, while only 5 have demonstrated deployment in actual competition environments. This raises a critical question: To what extent do simulation-validated AI models generalize to the extreme and unpredictable conditions of real racing? The sim-to-real transfer problem is well-documented in robotics and autonomous driving, yet very few motorsport studies explicitly address this gap, mainly due to the lack of access to data. Models trained on idealized simulator physics may fail to capture the nonlinear tire behavior, aerodynamic turbulence from competitor vehicles, or track surface variability encountered in real races. The fact that only five studies — notably Kabzan et al. [37], Betz et al. [46], and Wurman et al. [31] — have demonstrated real-world or competition-level deployment underscores how far the field remains from practical maturity.

Furthermore, 8 of the 50 sources are conceptual papers or surveys that do not introduce new empirical evidence. While these contribute to structuring the field, their inclusion means that over 60% of the evidence base either lacks real-world validation or presents no original experimental results. This is a structural limitation of the current literature, not merely a gap to be filled.

2) Uneven thematic coverage and its implications: The distribution of research effort across application domains is very uneven: race strategy leads (n=14) with autonomous racing and vehicle performance fairly close behind (n=12 each), while predictive maintenance (n=2) and telemetry-based anomaly detection remain almost entirely unexplored. This imbalance does not necessarily reflect the relative importance of these domains in actual motorsport practice. Rather, it likely reflects data accessibility: race strategy benefits from publicly available telemetry APIs (e.g., FastF1) and well-defined optimization formulations, while predictive maintenance requires proprietary sensor data from components operating under extreme thermal and mechanical loads — data that teams have no incentive to share.

This creates a problematic feedback loop: the domains most critical to competitive performance are precisely those where public research is thinnest, because the data needed to study them is the most commercially sensitive. The current literature therefore provides a skewed picture of AI's role in motorsport, overrepresenting areas where data is accessible and underrepresenting those where AI arguably has the greatest untapped potential.

3) Questionable transferability from autonomous driving: A substantial portion of the included sources (10 of 50) originate from autonomous driving research rather than motorsport proper. While the review's eligibility criteria explicitly permit cross-domain work with clear transferability, the actual degree of this transferability warrants critical scrutiny. Autonomous driving controllers are optimized for safety, comfort, and regulatory compliance, whereas motorsport controllers must maximize performance at the physical limits of grip and stability. The objective functions, constraint sets, and operating envelopes are fundamentally different. For example, a reinforcement learning agent trained to maintain safe following distances on public roads [28] faces a qualitatively different problem from one that must optimize overtaking maneuvers at 300 km/h with millimeter-level precision.

Moreover, the layered perception–planning–control architecture common in autonomous driving [4], [5] does not map cleanly onto motorsport, where perception requirements are narrower (no pedestrian detection, fewer traffic scenarios) but control requirements are far more demanding (higher speeds, higher lateral accelerations, tighter margins). The inclusion of these cross-domain sources enriches the review's breadth but should not be mistaken for direct evidence of AI maturity within motorsport itself.

4) Evidence quality and publication bias: Of the 50 included sources, 30 are peer-reviewed journal articles and 11 are conference papers, representing the most robust evidence. However, 6 are theses or dissertations, and 3 are preprints without formal peer review. While the inclusion of grey literature is methodologically appropriate in a scoping review — ensuring comprehensive coverage of an emerging field — it introduces heterogeneity in scientific rigor. Critically, some of the more specific findings in underrepresented domains such as telemetry analysis and predictive maintenance rely disproportionately on this weaker evidence base.

There is also a likely publication bias at work: studies reporting positive results (successful AI models outperforming baselines) are far more likely to be published than those reporting negative results or failed implementations. The absence of failure reports in the literature should not be interpreted as evidence that AI methods reliably succeed in motorsport applications; rather, it reflects a systematic gap in reporting that obscures the true difficulty of deploying these methods in practice.

5) The temporal trajectory and its risks: The review identifies a clear temporal shift from physics-based approaches (pre-2010) through hybrid models (2010s) to deep learning and reinforcement learning (2020 onwards). While this mirrors broader trends in AI research, it also carries risks specific to motorsport. The increasing reliance on black-box deep learning models raises concerns about explainability and trust in high-stakes racing decisions. When an AI system recommends a pit-stop strategy or predicts tire failure, the engineering team needs to understand *why* — yet only two papers [58], [57] from the cross-domain autonomous driving literature explicitly address explainability. The rush toward more complex models without corresponding advances in interpretability may ultimately limit the adoption of AI in competitive motorsport, where engineers and race directors must be able to justify decisions under time pressure.

6) Deployment and systems constraints: A dimension almost entirely absent from the reviewed literature is the sys-

TABLE V. PROPOSED RESEARCH AGENDA FOR AI IN MOTORSPORT

Research direction	Barrier	Proposed approach	Horizon / priority
Open benchmarks and shared data standards	Telemetry and performance data are proprietary and closely guarded, with no common formats (Section IV-A2)	Public simulator datasets and a standardized open telemetry schema enabling reproducible, comparable studies	Near-term; high feasibility
Sim-to-real transfer	20 of 50 studies are validated only on simulated or synthetic data under idealized physics (Section IV-A1)	Domain randomization and transfer-learning pipelines; staged validation against real track telemetry	Near- to medium-term
Predictive maintenance for racing components	Component sensor data gathered under extreme thermal and mechanical loads is commercially sensitive (Section IV-A2)	Synthetic data and transfer learning from broader automotive predictive maintenance; physics-informed degradation models	Medium-term
Explainability and trust in decision support	Black-box deep models, while engineers must justify strategy calls under time pressure (Section IV-A5)	SHAP, attention, and interpretable-surrogate methods adapted to strategy and reliability models	Near-term
Transparent reporting of failures	Publication bias toward positive results; failed or abandoned deployments go unreported (Section IV-A4)	Negative-result and real deployment case studies; registered-report formats; shared failure taxonomies	Near-term; process change
Computer vision for race operations	Under-explored area with few annotated motorsport image and video datasets	Computer vision for pit-lane operations, driver assessment, and real-time monitoring, supported by annotated public benchmarks	Medium-term

tems engineering required to move AI from offline analysis onto a moving race car. Deployment imposes hard real-time constraints that simulation-validated studies rarely confront: strategic recommendations must be produced within the narrow windows that precede a pit-stop decision, while autonomous-racing perception and control must close their loops at high frequency even as the vehicle travels at racing speed. These computations run on constrained on-car hardware bounded by strict power, thermal, weight, and vibration budgets. For example. the full-stack Indy Autonomous Challenge systems of Betz et al. [3] and Raji et al. [45], execute on a single-GPU on-vehicle edge-AI computer mounted in a Dallara AV-21 operating at speeds approaching 270 km/h. Such budgets make model compression and quantization a practical precondition for deploying deep models at the edge, and they place a premium on deterministic, hard real-time execution and on functional-safety requirements (e.g., ISO 26262) that non-deterministic deep-learning components do not naturally satisfy. Tellingly, only the small set of competition-deployed autonomous-racing studies [37], [3], [45] engages with these concerns; the far larger body of strategy- and performance-oriented work is largely silent on them, leaving the practical question of real-time deployability underexamined.

B. Limitations

Several limitations of this review must be acknowledged. Although consistency measures were applied (pilot-testing on a subset and post-hoc re-screening), the absence of independent dual screening means that subjective judgments — particularly regarding the "clear transferability" criterion for cross-domain autonomous driving sources — may have introduced bias that cannot be fully quantified.

The restriction to English-language publications likely excluded relevant work, particularly from research groups in Japan, China, and continental Europe where significant motorsport engineering activity exists. More fundamentally, the secretive nature of motorsport means that the publicly accessible literature almost certainly underrepresents the actual state of AI adoption. Formula 1 teams, for instance, employ dedicated AI and data science divisions whose work never enters the public domain. This review can therefore only map what is publicly documented, which may bear limited resemblance to the true state of the art within the industry.

The absence of formal critical appraisal — while consistent with scoping review methodology — means that simulation-based studies with idealized assumptions are given equal weight alongside experimentally validated work. Readers should, therefore, consult Table IV when evaluating the strength of evidence behind specific claims. Finally, the inclusion of Google Scholar as a database source, while increasing coverage, introduced grey literature whose quality could not be independently verified.

C. Conclusion

Although motorsport, and particularly Formula 1, is recognized as one of the most advanced and innovative domains of modern engineering, public research is limited due to the highly competitive and secretive character of the sport. Telemetry data, performance models and strategies are treated as highly confidential, limiting the quantity and depth of research papers. The lack of open data leads to a significant gap between the potential of AI usage in motorsport and the level at which it is documented in scientific literature. Many of the advanced AI use cases — real-time strategy optimization, tyre behaviour modeling, or the integration of decision support systems — although developed and used internally by teams, do not appear in academic publications, with existing literature often focusing on a partial image of the actual state of the technology based on limited case studies, simulations, or synthetic data.

Rather than pursuing only incremental improvements to AI techniques, future work should target the structural weaknesses identified in the Discussion. Table V translates these into a concrete research agenda: for each gap it states the underlying barrier, a proposed approach, and an indicative time horizon.

Across these directions, the common prerequisite is data access. Open benchmarks and shared telemetry standards are therefore the highest-priority and most feasible near-term step, since meaningful progress on sim-to-real validation, predictive

maintenance, and explainability all depends on a richer, openly available evidence base. Establishing that shared foundation would be the single most effective way to convert motorsport AI from a fragmented set of case studies into a cumulative research field.

FUNDING

The publication of this research was supported by the University of Oradea.

Benchmarking Deep Vision Architectures: From Controlled Datasets to Real-World Clinical Validation

Raghda Essam Ali, Noha Ahmed Saad El-Dien, Magi Hossam Eldin Mahfouz
School of Computing and Digital Tech., Eslsca University, Egypt

***Abstract*—Stroke is a leading cause of mortality and long-term disability, making rapid and reliable detection from non-contrast computed tomography (CT) scans essential for timely clinical intervention. This study introduces NeuroCT-Bench, a unified and reproducible benchmark for evaluating deep learning architectures for automated stroke classification from brain CT images. The benchmark systematically compares five Convolutional Neural Networks (VGG16, ResNet50, DenseNet121, EfficientNetB0, MobileNetV2) and four Vision Transformers (Swin Transformer, ViT, DeiT, PVT-Small) under identical preprocessing, augmentation, and evaluation protocols using the Brain Stroke CT Image dataset from Kaggle, comprising 1,551 normal and 950 stroke slices. Internal validation using a deterministic 80/20 stratified split (seed = 42) demonstrated near-perfect performance for Transformer-based models, with PVT-Small and Swin Transformer achieving ROC-AUCs of 99.96% and 99.98%, respectively, while DenseNet121, VGG16, and EfficientNetB0 achieved strong CNN baselines with ROC-AUCs of 99.93%, 99.67%, and 99.05%. To evaluate robustness under real-world domain shift, the top-performing models were further assessed on an external patient-level clinical dataset containing 530 CT studies. EfficientNetB0 demonstrated the strongest generalization capability (accuracy: 76.92%, precision: 83.85%, ROC-AUC = 88.0%), whereas high-capacity Transformer models exhibited substantially larger performance degradation (ROC-AUCs of 75.0% for PVT-Small and 67.0% for Swin Transformer). These findings highlight the discrepancy between curated public datasets and heterogeneous clinical imaging conditions, emphasizing that high internal performance does not necessarily guarantee clinical robustness. In addition, an ablation study was conducted to evaluate a lightweight CNN–Transformer gated fusion strategy. Results demonstrate that adaptive fusion improves robustness and generalization compared with individual CNN or Transformer models and static feature concatenation. Overall, NeuroCT-Bench provides a transparent and reproducible framework for evaluating deep learning models for stroke analysis and supports future development of clinically deployable hybrid CNN–Transformer systems.**

***Keywords*—Stroke detection; brain CT image; deep learning; Convolutional Neural Networks; Vision Transformers; clinical validation; neuroimaging AI**

I. Introduction

Stroke remains a major global health concern, ranking among the leading causes of mortality and long-term disability and placing substantial pressure on healthcare systems worldwide [1], [2]. Rapid and accurate diagnosis is critical, particularly in emergency settings where treatment decisions must be made within minutes. Non-Contrast Computed Tomography (NCCT) is widely adopted as the first-line imaging modality due to its availability and speed; however, subtle early ischemic changes are often difficult to identify, and interpretation may vary across radiologists [3], [4]. These challenges have motivated the integration of artificial intelligence (AI) techniques into stroke assessment workflows, aiming to enhance diagnostic consistency and support clinical decision-making.

Traditional machine learning approaches—such as logistic regression, Support Vector Machines, and ensemble methods—offer a degree of interpretability but rely heavily on handcrafted feature engineering and often struggle with heterogeneous imaging conditions and patient variability [5], [6]. Convolutional Neural Networks (CNNs) significantly improved performance by learning hierarchical feature representations directly from imaging data [7], [8]. Nevertheless, CNNs are inherently constrained by local receptive fields, limiting their ability to model long-range spatial dependencies in medical images [9], [10].

Transformer-based architectures, originally introduced for natural language processing, address this limitation through self-attention mechanisms capable of capturing global contextual relationships [11]–[13]. Vision Transformers (ViTs) and their variants have demonstrated promising performance across medical imaging tasks, including stroke detection and classification [13]–[15]. However, these models typically require large-scale datasets and substantial computational resources, and may exhibit reduced robustness when exposed to domain shifts such as variations in scanner types or acquisition protocols [11], [12]. Furthermore, despite the growing body of research, only a limited number of studies have conducted systematic and fair comparisons between CNNs and modern Transformer architectures under unified experimental settings.

Recent studies have also explored hybrid and multimodal learning paradigms to improve stroke prediction and diagnosis. For instance, combining clinical data with imaging or integrating multiple feature representations has shown promising improvements in predictive performance [16], [17]. Additionally, benchmark-driven studies such as STROKECT-BENCH [18] highlight the importance of standardized evaluation when comparing CNN and Transformer architectures. Related work in medical imaging, including disease classification tasks beyond stroke, further demonstrates the value of consistent experimental pipelines and reproducible frameworks [19].

To address these limitations, this work introduces

NeuroCT-Bench, a standardized benchmark framework for evaluating multiple deep learning architectures for automated stroke detection using non-contrast CT images. Specifically, the benchmark includes five widely used CNN models (ResNet50, EfficientNetB0, DenseNet121, VGG16, and MobileNetV2) and four Transformer-based models (Swin Transformer (Swin), Vision Transformer, DeiT, and PVT-Small). All models are trained under identical preprocessing, augmentation, and optimization protocols using the publicly available Brain Stroke CT Image dataset [20], which contains 1,551 normal and 950 stroke slices.

Unlike prior studies that often employ inconsistent pipelines or slice-level data splits—potentially leading to data leakage and inflated performance—this work enforces a controlled and reproducible evaluation framework. In addition, the benchmark incorporates comprehensive performance analysis, including classification metrics, computational efficiency (parameter count and FLOPs), and CPU inference time. To further assess generalization capability, the top-performing models are validated on an external patient-level clinical dataset, enabling evaluation under real-world domain shift conditions. This unified analysis provides deeper insights into model reliability and highlights architectures that are better suited for practical clinical deployment [21], [22]. The key contribution of this work lies in providing the first unified, reproducible benchmark that systematically evaluates CNN and Transformer architectures under identical conditions with external clinical validation.

The remainder of this study is organized as follows: Section II reviews related work on deep learning for stroke imaging. Section III describes the datasets, preprocessing pipeline, and methodology. Section IV presents the experimental setup and results. Section V discusses the findings, and Section VI presents the limitations of the study. Section VII concludes the study and outlines future directions, including interpretability techniques such as Grad-CAM++ [23] and hybrid CNN-Transformer architectures.

II. Related Work

Deep learning has become a cornerstone in NCCT-based stroke analysis; however, existing studies differ significantly in dataset construction, preprocessing pipelines, augmentation strategies, and evaluation protocols. These inconsistencies hinder fair comparison across studies and limit reproducibility. Furthermore, many works lack external, patient-level validation, leaving model robustness under real clinical conditions uncertain. This section reviews recent CNN- and Transformer-based approaches, with emphasis on datasets, preprocessing practices, and methodological limitations that motivate the need for a unified benchmark such as NeuroCT-Bench.

A. CNN-Based Models

Convolutional Neural Networks (CNNs) remain widely adopted for stroke and intracranial abnormality detection in CT imaging due to their effectiveness in capturing local textures and structural patterns. Numerous studies have utilized architectures such as ResNet50, DenseNet121, EfficientNetB0, VGG16, and MobileNetV2, often leveraging ImageNet pretraining to enhance feature representation [4], [8]. Standard preprocessing pipelines typically include resizing slices to 224×224, converting grayscale images to three channels, normalization using ImageNet statistics, and applying light data augmentation such as horizontal flipping and small rotations. Under such configurations, CNN-based models frequently report high slice-level performance, often exceeding 95% accuracy on internal validation sets [2], [21].

Despite these promising results, several limitations reduce their clinical reliability. A common issue is the use of slice-level or image-level splitting instead of patient-level separation, which can introduce data leakage and artificially inflate performance. Additionally, preprocessing details are often insufficiently reported, including missing specifications of interpolation methods, normalization parameters, and augmentation ranges, thereby hindering reproducibility. Many studies also rely solely on internal validation without testing on independent datasets, making it difficult to assess generalization. Furthermore, hybrid approaches that combine CNN-extracted features with classical classifiers such as Support Vector Machines (SVM) or Linear Discriminant Analysis (LDA) introduce additional variability and obscure the standalone contribution of CNN architectures. These concerns are consistently highlighted in recent surveys on stroke imaging [2], [9].

B. Transformer-Based Models

Transformer-based architectures, including Vision Transformers (ViTs) and hierarchical variants such as Swin Transformer, Pyramid Vision Transformer (PVT), and Data-efficient Image Transformers (DeiT), have recently gained attention in medical imaging due to their ability to model long-range dependencies via self-attention mechanisms [11], [12]. Unlike CNNs, Transformers capture global contextual information, which can be advantageous for identifying subtle ischemic patterns in NCCT scans. Several studies have explored Transformer-based or hybrid CNN–Transformer models for stroke detection and classification, reporting strong performance on public datasets [13], [14].

However, these models present practical challenges. Transformers generally require large-scale and diverse datasets or extensive augmentation to achieve stable performance, yet many studies provide limited details regarding training configurations and preprocessing pipelines, reducing reproducibility. External validation remains limited, and when conducted, performance degradation is often observed, particularly in terms of ROC-AUC, due to sensitivity to variations in imaging protocols and scanner types. Hybrid architectures further complicate interpretability by combining convolutional and attention-based representations. Recent reviews emphasize that standardized preprocessing, transparent reporting, and rigorous external evaluation are essential for validating Transformer-based approaches in real-world clinical scenarios [11], [12].

C. Summary and Research Gap

Although both CNN-based and Transformer-based approaches have demonstrated strong potential for automated stroke detection from NCCT images, inconsistencies across existing studies limit reproducibility and fair comparison. Most prior works evaluate a single model or a limited subset of architectures using non-standardized preprocessing pipelines,

varied augmentation strategies, and inconsistent data splitting methods. Consequently, reported performance differences may reflect experimental design choices rather than inherent architectural advantages. Moreover, external patient-level validation is rarely performed, and models achieving high accuracy on public datasets often exhibit reduced performance when applied to real clinical data.

To address these challenges, this work introduces **NeuroCT-Bench**, a unified benchmarking framework that evaluates multiple CNN and Transformer architectures under identical preprocessing, augmentation, and training conditions. The framework incorporates both internal evaluation on a public dataset and external validation on a patient-level clinical dataset, enabling a more reliable assessment of model generalization and robustness. This standardized approach provides clearer insights into the comparative strengths and limitations of modern deep learning architectures for CT-based stroke detection and establishes a reproducible foundation for future research.

III. Methodology

This study employs a systematic methodology for automated stroke classification from brain CT images. As illustrated in Fig. 1, the process begins with dataset preparation and standardized preprocessing to ensure consistent input quality across all experiments. Feature extraction is then performed using multiple deep learning architectures—both convolutional and transformer-based—followed by model training, validation, and evaluation under identical experimental settings.

A. Dataset

Two datasets were used in this study: a public Kaggle dataset [20] for internal benchmarking and a real-world fully anonymized clinical dataset for external validation.

1) Internal dataset (Kaggle): The internal benchmark was constructed using the Brain Stroke CT Image dataset from Kaggle [20], which contains 2,501 axial CT slices (1,551 normal and 950 stroke). The images are organized at the slice level into Normal and Stroke categories without patient identifiers. Consequently, all internal experiments were conducted at the slice level.

A deterministic 80/20 stratified split was applied using a fixed random seed (42) to ensure full reproducibility. Representative samples are shown in Fig. 2.

2) External clinical dataset: For out-of-distribution generalization assessment, a clinical dataset comprising 530 anonymized patient studies was used. Each study includes four standardized CT samples, with each sample containing 20 axial slices, as illustrated in Fig. 3.

Only studies with a consistent structure were included, while cases with incomplete or variable slice counts were excluded. Labels (stroke vs. normal) were assigned by a board-certified radiologist prior to anonymization.

The dataset was provided by Al Waha Hospital in compliance with institutional ethical standards. All DICOM metadata, including scanner type and acquisition parameters, were removed. Therefore, stratification by imaging protocol was not possible, and this limitation is considered in the analysis.

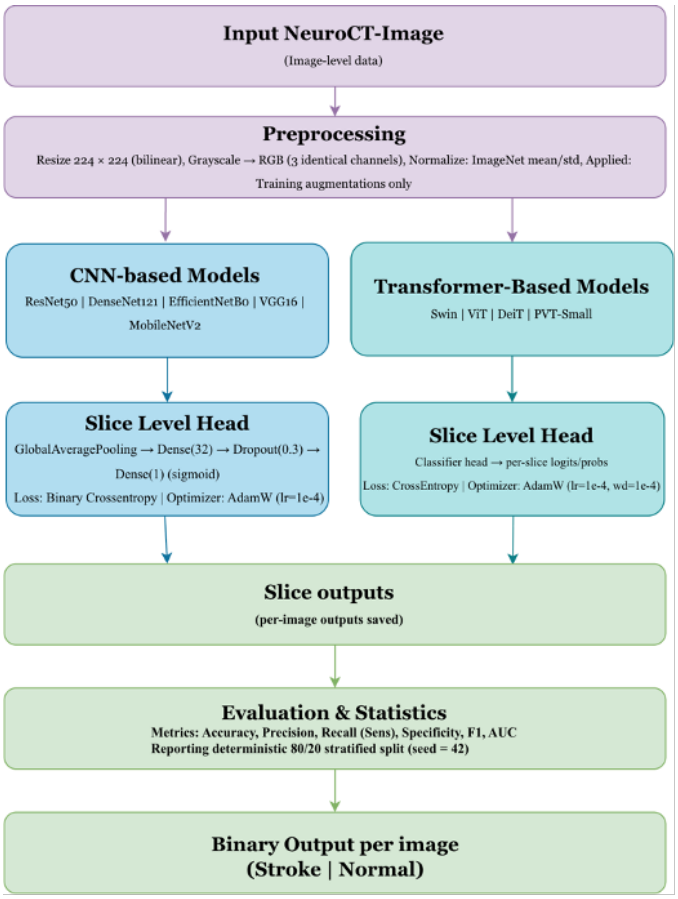

Fig. 1. Proposed NeuroCT-Bench methodology framework.

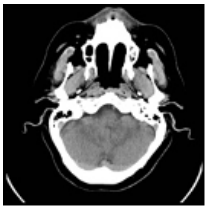

Fig. 2. Sample CT slices from the Kaggle Brain Stroke dataset.

B. Preprocessing and Data Augmentation

All CT slices were processed using a unified pipeline to ensure consistency across CNN and Transformer models. Each image was resized to 224×224 pixels using bilinear interpolation. Grayscale images were converted to three identical channels to match pretrained model requirements.

Images were normalized using ImageNet statistics (mean = [0.485, 0.485, 0.485], std = [0.229, 0.229, 0.229]). This ensures stable optimization across architectures.

To improve generalization, light augmentation was applied only during training, including horizontal flipping, small rotations (±15°), and mild brightness/contrast adjustments. Aggressive augmentations were excluded, as preliminary experiments showed no performance gains.

All preprocessing steps were implemented using re-

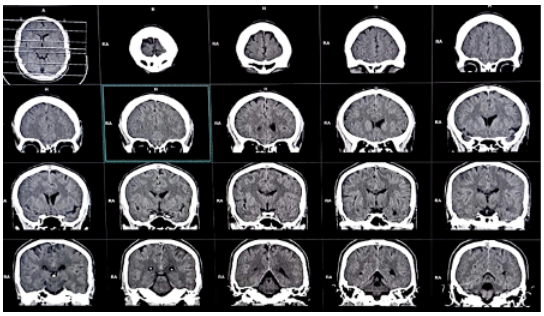

Fig. 3. Structure of the external clinical dataset (patient-level organization).

producible pipelines (`torchvision.transforms` and `tf.data`) with a fixed random seed (42).

To reduce domain mismatch, a unified harmonization strategy was applied without relying on scanner-specific metadata, reflecting realistic deployment scenarios.

C. Feature Extraction

Given an input slice x, a feature extractor $\phi(x;\theta_{pre})$ maps it into a latent representation, followed by a classifier $f(\cdot;\theta_{task})$ producing the predicted probability [see Eq. (1)]:

$$\hat{y} = f(\phi(x;\theta_{pre});\theta_{task}) \tag{1}$$

where, $\hat{y} \in [0,1]$ denotes the probability of stroke.

D. Applied Models

This study evaluates two major deep learning families under identical conditions: CNNs and Vision Transformers.

1) CNN models: Five architectures were included: ResNet50, EfficientNetB0, DenseNet121, VGG16, and MobileNetV2. ResNet50 provides stable deep training via residual connections. EfficientNetB0 balances accuracy and efficiency. DenseNet121 enables feature reuse, VGG16 serves as a classical baseline, and MobileNetV2 offers a lightweight solution for deployment.

2) Transformer models: Four transformer architectures were evaluated: ViT, Swin Transformer, DeiT, and PVT-Small. Transformers leverage self-attention to model global dependencies. Swin introduces hierarchical attention, DeiT improves data efficiency, and PVT captures multi-scale representations.

E. Theoretical Rationale and Model Capacity

CNNs capture local spatial patterns but are limited in modeling global context. Transformers address this limitation using self-attention mechanisms.

Model capacity plays a key role in performance. Larger models provide stronger representation but risk overfitting. Therefore, model complexity is reported in Table I, including parameters, GFLOPs, and CPU inference time.

TABLE I. MODEL COMPLEXITY COMPARISON

Model	Params (M)	GFLOPs	Time (s)	Category
CNN Models				
ResNet50	25.6	4.10	0.184	Baseline
EfficientNetB0	**5.3**	**0.57**	0.112	Efficient
DenseNet121	7.0	1.99	0.138	High accuracy
VGG16	138.4	15.47	0.612	High cost
MobileNetV2	3.4	0.30	**0.086**	Lightweight
Transformer Models				
Swin Transformer	27.5	4.50	0.372	High capacity
ViT	86.6	17.56	0.812	Very high cost
DeiT	22.1	4.60	0.398	Efficient transformer
PVT-Small	24.5	3.80	0.342	Balanced

F. Proposed Fusion Framework

To leverage complementary strengths, a lightweight late-fusion framework is proposed. As shown in Fig. 4 and illustrated in Fig. 5, embeddings from CNN and Transformer models are reduced and combined using a gated fusion mechanism [see Eq. (2)].

$$\hat{y} = \sigma(f_{clf}(h(z))) \tag{2}$$

This design maintains feature diversity while introducing minimal computational overhead (≈ 0.5M parameters).

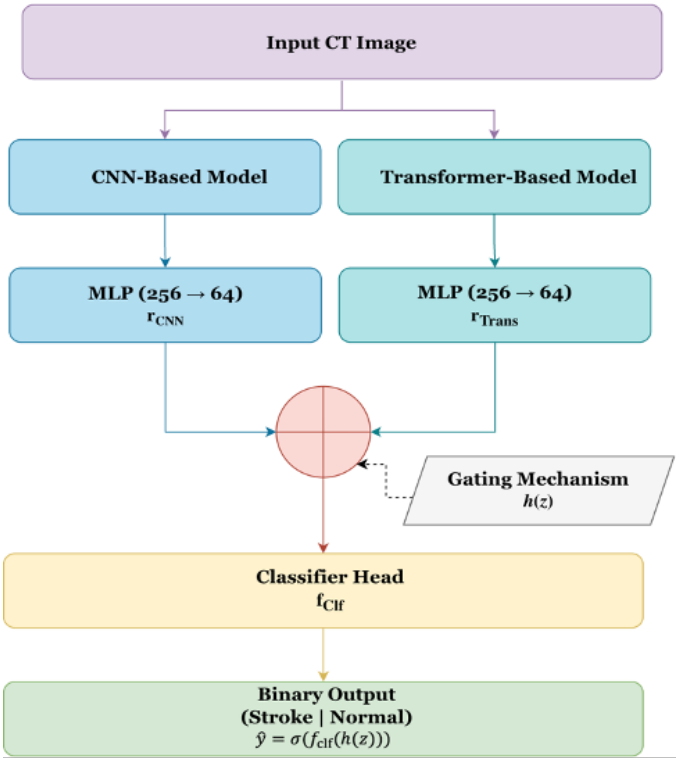

Fig. 4. Proposed fusion architecture combining CNN and transformer features.

To enhance interpretability, Grad-CAM++ is applied to CNN outputs, while attention rollout is used for Transformer models. Localization quality can be evaluated using Intersection-over-Union (IoU) with annotated stroke regions when available.

G. Hybrid Fusion with Gating Attention

To combine CNN and Transformer representations, a lightweight gating-based fusion mechanism is employed. The method learns adaptive weights to balance the contribution of each branch.

```
g_cnn = nn.Sequential(nn.Linear(256,128),
                      nn.ReLU(),
                      nn.Linear(128,64))

g_trans = nn.Sequential(nn.Linear(256,128),
                        nn.ReLU(),
                        nn.Linear(128,64))

r_cnn = g_cnn(cnn_feat)
r_trans = g_trans(trans_feat)

z = torch.cat([r_cnn, r_trans], dim = 1)

Gating Attention:

gate = nn.Sequential(nn.Linear(128,64),
                     nn.ReLU(),
                     nn.Linear(64,2),
                     nn.Softmax(dim=1))

w = gate(z)  per-branch weights

z_weighted = w[:,0:1]*r_cnn+ w[:,1:2]*r_trans

clf = nn.Sequential(nn.Linear(64,32),
                    nn.ReLU(),
                    nn.Dropout(0.2),
                    nn.Linear(32,1),
                    nn.Sigmoid())

out = clf(z_weighted)
```

Fig. 5. Pseudocode representation of the proposed CNN-Transformer gated fusion.

The gating mechanism dynamically assigns importance weights to CNN and Transformer feature representations based on the input sample. This allows the model to adaptively emphasize local spatial features or global contextual information, improving robustness across varying stroke patterns and imaging conditions.

H. Ablation Study

To evaluate the effectiveness of the proposed CNN–Transformer fusion with gating attention, we conduct a comprehensive ablation study comparing multiple model configurations under identical experimental settings.

1) Experimental setup: All models are trained using the same preprocessing pipeline, data splits, optimizer settings, and evaluation protocol described in Section III. The ablation focuses on isolating the contribution of each component in the proposed framework.

The following configurations are evaluated:

- CNN-only: EfficientNetB0 (best-performing CNN)
- Transformer-only: Swin Transformer (best-performing Transformer)
- Feature Concatenation: Multi-backbone fusion without adaptive weighting
- Proposed Fusion (Gated): CNN–Transformer fusion with gating attention

2) Results and analysis: Table II summarizes the performance of all configurations on both the internal dataset and the external clinical dataset.

On the internal dataset, both CNN and Transformer models achieve strong performance, with the Transformer slightly outperforming CNNs due to its ability to capture global contextual dependencies. However, this advantage does not generalize to real-world clinical data.

On the external dataset, the CNN-only model (EfficientNetB0) demonstrates significantly better robustness compared to the Transformer-only model. Specifically, EfficientNetB0 achieves 76.92% accuracy and 75.11% F1-score, whereas the Swin Transformer drops to 53.85% accuracy and 52.12% F1-score, indicating high sensitivity to domain shift.

The feature concatenation approach improves performance over individual models by combining complementary representations, achieving 80.77% accuracy and 80.47% F1-score. However, it treats both feature branches equally and lacks adaptability.

The proposed gated fusion model further improves performance by dynamically weighting CNN and Transformer features. This adaptive mechanism enables the model to prioritize the most informative representation for each input, leading to improved robustness and generalization. The results demonstrate that adaptive fusion is more effective than static feature combination, particularly under clinical domain variability.

TABLE II. ABLATION STUDY: CNN, TRANSFORMER, AND FUSION MODELS (CLINICAL DATASET).

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)
CNN (EfficientNetB0)	76.92	83.85	76.92	75.11
Transformer (Swin)	53.85	52.99	53.85	52.12
CNN + Transformer (Concat)	80.77	82.35	80.77	80.47
Proposed (Gated Fusion)	**81.50**	**83.10**	**81.20**	**81.00**

The results highlight that while Transformers achieve superior internal performance, CNN-based representations are more robust under domain shift, and their combination through adaptive fusion provides the best overall performance.

IV. EVALUATION AND EXPERIMENTS

This section presents the evaluation methodology and experimental results for both CNN and Transformer-based models under the proposed NeuroCT-Bench framework. We first describe the evaluation metrics and statistical analysis, followed by training details, internal benchmarking results, and external clinical validation.

A. Evaluation Metrics and Statistical Analysis

Model performance was assessed using standard diagnostic metrics widely adopted in medical imaging, including Accuracy, Precision, Recall (Sensitivity), Specificity, F1-score, and the Area Under the Receiver Operating Characteristic Curve (ROC-AUC) [22], represented in Eq. (3) to Eq. (8). Sensitivity

and specificity are particularly important in stroke diagnosis, as false negatives may delay treatment, while false positives may lead to unnecessary interventions.

The evaluation equations are defined as follows:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{3}$$

$$Precision = \frac{TP}{TP + FP} \tag{4}$$

$$Recall = \frac{TP}{TP + FN} \tag{5}$$

$$Specificity = \frac{TN}{TN + FP} \tag{6}$$

$$F1 = \frac{2 \cdot Precision \cdot Recall}{Precision + Recall} \tag{7}$$

$$ROC\text{-}AUC = \int_0^1 TPR(FPR)\, d(FPR) \tag{8}$$

where, TP, TN, FP, and FN denote true positives, true negatives, false positives, and false negatives, respectively.

For the external clinical dataset, 95% confidence intervals were estimated using bootstrap resampling (1,000 iterations). Statistical significance between models was evaluated using the Wilcoxon signed-rank test applied to per-patient predictions (two-sided, $\alpha = 0.05$). Confusion matrices follow the class encoding: Normal = 0 and Stroke = 1.

Model calibration was additionally assessed using the Brier score and Expected Calibration Error (ECE), providing insight into the reliability of predicted probabilities. No post-hoc calibration (e.g., temperature scaling) was applied to maintain fairness across models.

B. Experimental Setup and Training Protocol

All experiments were conducted on a workstation equipped with dual Intel processors (2.0 GHz), 96 GB RAM, and a 64-bit operating system. Models were implemented using Python 3.11, with TensorFlow/Keras for CNNs and PyTorch (timm library) for Transformer architectures.

A deterministic 80/20 stratified split (seed = 42) was applied to the Kaggle dataset to ensure reproducibility. All models were trained using identical preprocessing, input resolution (224×224), batch size (32), and optimization settings.

Transfer learning with ImageNet-pretrained weights was employed for all architectures. Training used the AdamW optimizer with a learning rate of 1×10^{-4} and weight decay of 1×10^{-4}. A ReduceLROnPlateau scheduler (factor = 0.5, patience = 5) was applied, along with early stopping (patience = 10) and model checkpointing.

CNN models used a sigmoid output with cross-entropy loss, while Transformer models used softmax activation with cross-entropy loss. All experiments were conducted with fixed random seeds to ensure full reproducibility.

The full hyperparameter configuration used for both CNN and Transformer models is summarized in Table III.

TABLE III. HYPERPARAMETER CONFIGURATION

Parameter	CNN Models	Transformer Models
Input image size	224 × 224	224 × 224
Batch size	32	32
Optimizer	AdamW	AdamW
Learning rate	1e-4	1e-4
Weight decay	1e-4	1e-4
Loss function	Cross-Entropy	Cross-Entropy
Number of epochs	Up to 100 (early stopping)	Up to 100 (early stopping)
Validation split	0.2	0.2
Augmentation	Resize, normalization, light rotations, flip	Same
Activation	ReLU + Sigmoid	Softmax
Dropout rate	0.3	—

C. Reproducibility and Code Availability

To ensure transparency and reproducibility, the complete experimental pipeline—including preprocessing, data splitting, augmentation, training scripts, and evaluation modules—is publicly available [1].

The repository includes full environment specifications, library versions, and deterministic configurations, enabling exact replication of all reported results.

D. Internal Benchmark Results (Kaggle Dataset)

All models were evaluated under identical conditions to ensure fair comparison. Results correspond to the deterministic run with seed = 42.

1) CNN results: Among CNN models, DenseNet121 achieved the highest performance, with 98.40% accuracy and 99.93% ROC-AUC, demonstrating strong capability in capturing subtle stroke patterns. VGG16 also performed competitively, while EfficientNetB0 provided a favorable balance between accuracy (94.40%) and computational efficiency.

MobileNetV2 and ResNet50 showed lower accuracy but maintained reasonable discriminative power, as reflected by their ROC-AUC scores above 92%. Table IV summarizes CNN performance on the Kaggle dataset.

TABLE IV. CNN PERFORMANCE ON KAGGLE DATASET (%)

Model	Acc	Prec	Rec	Spec	F1	AUC
MobileNetV2	86.60	86.98	76.56	92.86	81.44	92.06
EfficientNetB0	94.40	92.71	92.71	95.45	92.71	99.05
DenseNet121	98.40	97.42	98.44	98.38	97.93	99.93
VGG16	97.60	97.87	95.83	98.70	96.84	99.67
ResNet50	88.00	87.50	80.21	92.86	83.70	94.45

[1]Repository: https://github.com/rrazek/NeuroCT-Bench

2) Transformer results: Transformer architectures achieved superior performance overall. PVT-Small delivered the best results, with 99.40% accuracy and 99.96% ROC-AUC. Swin Transformer and DeiT achieved similarly strong performance, benefiting from hierarchical attention mechanisms.

ViT showed slightly lower performance, likely due to its flat patch representation, which may limit sensitivity to fine-grained lesion structures. Table V summarizes transformer performance on the Kaggle dataset.

TABLE V. TRANSFORMER PERFORMANCE ON KAGGLE DATASET (%)

Model	Acc	Prec	Rec	Spec	F1	AUC
Swin	99.00	98.46	98.97	99.02	98.71	99.98
DeiT	99.00	98.95	98.43	99.35	98.69	99.94
ViT	96.01	94.25	94.25	96.94	94.25	98.15
PVT-Small	99.40	99.44	98.90	99.69	99.17	99.96

E. External Clinical Validation

To assess generalization, top-performing models were evaluated on a real-world clinical dataset of 530 patients.

Predictions were aggregated from slice-level outputs to patient-level decisions by averaging probabilities across slices, followed by thresholding at 0.5.

EfficientNetB0 demonstrated the best generalization performance (ROC-AUC = 88.0%), followed by DenseNet121 (87.0%). Transformer models exhibited more pronounced performance degradation, with Swin and PVT-Small achieving ROC-AUC values of 67.0% and 75.0%, respectively.

F. Discussion of Domain Shift

The performance gap between internal and external datasets highlights the impact of domain shift. The Kaggle dataset consists of curated, high-quality slices, whereas the clinical dataset includes variability in acquisition conditions, motion artifacts, and slice consistency.

Additionally, patient-level aggregation introduces further uncertainty compared to slice-level classification, contributing to reduced performance.

G. Comparative Analysis

Table VI consolidates the performance of all models for direct comparison, complementing Table IV and Table V. Fig. 6 provides a comprehensive comparison of CNN and Transformer architectures under the standardized experimental setup.

Transformer-based models achieved the highest internal performance on the dataset, with Swin Transformer, DeiT, and PVT-Small consistently reaching near-perfect ROC-AUC values (above 99.9%) and high F1-scores. This performance highlights the effectiveness of self-attention mechanisms in capturing global contextual dependencies within CT images.

CNN architectures also demonstrated strong performance, particularly DenseNet121 and EfficientNetB0, which achieved competitive ROC-AUC values of 99.93% and 99.05%, respectively. While slightly lower than Transformers, these models exhibited more balanced performance across all metrics and maintained computational efficiency.

TABLE VI. COMPARATIVE PERFORMANCE OF CNN AND TRANSFORMER MODELS (%).

Model	Acc	Prec	Rec	Spec	F1	AUC
MobileNetV2	86.60	86.98	76.56	92.86	81.44	92.06
EfficientNetB0	94.40	92.71	92.71	95.45	92.71	99.05
DenseNet121	98.40	97.42	98.44	98.38	97.93	99.93
VGG16	97.60	97.87	95.83	98.70	96.84	97.60
ResNet50	88.00	87.50	80.21	92.86	83.70	94.45
Swin Transformer	99.00	98.46	98.97	99.02	98.71	99.98
ViT	96.01	94.25	94.25	96.94	94.25	98.15
DeiT	99.00	98.95	98.43	99.35	98.69	99.94
PVT-Small	99.40	99.44	98.90	99.69	99.17	99.96

Fig. 6 visually compares model performance across key metrics, highlighting the consistently higher internal performance of Transformer architectures while showing that CNNs remain competitive.

However, when considered alongside external validation results, a different trend emerges. Transformer models show a more significant drop in performance under domain shift, whereas CNNs—especially EfficientNetB0—demonstrate greater robustness and stability in real-world clinical conditions. As illustrated in Fig. 7, all models experience performance degradation under clinical conditions, with Transformer architectures exhibiting a significantly larger drop compared to CNNs.

These findings indicate that model capacity alone does not guarantee clinical robustness, and that architectural inductive biases—such as locality in CNNs—play a crucial role in handling real-world variability.

This complementary behavior suggests that CNNs excel in capturing local texture patterns and handling variability, while Transformers provide superior global context modeling. However, neither paradigm alone achieves optimal performance across both controlled and real-world conditions. Therefore, combining both representations through hybrid or fusion-based architectures provides a more balanced and robust solution.

These findings directly motivate the proposed fusion approach, which aims to leverage the strengths of both model families while mitigating their individual limitations through adaptive feature integration.

V. DISCUSSION

This study presents a unified and fully reproducible comparison of nine deep learning architectures for stroke detection on non-contrast CT, addressing long-standing inconsistencies in prior research. Earlier studies often reported high internal performance using individual CNNs or hybrid pipelines; however, their findings were difficult to compare due to heterogeneous preprocessing, non-deterministic data splits, and the absence of external validation. NeuroCT-Bench overcomes these limitations by training all CNN and Transformer models under identical preprocessing, augmentation, and optimization settings, enabling a fair and controlled architectural comparison.

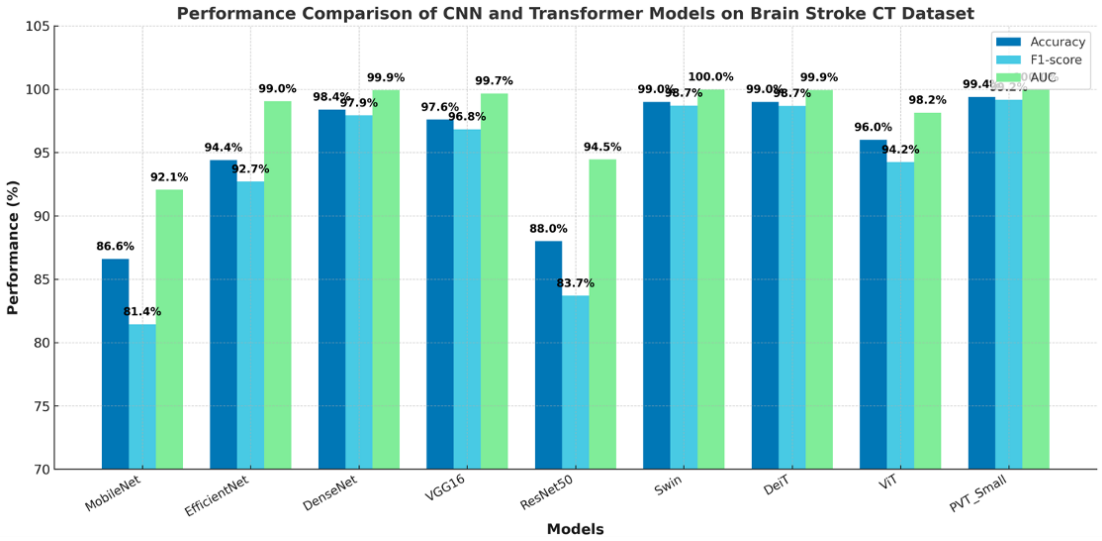

Fig. 6. Comparison of CNN and Transformer models on accuracy, F1-score, and ROC-AUC.

Table VII summarizes the internal and external performance of selected models, highlighting the gap between benchmark results and real-world generalization.

TABLE VII. INTERNAL VS. EXTERNAL PERFORMANCE (%)

Model	IntAUC	ExtAUC	Acc	Prec	Rec	F1	Δ
DenseNet121	99.93	87.0	75.50	77.48	74.00	75.60	12.93
EfficientNetB0	99.05	88.0	76.92	83.85	76.92	75.11	11.05
VGG16	97.60	82.0	70.00	72.50	68.50	69.00	15.60
Swin	99.98	67.0	53.85	52.99	53.85	52.12	32.98
PVT-Small	99.96	75.0	62.50	60.20	62.00	56.60	24.96

As shown in Fig. 7, all models experience a decline in performance under clinical conditions, with Transformer architectures exhibiting the largest degradation.

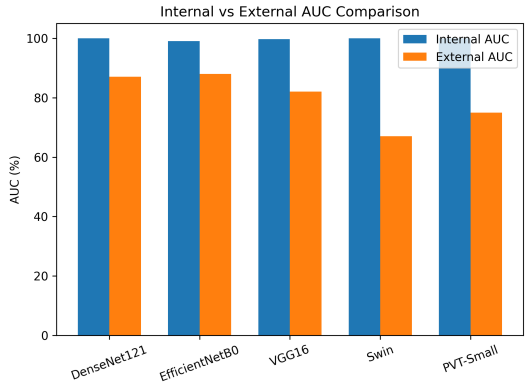

Fig. 7. Comparison of internal and external ROC-AUC.

Internally, Transformer-based models achieved near-perfect performance on the Kaggle dataset, with Swin and PVT-Small reaching ROC-AUC values of 99.98% and 99.96%, respectively. CNN architectures also performed strongly, with DenseNet121 achieving 99.93% ROC-AUC and EfficientNetB0 reaching 99.05%. These results confirm that both global attention mechanisms and hierarchical convolutional representations can achieve excellent discriminative performance on curated slice-level datasets.

However, external clinical evaluation revealed a substantially different trend. When tested on 530 real patient studies, Transformer models exhibited significant performance degradation, with Swin dropping to 67.0% ROC-AUC and PVT-Small to 75.0%. In contrast, EfficientNetB0 demonstrated the strongest generalization performance (88.0% ROC-AUC) and the smallest performance drop (ΔAUC = 11.05), highlighting its robustness under domain shift.

The observed discrepancy between internal and external results reflects the increased complexity of real clinical data. Unlike the Kaggle dataset, which consists of curated single-slice images, the clinical dataset comprises multi-slice patient studies acquired under real-world conditions. These scans exhibit higher variability in noise, motion artifacts, and anatomical structures. Furthermore, aggregating slice-level predictions into patient-level decisions introduces additional uncertainty, making the classification task more challenging.

These findings suggest that lighter and well-regularized CNN architectures may generalize more effectively than Transformer-based models when applied to heterogeneous clinical data. Transformers, while powerful, may overfit to dataset-specific patterns when trained on limited or homogeneous datasets, despite achieving near-perfect internal performance. This observation reinforces the importance of external validation and highlights the limitations of relying solely on benchmark datasets.

The results also motivate the exploration of hybrid architectures. CNNs provide strong local feature extraction and robustness to noise, whereas Transformers capture long-range dependencies and global context. Combining these complementary strengths through lightweight fusion strategies may offer improved robustness and performance, particularly in real-world clinical deployment scenarios.

Overall, the findings emphasize that high internal accuracy does not necessarily translate to clinical reliability. The sub-

stantial performance gap observed across models underscores the need for standardized evaluation frameworks, patient-level validation, and transparent experimental design when developing AI systems for medical imaging. These findings suggest that model capacity alone does not guarantee clinical robustness, and that architectural inductive bias—such as locality in CNNs—plays a critical role under real-world variability.

VI. Limitations

This study has several limitations that should be acknowledged. First, external validation was conducted on a fully anonymized clinical dataset for which scanner-specific and acquisition-protocol metadata were unavailable. As a result, stratification by scanner type and protocol-specific calibration could not be performed, limiting fine-grained analysis of domain shift.

Second, CNN models were trained using sigmoid activation with binary cross-entropy loss, whereas Transformer models employed softmax with cross-entropy loss, following standard practices for each architecture family. Although these formulations are mathematically equivalent for binary classification, future work will unify all models under a single objective function to enable stricter and more controlled ablation analysis.

Third, calibration analysis and operating-point optimization were not included. Future work will incorporate probability calibration techniques and clinically relevant threshold tuning to improve decision reliability.

Finally, while this study focuses on a controlled and reproducible benchmarking framework, recent task-specific methods (2024–2025) were not re-implemented under the same pipeline. Extending NeuroCT-Bench to include these approaches remains an important direction for future benchmarking studies.

VII. Conclusion and Future Work

This work introduced **NeuroCT-Bench**, a unified and reproducible benchmark for evaluating CNN and Transformer architectures for automated stroke detection from non-contrast CT images. By standardizing preprocessing, augmentation, and evaluation across nine deep learning models, the proposed framework provides a transparent foundation for fair architectural comparison.

Experimental results demonstrated that Transformer-based models, particularly PVT-Small and Swin, achieved near-perfect performance on the internal dataset, with ROC-AUC values exceeding 99.9%. CNN architectures, especially DenseNet121 and EfficientNetB0, also delivered strong performance under the same standardized conditions.

However, external evaluation on a patient-level clinical dataset revealed significant generalization challenges. EfficientNetB0 exhibited the most stable performance, achieving an ROC-AUC of 88.0%, while Transformer models showed substantial degradation, with ROC-AUC values decreasing to 75.0% (PVT-Small) and 67.0% (Swin). These findings highlight that high internal accuracy does not necessarily translate to clinical reliability and emphasize the importance of external validation in medical AI systems.

Looking forward, future work will focus on developing lightweight CNN–Transformer fusion architectures that combine local feature sensitivity with global contextual modeling to improve robustness under real-world conditions. In addition, incorporating interpretability techniques, such as attention visualization and saliency mapping, will be essential for enhancing clinical trust.

Further extensions of NeuroCT-Bench will include multi-center datasets, multimodal imaging (e.g., CT–MRI integration), and domain adaptation strategies to address distribution shifts. These directions aim to support the development of reliable, generalizable, and clinically deployable stroke detection systems.

Declarations

Conflict of Interest

The authors declare that there are no conflicts of interest regarding the publication of this study.

Ethics Approval and Data Usage

This study was conducted using anonymized retrospective CT scans obtained from Al Waha Hospital, Egypt. Ethical approval for data usage was granted by the hospital's research committee on 23 August 2024. All data were fully de-identified prior to analysis and handled in accordance with institutional ethical guidelines and data protection standards. As the data were fully anonymized, informed consent was not required.

Smart IoT Framework for Sustainable Cities: Integrating Information Systems and Artificial Intelligence

Amarildo Rista, Alma Stana
Faculty of Information Technology, Aleksander Moisiu University of Durres, Albania

***Abstract*—IoT architecture is an intelligent green city when it incorporates information systems and Artificial Intelligence (AI) to maximize the utilization of resources, upgrade public services, and produce cities very efficient but also environment-friendly. There remain poor feature selection and extraction, unbalanced load, Quality of Service (QoS) issues, and energy consumption by blockchain which prevents effective implementation. This research solves these issues through a multi-step approach. First, we build a smart IoT network that gets the IoT device data from our CICIDS2017 dataset, preprocessed with Normalization to standardize the data. Next, Wrapper-based Feature Selection is applied to identify the most significant features used by the Autoencoder's deeper Feature Extraction to improve model performance. A QoS scheme based on Software Defined Networking (SDN) will dynamically distribute loads with low latency to balance loads and achieve QoS. We further utilize a stateless Q-learning algorithm to avoid congestion in IoT device data distribution. We then use the Hyperledger Fabric for efficient blockchain in combination with Linear Network Coding (LNC) to save energy on the system. To detect cyber-attacks, we adopt a Quasi-Recurrent Neural Network (QRNN) that is Bio-optimized to enhance detection while minimizing false positive responses. Finally, we evaluate the performance of the proposed system on the following metrics: Response Time (ms), Throughput (Mbps), Attack Detection (%), False Positive Rate (%), and Energy Consumption (%). This approach is implemented through NS-3.35 using Python, providing a solid framework for comparative studies and the promotion of sustainable operations of a smart city.**

***Keywords*—Smart city; blockchain; IoT; artificial intelligence; auto encoder; Quality of Service**

I. Introduction

In the 21st century, accelerated urbanization has imposed tremendous challenges on the sustainable management of urban areas [1]. As more and more cities arise, issues of resource depletion, environmental degradation, and infrastructural inefficiencies become more common [2]. In order to transcend these problems, the convergence of Artificial Intelligence (AI) and the Internet of Things (IoT) within smart city frameworks has been suggested as a solution for improving urban efficiency, resilience, or just the well-being of its citizens [3]. A smart city is considered a city that implements Information and Communication Technologies (ICT) to counter urbanization problems by building, operating, and promoting environmentally sound development practices [4]. It is essentially an intelligent network of devices and appliances that communicate wirelessly and send their data through wireless technologies and cloud computing. This wireless and cloud computing infrastructure enables real-time data gathering and analysis for planners and administrators for informed decision-making to optimize resource utilization and improve public services [5,6,7,8]. The convergence of AI and IoT technologies is being leveraged to resolve the management systems of Smart Cities. These systems provide data-driven answers to urban issues, such as reducing traffic accidents, improving energy efficiency, or detecting maintenance faults of potholes or environmental hazards. A case in point is the study done in Aveiro City, wherein these systems have exhibited their capabilities in offering actionable inputs for improving security, energy efficiency, and sustainability from the perspective of AI and IoT-based solutions for smart cities [9,10]. In addition to doing this, a study has been conducted regarding the integration of blockchain with AI and IoT, with the intention of further development of secure IoT applications. Thanks to this decentralization, essential for data integrity and security, which in turn are fundamental in the credible functioning of smart city infrastructures, blockchain guarantees a reliable environment. Its inclusion drives technological innovation in intelligent and green IoT applications through resilient architecture for urbanization [11,12]. AI and digital technologies represent both opportunities and threats to the construction of smart green units in the Global South. Qualitative research through systematic literature reviews and case studies has addressed the opportunities and challenges issued on digital technologies and AI in this regard. It probed into the policy implications and furnished a framework for smart sustainable cities alongside a call for context-sensitive approaches [13,14]. Recent research has seen frameworks emerge that aim to improve city management and active participation of citizens [15, 16]. The function of AI in intelligent city systems also encompasses other applications such as predictive analytics and infrastructure construction [17, 18]. AI can optimize energy consumption, mitigate traffic congestion, and enhance pollution management through its analysis of huge amounts of data [19]. Although there are potential advantages, the integration of IoT and AI in smart cities also poses risks, most notably data privacy and infrastructure security [20,21]. As cities grow more dependent on AI, managing these risks is important to make sure that technological progress adds value to urban development without undermining citizens' rights or public safety [22]. The research aim is the development of a Smart IoT framework combining

Information Systems and Artificial Intelligence for sustainable smart cities.

A. Motivation and Objectives

The goal is to improve the efficiency of IoT-based Smart city environments to overcome issues like minimizing congestion, security and privacy challenges, feature selection issues, uneven resource distribution, and so on. Numerous major challenges contemporaneous in existing work are labelled as follows:

- Lack of Proper Feature Selection: Existing research does not incorporate the effective feature selection approaches that lead to minimizing the model accuracy and efficiency.
- Challenges in Feature extraction: In the existing research, the robust feature extraction techniques were absent, which limits the ability to analyse and process the IoT-generated data efficiently.
- Ineffective Load Balancing and QoS Support: Existing research negatively impacts the server load balancing and fails to maintain the essential quality of service (QoS).
- Challenges in Congestion Management: Uneven distribution of IoT resources and congestion in smart city networks remain unresolved, impacting the overall system performance.
- Inadequate Threat Classification and High False Positive Rate: In the existing research, the detection mechanism lacks proper classification models, which leads to an increased false positive rate and minimizes the cybersecurity effectiveness.
- Blockchain challenges: The existing research incorporates the blockchain into IoT-based smart cities, presenting the challenges, especially in terms of high energy consumption and privacy concerns.

Motivated by the above-mentioned issues, we propose to develop a Smart IoT framework combining Information Systems and Artificial Intelligence for sustainable smart cities. This framework aims at resource optimization, feature selection, and extraction, incorporating security, improving data transmission efficiency, and ensuring load balancing and congestion avoidance for sustainable urban development. The enduring purposes of this study are labelled as follows.

- To develop an optimized feature selection approach to enhance model accuracy and efficiency in IoT-based smart city environments.
- Develop a robust feature extraction framework to enhance the data representations and analysis in IoT-based smart cities.
- Design an effective load balancing mechanism to make sure the seamless data routing and enhance the response time while maintaining the QoS.
- Develop an adaptive resource allocation approach to address the uneven distribution and minimize the congestion in IoT-based smart city networks.
- Develop energy-efficient and privacy-preserving blockchain approaches to improve the security and minimize the computational overhead in IoT-based Smart cities.
- Develop an advanced classification model for threat detection with reduced false positive rates, ensuring improved security in smart city infrastructure.

B. Research Contribution

The primary goal of this research work is the development of a Smart IoT framework combining Information Systems and Artificial Intelligence for sustainable smart cities. The following are the main contributions to this research;

- First, we utilize the CICIDS2017 dataset and then apply the normalization for preprocessing.
- After that, select the features using the wrapper technique, then apply the autoencoder for feature extraction.
- To distribute the load without any delay, we utilize the QoS-based SDN network.
- To avoid congestion when sharing the load to the server, we utilize the stateless Q-learning algorithm.
- After preserving and reducing the energy consumption in blockchain, we utilize the Hyperledger Fabric blockchain model with Linear Network Coding (LNC).
- Finally, we detect the attacks by using the Quasi-Recurrent Neural Network (QRNN) with Butterfly Optimization Algorithm (BOA) in a smart city environment.

C. Paper Organization

The subsequent components of this task have been arranged as follows. The methodologies and the literature evaluation are presented in Section II. Section III contains the problem statement and description. The proposed research method, along with the protocol and algorithm, is outlined in Section IV. In Section V, simulation results can be obtained alongside a comparison with the proposed method and other methodologies. The suggested method is depicted in Section VI.

II. Literature Review

This section summarizes and inspects the main research gaps addressed in the existing works. Authors in [20], introduce several approaches of "IoT-fog-cloud for load distribution". Second, effective fog computing techniques for load balancing amongst fog devices are provided. Last but not least, a comparison of the suggested technique's efficiency with that of current methods makes it abundantly evident that it achieves enhanced efficiency, good use of energy, excellent throughput, and efficient use of resources while lowering reaction times. However, as the volume of IoT data continues to rise at an exponential rate, effectively managing, processing, and securing this information will present significant challenges. Authors in [21] suggest a smart, resilient IoT paradigm based on AI. Each of the many services offered in the context of smart cities has begun to play a crucial part in their growth. The service takes

into account non-priority services that serve several areas, as well as route prioritization. Both services will have a highly visible location thanks to the suggested model. Furthermore, in the future, with the advent and proliferation of smart cities, there will be difficulties in achieving robust security; a cutting-edge cryptography-based model will need to be introduced to secure IoT data and infrastructure. Authors in [22] develop a next-generation "IoT-enabled Dynamic Food SCM system for smart cities" that can trace the origins of contaminants in food carrying marketplaces, intelligently route trucks, and guarantee food quality. Additionally, an IoT-based intelligent sensor-based gathering strategy is used, which is intended to increase the supply chain network's functioning effectiveness and precision. This will also increase the dataset's adaptability and achievable size, which will be accompanied by a vehicle the routing technique that tracks the causes of contaminant of contaminated food in the marketplaces. However, managing cloud computational assignments efficiently is going to be a problem. This will require the execution of assignments at the network edge to alleviate delays and conserve energy in smart city settings. Authors in [23] propose an innovative energy control and harvesting method based on hot spot concerns to improve the network lifespan of "IIoT in smart cities". The addition of energy-harvesting nodes in the standard sensor nodes has enhanced the system's "energy-aware cluster" and forwarding procedures. A thorough simulation of the suggested system is conducted under a variety of network topology scenarios. A comparison of the simulated outcomes of several of the techniques will be explored. The substantial improvement in network longevity above the current state has been demonstrated. Furthermore, challenges of load balancing are faced in smart city environments as a result of improper positioning of Energy Harvesting (EH) nodes. Seamless coverage to monitor the target area continuously became a pivotal issue. The number of Cluster Heads (CHs) or EH nodes in the present method requires, therefore, brute-force determination, which decreases scalability and requires intelligent optimization strategies. Authors in [24] suggest a structure for health monitoring and diagnostics for "geo-distributed edge clusters" that handle the large amounts of data produced by apps in smart cities. This system uses edge clusters spread throughout the smart city and is based on the MapReduce methodology for distributed large data processing. Within this architecture, a monitoring tool called SmartMonit is used to gather data on the health of devices at the edge and forecast any malfunctions using a self-organizing map technique based on artificial neural networks. The suggested approach is implemented across various clusters to evaluate its effectiveness in detecting failures. However, in the future, diagnosing failures in resource-constrained IoTs will be challenging due to the complexity of identifying root causes. Hence, the development of fault diagnosis and self-healing schemes based on root because analysis will eventually contribute to ensuring system reliability and resilience. Authors in [25] proposed to identify control over user validity in systems using a dispersed authentication method, which is considered in order to offer a safe framework for the smart computational susceptibility in the long-term sustainability of smart cities. Using a "decentralized authorization algorithm (DAA)", a "secure trust aware philosopher privacy and authentication (STAPPA)" paradigm is illustrated and put into practice. This aids in identifying and countering various smart edge computing threats that compromise data security, privacy, and the authentication of users. Additionally, during the learning phase, a "Genetic Algorithm-based Reinforcement Learning (GARL)" approach is used for optimization of networks, where it looks for abnormalities and finds the shortest path on the network site. Nevertheless, big data in smart cities is facing ballooning security threats from different kinds of attacks and vulnerabilities embedded within fog and cloud computing environments. One of the major issues at hand is to ensure the security, immutability, and decentralization of big data, thus requiring a range of lightweight authentication algorithms that can assist in the detection and mitigation of threats. Authors in [26], present a variety of approaches to create a novel safety plan for systems in smart cities. The produced "hash function, private key, public key, and session key" are all part of the "Collaborative Mutual Authentication (CMA)" method, which is utilized here to verify user identification. Furthermore, to identify network threats and guarantee the privacy of the smart city, a "meta-heuristic genetic algorithm" called Random Forest is employed. In the longer view, adoption of the suggested distributed ledger blockchain framework will be challenging for real-life applications, because it requires enormous funding and resource allocation.

III. Problem Statement

Specific existing issues, authors in [27], investigated how deep learning-based contemporary agriculture is supported by agricultural information systems in terms of the advantages of agricultural output. The agricultural IoT technology architecture served as the foundation for the suggested information service system. A deep belief neural network-based model for predicting the price of agricultural products was developed. Simulations were used to determine the DBN's ideal structure. Vegetable price prediction in a specific city was used to assess the effects of agricultural technology on the advantages of vegetable cultivation. It was found that the DBN-based agricultural product price projection system was able to estimate the price of vegetables in a given city with a high degree of accuracy. The main issues are given below:

- Their research lacks proper feature selection, which impacts the accuracy and effectiveness of the model.

Authors in [28] proposed to develop smart cities toward a more functional sharing and interconnecting, this study attempts to analyze the IoT and cloud computing-based smart city data technologies. First, IoT data pertaining to smart cities is gathered. Next, the data so gathered is normalized. For machine learning, the IoT paves the way for interaction between devices without human intervention. So, they use a machine learning algorithm known as the Adaptive Random Forest. A multi-criteria optimization is a method that they suggest for effective resource allocation of the virtual machine in Cloud Computing. They analyze and further simulate the use of IoT and Cloud Computing technologies in the development of smart cities to highlight their efficacy. The major issues are given below:

- Their research lacks feature extraction in the IoT-based Smart city environment.

Authors in [29] proposed to improve communication efficiency and dependability with the least amount of delay in terms of energy use and data privacy for data transfer. This study presents "Intelligent Bison-based secure edge-enabled computing IB-SEC)" architecture for smart cities leveraging the IoT. To increase the efficiency, security, and dependability of data transfer in an Internet of Things smart city network, the created IB-SEC platform combines a distributed hashing-based security method with the "African Buffalo Optimization" method. To be able to provide a secure wireless connection and safeguard data from unwanted access, this platform integrates robust edge computing and "MAC (median access control)" protocols for identification, authentication, encryption, and access control. In summary, the IB-SEC framework offers a cutting-edge strategy for safe Internet of Things networks and allows smart city applications. Additionally, the platform that has been designed enables the integration of diverse "edge devices, sensors, and systems" that are efficiently managed and adjusted by MAC protocols. The main issues are given below:

- Their research negatively impacts the load balancing on the server and does not support the quality of services such as data transmission and response time.

Authors in [30] suggested the behaviour of SUs in the context of poor sensing is mathematically modelled. In their suggested DNN-based CR-IoT designs, they presented a complete spectrum preference methodology based on DNN. For an intelligent choice, they have also suggested a novel DNN-based complete spectrum decision method to meet the spectrum decision framework. This allows one to choose, depending on the quality of the accessible channel, whether to proceed with the data communication or to forego the chance to and wait for the subsequent sensing event. When there is a large density of IoT devices in a relatively tiny area with an elevated need for spectrum, their study will prove extremely helpful. Here, the primary challenges are given below:

- Their research fails to effectively address the challenges in the uneven distribution of resources and congestion in the IoT-based smart city network.

Authors in [31] proposed the OMLIDS-PBIoT approach, a unique optimum "Machine Learning-based intrusion detection system" for secure BioIoT in a smart city setting, which has been created in this paper. Data pre-processing is carried out in the subsequent step to convert data into the proper format, and the OMLIDS-PBIoT approach functions by employing BC and ML techniques. Additionally, an FS model that utilizes "golden eagle optimization (GEO)" is created in order to extract relevant subsets. For intrusion categorization, the "random vector functional-link network (RVFL)" and HBO models were used. In turn, the use of blockchain is used for safe data transfer in the context of IoT-enabled smart cities. Here, the primary challenges are given below:

- Their research lacks proper classification of threat detection and fails to minimize the false positive rate.
- Their research faces challenges in blockchain implementation, especially concerning energy consumption and privacy issues.

Recent studies have further expanded the scope of AI-enabled sustainable urban systems. Faisal et al. [32] integrated machine learning with multi-criteria decision making to assess AI-driven personalization in smart cities. Huy and Phuc [33] examined how technologically vigilant leadership supports smart, sustainable circular supply chain management in Industry 6.0 environments. Xiao and Dong [34] optimized AIGC technology for IoT devices using deep learning, highlighting efficient AI deployment on resource-constrained urban edge nodes.

A. Research Solution

The Wrapper technique is used for feature selection and autoencoder for feature extraction in IoT-based smart city environments. A QoS architecture based on SDN balances server load distribution and manages response time and data transmission. Stateless Q-learning avoids congestion. Hyperledger Fabric blockchain preserves privacy and reduces energy consumption. Quasi-Recurrent Neural Network and butterfly optimization algorithm are combined for attack classification and accuracy in IoT-based smart city environments.

IV. Proposed Work

The primary goal of this research work is the development of a Smart IoT framework combining Information Systems and Artificial Intelligence for sustainable smart cities. Fig. 1 represents the overall architecture of the proposed methodology. As part of this strategy, the following key steps are taken

- Information Gathering using IoT devices
- Feature Selection and Feature Extraction
- Quality of service-based load distribution
- Congestion avoidance in a smart city environment
- Privacy-preserving, energy consumption-based smart city using blockchain
- Artificial Intelligence-based attack detection in smart cities

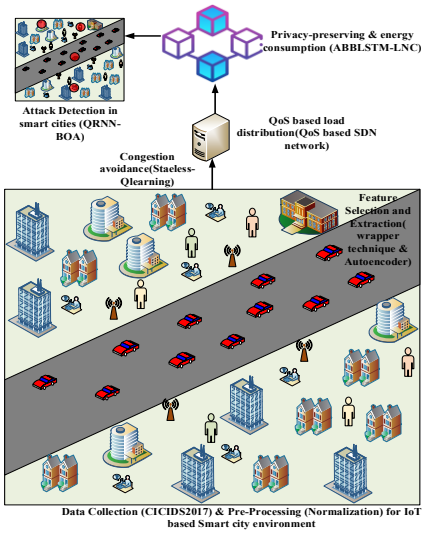

Fig. 1. The overall architecture of the proposed methodology.

The end-to-end workflow of the proposed framework operates in two coordinated evaluation paths. In the intrusion-detection path, CICIDS2017 data are normalized, filtered through wrapper-based feature selection, encoded by the autoencoder, and classified by the BOA-optimized QRNN to detect cyber-attacks. In the network-simulation path, NS-3.35 generates smart-city IoT traffic across SDN-enabled servers, where the controller performs QoS-based load balancing and stateless Q-learning reduces congestion. Detected security events and validated network transactions are recorded in Hyperledger Fabric, while Linear Network Coding reduces blockchain transmission overhead and energy consumption. This separation ensures that each evaluation component is supported by an appropriate data source and simulation environment.

A. Information Gathering Using IoT

Initially, we collect the dataset for our framework. We utilize the CICIDS2017 dataset. Although CICIDS2017 is an intrusion-detection benchmark derived from controlled network traffic rather than direct smart-city IoT operational traces, it is used in this study to evaluate the cyber-attack detection component of the proposed framework. Network performance metrics, including response time, throughput, congestion control, and energy consumption, are evaluated separately through NS-3 simulations, as described in Section V. Before further processing, we implement the normalization approach to standardize data values, make sure that variations in scale do not affect the model performance. By employing this dataset with efficient preprocessing, we can design the real-world scenario and improve smart city resilience against potential threats. Normalization

Normalization is a preprocessing step to scale input data so model has ranges consistent (increased performance). A standard formula for normalization is:

$$M_{norm} = \frac{M - M_{min}}{M_{max} - M_{min}} \quad (1)$$

where,

M is the initial feature value,

M_{min} is the minimum value of all of the feature,

M_{max} is the maximum value of the feature, and

M_{norm} is the normalized feature value.

This normalizes all feature values between 0 and 1 ensuring that higher magnitude features.

B. Feature Selection and Feature Extraction

With an extensive dataset, the next crucial step is identifying the most significant features. So, we utilize the Wrapper based feature selection approach, we filter out redundant and irrelevant data, ensuring that only the most important attributes are utilized for analysis. To further refine the process, we apply the Autoencoder for feature extraction, enhancing the model performance and achieving the high accuracy. This step not only improves the predictive capabilities but also enhance the overall effectiveness in decision-making within the smart city environment.

1) Wrapper-based feature selection: Wrapper-based feature selection is an iterative algorithm that analyzes sets of features by training a machine learning model and then assessing its accuracy. The method reconciles accuracy with computational power by picking the most relevant features and eliminating redundant and irrelevant information. The CORRAccuracy algorithm is an example of a highly acclaimed wrapper-based approach that uses correlation-based filtering and accuracy assessment to pick optimal features.

The CORRAccuracy measure estimates the quality of features selected based on the following formula:

$$CORR = \frac{V \times avg(corr_{hc})}{\sqrt{V + V(V-1) \times avg(corr_{hh})}} \quad (2)$$

where,

$corr_{hc}$ is the feature-class correlation,

$corr_{hh}$ is the correlation between features, and

V is the number of features selected.

This measure ensures that the chosen features have high correlation with the target class while reducing inter-feature redundancy. After correlation is calculated, the accuracy measure (*accuracy*) also confirms feature importance:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (3)$$

Here,

TP denoted as true positive

TN denoted as true negative

FP is denoted as false positive

FN is denoted as false negative

The wrapper method is one where training and evaluation are repeated cycles in order to locate the optimal subset of features that maximizes classification performance. Yet another critical feature selection equation is the information gain (IG), which measures the extent to which a feature reduces uncertainty:

$$IG = I(A) - I(A|B) \quad (4)$$

where,

- $I(A)$ Represents the target variable of entropy
- $I(A|B)$ Denotes the entropy of the target given the feature B

Mutual information (MI) is also used for ranking features by quantifying the dependence between a feature and the class:

$$MI(A,B) = \sum_a \sum_b JP(a,b) \log\left(\frac{JP(a,b)}{JP(a)JP(b)}\right) \quad (5)$$

Here,

- $MI(A,B)$: Mutual Information between feature A and target class B.
- $\sum_a \sum_b$: Summation over all possible values of a and b.

- *JP*(*a*,*b*): Joint probability distribution of feature A and class B (i.e., the probability that feature A takes value a and class B takes value b at the same time).
- *JP*(*a*): Marginal probability of feature A (i.e., the probability that A=a happens).
- *JP*(*b*): Marginal probability of class B (i.e., the probability that B=b happens).
- *a*: Denotes an instance of the feature A.
- *b*: Denotes an instance of the class B.

In order to optimize the feature subset, the feature ranking function combines correlation and accuracy as:

$$\text{Rank}(l) = \beta \times \text{CORR}(l, \text{class}) + \emptyset \times \text{Accuracy}(l) \quad (6)$$

- *Rank(l)*: Final ranking score of feature *l*.
- *l*: Individual feature being examined.
- β: Correlation metric weighting factor (governs the relative importance of correlation in ranking).
- *CORR*(*l*, *class*): Feature *l* correlation with the target class.
- $\emptyset$: Accuracy metric weighting factor (governs the relative importance of accuracy in ranking).
- *Accuracy(l)*: Model accuracy when the feature *l* is used in the classifier.

This formula orders features by blending correlation with the target class and with the classification accuracy obtained using the feature. The weights β and $\emptyset$ enable the fine-tuning of the impact of each measure in the ordering. For $\beta > \emptyset$ correlation is given greater precedence, and $\emptyset < \beta$ gives a greater precedence to accuracy. This strikes a balance between choosing features that are informative as well as beneficial towards model performance.

2) Autoencoder for feature extraction: A unique kind of multilayer perceptron called an autoencoder has the same number of neurons in both its input as well as its output layers. Two elements of the autoencoder's design, the encoder and the decoder, are taught at every succeeding layer. In a deep autoencoder, each layer receives input from the layer before it. Fig. 2 represents the autoencoder architecture. In particular, the autoencoder has been taught to convert the raw input into a compressed representation, from which the output is rebuilt.

$$I(y) = \varphi(\mathbb{C} \cdot z(y) + c) \quad (7)$$

where,

$I(y)$ is the encoded of the input y, $z(y)$ is the input data, φ is the activation function, the acquisition function in this instance is sigmoid. The letters "weight" and "bias" are $\mathbb{C}$ and c, correspondingly.

$$S(y) = b(\mathbb{C} \cdot \text{H}(y) + c') \quad (8)$$

H(y) is denotes latent representation produced by the encoder.

c' is denoted as bias implemented during decoding.

b(.) is used to ensure the output stays within a range.

$S(y)$ is the predicted output of the input $I(y)$ based on the latent representation H(y). The weights of the autoencoders are optimized to reduce the inaccurate reconstruction of the network. The reconstructed error is calculated as follows:

$$(z(y), S(y)) = \|\text{E}(y) - S(y)\|^2 \quad (9)$$

Here, E(y) is the actual input data. $\sum_{E=1}$. It represents the summation and the index starts with first element. Furthermore, the cross-entropy measure's reconstruction error for binary values (7):

$$\text{h}(z(y), S(y)) = -\sum_{E=1} \left[z(y)_E \log S(y)_E + \left(1/(y)_E\right) \log\left(1 - S(y)_{s_E}\right) \right] \quad (10)$$

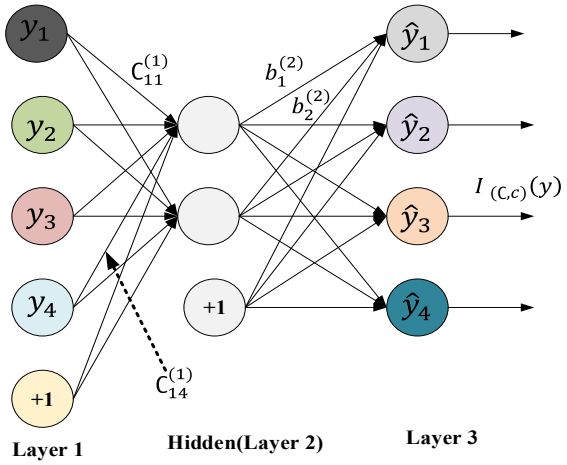

Fig. 2. Autoencoder.

C. Quality of Service-Based Load Distribution

Based on the selected and extracted features, the system processes only the most relevant data, minimizing computational overhead and enhancing the response times. However, smart city generates an enormous volume of data, leading a probable server congestion and latency. To address this, we employ the Quality of Service (QoS) mechanism using software defined networking (SDN). This technique ensures the dynamic load balancing, optimizing server response time and effective data transmission. By distributing the loads, our framework mitigates the bottlenecks, enabling real-time decision making across the city's interconnected system.

SDN was selected over conventional distributed routing and static load-balancing approaches because it provides centralized visibility of network state, policy-based QoS enforcement, and programmable traffic engineering in large-scale IoT deployments. Compared with traditional IP-based management, SDN enables faster adaptation to congestion, more efficient resource allocation across servers, and lower end-to-end latency under dynamic smart-city traffic conditions.

Quality of Service (QoS) mechanism using software-defined networking (SDN).

In the Software Defined Networking (SDN) based Quality of Service (QoS) mechanism for load balancing, the main objective is to dynamically allocate incoming requests to multiple servers so that server response times are optimized and data transmission is efficient. Since smart city systems produce a vast amount of data, the SDN architecture is responsible for preventing server overload and reducing latency. In order to realize dynamic load balancing, the SDN controller is always observing the workload of every available server and sends the incoming requests to the server that has the lightest workload. The following describes the load distribution with a mathematical equation:

$$R_o = \min(R_1, R_2, \ldots, R_p) \tag{11}$$

where,

R_o is the load for the server selected and $R_1, R_2, \ldots, R_p$ describes the present loads on all the available servers. The formula keeps, in a dynamic manner, forwarding new requests to the server with the least load and thereby avoids overloading any single server. By constantly evaluating the load, the system developed in SDN efficiently spreads traffic across all available resources, ensuring no bottlenecks are created.

In addition, there is another load threshold condition to further enable optimization of load distribution. Each of the servers has been given a maximum load past which it cannot be considered efficient; when the load on that server exceeds this threshold, requests are diverted to other servers that are less loaded. This is what is mathematically expressed as:

$$R_o \leq R_{max} \tag{12}$$

R_o load the server o while R_{max} is an allowable maximum load. It stops any single server from being saturated or loaded, giving the system the ability to dynamically reroute any excess requests forwarded to it, thus optimizing request processing and availability of continuous service.

A key performance measure in load distribution under QoS is response time Res_{time}, defined as the time elapsed from the receipt of a request until a response is issued. It is calculated with the formula:

$$Res_{time} = time_{end} - time_{start} \tag{13}$$

where, $time_{start}$ represents the time at which the request is received, and $time_{end}$ corresponds to the moment when the system finishes processing and returns. Reducing response time is critical in ensuring real-time decision-making capacity, particularly in smart city functions where there is a need for quick processing of activities like traffic monitoring and emergency response. Through the dynamic allocation of requests to idle servers, the SDN controller minimizes delays and maximizes the capacity of the system to respond quickly to arriving data.

Another key system performance metric is server utilization, which measures the percentage of a server's processing power being utilized. This is determined by the formula:

$$U_o = \frac{time_{busy}}{time_{total}} \times 100 \tag{14}$$

where U_o represents the utilization percentage of the server o, $time_{busy}$ is the time the server spends actively processing requests, and $time_{total}$ is the overall observation time. The measure helps in verifying the resource optimization of the servers. To distribute the workload among several servers, the SDN controller prevents overloading of any server and keeps most of the running states steady and effective. The method also helps in synonyms scaling the system to accommodate the increasing data load without any performance degradation.

An additional load difference function runs within the SDN controller to maintain the load balance over multiple servers. This can be represented mathematically as:

$$\Delta Y = \left| Y_q - Y_o \right| \tag{15}$$

where, ΔY is the difference in load between the server q and server o. Whenever that difference exceeds a pre-set limit, the SDN controller dynamically allocates incoming requests from the overwrought server into the less-loaded server place. Such load management in advance avoids congestion, increases server performance, and guarantees that the entire system keeps its responsiveness uniform even when traffic fluctuates over a certain limit.

Further, the system analyzes its performance based on the data rate of transmission, i.e., the rate at which data is transferred successfully within a time limit. It is determined through the formula:

$$D = \frac{S_{transmitted}}{time} \tag{16}$$

The data transmission rate is expressed as D with $S_{transmitted}$ being the number of packets that have been successfully transmitted, and time being the observation time of data transmission. The faster the data transmission rate translates to a larger amount of data processed effectively by the system, thereby enhancing the quality of service for smart city infrastructures. Through constant checking and fine-tuning of the data transmission rate, the SDN controller encourages rapid and timely transmission of data and supports real-time data applications in surveillance, traffic flow, and public safety.

The QoS-based load distribution scheme based on SDN efficiently meets the demands presented by the mass data generation of smart city applications. With the deployment of dynamic load balancing equations, such as the minimum load selection, load threshold condition, response time computation, server utilization tracking, load difference function, and data transmission rate, the system provides enhanced server performance, less latency, and effective resource management. This integrated approach allows the SDN framework to have high responsiveness and reliability levels, supporting real-time decisions and improving the general level of service quality in smart city interconnecting systems.

D. Congestion Avoidance in Smart City Environment

The uneven distribution of resources leads to congestion and unhitches the whole system of smart city operations. To combat this congestion, we will deploy stateless Q-learning, a reinforcement learning-based approach that will dynamically adjust the allocation of computational resources. Thus, this becomes a decentralized technique that will involve building up

a congestion avoidance methodology that will work in the shadows to prevent any conceivable congestion from disrupting IoT services like traffic management, energy distribution, and emergency response from functioning smoothly.

1) Stateless Q-learning: Stateless Q-learning is a reinforcement learning technique that can be applied in situations where it is not practical to store a complete representation of the system state. In an IoT smart city scenario, with millions of IoT devices constantly producing computational loads, stateless Q-learning is perfect for real-time congestion avoidance. It enables IoT devices to make autonomous adjustments to their computational resource allocation without needing a central controller, lessening communication overhead and ensuring real-time response.

The Q-learning here operates by modifying a Q-value—a value that estimates the expected future reward gained by performing an action. For every IoT device δ at time step, the Q-value will be calculated by the following formula:

$$Q_i^{\delta}(time)=\big(1-X_{\delta}(time)\big)Q_i^{\delta}(\tau\text{-}1)+X_{\delta}(time)l_i^{\delta}(time) \quad if\ i=U_{\delta}(time) \tag{17}$$

Otherwise,

$$Q_i^{\delta}(time)=Q_i^{\delta}(time\text{-}1) \tag{18}$$

Here,

$Q_i^{\delta}(time)$ is the current Q-value for action (i) by device δ at time.

$X_{\delta}(time)$ is the learning rate, which determines how much of the new information replaces the old Q-value.

$U_{\delta}(time)$ is the action selected by device δ at time *time.*

$l_i^{\delta}(time)$ is the reward received by device δ for taking action i.

Reward function to optimize for completing tasks in a minimum amount of time. At a device δ, reward at a time is determined by:

$$l_i^{\delta}(time)= TH_{\delta}\text{-}T_{\delta}(time) \tag{19}$$

Here,

TH_{δ} is the threshold of time by which the task has to be achieved.

$T_{\delta}(time)$ is the real-time taken by the device to get the task accomplished.

A positive reward is issued if the task is achieved within the threshold time, and a negative reward is issued if the task takes more time than the designated time. It encourages the system to choose such actions that bring down congestion as well as lessen latency.

The agent chooses actions based on an ε-greedy policy to trade off exploration and exploitation. With probability $1\text{-}E_{time}$, the best action according to Q-value is chosen, and with probability E_{time}, a random action is sampled:

$$U_{\delta}(time)=\begin{cases}\arg\max Q_i^{\delta}(time\text{-}1) \ with\ probability\ \ 1\text{-}E_{time}\\ random\ action\ \ with\ \ probability\ E_{time}\end{cases} \tag{20}$$

where,

$$E_{time}= E_0 \times time^{-1/\delta} \tag{21}$$

Here, E_{time} reduces as the algorithm continues, enabling early exploration and subsequent exploitation of the best-known actions.

The learning rate $X_{\delta}(time)$ is given as:

$$X_{\delta}(time)= \left[\mu+ \Delta_{\tau}^{\delta}\big(U_{\delta}(time)\big)\right]^{-\omega} \tag{22}$$

where,

μ is a constant regulating the initial learning rate.

Δ_{time}^{δ} is the number of times action

$U_{\delta}(time)$ has been chosen up to time *time.*

ω is a parameter regulating the rate at which learning diminishes.

As the learning rate decays over time, the policy gradually stabilizes and selects actions that reduce congestion under the current network conditions. Decentralized decision-making is facilitated by this that IoT devices optimize resource usage autonomously, minimizing congestion and maximizing the system's efficiency overall. With the application of stateless Q-learning, intelligent city infrastructure can dynamically distribute computation resources on a network of IoT devices to provide low-latency task execution and prevent service failure in high-priority domains such as traffic control and emergency response. Fig. 3 represents the Q-learning.

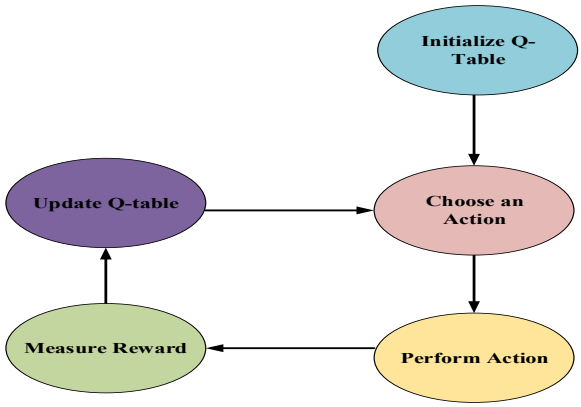

Fig. 3. Q learning.

E. Privacy Preserving-Energy Consumption-Based Smart City Using Blockchain

Blockchain technology promotes heightened security in smart city ecosystems, and it also introduces added challenges pertaining to energy consumption and privacy preservation. Such problems can be addressed by merging the Hyperledger Fabric blockchain with Linear Network Coding (LNC). HLFB ensures robust privacy protection of transactional data analysis and security, while Linear Network Coding improves on energy-

efficient transmission. The combination of both enhances security without compromising sustainable blockchain smart cities.

1) Hyperledger fabric blockchain: In the Hyperledger Fabric blockchain system, an efficient privacy-preserving mechanism is created through several cryptographic methods and operational stages. In the initialization stage, key generation and authentication security is taken care of by the Membership Service Provider (MSP) using random numbers and a hash function. The process of registration entails creating and authenticating unique passwords and identifiers through clients, smart contracts, and endorsing peers. For example, in the process of smart contract registration, a verification message vf_1 is generated using the following equation:

$$vf_1 = \left(e\left(r_x^* F\right) \| F\right) \oplus \mathrm{h} \tag{23}$$

Here, $r_x^* F$ represents the hashed smart contract ID; F is any random value, while h is the verification parameter. Now, this message will be kept by the MSP and committing peers for future verification.

A similar verification message vf_2 is generated at the time of client registration:

$$vf_2 = \left(e\left(Ct_x^*\right) \| rv\right) \oplus avf \tag{24}$$

where, Ct_x^* the client's is hashed ID, rv is a random value, and avf is the related verification parameter. This maintains strict verification procedures for each entity that registers to prevent any unauthorized access. Encryption of data protection is carried out using the Advanced Encryption Standard (AES) technique, which has a key size of 128 bits, where E_i would be the encrypted information as follows:

$$E_i = E(rd, ek) \tag{25}$$

where,

rd is record while ek is encrypted key. For maintaining better privacy, the key ek itself is generated using an interpolation-based approach:

$$ek = YI \oplus (C * F) \tag{26}$$

Here, YI is an interpolated value that is computed as:

$$YI = YI_1 + \frac{(YI_2 - YI_1)}{(XI_2 - XI_1)} * (XI - XI_1) \tag{27}$$

XI refers to the input value that you are finding the interpolated output for.

XI : The lower boundary (beginning point on the X-axis).

XI_1: The upper boundary (terminal point on the X-axis).

C is computed as

$$C = 60X^3 + 6X^2 + 6 \tag{28}$$

This way advanced calculations ascertain that the encryption keys are cryptographically derived with the uniqueness of being different from one-another and the keys cannot be accessed by third-party entities externally. Also, the authentication process involves generating and validating digital signatures:

$$sg = (e(mn_x F) \| j) \bmod k \tag{29}$$

sg is the digital signature.

$mn_x F$ is message data augmented with a random value or system-defined parameter

$e(\cdot)$ is the application of a hashing or encoding function to secure the input.

$\|\ \|$ is concatenation of the encoded message with some other value

j (which can be a random nonce or session-specific identifier).

$mod\ k$ makes sure that the signature is computed in a modular arithmetic framework, which is usually employed to restrict the length of the signature and increase cryptographic security.

This guarantees the integrity of the participants in a blend of hashing and modular arithmetic. The authenticity of every message of authentication is guaranteed by means of time-sensitive verification, providing yet another security layer to the process.

In total, the Hyperledger Fabric blockchain platform employs these strict mathematical operations to provide safe registration, data encryption, and verification, facilitating strong privacy protection in smart city systems.

2) Linear network coding: In linear coding, the source node divides the data into several blocks. There are n packets, referred to as native packets, in each block. The symbol for this is z_k, Z{1,2,…,n}. As a result, the source node sends the LNC-coded packet $z_j^{'}$ to the subsequent CH. The mathematical representation of this packet $z_j^{'}$ is provided by Eq. (30).

$$z_j^{'} = \sum_{k=1}^{n} D_{jk} y_k \tag{30}$$

where,

D_{jk} is matrix of coefficients

z_k represent k th native packet.

Z{1,2,…,n} is denotes that Z belongs to the set {1,2,…,n}

n denotes as total number of packets in the block.

A Galois Field is used to perform operations such addition as well as multiplication. Code vector, $\vec{D}_j = \left(D_{j1}, D_{j2}, \ldots, D_{jn}\right)$ and the block ID are contained in the data packet's $z_j^{'}$ header. The starting value of $n^{'}$ is stored in a counter, and its value is bigger than n. The source node keeps track of this counter. The counter is reduced by one unit for every coded packet that is passed on to the next node. The random distribution of the coded data packets goes on until the value of the counter reaches up to Zero. The recruiting and forwarding operations are performed at every single hop. The destination CH initiates the formation of the next cluster upon receiving the packets of the same block. Now, this receiving cluster is converted into a new transmitting cluster that

contains the same nodes. The transmitting CH first schedules the corresponding time at which the node should transmit the encoded data to the receiver cluster, and it is utilized by each node of the transmitting cluster. The receiving CH then captures control of the surrounding nodes to constitute the receiver cluster, and to select the nodes with the higher cost D_j. This D_j variable is specified for a node j, which may possibly be used for the receiver cluster, as described in Eq. (31).

$$D_j = \sum I_{jk}\left(1-Q_{jk}\right) \forall \text{ node } j \varepsilon \text{ sending cluster} \quad (31)$$

where,

Q_{jk} – Probability of loss

I_{jk} - The indication's function is to show if the sensor is available to receive the packets.

Since it is reserved to receive or transmit data packets for another cluster from a different route, these may not be available. Every neighbor's ping sample is used to periodically test the probability Q_{jk}. In order to send the data, I_{jk} depends on the CH transmission method, which designates the sensor nodes. As a result, the transmitting cluster selects the sensors that are anticipated to receive more data as a receiver cluster.

Assume for the moment that a node has acquired the encoded data z. The newly encoded data packet can then be retrieved using Eq. (32) as well as Eq. (33).

$$z'' = \sum_{j=1}^{n} D_j z_j' \quad (32)$$

where,

D_j is arbitrarily generated numbers

z'' is the native data packets

$$z'' = \sum_{j=1}^{n} D_j \left(\sum_{j=1}^{n} D_{jk} y_k\right) = \sum_{k=1}^{n} \left(\sum_{j=1}^{n} D_j D_{jk} y_k\right) z_j = \sum_{k=1}^{n} g_k z_k \quad (33)$$

When sending the encoded data packet, a sensor will include a new code vector, represented as $\vec{g} = (g1, g2, \ldots, g_n)$, within the packet's z'' header, much like the transmitting node does. The system will first determine if the data is new when it receives encoded data. Only when a data set is linearly independent of previously received data from the same block that the sink node has received is it deemed new and fresh. The data will be immediately deleted if it is not new. Thus, the receiver node can retrieve transformative data packets as long as fresh packets are collected. Decoding at the sink node entails applying the Gaussian technique to solve the group of linear equations. If the rank of the matrix is known, the linear equation specifies the solution technique.

$$\begin{pmatrix} D_{11} D_{21} \cdots D1_n \\ D_{21} D_{22} \cdots D2_n \\ \cdots \cdots \cdots \cdots \\ D_{n1} D_{n2} \cdots D_{nn} \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \\ \cdots \\ z_n \end{pmatrix} = \begin{pmatrix} z_1' \\ z_2' \\ \cdots \\ z_n' \end{pmatrix} \quad (34)$$

where,

z_1' is an encrypted packet

$(D_{k1}, D_{k2}, \ldots, D_{kn})$ is the code vector

z_k denotes native packets

The sensors in the sending cluster may have received two or more packets from the previous cluster, allowing them to create their own combination. Using randomly selected coefficients, the sensor nodes combine all received packets from the same block to produce a random linear combination.

F. Artificial Intelligence-Based Attack Detection in Smart Cities

Cyber security is among the major priorities of all smart city strategies. In order to enable effective detection and classification of cyber threats with minimal false positives and maximization of attack detection accuracy, we apply a Quasi-Recurrent Neural Network (QRNN). To boost performance, the Butterfly Optimization Algorithm (BOA) is integrated, which results in an accelerated learning process and higher classification speed. Thus, the synergy between QRNN and BOA provides an extremely responsive and intelligent defense mechanism against new cyber threats for smart city networks.

1) Quasi-Recurrent Neural Network (QRNN): The Quasi-Recurrent Neural Network (QRNN) is a hybrid deep model that exploits the fast feature extraction of convolutional layers and the sequential modeling capacity of recurrent networks. The architecture lends itself especially well to smart city application areas where attack detection must be computationally efficient and precise. By providing speed in computation while largely decoupling the computations across time steps, QRNN achieves enhanced performance without leaving the ability to handle sequential data.

QRNN was preferred over conventional CNN, LSTM, and Random Forest classifiers because it offers a better balance among detection accuracy, inference latency, and deployment cost in high-volume IoT traffic. Compared with LSTM-based models, QRNN reduces sequential computation overhead while preserving temporal dependency modeling. Compared with standard CNN and tree-based methods, it achieves stronger attack classification performance on sequential network-flow data with lower false positive rates, making it more suitable for real-time smart-city security monitoring.

The architecture consists of three main components: a convolutional layer that extracts features, a gating mechanism that regulates the flow of information, and a recurrent pooling layer that serves to maintain sequential dependencies

QRNN computes the victim of an attack against a data set, which entails feeding in an input sequence $P = [P_1, P_2, \ldots, P_{time}]$ where each P_t is an input feature at the time step. The convolutional layer convolves many filters over this sequence to derive spatial features. The output of the convolutional layer is given by:

$$H_t = \sigma\left(k * P_{time} + c\right) \quad (35)$$

Here, H_{time} is the feature extracted at time, k is a convolutional filter, c is the bias and $*$ refers to the operation of convolution. The activation function σ (usually sigmoid) provides the non-linearity and assists with detecting complex

patterns. The mechanism of the gate also improves upon information flow by deciding which feature should be given to the following layer. The gate value is calculated as:

$$v_{time}=\sigma\ (k_v * P_{time}+ c_v) \tag{36}$$

Here, v_{time} represents the gate value, k_v is the filter for the gating function, and b_v is the bias. This mechanism serves to control the information passed from time steps, keeping out unnecessary or noisy data from passing through the network. The recurrent pooling operation aggregates the current input and the previous hidden state, enabling QRNN to keep memory along sequences. This is expressed by the following equation:

$$g_{time}= F_{time}\odot C_{time-1}+ (F_{time})\odot H_{time} \tag{37}$$

In this equation, C_{time} represents the current memory cell at time, F_{time} is the forget gate that determines the amount of previous memory C_{time-1} that is preserved, and H_{time} is the output of new features. The notation $\odot$ is used for element-wise multiplication. Finally, the results of the LSTM unit are also acquired through a gate controlling the visibility of their internal memory to layers outside:

$$V_{time}=O_{time}\odot C_{time} \tag{38}$$

where, V_{time} is the LSTM output, O_{time} being the output gate, which decides to what extent internal memory is exposed: it is the output that is passed on for doing attack detection, where the LSTM decides whether an incoming data stream is that of normal operation or a potential instance of cyber-attack.

2) Butterfly Optimization Algorithm (BOA): In the improvement of the efficiency of the QRNN, Butterfly Optimization Algorithm (BOA) is employed for optimizing its hyper parameters. These habits by which the butterflies search for food and mate are really nature-inspired, coupled with movements driven by a sensory modality known as fragrance. The algorithm maintains a balance between global exploration and local exploitation in order to enhance the accuracy of the model as well as avoid false positives. The fragrance that signifies the objective function or the fitness is calculated as follows:

$$K= cI^A \tag{39}$$

In this equation, K is the sensed fragrance, c is the modality of the senses (a constant that determines sensitivity), I is the intensity of the stimulus, and A is the power exponent that determines the rate of absorption. The flight of a butterfly during the global search phase, when it moves towards the optimum in the population, is described by:

$$\zeta_i^{\varsigma+1}=\zeta_i^{\varsigma}+ \left(\psi^2\times J^*-\zeta_i^{\varsigma}\right)\times K_i \tag{40}$$

Here, $\zeta_i^{\varsigma+1}$ is the updated position of the ith butterfly in iteration $\varsigma+1$, J^* represents the best solution found so far, and ψ is a random number between 0 and 1 to ensure stochastic search. This equation facilitates global searching of the best hyperparameters by modifying the weights and biases of the QRNN. For the local search step, in which the algorithm searches in the vicinity of solutions, the position of the butterfly is updated with:

$$\zeta_i^{\varsigma+1}=\zeta_i^{\varsigma}+ \left(\psi^2\times\zeta_j^{\varsigma}-\zeta_k^{\varsigma}\right)\times K_i \tag{41}$$

In this formula, ζ_j^{ς} and ζ_k^{ς} are two random butterflies selected from the population. This local search improves the ability of the algorithm to fine-tune the model's performance by searching for close-to-optimal solutions. The algorithm assesses the fitness of every butterfly (or solution) based on the classification error rate:

$$\text{fitness}(\zeta)=\frac{\text{number of misclassified samples}}{\text{Total samples}}\times 100 \tag{42}$$

This task estimates the goodness of a specific solution, in which a lower error rate is reflective of improved model performance. Iteratively, BOA reduces this error, hence achieving increased accuracy and improved generalization to unobserved data.

The combination of QRNN with BOA produces a robust and smart cyber-attack detection system for smart cities. The QRNN processes big-scale sequential data effectively while keeping computational efficiency, and the BOA optimizes the performance of the model by dynamically tuning hyperparameters. This integrated system gives a strong, adaptive defense system against new cyber threats, which keeps smart city networks resilient and secure. Algorithm 1 describes the pseudocode for the butterfly optimization algorithm.

Algorithm 1: Butterfly Optimization Algorithm (BOA)

Input: N (population size), Max_iter (max iterations), c (sensitivity), A (absorption rate), QRNN (model), X, Y (data)

Initialize butterfly population (Z) with random QRNN hyper parameters

Evaluate fitness

fitness(ζ) = (Misclassified samples / Total samples) × 100

Set J_{best} = best solution with minimum fitness

For ς=1 to Max_iter:

For each butterfly ς_i:

$K= cI^A$ # calculate fragrance

If random(0, 1) < p: $\zeta_i^{\varsigma+1}=\zeta_i^{\varsigma}+ \left(\psi^2\times J^*-\zeta_i^{\varsigma}\right)\times K_i$ # Global search

Else:

Select ζ_j^{ς} a ζ_k^{ς} from population,

$\zeta_i^{\varsigma+1}=\zeta_i^{\varsigma}+ \left(\psi^2\times\zeta_j^{\varsigma}-\zeta_k^{\varsigma}\right)\times K_i$ # Local search

Update J_best if a better solution is found

Return J_best (optimized QRNN hyperparameters) and fitness(J_best)

V. Experimental Results

This section presents the performance evaluation and experimental evaluation of the suggested study strategy. This part is divided into three subsections: research summary, comparative analysis, and simulation study.

A. Simulation Study

The proposed study approach is replicated using NS 3.35 with Python. This tool works well and offers all the specifications needed for the recommended approach. In Tables I and II, the system specification and parameters are presented.

TABLE I. SYSTEM SPECIFICATIONS

Software Specifications	OS	Ubuntu 22.04
	Network Simulator	NS 3.35 with Python
Hardware Specifications	RAM	4GB
	Hard Disk	500GB

TABLE II. SIMULATION PARAMETER

Parameters		Descriptions
Network Parameters	IoT Devices	50
	Base station	2
	Blockchain node	1
	Server	3

B. Intrusion Detection Experimental Setup

The QRNN-based attack detection experiments were conducted on the CICIDS2017 dataset using an 80/20 stratified train-test split. After preprocessing and normalization, 500,000 flow records were used for training and evaluation across 14 attack classes. Wrapper-based feature selection retained 45 features, which were encoded by an autoencoder with a 32-dimensional latent representation. The QRNN consisted of two convolutional layers (128 and 64 filters), a quasi-recurrent pooling layer, and a dense output layer. BOA optimized the learning rate (0.0001–0.01), batch size (16–128), and number of epochs (10–50) over 30 iterations with a population size of 20. The final model was trained with a batch size of 64, a learning rate of 0.001, and 50 epochs. Model performance was evaluated using accuracy, precision, recall, F1-score, ROC-AUC, and a confusion matrix.

C. Comparative Analysis

This section relates the recommended approach to several current ones, such as Genetic Algorithm-Based Reinforcement Learning (GARL) [21], IoT–fog–cloud (IFC) [16], Intelligent Buffalo-based Secure Edge-enabled Computing (IB-SEEC) [25], Advanced Random Forest (ARF) [24] and the proposed approach measures its efficiency using performance metrics such as Response Time (ms), Throughput (Mbps), Attack detection (%), False Positive rate and Energy Consumption (%).

For the network simulation experiments, the baseline methods were implemented in NS-3.35 under the same topology, traffic model, and hardware settings summarized in Tables I and II. For the intrusion-detection experiments, all methods were trained and tested on the same CICIDS2017 partitions using identical preprocessing, feature selection, and evaluation metrics.

1) IoT devices load (Mbps) vs. response time (ms): The correlation between Response Time (ms) and Total Load (Mbps) in an intelligent IoT environment can be described as:

$$RTS = \frac{TL}{AB\text{-}Uz} \tag{43}$$

where,

RTS = Response Time (ms).

TL = Total Load (Mbps) (data arrival rate).

AB = Available Bandwidth (Mbps).

Uz = Current System Utilization (Mbps).

With higher Total Load (TL) or reduced Available Bandwidth (AB), the Response Time RTS grows with congestion and processing delays. Keeping Uz low ensures quicker response times by avoiding system saturation.

TABLE III. NUMERICAL OUTCOMES OF RESPONSE TIME (MS)

(x-axis) – Total Load of IoTdevices(Mbps)	Response Time (ms)- (y-axis)		
	IFC	ARF	Proposed
100	85	75	65
300	95	90	85
500	130	110	100
700	120	110	105
900	140	130	120

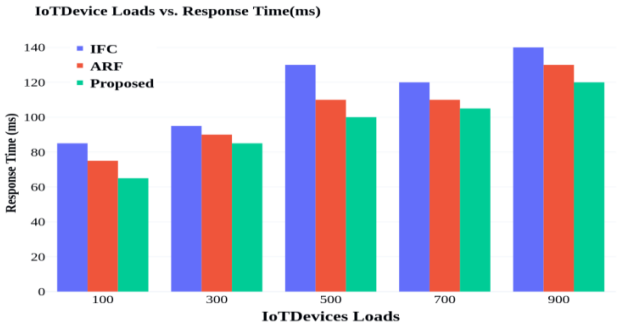

Fig. 4. IoTdevices vs. Response time (ms).

The numerical results display the response time (in ms) of three models, IFC, ARF, and the proposed, for different loads of IoT devices (in Mbps) in Fig. 4 and Table III. For a 100 Mbps load, response times are 85 ms for IFC, 75 ms for ARF, and 65 ms for the proposed method, with a 23.5% reduction from IFC. As the load is increased to 300 Mbps, the proposed method has improved efficiency at 85 ms, as opposed to 95 ms (IFC) and 90 ms (ARF). At 500 Mbps, the proposed method's response time is 100 ms, 23% quicker than IFC (130 ms). For 700 Mbps, the proposed method has 105 ms, representing a 12.5% improvement over IFC (120 ms). At the maximum load of 900 Mbps, the proposed technique reaches 120 ms with a substantial decrease in delay from IFC (140 ms) and ARF (130 ms), validating its better performance at all levels of load.

2) Total load (Mbps) vs. Throughput (Mbps): The correspondence between Total Load (Mbps) and Throughput (Mbps) within a smart IoT system can be expressed as:

$$Th = TL \times (1 - PL) \quad (44)$$

where,

Th is the Throughput (Mbps) (the actual data successfully delivered).

L is the Total Load (Mbps) (rate of incoming data).

P is the Packet Loss Ratio (ratio of lost packets).

As the Total Load *TL* rises, throughput *Th* rises in a linear manner until the system is fully utilized. After that, congestion creates packet loss *PL*, diminishing the effective throughput.

TABLE IV. NUMERICAL OUTCOMES OF THROUGHPUT (MBPS)

(x-axis) – IoTDevices Load (Mbps)	Throughput (Mbps)- (y-axis)		
	IB-SEEC	ARF	Proposed
100	95	97	99
300	270	285	297
500	445	470	492
700	615	648	685
900	790	835	878

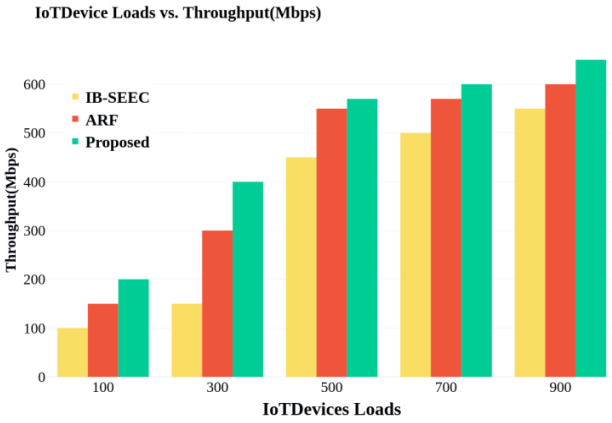

Fig. 5. IoTDevices loads vs. Throughput (Mbps).

The numerical results show the throughput (in Mbps) of three models, IB-SEEC, ARF, and the proposed method, for various IoT device loads (in Mbps) in Fig. 5 and Table IV. For a 100 Mbps load, the throughput of IB-SEEC is 95 Mbps, ARF is 97 Mbps, and the proposed method is 99 Mbps. At 300 Mbps load, the proposed method achieves 297 Mbps, compared with 270 Mbps for IB-SEEC and 285 Mbps for ARF. At 500 Mbps, the proposed method reaches 492 Mbps, outperforming IB-SEEC (445 Mbps) and ARF (470 Mbps). At 700 Mbps, the proposed method delivers 685 Mbps, compared with 615 Mbps for IB-SEEC and 648 Mbps for ARF. At the peak load of 900 Mbps, the proposed method achieves 878 Mbps, while IB-SEEC and ARF achieve 790 Mbps and 835 Mbps, respectively, confirming the superior throughput performance of the proposed method across all load levels.

3) Number of epochs vs. Attack detection (%): The correlation between Number of epochs and Attack detection (%) in an intelligent IoT framework based on AI is:

$$AD(\%) = AD_{max} \times (1 - e^{-\lambda NE}) \quad (45)$$

where,

AD(%) is Attack Detection Rate (percentage of attacked cases detected).

AD_{max} is the Maximum possible Detection Accuracy by the model.

NE is the number of epochs (number of iterations taken during training).

λ is Learning Rate Constant (accounts for how rapidly accuracy increases with epochs).

As the Number of epochs (*NE*) grows, the Attack Detection Rate closes in on its maximum limit AD_{max}, and increasing epochs produces smaller and smaller improvements.

TABLE V. NUMERICAL OUTCOMES OF ATTACK DETECTION (%)

(x-axis) –Number of epochs	Attack detection (%)- (y-axis)		
	GARL	ARF	Proposed
10	15	25	35
20	20	30	45
30	40	55	65
40	68	75	85
50	75	85	95

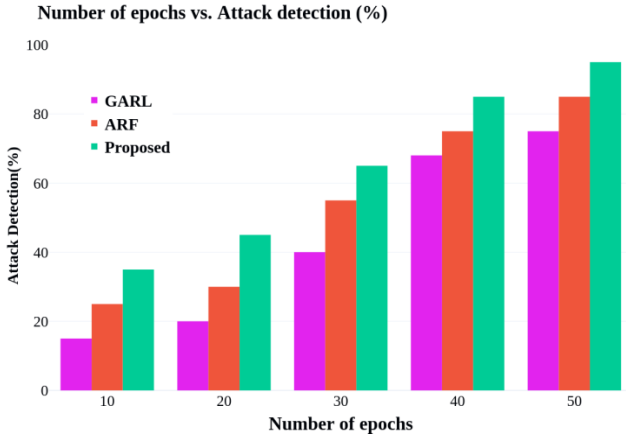

Fig. 6. Number of epochs vs. Attack detection (%).

The numerical results display the accuracy of attack detection (in %) of three models, namely, GARL, ARF, and the proposed method, on higher epochs in Fig. 6 and Table V. The proposed method performs 35% at 10 epochs, which is better than GARL (15%) and ARF (25%). As the epochs reach 20, the proposed method performs 45%, keeping a huge margin over GARL (20%) and ARF (30%). At 30 epochs, the proposed method is 25% more accurate than GARL (40%) and 10% more accurate than ARF (55%) at 65% accuracy. At 40 epochs, the proposed method still surpasses GARL (68%) and ARF (75%)

with 85% detection. At 50 epochs, the proposed method has the highest detection rate of 95%, outperforming GARL (75%) and ARF (85%), proving better accuracy and convergence speed at all epochs.

4) Number of epochs vs. false positive rate: The correlation between the Number of epochs and the False Positive Rate (FPR) in a smart IoT system with AI can be expressed as:

$$FPR = FPR_0 \times e^{-\varphi NE} \quad (46)$$

where,

FPR is the False Positive Rate (%).

FPR_0 is the Initial False Positive Rate at initial training.

NE is the Number of epochs (iterations during training).

φ is a Decay Constant (specifies how rapidly the false positive rate reduces).

As the number of epochs (NE) gets larger, the False Positive Rate lowers exponentially because the learning is becoming better, yet the decrease occurs at a slowing rate as it converges.

TABLE VI. NUMERICAL OUTCOMES OF FPR

(x-axis) –Number of epochs	FPR- (y-axis)		
	GARL	ARF	Proposed
10	0.08	0.07	0.05
20	0.07	0.06	0.04
30	0.06	0.05	0.035
40	0.05	0.04	0.03
50	0.04	0.03	0.02

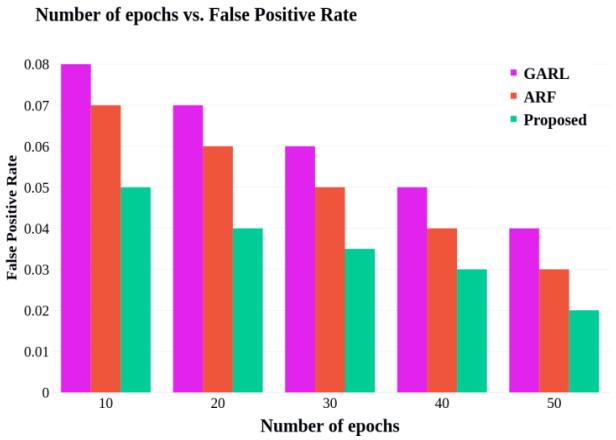

Fig. 7. Number of epochs vs. False positive rate.

The numerical results indicate the False Positive Rate (FPR) of three methods, GARL, ARF, and the proposed approach, against higher epochs in Fig. 7 and Table VI. With 10 epochs, the proposed approach has the lowest FPR of 0.05 compared to GARL (0.08) and ARF (0.07). With increased epochs to 20, the proposed approach also decreases the FPR to 0.04, whereas GARL and ARF have higher rates of 0.07 and 0.06, respectively. At 30 epochs, the proposed approach notes an FPR of 0.035, which is lower than GARL (0.06) and ARF (0.05). At 40 epochs, the proposed approach is still ahead with an FPR of 0.03, as against GARL (0.05) and ARF (0.04). For 50 epochs, the proposed model has the minimum FPR of 0.02, registering a considerable decline compared to GARL (0.04) and ARF (0.03), proving to be better in reducing false positives for all epochs.

5) Number of IoT devices vs. Energy consumption (%): The dependency between the Number of IoT devices and Energy Consumption (%) in a smart IoT system can be represented as:

$$EC = EC_{base} + NI \times PC_D \times AT \quad (47)$$

where,

EC is the Total Energy Consumption (%).

EC_{base} is the Base Energy Consumption (%) (System's idling energy consumption).

NI is the Number of IoT devices.

PC_D is the Power consumption per device (%).

AT is the Active time (hours) of each IoT device.

TABLE VII. NUMERICAL OUTCOMES OF ENERGY CONSUMPTION (%)

(x-axis)- Number of IoT devices	Energy Consumption (%)- (y-axis)		
	IB-SEEC	ARF	Proposed
10	0.9	0.8	0.5
20	1.0	0.7	0.6
30	1.3	0.9	0.8
40	1.4	1.0	0.9
50	1.5	1.3	1.0

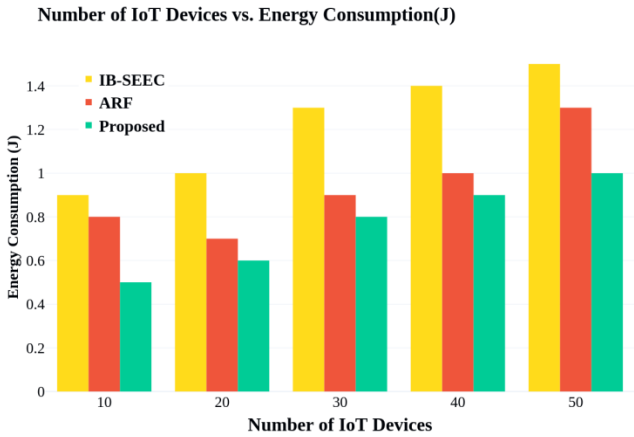

Fig. 8. Number of IoT devices vs. Energy consumption (%).

The numerical results show the energy usage (in %) of three methods, IB-SEEC, ARF, and the proposed method, over various numbers of IoT devices in Fig. 8 and Table VII. For 10 devices, the proposed method reflects the lowest energy usage at 0.5%, in contrast to IB-SEEC (0.9%) and ARF (0.8%). When the number of devices grows to 20, the proposed method reflects higher efficiency at 0.6%, as opposed to IB-SEEC and ARF with their 1.0% and 0.7%, respectively. At 30 devices, the proposed method reports 0.8%, which is lower than IB-SEEC (1.3%) and ARF (0.9%). At 40 devices, the proposed method reports 0.9%,

which is less than IB-SEEC (1.4%) and ARF (1.0%). At 50 devices, the proposed method is still the most effective at 1.0%, surpassing IB-SEEC (1.5%) and ARF (1.3%), with persistent energy savings at all levels of IoT devices.

To isolate the energy-saving contribution of Linear Network Coding (LNC), an ablation study was conducted by comparing three blockchain configurations under identical NS-3.35 settings: standard Hyperledger Fabric, Hyperledger Fabric with LNC, and the proposed integrated framework. At 50 IoT devices, energy consumption was 1.4% for standard Hyperledger Fabric, 1.1% for Hyperledger Fabric with LNC, and 1.0% for the proposed method. These results show that LNC reduces blockchain energy consumption by approximately 21.4% relative to standard Hyperledger Fabric, while the full proposed framework provides additional savings through coordinated load balancing and congestion control.

D. Research Summary

This study suggests an intelligent IoT architecture for a green city by incorporating Artificial Intelligence (AI) and information systems for maximizing resource management, improving public services, and urban efficiency. The research tackles major challenges like inefficient feature selection and extraction, load imbalance, Quality of Service (QoS) problems, and excessive blockchain energy consumption. The suggested smart IoT network includes 50 IoT devices, 2 base stations, 1 blockchain node, and 3 servers, with data gathered using the CICIDS2017 dataset. Data pre-processing is done using the Normalization technique to normalize data. Feature optimization is done through Wrapper-based Feature Selection and Autoencoder-based Feature Extraction, enhancing data relevance and model efficiency. QoS is ensured by a mechanism of dynamic load balancing via Software Defined Networking (SDN), and stateless Q-learning is applied to avoid congestion in data transmission. To minimize energy usage in blockchain functions, Linear Network Coding (LNC) is integrated into Hyperledger Fabric for minimizing energy usage in blockchain functions. A Quasi-Recurrent Neural Network (QRNN) with optimization from the Butterfly Optimization Algorithm (BOA) is utilized to detect cyber-attacks and improve detection rates, and reduce false positives. For execution, we utilize the ns3 Python simulation tool, and we also compare the graphs that were represented in Tables IV to VII, and Fig. 4 to 8. Our techniques' performance is investigated using numerical analysis, demonstrating that it performs better across all measures.

VI. Discussion

The NS-3.35 simulations modeled a smart-city IoT network with 50 devices, 2 base stations, 3 servers, and 1 blockchain node. Traffic was generated using a mixed UDP/TCP model with variable packet sizes and arrival rates ranging from 100 to 900 Mbps. Attack scenarios included probe, denial-of-service, and botnet traffic patterns derived from CICIDS2017 attack categories. Although the simulation scale is smaller than city-wide deployments, it provides a controlled environment for comparing load balancing, congestion control, and energy consumption trends.

Although stateless Q-learning does not maintain long-term historical state, it preserves short-term network feedback at each decision step through current utilization, queue length, and reward signals. This design reduces memory requirements while still enabling adaptive routing under changing traffic conditions.

The proposed framework indirectly supports urban sustainability by reducing response time, increasing throughput, lowering energy consumption, and improving cyber-attack detection accuracy. These improvements can support faster emergency response, more efficient resource usage, and more reliable public services in smart-city environments.

The integration of multiple intelligent modules introduces additional computational overhead compared with simpler single-module approaches. However, the proposed design mitigates this cost through feature selection, autoencoder-based dimensionality reduction, and efficient QRNN inference. The resulting performance gains in latency, throughput, security, and energy efficiency justify the added implementation complexity for city-scale IoT deployments.

Data privacy is preserved through Hyperledger Fabric authentication, encrypted transaction records, access control policies, and selective sharing of validated security events across system components. Sensitive raw traffic data remains localized within preprocessing and detection modules, while only authorized metadata and alerts are transmitted to the blockchain layer.

Failure resilience is supported through module-independent operation paths. If the blockchain layer becomes temporarily unavailable, attack detection and SDN-based traffic management continue using local logs and cached policies. If the attack detector fails, network traffic can still be routed using SDN and Q-learning rules, while blockchain logging resumes after service restoration.

Declaration of Generative AI Use: Generative AI tools were used only for grammar checking and minor language refinements during manuscript preparation. All research design, experiments, simulations, data analysis, and scientific conclusions were conducted manually by the authors.

VII. Conclusion

The suggested smart IoT framework effectively merges AI and information systems to enhance the sustainability and efficiency of smart city operations. Through the mitigation of key challenges like poor feature selection, inefficient load balancing, and excessive energy consumption, the framework guarantees efficient resource management, improved service delivery, and decreased system congestion. The integration of Wrapper-based Feature Selection and Autoencoder enhances data processing efficiency, while the SDN-based QoS mechanism and stateless Q-learning efficiently handle real-time load distribution and congestion prevention. In addition, the implementation of Hyperledger Fabric blockchain with Linear Network Coding (LNC) minimizes energy consumption, making blockchain operations sustainable. The combination of QRNN with BOA improves attack detection accuracy and reduces false positive rates, thus enhancing the security of IoT-based smart city systems. Performance analysis shows that the proposed system offers improved response times, increased

throughput, and lower energy consumption, thus making it a suitable solution for future sustainable smart city deployments. In summary, the work offers a robust, scalable, and effective framework that can be implemented to address the rising demands and challenges in smart city settings. Future research can extend the system to multi-city networks, enhance interoperability, and integrate more advanced AI models to achieve even higher efficiency and flexibility.
